Abstract

Helicobacter pylori (*H. pylori*) infection and the use of non-steroidal anti-inflammatory drugs (NSAIDs) including aspirin at any dosage and formulation represent well-established risk factors for the development of uncomplicated and complicated peptic ulcer disease accounting for the majority of such cases. Although the interaction between *H. pylori* and NSAID/aspirin use in the same individuals was questioned in some epidemiological studies, it has now become widely accepted that they are at least independent risk factors for peptic ulcer disease. According to data from randomized intervention trials, naive NSAID users certainly benefit from testing for *H. pylori* infection and, if positive, *H. pylori* eradication therapy prior to the initiation of NSAID. A similar strategy is also suggested for naive aspirin users, although the efficacy of such an approach has not been evaluated yet. Strong data also support that chronic aspirin users with a recent ulcer complication should be tested for *H. pylori* infection and, if positive, receive *H. pylori* eradication therapy after ulcer healing, while they appear to benefit from additional long-term therapy with a proton pump inhibitor (PPI). A similar approach is often recommended to chronic aspirin users at a high risk of ulcer complication. *H. pylori* eradication alone does not efficiently protect chronic NSAID users with a recent ulcer complication or those at a high-risk, who certainly should be treated with long-term PPI therapy, but *H. pylori* eradication may be additionally offered even in this setting. In contrast, testing for *H. pylori* or PPI therapy is not recommended for chronic NSAID/aspirin users with no ulcer complications or those at a low risk of complications.

INTRODUCTION

Salicylates have been used in therapeutic medicine since the Hippocrates' era and their use is still growing. During the last 50 years, there is a continuously increasing consumption of aspirin for cardioprotection and for secondary prophylaxis of recurrent stroke or other vascular occlusion, while the drug seems to have a possible role in chemoprevention of cancer and Alzheimer's disease^[1-4]. Non-steroidal anti-inflammatory drugs (NSAIDs) are also widely used agents^[5]. In the USA, it is estimated that more than 50% of the population over 65 years take aspirin or NSAIDs frequently^[6].

The increasing widespread consumption of aspirin/NSAIDs, however, is associated with an increasing incidence of their well-known gastrointestinal complications, which include dyspepsia, gastric and/or duodenal erosions and ulcers and peptic ulcer complications. Peptic ulcer complications, usually bleeding, represent the most frequent serious adverse events of the use of aspirin/NSAIDs^[1,7]. Peptic ulcer(s) may be found at endoscopy in up to 20-25% and ulcer complications requiring hospital admission develop in 2-5% of chronic users of NSAIDs^[7-12]. Use of NSAIDs has also been shown to increase the risk of lower gastrointestinal bleeding^[13]. The damaging effect of aspirin on the gastric mucosa may be less potent than the effect of NSAIDs^[14]. Thus, it is estimated that the chronic use of aspirin increases the absolute annual risk of gastrointestinal bleeding by 0.04% (absolute annual risk of bleeding with and without aspirin: 0.09% and 0.05% respectively)^[15]. Nevertheless, despite the relatively low absolute risk of bleeding in aspirin users, the numbers of aspirin related acute gastrointestinal bleeding episodes are rather high probably due to the huge numbers of individuals who take the drug regularly for long periods often having additional factors with increased risk for bleeding, such as old age and history of peptic ulcer disease. The use of selective NSAIDs, such as selective cyclooxygenase 2 (COX-2) inhibitors, significantly reduces but does not completely eliminate the risk of gastrointestinal complications^[11,12,16], while their gastrointestinal benefit appears to be significantly restricted in cases of concomitant use of aspirin, even at low doses^[11,17].

Helicobacter pylori (*H. pylori*) is undoubtedly associated with the development of gastritis and uncomplicated and complicated peptic ulcer diseases^[18]. Although the presence of two factors that can damage the gastric mucosa, such as *H. pylori* and aspirin/NSAIDs, would be reasonably considered

to increase the risk for development of uncomplicated and complicated peptic ulcer, data from several, mainly epidemiological, studies appear to be controversial and do not always confirm such an assumption^[19]. This review focuses on the role of *H pylori* infection and the need for its eradication for prevention of gastrointestinal complications among aspirin/NSAIDs users by evaluating the relevant pathophysiological and epidemiological data as well as the results of the randomized, controlled clinical trials of therapeutic intervention.

PATHOPHYSIOLOGY

Aspirin or NSAIDs use is associated with the development of peptic erosions or ulcers through several mechanisms. First, aspirin acts locally through the release of salicylic acid in the stomach, which is not ionized by the gastric acid. Salicylic acid enters and accumulates within the gastric epithelial cells, is ionized intracellularly and disrupts cell metabolic functions increasing mucosal permeability and permitting the back diffusion of H⁺ ions^[20]. Moreover, aspirin promotes topical inflammation by inducing recruitment of leukocytes, which eventually results in capillary constriction and topical ischemia. The topical gastrototoxic effect of aspirin, however, does not seem to be particularly important, since it is associated only with superficial ulcerations that often resolve spontaneously despite the continued aspirin use^[20]. The systemic gastrototoxic effect of aspirin is related to the inhibition of cyclo-oxygenase-1 (COX-1) and the subsequent disruption of prostaglandin synthesis and to the antiplatelet function that promotes bleeding complications^[20]. The key role of the systemic effects of aspirin in the development of gastrointestinal complications is strongly supported by the data showing that the risk of such complications is independent of the drug formulation^[17,21,22]. Even low doses of aspirin, such as 75 mg/d, have been shown to increase the risk of gastroduodenal ulcerations^[21,22]. Inhibition of COX-1 with disruption of prostaglandin production is also the main mechanism of NSAIDs induced gastroduodenal complications^[11-13].

H pylori infection induces a substantial inflammatory reaction in the gastric mucosa with recruitment of leukocytes and production of several inflammatory cytokines, which eventually result in attenuation of mucosal defense mechanisms^[18]. Thus, *H pylori* infection and aspirin/NSAID use impaired gastric mucosal defense by different mechanisms and therefore an interaction between these two factors is biologically plausible.

EPIDEMIOLOGICAL STUDIES

The interaction between *H pylori* infection and aspirin/NSAIDs use in the development of ulcer and ulcer complications has been initially evaluated in several cohort or case-control studies. The findings of these studies, however, have been controversial, since some studies suggested an independent or additive role of *H pylori* infection and aspirin/NSAIDs use in gastrointestinal complications^[21-30] and others proposed no association or even a protective role of *H pylori* infection in users of aspirin/NSAIDs^[31-33]. Moreover, in one study, *H pylori* infection was found to increase the risk of gastric but not of duodenal ulceration in this setting^[34]. The

heterogeneity in study design and methodology, definitions, power, outcome, and selection of controls have been suggested to be responsible for such conflicting results^[19].

In a systemic review published in 2002, the combined analysis of the data available up to October 2000 showed that there is synergism for the development of peptic ulcer and ulcer bleeding between *H pylori* infection and aspirin/NSAID use^[35]. In particular, the presence of *H pylori* infection was found to increase 3-5-fold the risk of peptic ulcer in aspirin/NSAID users (prevalence of peptic ulcer in *H pylori* positive: 53% and *H pylori* negative: 21%, OR: 3.5) and 18-fold in subjects not taking aspirin/NSAID (prevalence of peptic ulcer in *H pylori* positive: 18% and *H pylori* negative: 0%, OR: 18.1)^[35]. Thus, the risk of peptic ulcer is approximately 60-fold higher in *H pylori* positive aspirin/NSAID users compared with *H pylori* negative subjects not taking aspirin/NSAID^[35]. Moreover, *H pylori* infection was shown to increase the risk of ulcer bleeding 1.8-fold, aspirin/NSAID use 4.85-fold, and the presence of both factors 6.1-fold compared with the risk of bleeding among *H pylori* negative subjects not taking aspirin/NSAID^[35]. *H pylori* infection has also been found to increase the risk of upper gastrointestinal bleeding even in chronic users of low dose aspirin^[27]. In a more recent case-control study from our group, *H pylori* infection was again found to increase the risk for upper gastrointestinal bleeding in aspirin/NSAID users 2.9-fold, or 1.7-fold when adjustment for other risk factors for bleeding was performed^[28]. Taking all together, it seems that aspirin/NSAID use and presence of *H pylori* infection are at least independent risk factors for peptic ulcer and bleeding from peptic ulcer.

RANDOMIZED CLINICAL TRIALS

***H pylori* eradication in naive aspirin/NSAID users**

If *H pylori* gastritis does enhance the risk for ulcer bleeding in aspirin/NSAID users, then *H pylori* eradication should substantially reduce such a risk in this setting. Since the risk of bleeding in aspirin/NSAID users is strongly related to the duration of drug use, being higher in subjects with new or recent drug onset (<1-3 mo) than in chronic drug users (>1-3 mo)^[36-38], the possible beneficial effect of *H pylori* eradication on naive aspirin/NSAID users was initially evaluated. In fact, only naive users of non-aspirin NSAIDs have been included in the relevant clinical trials to date, while the possible benefit of *H pylori* eradication in naive users of aspirin has not been evaluated yet.

H pylori eradication before NSAID use was found to significantly reduce the occurrence of peptic ulcers in 92 *H pylori* positive, NSAID naive patients with musculoskeletal pain treated with an 8-wk course of naproxen at a daily dose of 750 mg (peptic ulcers: 3/45 or 7% of patients in the *H pylori* eradication group *vs* 12/47 or 26% of patients in the placebo group, *P* = 0.01)^[39]. In a longer trial with a similar design, *H pylori* eradication before NSAID use was again found to significantly reduce the risk of peptic ulcers in 100 *H pylori* positive, NSAID naive, patients with arthritis and a history of peptic ulcer or dyspepsia treated with a 6-mo course of diclofenac slow release at a daily dose of 100 mg (peptic ulcers: 5/51 or 12% *vs* 15/49 or 34%, *P* = 0.0085)^[40]. In the latter trial, *H pylori* eradication

was also found to significantly reduce the risk of ulcer complications as well [6-mo probability: 4.2% (1.3-9.7) *vs* 27.1% (14.7-39.5), $P = 0.0026$]^[40].

***H pylori* eradication in chronic aspirin/NSAID users without a history of peptic ulcer complications**

The results of the first large clinical trial of *H pylori* eradication in chronic NSAID users raised several questions for the benefit of such an intervention. In this trial^[41], 285 *H pylori* positive chronic NSAID users with past or current peptic ulcers or NSAID-associated dyspepsia who continued a minimum dosage of NSAID for at least 6 mo were randomized to receive *H pylori* eradication therapy with omeprazole, amoxicillin and clarithromycin ($n = 142$) or omeprazole plus placebo antibiotics ($n = 143$) for 1 wk. Subsequently, all patients received omeprazole 20 mg daily for 3 wk followed by an additional 4-wk omeprazole course in cases with endoscopically detected peptic ulcers at 4th wk. The probability of being peptic ulcer free at 6th mo was similar in the *H pylori* eradication [0.56 (95%CI: 0.47-0.65)] and the omeprazole-control group [0.53 (95%CI: 0.44-0.62)], while healing of gastric ulcers was significantly impaired in the *H pylori* eradication group (gastric ulcers healed at 8th wk: 72% in the *H pylori* eradication group *vs* 100% in the omeprazole-control group, $P = 0.006$)^[41].

The design of the latter trial, however, was different from the design of the trials in naive NSAID users, since *H pylori* eradication therapy was given to subjects with ulcers or at high-risk of ulcers, who had already been on long-term NSAID consumption. Moreover, both the *H pylori* eradication and control groups were treated with 4-8 wk of omeprazole for ulcer healing. The lower probability of gastric ulcer healing at 8th wk in the *H pylori* eradication group should be associated with the more potent antisecretory activity of the PPIs including omeprazole in the presence than absence of *H pylori* infection^[42]. Similar findings have also been observed in another large study including 692 chronic NSAID users, in which gastric ulcer healing with ranitidine or lansoprazole was shown to be significantly enhanced in the presence of *H pylori* infection (healing of gastric ulcers at 8th wk: 70% in *H pylori* positive *vs* 61% in *H pylori* negative, $P < 0.05$)^[43]. According to these data, it has been reasonably suggested that any attempt to eradicate *H pylori* infection should follow ulcer healing in the management of chronic NSAID users, although the efficacy of such an approach remains to be tested. The efficacy of *H pylori* eradication in chronic aspirin users has not been evaluated yet.

***H pylori* eradication in chronic aspirin/NSAID users with a recent peptic ulcer complication**

Subjects with a history of upper gastrointestinal bleeding or other peptic ulcer complications represent a particular subgroup of aspirin/NSAID users who are at a high risk for recurrent bleeding during continued aspirin/NSAID use^[44,45]. Strategies that may prevent bleeding in this setting include concurrent therapy with a PPI or eradication of *H pylori* infection in *H pylori* positive subjects. The efficacy of these two strategies was evaluated in a large clinical trial including 400 *H pylori* positive aspirin/NSAID users with a history of upper gastrointestinal bleeding^[46]. All patients initially discontinued

aspirin or NSAID therapy and were treated with omeprazole 20 mg daily for at least 8 wk to promote ulcer healing. Once the healing of ulcer was confirmed, 250 patients who were given 80 mg of aspirin daily for heart disease or stroke and 150 patients who were given 500 mg of naproxen twice daily for arthritis, both for at least 6 mo, were separately randomized to receive 20 mg of omeprazole daily for 6 mo or a 7-d course of *H pylori* eradication therapy followed by placebo once daily for 6 mo. In patients taking aspirin, no significant difference in the probability of recurrent bleeding during the 6-mo follow-up period was observed between those who received *H pylori* eradication therapy (1.9%) and those who received omeprazole (0.9%) (absolute difference: 1%, 95%CI: -1.9-3.9%). In contrast, in patients taking naproxen, the 6-mo probability of recurrent bleeding was significantly lower in the omeprazole (4.4%) than in the *H pylori* eradication group (18.8%) (absolute difference: 14.4%, 95%CI: 4.4-24.4%, $P = 0.005$)^[46]. According to these data, it seems that, after ulcer healing, *H pylori* eradication may be effective in preventing recurrence of upper gastrointestinal bleeding in chronic aspirin users, but not in chronic NSAID users, who require long-term potent antisecretory therapy with a PPI.

Whether the combination of *H pylori* eradication and long-term use of PPIs may further decrease the risk of recurrence of peptic ulcer complications in chronic aspirin users was evaluated in a recent clinical trial^[47]. Thus, 123 *H pylori* positive patients with a history of an aspirin-related peptic ulcer complication and current peptic ulcer were initially treated with a 7-d *H pylori* eradication therapy followed by 40 mg of famotidine daily for 5 or 13 additional weeks until ulcer healing. Then, they all restarted taking 100 mg of aspirin daily and randomized to receive 30 mg of lansoprazole daily or placebo. During a median follow-up of 12 mo, recurrence of ulcer complications was observed in 9 (14.8%) of 61 patients in the placebo group and in only 1 (1.6%) of 62 patients in the lansoprazole group (adjusted hazard ratio: 9.6, 95%CI: 1.2-76.1, $P = 0.008$)^[47]. It should be noted, however, that four of the nine placebo treated patients with a recurrence of ulcer complications were reinfected with *H pylori* and an additional two patients of this group took other NSAIDs. Despite these problems in the latter trial, it is becoming widely accepted that long-term therapy with a PPI after *H pylori* eradication offers additional benefit in preventing peptic ulcer complications in high risk *H pylori* positive chronic aspirin users^[19].

DISCUSSION

All existing data suggest that the presence of *H pylori* infection represents an additional risk factor for peptic ulcer complications in aspirin/NSAID users^[19,48]. However, in current clinical practice which should be guided by the evidence-based medicine and should take into account the cost/benefit analysis of any major intervention, the management of *H pylori* infection and generally the gastrointestinal prevention in aspirin/NSAID users should probably be individualized (Table 1). Thus, the optimal management of such subjects appears to depend on the main factors affecting the risk of ulcer complications, which are: (1) whether the subject is a

Table 1 Recommendations^[19,48] and evidence for the *H pylori* test-and-treat approach and/or the long-term therapy with a proton pump inhibitor (PPI) in users of aspirin or non-steroidal anti-inflammatory drugs (NSAIDs)

	<i>H pylori</i> test-and-treat approach	Long-term PPI therapy
Naive aspirin users	Recommendation	No
Naive NSAIDs users	Recommendation-evidence ^[39,40]	No
Chronic aspirin users		
With a recent ulcer complication	Recommendation ¹ -evidence ^[46,47]	Recommendation-evidence ^[47]
At high risk for ulcer complication	Recommendation ¹	Recommendation
At low risk for ulcer complication	No	No
Chronic NSAIDs users		
With a recent ulcer complication	Potential benefit ^{1,2}	Recommendation-evidence ^[46]
At high risk for ulcer complication	Potential benefit ^{1,2}	Recommendation
At low risk for ulcer complication	No	No

¹*H pylori* eradication therapy in chronic users of aspirin or NSAIDs with a recent ulcer complication or those at a high-risk should be administered after confirmation of ulcer healing. ²*H pylori* eradication therapy in chronic NSAIDs users with a recent ulcer complication or those at a high-risk may be given as a potentially beneficial intervention in addition to the long-term PPI therapy.

naive aspirin/NSAID user or already on long-term (>1-3 mo) or chronic drug use^[36-38]; (2) whether the subject is at high risk for bleeding or other complication of peptic ulcer (history of complicated or uncomplicated peptic ulcer, age older than 60-65 years, recent dyspepsia, treatment with anticoagulants)^[6,36-38,49]; and (3) perhaps whether they take aspirin or non-aspirin NSAID^[19,48].

In naive NSAID users, it is well accepted and supported by strong data^[39,40] that they should be tested for the presence of *H pylori* infection and, if positive, receive *H pylori* eradication therapy before NSAID use^[19-48]. A similar strategy is also suggested for naive aspirin users^[19], although the efficacy of such an approach has not been evaluated yet.

In chronic aspirin/NSAIDs users, the recommendations may depend on the risk for peptic ulcer complications^[6] and the type of drug. The indication for use of aspirin or NSAIDs should be first evaluated in all such users at high risk for peptic ulcer complications. Moreover, the probability and the cost/benefit of replacement of aspirin or NSAID with a less gastrototoxic antiplatelet agent or a selective COX-2 inhibitor respectively may be considered^[6,11,12].

All individuals, who should continue taking aspirin after development of a peptic ulcer complication, should be tested for the presence of *H pylori* infection and, if positive, receive *H pylori* eradication therapy after peptic ulcer healing. In addition, they should subsequently receive long-term therapy with a PPI^[19,47]. A similar approach may be recommended in chronic aspirin users without a recent ulcer complication but at high risk for ulcer complication, such as those with a history of peptic ulcer^[19]. It should be noted, however, that there are no strong data to support the combined prophylactic approach with both *H pylori* eradication and long-term PPI therapy in this setting.

All individuals, who should continue taking NSAIDs being at high-risk for peptic ulcer complication, certainly benefit from long-term therapy with a PPI^[19,46,48]. The risk of relapse of ulcer complication in chronic NSAIDs users taking PPI, however, is higher than the risk of such a relapse in aspirin users irrespective of the type of gastroprotection^[46]. Thus, given that *H pylori* infection represents an independent risk factor for gastrointestinal bleeding in chronic NSAIDs

users^[35], it is often recommended that testing for *H pylori* infection and, if positive, *H pylori* eradication therapy should be offered to high-risk chronic NSAIDs users in addition to the long-term PPI therapy^[19], despite that there are no strong data to support such an approach.

Finally, testing for *H pylori* infection or PPI therapy is not recommended for chronic users of aspirin or NSAIDs with no peptic ulcer or complication or those at a low risk of the same^[19].

Abstract

To review the preventive approaches for recurrence after curative resection of hepatic metastases from colorectal carcinoma, we have summarized all available publications reporting randomized control trials (RCTs) covered in PubMed. The treatment approaches presented above include adjuvant intrahepatic arterial infusion chemotherapy, systemic chemotherapy, neoadjuvant chemotherapy, and immunotherapy. Although no standard treatment has been established, several approaches present promising results, which are both effective and tolerable in post-hepatectomy patients. Intrahepatic arterial infusion chemotherapy should be regarded as effective and tolerable and it increases overall survival (OS) and disease-free survival (DFS) of patients, while 5-fluorouracil-based systemic chemotherapy has not shown any significant survival benefit. Fortunately chemotherapy combined with hepatic arterial infusion and intravenous infusion has shown OS and DFS benefit in many researches. Few neoadjuvant RCT studies have been conducted to evaluate its effect on prolonging survivals although many retrospective studies and case reports are published in which unresectable colorectal liver metastases are downstaged and made resectable with neoadjuvant chemotherapy. Liver resection supplemented with immunotherapy is associated with optimal results; however, it is also questioned by others. In conclusion, several adjuvant approaches have been studied for their efficacy on recurrence after hepatectomy for liver metastases from colorectal cancer (CRC), but multi-centric RCT is still needed for further evaluation on their efficacy and systemic or local toxicities. In addition, new adjuvant treatment should be investigated to provide more effective and tolerable methods for the patients with resectable hepatic metastases from CRC.

INTRODUCTION

Although many approaches have been invented for the treatment of liver metastases from colorectal cancer (CRC)^[1], resection continues to be the only curative therapeutic option. Liver resection is today a safe procedure, with a low mortality rate of 0.8%^[2] and a morbidity of 7.2%^[3]. Though the 5- and 10-year overall survival (OS) rates are 37% and 22% respectively^[4], recurrence is already evidenced, either in the liver or with extrahepatic disease in about half of all resected patients within 18 mo after resection^[5]. Intrahepatic recurrence, alone or with other localization, is common. However, about 60% recurrences are seen in the remnant liver^[6]. In the last two decades people have tried a number of approaches to prevent recurrence, but only a few of them were designed as randomized control trials (RCTs), which provide evidence-based results for those treatment modalities. In this paper, we summarized the results from RCTs, attempting to find a more suitable treatment modality for prevention of recurrence.

LITERATURE REVIEWS OF RANDOMIZED CONTROL TRIALS TO PREVENT RECURRENCE AFTER CURATIVE HEPATECTOMY FOR LIVER METASTASES OF COLORECTAL CARCINOMA

Hepatic arterial infusion

Rationale for regional therapy after resection of liver metastases is that hepatic metastases are perfused almost exclusively by the hepatic artery, while normal hepatocytes derive their blood supply from the portal vein, which provides the basis for the use of regional hepatic arterial infusion (HAI) therapy after resection of hepatic metastases. Though favorable long-term results can be achieved after surgery for colorectal metastases to the liver, recurrences both intrahepatic and extrahepatic commonly occur^[5,6]. Tumor cells from colorectal carcinoma spread hematogenously

via the portal circulation, making liver the first site of metastases. The most common site of failure after resection is within the remnant liver. Hence, additional therapy, either regional or systemic or both, has potential as an adjunct treatment after surgery. Extraction of drugs from the hepatic arterial circulation ensures high drug concentrations to residual cancer cells while minimizing systemic toxicity, provided the agent used has a high first-pass extraction. Of the various chemotherapy agents, 5-fluoro-2-deoxyuridine (FUDR) is the most commonly used drug for this purpose, which demonstrates 95% hepatic extraction when given via HAI. FUDR via HAI markedly increases its estimated exposure up to 400-fold. 5-FU is the other agent used in this setting of regional therapy and its response rate can be expected higher when used in combination with concomitant leukovorin^[7]. Combining 5-FU with other agents by hepatic artery infusion has been proven to be an effective treatment for liver metastases from CRC.

Table 1 summarizes the randomized series of adjuvant intrahepatic therapy (with or without systemic therapy) after potentially curative hepatic resection of metastatic CRC.

A small study by Lygidakis *et al.*^[8], prospectively randomized 40 patients to hepatic surgery alone or surgery combined with post-operative regional chemoimmunotherapy via implanted splenic and gastroduodenal arterial catheters, and found that liver resection supplemented with postoperative targeted transarterial locoregional immunotherapy-chemotherapy is associated with optimal results.

Asahara *et al.*^[9], conducted a study to evaluate the efficacy of postoperative transarterial infusion chemotherapy for the prevention of recurrence after hepatectomy following curative surgery for colorectal carcinoma. The result showed that the 3- and 4-year survival rates are 100% in the experimental group, and 60% and 47% respectively in the control group.

Kemeny *et al.*^[12], tried to improve the outcomes by treating patients with HAI of floxuridine plus systemic

fluorouracil after liver resection, and found that a 2-year OS and DFS benefit in HAI group is 86% *vs* 72%, 57% *vs* 42%. After 2 years, the rate of survival free of hepatic recurrence is 90% in the HAI group and 60% in the monotherapy group, suggesting that for patients who undergo resection of liver metastases from CRC, postoperative treatment with a combination of HAI of floxuridine and intravenous fluorouracil improves the outcome.

Tono *et al.*^[13], divided 19 patients who underwent curative hepatectomy for metastatic colorectal carcinoma into HAI group and control group. Patients in HAI group received continuous intra-arterial infusion of 5-FU (500 mg/d), 4 d a week for 6 wk. The study showed a significant 1-, 2-, 3-year prolongation of DFS in the HAI group (77.8% *vs* 50.0%, 77.8% *vs* 30.0%, 66.7% *vs* 20.0%, $P = 0.045$). The 1-, 3-, and 5-year cumulative survival rates for the HAI group were 88.9%, 77.8%, and 77.8%, respectively, whereas those of the control group were 100.0%, 50.0%, and 50.0%, respectively. This randomized study reveals that short-term HAI of 5-FU after curative resection of colorectal hepatic metastases is effective in preventing the recurrence of disease and has no serious complications.

Kemeny *et al.*^[14], studied the effect of postoperative hepatic arterial floxuridine combined with intravenous continuous infusion of fluorouracil on the OS and DFS of patients, and found that the 4-year recurrence-free rate is 25% in the control group and 46% in the chemotherapy group, the median survival time of the 75 assessable patients is 49 mo in the control group and 63.7 mo in the chemotherapy group, demonstrating that adjuvant intra-arterial and intravenous chemotherapy is beneficial to the prevention of hepatic recurrence after hepatic resection of CRC.

However, in a German co-operative multicenter study^[11], patients were randomized to resection only or resection plus 6 mo of HAI of 5-FU/LV given as a 5-d continuous

infusion every 28 d. No differences in time-to-progression, time-to-hepatic progression, or median OS are noted in this study.

Rudroff *et al.*^[10], evaluated the preventive effect of adjuvant intra-arterial chemotherapy after R0 liver resection and found that there is no significant difference in either 5-year survival or long-term disease-free status between the two groups. They concluded that routine application of adjuvant regional chemotherapy after R0 liver resection is not warranted.

A recent meta-analysis^[15] also showed that hepatic artery chemotherapy after curative hepatectomy metastases cannot improve the OS.

The above data suggest that adjuvant intrahepatic arterial chemotherapy combined with or without intravenous chemotherapy can inhibit the recurrence, and that the toxicity and side effects are tolerable.

At present, the superior rates of response and survival reported with irinotecan- and oxaliplatin-based regimens^[16-19] provide a new standard first-line treatment of metastatic CRC, which have led to more clinical trials to re-evaluate the efficiency of HAI combining irinotecan or oxaliplatin on recurrence after curative hepatectomy for CRC. At the Memorial Sloan-Kettering Cancer Center (MSKCC), a phase I/II study used HAI with floxuridine and dexamethasone in combination with systemic irinotecan as adjuvant therapy following curative hepatectomy in 90 CRC patients. The maximum tolerable dose of combined HAI+systemic irinotecan is 0.12 mg/kg FUDR with systemic CPT-11 at 200 mg/m² every other week, the 2-year survival rate is 87%^[20-22]. Oxaliplatin, a new cytotoxic agent, when used in combination with 5-FU/LV (FOLFOX), can achieve more than 50% clinical response and a median survival time of 16.2 mo in untreated patients with metastatic CRC^[18,19], suggesting that oxaliplatin-based regimens combined with HAI of FUDR have a promising result.

HAI of FUDR plus systemic 5-FU/LV following resection of hepatic metastases decreases local recurrence and improves OS. It is necessary to further study the effect of HAI combining newer systemic agents, such as irinotecan and oxaliplatin and to make it clear which combination of regimens are the most effective and well-tolerated.

Systemic chemotherapy

While patients who undergo resection of liver metastases from CRC can prolong their survival time, the majority will have relapse not only intrahepatically but also extrahepatically. Therefore, the investigation of adjuvant

therapies designed to decrease relapse is warranted. Adjuvant chemotherapy via HAI after resection of liver metastases has shown its efficacy in terms of both disease-free survival (DFS) and OS. On the contrary, the role of “adjuvant” chemotherapy following liver resection for hepatic colorectal metastases remains unclear. Some retrospective trials about adjuvant 5-FU-based systemic chemotherapy have not shown any significant survival benefit^[18,19]. Few prospective randomized studies have been performed to answer the question whether postoperative chemotherapy improves survival in comparison to liver resection alone. However, the effects on survival of postoperative systemic chemotherapy are currently under evaluation. The following are recent RCT studies on systemic chemotherapy (Table 2).

Lopez-Ladron *et al.*^[24], studied the outcome of 38 patients with resection of liver metastases from CRC, and found that the median OS time of patients who did not receive CT is 15 mo, while patients who received CT after hepatic surgery have a median survival time of 30 mo. The actual OS of patients who received adjuvant CT seems to be higher, suggesting that these results should be confirmed in phase III studies.

An intergroup multicentric randomized study^[23] was performed to evaluate the value of FU/FA after complete resection of liver metastases compared to surgery alone. The result is in favor of patients who received systemic chemotherapy after resection of liver metastases.

At present, more studies are focused on the effect of HAI combined with systemic chemotherapy on the OS and DFS^[12,14] (Table 1).

In general, systemic chemotherapy alone cannot inhibit recurrence in patients after resection of hepatic colorectal metastases, although systemic 5-FU/LV and HAI of FUDR following resection of hepatic metastases decrease local recurrence and improve 2-year survival. Both hepatic and extrahepatic relapses remain a problem. Studies on newer systemic agents such as irinotecan and oxaliplatin are under way.

Neoadjuvant therapy

The application of neoadjuvant chemotherapy has a number of potential advantages in patients with resectable liver metastases. Firstly, it helps the selection of chemotherapeutic agents after resection. The degree of response gives information on the *in vivo* chemosensitivity of the tumor. In patients with fewer responses or severe toxicity, the same agents should be avoided and alternative agents should

be considered after resection. Secondly, neoadjuvant chemotherapy may also help the selection of candidates for resection, which means patients who develop extrahepatic disease during a short course of chemotherapy are unsuitable for resection in the first place. Finally, neoadjuvant chemotherapy enhances resectability in some instances^[25-27]. Reduction of tumor volume may limit the amount of liver that needs to be removed to accomplish eradication of the tumor and preserve more normal hepatic tissues.

Most reports on neoadjuvant chemotherapy for liver metastasis focus on the strategies for unresectable tumors^[25,28]. The reported resectability rate ranges from 10% to 40% for unresectable colorectal liver metastases after preoperative chemotherapy.

Recently, Lorenz *et al.*^[29], conducted a prospective pilot study of neoadjuvant chemotherapy with 5-fluorouracil, folinic acid and oxaliplatin for resectable liver metastases of CRC, and found that neoadjuvant chemotherapy for resectable liver metastases induces significant remissions without increasing morbidity (Table 3).

Due to the potential advantage in patients with resectable liver metastases and new regimens using either oxaliplatin or irinotecan in combination with 5-FU, one phase II study^[30] of neoadjuvant 5-FU+leukovorin+CPT-11 in patients with resectable liver metastases from colorectal adenocarcinoma is under investigation. The general aim of this study is to determine the efficacy of neoadjuvant chemotherapy for patients with ablative liver metastases from CRC in reducing

recurrence rate. Response to the chemotherapy regimen will constitute an *in vivo* chemosensitivity test, and this will guide adjuvant chemotherapy following resection of liver metastases from CRC.

Immunotherapy

Since early 1990s, immunotherapy has become a very attractive cancer treatment modality. However, it is not so effective as expected in a number of clinical trials^[31,32]. Recently a series of clinical trials have begun to investigate the effect immunotherapy on recurrence of cancer after surgery. The summary of these RCTs are as follows (Table 4).

Lygidakis *et al.*^[8], compared the effect of liver resection combined with post-operative locoregional immunotherapy +chemotherapy on recurrence after curative hepatectomy of hepatic colorectal metastases, and found that the survival time of control group ranges from 4 to 25 mo (mean 11 mo), suggesting that liver resection in combination with postoperative targeted transarterial locoregional immunotherapy -chemotherapy is associated with good results. It is highly recommended as the procedure of choice for patients with liver metastasis of colorectal carcinoma.

Lygidakis *et al.*^[33], showed the same results, which support post-operatively locoregional chemotherapy for hepatic metastases of CRC. Lygidakis *et al.*^[34], reported that regional immunochemotherapy combined with systemic chemotherapy leads to a lower incidence of disease recurrence and a significant prolongation of the OS and DFS time.

Table 4 RCTs of immunotherapy

Authors	Treatment protocol	Sample size (Tx/Ctl)	Observation time	DFS Tx vs Ctl	OS Tx vs Ctl	Conclusions
Lygidakis <i>et al.</i> ^[8]	Surgery+post-operative HAI immunochemotherapy vs surgery alone	40 (20/20)	3 yr	NA	Median 20 vs 11 (mo) (P<0.05)	Beneficial
Lygidakis <i>et al.</i> ^[33]	Post-operatively locoregional immunochemotherapy vs post-operatively locoregional chemotherapy	45 (33/15)	NA	NA	Median 20.3 vs 9.9 (mo)	Beneficial
Lygidakis <i>et al.</i> ^[34]	Locoregional chemoimmunotherapy with systemic chemotherapy vs systemic immunochemotherapy	122 (62/60)	NA	2-yr 66% vs 48%	2-yr 92% vs 75% 5-yr 73% vs 60%	Beneficial
Elias <i>et al.</i> ^[35]	Preoperative rIL-2 continuous intravenous infusion	19 (12/7)	NA	NA	NA	Beneficial (well tolerated and reverse postoperative immunodepression)
Gardini <i>et al.</i> ^[36]	Post-operative TIL+IL-2 vs post-operative+chemotherapy	45 (25/22)	NA	1-, 3-, and 5- yr No difference	1-, 3-, and 5-yr No difference	Not beneficial

Tx: treatment; Ctl: control; DFS: disease-free survival; OS: overall survival; NA: not available.

Elias *et al.*^[35], investigated prehepatectomy immunostimulation with recombinant interleukin-2 (rIL-2) and evaluated the tolerance of rIL-2 in association with major hepatectomy to verify the effect of preoperative immunostimulation (neoadjuvant immunotherapy), and found that toxicity during rIL-2 infusion is acceptable, suggesting that infusion of rIL-2 before major hepatectomy for liver metastases of CRC is well tolerated and reverses postoperative immunodepression.

Gardini *et al.*^[36], also studied immunotherapy with tumor infiltrating lymphocytes (TIL) plus interleukin-2 (IL-2) as adjuvant treatment, and found that there are no significant differences in the actual and DFS rates after 1, 3, and 5 years, suggesting that whether TIL+IL-2 treatment is an effective adjuvant therapy needs to be further studied.

SUMMARY

Number of preventive treatment protocols for inhibiting recurrence after curative resection of liver metastases from colorectal origin have been evaluated by RCT. Although no standard treatment has been proven to be effective in all patients, several approaches present promising results, which are both effective and tolerable in post-operative patients. Generally intrahepatic arterial infusion chemotherapy is effective in preventing the recurrence of disease without serious complications, while systemic chemotherapy is not in favor of patients who receive systemic chemotherapy after liver metastases resection. Neoadjuvant chemotherapy has shown an advantage in patients with resectable liver metastases. Immunotherapy approaches can achieve a better outcome, but need more evidence before wide acceptance.

Abstract

AIM: The aim of the present study is to use immunohistochemical methods to investigate the clinical implications of tumor markers in esophageal squamous cell carcinoma and evaluate their impact on prognosis.

METHODS: From November 1990 to December 1996, 47 patients were treated with preoperative radiation followed by radical esophagectomy. All patients were confirmed pathologically as suffering from squamous cell carcinoma. Immunohistochemical stain was done for PCNA, cyclinD1 protein expression and DNA content analyzed by image cytometry. Kaplan-Meier method for single prognostic factor and log-rank test was used to test the significant difference. Cox stepwise regression model and prognosis index model were used for survival analysis with multiple prognostic factors.

RESULTS: Radio-pathological change, T stage and N stage, as the traditional prognostic factors had statistical difference in 3-, 5- and 10-year survival rates. While, tumor cell proliferating marked PCNA, cyclinD1 and DNA content served as independent prognostic factors of esophageal carcinoma. There was definitely an identity between the single and multiple factor analyses. PI was more accurate to evaluate the prognosis of esophageal carcinoma.

CONCLUSION: It is possible that tumor cell proliferating marked PCNA, cyclinD1 and DNA content would become the endpoints for evaluating the prognosis of esophageal carcinoma.

INTRODUCTION

Esophageal cancer, the sixth most common cancer worldwide, is one of the most interesting cancers in terms of its geographic distribution, variety of environmental factors including tobacco, alcohol, nutritional deficiencies and nitrosamines^[1,2]. The ratio of the incidence rates between high-risk and low-risk areas can be as great as 500:1, e.g., Cixian, in Hebei Province of northern China, has received worldwide attention over the past decades because of its high esophageal cancer incidence. Results from earlier studies show that malignant transformation of human esophageal mucosa is a multistage process. An early indicator of abnormality in persons predisposed to squamous cell carcinoma (SCC) is the proliferation of esophageal epithelial cells, morphologically manifested as basal-cell hyperplasia (BCH) and dysplasia (DYS). However, key molecular changes in the esophageal carcinogenesis still remain to be characterized^[3].

Furthermore, genetic factors, such as the activation of oncogene and the inactivation of tumor suppressor genes, are believed to play important roles. Earlier studies have shown the PCNA (proliferating cell nuclear antigen) is a 36-ku, 261-amino acid non-histone polypeptide that is localized in the nucleus and is associated with cell proliferation with function as an auxiliary protein to DNA polymerase-delta. PCNA appears to be necessary for DNA replication and elevated level of this protein at the G₁/S phase transition are present in cells undergoing division^[4,5].

Recent evidence has suggested that cyclinD1 gene (also referred to as *prad1*) amplification might also be involved in the development of esophageal carcinoma. The cyclinD1 gene has been mapped to the chromosome 11q13 locus close to the *int2* and *hst1* genes. The complex of cyclinD1 protein and cyclin-dependent protein kinases (cdks) may

govern key transitions in the cell cycle. Zhang^[6] found that cyclinD1 gene was amplified and its protein expression increased in only one-third of the esophageal SCC. However, the knowledge of the role of cyclinD1 in esophageal carcinogenesis is not yet definite in detail, since the level of cyclinD1 protein in different stages of carcinogenesis of esophageal carcinoma has not been determined^[6].

In the current study, it is possible to use only cancer cells for analyzing the DNA patterns and ploidy in cytophotometry. Most investigators have shown in clinical esophageal SCC, high-ploidy tumors grow more rapidly than low-ploidy ones, and the duration from curative esophagectomy to recurrence decreases in proportion to the degree of DNA aneuploidy^[7].

Thus, despite aggressive therapy for esophageal cancer, the outcome is generally poor with a large number of patients developing rapid recurrence even after curative operation^[8,9]. If the prospect of prognosis and metastasis could be predicted preoperatively, it would be appropriate to select the most adequate treatment for individual cancer patient. Thus multi-disciplinary treatment including chemotherapy and irradiation would be reserved for patients predicted to have a poor prognosis while a less aggressive approach could be undertaken for those with better prognosis. Though most of the previous lectures showing DNA ploidy, AgNoRs and amplification of some oncogenes had been investigated to determine their prognostic value in esophageal cancer, the indication by PCNA, cyclinD1 protein expression combined with DNA ploidy have not been reported. It is expected to be of interest to evaluate them together as predictors of the malignant potential. In this report, we examined the cyclinD1, PCNA protein and DNA ploidy of esophageal carcinoma in 47 paired specimens from endoscopic biopsy and surgical resection tissue, with biologic features and prognostic value was also discussed.

MATERIALS AND METHODS

Patients

There are 47 patients (median age 62 years, range 33-74 years, 28 males and 19 females) with SCC of esophagus treated from November 1990 to December 1993 by preoperative radiotherapy followed by curative esophagectomy at the Fourth Hospital, Hebei Medical University, in northern China. All patients had been examined by gastrointestinal endoscopy, barium swallow, chest X-ray and liver ultrasound scans. Patients with stage IV disease shown by computed tomography were excluded. Pathological evaluation done according to the criteria established by the Chinese Society for Esophageal Disease (Henan, 1987), showed all patients were suffering from SCC. We had obtained two sets of specimens from each patient: endoscopic biopsy before preoperative radiotherapy and the surgical specimens of the same patient after esophagectomy of which the tumor markers in all 47 paired specimens were investigated. The maximum follow-up was 144 mo with a median of 56 mo.

Radiotherapy

All the 47 patients received preoperative radiotherapy, the external beam radiation was given by a 10-MV X-ray (Linear Accelerator, SIEMENS, PRIMUS) using the

conventional fractionated irradiation. The irradiated volume included the gross tumor with a safety margin of 5.0 cm both proximally and distally. Treatment was given through two opposing fields (anterior and posterior); 2.0 Gy was delivered daily for 5 d a wk to a total dose of 30-40 Gy in 15-20 fractions over 3-4 wk.

Esophagectomy

Transthoracic esophagectomy, the most common approach through a right or left thoracotomy incision depending on the preference of the surgeon and the location of the tumor was performed. Tumor located in the lower third of the esophagus usually was approached through a left thoracotomy. A left sixth interspace incision provides excellent exposure of the lower mediastinum. Gastrointestinal reconstruction was subsequently achieved by prepared esophageal substitute (usually the stomach), by passing of a prepared esophageal substitute, usually the stomach underneath the aortic arch and suture to the esophageal stump. Definite esophagectomy was undertaken 3 wk after radiotherapy.

Immunohistochemical stain

Biopsy and surgical specimens were fixed in 40 g/L formaldehyde and embedded in paraffin wax. Five-micron sections cut from each specimen, dewaxed in xylene, rehydrated through grading concentrations of ethanol were immersed in 3% hydrogen peroxide to block the endogenous peroxidase and washed in phosphate buffered saline. For cyclinD1 and PCNA immunohistochemical stain, tissue sections were heated in 10 mmol/L sodium citrate (pH 6.0) in a microwave oven for 10 min to expose the antigens, and, then, treated with normal goat serum (10%) before staining to reduce nonspecific antibody binding. Tissue sections were incubated at 4 °C overnight for cyclinD1. CyclinD1 and PCNA stain with the following antibodies: mouse monoclonal anti-cyclinD1 antibody (Novocastra Laboratories Ltd., UK) at 1:20 dilution and mouse monoclonal anti-PCNA antibody (PC-10, Dakopath, Glostrup, Denmark) at 1:100 dilution. The sections were then washed and incubated with biotinylated goat anti-rabbit IgG (Vector Laboratories, Burlingame, CA) at room temperature for 30 min. After washing, the sections were incubated with avidin-biotin-peroxidase complex at room temperature for 30 min with the vectastain Elite ABC kit (Vector Laboratories Burlingame, CA). Color developed with 3,3-diaminobenzidine as the substrate. Sections were counter-stained with Harris acid hematoxylin to demonstrate the specificity of the immunostain and the primary antibodies were replaced with similar protein concentrations of normal rabbit IgG.

The PCNA, cyclinD1 protein expression of the endoscopic biopsy and surgical specimens were compared by two histopathologists by the double-blind arrangement in assessing the tumor response to radiotherapy. For cyclinD1 and PCNA, 1 000 tumor cells in five high-power fields were counted respectively. PCNA index was the percentage of nuclei stained positive. PCNA index greater than 25% was taken as PCNA positive. PCNA index lower than 25% was taken as PCNA-negative. For cyclinD1, positive cell nucleus not found was taken as negative. When the percentage of positive cell nucleus was greater than 30%, it was taken

as strongly positive. Between the two levels, it was positive. Therefore three grades were ascertained for cyclinD1 expression^[5,9,10].

Analysis of DNA content

Cellular DNA analysis was performed on paraffin sections cut 100 μm thick. The sections were stained with Feulgen stain and examined using a microspectrophotometer by two-wavelength method. Data processing was carried out with a personal computer (HP-85, Hewlett-Packard, Palo Alto, CA, USA). In each section, the mean DNA value of 20 stromal lymphocytes was used as a control of the normal diploid complement (2C). The relative DNA content as compared with the 2C value was determined in 100 tumor cells in each lesion as previously described^[11,12]. The DNA distribution patterns were then classified into four types, according to the degree of the peak and dispersion on the DNA histogram, as follows: Type I, a prominent peak in the 2C region with a dispersion to the 4C region, Type II, a relative high peak in the 2C-3C regions with a dispersion limited to the 6C region, Type III, a low peak beyond the 3C region with less than 20% of the cells beyond the 6C region and Type IV, multiple peaks with a broad dispersion and more than 20% of cells beyond the 6C region.

Statistical analysis

PCNA, cyclinD1 protein expression index and DNA distribution pattern were analyzed and regarded in the clinicopathological features as determined by the χ^2 test. Difference between the cumulative survival rates of patient groups were calculated by log-rank test for comparison of Kaplan-Meier survival curves. The significance of various parameters on survival were analyzed by multivariate Cox regression model. A *P* value of 0.05 or less was considered statistically significant (statistical software SPSS 10.0 for Windows).

RESULTS

Response to preoperative radiotherapy and the overall survival of patients

All the patients had received preoperative radiotherapy followed by definite surgical resection. The complete response rate as shown by pathology was 29.8% (14/47) for the entire group treated by preoperative radiotherapy and 5-year survival rate was 71.4% (10/14) for 14 patients with complete response by pathology. The overall survival rates of all these patients in the 3, 5 and 10-years were 54.3%, 46.2% and 38.8%, respectively.

Expression of PCNA, cyclinD1 immunoreactivity and DNA content in the tumor cells by histopathology

PCNA stain was almost entirely confined to the cell nuclei and showed diffuse and granular pattern or a mixture of both. While cyclinD1 stain was present in the cytoplasm around the cell nuclei in most parts, and a few parts in the tumor cell nuclei. At the same time, PCNA stain was observed in the basal layer of stratified squamous epithelium in normal tissue. In this study, all cyclinD1 present both in the stained nuclei and the cytoplasm around them were considered as protein expression positive carcinoma cells. We took both

Types I and II DNA content as the low ploidy pattern and Types III and IV as the high ploidy pattern.

Analysis of cyclinD1, PCNA expression and DNA distribution pattern with regard to clinicopathological features and prognosis

Kaplan-Meier method was used to analyze the single factors, including age, sex, irradiation dose, location of disease, length, and radiation response observed by pathology, T stage, N stage, PCNA index, cyclinD1 protein expression and DNA content pattern, e.g. Types I and II or Types III and IV influenced the prognosis of esophageal carcinoma obviously. The *P* value as checked by the log-rank test ≥ 0.05 was taken as significant. Only the four preoperative radiotherapy factors: radiation changes observed by pathology, T stage, N stage and cyclinD1 protein expression before radiation in the endoscopic biopsies; those observed in the surgery resected specimens showing PCNA index, cyclinD1 expression level, DNA content pattern, revealed significant difference ($P < 0.05$, Table 1), whereas age, sex, total tumor dose, location and length of disease possessed no value in prognosis.

Multiple varieties combined by Cox hazard risk model analysis

T stage, N stage, pathological changes after radiotherapy, pre-radiotherapy cyclinD1 protein expression and post-radiotherapy PCNA index, cyclinD1 protein expression and DNA content pattern with Cox hazard risk regression model were analyzed. The most significant factors were the post-radiotherapy PCNA index and DNA content pattern (specimens from surgical specimens). Furthermore, each factor by single parameter analysis gave the most marked prognostic difference, while multivariation considered by Cox model, clearly affected the prognosis of esophageal cancer patients (Table 2).

Analysis of esophageal squamous cell carcinoma by prognosis index model

According to the formulation of prognosis index (PI) model from statistic software, it was defined as 0 which had the least influence on prognosis. Number 2 had the greatest effect on prognosis. When the number was 1, the prognosis was between 0 and 2. For example, T stage divided by T₁, T₂, T₃ would show difference on patients survival and we gave them the number 0, 1, 2 respectively as shown in Table 2. The group's weight (0, 1, 2 or 0, 1) times the coefficient of Cox regression model (β value). Then by adding each group's data results would give each patient's PI value, e.g., different factors (T stage, N stage, PCNA, cyclinD1 expression, etc.) at the same weight number. For example, all number 0 patients, or number 1 patients, or number 2 patients would give the PI (prognosis index) value for each patient (Table 3).

Different PI values give different prognosis

According to the distribution of PI values in all patients, the four subgroups were divided according to different PI values. PI values lower than 2.0, between 2.0 and 5.0, between 5.0 and 7.0 or higher than 7.0 may go stepwise further with the median survival terms and 3-, 5-, 10-year survival rates of the four subgroup patients would reveal significant

DISCUSSION

Cancer of the esophagus is the most common cancer in northern China, for which current consensus of treatment varies from surgery, radiotherapy, chemotherapy, and endoscopic laser surgery or their combination. The outcome, however, remains dismal because most patients are seen with advanced disease on diagnosis^[13-15]. Thus, what the majority of patients need is a multimodality program. Yet how to know which patients really need which modality is still an open focus. Nevertheless, traditional prognostic factors: T stage, N stage are basically the most important. Yet up to now, their application has merely been used by the surgically treated patients. For conservative treatment, besides the TNM classification system, additional variables such as biological staging for the intrinsic malignant potential of the tumor, are to be useful to determine the treatment and long-term survival^[16].

Recently, with rapid advance in biological and genetic studies, more and more tumor markers are being correlated

with tumor characteristics^[8]. The ability to predict, on the basis of immunocytochemical assessment of pretreatment biopsy, which patients are likely to respond to chemoradiotherapy would be a major advance in the management of cancer patients. Thus, it is possible to provide the most adequate protocol for different patients by combining traditional factors and the markers of tumor cells^[16].

Several studies^[8,9,15] have shown that high PCNA expression in esophageal tumor is associated with a worse prognosis in surgical patients and greater likelihood of recurrence. However, such a report on PCNA, and cyclinD1 protein expression examined simultaneously in biopsy and resected specimens of esophageal carcinoma has never been seen. Nor possible correlation between PCNA, cyclinD1 protein expression and the traditional prognostic factors (T stage, N stage) to chemoradiotherapy has never been investigated. Immunohistochemical detection of PCNA being simple and useful for the study of cell kinetics, allows the retrospective evaluation of the proliferating state of the tumor as it can be used in conventionally fixed materials. Many authors^[17,18] showed the higher PCNA index patients usually gave the worse prognosis with local recurrence. In the past years, it has been proved that the combination of PCNA index with the AgNOR count appears to be an effective means of identifying patients with poor prognosis. For patients with a PCNA index of ≥ 44 and AgNOR count of ≥ 6 , multidisciplinary treatment should be recommended in an attempt to prolong survival. However, in this study, PCNA index as checked by endoscopic biopsies have not shown such influence on survival^[9].

Furthermore, we have found PCNA protein expression to be significantly high in surgically resected specimens with PCNA index 63.8% (30/47) compared to the endoscopic biopsy before radiation 55.3% (26/47). At the same time, patients with high PCNA index in the surgically resected specimens had the worse prognosis. PCNA protein expression examined after radiotherapy made a significant difference to esophageal cancer prognosis. The repopulation of tumor cells after radiation may exist which results in local recurrence of esophageal carcinoma after radiotherapy.

Table 4 Median survivals and survival rates with subgroups divided by prognosis index (%)

Prognosis indexes	Number patients	Median month	3 yr	5 yr	10 yr
<2.0	17	146	100	88.2	69.7
2.0-5.0	8	93.5	50	50	50
5.0-7.0	10	20	30	30	0
>7.0	12	13	9.6	0	0

The most important advantage of PCNA, cyclinD1 immunohistochemical assay is that the analysis changes are restricted to the tumor cells. In contrast, flow cytometry assay, all cells in the tissue block are measured and in DNA diploid cases, this means that SPF reflects the sum of cell proliferation that estimates the malignant and benign (stromal and inflammatory cells) components^[9].

Most studies^[6,19] reported patients with cyclinD1 amplification and protein expressions had a poor outcome and a higher incidence of distant metastasis than those in amplification-negative or protein expression-negative groups. The surgical survival rates and disease-free survival in the high cyclinD1 expression group were significantly shorter than in the cyclinD1 low or non-expression group. CyclinD1 amplification and protein expression in patients with SCC of the esophagus would mean a grave biological malignancy. Naiton *et al.*^[20] reported 55 esophageal cancer patients with a ratio of cyclinD1 protein-positive expression of 38% gave a 5-year survival rate of 7%, as compared with the 5-year survival rate of 59% in patients who showed cyclinD1 protein negative expression ($P < 0.01$). In 1998, Ishikawa^[21] studied cyclinD1 protein expression in esophageal SCC and observed similar results. Our checked results showing higher cyclinD1 protein expression both in endoscopic biopsy and surgical resected specimens also gave bad prognostic results (Table 1).

In our previous study, the clinical characteristics of patients with SCC of the esophagus, such as outcome and distant organ metastases, were found to be closely correlated with cyclinD1 amplification and protein expression in the tumor tissue. It was observed that parameters were independent from clinicopathological factors for the outcome and metastasis. It was the second highest partial regression coefficient after the pN factor in the life table with Cox proportional hazard model, and the probability rate was significant^[19,21]. In this study, the same results were obtained. From Table 2, it is apparent that both the cyclinD1 protein expression in biopsy and surgical specimens had a significant effect on the prognosis of SCC of the esophagus. Specially, cyclinD1 protein-positive expression in endoscopic biopsy was the third highest partial regression coefficient after the PCNA index and DNA content in the resected specimens in multivariate analysis using the Cox proportional hazard model. We speculate that the cyclinD1 protein prognostic value maybe relatively high as the most useful factor for predicting the outcome in SCC of the esophagus in the previous study, e.g., pN factor and pT. According to the results of both univariate and multivariate analyses, the fact that patients with cyclinD1 protein-positive had a poor outcome in every group implies this agent is a useful prognostic indicator in esophageal carcinoma. Hence, it may very well supplement the TNM classification for predicting clinical characteristics and outcome, especially for patients who are destined to undergo non-operative treatment. For these patients, TNM classification could hardly be of any assistance to offer an endpoint and select more appropriate protocol for patients with SCC of the esophagus. By checking cyclinD1 protein expression level, the ultimate combined TNM classification could thus be perfected.

The essence of cell division really is the DNA replication and changes of DNA distribution pattern which predict

tumor cell proliferation kinetics. Here cytophotometric technique is to analyze the DNA content pattern both in endoscopic biopsy and resected specimens. The most important advantage of DNA content checked by cytophotometric method is that the analysis is restricted to the tumor cells, as compared to flow cytometry, by which all cells in the tumor tissue are measured. It reflects the sum of cell proliferation which estimates both malignant and benign (stromal cell and inflammatory cell) components^[9]. In clinical esophageal carcinoma, high-ploidy tumors grow more rapidly than low-ploidy ones and the duration from curative esophagectomy to recurrence decreases in proportion to the degree of DNA aneuploidy, a view believed by many authors.

During early years, some authors^[9,11,22] reported the relationship between DNA content of a variety of human cancer cells and their malignant potential as measured by cytophotometric analysis, most of who reported that such measurement are useful in elucidating the pattern of tumor progression or the prognosis with most of the results being negative between DNA content and long-term survival. For example, Miun *et al.*^[22] reported 78 esophageal cancer patients who gave 5-year survival rate of 14% and 57% in high DNA content and low DNA content groups with statistical significance in the difference ($P = 0.03$). Matsuura^[11] found that not one patient survived over 5 years in DNA triploids or tetraploidy, but the 5-year survival rate was 70% in DNA diploidy patients. Our study shows no influence on survival or prognosis by biopsy DNA content measurement. The measured results may have been inaccurate due to the very small size of biopsy specimens. From Tables 1 and 2, the surgically resected specimens gave DNA content measurement showing significant correlation between the results and the prognosis of SCC of esophagus as assessed by univariate and multivariate analyses. This result conforms well to most of the studies reported so far^[9,11].

Through combination of the traditional prognostic factors and tumor cell markers, the radiation pathological changes, T stage, N stage, cyclinD1, PCNA protein expression and DNA content as analyzed by Cox proportional hazard model, it is found that patients with grade III pathological changes, T₁ stage, N₀ stage, cyclinD1 protein-negative, lower PCNA index and DNA content pattern Types I and II, give higher long-term survival than the control groups.

With the total patients divided into four subgroups according to the formulation of prognosis index model, prognosis is observed to be worse with higher prognosis index, giving significant difference in spite of the few patients allotted. This result clearly demonstrates the evaluation of SCC of esophagus by prognosis index model with multivariate factors is dependable and accurate.

Abstract

AIM: To observe the anti-cancer effect of iNOS selective inhibitor (aminoguanidine, AG) and investigate the relationship between iNOS inhibitor and angiogenesis, infiltration or metastasis in MFC gastric cancer xenografts.

METHODS: Fifty athymic mice xenograft models were established by inoculating gastric cancer cell MFC subcutaneously. Twenty-four hours later, 0.9% sodium chloride solution, mitomycin, low dosage AG, high dosage AG, mitomycin and AG were administered by intraperitoneal injection respectively. Thus these mice were divided into five groups of 10 each randomly: control group, MMC group, AG_L group, AG_H group, MMC+AG_H group. Two weeks later the mice were killed, and the tumor weight, inhibitory rate were evaluated. Greiss assay was used to detect the nitric oxide levels in plasma. HE and immunohistochemistry staining were used to examine microvessel density (MVD) and the expression of iNOS, VEGF, and PCNA. Apoptosis was detected by using TUNEL assay.

RESULTS: The inhibitory rates in MMC+AG_H group and AG_H group were 52.9% and 47.1% respectively, which is significant statistically compared with that of control group (0). In treatment groups, the cell proliferation index (PI) was lower and apoptosis index was higher than those of control group. Microvessel density, iNOS, and VEGF in MMC+AG_H group were 8.8 ± 2.6 , 2.4 ± 1.1 , and 2.1 ± 1.4 respectively, which is significant statistically compared with those of control group (68.3 ± 10.6 , 11.3 ± 1.3 , and 10.3 ± 1.6). The NO level in plasma of MMC+AG_H and AG_H group were 12.7 ± 2.1 and 12.9 ± 2.0 $\mu\text{mol/L}$. Compared with that of control group (46.6 ± 2.3 $\mu\text{mol/L}$), the difference is statistically significant.

CONCLUSION: AG has anticancer effect on gastric cancer, and it has positive synergistic effect with chemotherapeutic drugs. It may play important inhibitory roles in angiogenesis of gastric cancer. The anticancer effect of iNOS inhibitors

may include inducing cell apoptosis, suppressing cell proliferation and reducing angiogenesis.

INTRODUCTION

The incidence of gastric cancer is high in China, and more than 170 000 people die of it each year^[1]. It is significant if certain drugs are found to lower its incidence, even prevent it.

To date, we know that carcinogenesis has intimate correlation with angiogenesis^[2-4]. So to reduce angiogenesis probably may inhibit the growth and development of tumors^[5]. It is well known that vascular endothelial growth factor (VEGF) is an important angiogenesis factor^[6,7]. We have proved that inducible nitric oxide synthase (iNOS) can induce the expression of VEGF in gastric cancer, and microvessel density (MVD) can increase with the enhancement of iNOS and VEGF^[8-10]. So VEGF and iNOS both can induce angiogenesis. So if the activity of iNOS is inhibited, tumor angiogenesis may be reduced. As a result the growth and development of tumors will be inhibited. Although the roles that iNOS inhibitors play in various tumors and their mechanisms are being widely studied recently, few people have gone deep into *in vivo* experiment. Based on *in vitro* cytologic experiments, this study went further into *in vivo* experiment to confirm the anticancer effect of iNOS inhibitor (aminoguanidine, AG).

MATERIALS AND METHODS

Animals and cell line

Fifty Kunming mice (25 females, 25 males) weighing 20-25 g were purchased from Experimental Animal Center of Jilin University. Mice were maintained under specific pathogen-free conditions and fed with sterilized food and autoclaved water. Human gastric cancer cell line MFC was purchased from Shanghai Tumor Cell Research Institute.

Agents

Greiss reagent and AG were purchased from Sigma (St.

Louis, USA). Immunohistochemical S-P kit and polyclonal antibodies to iNOS, VEGF, PCNA, and FVIIIIRag were all from Fuzhou Maxim Biotechnical Company (Fuzhou, China).

Animal experiment procedure

Each mouse was inoculated with a subcutaneous injection of MFC cells (2×10^6 in 0.2 mL PBS) into the left hind legs. Then these mice were divided into 5 groups of 10 each according to different agents which were administered to mice by intraperitoneal injection for 14 d. These agents included 0.9% sodium chloride solution (control group), mitomycin (MMC group, twice a week 0.7 mg/kg), low dosage of AG (AG_L group, 50 mg/(kg · d)), high dosage of AG (AG_H group, 150 mg/(kg · d)) and MMC+AG_H group (MMC twice a week 0.7 mg/kg, AG 150 mg/(kg · d)). On the 15th d the mice were killed. The blood was taken from abdominal aorta, then centrifuged for plasma to detect NO level by Greiss assay. All tumors were resected from the body and weighed. The inhibitory rate was deduced according to the formula: inhibitory rate (%) = (1-tumor weight of treatment group/tumor weight of control group) × 100%. Then the tumors were fixed in 40 g/L phosphate-buffered formaldehyde.

HE and immunohistochemical staining

Streptavidin-peroxidase (SP) method was used to detect MVD and the expression of iNOS, VEGF and PCNA. The formalin-fixed tissues were embedded in paraffin, and sectioned at a thickness of 4 μm. The sections were deparaffinized and hydrated gradually and examined by histology of HE staining, immunohistochemistry, and TUNEL technique respectively. Sections were heated in a microwave oven for 15 min to retrieve antigens. Endogenous peroxidase was blocked with 3 mL/L hydrogen peroxide methanol for 10 min at room temperature. After washing with phosphate-buffered saline (0.01 g/L, pH 7.4) for 3 min × 5 min, the tumor sections were incubated with normal non-immune serum from bull for 15 min at room temperature to eliminate non-specific staining. The sections were then incubated with the primary antibody against iNOS, VEGF, PCNA, and FVIIIIRag (dilution 1/100) for 60 min at room temperature, washed with PBS for 3 min × 5 min, and incubated with the secondary antibody for 15 min followed by avidin-biotin-peroxidase for 15 min at room temperature. Finally, the slides were washed for 3-15 min with PBS, visualized with DAB reagent and counterstained with hematoxylin. Negative and positive controls were used simultaneously to ensure specificity and reliability of the staining process. The negative controls were performed by substituting the primary antibody with PBS, and a positive section supplied by the manufacturer of the staining kit was taken as positive control. Sections were observed under microscope after being mounted. High vessel density was found in 100×sights. Microvessels in 10 hot regions were counted in 400×sights, and the average of microvessels with FVIIIIRag staining in 10 hot regions was calculated as MVD. Positive staining with iNOS, VEGF and PCNA were defined by brown staining of cytoplasm. The staining degree was calculated quantitatively with CIMA-400 Colorful Image Assay System which can calculate the percentages of positive staining region of the whole region.

The percentage of positive cells with PCNA staining in five 400×sights was counted as proliferation index (PI).

Apoptosis detection by TUNEL method

The reagent kit for apoptosis detection, TdT-FragEL DNA fragmentation detection kit was bought from ONCOGENE. Test procedures consisting of the following sections were provided in the brochure of the kit. The specimens were deparaffinized and hydrated gradually, and rinsed with 1×TBS, then incubated with proteinase K (20 μg/mL in 10 mmol/L Tris-HCl) for 20 min. After immersed in 30 mL/L H₂O₂ at room temperature for 5 min and in TdT labeling reaction mixture at 37 °C for 1.5 h, specimens were covered with 1×conjugate for 30 min, visualized by DAB and counter-stained by hematoxylin afterwards. TBS took the place of primary antibodies as a negative control. After being mounted, sections were observed under microscope. The results of staining were analyzed and evaluated with American Image-Pro Plus software. The percentage of positive cells with TUNEL staining in five 400×sights served as apoptosis index (AI).

Statistical analysis

All data were presented as mean ± SD. The results were compared by one-way analysis of variance (ANOVA). All statistical calculations were performed with the SPSS11.0 software package. A *P* value less than 0.05 was regarded as statistically significant.

RESULTS

Effect of AG on tumor growth

The tumor volume of MMC group on the 7th d was (383.4 ± 179.3) mm³, and on the 10th d those of AG_H and MMC+AG_H groups were (382.8 ± 132.8) mm³ and (50.0 ± 16.6) mm³ respectively. The tumor cell proliferation was almost completely suppressed. On the 14th d the tumor weight of control group was (1.7 ± 0.5) g, and those of MMC, AG_H and MMC+AG_H groups were (1.0 ± 0.2), (0.9 ± 0.3) and (0.8 ± 0.2) g, respectively. Compared with control group, the difference was significant statistically (*P* < 0.01). The NO level of plasma in AG_L, AG_H and MMC+AG_H groups were lower than that of the control group, and there was dose-effect relationship. The difference was significant statistically (*P* < 0.05, Table 1).

Table 1 Inhibitory effects of AG on transplanted stomach cancer in mice (*n* = 10, mean ± SD)

Group	Concentration of NO in plasma (μmol/L)	Weight of tumor (g)	Inhibition rate (%)
Control	46.6 ± 2.3	1.7 ± 0.5	-
MMC	42.1 ± 2.3	1.0 ± 0.2 ^b	41.2
AG _L	17.3 ± 2.0 ^b	1.1 ± 0.3 ^a	35.3
AG _H	12.9 ± 2.0 ^b	0.9 ± 0.3 ^b	47.1
MMC+AG _H	12.7 ± 2.1 ^b	0.8 ± 0.2 ^b	52.9

^a*P* < 0.05, ^b*P* < 0.01 vs control group.

Expression of iNOS and VEGF and their correlation with MVD

MVD has positive correlation with iNOS and VEGF

respectively. The coefficient of product-moment correlation $r_{\text{VEGF}} = 0.80$, $r_{\text{iNOS}} = 0.85$, $P < 0.05$. The linear regression equation is $Y_{\text{VEGF}} = 2.3565 + 0.1087X$, $n = 46$, $Y_{\text{iNOS}} = 1.8485 \pm 0.1227X$, $n = 46$. Student's t test, $P < 0.05$ (Table 2).

Table 2 Effects of AG on the microvessel density, the expression of iNOS and VEGF in tumor ($n = 10$, mean \pm SD)

Group	iNOS	VEGF	MVD
Control	11.3 \pm 1.3	10.3 \pm 1.6	68.3 \pm 10.6
MMC	9.3 \pm 1.8 ^a	8.9 \pm 2.1	56.9 \pm 10.3
AG _L	7.1 \pm 1.7 ^a	7.6 \pm 1.2 ^a	44.4 \pm 16.5 ^a
AG _H	3.8 \pm 0.9 ^b	4.8 \pm 1.6 ^b	21.2 \pm 12.4 ^b
MMC+AG _H	2.4 \pm 1.1 ^b	2.1 \pm 1.4 ^b	8.8 \pm 2.6 ^b

^a $P < 0.05$, ^b $P < 0.01$ vs control group.

HE staining

In AG and MMC+AG_H groups many necrotic cells were seen and many inflammatory cells were invasive. The tumor tissues were separated by necrosis regions. In MMC group diffusely necrotic tissues could be seen. However, in control group there were a few nuclear mitotic phases in tumor cells and in tumor tissues few muscle fibers could be seen (Figures 1A and B).

Immunohistochemical staining

MVD and the expression of iNOS and VEGF in AG groups were apparently lower than those in the control ($P < 0.01$). The difference was significant statistically. This revealed that AG could suppress angiogenesis of MFC xenografts. (Table 2, Figures 1C-H).

Cell proliferation and apoptosis

PI of control group was significantly higher than that of AG

group and MMC+AG_H group ($P < 0.05$), but the difference was not notable between treatment groups. AI in treatment groups was higher than that in the control group ($P < 0.05$), while there was also no difference between the treatment groups. The AI/PI value was calculated and compared among all groups. Consequently, it was apparently larger in treatment groups ($P < 0.01$), however no difference was shown between them (data not shown).

DISCUSSION

NO which has many biological functions is a cytokine in mammifer^[11]. It is synthesized from L-Arginine by iNOS which is the only rate-limiting enzyme^[12]. It involves a serial physiological and pathological process, such as carcinogenesis. NO can induce angiogenesis, but the mechanisms are not clear^[13-16]. However, several researches have revealed that NO can regulate the roles of VEGF in inducing angiogenesis by stimulating vascular endothelial cell proliferation and migration and improving vascular penetration^[17-20]. VEGF can increase the activity of iNOS^[6,7]. So iNOS and VEGF have positive correlation^[8-10]. It has been observed that iNOS is highly expressed in many human tumors, such as colon cancer, gastric cancer, ovarian cancer, breast cancer, *etc.*^[21]. In our previous study we have observed that the expression of VEGF and iNOS in gastric cancer presents positive correlation^[8-10]. This indicates that iNOS plays an important role in the expression and activity of VEGF. We also found that iNOS and VEGF have positive correlation with the clinicopathological characteristics of gastric cancer, such as infiltration, lymphatic or hematogenous metastasis, *etc.* At the same time MVD was higher with the enhancement of VEGF and iNOS. This revealed that iNOS and VEGF can induce angiogenesis in gastric cancer^[8-10,21].

To explore the anticancer mechanisms of iNOS inhibitor (aminoguanidine), in this study we evaluated the effect of

Figure 1 HE staining: morphology of tumor cells in AG group (A, original magnification x100) and control group (B, original magnification x200); immunohistochemical staining of tumor cells: the expression of FVIII-Rag (C),

iNOS (E) and VEGF (G) in control group, and the expression of FVIII-Rag (D), iNOS (F) and VEGF (H) in AG group. (original magnification, x400).

AG on tumor cell proliferation and apoptosis in xenografts. The AI/PI, a value reflecting cytokinetics, showed a more significant difference. Finally it is shown that compared with control group, the inhibitory rate of treatment groups are apparently higher. We also observed that AG obviously decreases the expression of iNOS and VEGF, and reduces MVD compared to that of control group. By immunohistochemistry (SP method) and Greiss assay we detected the NO level in plasma. The results indicate that the anticancer mechanisms of AG are mainly to inhibit the expression of iNOS and reduce the NO level in plasma. Therefore, the growth of tumor and angiogenesis are inhibited directly, and MVD and the expression of VEGF are suppressed indirectly. In this way the nutrition supply of the tumor is impaired, and further cell proliferation is inhibited and cell apoptosis is improved. These results are consistent with those of Koh *et al.*, They observed that AG could inhibit the activity of iNOS in gastric cancer, and suppressed carcinogenesis. At the same time AG and COX-2 selective inhibitors could obviously inhibit the activity of iNOS and COX-2. So, the primitive pathology of colon cancer (aberrant crypt foci, ACF) is prevented.

Compared with traditional anticancer therapy, antiangiogenesis therapy has many superiorities. In this study the effect of MMC group is similar to that of AG group. However, the target of chemotherapeutic drugs is tumor cells which have genetic instability and are apt to mutation and drug-resistance, so the drug-resistance incidence of chemotherapeutic drugs is 30%. And these drugs have many toxic effects. In MMC+AG_H group the anticancer effect is the best which indicates that the effect of AG depends on proper treatment opportunity and scheme. MMC and AG have positive synergy. So certain drugs which can reduce the NO level by inhibiting the expression and activity of iNOS at cellular or genetic level probably may regulate the NO level of tumor microvessel to inhibit carcinogenesis and angiogenesis. And if combined with radiotherapy or bioreactive modulators, it will play a more important role in anticancer effect. This is the first part of a serial study, and we will carry out the further study afterwards with molecular biological technology, such as Southern blotting, Northern blotting, RT-PCR, *etc.*

Abstract

AIM: Hypermethylation of the promoter of the *hMLH1* gene, which plays an important role in mismatch repair during DNA replication, occurs in more than 30% of human gastric cancer tissues. The purpose of this study was to investigate the effects of environmental factors, genetic polymorphisms of major metabolic enzymes, and microsatellite instability on hypermethylation of the promoter of the *hMLH1* gene in gastric cancer.

METHODS: Data were obtained from a hospital-based, case-control study of gastric cancer. One hundred and ten gastric cancer patients and 220 age- and sex-matched control patients completed a structured questionnaire regarding their exposure to environmental risk factors. Hypermethylation of the *hMLH1* gene promoter, polymorphisms of the *GSTM1*, *GSTT1*, *CYP1A1*, *CYP2E1*, *ALDH2* and *L-myc* genes, microsatellite instability and mutations of *p53* and *Ki-ras* genes were investigated.

RESULTS: Both smoking and alcohol consumption were associated with a higher risk of gastric cancer with hypermethylation of the *hMLH1* gene promoter. High intake of vegetables and low intake of potato were associated with increased likelihood of gastric cancer with hypermethylation of the *hMLH1* gene promoter. Genetic polymorphisms of the *GSTM1*, *GSTT1*, *CYP1A1*, *CYP2E1*, *ALDH2*, and *L-myc* genes were not significantly associated with the risk of gastric cancer either with or without hypermethylation in the promoter of the *hMLH1* gene. Hypermethylation of the *hMLH1* promoter was significantly associated with microsatellite instability (MSI): 10 of the 14 (71.4%) MSI-positive tumors showed hypermethylation, whereas 28 of 94 (29.8%) the MSI-negative tumors were

hypermethylated at the *hMLH1* promoter region. Hypermethylation of the *hMLH1* gene promoter was significantly inversely correlated with mutation of the *p53* gene.

CONCLUSION: These results suggest that cigarette smoking and alcohol consumption may influence the development of *hMLH1*-positive gastric cancer. Most dietary factors and polymorphisms of *GSTM1*, *GSTT1*, *CYP1A1*, *CYP2E1*, *ALDH2*, and *L-myc* genes are not independent risk factors for gastric cancer with hypermethylation of the *hMLH1* promoter. These data also suggest that there could be two or more different molecular pathways in the development of gastric cancer, perhaps involving tumor suppression mechanisms or DNA mismatch repair.

INTRODUCTION

Gastric cancer is the most common cancer among Koreans. Environmental factors including cigarette smoking and dietary intake have been implicated in the etiology of gastric cancer^[1-4]. Genetic polymorphisms of xenobiotic-metabolizing enzymes can also affect susceptibility to cancer. Several studies have reported that the genetic polymorphisms of metabolic enzymes, such as cytochrome p450 2E1 (*CYP2E1*)^[5], glutathione S-transferase mu 1 (*GSTM1*)^[6], glutathione S-transferase theta 1 (*GSTT1*)^[7], aldehyde dehydrogenase 2 (*ALDH2*)^[8], and *L-myc* proto-oncogene^[9], and mutations of *p53*^[10] and *Ki-ras*^[11] genes are associated with the development of gastric cancer.

Promoter hypermethylation is an alternative mechanism of gene inactivation in carcinogenesis^[12]. Several studies have suggested that aberrant methylation of the promoter causes transcriptional silencing of some important suppressor genes, such as *p16*^[13], *E-cadherin*^[14], and von Hippel Lindau (*VHL*) gene^[15], and this has been implicated in the carcinogenic process in many cancers^[12]. In addition, it was recently shown that hypermethylation of gene promoters increases along

the pathway of development from chronic gastritis, intestinal metaplasia, and adenomas to carcinomas of the stomach^[16,17].

The *hMLH1* protein, a mismatch repair enzyme, maintains the fidelity of the genome during cellular proliferation. It has no known enzymatic activity and probably acts as a 'molecular matchmaker', recruiting other DNA-repair proteins to the mismatch repair complex^[18]. Dysfunction of a mismatch repair system such as *hMLH1* and *hMSH2* could alter microsatellites, short tandem repetitive sequences^[19]. Several reports have suggested that hypermethylation of the *hMLH1* promoter correlates with a loss of expression of the gene, resulting in microsatellite instability in gastric cancer^[20,21].

There is evidence that diet may be associated with hypermethylation of the *hMLH1* gene promoter in gastric cancer. Aberrant hypermethylation of the *hMLH1* gene promoter is frequently observed in cancers of digestive organs such as the colon, rectum, and stomach^[21,22], and decreased levels of folate, vitamin C, and niacin can induce hypermethylation of gene promoters^[23]. These facts led us to hypothesize that genetic polymorphisms and environmental factors, such as cigarette smoking, alcohol consumption, and diet, may interact during the hypermethylation of the *hMLH1* gene promoter and in the carcinogenesis of gastric cancer. We studied the association between hypermethylation of the *hMLH1* gene promoter and environmental factors, genetic polymorphisms of major metabolic enzymes, genetic mutation of p53 and Ki-ras genes, and microsatellite instability in gastric cancer.

MATERIALS AND METHODS

Subjects

One hundred and ten individuals with gastric cancer and 220 age-matched (within 3 years) and sex-matched controls were enrolled in this study. Cases of cancer were all histologically confirmed from February 1997 to June 2002 at Chungbuk National University Hospital and Eulji University Hospital, Korea. Control subjects were selected from patients newly diagnosed with diseases other than cancer at the same hospitals or from individuals receiving routine medical examinations in Chungbuk National University Hospital. Table 1 shows the age and gender distribution of the subjects according to hypermethylation of the *hMLH1* gene promoter. The mean±SD ages were 59.81±11.23 years for cases and 59.60±11.03 years for controls. This study was conducted in accordance with the recommendations outlined in the Declaration of Helsinki and all subjects provided written informed consent.

Table 1 Gender and age distribution of cases and controls

	Cases	Controls
Gender		
Male	70	140
Female	40	80
Age (yr)		
–39	6	12
40–49	11	22
50–59	34	68
60–69	40	80
70–	19	38

Exposure to environmental factors

Trained interviewers interviewed subjects using a structured questionnaire within a month after the diagnosis of gastric cancer or benign diseases or at the time of the hospital visit for control subjects undergoing routine medical examination. The questionnaire included questions on demographic factors, smoking habits, alcohol consumption, and diet. Dietary data were collected using a semiquantitative food frequency table previously evaluated for validity and reliability^[24]. All subjects were asked about their average frequency of consumption and portion size of 89 common food items during the year preceding the interview. These items were classified into 21 food groups having similar ingredients. The 21 food groups were as follows: cereals; potato; nuts; noodles; breads and cakes; vegetables; mushrooms; fruits; meats; eggs; fishes and shellfishes; stews; chicken; kimchi; soybean foods; soybean pastes; milk and dairy products; butter, cheeses, and margarine; jams, honey, candies, and chocolates; coffee and tea; seaweeds; and alliums.

The amount of calories, nutrients, vitamins, and minerals consumed for each food item was estimated by multiplying the intake amount of the food item and its nutrient value. The total intake of calories, nutrients, vitamins, and minerals was calculated for each subject by summing the respective calories, nutrients, vitamins, and minerals for each food item^[25]. The intake amounts of these factors were adjusted for caloric intake using the method of Willett *et al.*^[26].

Analysis of genetic polymorphisms

Genomic DNA was isolated from peripheral leukocytes by proteinase K digestion and phenol-chloroform extraction. A multiplex polymerase chain reaction (PCR) method^[27] was used simultaneously to detect the presence or absence of the *GSTM1* and *GSTT1* genes with slight modification. The primers used were 5'-GAA GGT GGC CTC CTC CTT GG-3' and 5'-AAT TCT GGA TTG TAG CAG AT-3' for *GSTM1*, 5'-TTC CTT ACT GGT CCT CAC ATC TC-3' and 5'-TCA CCG GAT CAT GGC CAG CA-3' for *GSTT1*, and 5'-CAA CTT CAT CCA CGT TCA CC-3' and 5'-GAA GAG CCA AGG ACA GTT AC-3' for β -globin, the internal reference gene. The PCR reactions were performed in 25 μ L of a solution containing 50 ng of genomic DNA, 1 \times PCR buffer [50 mmol/L KCl, 10 mmol/L Tris-HCl (pH 9.0), 1.5 mmol/L MgCl₂, and 0.1% Triton X-100], 5 pmol of each primer, 80 μ mol/L each dNTP, and 2.0 units *Taq* polymerase (Promega, Madison, WI). Amplifications were carried out in a thermocycler (MJ Research, Watertown, MA) as follows: 5 min of denaturation at 94 °C, followed by 35 cycles consisting of denaturation at 94 °C for 1 min, annealing at 58 °C for 1 min, and extension at 74 °C for 1 min. PCR products were separated on 2% agarose gels with ethidium bromide. *GSTM1* and *GSTT1* genotypes were not scored unless the PCR product of the β -globin gene was evident.

The A4889G polymorphism in exon 7 of the *CYP1A1* gene was analyzed for each subject as described previously^[28]. Briefly, PCR was performed using the primers 5'-GAA CTG CCA CTT CAG CTG TC-3' and 5'-GAA AGA CCT CCC AGC GGT CA-3'. The temperature program for the PCR

reaction was slightly modified. After initial denaturation for 5 min at 94 °C, a thermal cycle consisting of denaturation for 90 s at 94 °C, annealing for 90 s at 53 °C, and extension for 30 s at 74 °C, was repeated 35 times. The PCR products (187-bp fragments) were digested with *HincII* restriction enzyme at 37 °C overnight and subjected to electrophoresis on 12% polyacrylamide gels. PCR analysis resulted in the following genotype classification: a predominant homozygote (Ile/Ile), a heterozygote (Ile/Val), and a rare homozygote (Val/Val).

The 5'-flanking region polymorphism of the *CYP2E1* gene was analyzed using procedures described previously^[29]. Briefly, PCR was performed using the primers 5'-CCA GTC GAG TCT ACA TTG TCA-3' and 5'-TTC ATT CTG TCT TCT AAC TGG-3'. Initial denaturation was performed at 94 °C for 5 min, followed by 35 thermal cycles consisting of denaturation for 1 min at 94 °C, annealing for 1 min at 53 °C, and extension for 30 s at 74 °C. The 410-bp PCR product was digested with *RsaI* at 37 °C overnight and subjected to electrophoresis on 2% agarose gels. The genotypes of *CYP2E1* were classified as follows: a predominant homozygote (c1/c1), a heterozygote (c1/c2), and a rare homozygote (c2/c2).

The *MboII* polymorphism of *ALDH2* was identified using a PCR-RFLP method^[30] with slight modification. Briefly, PCR was performed using the primers 5'-CCA CAC TCA CAG TTT TCT CTT-3' and 5'-AAA TTA CAG GGT CAA CTG CT-3'. We used the same PCR conditions as in the *CYP1A1* gene analysis. The 134-bp amplicon was digested with *MboII* restriction enzyme at 37 °C overnight and subjected to electrophoresis on 15% polyacrylamide gels. The genotypes of *ALDH2* were identified as the predominant homozygote (NN), the heterozygote (ND), and the rare homozygote (DD).

The polymorphism of the *L-myc* gene was analyzed using procedures described previously^[31]. Briefly, PCR was performed using the primers 5'-ACG GCT GGT GGA GTG GTA GA-3' and 5'-AAG CTT GAG CCC CTT TGT CA-3'. Initial denaturation was performed at 94 °C for 5 min, followed by 35 thermal cycles consisting of denaturation for 45 s at 95 °C, annealing for 40 s at 60 °C, and extension for 40 s at 74 °C. The amplified 613-bp PCR product was directly digested with the restriction enzyme *EcoRI* at 37 °C overnight and separated by electrophoresis on 2% agarose gels. The genotypes of *L-myc* were classified as follows: a predominant homozygote (LL), a heterozygote (LS), and a rare homozygote (SS).

Methylation-specific PCR for hMLH1 promoter

Tissue samples from gastric cancer patients were immediately frozen and stored in liquid nitrogen until analysis. DNA was extracted using a DNA extraction kit (Promega) according to the manufacturer's instructions.

The promoter methylation status of the *bMLH1* gene was determined by methylation-specific PCR (MSP), as described previously^[32]. MSP distinguishes unmethylated from hypermethylated alleles in a given gene based on sequence changes produced after bisulfite treatment of DNA, which converts unmethylated, but not methylated, cytosines to uracils. Briefly, 2 µg of genomic DNA was

denatured by treatment with NaOH and modified by sodium bisulfite. DNA samples were then purified using a Wizard DNA Purification Resin (Promega), treated again with NaOH, precipitated with ethanol, and resuspended in water. Modified DNA was amplified using the primer pairs as follows: 5'-TTT TGA TGT AGA TGT TTT ATT AGG GTT GT-3' and 5'-ACC ACC TCA TCA TAA CTA CCC ACA-3' for the unmethylated reaction (124-bp), and 5'-ACG TAG ACG TTT TAT TAG GGT CGC-3' and 5'-CCT CAT CGT AAC TAC CCG CG-3' for the methylated reaction (115-bp)^[32]. PCR was performed in a thermocycler (MJ Research) as follows: 5 min of denaturation at 95 °C, then 35 cycles consisting of denaturation at 95 °C for 30 s, annealing at 55 °C for 30 s, and extension at 72 °C for 30 s. PCR products were separated on 6% polyacrylamide gels with ethidium bromide. DNA from blood samples was used as a negative control for hypermethylated *bMLH1*.

Microsatellite instability

Microsatellite instability (MSI) was examined using BAT25 and BAT26 mononucleotide microsatellite markers. PCR was performed in a 25 µL reaction volume containing 50 ng of genomic DNA, 1× PCR buffer, 5 pmol of each primer, 80 µmol/L each dNTP, 2.0 units *Taq* polymerase (Takara, Shiga, Japan), and 0.2 µCi of α -³²P-labeled dCTP. Amplifications were carried out as follows: 5 min of denaturation at 95 °C, then 35 cycles consisting of denaturation at 95 °C for 50 s, annealing at 58 °C for 90 s, and extension at 72 °C for 90 s. Two microliters of PCR product was electrophoresed on 6% denaturing polyacrylamide gels containing 6 mol/L urea at room temperature. The gels were dried and autoradiographed on X-ray film. MSI-positive results were identified when the mobility of the microsatellite fragment amplified from tumor DNA differed from the corresponding blood DNA. Tumors were considered microsatellite instability-positive (MSI+) if they manifested instability at one or two loci or microsatellite instability-negative (MSI-) if no unstable microsatellite was found.

Sequencing of p53 and Ki-ras genes

Reverse transcription (RT)-PCR and direct sequencing methods were used to detect mutations in *p53* and *Ki-ras* genes. Briefly, tissues from gastric cancer patients were homogenized and RNA was isolated using TRIzol solution (Invitrogen Life Technologies, Grand Island, NY). RT-PCR to amplify *p53* and *Ki-ras* cDNA were performed using reagents purchased from Promega. Specific primers synthesized by Bioneer Company (Cheongju, South Korea), *Ex Taq* polymerase (Takara), dNTPs, MgCl₂, PCR buffer, and cDNA template were mixed and then amplified for 40 cycles at 95 °C for 30 s and at 72 °C for 1 min. The cDNA regions were amplified using primers 5'-TCT AGA GCC ACC GTC CAG GGA G-3' and 5'-AAC CTC AGG CGG CTC ATA GGG CA-3' for the +2-+810 region of *p53*, and 5'-ACC AGG GCA GCT ACG GTT TCC GT-3' and 5'-TCA GTC TGA ATC AGG CCC TTC TGT-3' for the +443-+1 317 region of *p53*. Exons 1 and 2 of the *Ki-ras* gene were amplified using primers 5'-GAC TGA ATA TAA ACG TGT GGT AG-3' and 5'-ACT GGT CCC TCA TTG

CAC TG-3'. Before the RT-PCR products were sequenced by cycle sequencing, a PCR purification kit (Boehringer Mannheim, Indianapolis, IN) was used to remove unwanted reagents from the PCR reaction. The purified PCR products were then directly cycle-sequenced using an ABI PRISM 3100 Avant Genetic Analyzer (Applied Biosystems, Foster City, CA) according to the manufacturer's instructions.

Data analysis

Calorie-adjusted intakes of foods, nutrients, vitamins, and minerals were categorized into low- and high-intake groups based on the median values of the control population. Alcohol consumption per week was calculated from questions about the types, frequency, and average amount of alcohol consumed. Alcohol consumption was categorized into three groups: none, ≤ 280 g of alcohol/week, and >280 g of alcohol/week. Subjects who had smoked 20 cigarettes or more during their life were classified as smokers and those who had not were considered nonsmokers. Pack-year was used as an index of cumulative smoking.

The purpose of the study was to determine if dietary factors, genetic polymorphisms, MSI, and mutations of *p53* and *Ki-ras* genes were associated with hypermethylation of

the *hMLH1* gene promoter. We used unconditional logistic analysis to compare the risk of exhibiting or not exhibiting hypermethylation of the *hMLH1* promoter in tumors and controls using the SAS System for Windows (Release 8.1). *P*-values less than 0.05 were considered significant.

RESULTS

There were significant differences according to the smoking history, pack-years, and higher weekly alcohol intake between patients with gastric cancers with hypermethylation of the *hMLH1* promoter and controls (Table 2). As the amount of cigarette smoking or alcohol drinking increased, the risk of gastric cancer with the *hMLH1* promoter hypermethylation (Table 3).

High consumption of potatoes and butter, cheese and margarine was associated with lower risk of gastric cancer with hypermethylation of the *hMLH1* promoter. In contrast, consumption of vegetables was associated with higher risk of gastric cancer with hypermethylation of the *hMLH1* promoter. High intake of mushrooms and fruits and low intake of cereals and butter, cheese and margarine were associated with higher risk of gastric cancer without hypermethylation of the *hMLH1* promoter (Table 4). Among the nutrients, vitamins, and minerals evaluated, high intake of protein, phosphorus, potassium, vitamin C, zinc, and calcium was associated with higher risk of gastric cancer without hypermethylation of the *hMLH1* gene promoter. However, the intake of nutrients, vitamins, and minerals

did not differ significantly between patients with gastric cancers with the *bMLH1* promoter hypermethylation, those with gastric cancers without it, or controls (Table 5).

Genetic polymorphism of *GSTM1*, *GSTT1*, *CYP1A1*, *CYP2E1*, *ALDH2* and *L-myc* was not associated with development of gastric cancers with the *bMLH1* promoter hypermethylation or those without it (Table 6).

Hypermethylation of the *bMLH1* gene promoter was detected in 35.2% of patients with gastric cancer, in 13.6% of those with MSI, in 28.2% of those with mutations of *p53*, and in 4.9% of those with the *Ki-ras* gene (data not shown). Hypermethylation of the *bMLH1* promoter occurred in 10 of 14 MSI+ cases (71.4%) and in 28 of 94 MSI- cases (29.8%). We found a striking association between hypermethylation of the *bMLH1* promoter and MSI (Table 7). Hypermethylation of the *bMLH1* gene promoter was significantly inversely correlated with mutation of the *p53* gene (Table 7).

DISCUSSION

Cigarette smoking and alcohol consumption have been identified as risk factors for gastric cancer in some studies^[33-36], although others have not found a causal relationship between these factors^[37,38]. Data from our unconditional logistic models showed that both cigarette smoking and alcohol consumption play dominant roles in the development of gastric cancer with hypermethylation of the *bMLH1* promoter, but not in the development of cancer without

hypermethylation of the promoter. This finding suggests that smoking- or alcohol-related biological pathways leading to the development of gastric cancer involve hypermethylation of the *bMLH1* promoter. Although it is unclear whether smoking induces hypermethylation of the *bMLH1* gene promoter in humans, recent reports indicate an association between DNA methylation and tobacco carcinogens in animal models^[39,40]. Previous studies have also shown that smoking and alcohol consumption increase the risk of developing microsatellite-unstable tumors^[41,42].

The exact mechanism of DNA hypermethylation by alcohol is unknown. However, it has been hypothesized that

alcohol could influence carcinogenesis by influencing mucosal cell proliferation and related histological changes^[43]. These changes have been associated with mucosal hyper-regeneration, which may make the mucosa more susceptible to the action of other carcinogens such as cigarette smoke^[43]. Therefore, alcohol consumption might increase the bio-availability of DNA-binding smoke components in the mucosa of the upper digestive tract, increasing the plasma levels of these compounds, or might modify the metabolism of pro-carcinogenic compounds by inducing specific metabolic pathways involving an aberrant mismatch repair system^[44].

Folate deficiency is associated with hypermethylation of the H-cadherin promoter^[45]. However, we found no significant association between folate intake and hypermethylation of the *bMLH1* promoter. Su and Arab reported that low folate intake is aggravated by high alcohol intake^[46], probably because folate is degraded by acetaldehyde, an intermediate metabolite of alcohol^[47]. van Engeland *et al.*, suggested that intake of folate and alcohol is associated with changes in promoter hypermethylation in colorectal cancer^[48]. Our data showing that alcohol intake increased the risk of gastric cancer with hypermethylation of the *bMLH1* promoter are consistent with these previous reports.

Most dietary factors, nutrients, vitamins, and minerals are not associated with gastric cancer with hypermethylation of the *bMLH1* promoter, although we found that a high intake of vegetables and low intake of potato and butter, cheese, and margarine were associated with increased likelihood of gastric cancer without hypermethylation of the *bMLH1* promoter, and high intake of mushrooms and fruits and low intake of cereals and butter, cheese and margarine were associated with higher risk of gastric cancer without hypermethylation of the *bMLH1* promoter. We cannot be certain that these results did not occur by chance, given the low number of comparisons. However, we observed that different dietary factors selectively affected the pathways to gastric cancer with or without hypermethylation of the *bMLH1* promoter. For example, a high intake of butter, cheese, and margarine was associated with a lower risk of gastric cancers either with or without hypermethylation of the *bMLH1* promoter. These findings agree with epidemiological data showing a relatively low incidence of gastric cancer in countries with consumption of high butter, cheese, and margarine^[49]. Based on these facts, it could be suggested that butter, cheese and margarine decrease the risk of gastric cancer regardless of the *hMLH1* promoter hypermethylation.

It has been reported that vitamin C can induce hypermethylation of gene promoters^[23]. However, a higher intake of vitamin C is associated with an increased risk of gastric cancer in this present study. One of the main vitamin C sources for Koreans is kimchi, which has been reported as a potent risk factor for gastric cancer in some Korean epidemiologic studies^[3]. Therefore, kimchi intake increases vitamin C intake amount, and, at the same time, the risk of gastric cancer.

Few epidemiological studies on gastric cancer have included genetic polymorphisms in the analysis or evaluated the association between genetic polymorphisms and

hypermethylation of the *bMLH1* gene promoter. Several studies have reported an independent, increased risk of gastric cancer for the *GSTM1* null^[7], *GSTT1* null^[6], *CYP2E1* c1/c2 or c2/c2^[50], *2-allele containing *ALDH2* genotypes^[9], and shorter (s) allele-containing *L-myc*^[10] genotypes. However, other studies have not found any association between gastric cancer and these genotypes^[51–53]. We found no significant association between polymorphisms of *GSTM1*, *GSTT1*, *CYP1A1*, *CYP2E1*, *ALDH2*, and *L-myc* and the risk of gastric cancer with or without hypermethylation of the *bMLH1* promoter. These findings suggest that the genetic polymorphisms of the *GSTM1*, *GSTT1*, *CYP1A1*, *CYP2E1*, *ALDH2*, and *L-myc* genes might not be independent risk factors, but could act as effect modifiers of the risk of gastric cancer through environmental factors, such as dietary intake.

We examined the mononucleotide repeats BAT25 and BAT26 to detect genuine MSI because these repeats are considered as ideal diagnostic markers. Mononucleotide repeats are sufficient for the diagnosis of true MSI^[54]. A consensus mononucleotide locus, BAT26 is altered in all tumors with genuine MSI^[55,56]. We found that 10 of the 14 MSI+ gastric cancer cases (71%) in our patients were hypermethylated in the promoter region of *bMLH1*. We found a significant association between hypermethylation of the *bMLH1* promoter and MSI+ gastric carcinoma ($P = 0.006$), which is consistent with previous reports^[21,57].

Point mutations in the *p53* tumor suppressor gene^[58,59] and *ras* oncogenes^[60,61] are frequently found in human and rodent tumors. Mutations of the *p53* and *Ki-ras* genes were detected in 28.2% and 4.9% of our patients with gastric cancer, respectively. We also found a significant inverse association between hypermethylation of the *bMLH1* gene promoter and *p53* mutations. Previous studies have reported a significantly lower incidence of *p53* gene alterations in MSI+ gastric cancer, in MSI+ colorectal cancers, and in colorectal cancer cell lines^[62,63] than in MSI- gastric cancer^[64,65]. Together, these data confirm the existence of alternative genetic pathways for gastric cancer, such as the classical 'tumor suppressor' pathway and the 'mismatch repair' pathway.

In conclusion, despite its limited size, this study suggests that cigarette smoking and alcohol consumption are significantly associated with higher risk of gastric cancer having hypermethylation of the *bMLH1* promoter. Polymorphisms of *GSTM1*, *GSTT1*, *CYP1A1*, *CYP2E1*, *ALDH2*, and *L-myc* genes were not associated with gastric cancers either with or without hypermethylation of the *bMLH1* promoter, suggesting that these polymorphisms operate along disease pathways other than those involving the mismatch repair system in gastric cancer. Our data also highlight the importance of aberrant methylation of the *bMLH1* promoter in causing MSI in gastric cancer. The negative association between hypermethylation of the *bMLH1* gene promoter and *p53* mutations suggests that there could be two or more different molecular pathways in the development of gastric cancer, such as tumor suppression mechanisms and DNA mismatch repair.

Abstract

AIM: To determine if Fourier-transform infrared (FT-IR) spectroscopy of endoscopic biopsies could accurately diagnose gastritis and malignancy.

METHODS: A total of 123 gastroscopic samples, including 11 cases of cancerous tissues, 63 cases of chronic atrophic gastritis tissues, 47 cases of chronic superficial gastritis tissues and 2 cases of normal tissues, were obtained from the First Hospital of Xi'an Jiaotong University, China. A modified attenuated total reflectance (ATR) accessory was linked to a WQD-500 FT-IR spectrometer for spectral measurement followed by submission of the samples for pathologic analysis. The spectral characteristics for different types of gastroscopic tissues were summarized and correlated with the corresponding pathologic results.

RESULTS: Distinct differences were observed in the FT-IR spectra of normal, atrophic gastritis, superficial gastritis and malignant gastric tissues. The sensitivity of FT-IR for detection of gastric cancer, chronic atrophic gastritis and superficial gastritis was 90.9%, 82.5%, 91.5%, and specificity was 97.3%, 91.7%, 89.5% respectively.

CONCLUSION: FT-IR spectroscopy can distinguish gastric inflammation from malignancy.

INTRODUCTION

Fourier-transform infrared (FT-IR) spectroscopy can effectively provide chemical variation information of the structure and composition of biologic materials at molecular level^[1]. Therefore, vibrational spectroscopy is becoming an increasingly powerful tool for the research on biochemistry of cancer^[2-5]. Our research group has successfully used FT-IR spectroscopy to diagnose carcinomas, such as carcinoma of stomach, colon, esophagus, lung, salivary gland since 1995^[6-9]. There are significant differences between the spectra of malignant and corresponding normal tissues^[10-12]. In addition, FT-IR spectroscopy could detect molecular abnormalities which occur before the change in morphology seen under light microscope^[13]. Therefore, FT-IR technology makes it possible to detect inflammatory and precancerous changes. Rapid, accurate and convenient detection of gastroscopic tissues can be performed using FT-IR spectroscopy if mid-infrared fiber optics technology and stomach endoscopy technology are combined, however the flexible mid-infrared optical fiber and mini probe are not yet available^[14].

MATERIALS AND METHODS

Patients and materials

Informed consent was obtained from each patient prior to the study. A total of 123 fresh surgically resected gastric tissue specimens were obtained from the First Hospital of Xi'an Jiaotong University, China. There were 47 women and 76 men, aged between 18 and 80 years (mean 50.3 years). One endoscopic pinch biopsy, 1-3 mm in diameter, was obtained from each patient. The detected samples consisted of 11 cases of cancerous tissues, 63 cases of chronic atrophic gastritis tissues, 47 cases of chronic superficial gastritis tissues and 2 cases of normal tissues.

Spectral measurement

As the size of samples was too small to obtain an FT-IR spectrum with high quality, the modified ATR accessory linked to a WQD-500 FT-IR spectrometer was used. The FT-IR spectrometer was equipped with a liquid nitrogen cooled mercury cadmium telluride (MCT) detector.

The fresh tissue specimens were obtained in gastroscopy detection, and then immediately and non-invasively measured using the mobile FT-IR spectrometer near the operation

Figure 2 Subtraction spectra of gastric endoscopy samples. **A:** Spectrum of chronic atrophic gastritis tissue minus that of malignant gastric tissue; **B:** spectrum

of normal gastric tissue minus that of chronic superficial gastritis tissue.

the peak position was lower than 1 310/cm for 73% of atrophic gastritis tissues.

The spectra of chronic superficial gastritis tissues (Figure 1C) were similar to those of normal stomach tissues^[15] (Figure 1D). The spectral features were as follows. CH stretching vibrational band near 3 000-2 800/cm and C = O vibrational band at about 1 740/cm were strong in the spectra of superficial gastritis samples. In general, there existed strong and broad amide II bands in the spectra of superficial gastritis samples. The peak at 1 460/cm was stronger than that at 1 400/cm. The relative intensity of $I_{1\,460}/I_{1\,400}$ was higher than 1 in about 78% of superficial gastritis samples. The peak at about 1 250/cm was stronger, and the band near 1 308/cm disappeared or became weak and the position of this band often shifted to a high wave number, indicating that the peak position was higher than 1 310/cm in 80% of superficial gastritis tissues. Similar to normal gastric tissues, the intensity of peak near 1 160/cm increased and often became stronger than that at about 1 120/cm.

DISCUSSION

To enhance our understanding, the subtraction technique was performed in the spectral analysis^[16]. The subtraction spectra (Figures 2A and B) could highlight spectral differences between chronic atrophic gastritis tissue and malignant gastric tissue, and between normal gastric tissue and chronic superficial gastritis tissue. From the two subtraction spectra, some new information could be observed.

Figure 2A illustrates the subtraction result of the spectrum of chronic atrophic gastritis tissue minus that of malignant gastric tissue. It verified that chronic atrophic gastritis tissues exhibited relatively stronger C-H stretching vibration, C = O stretching band, amide I, amide II than gastric cancer tissue. In addition, there was more water in gastric cancer tissue due to the strong negative band located near 3 360/cm in the spectrum of subtraction malignant tissue from chronic atrophic gastritis tissue.

Figure 2B shows the spectral differences between normal gastric tissue and chronic superficial gastritis tissue. The positive peaks in the region of 2 800-3 000/cm and near 1 740/cm were observed in the subtraction spectrum, suggesting that normal gastric tissue contains more components

of long-chain C-H and C = O bonds. However, these peaks often decrease and even disappear in the spectra of gastritis and malignant tissues. Because triglyceride contains a large proportion of methyl, methylene and carbonyl, and fat in the region of malignant tissue is consumed because of the necessary nutritional and energy requirement in the development of carcinoma. At the same time, amide I and amide II bands are stronger in the spectrum of normal gastric tissue than in that of chronic superficial gastritis tissue, indicating that normal gastric tissue has more regular protein secondary structures, such as α helical structure.

In conclusion, the results in our study demonstrate that the sensitivity of FT-IR detection to gastric cancer, chronic atrophic gastritis and superficial gastritis is 90.9%, 82.5%, 91.5%, and specificity is 97.3%, 91.7%, 89.5% respectively. FT-IR spectroscopy is effective in distinguishing gastric inflammation from malignancy.

Abstract

AIM: To evaluate the expressions of apoptotic signal proteins FADD, TRADD, FasL, Fas, and NFκB in gastric carcinoma tissues and their clinical significance.

METHODS: Western blot immune trace method was adopted to detect the expressions of apoptotic signal proteins FADD, TRADD, FasL, Fas, and NFκB in 55 tissue specimens of gastric carcinoma.

RESULTS: Five apoptotic signal proteins had different expressions in the gastric carcinoma samples and their expressions were not correlated to age ($P = 0.085$). Expressions of the FADD, FasL, Fas, and NFκB proteins reduced with increase of the volume of tumor with the exception of increased expression the TRADD protein (64.7-71.1%, $P = 0.031$). With gradual increase of the malignancy of gastric carcinoma tissues, expressions of the FADD, FasL, and Fas proteins decreased (78.6-28.0%, $P = 0.008$; 78.6-65.9%, $P = 0.071$; 100.0-46.3%, $P = 0.014$), while expressions of the TRADD and NFκB proteins increased (42.9-78.1%, $P = 0.063$; 78.6-79.1%, $P = 0.134$). With gradual increase of serum CEA, expression of the FADD protein decreased (62.5-34.0%, $P = 0.073$), but expressions of the TRADD, FasL, Fas, and NFκB proteins increased (0.0-80.8%, $P = 0.005$; 62.5-70.2%, $P = 0.093$; 0.0-70.2%, $P = 0.003$; 62.5-80.9%, $P = 0.075$). When compared to the tissues of gastric carcinoma without metastasis, the positive rate of expressions of the FADD and FasL proteins increased, whereas expressions of the TRADD, FADD, and NFκB proteins decreased. There was no significant difference between them ($P = 0.095$).

CONCLUSION: Gastric carcinoma is endurable to Fas-related apoptosis and apoptotic signal proteins are differently expressed in gastric carcinoma.

INTRODUCTION

Gastric carcinoma is one of the most common causes of malignancy-related death in China^[1-4]. Its therapy in clinics is a big challenge. Better remedial method possibly depends on advances in basic research^[5-7]. Recent evidence suggests that apoptosis of cells is closely related to occurrence, progress and metastasis of the tumor^[8-10]. At present, studies on the apoptosis of tumor cells are an important field of tumor therapy and tumor molecular biology^[11-14]. The abnormalities in expressions of apoptotic signal proteins always influence the gastrocellular apoptosis, thus leading to the incidence and development of gastric carcinoma^[15-17]. We adopted the Western blot immune trace method to detect the expressions of apoptotic signal proteins FADD, TRADD, FasL, Fas, and NFκB in gastric carcinoma tissues and their significance in gastric carcinoma was assessed.

MATERIALS AND METHODS

Samples

A total of 55 cases were selected from patients with primary gastric carcinoma excision in our hospital from January 2000 to April 2001, who were pathologically diagnosed as adenocarcinoma. There were 35 male and 20 female cases aged 34-78 years with an average age of 54 years. According to Edmondson grading III, the samples were graded as I-II grade in 14 cases and III-IV grade in 41 cases. All samples were submerged in liquid nitrogen within half an hour after the excision and placed in a -80 °C refrigerator.

Protein extraction

Fifty-five tumor tissue specimens were homogenized, sonicated for 15 s twice in 500 μL of lysis buffer containing 1× phosphate-buffered saline (PBS), 1% Nonidet-P40, 0.5% sodium deoxycholate, 0.1% SDS and 0.1 mg/mL phenylmethylsulfonyl fluoride, and placed on ice for 30 min. The lysate was centrifuged at 13 000 g for 15 min at 4 °C, the supernatant was collected (450 μL) and the

Table 1 Expressions of FADD, TRADD, FasL, Fas and NFκB proteins in gastric carcinoma tissue specimens, *n* (%)

Sex	<i>n</i>	FADD	TRADD	FasL	Fas	NFκB
Male	35	12 (34.3)	26 (74.3)	25 (71.4)	21 (60.0)	28 (80.0)
Female	20	8 (40.0)	12 (60.0)	13 (65.0)	12 (60.0)	15 (75.0)
	55	20 (36.4)	38 (69.1)	38 (69.1)	33 (60.0)	43 (78.2)

protein concentration for each sample was determined by spectrophotometry (Pharmacia) and using a DC protein assay kit (Bio-Rad).

Reagents and methods

Sheep antihuman FADD, TRADD, FasL, and Fas polyclonal antibodies, rabbit antihuman NFκB polyclonal antibodies, alkaline phosphatase marking anti-sheep, anti-rabbit and protein molecular mass marker were also purchased from Santa Cruz Company. Western blot immune trace method was employed to determine the expression of apoptotic signal proteins. Twenty microliters of extracted protein for 120 g/L polyacrylamide gel electrophoresis. When it was semidry, electrical metastasis to the nitrocellulose film was made and enclosed with 100 mL/L bovine serum for 1 h. The first antibody (1:1 000) was put into PBST (1 g/L Tween20 in PBS) and stored overnight at 4 °C. After being washed, the sample was enclosed again with 100 mL/L bovine serum for 30 min, and then the second antibody was put in at room temperature for 1 h. After being washed with PBS for 1 h, NBTBCIP development method was performed for coloration.

Assessment standards

The protein molecular mass marker was taken as the standard. In the respective different molecular mass scope, the sample with black stripes was considered positive and vice versa negative. The molecular mass of FADD, TRADD, FasL, Fas, and NFκB proteins was 23, 34, 31, 48, and 65 ku respectively.

Statistical analysis

Chi squared test, accurate 4-chess table method and correlation analysis were used to analyze the correlation of protein expressions with sex, age, tumor size, pathological grading and tumor metastasis. $P < 0.05$ was considered statistically significant.

Figure 1 Western blot analysis of the accurate expression of apoptotic signal proteins. Lane 1: marker; lane 2: FADD; lane 3: TRADD; lane 4: FasL; lane 5: Fas; lane 6: NFκB.

RESULTS

Expression of apoptotic signal proteins in gastric carcinoma

The expression of FADD, TRADD, FasL, Fas, and NFκB proteins in gastric carcinoma tissue specimens was 36.4% (20/55), 69.1% (38/55), 69.1% (38/55), 60.0% (33/55) and 78.2% (43/55) respectively (Table 1). We carried out Western blot analysis to determine the accuracy of protein expression (Figure 1).

Relation between apoptotic signal proteins and clinical characteristics

Different expressions of the five apoptotic signal proteins were not correlated to age ($P = 0.085$, Figure 2A). Expressions of the FADD, TRADD, FasL, Fas, and NFκB proteins reduced with increase of the tumor volume, with the exception of increased expression of the TRADD protein (64.7-71.1%, $P = 0.031$). Among them, the positive rate of the expression of the Fas protein in the tissue of gastric carcinoma with a lump ≤ 5 cm was higher than that of gastric carcinoma > 5 cm and the difference was significant ($P = 0.037$, Table 2, Figure 2B).

With the increased of malignancy grade in adenocarcinoma tissues, expressions of the FADD, FasL, and Fas proteins decreased, while expressions of the TRADD and NFκB proteins increased. Expressions of the FADD and Fas

proteins were significantly different between the pathological grades (*P* = 0.008 and *P* = 0.014, Figure 3A). With the increase of serum CEA, expression of the FADD protein in gastric carcinoma tissues decreased, while expressions of the TRADD, FasL, Fas and NFκB proteins increased. Expression of the TRADD and Fas proteins were positively correlated with the serum CEA level (*r* = 0.700, *P* = 0.005) and the difference was very significant (*P* = 0.003, Figure 3B). When compared to the tissues of gastric carcinoma with metastasis, the positive expression rate of the FADD and FasL proteins increased, whereas expressions of the TRADD, FAS and NFκB proteins decreased. There was no significant difference between them (*P* = 0.095).

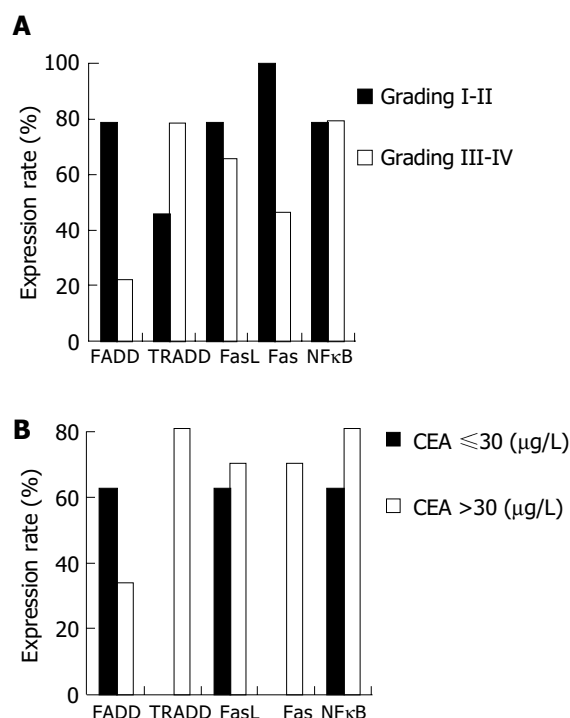

Figure 3 Different expressions of the five proteins with different pathological grading (A) and different serum CEA (B).

DISCUSSION

Apoptotic abnormality is considered as an important mechanism underlying the development of gastric carcinoma^[18,19] and even more crucial than the reproduction of cells of out control^[20,21]. The expression of apoptotic signal proteins play different roles in the death of gastric cancer cells. The current studies^[22,23] have denoted the main mechanism of the interaction of the apoptotic signal proteins to conduct down the apoptotic signal. FasL is polymerized with its corresponding Fas receptors^[24,25]. By activating the FADD and caspase family, the apoptosis of cancer cells ensues; and by activating TRADD, RIP is motivated, causing NFκB to be activated, thereby participating in gene transcription of the survival of cells. The balance between counter signals and paths eventually determines the survival or apoptosis of cells.

In this study, the expression of Fas protein was downregulated with increase of the gastric carcinoma volume and the malignancy degree and positively correlated with the expression of CEA. It was reported^[26] that gastric cancer cells inhibit expression of the downregulated FasL, thus escaping Fas-related apoptosis and immune monitoring of the host to enable cancer cells to reproduce continuously and increase their malignancy degree. Expression of the FADD protein is downregulated with increase of the malignancy degree of gastric carcinoma^[27]. Gastric cancer cells might through the expression of the downregulated FADD enable caspases 3 and 8 necessary for apoptosis of Fas-related cells to be devitalized, resulting in inhibition of the apoptosis of gastric cancer cells. If FADD is injected, such cells can become sensitive to Fas and induce Fas-related apoptosis, suggesting that the function of FADD is extremely crucial.

The TRADD protein is able to vitalize the NFκB transcription factor and prolong the survival of cells. In the present study, the TRADD protein expression was positively correlated with CEA only when CEA possessed the value of 30 μg/L, suggesting that both of them can be used as indexes to detect gastric carcinoma. However, this can be determined only after investigating a large size of samples^[28-30]. As the change of expressions of apoptotic

signal proteins is not much related to metastasis of gastric carcinoma, the abnormalities of the function of these proteins only contribute to the reproduction and rise of malignancy degree of gastric cancer cells, whereas metastasis of gastric carcinoma might correlate to other factors.

In summary, gastric carcinoma is a tumor endurable to Fas-related apoptosis. Apoptotic signal proteins are differently expressed in gastric carcinoma.

Abstract

AIM: To investigate the expression and clinical significance of *DEK*, *cyclin D1*, insulin-like growth factor II (*IGF-II*), glypican 3 (*GPC3*), ribosomal phosphoprotein 0 (*rpP0*) mRNA in hepatocellular carcinoma (HCC) and its paraneoplastic tissues.

METHODS: The expression of mRNAs of *DEK*, *cyclin D1*, *IGF-II*, *GPC3* and *rpP0* mRNA was detected in HCC and its paraneoplastic tissues by multiplex RT-PCR.

RESULTS: By the simplex RT-PCR, the overexpression of mRNAs of *DEK*, *cyclin D1*, *IGF-II*, *GPC3*, *rpP0* mRNA in HCC and its paraneoplastic tissues was 78.1%, 87.5%, 87.5%, 75.0%, 81.3% and 15.6%, 40.6%, 37.5%, 21.9%, 31.3% respectively ($P < 0.05$). By the multiplex RT-PCR, at least one of the mRNAs was detected in all HCC samples and in 75.0% of paraneoplastic samples ($P > 0.05$). However, all these five mRNAs were found in 68.8% of HCC samples, but only in 9.4% of paraneoplastic tissues ($P < 0.05$). The positive expression of mRNAs of *DEK*, *cyclin D1*, *IGF-II*, *GPC3*, *rpP0* in well- and poorly-differentiated HCC was 89.0%, 66.7%, 66.7%, 66.7%, 77.8% and 73.9%, 95.7%, 95.7%, 82.6%, respectively ($P > 0.05$). The expression of these genes in HCCs with α -feto protein (AFP) negative and positive was 90.0%, 80.0%, 90.0%, 90.0%, 90.0% and 72.7%, 86.3%, 77.3%, 90.9%, 68.2% respectively ($P > 0.05$).

CONCLUSION: The expression of *DEK*, *cyclin D1*, *IGF-II*, *GPC3*, *rpP0* mRNA in HCC is much higher in HCC than in its paraneoplastic tissues. Multiplex RT-PCR assay is an effective, sensitive, accurate, and cost-effective diagnostic method of HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is an aggressive malignancy with poor prognosis and one of the most common tumors in humans. The development of HCC is a chronic process and involves many factors, including infection of hepatitis virus and contamination with aflatoxin B1^[1]. Recent advances in molecular genetics indicate that some tumor suppressor genes, oncogenes, and growth factors may play an important role in hepatocarcinogenesis^[2].

Several methods such as DDRT-PCR, cDNA screening^[3] are used to identify differential expression of mRNA in tumor and non-tumor tissues. It is reported that some genes, such as *DEK*, *rpP0*^[4], *cyclin D1*^[5], *IGF-II*^[6], and *GPC3*^[7], are overexpressed in HCC tissue. The expression of *DEK*, *IGF-II* and *rpP0* is higher in HCC than non-tumor tissues in our previous study.

RT-PCR is widely used to analyze gene expression in HCC and paraneoplastic liver tissue. However, the overexpressed genes are only relatively higher in HCC than in paraneoplastic liver tissue and the positive detection rate is relatively low. Moreover, RT-PCR can detect only a single gene once in the past, and the results obtained are fluctuant and less useful in clinics. In order to find a method to enhance the specificity and positive rate, multiplex PCR was used to detect several genes, such as *DEK*, *cyclin D1*, *IGF-II*, *GPC3*, *rpP0*.

MATERIALS AND METHODS

Tissue samples and patients

HCC and corresponding paraneoplastic tissues were obtained with informed consent from 32 patients who underwent hepatectomy at the First Affiliated Hospital of Guangxi Medical University and Guangxi Tumor Hospital. The profiles were obtained from medical records of 20 male and 12 female patients with an average age of 42.5 years. Twenty-two patients were positive for α -feto protein (AFP). HCC and paraneoplastic tissues were enucleated separately and immediately frozen in liquid nitrogen. Histological classification was performed according to the Edmondson's grading criteria.

Multiplex RT-PCR

Total RNA was isolated from 100 mg of frozen tissue according to the manufacturer's instructions using TRIzol

kit (Sagon Company, Shanghai, China), and then dissolved in water that was treated by DEPC. Four micrograms of total RNA was used to produce cDNA using oligo(dT) primer and MuLV reverse transcription (MBI Company) in a final volume of 20 μ L at 42 $^{\circ}$ C for 1 h. The reaction was terminated by incubation at 75 $^{\circ}$ C for 10 min. One microgram of products was PCR amplified with multiple primer sets (0.5 μ mol/L, Sagon Company, Shanghai, China), 0.75 units of Taq DNA polymerase (MBI), 0.5 μ L 10 mmol/L dNTPs, 2.5 μ L 10 \times buffer. The primers were as follows: *DEK*: 5'-AGG CAC TGT GTC CTC ATT AA and 5'-TCT GAC AGA ATT TCA GGA CA (332 bp); *cyclin D1*: 5'-TAT TTG CAT AAC CCT GAG CG and 5'-GTG ACT ACA TGC ATA TGA GC (350 bp); *IGF*: 5'-AGG AGC TCC TGG ATA ATT TC and 5'-AAT ATT TCA CGT GAC AGA AC (421 bp); *GPC3*: 5'-TGG ACA TCA ATG AGT GCC TC and 5'-CAC ATT CTG GTG AGC ATT CG (204 bp); *rpP0*: 5'-ATG TGA AGT CAC TGT GCC AG and 5'-CTT GGC TTC AAC CTT AGC TG (549 bp). GAPDH was used as control, the primers were 5'-TGA GTA CGT CGT GGA GTC CA and 5'-CAA AGT TGT CAT GGA TGA CC (230 bp). The conditions were initial denaturation at 94 $^{\circ}$ C for 5 min, 30 cycles of amplification, each cycle consisting of denaturation at 94 $^{\circ}$ C for 45 s, annealing at 58 $^{\circ}$ C for 30 s, extension at 72 $^{\circ}$ C for 30 s, final extension at 72 $^{\circ}$ C for 7 min. Because of the limitation by the length of PCR products, the primers of *cyclin D1* and *GPC3* were used together in a single reaction and the primers of *DEK*, *IGF-II*, and *rpP0* were used together in a single reaction.

Analysis by electrophoresis

The amplified products were electrophoresed on 1.2% agarose gel to detect the expression of the genes in HCC and paraneoplastic tissues. The images were analyzed by Quantity One software.

Statistical analysis

Results were analyzed by χ^2 test to compare the differences between the groups. $P < 0.05$ was considered statistically significant.

RESULTS

Expression of GAPDH mRNA

The expression of *GAPDH* mRNA was detected in all HCC and non-HCC tissues. There was no difference between the two groups (Figure 1A).

Expression of *DEK*, *cyclin D1*, *IGF-II*, *GPC3*, *rpP0* mRNAs in HCC and adjacent noncancerous liver tissues

The expression of *DEK*, *cyclin D1*, *IGF-II*, *GPC3*, *rpP0* mRNAs in HCC and adjacent noncancerous liver tissues was 78.1%, 87.5%, 87.5%, 75.0%, 81.3%, and 15.6%, 40.6%, 37.5%, 21.9%, 31.3%, respectively ($P < 0.05$, Table 1), which were significantly higher in HCC tissues than in adjacent nontumorous tissue (Figures 1B and C). The density of the bands was also higher in HCC than in adjacent noncancerous liver tissues.

The expression of *DEK*, *cyclin D1*, *IGF-II*, *GPC3*, *rpP0* mRNAs in well- and poorly-differentiated HCC was 89.0%,

Figure 1 Expression of GAPDH (A), mRNA of *rpP0*, *DEK*, and *IGF-II* (B), mRNA

of *cyclin D1* and *GPC3* (C) in HCC tissue (H) and adjacent nontumorous tissue (N).

Table 1 Expression of *DEK*, *cyclin D1*, *IGF-II*, *GPC3*, *rpP0* mRNAs in HCC and adjacent noncancerous liver tissues

	Cyclin D1 ^a		GPC3 ^c		DEK ^e		IGF ^g		rpP0 ⁱ	
	T	N	T	N	T	N	T	N	T	N
Positive	28	13	24	7	25	5	28	12	26	10
Negative	4	19	8	25	7	27	4	20	6	22

T, HCC tumor tissue; N, adjacent nontumorous tissue. χ^2 -test: ^a $P < 0.05$, ^c $P < 0.05$, ^e $P < 0.05$, ^g $P < 0.05$, ⁱ $P < 0.05$ vs others.

66.7%, 66.7%, 66.7%, 77.8% and 73.9%, 95.7%, 95.7%, 95.7%, 82.6%, respectively ($P>0.05$, Table 2).

The expression of *DEK*, *cyclin D1*, *IGF-II*, *GPC3*, *rpP0* mRNAs in HCC with AFP negative and positive was 90.0%, 80.0%, 90.0%, 90.0%, 90.0% and 72.7%, 86.3%, 77.3%, 90.9%, 68.2%, respectively ($P>0.05$, Table 3).

Expression of *DEK*, *cyclin D1*, *IGF-II*, *GPC3*, *rpP0* mRNAs in HCC and adjacent noncancerous liver tissues shown by multiplex RT-PCR

By multiplex RT-PCR, at least one of the mRNAs could be detected in all HCC tissues and in 75.0% of paraneoplastic tissues ($P>0.05$) (Table 4). However, all these five mRNAs were found in 68.8% of HCC tissue, but only in 9.4% of paraneoplastic tissues ($P<0.05$, Table 4).

DISCUSSION

The growth of cells depends on the regulation by many factors, including oncogenes, tumor suppressor genes, growth factors, signal transduction factors, and apoptosis factors, *etc.* The origin of tumor is related to the modification of these genes. Genes such as *DEK*, *cyclin D1*, *IGF-II*, *GPC3*, *rpP0*, are involved in the initiation and development of HCC, and the possible markers for the diagnosis of HCC in clinic. To identify whether these genes were generally involved in hepatocarcinogenesis, multiplex PCR was used in the present study. We found that these genes had an upregulated expression in HCC and multiplex PCR could enhance the detective positive rate.

Cyclin D1

Cyclin, cyclin-dependent kinases, and tumor suppressor gene

products interact and regulate the normal cell cycle. *Cyclin D1* and cyclin-dependent kinases are required for completion of the G₁/S transition in normal mammalian cells^[8]. *Cyclin D1* is located on chromosome 11q13 and exhibits many characteristics of cellular oncogenes. Overexpression of *cyclin D1* may be associated with actual gene amplification or transcriptional dysregulation in cancer. *Cyclin D1* is overexpressed in hyperplastic lesions, such as endometrioid adenocarcinoma^[9], mantle cell lymphoma^[10], and ovarian carcinoma^[11]. The results in our study showed that the expression of *cyclin D1* was significantly higher in HCC than in adjacent nontumorous tissue. The mechanism of *cyclin D1* dysregulation in HCC is not clear, but it is likely that the dysregulation contributes to increasing the proportion of cells in transition from G₁ to S phase. The overexpression of *cyclin D1* may be one of the several mechanisms involved in hyperplasia of liver cells.

DEK

DEK is a 43-ku phosphoprotein that was first isolated as part of a fusion protein expressed in a subtype of acute myeloid leukemias with t(6;9) chromosomal translocations^[12]. *DEK* was lately identified as an autoimmune antigen in patients with pauciarticular onset juvenile rheumatoid arthritis, systemic lupus erythematosus^[13], and other autoimmune diseases. In recent study, it was demonstrated that *DEK* was a site-specific DNA binding protein that was involved likely in transcriptional regulation and signal transduction and it had implications not only for HIV-2 transcription^[14] but also for multiple cellular processes involving with *DEK*. Recent data demonstrated that the major portion of *DEK* is associated with chromatin

Table 2 Expression of *DEK*, *cyclin D1*, *IGF-II*, *GPC3*, *rpP0* mRNAs in well- and poorly-differentiated HCC

	Cyclin D1		GPC3		DEK		IGF-II		rpP0	
	+	-	+	-	+	-	+	-	+	-
Well-differentiated HCC	6	3	6	3	8	1	6	3	7	2
Poor-differentiated HCC	22	1	18	5	17	6	22	1	19	4
Total	28	4	24	8	25	7	28	4	26	6

	<i>n</i>	Cyclin D1+	GPC3+	DEK+	IGF-II+	rpP0+
AFP(-)	10	8	9	9	9	9
AFP(+)	22	20	15	16	19	17
Total	32	28	24	25	28	26

χ^2 test, $P>0.05$, the group of APF(+) vs the group of APF(-).

Table 4 Expression of *DEK*, *cyclin D1*, *IGF-II*, *GPC3*, *rpP0* mRNAs in HCC and adjacent noncancerous liver tissues by multiplex RT-PCR

Groups	<i>n</i>	Positive reaction		Negative reaction	
		Anyone of the five mRNAs (%)	All of the five mRNAs (%)	Anyone of the five mRNAs (%)	All of the five mRNAs (%)
T	32	32 (100)	22 (68.8)	10 (31.3)	0 (0)
N	32	24 (75.0)	3 (9.4)	29 (90.6)	8 (25.0)
		$P>0.05$	$P>0.05$	$P>0.05$	$P>0.05$

in vivo and suggested that it might play a role in chromatin architecture^[15]. Our present experiment shows that the percentage of overexpression of mRNA of *DEK* (78.1%) in HCC was higher than in adjacent nontumorous tissues (15.6%). It indicates the overexpression of *DEK* may be involved in the transformation from normal liver tissue to HCC, perhaps by activating the oncogenes.

GPC3

GPC3 gene is located at Xq26, and mutated in the Simpson-Golabi-Behmel syndrome^[16]. It may be regulated by methylation of the inactive X in expressing tissues, and encodes a developmentally regulated heparin sulfate proteoglycan that is bound to the cell surface through a glycosylphosphatidylinositol anchor. Based on their localization on the cell surface, such glypicans are thought to regulate interactions between growth factor and their receptors. It is associated with apoptosis and cell signal transduction. It is reported that *GPC3* is a tissue-specific gene in breast tumor^[17], ovarian tumor^[18], and malignant mesothelioma^[19] in which it is downregulated by aberrant methylation of the *GPC3* promoter region, and upregulated in HCC. In the present study, *GPC3* was overexpressed in HCC tissue and the positive expression rate was 75.0%, which was higher than that in adjacent nontumorous tissue (21.9%). Although the role of overexpression of *GPC3* in the development of HCC is not known, it may break the balance between cell growth and death.

IGF-II

It was reported that IGF-II is positive in some benign neoplastic nodules and HCC^[20]. In the present study, the levels of IGF-II was higher in HCC than in adjacent nontumorous tissue, suggesting that the growth factor may act as an autocrine regulation of cell proliferation, *GPC3* may act as a positive regulator of IGF-II, although we have not detected a direct interaction between *GPC3* and IGF-II. It is possible that *GPC3* positively regulates IGF-II activity by interacting with the components of its signaling system.

rpP0

Ribosome acts as a place for protein synthesis. It is composed of rRNA and ribosomal phosphoproteins. In the family of ribosomal phosphoprotein, there are five members: P0, P1 α , P1 β , P2 α , and P2 β . Three functional domains can be defined in the rpP0: one involved in binding to rRNA, one connected to P1/P2 protein interaction, and one associated with elongation factors^[21]. It was reported that rpP0 expression increases in colon carcinoma cells^[22]. In the present study, rpP0 was overexpressed in HCC tumor tissue, suggesting that upregulation of rpP0 is associated with HCC, which may be a signal for increasing protein synthesis.

Multiplex RT-PCR and HCC

In this study, we used multiplex RT-PCR to detect the expression of mRNAs of *DEK*, *cyclin D1*, *IGF-II*, *GPC3*, *rpP0* in HCC and adjacent nontumorous liver tissue. We found that at least one of the mRNAs could be detected in all HCC tissues and 68.8% of HCC tissues expressed all these five mRNAs, while only 9.4% of paraneoplastic tissues

expressed all of them ($P < 0.05$), suggesting that multiplex RT-PCR enhances the detective sensitivity and specificity when combining several specific primers. The expression of anyone of these mRNAs in liver tissue could be regarded as a risk factor for HCC. The higher the expression of these mRNAs the greater the risk. When all these mRNAs are negative in tissues, the possibility of HCC is lower. Multiplex RT-PCR provides an easy and quick method to detect the expression of these genes in liver tissues.

ACKNOWLEDGMENTS

The authors thank Dr. Dang-Rong Li for practical and productive technical advice regarding the RT-PCR technique and Dr. Le-Qun Li for providing useful tissues.

Abstract

AIM: To investigate expression and significance of inhibitor of apoptosis protein survivin in hepatocellular carcinoma (HCC).

METHODS: The expression of survivin and vascular endothelial growth factor (VEGF) was investigated in 38 cases of HCC tissues and 38 liver cirrhosis tissues by immunohistochemistry and Western blot. The relationship between the expression of survivin and clinicopathological factors of HCC was analyzed.

RESULTS: Survivin protein was detected in 23 (60.5%) of 38 HCCs and 3 (7.9%) of 38 liver cirrhosis tissues. In 23 cases of HCC which expressed survivin, the expression of VEGF was positive in 18 cases and slight positive or negative in 5 cases. While in 15 cases of HCC which did not express survivin, 12 cases did not express or slightly expressed, and 3 cases expressed VEGF. In liver cirrhosis tissues, the expression of VEGF was as follows: 24 cases were negative, 10 cases were weak positive and 4 cases were strong positive. The expression of survivin was coincident with the expression of VEGF in HCC ($P < 0.01$). The expression of survivin in HCC had no relationship with the patients' age, gender, tumor size and differentiation level of HCC, while it was related to the metastasis of HCC. The protein quantitative analysis by Western blot also showed that overexpression of survivin in HCC was closely correlated to the expression of VEGF ($P < 0.01$). Furthermore, stronger expression of survivin and VEGF was also found in patients with metastasis rather than in those with no metastasis ($P < 0.01$).

CONCLUSION: Survivin plays a pivotal role in the metastasis of HCC, and it has some correlation with tumorigenesis. The expression of survivin in the primary lesion is very useful as an indicator for metastasis and prognosis of HCC. It could become a new target of gene therapy of HCC.

INTRODUCTION

In organisms, cell death and cell cycle progression are two sides of the same coin, and these two different phenomena are regulated moderately to maintain the cellular homeostasis^[1]. On the other hand, gene mutation could be accumulated and cell growth cycle could be prolonged, thus finally facilitating the formation of tumor. At present, it has been confirmed that P53 and bcl-2 family are critical to the regulation of cell apoptosis. Survivin protein (M_r 16 500) is a recently described member of inhibitor of apoptosis protein (IAP) family of antiapoptotic proteins, which may act simultaneously with the bcl-2 family proteins, but has a different apoptosis inhibitory mechanism^[2]. Survivin is conserved across evolution with homologs found in both vertebrate and invertebrate animal species^[3]. The tissue distribution of survivin has obvious cell selectivity. Some research has found that survivin is undetectable in terminally differentiated adult tissues, yet it is abundantly expressed in fetal tissues and in a variety of human tumors including lung, colo-rectal, breast, prostate, melanoma, pancreatic, and gastric carcinoma as well as in high-grade lymphomas and neuroblastomas^[4-11]. However, the expression and implication of survivin in hepatocellular carcinoma are still unknown.

Vascular endothelial growth factor (VEGF) is considered to be the most primary factor prompting the angiogenesis in tumor tissue, which also holds the central position in the course of formation and metastasis of tumor. However, it is unclear how VEGF accelerates the metastasis of neoplasms.

To explore the role and mechanism of survivin in the progression of HCC and the relationship with VEGF, we adopted immunohistochemistry and Western-blot techniques to investigate the expression of survivin and VEGF in HCC.

MATERIALS AND METHODS

Patients and samples

A total of 38 cases of HCC was involved in this study. The

patients with HCC, who underwent potentially curative tumor resection at Hepatic Surgery Center of Tongji Hospital from 2001 to 2002, had received neither chemotherapy nor radiation therapy before surgery. Among them, there were 33 males and 5 females, and the mean age of the patients was 47.3 years (SD, 11.2 years; range, 18-76 years).

All the specimens were confirmed to be hepatocellular carcinoma by pathological diagnosis. Cell differentiation was graded by Edmondson-Steiner's criteria. Tumors with Edmondson-Steiner's grade I were regarded as moderate to well differentiation and those with grade II-IV were poorly differentiated. The criteria of metastasis included extrahepatic tissue or organ involvement; hilum or remote lymphoid nodule metastasis; tumor thrombus formation in the main portal trunk or hepatic vein or bile duct. Multifocal HCC was excluded from this study because it was a controversial issue^[12].

Routinely processed formalin-fixed, paraffin-embedded blocks containing principal tumor were selected. Serial sections of 2-4 μ m were prepared from the cut surface of blocks at the maximum cross-section of the tumor.

Immunohistochemical staining for survivin and VEGF

Immunohistochemical staining for survivin and VEGF antigen was carried out by the standard streptavidin-peroxidase-biotin technique (SP technique) using SP kit (Zhongshan Company, Beijing, China). Rabbit-anti-human survivin monoclonal antibody and rat-anti-human VEGF monoclonal antibody were obtained from Neomarkers Company. Experimental procedure was conducted according to the SP kit specification. Primary antibody was diluted at 1:200. Antigen retrieval was done by microwave citrate salt method. 3,3'-diaminobenzidine and hematoxylin were used for color development and counterstaining respectively. Cells whose cytoplasm was dyed brown were regarded as positive ones. One case of stage III gastric cancer was stained intensively and reproducibly for survivin expression in >30% of tumor cells, and was used as a positive control throughout the study. Negative control slides processed without primary antibody were included for each staining. In brief, deparaffinized and rehydrated sections were bathed in a 10^{-3} mol/L sodium citrate buffer (pH 6.0) then the solution was put to a pressure cooker and boiled for 20 min while maintaining the pressure. After endogenous peroxidase was quenched in 3% hydrogen peroxide and blocked for 5 min, the sections were incubated overnight at 4 °C with primary polyclonal antibody at a 1:200 dilution. Biotinylated immunoglobulin and streptavidin conjugated to peroxidase were then added. Finally, 3,3'-diaminobenzidine was used for color development, and hematoxylin was used for counterstaining. The mean percentage of positive tumor cells was determined in at least five areas at 200-fold magnification for survivin and 100-fold magnification for VEGF and scaled as the following: (0) <5%; (1) 5-25%; (2) 25-50%; (3) 50-75%; and (4) >75%. The intensity of survivin immunostaining was scored as follows: 1+, weak; 2+, moderate; and 3+, intense. Because tumors showed heterogeneous staining, the dominant pattern was used for scoring. The scores indicating percentage of positive tumor cells and staining intensity were multiplied to produce a weighed score for each case. Cases with weighed

scores <1 were defined as negative; cases with weighed scores >2 were defined as strongly positive and those in between were defined as positive.

Western blot

Proteins were extracted from tissues and cells by detergent lysis using NP-40 lysis buffer (0.2% NP-40, 100 mmol/L Tris-HCl, pH 8.0, 200 mmol/L NaCl, 0.01% SDS). Proteins were fixed quantitatively by ultraviolet spectrophotometer analysis. A total of 20 μ g of the proteins of HCC tissue was fractionated on a 75 g/L polyacrylamide slab gel containing 1 g/L SDS and then transferred onto a nitrocellulose filter by electroblotting. The filter was incubated for at least 1 h in 10 mmol/L Tris-HCl buffer (pH 8.0) containing 150 mmol/L NaCl, 0.05% Tween-20 and 50 g/L bovine serum albumin for survivin and in 10 mmol/L Tris-HCl buffer (pH 8.0) containing 150 mmol/L NaCl, 0.05% Tween-20 and 50 g/L milk powder for VEGF to prevent nonspecific binding of antibodies. Then it was incubated with primary antibody (survivin, 1:1 000; VEGF 1:2 000) for 12 h, and with second antibodies for 1 h at room temperature in the same buffer. Respectively, the second antibodies of survivin were goat-anti-rabbit polyclonal antibody labeled by alkaline phosphatase and those of VEGF were goat-anti-rat polyclonal antibody labeled by horseradish peroxidase. VEGF was dyed by 0.01% DAB/H₂O₂ form 5 to 15 min and brown straps were viewed as positive results. Survivin was dyed by NBT/BCIP for 10 min or so and blue-black straps were positive. At the same time protein molecular weight marker (M_r 14 000-70 000) was used to identify destined straps. The expressed protein quantity was automatically analyzed by GIS gel image processing system (version 3.10, Tanon Technological Limited Company, Shanghai, China). The net area of strap represented the expressed protein quantity.

Statistical analysis

All statistical analyses were performed using the SPSS 10.0 J software package for Macintosh (SPSS, Inc., Chicago, IL). Variables associated with survivin expression were analyzed by the χ^2 test. The coincident expression of survivin and VEGF protein in HCC or liver cirrhosis tissues was analyzed by the paired *t*-test. The correlation between HCC metastasis and expression of survivin and VEGF protein was tested by bivariate correlation analysis. $P < 0.05$ was considered significant and $P < 0.01$ was considered remarkably significant.

RESULTS

Immunohistochemical staining

Twenty-three cases (60.5%) of 38 HCCs expressed survivin protein, among them, 8 cases strongly expressed, 12 cases positively expressed, and 3 cases slightly expressed. Survivin protein was detected in only 3 (7.9%) of 38 liver cirrhosis. The relationship between the expression of survivin and clinicopathological factors of HCC is shown in Table 1. In 23 cases of HCC which expressed survivin, the expression of VEGF was positive in 18 cases and slightly positive or negative in 5 cases. In 15 cases which did not express survivin

Table 1 Relationship of the expression of survivin and clinicopathological factors of HCC

	<i>n</i>	Survivin		<i>P</i>
		Positive (<i>n</i>)	Percent (%)

<5	21	11	52.4	
Differentiation				>0.05
Moderate to well	16	9	56.3	
Poor	22	14	63.6	
Metastasis				<0.05
Positive	14	12	85.7	
Negative	24	11	45.8	

protein, 12 cases of HCC did not express or slightly expressed VEGF and 3 cases expressed VEGF. In liver cirrhosis tissue,

the expression of VEGF was negative in 24 cases, weak positive in 10 cases and strong positive in 4 cases. The staining of both survivin and VEGF was mainly localized in cytoplasm.

By statistical analysis, there was a remarkable difference in survivin expression between the tumor tissue and liver cirrhosis tissues ($P<0.01$). The expression of survivin in HCC had no significant relation with the patients' age, gender, tumor size and differentiation level of HCC, while it was related to the metastasis of HCC ($P<0.05$). Furthermore, a high expression of survivin was coincident with the expression of VEGF in HCC ($P<0.01$) (Table 2 and Figures 1 and 2).

Western blot

By analysis with GIS gel image processing system, the values of net area indicating the expressed protein quantity are as shown in Tables 3 and 4, Figures 3 and 4.

DISCUSSION

It has been identified that bcl-2 family and IAPs family have close relations with cell apoptosis. So far six members of IAPs family (NAIP, c-IAP1, c-IAP2, XIAP, Survivin and Bruce) have been cloned^[13]. IAPs family expresses extensively among many species, which are of homology in their

structures and the abilities of inhibiting apoptosis^[14]. Survivin is the smallest member among the IAPs family. Altieri of Yale University utilized EPR-1 (effector cell protease receptor-1) cDNA to screen and clone survivin from human GenBank in 1997^[3]. It has been suggested (but not proven) that EPR-1 may act as a natural anti-sense to survivin in cells^[15].

The expression of survivin depends on cell cycle. Hela blocked tumor cells in G1, S, G2/M phase separately to detect survivin mRNA amount. Survivin mRNA was not detectable in G1 phase, increased 6.2 times in S phase and elevated 40 times in G2/M phase. Therefore, the expression of survivin was closely related to cell proliferation. Survivin can suppress apoptosis of NIH3T3 cell induced by Taxol and 293 cell induced by Fas and Bax^[16]. Survivin inhibits apoptosis mainly through targeting the terminal effectors caspase-3 and -7 activity in apoptotic protease cascade reaction^[17,18]. These caspases operate in the distal portions of apoptotic protease cascades, functioning as effectors rather than initiators of apoptosis. Survivin is characterized by a unique structure with a single BIR and no zinc-binding domain known as the RING finger, thus survivin cannot bind caspase-3 directly. Survivin is expressed in the G2-M phase of the cell cycle in a cell cycle-regulated manner and associates with microtubules of the mitotic spindle by the coiled spirals zone^[19-21]. Survivins are also called chromosomal passenger proteins: they associate with inner centromere regions during prophase, but subsequently relocate to the midzone of the central spindle and concentrate at the midbody^[22]. Survivin has the double function of controlling spindle checkpoint and apoptotic checkpoint. The over-expression of survivin in neoplasms may obliterate this apoptotic checkpoint and allow aberrant progression of transformed cells through mitosis. The disruption of survivin-microtubule interaction results in loss of antiapoptosis function of survivin and increases caspase-3 activity during mitosis^[21].

**Figure 3** Expression of survivin in HCC and liver cirrhosis tissues. Lanes 1 and 2: liver cirrhosis tissues; lanes 3-5: HCC tissues. *M_r* of survivin: 16 500.**Figure 4** Expression of VEGF in HCC and liver cirrhosis tissues. Lanes 1 and 2: liver cirrhosis tissues; lanes 3-5: HCC tissues. *M_r* of VEGF: 21 000.

The results revealed that survivin was highly expressed in HCC and seldom detected in liver cirrhosis tissues. The expression of survivin had no association with the patients' age, gender, tumor size and differentiation level of HCC. It suggests that survivin may play some role in tumorigenesis of HCC. Simultaneously, in our series, we found that high expression of survivin was significantly correlated to VEGF in HCC. More importantly, stronger expression of survivin and VEGF was found in patients with metastasis than in those without metastasis. Consequently the expression of survivin seems to be involved in metastatic capacity of HCC.

As we know, VEGF is considered to be the most cardinal vascular growth factor prompting angiogenesis in tumor tissue. The mechanism of liver cancer cell shift induced by VEGF is closely related to increased proliferation ability of liver cells. Emerging studies have implicated a marked induction of survivin by VEGF in vascular endothelial cells, which can facilitate tumor metastasis by controlling apoptosis during angiogenesis. VEGF binding to VEGF-R2 activates the phosphatidylinositol 3-kinase (PI3K) survival pathway, resulting in phosphorylation and activation of the serine/threonine kinase protein kinase B (PKB/Akt). VEGF induces the expression of several anti-apoptotic effector molecules in Ecs by PKB/Akt pathway, including bcl-2, A1, and two members of the IAP family, X-linked IAP (XIAP), and survivin^[23-26]. VEGF-dependent upregulation of survivin could be prevented by cell cycle arrest in the G1 and S phases and allows for the maintenance of the microtubule network to inhibit apoptosis of endothelial cells^[27-30]. Our results demonstrate that the expression of survivin is consistent with that of VEGF in HCC and both are closely correlated to infiltration and metastasis of HCC. This is similar to findings in endothelial cells. As such, we assume that VEGF probably promotes the expression of survivin in HCC tissues, then the latter inhibits apoptosis of hepatocarcinoma cells and enhances tumor cell ability of infiltration and invasion,

thus accelerating tumor metastasis. To clarify the interaction mechanism between survivin and VEGF in HCC, further studies are needed.

The cancer-specific expression of survivin, coupled with its importance in inhibiting cell death and in regulating cell division, makes it a useful diagnostic marker of cancer and a potential target for cancer treatment^[31]. Recently some studies have set about to evaluate the possibility of targeting survivin function *in vivo* as an anticancer strategy in which it is shown that inhibition of survivin could effectively inhibit *de novo* tumor formation and progression^[32,33]. In the light of the effect of survivin on the progression of HCC, it is possible that inhibiting the function of survivin can be a new treatment of HCC.

In conclusion, inhibitor of apoptosis protein survivin plays a pivotal role in the metastasis of HCC, and it has some correlation with tumorigenesis. It is associated with the progression of HCC as a late event in tumorigenesis. The expression of survivin in the primary lesion can be an indicator for metastasis and prognosis of HCC. It could become a new target of gene therapy of HCC.

Abstract

AIM: To study the distribution pattern of transcription factors NF- κ B and AP-1 and their relations with the expression of apoptosis associated-proteins Fas/FasL and ICH-1L/S in human hepatocellular carcinoma (HCC).

METHODS: We performed *in situ* hybridization and immunohistochemical techniques for NF- κ B, AP-1, Fas/FasL and ICH-1 in 40 cases of human HCC along with corresponding nontumoral tissues and 7 cases of normal liver tissues.

RESULTS: Twenty-two (55%) and 25 (62.5%) of 40 cases for NF- κ B and AP-1 were presented for nuclear or both nuclear and cytoplasmic staining respectively, while less cases were presented for only cytoplasmic staining for NF- κ B (18%) and AP-1 (10%) in adjacent nontumoral tissues and negative staining in normal liver tissues. There was no statistically significant difference of NF- κ B or AP-1 activation between well differentiated tumors and poorly differentiated tumors ($P>0.05$). NF- κ B activity is positively corresponded to AP-1 activation. The expression of ICH-1L/S was associated with the activation of NF- κ B and AP-1 ($P<0.05$), but no significant relationship was found between Fas/FasL and NF- κ B or AP-1 ($P>0.05$).

CONCLUSION: Activation of both NF- κ B and AP-1 may be required for ICH-1L/S-induced apoptosis in HCC, but not for Fas/FasL-mediated apoptosis. NF- κ B and AP-1 may play important roles in the pathogenesis of human HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common cancers and cause of mortality in China. Much advanced progresses in the mechanism of hepatocarcinogenesis have been achieved for these years. Many genes such as proto-oncogenes, tumor suppressor genes, apoptosis genes and growth factors genes have been implicated and apoptosis genes may play an important effect in the process of hepatocarcinogenesis^[1-6]. Apoptosis-related genes such as bcl-2/bax, Fas/FasL and caspase are involved in the pathogenesis of HCC^[3-6]. However, more steps of apoptosis genes in this process remain unknown yet.

Activated protein-1 (AP-1) and nuclear factor κ B (NF- κ B), two of important transcription factors, play important roles in signal transduction pathways of cell differentiation, proliferation and apoptosis in response to a variety of physiological and pathological stimuli^[7-13]. AP-1 consists of homodimers and heterodimers of the Jun family (c-Jun, JunB, JunD), and the Fos family (c-Fos, FosB, Fra1, Fra2). NF- κ B is a heterodimeric complex composed of two subunits of the Rel/NF- κ B family, factors including NF- κ B1 (p50), NF- κ B2 (p52), c-Rel, RelA/p65, and RelB^[14]. Some investigators have presented aberrant DNA binding activity of AP-1 and NF- κ B in various types of human tumor such as HCC, gastric carcinoma, breast carcinoma and so on^[15-22]. These findings suggested that AP-1 and NF- κ B may be important in the control of cell proliferation and oncogenesis of these tumors.

The molecular mechanisms of NF- κ B and AP-1 in the regulation of Fas/FasL mediated apoptosis may be different in T cells, Jurkat cells, hepatocyte-derived cell lines and colon carcinoma cell^[23-27]. However, whether NF- κ B and AP-1 play important roles in regulation of Fas/FasL and ICH-1L/S expression in human HCC is still not known. In the present study, we undertook to investigate whether AP-1 and NF- κ B are constitutively activated in human HCC tissues and to evaluate the relationship between AP-1 or NF- κ B activity and the expression of apoptosis associated proteins (Fas/FasL and ICH-1L/S) by *in situ* hybridization and immunohistochemical techniques.

MATERIALS AND METHODS

Tissue preparation

Forty samples were obtained by surgical resection in our department. All samples were independently reviewed by two pathologists. The cases of HCC were classified according to the criteria described by Edmondson-Steiner and grouped as well differentiated (grade I-II; $n = 25$) or poorly differentiated (grade III-IV; $n = 15$). Seven undamaged liver tissues from surgical resection specimens of young adults with minor liver injury who underwent partial hepatectomy were used as normal control. All tissues were fixed in 40 g/L formaldehyde (pH 7.0) for 12-24 h and embedded in paraffin wax and then 4 μ m serial sections were cut and mounted on poly-L-lysine coated slides.

Immunohistochemistry staining

Sections were deparaffinized and rehydrated routinely. Antigen was retrieved by heating sections in a microwave oven at 700 W in 10 mmol/L citrate buffer (pH 6.0) for 10 min. After blocking with 0.3% H_2O_2 and swine serum, specimens were then incubated with the primary antibodies, directed against Fas, FasL, and ICH-1L/S (Santa Cruz product, dilution 1:100) at 4 °C overnight. Secondary antibodies were applied according to the manufacturer's recommendations (Amersham). The staining was performed by streptavidin-peroxidase enzyme conjugate method using a S-P kit (Zymed product). Reaction products were visualized by DAB (diaminobenzidine). The slides were counterstained with hematoxylin before mounting in paramount. Brown-yellow granules in cytoplasm were recognized as positive staining.

In situ hybridization

Sections were deparaffinized and rehydrated routinely. Oligonucleotides containing the consensus sequence of

AP-1 (5'-CGCTTGATGAGTCAGCCGGAA-3') and NF- κ B (5'-AGTTGAGGGGACTTCCAGGC-3') were respectively used as probes and 3'-labeled with biotin. Preparations were incubated with the labeled probes (37 °C, overnight). Non-specific antigen was blocked with 2% bovine serum and 0.3% Triton X-100, followed by incubation with anti-biotin antibody alkaline phosphates mixture for 1 h. Slides were then visualized with BCIP/NBT. Purple-blue granules were regarded as positive staining. In general, inactivated NF- κ B and AP-1 were located in cytoplasm and nuclei staining scored as activated NF- κ B and AP-1.

Negative controls

We used the following negative controls: (a) absence of probes, (b) mutant AP-1 or NF- κ B probes 5'-CGCTTGAT-AAATCAGCCGGAA-3', and 5'-AGTTGAGGCTC-CTTCCAGGC-3', respectively, labeled with biotin, (c) competition assays with a 100-fold excess of unlabeled AP-1 or NF- κ B probes, followed by incubation with its respective labeled probe.

Statistical analysis

Statistical significance was calculated by χ^2 test. The χ^2 test was used to analyze the association between NF- κ B/AP-1 and histopathological grades and Fas/FasL and ICH-1L/S. $P < 0.05$ was regarded as significant difference.

RESULTS

Detection of NF- κ B and AP-1 in HCC

In situ hybridization was performed to detect the activity status of NF- κ B and AP-1 in all 40 HCCs. NF- κ B and AP-1 distribution in nuclear or both nuclear and cytoplasm of cancer cells are illustrated in Figures 1 and 2. Of 40

Figure 1 Hepatocellular carcinoma showing nuclear and cytoplasmic positivity for NF- κ B (A) and AP-1 (B). *In situ* hybridization (magnification $\times 200$).

Figure 2 Nontumor liver tissue showing focal and weak cytoplasmic positivity for NF- κ B (A) and AP-1 (B). *In situ* hybridization (magnification $\times 200$).

HCCs, 22 (55%) presented nuclear or both nuclear and cytoplasmic staining of NF- κ B by *in situ* hybridization in which 13/25 (52%) were well differentiated tumors and 9/15 (60%) were poorly differentiated tumors. While 25 (62.5%) of 40 cases for AP-1 positive staining were shown in which 14/25 (56%) were well differentiated tumors and 10/15 (66.7%) were poorly differentiated tumors. There was no statistically significant difference of NF- κ B or AP-1 activation between well differentiated tumors and poorly differentiated tumors ($P>0.05$). In adjacent non-tumor tissues, cytoplasmic staining of NF- κ B or AP-1 was noted in 27(68%) and 23(58%) respectively. But lower nuclear staining for NF- κ B (17.5%) and AP-1 (10%) was found in non-tumor tissues than those in HCC with a statistical significance ($P<0.05$). Only few hepatocytes showed cytoplasmic staining for NF- κ B (1/7) and AP-1 (2/7) in normal liver tissues, but no staining in the nucleus. NF- κ B activity positively corresponded to AP-1 activation (Table 1).

Table 1 Detection of NF- κ B and AP-1 in HCC

Group	Cases	NF- κ B nucleus/cytoplasm + nucleus (+) (%)	AP-1 nucleus/cytoplasm + nucleus (+) (%)
Tumor tissue	40	22 (55) ^a	24 (60)
Well differentiated	25	13 (52)	14 (56)
Poorly differentiated	15	9 (60)	10 (66.7)

Normal tissue	7	0	0

^a $P<0.05$ vs tumor tissue.

Expression of apoptosis proteins in HCC

Table 2 summarizes the results of immunohistochemical studies on apoptosis proteins including Fas, FasL, ICH-1L and ICH-1S. Fas, FasL, ICH-1L, and ICH-1S presented cytoplasmic reactivity in 7 (17.5%), 6 (15%), 15 (37.5%) and 21 (52.5%) of tumors, while in 21 (52.5%), 18 (45%),

29 (72.5%) and 31 (77.5%) of nontumor tissues, in 0%, 0%, 2/7 and 1/7 of normal liver tissues, respectively. There were statistically significant differences of the expression of Fas, FasL, ICH-1L, and ICH-1S between non-tumor tissues and tumor tissues ($P<0.05$). The differences of Fas and ICH-1S expression except FasL and ICH-1L were also statistically significant between nontumor tissues and normal liver tissues ($P<0.05$, Figure 3).

Table 2 Expression of Fas, FasL, ICH-1L, and ICH-1S in HCC

Group	Cases	Fas (%)	FasL (%)	ICH-1L (%)	ICH-1S (%)
Tumor tissue	40	7 (17.5) ^a	6 (15)	15 (37.5)	21 (52.5)
Nontumor tissue	40	21 (52.5) ¹	18 (45) ²	29 (72.5) ³	31 (77.5) ⁴
Normal tissue	7	0 ⁵	0 ⁶	2	1 ⁶

^a $P<0.05$ vs tumor tissue. ¹ $\chi^2 = 10.2692$, ² $\chi^2 = 8.5714$, ³ $\chi^2 = 9.8990$, ⁴ $\chi^2 = 5.4945$, ⁵ $\chi^2 = 4.6890$, ⁶ $\chi^2 = 8.2398$.

Relationship between activated NF- κ B and apoptosis proteins in HCC

The expression of Fas and FasL was more frequent in 22 cases of HCC with activated NF- κ B compared with 18 cases of HCC with inactivated NF- κ B, but the differences were not significant statistically between cases with activated NF- κ B group and with inactivated NF- κ B group ($P>0.05$). However, there was positive relationship between the expression of ICH-1L and ICH-1S in the cases with activated NF- κ B and those with inactivated NF- κ B ($P<0.05$, Table 3).

Relationship between activated AP-1 and apoptosis proteins in HCC

The expression of ICH-1L and ICH-1S in HCC with activated AP-1 was also more common with a statistical significance as compared with those with inactivated AP-1 respectively ($P<0.05$). But there was no significant difference between the expression of Fas and FasL in the cases with activated AP-1 and those with inactivated AP-1 ($P>0.05$, Table 4).

DISCUSSION

Electrophoretic mobility shift assays is a common and useful technique for studying transcription factors. However, the distribution of transcription factors either in nucleus or cytoplasm cannot be shown using this technique. *In situ* detection using nonradioactive oligonucleotides in paraffin wax-embedded tissues was successfully used for studying NF- κ B and AP-1 activation in kidney and injured vessels^[28]. In this study, we performed this technique to detect NF- κ B and AP-1 in HCC and obtained ideal results. The distribution of NF- κ B and AP-1 was presented in nuclear and cytoplasmic types. Positive signals in HCC were mainly located both in nuclei and cytoplasm while cytoplasmic staining mainly in nontumor. We concluded that *in situ* hybridization is a convenient and efficient tool for studying transcription factors (Table 5).

Some studies have shown that DNA binding activity of NF- κ B and AP-1 was aberrant in HCC^[15,16]. Liu *et al.*, measured the DNA binding activity of AP-1 and NF- κ B in the peritumoral and the tumoral parts of 15 primary liver cancers. AP-1 and NF- κ B binding activities were in 73%

and 87% of the cases in the peritumoral tissue respectively. A further activation of AP-1 and NF- κ B binding in the tumoral parts was detected in 40% and 80% of the cases respectively. Early activation of AP-1 and NF- κ B contributes probably to the acquisition of a transformed phenotype during hepatocarcinogenesis, whatever the etiology^[15]. Tai *et al.*, studied the NF- κ B-DNA binding activity and its dimmer, active nuclear RelA and nuclear IkappaB-alpha proteins expression in HCC using electrophoretic mobility shift assay and Western blot analysis. The results showed that nuclear NF- κ B DNA binding activity and nuclear RelA protein expression were greater in tumor tissue compared with nontumor tissue^[16]. Constitutive activation of NF- κ B was found more frequently in tumor tissue compared with nontumor tissue. In our study, the results are similar to that by electrophoretic mobility shift assay. Furthermore, our findings presented positive staining for NF- κ B and AP-1 distribution in cytoplasm (inactive form) at 68% and 58% in adjacent liver tissues, 1/7 and 2/7 in normal liver, and in nuclei (active form) at 55% and 62.5% in tumor tissues. The possible activation of NF- κ B has been shown in some

Table 5 Relationship between activated NF- κ B and apoptosis proteins in nontumor tissues

carcinoma tissues such as human pancreatic carcinoma, gastric carcinoma and breast carcinoma. NF- κ B activation was evaluated on the basis of nuclear translocation from inactive form with NF- κ B-I κ Bs complex in cytoplasm^[18,20-22]. However, the mechanism concerning AP-1 activation in carcinoma is not available. We further found that NF- κ B activity positively corresponded to AP-1 activation. Taken together, these results demonstrated that NF- κ B and AP-1 translocated from cytoplasm (inactive form) to nucleus (active form) during hepatocarcinogenesis and suggested that activation of both NF- κ B and AP-1 may be required to produce potential biological function and play important roles in the oncogenesis of human HCC.

Fas/FasL system is involved in apoptosis in human HCC^[5,6]. In this study, we further investigated whether there is a relationship between NF- κ B or AP-1 activity and Fas/FasL expression in HCC. The results showed that more expression of Fas and FasL was found in cases with activated NF- κ B or AP-1 than those with inactivated NF- κ B or AP-1 in HCC but the differences were not significant statistically ($P>0.05$). These data indicated that NF- κ B and AP-1 activation may not be required for Fas/FasL-induced apoptosis in HCC. Similar results have been reported in other different cells. Nagaki *et al.*, found NF- κ B blocks hepatocyte apoptosis mediated by the TNF receptor, but not by Fas^[23]. In T cells, NF- κ B signaling pathway is not required for activation-induced FasL expression^[24]. Lack of a requirement for AP-1 induction in Fas-mediated death was substantiated with Jurkat cell^[25]. However, the results contrary to those stated above have been implicated in some studies. Marusawae *et al.*, demonstrated that NF- κ B activity is related to Fas signaling in hepatocyte-derived cell lines, HepG2 and Huh-7 cells. Overexpression of kinase-inactive NF- κ B-inducing kinase (NIK) and IkappaB kinase (IKK) inhibited the activation of NF- κ B introduced by anti-Fas treatment in these cells. Inactivation of NF- κ B by the production of IkappaB-alpha protein made these cells more susceptible to apoptosis induced by Fas stimulation^[26]. NF- κ B and AP-1 are also found involving in the transcriptional regulation of FasL in Fas-mediated thymineless death of colon carcinoma cell^[27]. These results suggested NF- κ B and AP-1 may play different roles in the regulation of Fas/FasL-mediated apoptosis in different cells.

ICH-1, a gene related to the *C. elegans* cell death gene *ced-3* and the mammalian homolog of *ced-3*, interleukin-1 beta-converting enzyme (ICE). Alternative splicing results in two distinct ICH-1 mRNA species. One mRNA species encodes a protein product of 435 amino acids (ICH-1L) that is homologous to both the P20 and P10 subunits of ICE (27% identity) and the entire CED-3 protein (28% identity). The other mRNA encodes a 312 amino acid truncated version of ICH-1L protein (ICH-1S). Overexpression of ICH-1L induces programmed cell death, while ICH-1S suppresses Rat-1 cell death induced by serum deprivation. ICH-1 plays an important role in both positive and negative regulation of programmed cell death in vertebrate animals^[29]. In this study, we found that aberrant expression of ICH-1 in HCC and adjacent tissues compared to normal liver. The results also showed that there are statistical differences between expression of ICH-1L or ICH-1S and NF- κ B or AP-1

activation. These findings suggested that NF- κ B and AP-1 may play a role in mediating ICH-1L/S expression during pathogenesis of HCC.

Abstract

AIM: To investigate the value of spiral CT pneumocolon in preoperative colorectal carcinoma.

METHODS: Spiral CT pneumocolon was performed prior to surgery in 64 patients with colorectal carcinoma. Spiral CT images were compared to specimens from the resected tumor.

RESULTS: Spiral CT depicted the tumor in all patients. Comparison of spiral CT and histologic results showed that the sensitivity and specificity were 95.2%, 40.9% in detection of local invasion, and 75.0%, 90.9% in detection of lymph node metastasis. Compared to the Dukes classification, the disease was correctly staged as A in 6 of 18 patients, as B in 18 of 23, as C in 10 of 15, and as D in 7 of 8. Overall, spiral CT correctly staged 64.1% of patients.

CONCLUSION: Spiral CT pneumocolon may be useful in the preoperative assessment of patients with colorectal carcinoma as a means for assisting surgical planning.

INTRODUCTION

With the development of high-resolution scanners, technical refinements in obtaining better quality studies, and the accumulated clinical experience leading to better interpretation,

the role, indications, and accuracy of CT of the colon have dramatically enlarged and improved^[1-3]. Reliable preoperative determination of the extent of spread of a colorectal carcinoma not only indicates the expected prognosis but also assists management. For obtaining reliable results from CT scan, preparation of the patients, especially complete distention of the colon using water or air as contrast agent, is the most important precondition. Otherwise, collapse of the colon and feces can easily be misinterpreted as tumor. Many studies have shown that water enema spiral CT is a useful modality for preoperative staging of patients with colorectal carcinoma^[4-7]. However, water enema can be difficult and distressing in frail elderly patients and has risk of water incontinence. Air insufflation for the colon can be achieved easily and rapidly and is well tolerated by the patients, and air provides an excellent CT contrast medium^[8]. There have been few reports concerning the preoperative staging of colorectal carcinoma with spiral CT pneumocolon. Therefore, this study aimed to assess the value of spiral CT pneumocolon in preoperative colorectal carcinoma.

MATERIALS AND METHODS

Patients

From August 1998 to December 2002, 64 patients with colorectal carcinoma, who were operated on at our institution, underwent spiral CT pneumocolon. There were 40 men and 24 women, ranging in age from 32 to 88 years (mean 59 years). Among the 64 patients who had a prior colonoscopy, 4 of 15 patients had an incomplete barium enema due to barium incontinence, and 19 of 64 patients had incomplete colonoscopy due to inability to cross a distal stricture.

Technique

All patients were fasted for at least 12 h before the study and given an oral colon cleansing preparation the night before CT scan. Nine-hundred milliliters of 3% diluted gastrografin solution was given orally 45 min before, so that small bowel loops were opacified. Anisodamine hydrochloride (10 mg, IM) was used to control peristaltic artifact and relax the colon. The patient was previously instructed not to void. As the study progressed, interpretation was more straightforward when the bladder was full.

The patients were positioned on the CT table in supine position. A Foley catheter was inserted into the rectum and 1 500-2 000 mL room air was administered per rectum to distend the colon. The enema was stopped if the patient experienced abdominal discomfort. Adequate distention of the whole colon was confirmed on the scanogram.

Studies were performed on a Toshiba Xpress/SX spiral

CT scanner with a 10-mm collimation and pitch of 1-2, at 120 kV and 200 mA. After plain scanning, 1.5 mL/kg of non-ionic iodinated contrast medium (iopromide, Ultravist 300; Schering, Berlin, Germany) was administered via the antecubital vein at a rate of 3 mL/s using an autoinjector, and scanning commenced 60 s after start of the injection from the dome of the liver to the anal verge. The time between CT scan and surgery ranged 1-8 d (mean 4.7 d).

Evaluating criteria

Based on previous reports^[5,7,8] and our own experience, the following three parameters were established and evaluated: (1) local extramural invasion (irregularly serrated or speculated outer contour, tumor mass or strands of soft tissue extending out, and/or indistinctly increased density of the pericolic fat), (2) lymph node involvement (lymph node short axis 1 cm or larger, or node less than 1 cm in diameter with obvious enhancement), and (3) distal and/or extensive disease (liver or lung metastases, direct extension into adjacent solid or hollow organs).

All patients with colorectal carcinoma were staged on CT according to the modified Dukes' classification^[7]: stage A, tumor limited to the colonic wall; stage B, tumor affecting the serosa or the pericolic fat; stage C, lymph node involvement; and stage D, tumor infiltrating adjacent organs and/or with metastases. The modified Dukes' classification was used because this system was currently used by surgeons at our institution.

Image interpretation

Two experienced radiologists, who were blind to the surgical and pathologic findings of each patient, interpreted the images as compared to above parameters, and any discrepant readings were solved by consensus. After a minimum of 4 wk, the same two radiologists reviewed the images for the second time. Intraobserver variability was evaluated by means of a weighed κ -statistic^[9].

RESULTS

The overall results showed good agreement between the two reviews by the two radiologists. The κ -statistic for the data was 0.77, representing good intraobserver agreement.

Normal findings and primary tumor

All patients tolerated the spiral CT pneumocolon well with no significant discomfort, and had good bowel preparation and no fluid levels or residual fecal material. The distended colon lumen and normal colonic wall were well seen on spiral CT (Figure 1). Using this technique the normal colonic wall represented a single layer which was 1-2-mm thick.

Spiral CT detected the tumor in all patients and the smallest mass was 0.7 cm×1.0 cm. The lesion was shown as an eccentric focal mass with irregular segmental or circumferential wall ranging 0.7-4.5 cm in thickness, and their extension ranged 1.0-10.0 cm (Figures 2A-C). Most lesions had an uneven, lobulated configuration and large masses had patchy areas of necrosis. Different degrees of distal colonic stricture were presented. The majority of the mass showed moderate to obvious enhancement.

Figure 1 Optimal visualization of normal rectal wall (arrowheads), small intestine (arrow), and urinary bladder (star).

Local invasion

Tumor invasion of serosa and/or pericolic fat was correctly staged by spiral CT in 49 (76.6%) of 64 patients (Figures 2A and B). In the incorrectly staged group, spiral CT overstaged 12 patients (Figure 3A) and understaged 2 patients (Figure 3B). Spiral CT evaluation had a sensitivity of 95.2% and a specificity of 40.9%.

Lymph node involvement

Involvement of lymph nodes less than 5 mm in diameter was seen in 7 (35.0%) of 20 patients. Spiral CT correctly diagnosed lymph node metastasis in 15 of 20 patients (Figure 2C). In the correctly diagnosed group, seven patients showed nodal enhancement, and eight patients showed no enhancement of lymph nodes larger than 1 cm in diameter. Clusters of three or more smaller nodes (each less than 1 cm in diameter) were seen by CT in five patients, histology revealed no evidence of nodal involvement.

Nodal involvement was correctly staged by spiral CT in 55 (85.9%) of 64 patients. In the incorrectly staged group, spiral CT overstaged 3 (Figure 3C) and understaged 5 of 20 patients. Spiral CT evaluation had a sensitivity of 75.0% and a specificity of 90.9%.

Distal metastasis

Liver metastasis was presented in four patients (Figure 2D), lung metastasis in two patients, and abdominal wall metastasis in one patient. They were all correctly diagnosed by CT. Only one patient with peritoneal seeding was missed due to the small lesion.

Preoperative staging

Staging results are presented in Table 1. CT stage A was correct in 6 of 18, stage B in 18 of 23, stage C in 10 of 15, and stage D in 7 of 8 patients. Overall, the diagnostic accuracy was 64.1% (41/64).

DISCUSSION

Colonoscopy and barium enema are the main methods for diagnosis of colorectal tumors. However, both modalities do not permit a precise preoperative prediction as to whether a tumor is limited to the colonic wall or has spread into surrounding tissues. Patients with severe colonic stricture

Figure 2 Correctly staged lesions. **A:** Dukes stage A carcinoma (arrow); **B:** Dukes

stage B carcinoma; **C:** Dukes stage C carcinoma; **D:** Dukes stage D carcinoma.

Figure 3 Incorrectly staged lesions. **A:** Dukes stage A carcinoma; **B:** Dukes

stage B carcinoma (arrow); **C:** Dukes stage B carcinoma.

or barium incontinence may be poor candidates for the two examinations. Our study showed that CT pneumocolon had the potential utility as an adjunctive imaging technique for patients with colorectal carcinoma.

Imaging with spiral CT pneumocolon could clearly show the lumen and wall of the colon and colonic lesions. Normal colonic wall thickness should not exceed 3 mm in a well-distended segment, and the thickness greater than 6 mm is

Table 1 CT findings and pathologic staging

CT staging	Pathologic staging				Total
	A	B	C	D	
A	6	2	1		9
B	12	18	4		34
C		3	10	1	14
D				7	7
Total	18	23	15	8	64

considered abnormal^[1]. In our study with spiral CT pneumocolon technique, the thickness of the normal colonic wall ranged 1-2 mm, and the thickness of the lesion was greater than 6 mm. We were unable to identify the mucosal lining nor the different anatomic layers of the colonic wall as reported by others who used water enema technique^[6,7].

The sensitivity of CT detection depends mainly on the size of the lesion and on the quality of the CT examination. It varies from 68% if no special attempts are made to promote visualization of the colonic lumen to 95% when the colonic lumen is distended well. In this study, the overall detection rate was 100%, and masses with a diameter in 1 cm were identified. Our results corresponded favorably with previous reports^[10,11]. This may be due to the adequate preparation of patients and CT pneumocolon technique. CT colonography generated from CT pneumocolon has emerged in recent years. This technique can detect lesions less than 5 mm in diameter, and its sensitivity is over 85% in detection of polyps 10 mm or greater in size, 70-80% of polyps 5-9 mm in size and 60% of polyps smaller than 5 mm^[12,13]. It is a viable alternative for screening primary colorectal neoplasms and examining portions of the colon proximal to an obstructing lesion that cannot be traversed by colonoscopy or by barium^[3,10,13].

In our experience, CT has a sensitivity of 95.2% and an accuracy of 76.6% in evaluating the local invasion. However, the specificity is only 40.9%. Harvey *et al.*^[8], reported that its sensitivity is 100% and specificity is 33%. Zhou *et al.*^[2], reported that its sensitivity is 92.9% and specificity is 50.0%. The reasons for the low specificity in local extension may be that CT is not possible to distinguish the single layers comprising the wall and there is no simple CT criterion to differentiate inflammation of the serosa from tumor invasion^[2,8]. Matsuoka *et al.*^[14], reported that using sagittal or coronal sections improves diagnostic accuracy from 79.4% to 90.4% in assessing the depth of tumor invasion. Endoscopic ultrasonography (EUS) is superior to CT in detecting the exact depth of parietal invasion, and its accuracy is 84.9%^[15]. In our study, the accuracy of EUS was 87.5%, and its specificity was 100% in assessing the local extension.

Traditionally, CT detection of abnormal lymph nodes is based on imaging nodes greater than 1 cm in diameter or finding of clustered lymph nodes^[5,8]. However, lymph node metastasis in colon cancer occurs frequently in lymph nodes measuring less than 5 mm. Herrera-Ornelas *et al.*^[16], have reported a 65% incidence of lymph node metastasis. Whereas enlarged lymph nodes may be infiltrated by inflammatory or neoplastic cells. A relatively low sensitivity of CT in detecting nodal metastases is anticipated. Harvey *et al.*^[8], reported that its sensitivity is 56% and specificity is

95%. Gazelle *et al.*^[5], reported that its sensitivity is 60% and specificity is 79%. Hundt *et al.*^[4], reported that its sensitivity is 84.3%, its specificity being 60% and accuracy being 81.0%. In this present study, its sensitivity, specificity, and accuracy in detecting lymph node involvement were 75.0%, 90.9%, and 85.9%, respectively. The disparity in these reports is probably due to the different criteria used. In our study, five patients with clustered lymph nodes (<1 cm) had no pathologic evidence of nodal involvement, suggesting that this criterion is unreliable. Further investigation is needed.

The data in this series showed that compared to the Dukes classification, CT correctly staged 64.1% of all patients, which is consistent with previous reports^[2,8]. CT staging accuracy, however, showed significant variations in different Dukes categories. It correctly staged 6 (33.3%) of 18 patients with Dukes A lesion, 18 (78.3%) of 23 patients with Dukes B lesion, 10 (66.7%) of 15 patients with Dukes C tumor, and 7 (87.5%) of 8 patients with Dukes D tumor.

Colon cancer is potentially curable and decision on treatment is based on the extent of tumor. If extensive local spread of tumor is shown by CT or MRI, the patients can be treated with radiation therapy alone or undergo tumor resection after radiation therapy. The success of subsequent chemotherapy and irradiation can be determined in patients by follow-up CT or MRI, which can be compared to the base-line study before treatment. Recent studies showed that endorectal surface coil MR imaging is valuable in patients with rectal carcinoma to assess involvement of the levator ani^[1]. If involvement of the levator ani is demonstrated, an abdominoperineal resection is needed.

In conclusion, spiral CT pneumocolon is a quick and noninvasive method for detecting colorectal carcinoma, and can provide valuable information preoperatively. In addition, it may represent a useful adjunct to colonoscopy or barium enema in patients with colorectal carcinoma.

Abstract

AIM: Fourteen urinary nucleosides, primary degradation products of tRNA, were evaluated to know the potential as biological markers for patients with colorectal cancer.

METHODS: The concentrations of 14 kinds of urinary nucleosides from 52 patients with colorectal cancer, 10 patients with intestinal villous adenoma and 60 healthy adults were determined by column switching high performance liquid chromatography method.

RESULTS: The mean levels of 12 kinds of urinary nucleosides (except uridine and guanosine) in the patients with colorectal cancer were significantly higher than those in patients with intestinal villous adenoma or the healthy adults. Using the levels of 14 kinds of urinary nucleosides as the data vectors for principal component analysis, 71% (37/52) patients with colorectal cancer were correctly classified from healthy adults, in which the identification rate was much higher than that of CEA method (29%). Only 10% (1/10) of patients with intestinal villous adenoma were indistinguishable from patients with colorectal cancer. The levels of m1G, Pseu and m1A were positively related with tumor size and Duke's stages of colorectal cancer. When monitoring the changes in urinary nucleoside concentrations of patients with colorectal cancer associated with surgery, it was found that the overall correlations with clinical assessment were 84% (27/32) and 91% (10/11) in response group and progressive

INTRODUCTION

Modified nucleosides, derived predominantly from transfer ribonucleic acid (tRNA)^[1-3], have been shown to be excreted in abnormal amounts in the urine of cancer patients^[4-7]. Interest in these materials as potential biological markers was stimulated following evidence that tRNA methyltransferase from cancer tissue had both increased activity and capacity when compared to the enzyme derived from the corresponding normal tissue of origin^[8]. Studies by Borek *et al.*^[9], also showed that tRNA from neoplastic tissue had a much more rapid turnover rate than the tRNA from the corresponding normal tissue. Evidence indicates that methylation of tRNA occurs only after synthesis of the intact macromolecule. Because there are no specific enzyme systems to incorporate the modified nucleosides into the macromolecular nucleic acid, these nucleosides once released in the process of tRNA turnover cannot be reutilized, nor are they further degraded, but are excreted in urine^[10]. Studies have also shown that urinary nucleosides excretion in human beings is little affected by diet, and when normalized to urinary creatinine the daily excretion rate is remarkably constant in a healthy individual^[11].

Methodically in most of the studies urinary nucleosides are isolated by phenylboronate affinity gel chromatography and separated by reverse-phase high performance liquid chromatography (HPLC)^[1,5,6,12,13]. But these methods still involve elaborate and manually performed sample-processing steps due to the complexity of the sample matrix. Among the various types of cancer, colorectal cancer is known to be one of the most prevalent and its early

detection is thus desirable. However, attempts were rarely made to measure the levels of urinary nucleosides from patients with colorectal cancer to date. In this study, we developed the automated column switching HPLC method to investigate the excretion pattern of urinary nucleosides associated with colorectal cancer and intestinal villous adenoma. Differences in 14 urinary nucleoside levels were quantified in 52 patients with colorectal cancer, 10 patients with intestinal villous adenoma and 60 healthy adults. The relationship of urinary excretion of these compounds from patients with colorectal cancer with the tumor size, Duke's stages and differentiation were studied. Changes in the levels of urinary nucleosides were examined preoperatively and postoperatively in patients with colorectal cancer. These data were collected to test the utility of urinary nucleosides as biological markers for colorectal cancer.

MATERIALS AND METHODS

Chemicals and equipment

The following 14 nucleoside standards including the internal standard 8-bromoguanosine hydrate (Br8G) were obtained from Sigma (St. Louis, MO, USA): pseudouridine (Pseu), cytidine (C), uridine (U), 1-methyladenosine (m1A), inosine (I), 5-methyluridine (m5U), guanosine (G), 1-methylinosine (m1I), 1-methylguanosine (m1G), N⁴-acetylcytidine (ac4C), N²-methylguanosine (m2G), adenosine (A), N², N²-methylguanosine (m22G), N⁶-methyladenosine (m6A). Methanol (MeOH) was HPLC-grade purchased from Tedia (Fairfield, OH, USA). Ammonium acetate (NH₄AC), ammonia (NH₃·H₂O) and potassium dihydrogenphosphate (KH₂PO₄) were all analytical reagents obtained from China. Water was deionized and purified by a Milli-Q system (Millipore, Bedford, MA, USA).

The HPLC system (Figure 1) consisted of three Shimadzu LC-10ATVP pumps (Kyoto, Japan), an autoinjector model SIL 10ADVP, an SPD-10AVP UV-Vis detector and an SCL 10AVP interface. An electric six-port valve (Rheodyne, USA) was used for the automated column switching. Valve switching and data acquisition were done on Shimadzu Class-VP version 6.10 software. The column 1 (40 mm×4.0 mm ID) was packed with a laboratory prepared boronic acid-substituted silica material. It can tolerate pH values of the buffers from 2 to 12 as well as the usual organic solvents. The column 2 (250 mm×4.6 mm ID) was packed with 5 μm Hypersil ODS₂ (Elite, Dalian, China).

Urine samples

Sixty healthy adults (31 males, 29 females, from 21 to 71 years, median age 52 years), who have the normal physical indices including hepatic function, renal function, chest X-ray and colonoscopy during a regular physical examination period in our institute, have been chosen as control material. Fifty-two patients with colorectal cancer and 10 patients with intestinal villous adenoma were from Ruijin Affiliated Hospital of Shanghai Second Medical University, the First and Second Affiliated Hospitals of Dalian Medical University of China. No patient had received chemotherapy or radiation therapy before surgery. Diagnoses of colorectal cancer and intestinal villous adenoma were made on the

basis of usual clinical and laboratory findings and were confirmed by histopathology. Table 1 shows the clinical pathological parameters of patients with colorectal cancer.

Spontaneous urine samples were collected from healthy adults, patients with colorectal cancer and intestinal villous adenoma. In 43 patients with colorectal cancer, urine samples were also obtained 2 wk after surgery. All persons had normal renal function and were free of bacterial infection at the time when the urine was collected. After collection the samples free of preservatives were frozen immediately and stored at -20 °C. Prior to analysis, the samples were thawed at room temperature and adjusted to pH 8.0 with 50 mL/L NH₃·H₂O and vortex for 3 min at 5 000 r/min. Aliquots of 1 mL centrifuged urine containing 30 μL of Br8G (0.30 mmol/L) were transferred to autosampler vials and samples of 150 μL were injected to a column-switching HPLC system.

Table 1 Clinicopathological parameters of 52 patients with colorectal carcinoma

Clinicopathological parameters		Numbers(%)
Gender	Male	29 (55.8)
	Female	23 (44.2)
Age (yr)	Range	26-87
	Mean	56.4
	Median	60.0
Primary site	Rectum	15 (28.8)
	Sigmoid colon	6 (11.5)
	Colon	31 (59.6)
Duke's stage	Duke's A	7 (13.5)
	Duke's B	23 (44.2)
	Duke's C	15 (28.8)
	Duke's D	7 (13.5)
Tumor size	≥5 cm	23 (44.2)
	<5 cm	29 (55.8)
Histological grade	Well differentiated tumor	9 (17.3)
	Moderately differentiated tumor	32 (61.5)
	Poorly differentiated tumor	11 (21.2)
CEA	≥5 mg/L	15 (28.8)
	<5 mg/L	37 (71.2)

Column switching HPLC method

Column 1 (Figure 1) was equilibrated for 5 min with the mobile phase delivered by pump 1. After sample injection (150 μL urine), column 1 was washed for 7 min with the same buffer. During that time, nucleosides were selectively retarded on the column 1 and the sample matrix was discharged. At the same time, column 2 was conditioned with the mobile phase delivered by pump 2 (position 1; Figure 1). After this clean-up step, column 1 was series-connected in front of the column 2. The group-specifically bound nucleosides on the column 1 were then eluted and concentrated on top of the column 2 over a period of 3 min (position 2; Figure 1). Separation of nucleosides on the column 2 was carried out with a linear gradient elution program over 40 min, while the column 1 was regenerated for a new extraction cycle (position 1; Figure 1). The nucleosides were detected at 260 nm and quantified using the internal standard method. Table 2 shows the time events

used for the analytical procedure.

Peak identification was performed on the basis of retention times. Standard solutions were run daily before and after the samples to monitor reproducibility of retention times. The standard addition method was also used to confirm peak identification. The levels of the urinary nucleosides were calculated by the calibration curves, and then were transformed into nmoL/ μ moL creatinine. Urinary creatinine levels were determined as described by Zheng *et al.*^[7].

Figure 1 Schematic diagram of the column-switching HPLC system.

Data analysis

The mean excreted amounts of urinary nucleosides have been calculated using MS Excel software. Differences of urinary nucleoside concentrations of healthy adults, patients with intestinal villous adenoma and colorectal cancer were compared with SPSS 10.0 software. Spearman Correlation Analysis was used to examine the relationship of urinary nucleoside concentrations from patients of colorectal cancer with the tumor size, clinical stage and differentiation. Principal component analysis (PCA) software, a home-made pattern recognition software, was used to classify healthy controls, patients with intestinal villous adenoma and colorectal cancer. It was also used to monitor changes in the urinary excretion of nucleosides before and after surgery. Principal components plots were drawn on the basis of the first principal component analysis function (PC1) against

the second principal component analysis function (PC2) of the nucleosides for each urine specimen. The oblique rotational method used in the software is the Promax method^[6].

RESULTS

Analytical characteristics of the method

Figure 2A is a standard chromatogram showing the resolution of 14 nucleosides as well as the internal standard Br8G under the condition newly developed. The calibration curves for 14 nucleosides, linear responses in peak area ratios of nucleosides to the internal standard *vs* the nucleoside concentrations were obtained with the correlation coefficients varying from 0.995 to 0.9995. The intra- and inter-day precisions of the method were determined by five repetitive analyses of an aqueous solution of standard nucleosides on three nonconsecutive days. The relative standard deviation (RSD) of retention times was less than 1.70% (intraday) and 3.51% (interday), and that of peak areas was less than 3.84% (intraday) and 7.85% (interday). The limits of detection ranged from 0.05 to 0.56 μ mol/L, which are better than the previous reports^[13,15,16], thus being suitable for the quantitative analysis.

When applied to the urine specimens from 60 healthy adults, 10 patients with intestinal villous adenoma and 52 patients with colorectal cancer, a total of 14 nucleosides were positively identified. A typical chromatogram of urinary nucleosides from a normal person with peak identification is given in Figure 2B.

Comparison of urinary excretion of nucleosides in healthy adults, patients with intestinal villous adenoma and colorectal cancer

Fourteen nucleoside concentrations of healthy adults (group 1), patients with intestinal villous adenoma (group 2) and patients with colorectal cancer (group 3) are listed in Table 3. In the mean values of three groups, the most abundant nucleoside was Pseu, followed by m1A and m1I. Pseu level was elevated above the normal values plus two standard deviation (s) in the 58% (30/52) of patients with colorectal cancer, while 20% (2/10) of patients with intestinal villous adenoma was elevated. Clearly, the concentrations of 12 nucleosides (except U, G) were significantly elevated in patients with colorectal cancer ($P < 0.05$). Only four kinds of nucleoside concentrations of patients with intestinal villous adenoma were higher in comparing with those of

healthy adults. Using 14 nucleoside concentrations as the data vectors for PCA technique, 71% (37/52) patients with colorectal cancer was distinguishable from healthy adults, while healthy adults are correctly classified at 96% (58/60) specificity. Serum CEA is the tumor marker being used in clinic to diagnose colorectal cancer (cut-off level: 5 mg/L). But the sensitivity of CEA method is 29% (15/52) based on the data provided by the hospitals. Based on the equation of classification of patients with colorectal cancer and healthy adults, 14 urinary nucleoside concentrations of patients with intestinal villous adenoma were calculated and the results was marked into Figure 3A, it was found that 10% (1/10) of patients with intestinal villous adenoma were in the area of patients with colorectal cancer.

Urinary excretion of nucleosides and clinical pathological characteristics of colorectal cancer

We examined the relationship of urinary nucleoside concentrations from patients of colorectal cancer with the tumor size, Duke's stages and differentiation. These results are listed in Table 4. The level of m1G, Pseu and m1A were positively correlated with the tumor size and Duke's stages of colorectal cancer, respectively (*P*<0.05). No significant correlation was noted in observed values with regard to tumor differentiation.

Preoperative and postoperative urinary excretion of nucleosides

The changes in six urinary modified nucleoside concentrations (Pseu, m1A, m1I, m1G, ac4C, m22G) before and after surgery in 43 patients with colorectal cancer were studied. The patients were classified into two groups: response group (32 persons) and progressive disease group (11 persons). Using the paired *t*-test, these urinary modified nucleoside concentrations of response group before surgery were

Figure 3 PCA based on 14 nucleoside concentrations from healthy controls (+) and patients with colorectal cancer (o). A: Positions of patients with intestinal villous adenoma (*) were marked into the figure based on classification equation from healthy controls and patients with colorectal cancer; B: Positions of 32 of responsive cases after surgery (*) were marked into the figure based on

classification equation from healthy controls and patients with colorectal cancer; C: Positions of 11 of progressive cases after surgery (*) were marked into the figure based on classification equation from healthy controls and patients with colorectal cancer.

Table 4 Relationship of the levels of urinary nucleosides from patients of colorectal cancer with the tumor size, Duke's stage and differentiation

Nucleoside	Tumor size R	Duke's stage R	Differentiation R

significantly higher than those of patients after surgery ($P < 0.05$). However, the pre- and post-surgery difference in levels of these nucleosides for progressive disease group had no significant changes.

PCA technique based on 14 nucleoside concentrations as the data vectors was used to monitor changes in the urinary excretion of nucleosides for patients with colorectal cancer before and after surgery. When urinary nucleoside concentrations of patients with colorectal cancer after surgery were fed to the principal component regression and marked to the space produced by the first two principal components (PC1, PC2) of healthy adults and patients with colorectal cancer before surgery (the process was similar to the position prediction of the patients with intestinal villous adenoma), it can be seen that points of 84% (27/32) patients with effective treatment have come back to the normal person area (Figure 3B). In the mean time, points of 91% (10/11) patients with ineffective treatment have entered into the area of colorectal cancer (Figure 3C).

DISCUSSION

Urinary nucleosides as biological markers of malignancy have previously been reported for a wide variety of cancers^[1-7,17,18]. However, only few reports existed regarding colorectal cancer. Our preliminary examination revealed that patients with colorectal cancer excreted in their urine significantly elevated amounts of nucleosides by HPLC method^[13]. But the method analysis of urinary nucleosides involves manual sample extraction steps, resulting in artificial error and time-consumption. In the current study, we developed the automated column switching HPLC method to examine the relationship between urinary nucleosides and pathological characteristics of colorectal cancer and the potential value of these compounds in monitoring progress of the disease during surgery. The method is simple and rapid, requiring a total analysis time of 50 min per sample, with no time involved for sample processing. Its application to routine urine samples suggests utility for mass patient screening.

The present study also confirmed that significantly elevated levels of urinary nucleosides were detected in patients with colorectal cancer by the column-switching HPLC method developed. Our data revealed that the mean nucleoside concentrations from patients with intestinal villous adenoma were significantly lower than those from patients with colorectal cancer. Only 10% (1/10) of patients with intestinal villous adenoma were in the area of patients with colorectal cancer. This is in accordance with the previous studies showing that patients with noncancerous diseases and acute infections^[19,20] do not excrete significantly elevated levels of urinary nucleosides. A current study on urinary nucleosides in colorectal cancer patients demonstrate that in the malignant disease not just one but several of the nucleosides is elevated. In such a multi-component alteration of the nucleoside levels, a pattern recognition method could reveal more information on difference among healthy adults, patients with intestinal villous adenoma and colorectal cancer than the evaluation of single components. The PCA method was applied for evaluation of the nucleoside levels in the three groups. The sensitivity of urinary nucleosides in patients with colorectal cancer was 71%, whereas the sensitivity of currently used tumor marker CEA is 29%. Urinary nucleosides may be a satisfactory biological marker for this disease.

It was also found that the level of m1G, Pseu and m1A were positively correlated with the tumor size and Duke's stages of colorectal cancer, respectively. These nucleosides may be useful as prognostic factors. Modified nucleosides have a much shorter half-life in the body than protein. A faster response to therapy and recurrence of disease is therefore feasible. Our results show that the changes in urinary nucleoside concentrations of patients with colorectal cancer almost paralleled with the change of disease status of patients after surgery (Figures 3B and C). The results are in agreement with the previous studies about urinary nucleosides being useful for monitoring progress of lymphoma and small cell carcinoma of the lung^[21,22]. These facts indicated that urinary nucleosides may be of value for a rapid assessment of disease course in monitoring colorectal cancer.

These studies have indicated the potential utility of urinary nucleosides as biological marker for colorectal cancer, especially when the column switching HPLC method developed is combined with the PCA data processing method. Because the whole-body RNA turnover correlates quite well with the protein turnover^[23], attention has to be paid to the alterations of urinary nucleosides under various catabolic conditions other than those occurring in malignancies, e.g. malnutrition, endocrine abnormalities, alcoholism and stress. More works are currently in progress to evaluate the usefulness of urinary nucleosides in differentiating cancer from other disease status.

Abstract

AIM: Hepatocyte growth factor (HGF) is a multifunctional growth factor which has pleiotrophic biological effects on epithelial cells, such as proliferation, motogenesis, invasiveness and morphogenesis. There are few reports about the role of HGF played in the colorectal cancer invasion. In the present study, we tried to investigate the possible mechanism of HGF involved in the invasion of colorectal cancer cells *in vitro*.

METHODS: Matrigel migration assay was used to analyze the migrational ability of Caco-2 and Colo320 *in vitro*. We detected the mRNA expressive levels of MMP-2, MMP-9 and their natural inhibitors TIMP-1, TIMP-2 in Caco-2 cells by reverse-transcription polymerase chain reaction (PCR) technique.

RESULTS: After 48 h incubation, there were notable differences when we compared the migrational numbers of Caco-2 cells in the group of HGF and PD98059 (the inhibitor of p42/p44MAPK) with the control (104.40 ± 4.77 vs 126.80 ± 5.40 , $t = 7.17$, $P = 0.002 < 0.01$; 104.40 ± 4.77 vs 82.80 ± 4.15 , $t = 7.96$, $P = 0.001 < 0.01$). The deviation between the HGF and PD98059 was significant ($P < 0.01$). Compared with controls, MMP-2 and MMP-9 mRNA expressions were up-regulated by HGF (0.997 ± 0.011 vs 1.207 ± 0.003 , $t = 35.002$, $P = 0.001 < 0.01$; 0.387 ± 0.128 vs 0.971 ± 0.147 , $t = 106.036$, $P = 0.0000 < 0.01$, respectively); compared with controls, TIMP-1, TIMP-2 mRNA expressions were increased by PD98059 (1.344 ± 0.007 vs 1.905 ± 0.049 , $t = 17.541$, $P = 0.003 < 0.01$; 1.286 ± 0.020 vs 1.887 ± 0.022 , $t = 24.623$, $P = 0.002 < 0.01$, respectively).

CONCLUSION: HGF promoted Caco-2 migration mainly by p42/p44MAPK pathway; HGF/SF stimulated the expression of MMP-2, MMP-9 in Caco-2 and enabled tumoral cells to damage the ECM and reach the distant organ and develop metastasis; HGF played the function of promoted-invasion and promoted-metastasis, in which cellular selection was possible.

INTRODUCTION

Hepatocyte growth factor/scatter factor is a polypeptide growth factor, which enhances strong cellular disintegration, tissue formation, inducing the migration, invasion and angiogenesis of epithelial cells^[1]. The protein production of the c-met proto-oncogene encodes trans-membrane tyrosine kinase and is the receptor for hepatocyte growth factor, which regulates proliferation, differentiation, morphogenesis and motility in various cells after being activated by HGF. Thus, it relates with the genesis and progress in many types of human tumors. The mechanism for HGF-c-met in the invasion and metastasis of malignant tumor includes that they can promote cellular migration and increase the abilities of invasion, they also can trigger Ca^{++} -dependent signaling system, so activate the Ras, then activate extracellular-signal regulated kinase (Erk), thereby regulate the contraction and motion of cells and phosphorylate microfilament relating-protein, regulate cellular skeleton and reinforce the ability of cellular movement. HGF can coordinate other factors *in vivo* and therefore enlighten the abilities of migration and invasion in some malignant cells^[2]. Yi found that HGF could increase the invasion of 13 lung cancer cells in which the receptor of c-met was expressed^[3]. The motility of tumoral cells correlated closely with the metastasis in tumor.

Tumoral invasion occurs in three main steps: adhesion, degradation of basement membrane and movement, in which the degradation of basement membrane passes mainly through proteolytic kinases. Matrix metalloproteinases (MMPs) are part of these kinases, in which MMP-2 and MMP-9 correlated with the tumoral metastasis. The report showed that HGF could regulate the expression of MMPs.

Mitogen-activated protein kinases (MAPK) are the kinases between the receptors of cell membrane and the significant intracellular regulating-targets. Cells apply this system conducting extracellular stimulating-signal to the nucleus of cell so that the biological effects from the cells can be transmitted. The pathway of intracellular signal conduction for HGF-c-met induced-biological effects is not clear.

Cellular migration is the premise of tumoral metastasis. The characters of tumoral infiltration and metastasis are the key factors affecting the survival and prognosis in patients. To

confirm the conclusion that HGF can promote migration *in vitro*, regulate the expression of MMPs and exist the MAPK pathway during these processes, we applied the HGF together with the inhibitors of p42/p44MAPK(PD98059) and p38MAPK(SB203580) dealt with the colorectal cancer cells: in Caco-2 and Colo320, we also observed mRNA expression of MMP-2, MMP-9 and tissue inhibitor of metalloproteinase-1 (TIMP-1) and tissue inhibitor of metalloproteinase-2(TIMP-2) in order to investigate the function of HGF in the invasion of colorectal cancer cells *in vitro*.

MATERIALS AND METHODS

Materials

Cells and cell culture The human colorectal cancer cell lines Caco-2 and Colo320 were purchased from China Academy of Science in Shanghai Institute of Life Science, Caco-2 were cultured in DMEM supplemented with 10% fetal bovine serum, 100 U/mL penicillin and 100 µg/mL streptomycin at 37 °C in a 50 mL/L CO₂ atmosphere. Medium were exchanged every other day, when the cells reached confluence, we digested them with 0.02% EDTA+trypsin and delivered them according to 1:2 or 1:4. Colo320 were cultured in DMEM supplemented with 20% fetal bovine serum, others were identical with Caco-2.

Reagent and apparatus DMEM were purchased from GibcoBRL; FBS from TBD; HGF from JingMei Biol in ShenZhen and were compounded with free serum medium, the concentration was 20 ng/mL. PD98059 and SB203580 were from Promega, they were compounded with DMSO and made up to 10 and 20 mmol/L for storage and the applicable concentration was 40 µmol/L combined with free serum, stored at 4 °C. Matrigel from Gene Company in ShenYang was compounded with DMEM according to 1:3, 0 °C fusion; 8 µmol/L polycarbonate size membrane and TRIzol were from HuaMei Company, Boyden chamber were from the Department of Oncology in China Medical University. RT-PCR kit was from Takara, the primers of MMP-2, MMP-9, TIMP-1, TIMP-2, β-actin were synthesized by BoYa Bio Company in Shanghai. Amplified sections were 307, 215, 285, 265, and 690 bp respectively. Autoradiography were purchased from Olympus and PCR amplification instrument were from PE Company in the USA.

Methods

Matrigel migration assay This assay is similar to that described previously^[5], Boyden chambers system whose upper and lower compartments were used to analyze the invasive ability of Caco-2 and Colo320. The chambers were washed, dried and irradiated under ultraviolet rays for 30 min, the experiments were divided into four groups DMEM, HGF, PD98059, and SB203580.

DMEM, 20 ng/mL HGF, 10% FBS (Caco-2) or 20% FBS (Colo320), 200 µL in the lower compartment with 50 µg Matrigel onto a polycarbonate membrane, and then 1 mL (about 3 ± 10^5 cell/mL) colorectal cancer cells were put in the upper compartment of the chamber, and the chambers were incubated at 37 °C in humidified air containing 50 mL/L CO₂ for 48 h, at the end of incubation, the cells on the upper side of polycarbonate membrane were wiped off with a cotton swab and the remaining cells that traversed

the Matrigel and spread on the lower surface of the membrane were rinsed using distilled water twice, the membrane were fixed for 30 min with 5 mL methanol, dried and stained with hematoxylin for 10 min, rinsed with 1% HCl+10% alcohol and distilled water for 1-5 min, rinsed with 1% ammonia water and distilled water for 1-5 min, stained with eosin 1-10 min, at last rinsed and fixed with gradient alcohol and xylene, enclosed and counted five fields of vision using light microscope. Results were expressed as the number of colorectal cancer cells invaded per filter. Experiments were done in triplicate and results are shown as mean±SD.

Effect of PD98059 on HGF-induced migration 40 µmol/L PD98059 were added to the upper compartment with 1 mL cells for 30 min before 20 ng/mL HGF was added to the lower side of chamber which was incubated at 37 °C in a 50 mL/L CO₂ atmosphere for 48 h. After incubation, similar treatment as the above-mentioned, was carried out.

Effect of SB203580 on HGF-induced migration: 40 µmol/L SB203580 were added to the upper compartment with 1 mL cells for 30 min before 20 ng/mL HGF was added to the lower side of chamber which was incubated at 37 °C in a 50 mL/L CO₂ atmosphere for 48 h. After incubation, the treatment was identical with the above-mentioned.

Detection of MMP-2, MMP-9, TIMP-1, TIMP-2 mRNA by RT-PCR

Total RNA was extracted from subconfluent cell layers according to Single-step method of RNA isolation by acid guanidinium thiocyanate-phenol-chloroform extraction, 2 µL RNA was reverse-transcribed using AMV, 3 µL of the reaction were used for amplification. The primers used are as follows:

MMP-2-F: 5'-TCAACGGTTCGGAATACA-3'

MMP-2-R: 5'-CCCACAGTGGACATAGCG-3'

MMP-9-F: 5'-TCGAACCTTGACAGCGACAAGAA-3'

MMP-9-R: 5'-TCAGGGCGAGGACCATAGAGG-3'

TIMP-1-F: 5'-CTTCCACAGGTCCCACAACC-3'

TIMP-1-R: 5'-CAGCCCTGGCTCCCGAGGC-3'

TIMP-2-F: 5'-AAACGACATTTATGGCAACCCT-ATC-3'

TIMP-2-R: 5'-ACAGGAGCCGTCACCTTCTCTTG-ATG-3'

β-actin-R: 5'-GATTGCCTCAGGACATTTCTG-3'

β-actin-F: 5'-GATTGCTCAGGACATTTCTG-3'

PCR reaction conditions were as follows: Thirty-five cycles of MMP-2 PCR were performed, each consisting of denaturation for 3 min and 45 s at 94 °C, annealing for 1 min at 55 °C and elongation for 1 and 7 min at 72 °C. Thirty-five cycles of MMP-9 PCR were performed, each consisting of denaturation for 3 min and 45 s at 94 °C, annealing for 1 min at 60.5 °C and elongation for 1 and 7 min at 72 °C. Thirty cycles of TIMP-1 PCR were performed, each consisting of denaturation for 3 min and 30 s at 94 °C, annealing for 1 min at 63 °C and elongation for 30 s and 7 min at 72 °C. Thirty cycles of TIMP-2 PCR were performed, each consisting of denaturation for 3 min and 45 s at 94 °C, annealing for 1 min at 65 °C and elongation for 30 s and 7 min at 72 °C. Agarose gel electrophoresis consisting of 20 g/L ethidium bromide (EB) was used to analyze the production of PCR. Electrophoresis zones were reserved for 1 D kodak autoradiography system, β-actin was for controls; measure values were counted/β-actin.

Statistical analysis

SPSS12.0 software was used, all values were expressed as mean \pm SD, *t*-test was used to determine the significance of differences in multiple comparisons. Values of $P<0.05$ were considered to be statistically significant.

RESULTS

Migration of Caco-2

After 48 h incubation, there were notable differences when we compared the migrational numbers of Caco-2 cells in the group of HGF and PD98059 with the control ($P<0.01$). The deviation between the HGF and PD98059 was significant ($P<0.01$). The group of SB203580 had no implication. We did not find the phenomenon in the Colo320 cells. HGF increased the number of invading Matrigel cells, the more numbers, the more the invading ability. We found that PD98059 inhibited the migration of HGF-induced Caco-2. (Figure 1 and Table 1).

Table 1 Migrational numbers of Caco-2 in different factors

The migrational numbers of Caco-2 (mean \pm SD)	
Control	104.40 \pm 4.77
HGF/SF	126.80 \pm 5.40 ^b
PD98059	82.80 \pm 4.15 ^d
SB203580	108.4 \pm 14.38

^b $P<0.01$, $t=7.17$; ^d $P<0.01$, $t=7.96$.

Expression of MMP-2, MMP-9, TIMP-1, TIMP-2 mRNA in Caco-2 cell conditions were identified with Matrigel migration assay. Examination of MMP-2, MMP-9, TIMP-1, TIMP-2 expression were by RT-PCR. DMEM was control, MMP-9 expressed all groups except control, MMP-2 was high expression in HGF group, TIMP-1 and TIMP-2 were high expression in the group of PD98059. HGF could stimulate the expression of MMP-2 and MMP-9, but the function was inhibited in the presence of PD98059 ($P<0.01$). There were different expressions of MMP-2, MMP-9 and TIMP-1, TIMP-2 in the group of PD98059, with no significance. Expression of MMP-2, MMP-9 and TIMP-1, TIMP-2 in the group of HGF were not divergent. (Figure 2 and Table 2).

Table 2 Expression of MMPs and its inhibitors in Caco-2 (mean \pm SD)

	MMP-2	MMP-9	TIMP-1	TIMP-2
Control	0.997 \pm 0.011	0.387 \pm 0.128	1.344 \pm 0.007	1.286 \pm 0.020
HGF	1.207 \pm 0.003	0.971 \pm 0.147	0.846 \pm 0.075	0.992 \pm 0.009
PD98059	0.824 \pm 0.037	0.350 \pm 0.007	1.905 \pm 0.049	1.887 \pm 0.022

DISCUSSION

In vitro, HGF/SF has the function of strongly promoting mitogen and stimulating the growth of normal and malignant cells^[6]. HGF/SF could agitate directly cellular mobility and spreadable effects and colon formation gets diffused by it.

Figure 1 Migration of Caco-2 in different factors: control (A), Effect of HGF (B),

PD98059 (C), and SB203580 (D).

Figure 2 Expression of MMPs and TIMPs in Caco-2 cell: MMP-2 amplification section (A), MMP-9 amplification section (B), TIMP-1 amplification section (C),

TIMP-2 amplification section (D).

The activity of HGF-promoted motogen and morphogen could promote adhesion, migration and infiltration of the cancer cells^[7], as it enhanced Integrins-modulated adhesion so that lymphocyte invasion increased six-fold^[8]. About the mechanism of HGF-promoted tumoral metastasis, Fujisaki^[9] reported that the stimulation of CD44 could induce the expression of c-met; HGF/SF amplified CD44-induced adhesion of LFA-1 (lymphocyte function associated antigen-1), further amplified and agitated the Integrin-modulated adhesion, enabled the cancer cells to adhere blood vessel endothelium and pass through the vessel walls. The experiments of cotransfection for c-met and CD44 found that CD44, acted as the co-receptor of HGF, promoted the c-met tyrosine kinases phosphorylation and downstream signaling conduction protein kinases activation (activated MAPK), induced tumoral growth and metastasis^[10].

Recently, the research of extracellular-signal transduction has made great progress in the interior and exterior parts of the country. Extracellular stimulation entered from the cellular surface and activated the signaling transduction pathway in the cytoplasm, transduced the signaling to the nucleus through many pathways and promoted or inhibited special expression of the target-gene^[11], including the pathway of Ras-MAPK which played a main role in promoting cellular proliferation and regulating genetic transcription. The character of the cytokine receptor decided the manner of signaling transduction, many cytokines transmitted to the nucleus through mainly MAPK-cascades, induced the same genetic expression procedures, produced the same biological effects so that MAPK-cascades originated together or from the last pathway in which many membrane receptors transduced growth signaling to pass through the membrane^[12]. MAPK was the important intercellular signaling system, cells applied it to transmit stimulating extracellular signal to the nucleus and modulated biological effects produced by cells^[13]. It had decided four MAPK pathways in eukaryotic cell, including ERK, JNK, p38MAPK, and ERK5^[14]. MAPK was a kind of serine/threonine protein kinase, activated by phosphorylation^[15]. An extracellular stimulator could activate synchronously several members of MAPK families, Xia^[16] found if they removed neurogenic growth factor from incubation systems, and then induced the apoptosis of PC12, there existed activation of p38MAPK, JNK and inhibition of ERK, the deduced apoptosis and survival were decided by the balance between ERK-activated by growth factor and p38MAPK, and JNK-activated by stress.

In our study, we found that PD98059, the inhibitor of p42/p44MAPK, could restrain the numbers of HGF-induced colorectal cancer cells passed Matrigel, as such, we confirmed that p42/p44MAPK was one of the pathways of HGF-promoted Caco-2 invasion.

The main components of extracellular matrix (ECM) including collagen, glucoprotein, proteoglycan and glycosamine existed as the form of basement membrane and intercellular tissues. There was a kind of anti-adhesion protein in extracellular matrix called basement membrane protein, the sections of these molecules degradation had chemotaxis so that promoted the mobility of the cancer cells^[13]. A lot of barriers were during the metastatic processes, it was of significance for the basement membrane beside tumoral cells and interstitial matrix to maintain tissue morphogenesis and biological specificity. Tumor cells might produce proteolytic ferment through autosecretion or stimulate host to cross basement membrane so that metastasis occurred. Therefore, the degradation of tumor to ECM was the prerequisite for tumoral invasion and metastasis^[14]. Matrix metalloproteinases (MMPs) were this kind of peptidase which Zn^{2+} -dependently degraded ECM, at present, 20 members of MMPs families were determined. According to the different substrates, MMPs were divided as follows: interstitial collagenase, gelatinase, stromelysin, membrane-type MMPs^[17]. In the 1980s, it was first reported that MMPs related with the potency of cancer metastasis^[18]. The mechanism of tumor cells degraded ECM including the activation of MAPK, cells applied the pathway to promote the secretion of MT-MMPs and the rearrangement of microfilament skeleton formed by myoprotein and increased the ability of decomposing collage of ECM and migration, then, induced tumoral infiltration and metastasis. MMPs were the major kinases during the physiological and pathological processes in the rebuilding or degradation of ECM, they were the key to removing the barrier of cellular migration. Increasing activities of MMPs was one of the essential conditions in tumor invasion and metastasis, MMPs could affect cellular adhesion and migration directly. But the total degradation of ECM was controlled strictly by the balance between activated MMPs and TIMPs (inhibitors of MMPs)^[19]. Our results showed that HGF/SF up-regulated the expression of MMP-2, MMP-9 and TIMPs in Caco-2 compared with the control groups, we confirmed *in vitro* that HGF increased the numbers of migrational Caco-2, the results suggested that increasing activities of MMPs in the presence of HGF enabled tumoral cells to damage the

ECM and easily developed metastasis.

In conclusion, HGF promoted Caco-2 migration mainly by p42/p44MAPK pathway; HGF/SF up-regulated the expression of MMP-2, MMP-9 in Caco-2 and enabled tumoral cells to damage the ECM; HGF played the function of promoted-invasion and promoted-metastasis in cellular selection; HGF could play the biological effects by MAPK, therefore, it had a major significance for we studied the regulation about MAPK in tumoral metastasis to understand the relationship between the MAPK pathway and colorectal cancer, furthermore, it would provide the evidence for MAPK to become the target of tumoral treatment.

Abstract

AIM: To examine the correlation between the porto-systemic hypertension evaluated by portal shunt index (PSI) and life-threatening complications, including hepatocellular carcinoma (HCC), liver failure (Child-Pugh stage progression), and esophagogastric varices.

METHODS: Two hundred and twelve consecutive subjects with HCV-related cirrhosis (LC-C) underwent per-rectal portal scintigraphy. They were allocated into three groups according to their PSI: group I, $PSI \leq 10\%$; group II, $10\% < PSI < 30\%$; and group III, $30\% \leq PSI$. Of these, selected 122 Child-Pugh stage A (Child A) subjects were included in analysis (a mean follow-up period of 5.9 ± 5.4 years, range 6 mo-21 years).

RESULTS: No significant correlation between PSI and cumulative probability of HCC incidence was observed. Cumulative probability of Child A to B progression was tended to be higher in group III than in group I, and significantly higher in group III than in group II (62% vs 34%, 62% vs 37%; $P = 0.060$, < 0.01 ; respectively). Cumulative probability of varices tended to be higher in group III than in group I (31% vs 12%, $P = 0.090$). On multivariate analyses, significant correlation between PSI and Child A to B progression was observed, and no significant correlation between PSI and HCC incidence or varices progression was observed.

CONCLUSION: Patients with LC-C of Child A will progress to Child B rapidly after their PSI reaches 30% or higher. PSI can be used to predict occult progressive porto-systemic

INTRODUCTION

Hepatitis C virus (HCV) is the most common cause of chronic liver disease in several countries, including Japan, and chronic hepatitis due to HCV (CH-C), which exhibits a variable natural course, is becoming a subject of worldwide interest. CH-C progresses to cirrhosis of the liver (LC), and may be complicated by hepatocellular carcinoma (HCC), hepatic decompensation, and esophagogastric varices^[1,2], although its clinical course has not been fully defined. Despite treatment such as injection of interferon plus oral ribavirin^[3], many patients with CH-C progress to cirrhosis^[4], and develop portal hypertension as CH-C advances to the early phase of LC^[5].

Portal hypertension evaluated by “invasive” hepatic venous pressure gradient (HVP) is associated with progression of liver failure and death^[6-8]. Using the method described in this study, the extent of porto-systemic shunting (PSS) can be evaluated with the portal shunt index (PSI) using relatively “non-invasive” per-rectal portal scintigraphy with ^{99m}Tc pertechnetate, because PSI correlates strongly with portal pressure^[9,10]. This study monitored three life-threatening complications of LC, including the incidence of HCC, Child-Pugh stage progression, and progression of esophagogastric varices, and examined the correlation between PSI and these three complications.

MATERIALS AND METHODS

Patients

A retrospective cohort study was performed on 212 subjects with HCV-related cirrhosis (LC-C), who were admitted to

our hospital during the 24 years between March 1979 and June 2002, and who were evaluated with PSI obtained by per-rectal portal scintigraphy with ^{99m}Tc pertechnetate. These subjects were diagnosed by examination of liver specimens obtained by laparoscopy, or needle biopsy performed under ultrasonic guidance. Exclusion criteria for this study were as follows: other causes of cirrhosis such as HBV, autoimmune disease, any alcohol consumption; past treatment with interferon, endoscopic sclerotherapy or open surgery for varices; and trans-arterial embolization or open surgery for HCC. Within a week of hospitalization, all subjects underwent abdominal ultrasonography for detection of ascites, Child-Pugh staging as an index of liver failure and endoscopy for detection of esophagogastric varices^[11]. Three Child-Pugh stages were considered: stage A (score 5-6), stage B (7-9), and stage C (10-15). The 212 subjects with cirrhosis were distributed as follows: Child-Pugh stage A (Child A), 122; Child B, 73; and Child C, 17. At entry, we used other possible predictors of LC prognosis, including sex, age, serum albumin, total bilirubin (T-bil), prothrombin time (PT), and platelets^[12].

Longitudinal study

We selected 122 Child A subjects for a longitudinal study; these subjects gave their informed consent to participate, and agreed to return after discharge to our outpatient clinic for monitoring. The procedures were approved by the Ethics Committee of Graduate School of Medicine, Osaka City University. A total of 122 subjects were monitored for a mean period of 5.9 ± 5.4 years (range 6 mo to 21 years). Monitoring was maintained for each evaluation until confirmation of HCC, or Child A to B progression, or varices progression, or the end of the outcome observation period (June 2002). Subjects were excluded from the study if they were followed by another hospital, or their monitoring periods were less than 6 mo.

After excluding dropouts, we were able to monitor the following subjects for at least 6 mo: for HCC incidence, 108 subjects; for Child A to B progression, 107; and for varices progression, 109. A PSI value of 10% or higher is considered to be abnormal^[9], and a PSI of 30% or higher has an especially poor prognosis for chronic liver diseases^[5]. We defined three groups according to their PSI: group I, $\text{PSI} \leq 10\%$; group II, $10\% < \text{PSI} < 30\%$; and group III, $30\% \leq \text{PSI}$. The subjects were further divided as follows: for

HCC incidence, 108 subjects-group I, 33; group II, 41; and group III, 34; for Child A to B progression, 107 subjects-group I, 32; group II, 41; and group III, 34; for varices progression, 109 subjects-group I, 33; group II, 41; and group III, 35. These subjects underwent the following examinations: laboratory studies and physical assessment of the extent of hepatic encephalopathy for Child's staging, with a mean interval of 4.1 ± 0.8 mo; abdominal ultrasonography or dynamic CT for assessment of the extent of ascites or the existence of HCC, with a mean interval of 2.1 ± 0.6 mo; and endoscopy for varices, with a mean interval of 8.1 ± 2.1 mo. HCC was confirmed by histology obtained by needle biopsy performed under ultrasonic guidance, or confirmed by selective angiography. The extent of hepatic encephalopathy was defined from detection of tremor and/or disorientation by physicians. The extent of ascites was confirmed by abdominal ultrasonography and/or physical assessment. We defined progression (or incidence) of each complication as the first confirmation of HCC, or Child B or a new variceal factor^[13]. Figure 1 shows flow of participants through monitoring.

Measurement of the portal shunt index

The subjects fasted after the evening meal on the day before examination. In the morning, the rectum was emptied by administration of a laxative. First, 370 MBq of ^{99m}Tc pertechnetate (2 mL solution) was given per rectum through a polyethylene tube (Nélaton's catheter, French 16) into the upper rectum, followed by 15 mL of air. Time-activity curves for the heart and liver areas were obtained every 4 s using a large-field scintillation camera (Vertex-Plus, ADAC Laboratories, Silicon Valley, USA). It was equipped with a low-energy, multipurpose, parallel-hole collimator and was interfaced with a digital computer. The camera was positioned over the patient's abdomen so that the field of view included the heart, liver, and spleen. At the end of the 5-min examination, a 5-min summed color image was recorded. To measure the extent of PSS by PSI, we calculated the number of counts for the heart as a percentage of the counts for the heart and liver integrated for 24 s immediately after the appearance of the liver time-activity curve^[9].

Statistical analysis

Results were analyzed by SAS 8.12 statistical software (SAS

Figure 1 Flow of monitoring, group I, $\text{PSI} \leq 10\%$; group II, $10\% < \text{PSI} < 30\%$; group III, $30\% \leq \text{PSI}$. LC-C, HCV-related cirrhosis; Child A, Child-Pugh stage

A; PSI, portal shunt index.

Institute Inc., Cary, NC)^[14,15]. Data were expressed as mean±SD. Comparisons between PSI groups were made by the Kruskal-Wallis test, the Mantel-Haenszel test, or ANOVA. The cumulative progression rates were calculated and plotted by the Kaplan-Meier method, and were compared by the log-rank test. Any significant variable was considered suitable for the multivariate analysis using Cox's regression model. $P<0.05$ was taken as statistically significant.

RESULTS

Patient characteristics at entry

Table 1 presents patient data at entry classified by PSI. The differences between the PSI groups were significant for the following parameters: age, albumin, T-bil, platelets ($P<0.01$, <0.01 , <0.05 , and <0.01 , respectively).

Cumulative progression

No significant correlation between PSI and cumulative probability of HCC incidence was observed (Figure 2A). Cumulative probability of Child A to B progression was tended to be higher in group III than in group I, and significantly higher in group III than in group II (62% *vs* 34%, 62% *vs* 37%; $P = 0.060$, <0.01 ; respectively) (Figure 2B). Cumulative probability of esophagogastric varices tended to be higher in group III than in group I (31% *vs* 12%, $P = 0.090$) (Figure 2C).

Morbidity

Table 2 presents the proportions of Child A to B progression and relative risks as uni- and multivariates of possible

predictors, which were classified at the entry of the study. The total proportion of each predictor, except PSI, was divided into two between better (upper line) and worse (lower line) at a cut-off value according to Child staging, or reports by other authors: for instance, albumin, at 3.5 g/dL^[11,12,16].

Group III had the highest rate of Child A to B progression (21 of 34, 61.8%), followed by <3.5 albumin (50.0%), and <100 PT (48.8%) (Table 2). A significant relationship was found between group (I+II) and group III (crude RR = 2.44, 95%CI = 1.33-4.48, $P<0.01$), and between group II and group III (2.95, 1.40-6.24, $P<0.01$), with a trend of significance ($P<0.05$). No significant increase of other predictors was revealed. PSI and the common useful predictors such as albumin and platelets were included in multivariate analysis; only group III remained significant (adjusted RR = 2.98, 95%CI = 1.29-6.87, $P<0.05$).

The group with <10 platelets had the highest incidence of HCC and the highest progression of varices (30.3%, 47.1%, respectively). On multivariate analyses, no significant associations were found between PSI and incidence of HCC or progression of esophagogastric varices.

DISCUSSION

Even if physical symptoms and serum biochemical tests indicate the early phase of LC-C, the patient may already have occult advanced hepatic damage. PSI is a possible predictor of occult progressive stages of LC-C for outcome patients. While PSI obtained by per-rectal portal scintigraphy has its own weaknesses (it emphasizes PSS via the inferior mesenteric vein, rather than via the superior mesenteric vein, and

expresses the extent of PSS indirectly), it should be useful for the observation of LC-C because it is a simple and non-invasive technique unlike hepatic venous catheterization^[9].

In this study, we used ^{99m}Tc pertechnetate for per-rectal portal scintigraphy because of its short half-life and low cost^[17]. Our study had three major findings.

First, there was no correlation between the porto-systemic hypertension and HCC incidence. This finding suggests that HCC occurs independently of the decrease in hepatic blood flow due to the development of PSS.

Second, patients with LC-C of Child A will progress to Child B rapidly after their PSI reaches 30% or higher. Shiomi *et al.*^[5] have reported that changes in the portal hemodynamics of chronic liver disease subjects were not gradual. The development of PSS causes hepatic functional reserve to deteriorate rapidly. We propose that per-rectal portal scintigraphy is useful to predict occult progressive portal hypertension and liver failure in the early phase of LC-C, on the basis of the strong relationship between PSI and the Child-Pugh staging.

Third, the natural advance of PSS has relevance to esophagogastric varices progression in patients with the early phase of LC-C. Other authors have reported that the porto-systemic pressure gradient is a strong predictor for varices progression^[18,19]. But in this study, PSI showed no statistical advantage over platelets, albumin, or T-bil for detecting the progression of varices. The reason why PSI was worse than these laboratory data is because esophagogastric varices mainly reflect the flow of superior mesenteric vein.

Progressive viral hepatitis has been acknowledged as a major indication for liver transplantation^[20,21]. Kiuchi *et al.*^[22] have emphasized the need to evaluate the recipients preoperatively. One of the important recipient factors is the presence of collateral circulation^[23]. Bruix *et al.*^[24] have reported that LC patients with increased portal pressure are at high risk of hepatic decompensation after resection of HCC. We propose that preoperative per-rectal portal

scintigraphy would be useful for early detection of occult portal hypertension, to assess graft size requirement to prevent graft failure after liver transplantation, or to avoid liver failure after hepatectomy.

In summary, physicians can monitor the porto-systemic hypertension gradient in LC patient during the outcome observation period by using "non-invasive" per-rectal portal scintigraphy; on the other hand, measurement of HVPG needs hospitalization. In the early phase of LC-C, PSI can be used to predict occult progressive PSS and liver failure. Therefore, even for patients diagnosed as being in the early phase of LC-C on the basis of other indicators, those with an initial PSI ≥30% should be observed by keeping early liver transplantation, or liver failure after hepatectomy in mind; HCC should be watched for, regardless of PSI.

Abstract

AIM: We have previously demonstrated that hepatitis C virus (HCV) core protein is efficiently released into the culture medium in insect cells. The objective of this study is to characterize the HCV core secretion in insect cells.

METHODS: We constructed recombinant baculoviruses expressing various-length of mutant core proteins, expressed these proteins in insect cells, and examined core protein secretion in insect cells.

RESULTS: Only wild type core was efficiently released into the culture medium, although the protein expression level of wild type core was lower than those of other mutant core proteins. We found that the shorter form of the core construct expressed the higher level of protein. However, if more than 18 amino acids of the core were truncated at the C-terminus, core proteins were no longer secreted into the culture medium. Membrane flotation data show that the secreted core proteins are associated with the cellular membrane protein, indicating that HCV core is secreted as a membrane complex.

CONCLUSION: The C-terminal 18 amino acids of HCV core were crucial for core secretion into the culture media. Since HCV replication occurs on lipid raft membrane structure, these results suggest that HCV may utilize a unique core release mechanism to escape immune surveillance, thereby potentially representing the feature of HCV morphogenesis.

INTRODUCTION

Hepatitis C virus (HCV) is the major etiologic agent of transfusion-associated hepatitis^[1-3] and is associated with a chronic infection that leads to liver cirrhosis and hepatocellular carcinoma^[4,5]. HCV is an enveloped virus and its virion size has been estimated at a diameter of 30-60 nm^[6]. The virion contains a single-stranded, positive-sense RNA genome of approximately 9 600 nucleotides^[7-10]. HCV belongs to the *Flaviviridae* family^[11,12] and its genomic sequence is related to the flaviviruses and the pestiviruses^[9,13]. The viral genome encodes a polyprotein precursor of 3 010-3 030 amino acids from one long open reading frame and is further processed into multiple viral proteins^[14-16]. The structural proteins are processed by a host signal peptidase into a core protein, envelope proteins E1 and E2, and p7^[13,16,17]. The viral nonstructural proteins are cleaved by viral proteinase into serine protease, helicase, RNA polymerase, and functionally undefined proteins. Biochemical properties of many structural and nonstructural proteins have been extensively characterized. However, studies on virion morphogenesis and viral replication have been hampered by the inability to propagate the viruses in a cell culture system.

The mechanism of HCV virion assembly is not yet known because the expression of the HCV structural gene in mammalian cells generates no detectable virion particles. However, it has been reported that either virus-like particles (VLPs) were produced in insect cells infected with recombinant baculoviruses expressing HCV structural proteins^[18] or nucleocapsid-like particles were self-assembled from recombinant proteins purified in *E. coli*^[19]. Furthermore, previous study showed that HCV core proteins were secreted in insect cells^[20] and in mammalian cell culture^[21]. In the present study, we have further characterized the HCV core secretion using recombinant baculovirus expression system in insect cells. We found that C-terminal 18 amino acids of the core were necessary for the secretion of core protein into the culture media. Furthermore, HCV core is efficiently released into the culture medium as a membrane-associated protein, which may represent a unique mechanism of HCV core assembly.

MATERIALS AND METHODS

Construction of recombinant baculovirus shuttle vector

HCV cDNA sequence corresponding to the core protein of the Korean isolate (genotype 1b)^[22] was subcloned into the baculovirus shuttle vector, pVL941, as described previously^[23]. Briefly, cDNAs corresponding to the both wild type and mutant forms of HCV core protein were amplified by polymerase chain reaction (PCR) using *Taq*

DNA polymerase (Boehringer Mannheim). Each primer contains a *Bam*HI or a *Bgl*II site and a protein initiation codon (ATG) at the front, and a stop codon (TGA) plus a *Bam*HI or a *Bgl*II endonuclease site at the end. The amplified PCR product was gel-purified and digested with either *Bam*HI or *Bgl*II and inserted into the *Bam*HI site of the pVL941 vector behind polyhedrin promoter.

Production of recombinant baculoviruses

Spodoptera frugiperda (Sf9) insect cells were co-transfected with wild type baculovirus (*Autographa californica* nuclear polyhedrosis virus, AcNPV) DNA and each recombinant transfer vector DNA as described previously^[23]. The supernatant was harvested at 4 d after transfection and used for plaque assays. Each virus isolated from a plaque was used to infect Sf9 cells to obtain high titer of recombinant viruses. Protein expression was examined either by SDS-PAGE and Coomassie blue staining or by Western blot analysis.

Purification of secreted core protein

Sf9 cells were infected with recombinant baculoviruses at a multiplicity of infection (m.o.i.) of 3 and incubated at 27 °C. The culture supernatant was collected at 3 d after infection and cell debris were removed by centrifugation at 3 500 r/min for 15 min. Supernatant was further subjected to centrifugation at 12 000 g for 30 min to eliminate the baculoviruses. The supernatant was pelleted through 300 g/L sucrose cushion for 90 min at 27 000 g using a SW 28 rotor. For velocity centrifugation, the pellet was resuspended in PBS and layered onto 200–600 g/L sucrose gradient and centrifuged at 38 000 g for 12 h at 4 °C using a SW 41 rotor. Twelve fractions were collected from the top, diluted in PBS, and subjected to centrifugation at 48 000 g for 90 min using a SW 55 Ti rotor. The peak fractions were pooled and pelleted as described above. The pellet was dissolved in sample buffer and analyzed by Western blot using HCV patient sera.

Western blot analysis

Recombinant baculovirus-infected Sf9 cells were harvested at 3 d after infection and washed twice in PBS. Either cell lysates or secreted proteins were separated by electrophoresis in 10–15% polyacrylamide gel containing 0.5% SDS and transferred to a nitrocellulose membrane for 1 h. The membrane was incubated with either HCV patient serum or rabbit anti-HCV core antibody and proteins were visualized as previously described^[23].

Membrane flotation analysis

Sf9 insect cells were infected with recombinant baculoviruses expressing full-length of HCV core protein. At 60 h after infection, the culture supernatant was collected and cell debris was removed by centrifugation at 3 500 r/min for 20 min. Culture supernatant was further subjected to centrifugation at 12 000 g for 30 min to eliminate the baculoviruses. The supernatant was pelleted through 300 g/L sucrose cushion for 90 min at 27 000 g using a SW 28 rotor. The secreted HCV core proteins were subjected to equilibrium density centrifugation and 1 mL of each fraction was analyzed by immunoblotting using rabbit anti-HCV core antibody as previously described^[23].

RESULTS

Expression of HCV core protein in insect cells

In order to understand the mechanism of HCV core secretion in culture media, we generated recombinant baculoviruses encoding full-length of HCV core protein and used them to infect insect cells with low m.o.i. (10^3). Cell lysates were prepared at 3 d after infection and analyzed for protein expression by immunoblotting with HCV patient sera. As shown in Figure 1A, recombinant baculovirus-infected cells expressed the corresponding HCV core protein (lane 3). Both wild type baculovirus (AcNPV)-infected and recombinant baculovirus expressing small hepatitis delta antigen (SHDAg)-infected cells^[24] were compared as controls. To examine whether HCV core proteins are released into the culture medium, Sf9 cells were infected with either wild type or recombinant baculoviruses and cell culture supernatants were harvested at d 3 postinfection. The supernatants were pelleted through a 300 g/L sucrose cushion and examined for core secretion using HCV patient serum. The result showed that the supernatant collected from the core-expressing cells contained the core protein reacting with HCV patient serum (Figure 1B, lane 3). Although SHDAg protein was highly expressed in insect cells^[24], this protein was not released into the culture medium (data not shown). We further looked for SHDAg release in the culture supernatant harvested from SHDAg-expressing cells at d 4 postinfection. Although cytolysis started to occur at d 4 postinfection in insect cells^[25], we were unable to detect SHDAg in supernatant collected from SHDAg-expressing cells (data not shown).

Figure 1 Core proteins are secreted into the culture medium in insect cells. **A:** Expression of HCV core protein in insect cells. cDNA corresponding to the HCV core was subcloned into the *Bam*HI site of the transfer vector pVL941 behind polyhedrin promoter. Recombinant baculoviruses expressing HCV core protein were produced as described in Materials and methods. Sf9 cells were infected with either wild type (AcNPV) or recombinant baculoviruses expressing SHDAg, or recombinant baculoviruses expressing HCV core protein and were harvested at d 3 postinfection. Cell lysates were separated by SDS-containing polyacrylamide gel electrophoresis, transferred to a nitrocellulose membrane. Proteins were detected by Western blotting using HCV patient sera. Lane 1, Sf9 cells infected with wild type baculoviruses; lane 2, Sf9 cells infected with recombinant baculovirus expressing SHDAg; lane 3, Sf9 cells infected with recombinant baculovirus expressing HCV core; **B:** The culture medium from (A) was centrifuged at 3 500 r/min for 15 min to remove cell debris. Supernatant was further centrifuged at 12 000 g for 30 min to remove baculoviruses. The resultant supernatant was then pelleted through a 300 g/L sucrose cushion for 90 min at 27 000 g. The pellet was dissolved in sample buffer and analyzed by Western blotting using HCV patient sera.

Characterization of secreted core proteins

To characterize the secreted core proteins, culture supernatant harvested from recombinant baculovirus-infected cells was pelleted through the 300 g/L sucrose cushion. The pellet was then further subjected to sucrose velocity gradient centrifugation. As shown in Figure 2, secreted core proteins were located in specific fractions. When the peak fractions were examined by electron microscopy, most of the released core proteins were heterogeneous in size as reported^[19] with amorphous structure (Choi *et al.*^[20], and data not shown). We observed that some of the core proteins were easily aggregated during preparation for electron microscopy. As we previously reported, these secreted proteins have a buoyant density of 1.25 g/mL in CsCl gradient separation^[20].

Figure 2 Isolation of core proteins from cell culture supernatant. Sf9 cells were infected with recombinant baculoviruses expressing HCV core protein. The culture supernatant was collected at d 3 postinfection. Following removal of cell debris and recombinant baculoviruses, the released core proteins were partially purified through a sucrose cushion and were subjected to velocity gradient centrifugation. Twelve fractions were collected and proteins were detected by Western blot analysis using HCV patient sera.

Kinetics of core secretion

The HCV core secretion in recombinant baculovirus-infected cells was examined over a 4-d period following infection. Sf9 cells were infected with recombinant baculovirus expressing full-length HCV core and kinetics of protein expression in cells and core secretion in culture media were examined. Cell lysates and secreted core protein were prepared from d 1 to d 4 after infection as described above. Two species of HCV core proteins, M_r 19 000 and M_r 21 000, were expressed in cells as early as d 1 (Figures 3A and C). Two days after virus infection, intracellular core levels reached plateau and gradually decreased thereafter. In contrast, secreted core proteins were detected 2 d after the infection, efficiently released into the culture medium and reached plateau on the 3rd d, and maintained the similar level for an additional day (Figures 3B and D). Trypan blue staining result indicated that most of the recombinant baculovirus-infected cells were viable for 4 d (data not shown).

C-terminal 18 amino acids of core protein are essential for core secretion

To examine which domain of the HCV core is required for core secretion in insect cells, we constructed a series of C-terminal-deleted mutants (Figure 4A) and generated

Figure 3 Kinetics of core protein secretion in culture medium of the recombinant baculovirus-infected insect cells. Sf9 insect cells were infected with recombinant baculoviruses expressing full-length core protein (A). Cell lysates were prepared from d 1 to d 4 postinfection, and separated by SDS-PAGE on a 15% gel and Western blotted with an HCV patient serum (B); Culture supernatants were harvested from d 1 to d 4 postinfection and secreted core proteins were detected by Western blot analysis. Kinetics of intracellular core protein (C) and extracellular core protein (D) productions were quantified using a densitometric scanner (Molecular Dynamics).

recombinant baculoviruses by co-transfecting insect cells with each mutant DNA and wild type baculovirus DNA. Using low titer (10^3 PFU/mL) of these recombinant baculoviruses, Sf9 insect cells were infected and protein expressions were determined using cell lysates. As shown in Figure 4B, all mutant viruses expressed the expected molecular mass of proteins. This was further confirmed by Western blot analysis (Figure 4C). It is noteworthy that the shorter form of the core construct expressed the higher level of protein. We proceeded to purify the secreted core from each culture supernatant in the same way as described above. Figure 4D showed that full-length core (C191) was efficiently released into the culture medium, although the protein expression level of C191 was lower than those of other mutant core proteins. However, if C-terminal 18 amino acids of the core were deleted, core proteins were no longer secreted into the culture medium, indicating that C-terminal 18 amino acids of HCV core were crucial for core secretion into the culture media. We next examined whether the C-terminal domain of HCV core could be replaced with the comparable domains of other related hepatitis viruses. For this purpose, we replaced C-terminal 18 aa of HCV core with either C-terminal 18 aa of hepatitis B virus surface antigen (HBsAg) or C-terminal 19 aa of large delta antigen of hepatitis delta virus^[24]. Although these chimera proteins were highly expressed in insect cells, none of these proteins were released into the culture medium (data not shown), suggesting that authentic core sequence is necessary for secretion.

Membrane association of the secreted core protein

Recently, we showed that HCV core and NS5A protein are

Figure 4 Effects of mutant core proteins on core secretion. (A) Schematic diagram illustrating the recombinant baculoviruses expressing truncated forms of core protein. Mutant core constructs were generated by PCR and the subsequent recombinant baculoviruses were made as described in Materials and methods. Protein expression of each mutant was confirmed by SDS-PAGE and Coomassie Brilliant Blue staining (B) and Western blot analysis by using HCV patient serum

(C). (D) Determination of extracellular core release among wild type and mutant core proteins. Insect cells were infected with recombinant baculoviruses expressing wild type and various mutant forms of core proteins and harvested at d 3 postinfection. Culture supernatants were partially purified and determined for core secretion by Western blot analysis as described in the legend to Figure 1B.

associated with cellular membrane^[26] and HCV replication occurs on lipid raft membrane structure^[27]. To investigate whether extracellular form of core proteins were secreted as a membrane complex, we separated the released core proteins into membrane and cytosol fractions using the membrane flotation method as previously described^[23]. The presence of the core protein in each fraction was determined by immunoblotting using a rabbit anti-core antibody. As shown in Figure 5, the secreted HCV core protein was found in both membranous and cytosolic fractions. This result indicates that the secreted core proteins are associated with some membranous materials.

Figure 5 Membrane flotation analysis of secreted core proteins. Sf9 insect cells were infected with recombinant baculoviruses expressing full-length HCV core protein. Culture supernatant was collected at 60 h postinfection and secreted core proteins were partially purified as described in Materials and methods. The sample was then subjected to fractionation by equilibrium sucrose gradient centrifugation. Eleven fractions collected from the top were analyzed by Western blotting using rabbit anti-HCV core antibody.

DISCUSSION

It has been previously reported that HCV core without envelope proteins could form a capsid in an acellular assay^[19,28] and secreted core protein has also been detected in mammalian cells^[21]. Recently, we have demonstrated that HCV core protein is efficiently released into the culture medium in insect cells^[20]. To further understand the mechanisms of core assembly and HCV morphogenesis, we studied the HCV core secretion in insect cells using mutant forms of core protein. We constructed recombinant baculoviruses expressing various-length of HCV core proteins and were used to infect Sf9 insect cells. Culture supernatants harvested from recombinant baculovirus-infected cells were examined to see which domain of core protein is required for core secretion. As we previously reported^[20], full-length HCV core protein was efficiently released in cell culture media. However, C-terminal-truncated mutant core proteins were not able to be released into culture media although protein expression levels were higher than that of wild type core protein. This result suggests that C-terminal 18 amino acids are essential for core protein secretion in insect cells. We further showed that secreted core proteins are amorphous in structure and are released into the medium as a membrane complex. This result is consistent with the finding that both core and NS5A are associated with intracellular membranes^[27], which may play a role in the pathogenesis of HCV. Previously, it has been demonstrated that VLPs produced from recombinant baculoviruses expressing a part of the 5' UTR and structural proteins were retained in intracellular membrane vesicles

and were not released into the culture medium^[18]. In fact, transmembrane domains of E1 and E2 function as retention signals in the endoplasmic reticulum (ER) compartment. It has been reported that E1 and E2 of HCV formed a complex and were retained to the ER^[29,30]. Moreover, core protein co-localized with the E2 protein^[31]. This may be the reason why core protein alone, if envelope proteins were not present, was efficiently released into the culture media.

Previously, many capsid proteins of non-enveloped viruses were reported to assemble into VLPs, including B19 parvovirus^[32], Norwalk virus^[33], papillomavirus^[34], rotavirus^[35,36], and rabbit hemorrhagic disease virus^[37]. Similarly, HCV core protein without envelope proteins may be assembled into particle-like structure. HCV is an enveloped virus. How HCV core alone, in the absence of envelope proteins, could be assembled into particles is an intriguing question. Nevertheless, there are similar bodies of evidence that gag protein precursor of HIV-1^[38], HIV-2^[39], or simian immunodeficiency virus^[40] self-assembled into VLPs in recombinant baculovirus-infected insect cells. Budding of rabies virus particles also occurred in the absence of glycoprotein^[41]. Therefore, HCV seems to employ a similar assembly mechanism to those of retroviruses and rhabdoviruses. One study showed that VLPs were not produced from the Huh-7 cells carrying the full-length HCV genome^[42]. To date, it is uncertain how virions are assembled in HCV-infected patients.

It is not clear how HCV core protein itself can be efficiently secreted into insect culture media. In this study, core protein was released out of the cells as early as 2 d after infection. This result suggests that HCV core has the intrinsic capacity to be secreted in culture media. Kunkel *et al.*^[19], reported that N-terminal 124 aa residues of the core (genotype 1a) were sufficient for self-assembly into nucleocapsid-like particles. In contrast, our data suggest that full-length of core should be necessary for core assembly. The discrepancy between the two systems may be due to the different genotypes or different expression systems. However, it is consistent that C-terminal hydrophobic sequence (E1 peptidase signal) inhibits high level of protein expression in both prokaryotic and eukaryotic cell culture systems. In mammalian cells, the C-terminally truncated core 173 is translocated into the nucleus, whereas intact core is destined to the ER^[43,44]. This is why core 173 could not be released into the medium although its intracellular expression level was high. In this study we showed that only the full-length core was efficiently released into the culture medium, although the protein expression level of the full-length core was lower than those of other mutant core proteins. Furthermore, the comparable domains of other hepatitis viruses were unable to replace the function of C-terminal region of HCV core. It is hence conceivable that the C-terminal domain of HCV core, in addition to being a signal sequence for E1 protein, has intrinsic function in secretion. It is also possible that C-terminal domain of HCV core may interact with cellular proteins specifically.

We have compared the viability of cells infected with recombinant baculovirus expressing HCV core and those infected with wild type or recombinant baculoviruses expressing HCV 5A or 5B. All of these cells showed the similar level of viability after virus infection, indicating that HCV core

was not toxic to the insect cells (data not shown). We also used low titer of virus (m.o.i. of 3) to infect cells in order to prevent cells from baculovirus-induced cytolysis^[25]. Since most of the cells were alive at the time of harvest, the release of core protein in culture media is not due to cytolysis. It may represent a unique mechanism of the HCV core secretion. Indeed, it has been shown that HCV core protein was also secreted from mammalian cell lines in culture^[21]. Recently, Maillard *et al.*^[45], reported that nonenveloped HCV nucleocapsids were overproduced in the plasma of HCV patients and released into the bloodstream. They also found that nucleocapsid-like particles but not VLPs were produced in insect cells infected with recombinant baculovirus expressing entire structural proteins. Our study together with these reports strongly suggests that the production of nonenveloped HCV capsids may represent the feature of HCV morphogenesis. HCV may utilize a unique core release mechanism to escape immune surveillance and hence may play a role in HCV pathogenesis.

Abstract

AIM: To investigate the transactivating effect of complete S protein of hepatitis B virus (HBV) and to construct a subtractive cDNA library of genes transactivated by complete S protein of HBV by suppression subtractive hybridization (SSH) technique and to clone genes associated with its transactivation activity, and to pave the way for elucidating the pathogenesis of hepatitis B virus infection.

METHODS: pcDNA3.1(-)-complete S containing full-length HBV S gene was constructed by insertion of HBV complete S gene into *BamH I/Kpn I* sites. HepG2 cells were cotransfected with pcDNA3.1(-)-complete S and pSV-lacZ. After 48 h, cells were collected and detected for the expression of β -galactosidase (β -gal). Suppression subtractive hybridization and bioinformatics techniques were used. The mRNA of HepG2 cells transfected with pcDNA3.1(-)-complete S and pcDNA3.1(-) empty vector was isolated, and detected for the expression of complete S protein by reverse transcription polymerase chain reaction (RT-PCR) method, and cDNA was synthesized. After digestion with restriction enzyme *RsaI*, cDNA fragments were obtained. Tester cDNA was then divided into two groups and ligated to the specific adaptors 1 and 2, respectively. After tester cDNA had been hybridized with driver cDNA twice and underwent nested PCR twice, amplified cDNA fragments were subcloned into pGEM-Teasy vectors to set up the subtractive library. Amplification of the library was carried out within *E. coli* strain DH5 α . The cDNA was sequenced

and analyzed in GenBank with BLAST search after polymerase chain reaction (PCR) amplification.

RESULTS: The complete S mRNA could be detected by RT-PCR in HepG2 cells transfected with the pcDNA3.1(-)-complete S. The activity of β -gal in HepG2 cells transfected with the pcDNA3.1(-)-complete S was 6.9 times higher than that of control plasmid. The subtractive library of genes transactivated by HBV complete S protein was constructed successfully. The amplified library contains 86 positive clones. Colony PCR showed that 86 clones contained DNA inserts of 200-1 000 bp, respectively. Sequence analysis was performed in 35 clones randomly, and the full length sequences were obtained with bioinformatics method and searched for homologous DNA sequence from GenBank, altogether 33 coding sequences were obtained. These cDNA sequences might be target genes transactivated by complete S protein of HBV. Moreover, two unknown genes were discovered, full length coding sequences were obtained by bioinformatics techniques, one of them was named complete S transactivated protein 1 (CSTP1) and registered in GenBank (AY553877).

CONCLUSION: The complete S gene of HBV has a transactivating effect on SV40 early promoter. A subtractive cDNA library of genes transactivated by HBV complete S protein using SSH technique has been constructed successfully. The obtained sequences may be target genes transactivated by HBV complete S protein among which some genes coding proteins are involved in cell cycle regulation, metabolism, immunity, signal transduction, cell apoptosis and formation mechanism of hepatic carcinoma.

INTRODUCTION

Hepatitis B virus (HBV) genome is defined as four open

read frames (ORFs), which are named as the regions of S, C, P, X, respectively. The region of S is divided into the sub-regions of pre-S1, pre-S2 and S according to different initial code ATG in frame. Dong *et al.*^[1] have shown that there is ORF before pre-S1 region in the genome of HBV from serum of patients with long and accurate polymerase chain reaction (LA-PCR). This region is 135 bp, which is named temporarily as pre-pre-S and its promoter activities are confirmed in 277 bp upstream nucleotide sequences before pre-S1 gene^[2]. Pre-pre-S, pre-S1, pre-S2 and S genes are translated in frame according to the same ORF. It is well-known that HBV causes acute and chronic infections of the liver, especially chronic infections may result in remarkable consequences^[3]. HBV is considered to be a major etiological factor in the development of human hepatocellular carcinoma (HCC)^[4-9]. Although the precise role of HBV in the etiology of HCC is not well understood, data have shown that some HBV proteins can exert a significant transactivating activity on both viral and cellular promoter^[10]. This mechanism may have a close relation with the formation of HCC.

Suppression subtractive hybridization (SSH) is a widely used new technique in the cloning of genes transactivated by viral proteins^[11]. Complete S of HBV includes pre-pre-S, pre-S1, pre-S2 and S regions, complete S protein functions as a transcriptional transactivator. In the present study, we have successfully constructed the subtractive library of genes transactivated by HBV complete S protein.

MATERIALS AND METHODS

Construction and identification of expression vector

The complete S gene was prepared by PCR amplification using plasmid G376 A7 (GenBank number: AF384371) as template^[1,12,13], sense (5'-GGA TCC ATG CAG TTA ATC ATT ACT TCC-3') and antisense (5'-GGT ACC AAT GTA TAC CCA AAG ACA AAA G-3') primers (Shanghai BioAsia Biotech Co., Ltd, China). As these primers contain *Bam*HI and *Kpn*I (Takara) recognition sites on their respective 5'-ends, the amplified 1 338 bp PCR fragment was subcloned into the *Bam*HI and *Kpn*I sites of pcDNA3.1(-) vector (Invitrogen Co., USA). The expression vector, pcDNA3.1 (-)-complete S which could directly express complete S fusion protein was obtained, then identified by PCR and digested by *Bam*HI/*Kpn*I.

Expression of pcDNA3.1 (-)-complete S in HepG2 cells

HepG2 cells were transiently transfected with pcDNA3.1 (-)-complete S. At the same time, empty vectors were also transfected into cells as controls. HepG2 cells were plated at a density of 1.5×10^6 in a 35 mm plate in Dulbecco's modified Eagle's medium (DMEM) supplemented with 100 mL/L heat-inactivated fetal bovine serum (FBS). After 24 h of growth to 40-50% confluence, the cells were transfected with plasmids using FuGENE6 transfection reagent following the manufacturer's protocol (Roche C, USA).

mRNA and cDNA isolation

The mRNA from HepG2 cells transfected with pcDNA3.1

(-)-complete S and pcDNA3.1(-) empty vector was isolated using micro mRNA purification kit (Amersham Biosciences, Co., USA). cDNAs were reverse-transcribed from total RNA. Identification was done by PCR with complete S sequence-specific primers.

Cotransfection with reporter vector pSV-lacZ

HepG2 cells were transfected with various concentrations of plasmid pSV-lacZ (0.1-1.8 μ g) (Promega Co., USA). Expression of β -gal was detected by a β -gal assay kit (Promega, Co., USA). In pSV-LacZ the LacZ gene was under the control of the SV40 early promoter element. The optimal concentration of pSV-lacZ plasmid DNA was selected, HepG2 cells was cotransfected with pSV-lacZ and pcDNA3.1 (-)-complete S (2.0 μ g). At the same time, cotransfected HepG2 cells transfected with empty pcDNA3.1(-) (2.0 μ g) and pSV-lacZ were used as controls. After 48 h, cells were collected and detected for the expression of β -gal.

Generation of subtractive cDNA library

Gene expression comparisons by suppression subtractive hybridization according to the manufacturer's instructions of PCR-selectTM cDNA subtraction kit (Clontech Co., USA). In brief, 2 μ g of mRNA from the tester and the driver was subjected to cDNA synthesis. Tester and driver cDNAs were digested with *Rsa*I. The tester cDNA was subdivided into two portions, and each was ligated with a different cDNA adapter. In the first hybridization reaction, an excess of driver cDNA was added to each sample of tester. The samples were heat denatured and allowed to anneal. Because of the second-order kinetics of hybridization, the concentration of high- and low-abundance sequences was equalized among the single-stranded tester molecules. At the same time single-stranded tester molecules were significantly enriched for differentially expressed sequences. During the second hybridization, two primary hybridization samples were mixed without denaturation. Only the remaining equalized and subtracted single-stranded tester cDNAs could re-associate forming double-stranded tester molecules with different ends. After filling in the ends with DNA polymerase, the entire population of molecules was subjected to nested PCR with two adapter-specific primer pairs.

PCR analysis of subtraction efficiency

PCR was performed on un-subtracted and subtracted secondary PCR products with the G3PDH 5'- and 3'-primers, respectively. From each reaction, 5 μ L sample was removed, and the rest of the reaction was put back into the thermal cyclor for five more cycles. The above step was repeated thrice, and then 5 μ L sample (i.e., the aliquots were removed from each reaction after 18, 23, 28, and 33 cycles) was examined on 2.0% agarose gel.

Cloning subtractive library into pGEM-teasy vector

The amplified products containing a subtractive cDNA library (6 μ L) were cloned into a pGEM-teasy vector (Promega Co., USA). Subsequently, Plasmid DNA was transformed into *E. coli* strain DH5 α . Bacteria were taken up in 800 μ L of LB medium and incubated for 45 min at 37 $^{\circ}$ C. Bacteria were plated onto agar plates containing

ampicillin (100 µg/mL), 5-bromo-4-chloro-3-indolyl-β-D-galactoside (X-Gal; 20 µg/cm²), and isopropyl-β-D-thiogalactoside (IPTG; 12.1 µg/cm²) and incubated overnight at 37 °C. Positive (white) colonies were picked out and identified by PCR. Primers were T7/SP6 primer of pGEM-teasy vector. After the positive colonies were sequenced (Shanghai BioAsia Biotechnology Co., Ltd, China), nucleic acid sequence homology searches were performed using the BLAST (basic local alignment search tool) server at the National Center for Biotechnology Information.

RESULTS

Identification of expression vector

Restriction enzyme analysis of pcDNA3.1(-)-complete S plasmid cleaved with *Bam*HI and *Kpn*I yielded two bands: 5 396 bp empty pcDNA3.1(-) and 1 338 bp HBV complete S, and only one 6 734 bp band (5 396 bp+1 338 bp), it was cleaved with *Kpn*I. The plasmid by PCR amplification with complete S-specific primers got a clear band with the expected size (1 338 bp). The sequence of the PCR product was correct (Figure 1).

Figure 1 Electrophoresis of PCR products of pcDNA3-complete S and cleaved restriction enzyme (A). Structure of expression vector pcDNA3.1(-)-complete S plasmid(B).

Figure 2 Electrophoresis of RT-PCR products in 0.9% agarose gel. Lane 1: negative control; lanes 2-4: mRNA isolated from pcDNA3.1(-)-complete S; lane 5: blank control; M: DNA marker (2 000 bp).

Identification of HBV complete S transient expression

Reverse-transcription by three different Oligo dT, identification of cDNA by PCR yielded a common 1.338 bp band (Figure 2).

The stable expression of pcDNA3.1(-)-complete S in HepG2 cells was also confirmed by Western blotting hybridization at a high level.

Result of cotransfection of pSV-lacZ and pcDNA3.1(-)-complete S

The best concentration was at 1.0 µg of pSV-lacZ. When cotransfected with pcDNA3.1(-)-complete S and pSV-lacZ, the β -gal data about the expression of β -gal were 0.228. In contrast, the expression of β -gal cotransfected with empty pcDNA3.1(-) and pSV-lacZ was 0.033. Expression of β -gal was 6.9-fold higher when cotransfected with pcDNA3.1(-)-complete S and pSV-lacZ than when cotransfected with empty pcDNA3.1(-) and pSV-lacZ. The significant increase of expression of β -gal was attributed to the transactivating effect of HBV complete S protein on early promoter of SV40, thus increasing the expression of downstream gene lacZ (Figure 3).

Result of PCR analysis of subtraction efficiency

The G3PDH (a housekeeping gene) primers were used to confirm the reduced relative abundance of G3PDH following the PCR selection procedure. The result displayed that the G3PDH abundance of subtracted secondary PCR products significantly decreased compared to the un-subtracted one, indicating that the subtractive library had a high subtraction efficiency (Figure 4).

Figure 3 Result of β -galactosidase enzyme analysis.

Figure 4 Reduction of G3PDH abundance by PCR-selection subtraction. Lanes 1 and 5: 18 cycles; lanes 2 and 6: 23 cycles; lanes 3 and 7: 28 cycles; lanes 4 and 8: 33 cycles. Lane M: marker (2 000 bp).

Analysis of subtractive library

Using suppression subtractive hybridization technique, we obtained a total of 86 positive clones. These clones were prescreened by PCR amplification to ensure that only clones with different inserts were subjected to sequencing analysis (Figure 5). Eighty-six clones contained 200-1 000 bp inserts. A total of 35 clones from cDNA library were randomly selected and sequenced, and 33 coding sequences were obtained. The data are presented in Table 1. The smear difference in subtractive library was displayed after electrophoresis of PCR products on 2% agarose gel (Figure 6).

Figure 5 Electrophoresis of PCR products of part clones (42-63) on 0.9% agarose gel; M: marker (2 000 bp).

Figure 6 Smears of HBV complete S after PCR.

DISCUSSION

The open reading frame of HBV complete S gene consists of four coding regions: pre-pre-S, pre-S1, pre-S2 and S, each starting with an ATG codon in frame. Through in frame translational initiation at each of the four ATG codons, complete S (pre-pre-S + pre-S1 + pre-S2 + S), large (LHBs; pre-S1 + pre-S2 + S), middle (MHBs; pre-S2 + S) and small (SHBs; S) envelope glycoproteins can be synthesized^[14-18]. The transactivator function of the surface protein requires the cytoplasmic orientation of the pre-S2 domain (the minimal functional unit) that occurs in the case of MHBs^t and in a fraction of Labs^[19,20]. Some studies indicate the biological significance of the pre-S2 transactivators^[21]. But we firstly discussed the transactivator function of HBV complete S protein in the present study.

We cotransfected HepG2 cells with pcDNA3.1(-)-complete S and pSV-lacZ and demonstrated that the HBV

complete S protein was successfully expressed in transfected HepG2 cells. Expression of β -gal was 6.9-fold higher when cotransfected with pcDNA3.1(-)-complete S and pSV-lacZ than when cotransfected with empty pcDNA3.1(-) and pSV-lacZ. HBV complete S had significant transactivating effect on early promoter of SV40 virus, thus increasing the expression of downstream gene lacZ. This result indicates that the HBV complete S protein expressed in HepG2 cells retains its biological activity in terms of transcriptional activation.

To get insight into the transactivation mechanism of HBV complete S protein, SSH was used for identification of transactivating target genes of complete S protein, and subtractive library was set up successfully. Sequence analysis was performed for 35 clones, and 33 coding sequences were obtained. These genes can be divided into four groups:

(1) The genes involved in cell structure and cell cycle that possess the important ability to control cell growth, differentiation and adherence, such as ribosomal protein, mitochondrion, eukaryotic translation elongation factor.

(2) The genes related to cell energy or substance metabolism (i.e., NADH dehydrogenase 2, cytochrome C oxidase II, etc.).

(3) The genes involved in the mechanism underlying the development of hepatocellular carcinoma. Cyclin-dependent kinase 4 (CDK4) is a key regulator of cell cycle. It has been shown that a variety of cell cycle-related proteins play an important role in the process of hepatocarcinogenesis. CDK4 is related to the regulation of the cyclin G1 phase, and significantly elevates in HCC compared to surrounding cirrhotic tissues by Western blot and *in vitro* kinase assays. The enhanced cyclin D1-related kinase activity in HCC was accompanied with the up-regulation of CDK4 activity. In addition, the protein levels and kinase activities of CDK4 are higher in poorly differentiated and advanced HCC. In

conclusion, the increases of cyclin D1 and CDK4 play an important role in the development of HCC. CDK4 activation may be closely related to the histopathologic grade and progression of HCC^[22-24]. But CDK4 does not increase in children with hepatic carcinoma^[25]. Amino acid transporter system A2 (ATA2) is responsible for Na⁺-independent amino acid transporter system. When amino acid is starved, the expression of ATA2 increases, suggesting that this expression is directly related to the activity of amino acid transporter^[26]. Its mRNA increases in the biopsy of hepatocirrhosis and hepatic carcinoma^[27], especially in chorion after hepatectomy, suggesting that ATA2 is closely associated with hepatic regeneration^[26,28]. ATA2 is cloned in hepatic carcinoma HepG2, and increases in patients of hepatic carcinoma^[29].

(4) The genes controlling hepatic cell infection and apoptosis, such as adenylate kinase 2(AK2) protein. AK2 gene located at the right arm of the second chromosome may play a role in maintaining the levels of ADP/ATP by releasing two-molecule ADP from ATP to AMP^[30]. The release of two mitochondrial proteins, cytochrome C and apoptosis-inducing factor (AIF), into the soluble cytoplasm of cells undergoing apoptosis has been well established. Since only AK2 intermembrane proteins release from mitochondria during the early phase of the apoptotic process, AK2 is very important in cell apoptosis. AK2 and cytochrome C are translocated in cytoplasm gelatum in apoptosis model^[31]. Therefore AK2 plays a role in inducing cell apoptosis. Apolipoprotein H (APOH), is named as beta-2-glycoprotein I and anticoagulative serum protein. The polymorphous APOH gene is closely related to fat metabolism, coagulation and hypertension^[32]. It is the pre-S of HBsAg that results in HBsAg combination with APOH. Resecting phosphatide and oxygenated phosphatide could disturb this mutual action, suggesting that this action is involved in the ectoblastic phosphatide^[33]. Furthermore, it is restrained from rebuilding HBsAg, anti-HBsAg and APOH. APOH may be the vector of HBV and plays a role in HBV infection. APOH chiefly combines with complete Dane HBV particle with telescope, and the activity of APOH-HBsAg is the highest in patients with active duplication^[33]. This combination facilitates virus particle entrancing hepatic cells, and plays an important role in the beginning of HBV infection^[34].

We testified the transactivator ability of HBV complete S protein, and constructed the subtractive cDNA library of genes transactivated by complete S protein. These genes are closely correlated with carbohydrate metabolism, immunoregulation, occurrence and development of tumor. How these genes affect occurrence and development of chronic hepatitis B, hepatic fibrosis and hepatocarcinoma needs to be further studied.

Abstract

AIM: To investigate the biological function of complete S protein and to look for proteins interacting with complete S protein in hepatocytes.

METHODS: We constructed bait plasmid expressing complete S protein of HBV by cloning the gene of complete S protein into pGBKT7, then the recombinant plasmid DNA was transformed into yeast AH109 (a type). The transformed yeast AH109 was mated with yeast Y187 (α type) containing liver cDNA library plasmid in 2 \times YPDA medium. Diploid yeast was plated on synthetic dropout nutrient medium (SD/-Trp-Leu-His-Ade) containing X- α -gal for selection and screening. After extracting and sequencing of plasmids from positive (blue) colonies, we underwent sequence analysis by bioinformatics.

RESULTS: Nineteen colonies were selected and sequenced. Among them, five colonies were *Homo sapiens* solute carrier family 25, member 23 (SLC25A23), one was *Homo sapiens* calreticulin, one was human serum albumin (ALB) gene, one was *Homo sapiens* metallothionein 2A, two were *Homo sapiens* betaine-homocysteine methyltransferase, three were *Homo sapiens* Na⁺ and H⁺ coupled amino acid transport system N, one was *Homo sapiens* CD81 antigen (target of anti-proliferative antibody 1) (CD81), three were *Homo sapiens* diazepam binding inhibitor, two colonies were new genes with unknown function.

CONCLUSION: The yeast-two hybrid system is an effective method for identifying hepatocyte proteins interacting with complete S protein of HBV. The complete

INTRODUCTION

Hepatitis B virus (HBV) causes acute and chronic infections of the liver. Acute infections may produce serious diseases, and approximately 0.5% of the diseases will develop into fatal, fulminant hepatitis. Chronic infections may also have remarkable consequences^[1]. Thus HBV is considered to be a major etiological factor in the development of human hepatocellular carcinoma (HCC), one of the most frequent fatal malignancies worldwide, and worldwide deaths of HCC exceed one million per year^[2-7]. Epidemiological studies have demonstrated an approximately 10-fold increase in the relative risk of HCC among HBV carriers compared to non-carrier.

The precise role of HBV in the etiology of HCC is not well understood. Only occasionally, genes controlling cell growth and differentiation are disturbed by integration of HBV DNA sequences. An alternative mechanism of chronic infections and hepatocarcinogenesis may be the key steps to mutual interaction between viral proteins and hepatocellular proteins, this action may mediate virus to enter into the liver cells and affect the activities and function of these proteins. Moreover, the protein from hepatocytes infected with HBV inversely disturbs virus replication and reduces immunity of the host, resulting in chronic liver diseases and HCC. Elucidating this interaction between these proteins may help to bring some new clues for discovering the pathogenesis of viral hepatitis.

The first full length nucleotide sequence of HBV was published in 1979. Its length is 3 182 nt, and the serum type is ayw. The four open read frames (ORF) defined in HBV genome at that time, are named as the regions of S, C, P and X. The region of S is divided into the sub-regions of pre-S1, pre-S2 and S according to different initial code ATG in frame. Dong *et al.*^[8], have shown that there is an

open read frame (ORF) before pre-S1 region in the genome of HBV, amplified from serum of patients infected with HBV by long and accurate polymerase chain reaction (LA-PCR). This region is 135 bp, and named temporarily as pre-pre-S and its promoter activities have been confirmed in 277 bp upstream nucleotide sequences before pre-S1 gene^[9]. Pre-pre-S, pre-S1, pre-S2 and S genes are translated in frame according to the same ORF, complete S of HBV, including pre-pre-S, pre-S1, pre-S2 and S regions.

The function of the complete S protein in the life cycle of HBV remains unknown. To investigate the biological importance of the complete S protein, we screened and identified the proteins interacting with HBV complete S protein by yeast-two hybrid system to elucidate the biological functions of complete S protein of HBV genome.

MATERIALS AND METHODS

Bacterials, yeast strains and plasmids

All yeast strains and plasmids for yeast-two hybrid experiments were obtained from Clontech Co. (Palo Alto, CA, USA) as components of the MATCHMAKER two hybrid system 3. Yeast strain AH109 (MATa, *trp1-901*, *leu2-3,112*, *ura3-52*, *his3-200*, *gal4Δ*, *gal80Δ*, *LYS2: GAL1_{UAS}-GAL1_{TATA}-HIS3*, *GAL2_{UAS}-GAL2_{TATA}-ADE2*, *URA3: MEL1_{UAS}-MEL1_{TATA}-LacZ*) containing pGBKT7-53, coding for DNA-BD/mouse p53 fusing protein was used for cloning of bait plasmid. Yeast strain Y187 (MATa *ura3-52*, *his3-200*, *Ade2-101*, *trp1-901*, *leu2-3, 112*, *gal4Δ*, *gal80Δ*, *met-*, *URA3: GAL1_{UAS}-GAL1_{TATA}-lacZ MEL1*) containing pTD1-1, coding for AD/SV40 large T antigen fusing protein was used for cloning of library plasmids. Pre-transformed human cDNA liver cell library Y187 and bacterial strain DH5a were used for cloning of shuttle plasmids. Yeast-*Escherichia coli* shuttle plasmids, pGBKT7 DNA-BD cloning plasmid, pGADT7 AD cloning plasmid, pGBKT7-53 control plasmid, pGADT7, pGBKT7-Lam control plasmid, pCL1 plasmid were all from Clontech Co. (K1612-1). pGEM T vector was from Promega Co., USA.

Chemical agents and culture media

Taq DNA polymerase was purchased from MBI Co., T4 DNA ligase, *Eco*RI and *Bam*HI restriction endonuclease were from Takara Co., Japan. Anti-c-myc monoclonal antibody secreted by 1-9E10.2 hybridoma (ATCC) was prepared in our laboratory. Goat anti-mouse IgG conjugated with horseradish peroxidase was from Zhongshan Co., China. Lithium acetate, semi-sulfate adenine, acrylamide and N, N'-bis-acrylamide were from Sigma Co., and TEMED was from Boehringer Mannheim Co. Tryptone and yeast extracts were from OXOID Co. X- α -gal and culture media: YPDA, SD/-Trp SD/-Leu, SD/-Trp/-Leu, SD/-Trp/-Leu/-His, SD/-Trp/-Leu/-His/-Ade were from Clontech Co., protein-G agarose was from Roche Co., and pGEM-T vector was from Promega Co.

RT-PCR kit and TNT[®] coupled reticulocyte lysate systems were from Promega Co. [³⁵S]-methionine (1 000 Ci/mmol, 10 mCi/mL) was from Isotope Company of China. Amplification fluorographic reagent (#NAMP100) was from Amersham Life Sciences Co. Others reagents were from Sigma Co., USA.

Construction of "bait" plasmid and expression of HBV complete S protein

HBV-complete S sequences were generated by PCR amplification using the plasmid G376 A7 (GenBank number: AF384371^[8,10-13]) as template. The sequences of the primers containing the *Eco*RI and *Bam*HI restriction enzyme sites were: sense primer (*Eco*RI): 5'-GAA TTC ATG CAG TTA ATC ATT ACT TCC-3'; antisense primer (*Bam*HI): 5'-GGA TCC TCA AAT GTA TAC CCA AAG AC-3'. The PCR conditions were at 94 °C for 60 s, at 55 °C for 60 s, at 72 °C for 90 s. Ten nanograms of PCR product was cloned with pGEM-T vector. The primary structure of insert was confirmed by direct sequencing. The fragment of encoding complete S was released from the pGEM-T- complete S by digestion with *Eco*RI and *Bam*HI, and ligated to pGBKT7. Vector pGBKT7 expressing proteins were fused with amino acids 1-147 of the GAL4 DNA binding domain (DNA-BD), pGADT7 expressing proteins were fused with amino acids 768-881 of the GAL4 activation domain (AD). Plasmid pGBKT7-complete S (Figure 1) containing full-length HBV complete S gene could express DNA binding domain, c-myc and complete S fusion protein. The plasmid was transformed into yeast strain AH109 by lithium acetate method^[14]. Western blotting was performed to confirm the expression of the fusion protein using anti-c-myc monoclonal antibody. Transformed AH109 (bait) was cultured on quadruple dropout media to exclude the auto-activation activity.

Figure 1 Structure of "bait" plasmid pGBKT7-complete S.

Yeast-two hybrid library screening using yeast mating

One large (2-3 mm), fresh (<2 mo old) colony of AH109 [bait] was inoculated into 50 mL of SD/-Trp and incubated at 30 °C overnight (16-24 h) and shaken at 250-270 r/min. Then the cells were spanned down by centrifuging the entire 50 mL culture at 1 000 r/min for 5 min. After the supernatant was decanted, the cell pellet was resuspended in the residual liquid by vortexing. A human liver cDNA library cloned into pACT2 and yeast reporter strain Y187 (Clontech Co., USA) were co-cultured. The entire AH109 [bait] culture and the 1 mL human liver cDNA library (1×10⁶ cfu/mL) were combined and cultured in a 2-L sterile flask and 45 mL of 2X YPDA/Kan was added and swirled gently. After 20 h of mating, the cells were spanned down and resuspended, and then spread on 50 large (150 mm) plates containing 100 mL of SD/-Ade/-His/-

Leu/-Trp (QDO). After 6-15 d of growth, the yeast colonies were transferred onto the plates containing X- α -gal to check for expression of the MEL1 reporter gene (blue colonies).

Plasmid isolation from yeast and transformation of *E. coli* with yeast plasmid

Approximately 1×10^6 colonies were screened and positive clones were identified. Yeast plasmid was isolated from positive yeast colonies with lysis method (Clontech Co., USA), and transformed into super-competence *E. coli* DH5 α using chemical method. Transformants were plated on ampicillin SOB selection media and grown under selection. Subsequently, pACT2-cDNA constructs were re-isolated, analyzed by restriction digestion and sequencing.

Bioinformatic analysis

After the positive colonies were sequenced, the sequences were blasted with GenBank to analyze the function of the genes (<http://www.ncbi.nlm.nih.gov/blast>).

Cell culture and new gene cloning

Hepatoblastoma cell line HepG2 was propagated in DMEM supplemented with 10% FBS, 200 μ mol/L L-glutamine, penicillin, and streptomycin. HepG2 cells were plated at a density of 1×10^6 /well in 35-mm dishes. Total cellular RNA was isolated using TRIzol (Invitrogen Co., USA) according to the manufacturer's instructions. cDNAs were reverse-transcribed from total RNA.

On the basis of liver cDNA library of genes of proteins interacting with HBV-complete S protein, the coding sequence of a new gene without known function, HBV CSBP1, was obtained by bioinformatics methods. The standard PCR cloning technique was used to amplify HBV CSBP1 gene. Total cell RNA was isolated from HepG2 cells. RNA was used for RT-PCR amplification. The PCR conditions were: 94 °C for 60 s, 58 °C for 60 s, and 72 °C for 60 s, for 35 cycles. The PCR product was cloned with pGEM-T vector (Promega Co., USA). The primary structure of insert was confirmed by direct sequencing. The gene fragment was cloned into yeast plasmids pGBKT7 and pGADT7.

Confirmation of the true interaction in yeast

To confirm the true protein-protein interaction and exclude false positives, the plasmids of positive colonies were transformed into yeast strain Y187, and then mating experiments were carried out by mating with yeast strain AH109 containing pGBKT7-complete S or pGBKT7-Lam. After mating, the diploids yeast was plated on SD/-Ade-His-Leu-Trp (QDO) covered with X- α -gal to test the specificity of interactions.

In vitro translation

Twenty-five microliter mixture of TNT[®] reticulocytes, 2 μ L TNT[®] reaction buffer, 1 μ L T7 TNT[®] RNA polymerase, 1 μ L amino acids mixture (minus methionine, 1 mol/L), 1 μ L [³⁵S]-methionine 2 μ L, RNasin RNase inhibitor (40 u/mL), 2 μ L DNA template (pGBKT7-complete S or pGADT7-library gene) (0.5 μ g/mL), 16 μ L ddH₂O, were incubated at 30 °C for 90 min.

Coimmunoprecipitation

The following reactants were combined in a 1.5 mL microce-

ntrifugation tube on ice: 5 μ L *in vitro*-translated bait protein, 5 μ L *in vitro*-translated library protein. The only control added was 10 μ L pGBKT7-complete S plasmid. The mixtures were incubated at 30 °C for 1 h. Then, the following reagents were added into the reaction tubes: 470 μ L coimmunoprecipitation buffer (20 mol/L Tris-HCl (pH 7.5), 150 mol/L NaCl, 1 mol/L DTT, 5 μ g/mL aprotinin, 0.5 mol/L PMSF, 0.1 % Tween 20, 10 μ L protein-G agarose beads, 10 μ L anti-c-myc monoclonal antibody. Incubation was done at 4 °C for 2 h with continuous shaking. The tubes were centrifuged at 14 000 *g* for 1-2 min. The supernatants were removed. Half a milliliter of TBST was added into the tubes. Rinse steps were repeated thrice. Fifteen microliters of SDS-loading buffer was added. The samples were heated at 80 °C for 5 min. The tubes were placed on ice and then briefly centrifuged, and 10 μ L was loaded onto a SDS-PAGE mini-gel to begin the electrophoretic separation. After electrophoresis, the gel was transferred onto a tray containing gel fixation solution, and placed on a rotary shaker for 10 min at room temperature. The gel was rinsed with H₂O, then amplification fluorographic reagent was added and shaken for 20 min at room temperature, then dried at 80 °C under constant vacuum. The gel was exposed to an X-ray film overnight at room temperature. The film was developed by standard techniques.

RESULTS

Identification of recombinant plasmid

The full length sequences of HBV complete S were generated by PCR amplification of the plasmid G376 A7 (GenBank number: AF384371)^[1,10-13], and a 942-bp fragment of HBV CSBP1 was amplified by RT-PCR after total RNA was prepared from HepG2 cells, sequenced and analyzed by comparing Vector NTI 6 and BLAST database homology search (<http://www.ncbi.nlm.nih.gov/blast>). After being cut by *Eco*RI/*Bam*HI, the fragments were in-frame ligated, respectively into pGBKT7 and pGADT7 at the *Eco*RI/*Bam*HI sites. Restriction enzyme analysis of pGBKT7-complete S, pGBKT7-CSBP1 and pGADT7-CSBP1 plasmids with *Eco*RI/*Bam*HI yielded respectively two bands: 7 300 bp empty pGBKT7 and 1 338 bp HBV complete S, 7 300 bp empty pGBKT7 and 942 bp of HBV CSBP1, 7 900 bp empty pGADT7 and 942 bp HBV CSBP1. The products of plasmid were amplified by PCR. Analysis of the PCR amplified products by agarose gel electrophoresis showed the clear bands with the expected size (1 338 bp of complete S, 942 bp of CSBP1). Sequences of the PCR products were correct (Figures 2A-D).

Expression of "bait" fusion protein

Yeast strain AH109 transformed with pGBKT7-complete S and pGBKT7-CSBP1 could stably express the fusion protein at high level (Figure 3) and could only grow on SD/-Trp medium but not on QDO medium. Thus, the transformed yeast could be used for yeast hybrid analysis.

Screening of liver cell cDNA library

We isolated plasmids from the blue colonies containing only pGBKT7-complete S and one library plasmid other than other plasmids. Because plasmid pACT2-cDNA contains

Figure 2 One thousand three hundred and thirty eight basepair fragment-complete S amplified by RT-PCR (A), pGBKT7-complete S cut by *EcoRI*/

BamHI (B), a 945 bp fragment-CSBP1 amplified by RT-PCR (C), pGBKT7-CSBP1 and pGADT7-CSBP1 cut by *EcoRI*/BamHI (D).

Figure 5 Interaction between HBV complete S protein and CSBP1 protein identified by coimmunoprecipitation. Lane 1: HBV complete S protein; lane 2: interaction with two proteins.

Figure 4 Identification of different colonies with *BglII* digestion.

two restriction endonuclease sites of *BglII* on both sides of multiple cloning sites, the gene fragments of the liver cell cDNA library (pACT2-cDNA) screened were released by *BglII* digestion (Figure 4). The gene fragments of different lengths in Figure 5 proved that these screened clones were positive colonies growing on SD/-Trp/-Leu/-His/-Ade culture medium after mating.

Analysis of cDNA sequencing and homology

We obtained a total of 19 positive colonies growing on the selective SD/-trp-leu-his-ade/X- α -gal medium. These colonies were prescreened by *BglII* digestion to make sure that only colonies with different inserts were subjected to sequencing. Nineteen colonies from cDNA library were sequenced. Using the BLAST program at the National Center for Biotechnology Information, 17 sequences had a high similarity to known genes. The data are presented in Table 1.

Table 1 Comparison between positive clones and similar sequences in GenBank

High similarity to known genes	Number of similar (%)	Homology (%)
<i>Homo sapiens</i> calreticulin	1	99
<i>Homo sapiens</i> solute carrier family 25, member 23 (SLC25A23)	5	99
Human serum albumin (ALB) gene	1	100
<i>Homo sapiens</i> metallothionein 2A	1	98
<i>Homo sapiens</i> betaine-homocysteine methyltransferase, mRNA	2	98
<i>Homo sapiens</i> diazepam binding inhibitor	3	96
<i>Homo sapiens</i> Na ⁺ and H ⁺ coupled amino acid transport system N	3	100
<i>Homo sapiens</i> CD81 antigen (CD81)	1	100

In vitro coimmunoprecipitation

HBV complete S protein containing 447 aa, was smaller than CSBP1 containing 280 aa (Figure 5).

DISCUSSION

The open reading frame of HBV complete S gene consists of four coding regions: pre-pre-S, pre-S1, pre-S2 and S, each starting with an ATG codon in frame. Through in frame translational initiation at each of the four ATG codons, complete S (pre-pre-S+pre-S1+pre-S2+S), large (LHBs; pre-S1+pre-S2+S), middle (MHBs; pre-S2+S) and small (SHBs; S) envelope glycoproteins can be synthesized^[12,13,15-17]. Interactions between viral and hepatocellular proteins play an important role in the pathogenesis of the virus and may mediate virus

to enter into hepatocytes. Their network interactions can change normal biological functions of proteins, influence self-replication of virus, and result in diseases. Yeast-two hybrid system 3 is an effective gene analysis method to analyze the interactions between protein and protein, protein and DNA, protein and RNA in eukaryotic cells and a new genetics technique for studying interactions of proteins in physiologic conditions *in vivo*.

Yeast-two hybrid system 3 is based on the system originally designed by Fields and Song by taking advantage of the properties of the GAL4 protein of the yeast *Saccharomyces cerevisiae*. GAL4-yeast-two hybrid assay uses two expression vectors, one uses GAL4-DNA-binding domain (DBD) and the other uses GAL4-activation domain (AD). The GAL4-DBD fused to protein 'X' and a GAL4-AD fused to protein 'Y' to form the bait and the target of the interaction trap, respectively. A selection of host cells with different reporter genes and different growth selection markers provides a means to detect and confirm protein-protein interactions and has significantly fewer false positives^[18-21].

In this study, the "bait" plasmid pGBKT7-complete S was transformed into yeast strain AH109. HBV complete S gene was expressed in yeast cells. After the "bait" plasmid pGBKT7-complete S yeast strain AH109s mated with liver cDNA library yeast strain Y187, the diploid yeast cells were plated on QDO media containing X- α -gal, 19 true positives were obtained. By sequencing analysis of isolated library plasmids, we got the sequences of the 17 genes with known functions and two genes with unknown functions, one of them was named as complete S-binding protein 1 (CSBP1). In order to further confirm the interaction between the expressed protein and HBV complete S protein, we performed the experiment of coimmunoprecipitation of both proteins. A strong interaction between HBV complete S protein and CSBP1 protein *in vitro* was observed.

We screened *Homo sapiens* metallothionein 2A (MT) interacting with complete S protein from liver cDNA library. Metallothionein is a low-molecular weight protein with pleiotropic functions and a family member of metal binding proteins. MT is localized in nuclei and/or cytoplasm of tumor cells^[22]. It may be involved in the regulation of carcinogenesis and apoptosis in addition to various physiological processes. Metallothionein is a small stress response protein that can be induced by exposure to heavy metal cations, oxidative stressors, and acute phase cytokines that mediate inflammation^[23]. In humans, there are four groups of MT proteins. MT-2A is highly expressed in epithelial cells of breast cancer, and differentially up-regulated in invasive breast cancer cells^[24]. Jin *et al.*^[25], reported that 26-100% of invasive ductal breast cancers express the MT protein, and are associated with cell proliferation and higher histological grade in invasive ductal breast cancer tissues. Rao *et al.*^[26], thought that the mechanism may be completed through interaction between protein kinase C (PKC) signal transduction and MT 2A. Therefore this protein plays an important role in maintaining transition metal ion homeostasis, redox balance in cells and fundamental cellular processes such as proliferation, apoptosis, and regulation of carcinogenesis^[27,28]. MT 2A is also involved in human prostate homeostasis and carcinogenesis^[29]. MT-2A is expressed in retinal pigment epithelial

(RPE) cells, photoreceptor cells, inner nuclear layer cells and ganglion cells, and can protect cells against oxidative stress and apoptosis^[30].

Another important protein interacting with complete S protein from liver cDNA library is *Homo sapiens* calreticulin. Yoon *et al.*^[31], have analyzed nuclear matrix proteins in 11 hepatocellular carcinomas and compared them with corresponding non-neoplastic liver tissue by two-dimensional gel electrophoresis. Calreticulin is also found in the nuclear matrices of various carcinoma cell lines. The formation and/or expansion of calreticulin-nuclear matrix may be related to the activated cell growth. Le Naour *et al.*^[32], showed that autoantibodies of calreticulin are detectable in patients with HCC (27%), suggesting that a distinct repertoire of autoantibodies is associated with HCC. Therefore it may play a role in early diagnosis of HCC.

HBV complete S protein also interacts with *Homo sapiens* CD81 antigen (CD81). The protein encoded by this gene is a member of the transmembrane four superfamily, also known as the tetraspanin family^[33]. Most of these members are cell-surface proteins characterized by the presence of four hydrophobic domains. CD81, a signal transducing molecule, significantly increases in peripheral blood and more dramatic in the liver of HCV-infected individuals^[34]. Recently, CD81 has been identified as a hepatitis C virus (HCV) receptor of B lymphocytes, the large extracellular loop of CD81 is a determinant combination position for viral entry^[35-39]. These data suggest a functional role for CD81 as a coreceptor for HCV glycoprotein-dependent viral cell entry, providing a mechanism by which B cells are infected with and activated by the virus. It has recently been shown that peripheral B-cell CD81 overexpression is associated with HCV viral load and development of HCV-related autoimmunity. The human CD81 (hCD81) molecule has been identified as a putative receptor in B lymphocytes for hepatitis C virus with murine fibroblast cell line NIH/3T3 model. CD81 chimeras could internalize recombinant E2 protein and E2-enveloped viral particles from serum of HCV-infected patients into Huh7 liver cells. The latter result in persistent positive-strand viral RNA and accumulation of replication, therefore CD81 represents one of the pathways by which HCV can infect hepatocytes. Although CD81 can bind to HCV E2 protein, its role as a receptor for HBV remains controversial. These questions need further study. Whether CD81 could be used as the receptor or co-receptor for hepatocytes, should be studied intensively. CD81 proteins mediate signal transduction events that play a role in the regulation of cell development, activation, growth and motility. This protein appears to promote muscle cell fusion and support myotube maintenance. Also it may be involved in signal transduction. This gene is localized in the tumor-suppressor gene region, thus it is a candidate gene for malignancies.

These interacting proteins screened by yeast-two hybrid are closely correlated with carbohydrate metabolism, immunoregulation, occurrence and development of tumor, and may provide a new study clue for revealing biological functions of HBV complete S protein, pathogenesis of HBV and causes of malignancy conversion. How the interactions between HBV complete S protein and the above-mentioned interacting proteins affect the occurrence and development

of chronic hepatitis B, hepatic fibrosis and hepatocarcinoma, needs to be further studied.

Abstract

AIM: To assess the prevalence of the two mutations, C282Y and H63D of HFE gene, in healthy subjects, patients with chronic hepatitis C (CHC), and patients with nonalcoholic fatty liver disease (NAFLD) in Taiwan and to explore the contribution of the HFE mutation on serum iron stores in CHC and NAFLD groups.

METHODS: We examined C282Y and H63D mutations of HFE gene in 125 healthy subjects, 29 patients with CHC, and 33 patients with NAFLD. The serum iron markers, including ferritin, iron, and total iron binding capacity (TIBC), were assessed in all patients.

RESULTS: All of the healthy subjects and patients were free from C282Y mutation. The prevalence of H63D heterozygosity was 4/125 (3.20%) in healthy subjects, 2/29 (6.90%) in CHC group, and 1/33 (3.03%) in NAFLD group. The healthy subjects showed no significant difference in the prevalence of H63D mutation as compared with the CHC or NAFLD group. Increased serum iron store was found in 34.48% of CHC patients and 36.36% of NAFLD patients. In three patients of H63D heterozygosity, only one CHC patient had increased serum iron store. There was no significant difference in the prevalence of HFE mutations between patients with increased serum iron store and those without in CHC or NAFLD group.

CONCLUSION: The HFE mutations may not contribute to iron accumulation in the CHC or NAFLD group even when serum iron overload is observed in more than one-third of these patients in Taiwan.

INTRODUCTION

Hereditary hemochromatosis is one of the most common inherited diseases among Caucasians. It occurs with a frequency of 1:200 to 1:400 and a carrier rate approaching 1:10^[1,2]. Hereditary hemochromatosis is an autosomal recessive condition in which excessive iron is absorbed by the intestine. Iron accumulation in many organs causes the clinical manifestations including heart failure, diabetes, and liver cirrhosis. Early diagnosis has been difficult because the tests based on measurement of serum transferrin saturation and serum ferritin concentration not only gave many false positive results but do not always identify patients in the early stage of iron accumulation^[3]. The excessive iron can be removed by venesection^[4]. Although venesection is a simple, effective and safe therapy, much of the organ damage is irreversible when hereditary hemochromatosis is diagnosed. Because the major clinical presentations are often non-specific, appropriate screening tests are important.

The gene responsible for hereditary hemochromatosis was identified and designated as HFE in 1996^[5]. The two recognized recessively-inherited missense mutations of the HFE gene result in amino acid substitutions at position 282 (cysteine to tyrosine, C282Y) and at position 63 (histidine to aspartic acid, H63D). A total of 64-100% patients of Western population with hereditary hemochromatosis were C282Y homozygotes^[6-10]. In individuals of the northern European descent, the frequency of C282Y homozygote was about 0.5%^[11]. The allele frequencies for C282Y mutation and H63D mutation were 5-10% and 6-30%, respectively^[1,2,11]. In Taiwan, a very low frequency of C282Y mutation in the general population (0.33% of carrier rate) was reported^[12]. The C282 heterozygote may have higher serum and hepatic iron levels than controls, but levels are only mildly elevated^[13]. The clinical significance of the H63D mutation still remains undetermined. It seems to be associated with hereditary hemochromatosis only when inherited together with the C282Y mutation (compound C282Y/H63D heterozygote).

Mild to moderate hepatic iron overload is common in patients with chronic hepatitis C (CHC)^[14-16] and in patients with nonalcoholic fatty liver disease (NAFLD)^[17,18]. Iron-induced oxidative stress may play an important role in the

exacerbation of liver cell injury^[19,20]. The HFE mutation may also be associated with elevated markers of iron store in the two disorders. This study was performed to assess the prevalence of the two mutations, C282Y and H63D of HFE gene, in healthy subjects, patients with CHC, and patients with NAFLD in Taiwan. We also checked the serum iron markers and explored the contribution of the HFE mutation on serum iron stores in patients with CHC and patients with NAFLD.

MATERIALS AND METHODS

Healthy subjects and patients

C282Y and H63D mutations of HFE gene were analyzed in 125 healthy subjects, 29 patients with CHC, and 33 patients with NAFLD. Local healthy subjects with normal liver function test, no history of liver disease, other severe chronic disease, heavy drinking (ethanol consumption >20 g/d), anemia or iron overload were collected from the health checkup at our hospital in 2003. The patients with CHC or NAFLD were collected at our out-patient department from 2002 to 2003. CHC was diagnosed by biochemical liver damage for more than 6 mo and positivity of serum antibody to hepatitis C virus (HCV). Patients with secondary causes of iron overload were excluded, including heavy drinking, ribavirin therapy, and multiple transfusions. Co-infection with HBV was also excluded. The diagnosis of NAFLD was made on the basis of the presence of elevated serum AST or ALT and fatty change of liver by sonography. No subject consumed alcohol more than 20 g/d. They were negative for hepatitis B surface antigen and HCV antibody. Their serum levels of ceruloplasmin were within normal range. Serological tests for autoimmune hepatitis (anti-nuclear antibody, anti-smooth muscle antibody) and for primary biliary cirrhosis (anti-mitochondrial antibody) were negative.

Serological evaluation

The serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT) were determined using an Olympus 5000 analyzer. The upper limit of normal for ALT is 34 U/L. HCV antibody was tested by a commercially available ELISA (AxSYM, Abbott Diagnostic Corporation, USA). Total iron status of each patient was evaluated using biochemical tests. Serum iron (normal range, 60-160 µg/dL) was measured by the colorimetry and ferritin (normal range: 18-274 ng/mL

in men and 6-283 ng/mL in women) was measured by a commercially available ELISA (AxSYM, Abbott Diagnostic Corporation). Transferrin saturation was calculated as (the serum iron divided by the total iron binding capacity (TIBC)) ×100%. The increased serum iron store was defined by transferrin saturation >50% and/or ferritin >upper normal limit.

Mutational analysis of HFE gene

We used the method of polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) to analyze the HFE mutations. Genomic DNA was isolated from whole peripheral blood using the High Pure Viral Nuclear Kit (Roche Diagnosis Corporation, USA). The DNA fragments of HFE gene were amplified by PCR using the following primers^[5]: 5'-TGGCAAGGGTAAACAGATCC and 5'-CTCAGGCACTCCTCTCAACC for C282Y; and 5'-ACATGGTTAAGGCCTGTTGC and 5'-GCCACATCTGGCTTGAAATT for H63D. Restriction fragment length analysis was then performed by digesting the PCR products with *RsaI* for C282Y and *BclI* for H63D^[21].

Statistical analysis

Data are summarized as mean±SD. Categorical variables were compared with the χ^2 test or Fisher's exact test as required. Comparison between groups was performed using the unpaired *t*-test as appropriate.

RESULTS

The demographic and laboratory data of subjects are summarized in Table 1. CHC patients were older than healthy subjects (60.83±8.55 years *vs* 44.62±11.19 years, *P*<0.01) and NAFLD patients were not (49.48±14.58 years *vs* 44.62±11.19 years, *P* = 0.082). There was no significant difference in the male to female ratio between healthy subjects (44/81) and CHC (12/17) or NAFLD (16/17) group.

All of the healthy subjects and patients were free from C282Y mutation. Four healthy subjects (one man and three women) were heterozygotes of H63D, two CHC patients (one man and one woman) and one NAFLD patient (woman) were heterozygotes of H63D. The prevalence of H63D mutation was 4/125 (3.20%) in healthy subjects, 2/29 (6.90%) in CHC group, and 1/33 (3.03%) in NAFLD

Table 1 Demographic and laboratory data of healthy subjects, CHC and NAFLD (mean±SD)

	Reference range	Healthy subjects	Chronic hepatitis C	<i>P</i>	NAFLD	<i>P</i>
Age (yr)		44.62±11.19	60.83±8.55	<0.01	49.48±14.58	0.082

CHC, chronic hepatitis C; NAFLD, nonalcoholic fatty liver disease. *P* value: comparing data obtained from healthy subjects with chronic hepatitis C or NAFLD. The increased serum iron store was defined by transferrin saturation >50% and/or ferritin >upper normal limit.

group. The healthy subjects showed no significant difference in the prevalence of H63D mutation as compared with the CHC or NAFLD group (Table 2).

Table 2 Statistical analysis of H63D mutation between healthy subjects and CHC, and healthy subjects and NAFLD

	Male	Female	Total
Healthy subjects:CHC	1/44:1/12	3/81:1/17	4/125:2/29
<i>P</i>	0.386	0.539	0.315
Healthy subjects:NAFLD	1/44:0/16	3/81:1/17	4/125:1/33
<i>P</i>	0.999	0.539	0.999

CHC, chronic hepatitis C; NAFLD, nonalcoholic fatty liver disease.

Ten CHC patients (4 men and 6 women) and 12 NAFLD patients (8 men and 4 women) had increased serum iron stores. The percentage was 34.48% and 36.36% in CHC and NAFLD patients, respectively. There was no gender-related difference in the frequency of increased serum iron stores in either the CHC or NAFLD group (Table 3). In the three patients of H63D heterozygosity, only one CHC patient had increased serum iron store. There was no significant difference in the prevalence of HFE mutations between patients with increased serum iron store and those without in the CHC or NAFLD group (Table 4).

Table 3 Statistical analysis of increased serum iron stores between male and female patients with CHC or NAFLD

	CHC	NAFLD

<i>P</i>	0.999	0.999

CHC, chronic hepatitis C; NAFLD, nonalcoholic fatty liver disease.

DISCUSSION

A population study of global prevalence in HFE mutation showed that there were nine H63D heterozygotes in one Asian population of 242 cases and no other HFE genotypes were found^[1]. The H63D allele frequency was 1.9% (9/484). Similar results were reported in a Japanese population^[22]. All of the 151 healthy volunteers were free from C282Y mutation and only 8 subjects were H63D heterozygotes. The prevalence of chromosomes with H63D was 2.6% (8/302). We firstly found no C282Y mutation and an incidence of 1.6% (4/250) for H63D allele in 125 healthy subjects in Taiwan. The results were similar to that in other Asian area. No mutations of C282Y were found probably because of the limited number of subjects studied. The very low frequency

of HFE mutation in the Asians, especially C282Y, reflects the ethnic differences in the prevalence of hereditary hemochromatosis from Caucasians.

Similar prevalence of HFE mutations was found between controls and patients with CHC^[22-25]. Our findings were in lines with these studies. However, the equal distribution of HFE mutations does not allow the conclusion that HFE mutations play no or only a minor role in patients with CHC. It should depend on the contribution of HFE mutations on the iron stores. Either the prevalence of C282Y mutation^[18,26] or combined C282Y and H63D mutations^[27] was increased in nonalcoholic steatohepatitis (NASH) population. Because there was no pathological diagnosis of steatohepatitis in our patients, the patient group in our study is called NAFLD, instead of NASH. Our study showed no significant difference in the frequency of HFE mutations between healthy subjects and NAFLD patients. In another study of NAFLD, the prevalence of the two HFE mutations also was not significantly increased in NAFLD patients and matched those of the general population. These findings gave us a hint that HFE mutation may play a role in the progression of NAFLD.

Elevations in serum iron, ferritin, and transferrin saturation are common in patients with CHC or NASH, as are mild increases in hepatic iron concentration. In CHC, 40-46% of patients had elevated serum iron, ferritin, or transferrin saturation level^[14,15], and 10-36% of patients had increased hepatic iron concentration^[15,16]. In NASH, 58% of patients had elevated serum iron indices and in some cases increased hepatic iron stores^[18]. In our study, we found that 34.48% and 36.36% of patients had increased serum iron stores in CHC and NAFLD group, respectively. Normal or only mildly increased amounts of iron in the liver can be damaging because iron increases oxidative stress^[19,20]. It appears that iron overload may play a role in pathogenesis of some chronic liver diseases, especially when iron is combined with other hepatotoxic factors such as virus, free fatty acid, and alcohol^[17]. In addition to the effect of production of oxidative stress, the iron may enhance the rates of viral replication and mutation as well as cause impairment of the host immunity^[20]. However, the iron can be released from damaged hepatocytes in inflammatory conditions, and it has not been clear whether the iron accumulation is the cause or result of liver injury.

Our data demonstrated no significant difference in the prevalence of HFE mutations between the subgroup of HCV or NAFLD patients with increased serum iron store and the subgroup without. The findings suggested that HFE mutations played no or only a minor role in contribution to serum iron overload in patients with CHC or NAFLD in Taiwan. In addition to the reason of low prevalence of HFE mutations in Taiwan, the fact that only H63D heterozygote was found in our study may explain the results. The H63D heterozygosity usually does not lead to iron overload. Only in conjunction with the heterozygous C282Y mutation (compound C282Y/H63D heterozygote) has the H63D mutation been associated with an increased risk of iron overload^[5].

There were many reports suggesting that the C282Y mutation plays a role in the hepatic iron accumulation and favors the progression of CHC^[23-25]. However, the relationship

between HFE mutations, iron stores, and NASH still remains as a controversial area. Previous studies have found conflicting results. George *et al.*^[18], found that the C282Y mutation was responsible for most of the mild iron overload in NASH and had a significant association with hepatic damage in these patients. Bonkovsky *et al.*^[27], also found that C282Y heterozygotes were more likely to have advanced fibrosis. These authors did not adjust for potential confounders such as age, body mass index, and diabetes. After adjustment for these confounders, Chitturi *et al.*^[26], reported in NASH and Bugianesi *et al.*, reported in NAFLD patients that iron burden and HFE mutations did not contribute significantly to hepatic fibrosis. Therefore, we believe that continued exploration of the link between hepatic iron, HFE mutation, and NAFLD patients is warranted.

In conclusion, HFE mutations are infrequent in Taiwan. The prevalence of HFE mutations associated with hereditary hemochromatosis is not increased in the patients with CHC or NAFLD. The HFE mutations may not contribute to iron accumulation in the CHC or NAFLD group even when serum iron overload is observed in more than one-third of these patients in Taiwan.

INTRODUCTION

Bleeding is a common and serious complication of peptic ulcer diseases. It is estimated that peptic ulcer bleeding accounts for approximately 150 000 hospitalizations per year in the USA^[1,2]. The prevalence of *Helicobacter pylori* (*H. pylori*) in bleeding peptic ulcers has not been definitely determined, but it is estimated to be 70%^[3-5]. The accurate diagnosis of *H. pylori* infection is crucial in the short-term and long-term management of patients with bleeding peptic ulcers^[6]. If a patient with a bleeding ulcer requires surgical intervention, knowledge of his or her *H. pylori* status may guide the selection of procedures for the patient (i.e., a simple closure *vs* full-blown ulcer surgery)^[6]. Patients whose bleeding episodes cease in the short term, one-third of those who do not receive maintenance therapy, surgery or anti-*H. pylori* therapy will experience recurrent bleeding within the next 1-2 years^[7]. However, numerous studies have demonstrated that eradicating *H. pylori* can drastically reduce the incidence of rebleeding in patients with bleeding peptic ulcers, preventing the need for long-term antisecretory therapy or surgical intervention^[8-10]. Therefore, the *H. pylori* status in a patient with bleeding peptic ulcers must be documented.

Currently, *H. pylori* infection can be diagnosed by invasive assays, i.e., those requiring esophagogastroduodenoscopy (EGD), or by non-invasive assays in which EGD is not necessary. Invasive diagnostic tests include culture, histology, rapid urease test (RUT) and polymerase chain reaction (PCR). Non-invasive tests comprise serology, stool antigen test and urea breath test (UBT). The choice of a diagnostic test should depend on the clinical circumstances, sensitivity

Abstract

AIM: To assess the sensitivity and specificity of polymerase chain reaction (PCR) in detecting *Helicobacter pylori* (*H. pylori*) infection in patients with bleeding peptic ulcers, and to compare its diagnostic efficacy with other invasive and non-invasive tests.

METHODS: From April to September 2002, *H. pylori* status in 60 patients who consecutively presented with gastroduodenal ulcer bleeding was examined by rapid urease tests (RUT), histology, culture, PCR, serology and urea breath tests (UBT).

RESULTS: The sensitivity of PCR was significantly higher than that of RUT, histology and culture (91% *vs* 66%, 43% and 37%, respectively; $P = 0.01$, <0.001 , <0.001 , respectively), but similar to that of serology (94%) and UBT (94%). Additionally, PCR exhibited a greater specificity than serology (100% *vs* 65%, $P < 0.01$). However, the specificity of PCR did not differ from that of other tests. Further analysis revealed significant differences in the sensitivities of RUT, culture, histology and PCR between the patients with and those without blood in the stomach ($P < 0.01$, $P = 0.09$, $P < 0.05$, and $P < 0.05$, respectively).

and specificity of the tests, and the cost effectiveness of the testing strategy. Because of its simplicity, accuracy and rapid determination of *H pylori* status, RUT is generally considered to be the initial endoscopic test of choice for uncomplicated peptic ulcers^[11]. However, many studies have demonstrated that RUT lacks sensitivity in *H pylori* diagnosis when peptic ulcer diseases are presented with bleeding^[5,12]. Moreover, a recent study by Colin *et al.*^[13], indicated that all direct tests on *H pylori* including RUT, culture and histology reduced the sensitivity in the setting of ulcer bleeding. The sensitivities of aforementioned three tests were 31%, 25% and 26%, respectively.

PCR can diagnose *H pylori* infection under non-bleeding conditions much more accurately than histology or culture^[14,15]. The level of sensitivity of this test is extremely high and has a threshold of 10 to 100 *H pylori* strains per specimen^[14-16]. An accurate diagnosis of *H pylori* at the time of bleeding episode is essential, but few studies have addressed the application of PCR to bleeding ulcers. We performed this prospective study to evaluate the sensitivity, specificity and accuracy of PCR assay for detecting *H pylori* infection in patients with bleeding peptic ulcers and to compare its diagnostic efficacy with that of other invasive and non-invasive tests.

MATERIALS AND METHODS

Patients

From April to September 2002, 60 consecutive patients with hematemesis, melena, or both due to gastroduodenal ulcer bleeding, who underwent an EGD, were enrolled in this study. Exclusion criteria included: age <15 or >80 years; history of coagulopathy or other disorders contraindicated for EGD or biopsy sampling; previous history of anti-*H pylori* therapy. Data regarding age, sex, medical history, drug history, presenting symptoms, gastroduodenal lesions and presence or absence of blood in the stomach were recorded. Written informed consent was obtained from each subject. This study was approved by the Human Medical Research Committee of the Kaohsiung Veterans General Hospital, Kaohsiung, Taiwan.

Endoscopy and biopsy sampling

During endoscopy, gastric biopsy specimens were taken from the lesser curvature of the antrum and corpus for RUT (one antrum biopsy specimen), histology (one antrum and one corpus biopsy specimen), culture (one antrum biopsy specimen) and PCR (one antrum biopsy specimen). Endoscopes were cleaned by a mechanical wash and then washed in an Olympus washing machine. They were then air-dried and cleaned with 70% ethanol.

RUT

RUT was performed according to our previous study^[17,18]. A biopsy specimen from antrum was immediately placed in 1 mL of a 10% solution of urea in deionized water (pH 6.8) to which two drops of 1% phenol red solution was added and incubated at 37 °C for up to 24 h. If the yellowish color around the area of inserted specimen changed to bright pink within the 24-h limit, the urease test was considered

positive. In our laboratory, the sensitivity and specificity of RUT were 96% and 91%, respectively^[17].

Histological examination

Biopsy specimens were fixed in 10% buffered formalin, embedded in paraffin, and sectioned. One 4-μm-thick section was cut and stained with hematoxylin-eosin to observe the presence of curved rod shaped bacteria on the mucosal surface^[19,20]. The specimens were interpreted by a histopathologist (H-H Tseng) blinded to the patient status and the results of other laboratory tests.

Culture

The specimen for culture was transferred with brain heart infusion on ice for microbiological examination and inoculated onto the CDC anaerobic blood agar (Becton Dickinson Microbiology System, Cockeysville, MD) according to our previous studies^[21,22]. The agar was incubated at 35 °C for two days in a micro-aerophilic gas mixture containing 5% O₂, 100 mL/L CO₂, and 85% N₂. Culture-positive patients were those with bacterial colonies grown in culture within 7 d. The organisms were identified as *H pylori* by Gram staining, colony morphology and positive oxidase, catalase and urease reaction.

PCR amplification

DNA extraction was performed using a commercially available kit (QIAamp Tissue kit, QIAGEN Inc., Valencia, CA) according to the manufacturer's instructions^[23]. The primers used were derived from the internal 411-bp fragment of the *urease A* gene as described by Clayton *et al.*^[24]: HPU1 (5'GCCAATGGTAAATTAGTT3') and HPU2 (5'CTCCTTAATTGTTTTTAC3'). Reactions were performed in a 25 μL volume in a thermal cycler 480 (Perkin Elmer Applied Biosystems, Foster City, CA). A reaction mixture contained 2.5 μL of extracted DNA, 0.5 μmol/L of each primer, 2.5 mmol/L of MgCl₂, 2.5 μL of 10× PCR buffer, 1 U of AmpliTaq DNA polymerase (Perkin-Elmer Corp., Foster City, CA) and 100 μmol/L of each of dATP, dCTP, dGTP and dTTP. The amplification cycle consisted of an initial denaturation at 94 °C for 1 min, primer annealing at 45 °C for 1 min, and extension for 5 min at 72 °C to ensure a full extension of the products. Samples were amplified in 35 consecutive cycles. The final cycle included a 7-min extension step to ensure a full extension of the PCR products. PCR products were analyzed on a 2% agarose electrophoresis gel stained with ethidium bromide.

UBT

UBT was performed according to our previous studies^[21,25] within 1 d of EGD. The patients were fasted for at least 6 h. Fresh milk (1 000 mL) was taken to delay gastric emptying. The test consisted of a baseline breath sample and a second breath sample collected 15 min after oral administration of 100 mg of ¹³C-labeled urea (INER-Hp C-tester, Taiwan) dissolved in 50 mL sterile water. Values were expressed as an excess $\delta^{13}\text{CO}_2\text{‰}$ excretion. The $\delta^{13}\text{CO}_2$ was the ratio of ¹³C to ¹²C in the sample compared to the Pee Dee Belemnite (PDB) standard. The equation was given as: $\delta^{13}\text{CO}_2 = (R_{\text{samp}} - R_{\text{std}}) / R_{\text{std}} \times 1\,000$. R_{samp} and R_{std}

represented the ratio of ^{13}C to ^{12}C in samples and standard, respectively. If the value of $\delta^{13}\text{CO}_2$ was more than 4.8‰, this was considered as a positive result.

Serology

Blood samples for serological evaluation were obtained before EGD. A serological assay for IgG antibodies against *H pylori* was performed by an indirect solid-phase immunochromatographic assay using the ASSURE™ *H pylori* rapid test kit (Genelabs Diagnostics, Cavendish Singapore Science Park, Singapore). The sensitivity and specificity of the assay were 96% and 92%, respectively according to the manufacturer's instructions.

Gold standard definition

A patient was classified as being *H pylori*-positive on the basis of either a positive culture or a negative culture, at least three positive results of RUT, histology, UBT and serological tests.

Statistical analysis

Statistical tests were performed using the SPSS system. Sensitivity, specificity, accuracy, predictive values of positive and negative results were calculated in accordance with standard methods. χ^2 test and 95%CI were used to compare the sensitivity, specificity and accuracy of different diagnostic methods. Two-sample *t*-tests were used to compare the excess $\delta^{13}\text{CO}_2$ values of UBT between the true-positive and false-negative groups of various invasive tests. $P < 0.05$ was considered statistically significant.

RESULTS

Of the 60 patients initially enrolled in this study, five did not complete all the tests and were excluded from the statistical analysis. Table 1 presents the demographic data of the remaining 55 patients (37 males, 18 females; mean age: 62.2 ± 14.5 years) who finished all of the invasive and non-invasive assays. EGD of these subjects showed a gastric ulcer in 19 patients (35%), a duodenal ulcer in 13 (24%) and both gastric and duodenal ulcers in 23 (42%). According to the gold standard definition, 35 (63.6%) were *H pylori*-positive and 20 (36.4%) were *H pylori*-negative.

Comparison of various tests for detecting *H pylori* infection in bleeding peptic ulcers

Table 2 presents the sensitivity, specificity and accuracy of various tests in diagnosing *H pylori* infection. The sensitivities

of RUT, histology and culture were low (66%, 43% and 37%, respectively) although these assays exhibited a high specificity (95–100%). Their overall accuracies were 76%, 62% and 60%, respectively. Among the four biopsy-based methods, only PCR exhibited the satisfactory sensitivity (91%), specificity (100%), and accuracy (94%). Its sensitivity and accuracy were significantly higher than those of RUT, histology and culture (sensitivity: $P < 0.05$, $P < 0.001$ and $P < 0.001$, respectively; accuracy: $P < 0.05$, $P < 0.001$, $P < 0.001$, respectively).

Of the non-invasive assays, the serological test had a high sensitivity (95%) but its specificity (65%) was lower than that of PCR ($P < 0.05$). The sensitivity (94%), specificity (85%) and accuracy (91%) of UBT were similar to those of PCR. Among all of the tests investigated herein, PCR and UBT were the most accurate methods for diagnosing *H pylori* infection in patients with bleeding peptic ulcers.

Relationship between intragastric blood and sensitivity of various tests in diagnosis of *H pylori* infection

The patients were divided into two groups according to the presence or absence of blood in the stomach, to investigate the relationships between intragastric blood and sensitivities

Table 1 Baseline characteristics of patients with bleeding peptic ulcers ($n = 55$)

of biopsy-based tests for *H pylori* infection. The sensitivities of RUT, histology, culture, PCR, serology and UBT were 29%, 21%, 21%, 79%, 93% and 100% in the patients with intragastric blood, respectively, and 90%, 57%, 48%, 100%, 95% and 91% in the patients without intragastric blood, respectively. There were statistically significant differences in the sensitivities of RUT, histology and PCR between the patients with and without blood in the stomach (Figure 1; $P < 0.01$, $P < 0.05$ and $P < 0.05$, respectively). Additionally, there was a trend towards decreased sensitivity of culture in the patients with blood in the stomach ($P = 0.09$).

Figure 1 Sensitivities of various tests for detecting *H pylori* infection between the bleeding ulcer patients with and without blood in the stomach.

Comparison of bacterial loads between true-positive and false-negative groups of biopsy-based tests

Since the quantitative data obtained by UBT could reflect the intragastric bacterial load of *H pylori*, we further compared the excess $\delta^{13}\text{CO}_2$ values of UBT between the true-positive and false-negative groups in biopsy-based tests. The excess $\delta^{13}\text{CO}_2$ values of RUT, histology, culture and PCR were 26.7 ± 18.1 , 31.5 ± 21.4 , 33.7 ± 21.8 and 26.3 ± 19.4 in the group with true-positive results respectively, and 20.5 ± 16.3 , 19.5 ± 16.3 , 19.3 ± 15.9 and 7.2 ± 2.6 in the group with false-negative results respectively. The excess $\delta^{13}\text{CO}_2$ values in the false-negative group were significantly lower than that in the true-positive group of culture test (Figure 2; $P = 0.03$). In addition, there was also a trend toward decreased $\delta^{13}\text{CO}_2$ values in the false-negative group of histological examination and PCR assay (both $P = 0.07$).

Figure 2 Comparison of the excess $\delta^{13}\text{CO}_2$ values of UBT between the true-positive and false-negative groups in the biopsy-based methods.

DISCUSSION

The *H pylori* status in a patient presenting with a bleeding ulcer must be documented to determine the method of further management. However, many studies have disclosed that biopsy-based tests including RUT, histology and culture have low sensitivities in detecting *H pylori* in bleeding peptic ulcers^[5,12,13]. Additionally, two recent reports^[26,27] also revealed a lack of accuracy in *H pylori* stool antigen (HpSA) tests in patients with ulcer bleeding. In this study, we also demonstrated that the sensitivities of RUT, histology and culture in bleeding peptic ulcer were only 66%, 43% and 37%, respectively. However, PCR could reach a diagnostic sensitivity of 91%, much higher than that of RUT, histology and culture. Additionally, the test had 100% specificity in diagnosing *H pylori* infection under bleeding conditions. This, therefore, is the most accurate biopsy-based method for determining *H pylori* status in bleeding peptic ulcers.

UBT is one of the non-invasive methods for diagnosing *H pylori* infection. Both its sensitivity and specificity are greater than 90% in patients with bleeding peptic ulcers. Its accuracy is comparable to that of PCR. Although the serological test has a high sensitivity in patients with bleeding peptic ulcers, it may not be a good choice for diagnosing *H pylori* infection in patients with a complicated ulcer because antibody tests lack a good specificity (only 65%). The presence of anti-*H pylori* IgG antibody implies prior exposure to the organisms, but does not imply the presence of a current infection. If a patient presenting with ulcer bleeding has a false-positive antibody test and is treated by eradication therapy, the physician may mistakenly believe that the cause of bleeding has been removed and will then not provide further preventive therapy to the patient. In such a case, the patient would have a high risk of recurrent bleeding^[6]. Therefore, establishing the *H pylori* status with certainty at the time of bleeding episode is quite important.

Following this work, we recommend that an endoscopist may initially perform a RUT to detect *H pylori* infection in a patient with bleeding peptic ulcer because of its simplicity, low cost, moderate sensitivity and excellent specificity. If the RUT is negative, either PCR or UBT can be used for the definite diagnosis of *H pylori* status. The choice of the final diagnostic modality may depend on the availability of tests in the hospital. Nonetheless, the aim of PCR is to detect specific DNA sequences rather than the whole viable bacterium. No special requirements pertain to the treatment, transport, or storage of the biopsy specimens for PCR^[28,29]. Several laboratories have reported the successful detection of *H pylori* by PCR from a biopsy specimen placed and transported by mail in the RUT^[16,30,31]. This capability is particularly useful for a gastroenterologist who does not have access to laboratory facilities and requires a confirmation of the RUT^[16].

In this study, the sensitivities of RUT, histology, culture and PCR were found to be 29%, 21%, 21% and 79% in patients with intragastric blood, and 90%, 57%, 48% and 100% in patients without intragastric blood. These data imply that blood may reduce the diagnostic yield of all endoscopic biopsy tests in patients with bleeding peptic ulcers. Additionally, we also demonstrated that the bacterial load in the false-negative group of culture was significantly lower

than that in the true-positive group. Furthermore, there was also a trend toward decreased bacterial load in the false-negative group of histological examination and PCR assay. The decreased bacterial density therefore, may be the major cause for decreased sensitivities of all biopsy-based assays. There are several possible reasons for the aforementioned findings. The decreased bacterial load in bleeding ulcer patients may be related to a direct suppression effect of intraluminal blood on *H pylori*, the administration of antisecretory drugs, or the removal of some *H pylori* from the gastric epithelium or mucus by gastric lavage before EGD^[32]. Recently, Leung *et al.*^[33], reported that a false-negative result of RUT in bleeding ulcer might be caused by the buffered effects of blood. An *in vitro* study^[34] also showed that sheep's blood inhibited the growth of *H pylori* in broth media. The exact reason concerning the association between bleeding ulcer and intragastric bacterial density merits further investigations.

In conclusion, PCR is the most accurate biopsy-based method for determining *H pylori* status in patients with bleeding peptic ulcers. RUT, histology and culture have a poor sensitivity under bleeding conditions. A decline in the intragastric bacterial density during bleeding ulcer may be a major cause of the reduced sensitivity of biopsy-based assays.

Abstract

AIM: To investigate the potential role of cytokines in promoting Fas ligand (FasL)-expressing colon cancer cells.

METHODS: Immunohistochemical SABC method was used to observe the expression of Fas receptor and ligand in SW620 colon cancer cell line and Jurkat T cells in order to provide the morphological evidence for the functions of Fas receptor and ligand. To examine the cytotoxicity of effector cells, CytoTox96® non-radioactive cytotoxicity assay was adopted to measure the lactate dehydrogenase-releasing value after SW620 cells were co-cultured with Jurkat T lymphocytes.

RESULTS: The FasL of colon cancer SW620 cells was positive. The positive substances were distributed in the cell membrane and cytoplasm. The Fas receptor of colon cancer SW620 cells was negative. The Fas receptor and ligand of Jurkat T lymphocytes turned out to be positive. The positive substances were distributed in the cell membrane. After phytohemagglutinin (PHA)-stimulated Jurkat T lymphocytes were co-cultured with phorbol 12-myristate 13-acetate (PMA)-plus-ionomycin-stimulated (for 48 h) SW620 cells or tumor necrosis factor-alpha (TNF- α)-stimulated (for 48 h) SW620 cells or unstimulated SW620 cells for 4 h, the cytotoxicity of SW620 cells to PHA-stimulated Jurkat cells at effector-to-target ratios of 10:1, 5:1, 2.5:1, and 1.25:1 was 74.6%, 40.8%, 32.4%, and 10.9% ($F = 8.19$, $P < 0.05$); or 54.9%, 35.3%, 22.0%, and 10.3% ($F = 11.12$, $P < 0.05$); or 14.9%, 10.5%, 6.9%, and 5.8% ($F = 3.45$, $P < 0.05$). After PHA-stimulated Jurkat T lymphocytes were co-cultured with unstimulated SW620 cells for 8 h, the cytotoxicity of SW620 cells to PHA-stimulated Jurkat cells at effector-to-target ratios of 5:1, 2.5:1, and 1.25:1 from the experiment was 83.9%, 74.1%, and 28.5% ($F = 137.04$, $P < 0.05$) respectively. Non-radioactive cytotoxicity assay showed that the apoptotic rate of Jurkat cells remarkably increased

with the increase of planting concentration of SW620 cells and co-culture time after the SW620 cells were co-cultured with the Jurkat T lymphocytes. The cytotoxicity was significantly enhanced by PMA+ionomycin or TNF- α .

CONCLUSION: The FasL expressed in human colon cancer cells may be regulated by endogenous factors in the microenvironment of the host and facilitate the escape of tumor cells from the host immune system.

INTRODUCTION

The Fas/Fas ligand (FasL) system plays an important role in the transduction of apoptotic signal into cells. In recent years, numerous studies have demonstrated that Fas is expressed on the surface of cells, whereas FasL expression is restricted to a small number of cell types, such as lymphocytes, cells of the immune-privileged organs and many types of malignant tumor cells^[1]. Evidence has pointed to an abnormal increase in apoptosis among activated Fas-positive lymphocytes, mainly in the periphery of the FasL-expressing tumors^[2]. On the other hand, the occurrence of tumor is due to the fact that the converted cells cannot undergo a normal process of apoptosis. Resistance to apoptosis through the Fas receptor pathway coupled with expression of the FasL might enable many cancers to deliver a pre-emptive strike or counterattack against the immune system^[2-4]. This study aimed to observe the interaction *in vitro* between T cells expressing Fas and tumor cells expressing FasL, and to investigate the potential role of FasL-expressing colon cancer cells *in vitro* and the effect of endogenous cytokines on tumor cells counterattacking T lymphocytes.

MATERIALS AND METHODS

Reagents, antibodies, and apparatus

Ionomycin, PMA, and phytohemagglutinin (PHA) were purchased from Sigma Chemical Co., USA. Tumor necrosis factor-alpha (TNF- α) and CytoTox96® non-radioactive

cytotoxicity assay kits were purchased from Promega Co., USA. RPMI1640 and DMEM were obtained from Gibco Co. Fetal bovine serum (FBS) was purchased from Hyclone Co. Monoclonal mouse anti-human CD95/FAS and monoclonal mouse anti-human FasL were purchased from Zhongshan Co., Beijing, China. SABC detection kit was purchased from Bosden Co., Wuhan, China. A-5082 Sunrise automated ELISA reader was purchased from Tecan, Austria.

Cell lines and cell culture

The human colon cancer cell line SW620 from American Tissue Culture Collection (ATCC) was kindly donated by Dr. Joe O'Connell, Cork University Hospital, Ireland. The acute T cell leukemia cell line Jurkat (ATCC) was provided by Institute of Hematology, Chinese Academy of Medical Sciences. The human glioma cell line TJ905 was kindly donated by Dr. Zhang WZ, Tianjin Huanhu Hospital, China. SW620 and TJ905 cells were cultured in DMEM supplemented with 100 mL/L FBS. Jurkat T lymphocytes were cultured in RPMI1640 medium (with 100 mL/L FBS) and stimulated with 4 mg PHA/L^[3]. All cell lines were incubated at 37 °C in a humidified 50 mL/L CO₂ atmosphere.

Immunocytochemical procedures for detection of FasL and Fas protein

Jurkat, TJ905, and SW620 cells were cultured on glass chamber slides respectively. After fixation in 4% paraformaldehyde for 60 min respectively, slides were washed twice for 5 min in a wash buffer containing 50 mmol/L Tris-Cl, pH 7.6, 50 mmol/L NaCl, and 0.001% saponin. Endogenous peroxidase was quenched with 3% hydrogen peroxide in methanol for 5 min. Slides were washed as before except that the wash buffer contained 1% normal goat serum, and then blocked for 1 h in wash buffer containing 5% normal goat serum^[5]. Slides were washed and incubated overnight at a dilution of 1:200 with monoclonal mouse anti-human primary antibodies at 4 °C in a high-humidity chamber. Antibody binding was localized using biotinylated secondary antibody, avidin-conjugated horseradish peroxidase, and diaminobenzidine substrate. Slides were counterstained with hematoxylin, washed for 1 h with PBS, air-dried and covered with mounting medium. Negative control slides were processed with PBS in place of primary antibodies.

Fas-mediated cytotoxicity assay

To examine the cytotoxicity of effector cells, CytoTox96® non-radioactive cytotoxicity assay^[6] was adopted to measure lactate dehydrogenase (LDH)-releasing value after SW620 or TJ905 cells (control) were co-cultured with Jurkat T lymphocytes. Jurkat cells were incubated with PHA (4 mg/L)^[3] in RPMI1640 (50 mL/L FBS) for 24 h and counted with a hemocytometer before cytotoxicity assay. SW620 or TJ905 cells (control) were seeded on 96-well U-bottom tissue culture plates (Falcon) at a density of 2×10^9 /L, 1×10^9 /L, 5×10^8 /L, and 2.5×10^8 /L respectively, and kept under controlled conditions or stimulated with 10 µg/L PMA+500 µg/L ionomycin or with 20 µg/L TNF-α for 48 h. For a further 24 h of culture PHA-stimulated Jurkat cells (2×10^4 in 100 µL) were added, keeping effector-to-target cell ratios at 10:1, 5:1, 2.5:1, and 1.25:1. PHA-stimulated Jurkat cells were co-

cultured with effector cells in 100 µL RPMI1640 medium (50 mL/L FBS) each well. Tissue culture plate was centrifuged at 250 r/min for 5 min at 4 °C to ensure cell-cell contact^[6]. In each experiment triplicate wells were analyzed. At the same time, the values of effector cell spontaneous LDH release, target cell spontaneous LDH release, target cell maximum LDH release, volume correction control, and culture medium background were measured. Then the following formula was applied in the calculation of percent cytotoxicity: $\text{cytotoxicity (\%)} = (\text{experimental LDH release} - \text{effector cell spontaneous LDH release} - \text{target cell spontaneous LDH release}) / (\text{target cell maximum LDH release} - \text{target cell spontaneous LDH release}) \times 100$.

Statistical analysis

Results were compared by analysis of variance (ANOVA) using SPSS10.0 software. $P < 0.05$ was considered statistically significant.

RESULTS

Immunocytochemical detection of FasL and Fas protein in SW620, Jurkat and TJ905 cells

FasL expression in colon cancer SW620 cells was strongly positive. The positive substances were distributed in the cell membrane and cytoplasm (Figure 1A), while Fas expression in SW620 cells was negative (Figure 1B). Fas and FasL expression in Jurkat T lymphocytes turned out to be positive. The positive substances were distributed in the cell membrane and cytoplasm, while the nuclei of the cells were negative (Figures 1C and D). Fas expression in TJ905 cells was positive. The positive substances were distributed in the cell membrane and cytoplasm (Figure 1E). FasL expression in TJ905 cells was weakly positive (Figure 1F).

Results of cytotoxicity assay

After the SW620 cells were co-cultured with the PHA-stimulated Jurkat T lymphocytes for 4 h, the cytotoxicity (Figure 2) of SW620 cells to PHA-stimulated Jurkat cells at different effector-to-target ratios had significant differences ($F = 3.45$, $P < 0.05$). After stimulation with 10 µg/L PMA+500 µg/L ionomycin for 48 h, the SW620 cells were co-cultured with the PHA-stimulated Jurkat T lymphocytes for 4 h. The cytotoxicity (Figure 2) of SW620 cells to PHA-stimulated Jurkat cells at different effector-to-target ratios had significant differences ($F = 8.19$, $P < 0.05$). After stimulation with 20 µg/L TNF-α for 48 h, the SW620 cells were co-cultured with the PHA-stimulated Jurkat T lymphocytes for 4 h. The cytotoxicity (Figure 2) of SW620 cells to PHA-stimulated Jurkat cells at different effector-to-target ratios had significant differences ($F = 11.12$, $P < 0.05$). After the SW620 cells were co-cultured with the PHA-stimulated Jurkat T lymphocytes for 8 h, the cytotoxicity of SW620 cells to PHA-stimulated Jurkat cells at effector-to-target ratios of 5:1, 2.5:1, and 1.25:1 was 83.9%, 74.1%, and 28.5% respectively and had significant differences ($F = 137.04$, $P < 0.05$). The cytotoxicity of Jurkat cells after co-culture with SW620 (different effector-to-target ratios) for 8 h was much higher than that after being co-cultured with SW620 (different effector-to-target ratios) for 4 h ($P < 0.05$, Table 1).

Figure 1 Expression of FasL and Fas in SW620 cells (A and B), Jurkat cells (C and D), and TJ905 cells (E and F).

Figure 2 Comparison of cytotoxicity assay among three groups.

After PMA-plus-ionomycin-stimulated (for 48 h) SW620 cells or unstimulated SW620 cells were co-cultured with PHA-stimulated Jurkat T lymphocytes for 4 h, the cytotoxicity of PMA-plus-ionomycin-stimulated SW620 cells was much higher than that of control. The cytotoxicity had significant differences between the two groups ($P<0.05$, Table 1). After TNF- α -stimulated (for 48 h) SW620 cells or unstimulated SW620 cells were co-cultured with PHA-stimulated Jurkat T lymphocytes for 4 h, the cytotoxicity of TNF- α -stimulated SW620 cells was much higher than that of control. The cytotoxicity had significant differences between the two groups ($P<0.05$, Table 1).

After the TJ905 cells were co-cultured with the PHA-stimulated Jurkat T lymphocytes for 4 h, the cytotoxicity of TJ905 cells to PHA-stimulated Jurkat cells at different effector-to-target ratios had no differences ($F = 0.25$, $P>0.05$).

TJ905 cells were not cytotoxic to Jurkat cells. After the TJ905 cells were co-cultured with the PHA-stimulated Jurkat T lymphocytes for 8 h, the cytotoxicity of TJ905 cells to PHA-stimulated Jurkat cells at different effector-to-target ratios had no differences ($F = 2.92$, $P>0.05$). TJ905 cells were not cytotoxic to Jurkat cells. After the TJ905 cells were stimulated with 10 $\mu\text{g/L}$ PMA+500 $\mu\text{g/L}$ ionomycin for 48 h, the TJ905 cells were co-cultured with the PHA-stimulated Jurkat T lymphocytes for 4 h. The cytotoxicity of TJ905 cells to PHA-stimulated Jurkat cells at different effector-to-target ratios had no differences ($F = 0.04$, $P>0.05$), TJ905 cells were not cytotoxic to Jurkat cells. After the TJ905 cells were stimulated with 20 $\mu\text{g/L}$ TNF- α for 48 h, the TJ905 cells were co-cultured with the PHA-stimulated Jurkat T lymphocytes for 4 h. The cytotoxicity of TJ905 cells to PHA-stimulated Jurkat cells at different effector-to-target ratios had no differences ($F = 0.97$, $P>0.05$), TJ905 cells were not cytotoxic to Jurkat cells. Cytotoxicity assay showed that no cytotoxicity to human glioma TJ905 cells was observed in the PHA-stimulated Jurkat T lymphocytes.

DISCUSSION

Fas is constitutively expressed in lymphocytes of normal subjects. After lymphocytes are triggered by inflammatory cytokines or tumor antigen, Fas expression is significantly augmented. Since the expansion of tumor-specific CD4 and CD8 cells is the current goal of many promising immunotherapeutic strategies, it is important to understand the factors that may influence the fate of such specific cells. Moreover, uncloned CD4 cell line originally isolated from human tumor tissue^[7]

as well as tumor-specific human cytotoxic T lymphocytes (CTLs) clones^[8] are also reported to express Fas *in vitro* and to be sensitive to its ligation. Recent evidence shows that tumor-infiltrating lymphocytes (TILs) exhibit significantly increased expression of Fas relative to peripheral blood lymphocytes^[9]. There is evidence that the lack of co-stimulatory signals such as B7.1, a feature of many tumors, promotes T-cell sensitivity to FasL in the tumor microenvironment^[10]. Since TILs are difficult to be isolated and expanded *in vitro*, we chose Jurkat T lymphocytes instead of TILs in our study.

Fas is expressed in each colonocyte of normal colon mucosa, and downregulated or lost in the majority of colon cancers. Immunohistology revealed that the majority of colon cancers express Fas at abnormally low levels or entirely lack Fas^[11]. Our results are compatible with these findings. Further more data have confirmed that colon cancer cell line is constitutively or at least relatively resistant to Fas-mediated apoptosis^[12,13]. Resistance to Fas-mediated apoptosis is a common feature of cancers, irrespective of cell surface expression of Fas^[14]. Thus, the downmodulation or abrogation of Fas on tumor cells and/or acquirement of relative resistance to Fas ligation might be a selection advantage, and constitute a mechanism of immune evasion to Fas-mediated killing by T cells^[15,16].

The FasL-expressing SW620 cell line is derived from a lymph node metastasis of primary colon cancer. The present study further confirmed that the expressed FasL was demonstrated to be functional, since co-culture experiments using FasL-expressing SW620 cells resulted in the apoptosis of Jurkat T leukemia cells that are sensitive to Fas-mediated apoptosis, which consequently may facilitate metastatic development. Our findings and other data suggest that tumor cells can evade immune attack by downregulating the Fas and inducing apoptosis in activated T lymphocytes through the expression of FasL. Furthermore, the constitutive expression of FasL in hepatic metastatic tumors suggests that FasL may also be important in their colonization in the liver through induction of apoptosis in the surrounding Fas-expressing hepatocytes^[17]. FasL expression in human colon cancers is associated with apoptotic depletion of TILs *in vivo*^[2]. In addition, upregulation of FasL expression probably induces killing of Fas-bearing tumor cells by promoting the selection of malignant tumor variants, because its Fas pathway has become insensitive to FasL binding. In the tumor microenvironment, IFN and other potentially relevant cytokines may be provided endogenously by immune system interaction, such as CD4⁺ T cells, following interaction with MHC class II⁺ antigen-presenting cells. Ag-specific CD8⁺ CTLs may then lyse cytokine-modified tumor cells through Fas-dependent and/or Fas-independent pathways, depending upon the intrinsic susceptibility of the tumor population to one or more immune effector mechanisms. Zeytun *et al.*^[18], reported a mutual killing model in which FasL⁺, Fas⁺ tumor cells, LSA and EL-4, kill Fas⁺ tumor-specific CTLs and are also killed by tumor-specific FasL⁺ CTLs. They concluded that the survival of the tumor or the host might depend on the cells which can accomplish FasL-based killing more efficiently. It is clear that the highly sophisticated and flexible adaptive immune response of higher vertebrates requires subtle regulation, particularly of receptors that can deliver

such a devastating outcome as cell death. Ding *et al.*^[19], reported that PMA+ionomycin and endogenous cytokines such as interleukin-18 (IL-18), TNF- α and IFN- γ upregulate the expression of FasL protein in human colon cancer cell lines DLD-1 and SW620. We further showed that the cytotoxicity was significantly enhanced by PMA+ionomycin and TNF- α . Since IFN- γ , TNF- α , and other potentially relevant cytokines are mainly secreted by activated T cells and macrophages, the upregulation of FasL in cancer cells in response to some cytokines may thus counterselect activated TILs and favor a microenvironment of T-cell anergy and the immune escape of cancer cells. Our data suggest that the FasL expressed in human colon cancer cells may be regulated by endogenous factors in the microenvironment of the host and facilitate the escape of tumor cells from the host immune system. Pages *et al.*^[20], observed that synthesis of IL-18 decreases or is abolished in colon adenocarcinomas compared to that in normal mucosa, thus resulting in decreasing IFN- γ production and impairing FasL-dependent cytotoxicity of immune cells. This feature is correlated with the existence of distant metastasis and an unfavorable outcome. Xu *et al.*^[21], reported that IFN- γ upregulates the expression of Fas and FasL in HT29 cells, a human colon adenocarcinoma cell line, and subsequently induces apoptosis of these cells in an autocrine and paracrine manner. However, it is important to note that many mechanisms of Fas-resistance can also occur, such as Fas-associated phosphatase-1, overexpression of bcl-2 and secretion of soluble Fas from tumor cells in a variety of human tumor cell lines that express Fas^[22,23]. TNF- α and IFN- γ are potent immunostimulatory cytokines with tumoricidal effects in a variety of cancers. But at the same time these cytokines might facilitate escape of tumor cells from the host immune system.

Taken together, we also considered a new mechanism of immune evasion, namely, the active destruction of T lymphocytes by tumor cells expressing CD95 ligand. It may provide insights into the processes of both tumor immunity and tumor escape for at least a potential subset or fraction of malignancies. Disarming the Fas counterattack is a conceptually appealing and exciting potential goal for tumor immunotherapy. Ongoing studies are aimed at further understanding the basis of Fas resistance and counterattack, thus determining how to restore tumor cell sensitivity to Fas or block expression or function of FasL in tumor cells.

ACKNOWLEDGMENTS

The authors thank Dr. Joe O'Connell (Cork University Hospital, Ireland) for generously providing the SW620 cell line. The authors also thank Dr. WZ Zhang for excellent technical assistance.

Abstract

AIM: To investigate the protective effect of isoflurane on energy balance in isolated hepatocytes during *in vitro* anoxia/reoxygenation, and to compare isoflurane with halothane.

METHODS: Hepatocytes freshly isolated from fed rats were suspended in Krebs-Henseleit buffer, and incubated in sealed flasks under O₂/CO₂ or N₂/CO₂ (95%/5%, V/V) for 30 or 60 min, followed by 5 or 10 min of reoxygenation, with an added volatile anesthetic or not. ATP, ADP, and adenosine monophosphate in hepatocytes were determined by high performance liquid chromatography, and energy charge was calculated.

RESULTS: During 30 min of anoxia, the energy charge and total adenine nucleotide steadily increased with the isoflurane dose from 0 to 2 minimum alveolar anesthetic concentration (MAC), then decreased from 2 to 3 MAC. In short incubations (30-35 min) at 1 MAC isoflurane, energy charge modestly decreased during anoxia, which was partially prevented by isoflurane and completely reversed by reoxygenation, and total adenine nucleotide did not decrease. In long incubations (60-70 min), both energy charge and total adenine nucleotide greatly decreased during anoxia, with partial and no reversal by reoxygenation, respectively. Isoflurane partly prevented decreases in both energy charge and total adenine nucleotide during anoxia and reoxygenation. In addition, 1 MAC isoflurane obviously increased ATP/ADP, which could not be changed by 1 MAC halothane.

CONCLUSION: Isoflurane partially protects isolated hepatocytes against decreases in both energy charge and total adenine nucleotide during short (reversible) or long (irreversible) anoxia.

INTRODUCTION

Hepatic anoxia, alone or as a component of ischemia, is an ever-present concern during abdominal surgery, because associated inhibition of energy supply threatens liver cell function and viability^[1,2]. Evidence is mounting that the inability of the liver to maintain or regain energy balance during and after surgery is one of the strongest predictors of liver damage and adverse outcome^[3,4]. Also, release from injured tissue of metabolites, such as adenosine, with cardiovascular effects may further compromise the anesthetic management of seriously ill or injured patients. Thus, surgeons and anesthesiologists need to be aware of, and to use, whatever measures are available to preserve energy balance in tissues.

The sum of ATP splitting by many concurrent energy-requiring reactions is called "ATP demand." ATP supply occurs mainly via mitochondrial oxidative phosphorylation, which is absolutely dependent on O₂. Under normal conditions, ATP supply easily keeps pace with ATP demand, and adenine nucleotide (high-energy phosphate) exists mainly in the form of ATP, along with relatively small amounts of ADP and adenosine monophosphate (AMP). However, when ATP supply is inhibited by lack of oxygen, ATP demand predominates, ADP and AMP then accumulate at the expense of ATP, and eventually adenosine and other non-nucleotide metabolites appear. Thus, shifts in the balance between ATP supply and demand can be assessed by measuring changes in the absolute and relative levels of ATP and its metabolites. A more complete and accurate expression is energy charge. Energy charge = (ATP+1/2ADP)/(ATP+ADP+AMP).

MATERIALS AND METHODS

Hepatocytes were isolated from adult male Sprague-Dawley rats (250-300 g) having free access to food and water^[5]. Livers were perfused *in situ* by using Ca²⁺-free Krebs-Henseleit buffer (pH 7.4) supplemented with 20 mmol/L

4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid, maintained at 37 °C and equilibrated with O₂/CO₂ (95/5). Perfusion was continued for 10 min with buffer alone, then for another 12–14 min with added collagenase (Type I, Sigma Chemical Co., St. Louis, MO). The softened liver was transferred to a plastic weighing dish containing 25 mL Krebs+2% dissolved bovine serum albumin, teased apart with a spatula and chopped finely with sharp scissors. After further dilution to 100 mL with Krebs+2% dissolved bovine serum albumin, the cell slurry was washed into a 500-mL Erlenmeyer flask, gently swirled under a flowing O₂/CO₂ (95%/5% V/V) atmosphere at 37 °C for 15 min, then filtered through nylon mesh. Each 12 mL of crude cell suspension was mixed with 28 mL Percoll (Pharmacia, Sweden, obtained from Sigma) and centrifuged at 10 000 *g* for 10 min. The layer of intact, purified hepatocytes at the bottom of the gradient was rinsed free of Percoll by suspension in Krebs and centrifugation for 2 min at 50 r/min. The final pellet contained a total of 2.4×10^8 cells that were 90–95% viable by dye exclusion. Cells were stored for 2 h on ice before use without loss of viability.

In 25-mL round-bottomed flasks, 12.5 million cells were suspended in a total volume of 2.5 mL Krebs+2% dissolved bovine serum albumin (pH 7.4). Flasks were sealed with rubber caps through which 14-gauge needles were inserted for in- and out-flow of gas mixture. After 10 min preincubation under O₂/CO₂, regassing and experimental incubations were carried out as follows: O₂/CO₂ for 35 or 70 min (= oxygenated), N₂/CO₂ for 30 or 60 min (= anoxic), or N₂/CO₂ for 30 or 60 min followed by O₂/CO₂ for 5 or 10 min, respectively (= reoxygenated). All incubations were performed by swirling the flasks in a water bath at 37 °C. When needed, anesthetics were added at the desired concentrations to the gas mixture used for gassing the flasks by means of a copper kettle vaporizer. Gas chromatography measurements established that anesthetic concentrations in liquid phase reached a constant value within 5–10 min. (The absolute concentrations in the liquid phase varied with anesthetic dose and cell concentration.) Incubations were terminated by injecting 0.5 mL 2 mol/L perchloric acid forcefully into the suspension to arrest enzyme-catalyzed reactions. After removal of precipitated membranes and protein by centrifugation, the clear supernatant containing extracted adenine nucleotides and other metabolites was neutralized with 2 mol/L potassium hydroxide and cooled on ice to precipitate excess potassium perchlorate. The supernatant was decanted and stored at -20 °C before metabolite measurements.

ATP, ADP, and AMP were analyzed by high performance liquid chromatography (LDC Analytical, Riviera Beach, FL, USA) using a CM4000 pump interfaced with a SM5000 detector. The separation was accomplished on a C18 reversed phase column. Elution with a binary gradient was carried out at a flow rate of 1.0 mL/min. Mobile phase A consisted of 30 mmol/L potassium phosphate as buffer (pH 6.0) and 8 mmol/L tetrabutylammonium hydrogen sulfate as ion-pairing reagent. Mobile phase B was identical except that it contained 500 mL/L methanol. Recovery of ATP, ADP, and AMP routinely exceeded 90–95%, as estimated from the concentration of caffeine added as an internal standard.

Statistical analysis

Data were presented as mean \pm SD. One- or two-way analysis of variance with replications and Scheffé's or paired *t*-tests were used for statistical analysis. *P* < 0.05 was considered statistically significant.

RESULTS

Figure 1A shows the effect of isoflurane dose on adenine nucleotide levels in isolated hepatocytes after exposure to anoxia for 30 min. ATP levels increased and AMP levels decreased from their respective control values as isoflurane increased from 0 to 2 minimum alveolar anesthetic concentration (MAC, 0–3% concentration), with a slight reversal from 2 to 3 MAC (3–5% concentration). Total adenine nucleotide increased to a lesser degree with isoflurane dose and was significantly higher than baseline only at 2 MAC. Values of ADP did not change significantly from baseline at any dose of isoflurane. Values of energy charge (not shown) paralleled those of ATP.

Figure 1B shows data obtained from incubations performed for 30–35 min. In cells incubated under O₂ for 35 min, amounts of ATP were maximal and balanced by relatively small amounts of ADP and AMP. Isoflurane slightly decreased ATP while increasing ADP and AMP. Although changes in individual nucleotide concentrations were not statistically significant, they combined to produce a significant decrease in energy charge.

In cells anoxic for 30 min (under N₂ rather than O₂), ATP substantially decreased and ADP and AMP increased compared to oxygenated cells. The associated decrease in energy charge confirmed that anoxia shifted energy balance toward a much lower degree of phosphorylation in the adenine nucleotide pool. When isoflurane was present during anoxia, ATP remained significantly higher and AMP lower than in anoxic cells without isoflurane. These two effects of isoflurane combined to maintain a proportionately higher value of energy charge.

Cells exposed to 30 min of anoxia followed by 5 min of reoxygenation showed values of all three adenine nucleotides and energy charge that were not significantly different from those of cells exposed to O₂ continuously for 30 min. Furthermore, no difference in any of these variables was seen for +isoflurane compared to -isoflurane.

Figure 1C shows results obtained from a second set of cell preparations subjected to incubations for 60–70 min. In cells incubated under O₂ alone for 70 min, absolute and relative amounts of ATP, ADP, and AMP were not significantly different from those incubated for 30 min. The changes produced by inclusion of isoflurane along with O₂ decreased ATP, increased ADP and AMP, and a statistically significant decrease in energy charge were only slightly (and not significantly) larger than in cells incubated for 35 min.

In cells that were anoxic (exposed to N₂) for 60 min, values of ATP, ADP, AMP, total adenine nucleotide, and energy charge were all significantly lower than in cells exposed to anoxia for 30 min. The effects of including isoflurane during anoxia were also generally more pronounced in cells exposed to anoxia for 60 min: compared to values in the absence of isoflurane, ATP was more than double and energy charge almost double, ADP and total

Figure 1 Dependence of ATP, ADP, AMP and total adenine nucleotide and energy charge in isolated hepatocytes on isoflurane during 30 min exposure to anoxia (A), anesthetic and oxygenation status during 30-35 min incubation (B) and during 60-70 min incubation (C). Iso, isoflurane; O₂, oxygenated; N₂,

anoxic; ReO₂, reoxygenated after anoxia. Values shown are means for $n = 8$ experiments. ^a $P < 0.05$ vs initial values at 0% isoflurane; ^c $P < 0.05$ vs control groups (isoflurane absent).

adenine nucleotide were significantly higher while AMP was not significantly lower.

Reoxygenated cells incubated for longer periods (N₂ for 60 min, O₂ for 10 min) differed greatly from cells subjected to shorter incubations (N₂ 30 min, O₂ 5 min), whereas values of ADP and AMP were not much different from those of oxygenated cells. Energy charge, ATP and total adenine nucleotide were drastically decreased. Another difference between longer and shorter incubations of reoxygenated cells was that in the longer ones, isoflurane-related differences in energy status persisted into the reoxygenation period; increases in ATP, ADP, and total adenine nucleotide during anoxia were maintained during reoxygenation.

Table 1 shows the data from a separate experiment carried out solely to compare isoflurane and halothane at approximately 1 MAC for their ability to alter energy status in isolated hepatocytes during 30-min exposure to anoxia. ATP/ADP was again higher with 1 MAC isoflurane present than in paired control incubation (isoflurane absent) using cells from the same preparation. With 1 MAC halothane, no difference at all in ATP/ADP during anoxia was seen, each incubated in the presence and absence of that agent.

Table 1 Different effects of isoflurane and halothane on energy status in hepatic cells during 30 min exposure to anoxia (mean±SE)

ATP/ADP	Isoflurane		Halothane	
	O ₂	N ₂	O ₂	N ₂
Non-anesthetics Group	5.3±0.6	0.7±0.1	7.4±1.1	1.1±0.3
Anesthetics Group	4.8±0.5	1.2±0.1 ^a	7.3±1.5	1.2±0.2

^a $P < 0.05$ vs non-anesthetics group, $n = 8$.

DISCUSSION

Intact isolated hepatocytes embody a physiologic balance of the reactions involved in ATP supply and demand in a form that permits uniform control and ready measurement of biochemical variables. We have studied these cells extensively under simulated intra-operative conditions to predict energetic responses at the tissue and organ level.

The data in Figure 1B show that the energy-protective

effect of isoflurane in anoxic hepatocytes varied in a systematic way with isoflurane dose. There was a graded dose-response relationship from 0 to 2 MAC, with a slight reversal of protection at 3 MAC. It seems that, at least in isolated cells, the energy-protective effect of isoflurane is optimal in the dose range used for clinical anesthesia. The basis for the response “ceiling” at 2 MAC awaits an understanding of the biochemical basis of the protective effect. An important question still to be addressed in this line of investigation is the extent to which the protective effect is associated with the anesthetic state. Is this effect limited to isoflurane or to other halogenated or volatile agents? Does ED₅₀ for the protective effect correlate with MAC?

In the shorter incubation (30-35 min) that examined varying oxygenation status, 1 MAC isoflurane tended to decrease ATP and increase ADP and AMP in cells exposed to oxygen, presumably because isoflurane inhibits mitochondrial recycling of ADP to ATP via oxidative phosphorylation^[6,7]. An opposite and larger effect of isoflurane on energy status was found in anoxic cells: superimposed on the great decrease in ATP and energy charge produced by anoxia, the effect of isoflurane was to enhance energy balance rather than to further impair it. In reoxygenated cells, there were neither protective nor detrimental effects of isoflurane on energy balance; and isoflurane produced no effect at all on any of the measured variables of energy status. The similarity between reoxygenated and continuously oxygenated cells indicates that exposure to 30-min anoxia with or without isoflurane has no irreversible effect on the energy status of hepatocytes.

The longer incubation (60-70 min) produced physiologically significant and/or irreversible effects of anoxia on cellular energy status. As in the 35-min incubation, data from cells oxygenated for 70 min showed that non-anoxic injury might have occurred during that period of incubation. The similarities in ATP, ADP, AMP, and total adenine nucleotide values suggest that the longer period of incubation is well tolerated, because damaged cells rapidly lose adenine nucleotides. The effects of anoxia on adenine nucleotide content and energy balance were considerably greater after 60-min exposure to anoxia than after 30-min exposure to anoxia. In anoxic cells after 60-min exposure to anoxia, there was a great decrease in total adenine nucleotide compared to oxygenated cells (P

none at 30 min), the decrease in energy charge was also greater after 60-min exposure to anoxia than after 30-min exposure to anoxia. In reoxygenated cells, none of the effects of 60-min exposure to anoxia were reversed, in contrast to all of the effects of 30-min exposure to anoxia. The importance of total adenine nucleotide in limiting the levels of ATP, ADP, and AMP during brief recovery from anoxia was shown clearly by the almost identically lowered values of total adenine nucleotide in corresponding anoxic and reoxygenated cells after 70-min exposure to anoxia. Also, in contrast to the shorter incubation, in the longer incubation the protective effect of isoflurane was observed during anoxia-increased energy charge and total adenine nucleotide was persistent through the reoxygenation period.

As mentioned earlier, the measured values of ATP, ADP, and AMP concentrations and the calculated values of total adenine nucleotide and energy charge in isolated hepatocytes are sensitive indicators of changes in the dynamic balance of ATP supply and demand. The anesthetic effects reported here may well be due to the direct action of the drug on one or more of the intracellular reactions involved in producing or consuming ATP^[8-10]. The results of other studies suggested that the protective effect of isoflurane may be due to "decreased metabolism" and, more precisely, due to inhibition of ATP demand^[11-13]. The conclusion holds also for the findings of the present study. Previous studies showed that isoflurane causes a dose-related decrease in O₂ consumption in isolated hepatocytes^[14]. However, it would be erroneous to conclude that this decrease in O₂ consumption reflects primary inhibition of ATP demand (with secondary inhibition of mitochondrial oxidative phosphorylation via respiratory control), because volatile anesthetics are also able to inhibit oxidative phosphorylation directly^[15,16]. In fact, inhibition of ATP demand in intact cells can be ascertained only by direct measurement of ATP consumption.

Two possible mechanisms may be mentioned by which decreased AMP formation can maintain ATP levels. An anoxia-induced increase in AMP promotes its degradation to adenosine and other non-nucleotide metabolites^[17]. The latter step seems to be a physiologic "point of no return", because ATP is not easily resynthesized from its non-nucleotide metabolites when oxygen and ATP supply are restored^[17]. Thus, a decrease in AMP formation would decrease the rate of ensuing AMP degradation and loss of total adenine nucleotide. Also, a decrease in AMP formation from ADP via inhibition of adenylate kinase can preserve the availability of ADP for conversion back to ATP via glycolysis.

The present study demonstrates that 1 MAC isoflurane actually helps to preserve liver cell energy balance during anoxia (whereas 1 MAC halothane has no such effect). The demonstration of this protective effect might be crucially dependent on the specific experimental conditions used in this study. Relatively short periods of anoxic exposure may prevent enzymes that catalyze ATP-consuming reactions from being degraded to the extent that inhibition of their activity by isoflurane could not be detected. Also, the use of anoxia (0% O₂) rather than hypoxia may eliminate vestiges of mitochondrial ATP formation, anesthetic inhibition of which may decrease ATP/ADP and thus opposing or even

canceling ATP/ADP increases resulting from anesthetic inhibition of ATP consumption^[18,19].

For optimal anesthetic and surgical care, we need to know as much as possible about the effects and actions of the drugs we use, especially with regard to a process as essential as energy balance. The work described here has documented certain effects of isoflurane on ATP supply and demand at the cellular level and laid the groundwork for explaining them in terms of actions on specific biochemical reactions that produce and consume ATP. In addition to further elucidate such basic mechanisms, we also need to examine the consequence of these cellular effects in physiologic and clinical terms, by using more intact systems and measures of outcome.

Abstract

AIM: To assess the effectiveness and safety of perioperative growth hormone (GH) in patients undergoing abdominal surgery.

METHODS: We searched the following electronic databases: MEDLINE, EMBASE, the Cochrane Controlled Trials Register, Chinese Bio-medicine Database. The search was undertaken in February 2003. No language restrictions were applied. Randomized controlled trials (RCT) comparing GH with placebo in patients undergoing abdominal surgery were extracted and evaluated. Methodological quality was evaluated using the Jadad scale.

RESULTS: Eighteen trials involving 646 patients were included. The combined results showed that GH had a positive effect on improving postoperative nitrogen balance (standardized mean difference [SMD] = 3.37, 95%CI [2.46, 4.27], $P < 0.00001$), and decreasing the length of hospital stay (weighted mean difference [WMD] = -2.07, 95%CI [-3.03, -1.11], $P = 0.00002$), and reducing the duration of postoperative fatigue syndrome (SMD = -1.83, 95%CI [-2.37, -1.30], $P < 0.00001$), but it could increase blood glucose levels (WMD = 0.91, 95%CI [0.56, 1.25], $P < 0.00001$).

CONCLUSION: GH for patients undergoing abdominal surgery is effective and safe, if blood glucose can be controlled well. Further trials are required with a sufficient size to account for clinical heterogeneity and to measure other important outcomes such as infection, morbidity, mortality, fluid retention, immunomodulatory effects, and tumor recurrence.

INTRODUCTION

Catabolism and negative nitrogen balance is a part of the metabolic reaction to major abdominal surgical trauma. It is a concern to surgeons because the catabolic response is correlated with the overall surgical morbidity rate, causing prolonged convalescence. Growth hormone (GH) has been shown to have anabolic effects and to reduce or even prevent nitrogen catabolism in patients undergoing abdominal surgery. The effect of GH has recently been studied by many researchers. In 1974 Wilmore *et al.*^[1], suggested that adequate nutritional intake was necessary for GH to have nitrogen-saving effects. In 1986 the study by Phillips^[2] demonstrated that GH stimulated hepatic production of somatomedin (insulin-like growth factor-I, IGF-I) whose action could promote diverse anabolic processes, such as synthesis of RNA, DNA, proteins or proteoglycans. However, the effects of GH on nonmetabolic clinical outcome remain unclear.

Meta-analysis has been gradually used in medicine to improve the statistical efficiency, to evaluate the disadvantages of formulated researches and hypothesis, and to reach reliable conclusions from the mixed assortment of potentially relevant studies to determine the most promising directions for future researches. We performed a meta-analysis of available studies to assess the effectiveness and safety, in order to improve our understanding of the clinical effects of perioperative GH treatment of patients undergoing abdominal surgery; clinical outcomes including nitrogen balance, length of hospital stay, blood glucose, and postoperative fatigue syndrome were measured. Other important outcomes, such as infection, morbidity, mortality, fluid retention, immunomodulatory effects and tumor recurrence, were also measured.

MATERIALS AND METHODS

Identification of trials

Our aim was to identify all relevant randomized controlled trials (RCT) that compared GH with placebo in patients undergoing abdominal surgery. A RCT was defined as a

trial in which patients were assigned prospectively to one of two interventions by random allocation. We used a multimethod to identify relevant studies for the present review. A computerized literature search of MEDLINE from 1966 to October 2002 was conducted using the following search terms: operation OR surgery OR postoperative OR perioperative AND GH AND RCT (publication type) or controlled clinical trials or clinical trials, randomized. In addition, we searched Embase (1980-2002), Cochrane Controlled Trials Register (Issue 1, 2003), and Chinese Biomedicine Database (1979-2002), reviewed our personal files, and contacted experts in the field. Bibliographies of all selected articles and review articles that included information on GH were reviewed for other relevant articles. This search strategy was done iteratively, until no new potential, randomized, controlled trial citations were found on review of the reference lists of retrieved articles.

Study selection and data extraction

The following selection criteria were used to identify published studies for inclusion in this analysis: study design - randomized clinical trial, population - hospitalized adult patients undergoing abdominal surgery, intervention - GH *vs* placebo initiated at the same time and with the same nutrition support, and outcome variables - at least one of the following primary outcome variables: nitrogen balance, length of hospital stay, blood glucose, postoperative fatigue syndrome, incidence of infection, morbidity, mortality, fluid retention, immunomodulatory effects, and tumor recurrence. Study selection and data abstraction were conducted independently by the two investigators.

Data analysis

The incidences of infection, tumor recurrence, fluid retention, morbidity, and mortality were treated as binary variables. Nitrogen balance, length of hospital stay, blood glucose, postoperative fatigue syndrome, and immunomodulatory effects were treated as continuous variables. Data analysis was performed using the random effect model with meta-

analysis software (RevMan 4.2; Cochrane Collaboration, Oxford, UK). The continuous data outcomes were presented with 95% confidence intervals (CIs). When authors reported standard deviations, we used them directly. When standard deviations were not available, we computed them from the observed mean differences (either differences in changes or absolute readings) and the test statistics. When the test statistics were not available, given a *P* value, we computed the corresponding test statistics from tables for the normal distribution. We tested heterogeneity between trials with χ^2 tests, with *P*<0.05 indicating significant heterogeneity^[3]. Methodological quality was evaluated using the Jadad scale^[4].

RESULTS

From 460 articles screened, 38 were identified as RCT comparing GH with placebo and included for data extraction. Twenty studies were excluded, and the remaining 18 trials were included in the present meta-analysis^[5-22]. Only one study^[19] was in Chinese. Articles were excluded for the following reasons, namely the outcomes of interest were not recorded^[23-37] and some articles repeated^[38-42]. A total of 646 patients were enrolled in the included studies. The characteristics of studies included in meta-analysis comparing GH with placebo are presented in Table 1. Not all of the studies reported the outcome of interest, postoperative nitrogen balance was reported in 11 studies^[5-15], length of hospital stay in 3 studies^[17-19], postoperative fatigue syndrome in 3 studies^[20-22], blood glucose in 6 studies^[12-17].

The combined results showed that GH had a positive effect on improving the postoperative nitrogen balance (standardized mean difference [SMD] = 3.37, 95%CI [2.46, 4.27], *P*<0.00001) (Table 2A), and decreasing the length of hospital stay (weighted mean difference [WMD]=-2.07, 95%CI [-3.03, -1.11], *P* = 0.00002) (Table 2B), and reducing the duration of postoperative fatigue syndrome (SMD = -1.83, 95%CI [-2.37, -1.30], *P*<0.00001) (Table 2C), but it could increase blood glucose levels (WMD = 0.91, 95%CI [0.56, 1.25], *P*<0.00001) (Table 2D).

Test for heterogeneity: $\chi^2 = 23.97$, $df = 5$ ($P = 0.0002$), $I^2 = 79.1\%$. Test for overall effect: $Z = 5.13$ ($P < 0.00001$).						

DISCUSSION

The results must be interpreted with the difference in patients, dose or length of treatment, and unexplained heterogeneity. Clinical heterogeneity in the form of age, etiology and operation of patients points to the possibility of bias.

This meta-analysis did not show that GH had a positive effect on improving postoperative nitrogen balance. Eleven studies involving 233 patients were included. Although there was a heterogeneity (test for heterogeneity $\chi^2 = 44.48$, $df = 10$, $P < 0.00001$), the result was sure. Because all the 11 studies showed that GH had a positive effect on improving postoperative nitrogen balance with a statistical significance (minimum of SMD = 1.24, 95%CI [0.24, 2.25]). However,

it seems that different doses had different effects, subgroup was not used. What attention should be paid to is that some studies only reported the cumulated nitrogen balance or the daily nitrogen balance. Further research should be done to assess the possible best dose.

To date, only three studies involving 218 patients, have examined whether treatment with GH could influence the length of hospital stay. The combined results showed that administration of GH could decrease the length of hospital stay. The results must be interpreted with caution due to the small size. Two of three trials^[17,18] showed statistically and clinically significant differences in the length of hospital stay. So, further trials are required with a sufficient size to

account for clinical heterogeneity and length of hospital stay.

This meta-analysis showed that administration of GH could reduce the duration of postoperative fatigue syndrome after 1 mo. Three studies involving 84 patients were included. The evidence was not strong due to the small size and unexplained heterogeneity. It is also important to recognize that two^[20,21] of the RCTs included in this review were not designed specifically to reduce postoperative fatigue and provided few or no theoretical rationales as to why the intervention under study might be expected to attenuate it. Attempts to assess fatigue objectively by measuring, for example, physical activity, time taken to return to normal routine, or involuntary or voluntary muscle force were problematic because they could be confounded by numerous factors including pain and anxiety. Much effort has therefore been devoted to developing short and easy-to-use questionnaires that could provide some quantification of a patient's subjective feeling of fatigue. Future research should ensure that an adequate measure of subjective fatigue is employed, possibly in tandem with important objective measures, such as time taken to return to work.

This meta-analysis did not show that GH might increase blood glucose levels. Six studies involving 265 patients were included. Of the six, only the study of Jiang *et al.*^[14], did not reach a statistical significance (SMD = 0.11, 95%CI [-0.36, 0.58]). Low-dose GH and hypocaloric nutrition may be the reason. Confirmation of the diabetogenic properties of GH was made after it was administered in excess to experimental animals and men. Transgenic animals, which over-expressed GH, developed insulin resistance, marked hyperinsulinemia, hyperglycemia, and hypertriglyceridemia in association with a number of molecular abnormalities^[43,44]. Patients with acromegaly developed insulin resistance and hyperinsulinemia, while up to 40% became diabetic^[45,46]. There is evidence that insulin resistance caused by GH plays an important role in the rise of blood glucose. In addition, GH could stimulate lipolysis with the release of glycerol and non-esterified fatty acids (NEFA). This provides a further mechanism for the diabetogenic properties of GH through the effect of NEFA to increase hepatic glucose output and decrease peripheral glucose oxidation according to the glucose-fatty acid cycle^[47,48]. In fact, in the study of Berman *et al.*^[23], the GH group had significantly elevated urine glucose levels throughout the study period, consistent with the demonstrated hyperglycemia and only moderately elevated insulin levels. Treatment with GH did result in hyperglycemia, and two patients were removed from the study. Hyperglycemia associated with GH administration could be treated easily by insulin, especially in long-term GH administration.

Only one RCT^[36] conducted an analysis of a multicenter study with 104 patients undergoing major gastrointestinal surgery to assess the risk of long-term tumor recurrence after short-term (5 d) postoperative GH treatment. The study was a follow-up of a previous randomized study investigating the effect of three different doses of GH (0.075, 0.15, and 0.30 IU/kg/d) on the postoperative cumulative nitrogen balance in patients undergoing major surgery. Tumors recurred in 20 (35%) patients who were evaluated for and treated with GH ($n = 57$). This accounted for 4 of 17 (23%) patients given 0.075 IU/kg/d of GH, 9

of 20 (45%) given 0.15 IU/kg/d of GH, and 7 of 20 (35%) given 0.30 IU/kg/d. By comparison, tumors recurred in 8 of 18 (44%) of patients given placebo. The result of this study demonstrated that short-term treatment with GH for 5 d after major gastrointestinal surgery for adenocarcinoma did not increase the risk of tumor recurrence. But the group size was too small to further stratify the patients according to tumor type and tumor stage, so that no information was gained about the influence of GH dose in certain tumor stages.

Fluid retention is one of known side effects of GH administration. The sodium and fluid retaining impact of GH was demonstrated in humans almost 50 years ago by Ikkos *et al.*^[49]. Underlying mechanisms of GH-induced fluid retention are as follows. GH could increase glomerular filtration rate mediated by insulin-like growth factor (IGF-I)^[50-52], stimulate the renin-angiotensin-aldosterone system (RAAS)^[53-57], reduce atrial natriuretic factors^[58-61], and prostaglandins could play a role in GH-induced fluid retention^[62]. In the study of Berman *et al.*^[23], two GH patients were removed from the study for fluid retention. These patients were in the immediate postoperative period. However, whether the fluid retention was a result of surgery or GH administration could not be determined.

GH should not be given in acute inflammatory disease states. Findings by Takala *et al.*^[63], pointed to the immunomodulatory effects of GH. These authors described higher hospital mortality in a Finish and an European study on critically ill non-cancer patients. It was proposed that the higher mortality was due to the application of GH at a later stage during the inflammatory disease process, leading to uncontrolled systemic inflammation. However, infection was not measured in these trials except one^[17]. Only one RCT^[18] reported the morbidity and mortality, so we could not draw a conclusion due to the small size. But there are still four studies^[64-67] awaiting assessment in other languages or we cannot find the full text.

In conclusion, perioperative GH treatment of patients undergoing abdominal surgery can improve the postoperative nitrogen balance, and decrease the length of hospital stay, and reduce the duration of postoperative fatigue syndrome. But it might increase blood glucose levels. However, the evidence is not strong due to the difference in patients, dose or length of treatment, and unexplained heterogeneity. In order to examine the effectiveness and safety of perioperative GH treatment of patients undergoing abdominal surgery, further trials are required with a sufficient size to account for the clinical heterogeneity and to measure other important outcomes such as infection, morbidity, mortality, fluid retention, immunomodulatory effects, and tumor recurrence.

ACKNOWLEDGEMENTS

We are sincerely grateful to the principal investigators of all the trials who provided additional unpublished information. We also thank Susanne Ebrahim and Karla Bergerhoff for diligent working in Cochrane Metabolic and Endocrine Disorders Group and Ming Liu, He-Ming Huang, Bin Lv, Eewen, Jian-Kun Hu, Hua Jiang and Shu-Ai Xiao for providing additional references.

Abstract

AIM: To investigate the autofluorescence spectroscopic differences in normal and adenomatous colonic tissues and to determine the optimal excitation wavelengths for subsequent study and clinical application.

METHODS: Normal and adenomatous colonic tissues were obtained from patients during surgery. A FL/FS920 combined TCSPC spectrofluorimeter and a lifetime spectrometer system were used for fluorescence measurement. Fluorescence excitation wavelengths varying from 260 to 540 nm were used to induce the autofluorescence spectra, and the corresponding emission spectra were recorded from a range starting 20 nm above the excitation wavelength and extending to 800 nm. Emission spectra were assembled into a three-dimensional fluorescence spectroscopy and an excitation-emission matrix (EEM) to exploit endogenous fluorophores and diagnostic information. Then emission spectra of normal and adenomatous colonic tissues at certain excitation wavelengths were compared to determine the optimal excitation wavelengths for diagnosis of colonic cancer.

RESULTS: When compared to normal tissues, low NAD (P)H and FAD, but high amino acids and endogenous porphyrins of protoporphyrin IX characterized the high-grade malignant colonic tissues. The optimal excitation wavelengths for diagnosis of colonic cancer were about 340, 380, 460, and 540 nm.

CONCLUSION: Significant differences in autofluorescence peaks and its intensities can be observed in normal and adenomatous colonic tissues. Autofluorescence EEMs are able to identify colonic tissues.

INTRODUCTION

Colonic cancer is an important public health concern in industrialized countries and around the world. Diagnosis and localization of early carcinoma play an important role in the prevention and curative treatment of colonic cancer. However, physical biopsies do not fully solve this problem because they are sampled at random locations, which is highly dependent on the skill and experience of the investigator. As a result, a significant number of lesions, especially the carcinoma *in situ* lesions, are not sampled and subsequently diagnosed^[1,2]. Laser-induced autofluorescence depends on endogenous fluorophores in the biological tissue, which undergoes a change related to malignant transformations. Therefore, it is possible for us to develop more sensitive techniques for the detection of early colonic tissue. During the past two decades, autofluorescence spectroscopy has been investigated as an effective and noninvasive method for detecting and imaging the abnormal tissues from the surrounding normal tissues.

Measurement of three-dimensional fluorescence spectroscopy or fluorescence excitation-emission matrices (EEMs) for tissue samples *in vitro* is a crucial step to exploit the endogenous fluorophores and determine which excitation wavelengths contain the most diagnostic information for clinical diagnostic analysis^[3-6]. However, an important limitation of most studies on the autofluorescence diagnosis of colonic cancer is that the selection of excitation wavelengths is based on the availability of a special light source, and few studies have been done to understand the real reasons responsible for the spectral differences^[6-9]. In this study, we conducted the measurement of autofluorescence EEMs in order to investigate the spectroscopic differences in normal and adenomatous colonic tissues, and to further determine the optimal excitation wavelengths. It is hoped that information from this investigation may be useful for subsequent studies and clinical diagnosis.

MATERIALS AND METHODS

Adenomatous colonic tissues ($n = 5$) were obtained from four patients during surgery for malignant tumors of the colon, and normal tissue sample ($n = 4$, matched controls) was also collected from the same patient. Each tissue sample was cut into two specimens. One specimen was sent to the

pathologist for standard histopathological evaluation, the other unstained and unfixed specimen was placed on a non-fluorescence quartz substrate for laser-induced autofluorescence within 2 h after surgical resection.

Autofluorescence EEM was performed using a FL/FS920 combined TCSPC spectrofluorimeter and a lifetime spectrometer system (Edinburgh Instruments Ltd, UK). The wavelength-selected excitation light onto the sample with a 60° incident angle and fluorescence emission was collected at 45° with respect to the normal quartz substrate in order to minimize the detection of the backscattered excitation light. The slit sizes of excitation and emission monochromator were 1.5 and 0.5 mm, respectively. The wavelength dependence of the excitation power and the detector response was corrected and calibrated for all emission spectra. Fluorescence EEMs were recorded by measuring the fluorescence emission spectra over a range of excitation wavelengths. The excitation wavelengths varied from 260 to 540 nm in 20-nm increments. At each excitation wavelength, the fluorescence emission spectra were recorded from a range starting 20 nm above the excitation wavelength and extending to 800 nm at 5-nm intervals. These wavelength ranges enabled characterization of all endogenous fluorophores, tryptophan, collagen, and elastin, NAD(P)H, FAD and endogenous porphyrins, present in tissues in the UV-Vis spectrum^[10,11]. This resulted in a total measurement time about 25 min for each EEM. After each measurement, a repeat fluorescence spectrum was measured at 260 nm excitation and compared to that measured at the beginning of the experiment to confirm that the measurement protocol used did not induce photobleaching. Fluorescence data from each single measurement were then combined to construct EEM containing fluorescence intensity as a function of both excitation and emission wavelengths.

RESULTS

No significant differences were observed in the autofluorescence spectra of normal and cancerous tissues. However, remarkable differences in fluorescence peaks and intensities were detected between normal and adenomatous tissue from the same patient. The representative three-dimensional autofluorescence spectra for the normal colonic tissue and adenomatous colonic tissue are shown in Figures 1A and B, respectively. The relative fluorescence intensity was recorded as a function of both excitation and emission wavelengths. Although the fluorescence intensities were indicated in arbitrary units, the same experimental set-ups were maintained throughout our measurements for comparison.

The corresponding autofluorescence EEMs for normal and adenomatous colonic tissue are displayed in Figures 2A and B, respectively. The colorized scale represents different fluorescence intensities. The plots are shown on a log contour scale, where each contour connects points of equal fluorescence intensity.

In the case of autofluorescence EEM for normal colonic tissue in Figure 2A, the primary fluorescence peaks occurred at the excitation-emission wavelength pairs of 280-330, 350-480, 350/460-605, and 460-520 nm. According to the previous studies, these fluorescence peaks were attributed to the amino acids tryptophan and tyrosine, reduced nicotinamide adenine dinucleotide (NADH) or reduced nicotinamide adenine dinucleotide phosphate (NADPH), ceroid and flavin adenine dinucleotide (FAD), respectively^[10,12]. Adenomatous tissues exhibited emission peaks at 635 and 710 nm (Figure 2B) that were not observed in the emission spectra of normal colonic tissues. These remarkable peaks were the contribution of naturally occurring high endogenous porphyrins of protoporphyrin IX in cancerous tissues^[13-15]. Furthermore, the emission intensity from tryptophan and

Figure 1 Three-dimensional autofluorescence spectra for normal colonic tissue (A) and adenomatous colonic tissue (B).

Figure 2 Autofluorescence EEMs for normal colonic tissue (A) and adenomatous colonic tissue (B).

Figure 3 Fluorescence spectra of normal and cancerous tissues at excitation wavelengths of 280 (A), 340 (B), 380 (C), 460 (D), and 540 nm (E).

tyrosine was more intense in cancerous tissue than in normal tissue EEM. However, the endogenous fluorescence near 500 nm reduced in tumor tissues relative to normal colonic tissues. The differences might lie in the decrease of the oxidized forms of flavins and the relative amount of NAD(P)H in malignant tissues. As a result, low NAD(P)H and FAD but high amino acids and protoporphyrin IX accumulated in the human colonic malignancy. An evaluation of the average fluorescence spectrum at 260 nm excitation collected at the end of each EEM indicated that its peak fluorescence intensity was within 8% of that acquired at the beginning of each EEM. This means that minimal photobleaching occurred during the process of the 25-min EEM measurement.

In order to further determine the optimized excitation wavelengths for the diagnosis of colonic cancer, autofluorescence emission spectra at certain excitation wavelengths of 280, 340, 380, 460, and 540 nm for normal and adenomatous colonic tissues were compared in Figure 3, respectively. The greatest spectroscopic differences could be achieved for diagnosis of colonic cancer when the excitation wavelengths were 340, 380, 460, and 540 nm. In particular, the emission from endogenous phorphyrins of protoporphyrin IX demonstrably characterized the autofluorescence spectroscopy of cancerous tissues when the excitation wavelength was higher than 380 nm.

DISCUSSION

In this study, autofluorescence EEMs were measured using a standard spectrofluorimeter to determine the location of the endogenous fluorescent peaks and their relative intensity in normal and adenomatous colonic tissues. We observed significant differences in the autofluorescence spectra of normal tissues and adenomatous colonic tissues, and these

differences could be attributed to the differences in fluorophores expression. The endogenous fluorophores that are speculated to cancerous transformations are the amino acids tryptophan and tyrosine, the structural proteins collagen and elastin, the coenzymes NAD(P)H and FAD, and phorphyrins^[12].

Our results indicate that the fluorescence intensity of the amino acids tryptophan and tyrosine is dominant in both normal and cancerous colonic tissues at 280 nm excitation, which demonstrates the fact that amino acids are the basic structural units of protein and play an important role in biological tissues. These results also agree well with those of Pradhan *et al.*^[16], who suggested that there is an increase in tryptophan as cells progress from normal to cancerous state. Secondly, we observed that the intensity in the blue region of the autofluorescence spectra significantly reduced in adenomatous colonic tissues compared to normal tissues, which is in substantial agreement with the early work showing that the concentration of NADH and NADPH in adenomatous tissues is lower than that in normal tissues^[6,7]. Moreover, Anidjar *et al.*^[17], have demonstrated a decrease of FDA in cancerous tissues, which is proved in our research. However, Georgakoudi *et al.*^[18] and Drezek *et al.*^[19], suggested that low collagen and high NAD(P)H fluorescence characterize the high-grade dysplastic lesions when compared to nondysplastic cervix tissues. It is possible that the differences in NAD(P)H fluorescence may be due to different colonic and cervix tissues and the comparable measurements should be carried out for further confirmation. In addition, it should be noted that the emission specific peaks from collagen and elastin were not shown in our tissue EEMs except for one case, suggesting that the increments of excitation wavelength should be limited to 10 nm in order to exploit the emission fluorescence from structural proteins collagen and elastin. Bottiroli *et al.*^[7], have observed

a red fluorescence in some parts of tissue section from a cancerous colon. The red fluorescence has been reported by Moesta *et al.*^[13], and also demonstrated in this investigation, which can be definitely attributed to high endogenous porphyrins of protoporphyrin IX accumulating naturally in colonic cancer.

In summary, the presence or absence of fluorescence peaks in both normal and adenomatous colonic tissues can be explained by the different endogenous fluorophores to generate autofluorescence signals, and the ability of laser-induced autofluorescence EEMs to distinguish normal from cancerous colonic tissues. The present investigation offers evidence that low NAD(P)H and FAD but high amino acids and protoporphyrin IX characterize the high-grade malignant colonic tissues. Based on our results, the optimal excitation wavelengths for diagnosis of colonic cancer are 340, 380, 460, and 540 nm.

ACKNOWLEDGMENTS

We thank Professor Ming-Ren Li at the Department of Oncology of the First Affiliated Hospital of Fujian Medical University for providing the colonic tissue samples and the results of standard histopathological diagnosis.

Abstract

AIM: To evaluate the effects of dietary fiber (DF) as a part of enteral nutrition (EN) formula on diarrhea, infection, and length of hospital stay.

METHODS: Following electronic databases were searched for randomized controlled trials about DF: Chinese Biomedicine Database (CBM), MEDLINE, EMBASE and Cochrane Controlled Trials Register. RevMan 4.1 was used for statistical analysis.

RESULTS: Seven randomized controlled trials with 400 patients were included. The supplement of DF in EN was compared with standard enteral formula in five trials. Combined analysis did not show a significant reduction in occurrence of diarrhea, but there were valuable results for non-critically ill patients. Combined analysis of two trials observing the infection also did not show any valid evidence that DF could decrease the infection rate, though the length of hospital stay was reduced significantly.

CONCLUSION: Based on the current eligible randomized controlled trials, there is no evidence that the value of DF in the diarrhea can be proved. Though length of hospital stay was shortened by the use of DF, there is no available evidence in preventing infection by DF. Further studies are needed for evaluating the value of DF in EN.

INTRODUCTION

Dietary fiber (DF) is a category of carbohydrates that cannot be ingested by endogenic digestive enzymes in human body^[1].

Nevertheless, DF can be fermented into methane, hydrogen, CO₂, and short-chain fatty acid (SCFA) by bowel microflorae. SCFA, a primary important energy substance for colonic mucosal epithelium, is essential to maintain the metabolism and regeneration of epithelia, protect the structure and function, promote absorption of water and sodium, and regulate the function of bowel^[2-6]. Recent studies also suggest that SCFA can protect the intestinal barrier and prevent bacterial translocation^[7-9]. So DF has been widely recommended as an essential component of enteral nutrition (EN) in the last 20 years^[10-13]. It is believed that DF may play an important role in controlling diarrhea associated with EN, improving restoration of bowel function, reducing infection and improving prognosis of critically ill patients^[14-18]. But the conclusions of existing trials are controversial. The practical value of DF in clinical EN lacks evidence. This review is to evaluate the value of DF in clinical EN with the method of meta-analysis and to seek the best evidence for clinical EN.

MATERIALS AND METHODS

Data extraction and outcomes

We searched the following electronic databases for eligible trials: PubMed (from January 1980 to January 2003), EMBASE (from January 1989 to December 2002), Cochrane Controlled Trials Register and Chinese Biomedicine Database (from 1980 to 2002). The searching words were dietary fiber and enteral nutrition. Languages were restricted to English and Chinese.

The criteria were open or blind randomized studies. Patients were randomly allocated into receiving EN emended with DF or EN without DF, regardless of the type of DF.

Assessment of methodological quality

The assessment of methodological quality was undertaken by two of the authors independently, differences in assessment were solved by consensus. From each study, data were extracted on the type of patients, the method of administration of EN. Outcomes were the occurrence of diarrhea, infection of any type and length of hospital stay.

Jadad score and allocation concealment were adopted to evaluate the methodological quality of each trial: 0 for non-randomized controlled trials, 1-2 scores for poor-quality trials and 3-5 scores for high-quality trials. The concealment of allocation also was divided into three grades: A for adequate concealment, B for unclear concealment, C for inadequate concealment.

Analysis

RevMan 4.1 software supplied by Cochrane Collaboration

was used. The effect size of categorical variables was odds ratio (OR). For numerical variables, if the unit was identical, weighed mean difference (WMD) was used, and standardized mean difference was used when the unit was different. The homogeneity of adopted trials was tested before meta-analysis. If the heterogeneity had no statistical significant difference, a fixed effect model was used during meta-analysis. In contrast, we used a random effect model and subgroup analysis. Sensitivity analysis was also proceeded after the non-blinded, inadequate concealed trials were excluded.

RESULTS

Characteristics of trials and patients

Eight hundred and eleven papers were obtained by searching the databases, 587 in English, 224 in Chinese. Seventeen trials, all in English, were identified for further evaluation after the title and abstract were read. Seven measured up to the criteria and were included^[19-25]. There were no repetitive studies and meta-analysis. Seven of the 17 included trials, three were conducted in Germany^[19,20,24], one in USA^[22], one in Australia^[25], one in Belgium^[21] and Singapore^[23]. Two included critically ill patients^[22,25], three included postoperative patients^[19,20,23], one included sepsis^[21] and the other included a variety of diseases^[24]. The earliest study was published in 1990^[25], all were published in the past 14 years.

Methodological quality of trials

Of the seven trials, three were of a high quality (one had five scores according to Jadad, one had four scores, one had three scores), the other four were of a poor quality. Computerized random number was used in two trials, sealed envelopes in two, no randomization method in three. Four trials were double-blinded. The baselines of included subjects were compared in all studies, and no statistically significant differences existed. Table 1 gives the details of the seven trials.

Outcomes

Effect of DF on diarrhea in EN The occurrence of diarrhea in 276 patients receiving EN supplemented with or without DF was observed in five trials. There was no heterogeneity ($P = 0.087$) and fixed effect model was used. The combined OR was 0.61, 96% confidence interval was from 0.36 to 1.05 ($P = 0.07$) (Table 2). Subgroup analysis of two trials on uncritically ill patients showed that the combined OR was 0.33 (from 0.13 to 0.87, $P = 0.03$).

Effect of DF on infection The risk of infection was reported in two trials. The types of infection included pneumonia, sepsis, abdominal infection, urinary infection and incision infection. Two trials had homogeneity. Combined OR was 0.44 when the fixed effect model was used (0.20-1.00, $P = 0.05$).

Effect of DF on length of hospital stay Three trials reported the length of hospital stay of 124 postoperative patients. Among the three trials, one was excluded because it did not supply the standard deviation. Two adopted trials had homogeneity, combined WMD was -2.85 (from -3.76 to -1.93, $P < 0.00001$).

Sensitivity analysis

Three high-quality trials on diarrhea of 160 cases in EN were included. There was no heterogeneity among them ($P = 0.069$). Combined OR was 0.83 (0.43-1.60, $P = 0.6$). The result was identical with the previous analysis (Table 3). Sensitivity analysis was abandoned for the quality of trials about infection and length of hospital stay was poor.

DISCUSSION

Diarrhea is the most frequent complication in EN. Infusion speed, temperature, osmolality, bacterial contamination, hypoalbuminemia and antibiotics may play a part in diarrhea^[26]. Laboratory studies suggested that DF and SCFA, fermentation products of DF, were able to improve the rhythm of bowel peristalsis, promote absorption of water and sodium, and

regulate the inhibitor feedback mechanism^[27-31]. Accordingly, DF may have potentials beneficial to controlling diarrhea in EN^[32-35]. But the existing clinical trials did not show identical results, so strict evaluation is essential. The occurrence of diarrhea in trials adopted in this review was 30.01%, combined OR was 0.61, 95% confidence interval was from 0.36 to 1.05 ($Z = -1.79$, $P = 0.07$). The difference was not statistically significant. Subgroup analysis revealed that DF was beneficial to diarrhea in non-critically ill patients but uncertain in critically ill patients. Critically ill patients were apt to complicate severe hypoalbuminemia and superinfection, which could lead to refractory diarrhea^[34,35]. In the review, diarrhea occurred in 34.78% of critically ill patients, far higher than that in the non-critical patients (20.69%).

Diarrhea diagnosis is lack of objective criteria. Three trials in the review adopted Hatt and Dobb diarrhea score, which records defecation by volume and consistency. Diarrhea was defined as the scores more than 12. This score was convenient to compare different trials.

High attention has been paid to intestinal bacterial translocation leading to a considerable amount of infections. A series of animal experiments suggested that DF could effectively reduce the intestinal bacterial translocation in stress status^[36]. The mechanism remains unclear. DF is able to maintain the structure and function of epithelia, regulate immunological reactions, promote secretion of IgA and mucus, all these may play a role in diarrhea^[37-39]. Administration of DF can reduce the infection theoretically. However, analysis of the seven trials failed to show the anticipated results (combined OR 0.44, $P = 0.05$). The review suggests that DF could significantly shorten the length of hospital stay of patients who had undergone liver transplantation or abdominal surgery.

There is little evidence from these trials that DF is beneficial to diarrhea and infection of critically ill patients. It is necessary to design more large size and high-quality randomized controlled trials. The effect of DF on a variety of patients should also be further studied.

Abstract

AIM: To introduce the American Pittsburgh's method of rapid liver procurement under the condition of brain death and factors influencing the quality of donor liver.

METHODS: To analyze 32 cases of allograft liver procurement retrospectively and observe the clinical outcome of orthotopic liver transplantation.

RESULTS: Average age of donors was 38.24 ± 12.78 years, with a male:female ratio of 23:9. The causes of brain death included 21 cases of trauma (65.63%) and nine cases of cerebrovascular accident (28.13%). Fourteen grafts (43.75%) had hepatic arterial anomalies, seven cases only right hepatic arterial anomalies (21.88%), five cases only left hepatic arterial anomalies (15.63%) and two cases of both right and left hepatic arterial anomalies (6.25%) among them. Eight cases (57.14%) of hepatic arterial anomalies required arterial reconstruction prior to transplantation. Of the 32 grafts evaluated for early function, 27 (84.38%) functioned well, whereas three (9.38%) functioned poorly and two (6.25%) failed to function at all. Only one recipient died after transplantation and thirty-one recipients recovered. Four recipients needed retransplantation. The variables associated with less than optimal function of the graft consisted of donor age (35.6 ± 12.9 years vs 54.1 ± 4.3 years, $P < 0.05$), duration of donor's stay in the intensive care unit (ICU) (3.5 ± 2.4 d vs 7.4 ± 2.1 d, $P < 0.005$), abnormal graft appearance (19.0% vs 100%, $P < 0.05$), and such recipient problems as vascular thromboses during or immediately following transplantation (89.3% vs 50.0%, $P < 0.005$).

CONCLUSION: During liver procurement, complete heparization, perfusion *in situ* with localized low temperature and standard technique procedures are the basis ensuring the quality of the graft. The hepatic arterial anomalies should be taken care of to avoid injury. The donor age, duration of donor's staying in ICU, abnormal graft appearance and recipient problem are important factors influencing the quality of the liver graft.

INTRODUCTION

Enormous progress including surgical techniques has been achieved since the first orthotopic liver transplantation (OLT_x) was performed in humans in 1963 and OLT_x has established its role as a therapeutic option for patients with end-stage liver disease. Primary graft nonfunction (PGN) remains a dreadful complication of OLT_x, one that is associated with a high mortality and morbidity, and therefore liver allograft with good function is the most important point for ensuring the success of liver transplantation. A single donor surgeon's experience procuring the livers from 32 donors in Pittsburgh Transplant Center is analyzed in order to identify the role of a number of variables pertinent to the clinical outcome of OLT_x.

MATERIALS AND METHODS

Donor data

The author performed 32 allograft hepatectomies at the University of Pittsburgh Transplant Center. All donors were brain dead and the age of the donors varied from 12 to 63 years with the average of 38.24 ± 12.78 years. Among them, there were 23 male donors and 9 female donors. Table 1 lists the causes of death of the donors.

Table 1 Causes of brain death among 32 liver donors

Cause	n (%)
Trauma	21 (65.63)
Motor vehicle accident	16
Gunshot wound	1
Fall	2
Other	2
Cerebrovascular accident	9 (28.13)
Cerebral infarct	6
Subarachnoid hemorrhage	3
Others	2 (6.24)
Total	32 (100)

Donor selection criteria

In general, donors were selected who were less than 65 years

of age, had no history of liver disease such as hepatitis or alcoholism, and a total serum bilirubin less than 34 $\mu\text{mol/L}$, normal or near-normal alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (AKP), γ -glutathione transferase (γ -GT) and prothrombin time (PT), and adequate arterial blood gas. Elevations of ALT, AST, AKP and γ -GT, with a tendency to decline, were not regarded as a contraindication for donation of the liver.

Donor maintenance

Donors were fluid-resuscitated once they had been pronounced brain dead in order to maintain a central venous pressure of 8-10 cm H_2O and urine output over 1 mL/(kg \cdot h) as a guide. For donors receiving vasopressin for diabetes insipidus, the vasopressin was discontinued as soon as possible to avoid liver ischemia secondary to a decreased splanchnic blood flow. Urine output was replaced vigorously with intravenous fluids, usually one-half or quarter normal saline solution with potassium chloride. Electrolytes were checked frequently, especially to correct hypokalemia. Normothermia was maintained with a thermoblanquet. Blood was transfused to maintain the hematocrit above 30% in order to maintain adequate oxygen delivery to the tissues.

Operative technique

The technique of allograft hepatectomy involved both rapid perfusion and modified rapid perfusion^[1-3]. Rapid perfusion technique is as follows. Briefly, both the terminal aorta and the inferior mesenteric vein were dissected to insert aortic and portal perfusion cannulae. The supraceliac abdominal aorta was encircled and crossclamped. Following cardiectomy, dissection of liver hilum was performed in a bloodless field^[4,5]. Following identification of whether or not an aberrant right hepatic artery (HA) originating from superior mesenteric artery (SMA) in the retropancreatic portion, the right side of the SMA was dissected toward the aorta. A Carrel patch of aorta was excised, with care not to injure the origin of the renal arteries. This has been our preferred method of hepatectomy in unstable donors, or in cases of extreme urgency when the recipient is in fulminant liver failure due to fulminant hepatitis or graft nonfunction following OLTx. Modified rapid perfusion technique differs from the rapid perfusion technique in that dissection of the liver hilum occurs prior to crossclamping of the aorta and cannulation of the distal splenic vein with a larger caliber catheter for a quicker portal perfusion. This preliminary dissection allows more selective and rapid cooling of the liver than does the rapid perfusion technique. These additional preparatory steps required 30-45 min. This technique has been our choice for stable donors and for donors whose livers are of a questionable quality. During the preparatory dissection, changes in the color or consistency of the allograft were observed in response to diuresis, or better oxygenation.

Technique of vascular reconstruction for arterial anomalies

Arterial reconstruction of the liver graft is required prior to transplantation and is very pivotal if a common arterial channel is absent due to an anomaly. The most common arterial anomaly requiring reconstruction was the aberrant

right HA arising from the SMA, for which an end-to-end anastomosis was performed between the distal donor splenic artery and the proximal aberrant right HA. This was achieved with a Carrel patch of the SMA, obviating a small caliber anastomosis^[6]. Care was taken to avoid an inadvertent anastomosis with rotation. The continuous suture technique with 8-0 monofilament polypropylene (Prolene) was used for the reconstruction. Just before the sutures were tied, the reconstructed HA was allowed to distend by pulsatile infusion of cold solution. With the application of "growth factor" principle to the *ex vivo* condition, this method facilitated migration of Prolene sutures into the anastomosis and allowed secure anastomosis without leakage or stricture.

Classification of early graft function

Early graft function was divided into four grades as good, fair, poor and PGN. Good meant AST < 1 500 IU/L, ALT < 1 000 IU/L and fresh frozen plasma (FFP) was not necessary. Fair meant AST 1 500-3 500 IU/L, ALT 1 000-2 500 IU/L and FFP was not required. Poor meant AST > 3 500 IU/L, ALT > 2 500 IU/L and FFP was required. PGN was defined as the inability of graft to sustain the metabolic homeostasis of the recipient during the first postoperative week, presenting with the clinical manifestations of grade III or IV coma, coagulopathy with prothrombin time over 20 s, high ALT and AST values, renal failure, and progressive or persistent hyperbilirubinemia, resulting in retransplantation of the graft or death of the recipient.

Statistical analysis

Student's *t* and χ^2 tests were used for the statistical evaluation of the data.

RESULTS

Vascular anomalies

Table 2 lists the incidence of hepatic arterial anomalies and various methods of arterial reconstruction. Hepatic arterial anomalies were present in 14 grafts (43.75%): the aberrant right HA in seven (21.88%), the aberrant left HA in five (15.63%), and both aberrant right and left hepatic arteries in two grafts (6.25%). Of these, eight grafts (57.14%) required vascular reconstruction at the back table in order to construct a common arterial channel, and one of the anastomoses constructed at the back table required the revision due to rotation.

Table 2 Vascular reconstruction for hepatic arterial anomalies

Anomaly	n (%)	Method of reconstruction (n)
Aberrant RHA	7 (21.88)	
From SMA	6	Donor SpA to aberrant RHA (4)
From aorta	1	Donor SpA to aberrant RHA (1)
Aberrant LHA	5 (15.63)	
From CA	3	
From aorta	2	Donor SpA to PHA (1)
Aberrant RHA and LHA	2 (6.25)	
RHA from SMA	1	Donor SpA to RHA (1)
LHA from CA	1	CA to distal SMA (1)
Total	14 (43.75)	

RHA: right hepatic artery; SMA: superior mesenteric artery; SpA: splenic artery; LHA: left hepatic artery; CA: celiac axis, PHA: proper hepatic artery.

Injury of hepatic artery

A total of four complications (6.25%) occurred during or after allograft hepatectomy due to aberrant HA: inadvertent transection of the aberrant right HA, once originating directly from the aorta and once from the left side of the SMA. The transected aberrant right hepatic arteries were reconstructed using end-to-end anastomosis with the donor splenic artery with interrupted 8-0 Prolene sutures. Overall, none of the complications affected the outcome of the liver or other organ recipients.

Early graft function

Table 3 lists the early graft function of the 32 allografts after OLTx. Graft function was good or fair in 25 out of 28 (89.3%) of the grafts without recipient problems, whereas as many as two out of four (50%) of the grafts with recipient problems during or immediately following OLTx exhibited poor or nonfunction ($P < 0.005$; $\chi^2 = 12.96$). This was due to HA thrombosis and multi-organ failure and meanwhile HA thrombosis was caused not by HA anomaly during allograft procurement but by HA reconstruction. Table 4 shows the correlation between the donor or graft variables and the early graft function of the 28 grafts that survived the operation and did not develop the aforementioned recipient complications during or

immediately following OLTx. A statistically significant difference was noticed in the duration of patient's stay in ICU, requirement of cardiopulmonary resuscitation and the presence of abnormal graft appearance ($P < 0.05$). The donors of grafts with fair or poor function stayed in ICU longer than those with good function ($P < 0.005$), and the grafts with abnormal appearance were associated with a higher incidence of fair or poor graft function in recipients ($P < 0.05$; $\chi^2 = 6.21$). The donors of graft with poor or nonfunction were significantly older than those with good or fair function and there was no significant difference between good and fair groups. On the other hand, no definitive correlation with early graft function was observed in sex, results of liver function tests, infusion of high-dose vasopressors and cold ischemia time.

Recipient survival

Of the 32 patients who received liver allografts, 27 patients recovered and remained alive and well after first liver transplantation, four patients needed retransplantation and all were discharged. One patient died of multi-organ failure in one month after transplantation due to primary graft nonfunction.

DISCUSSION

Early graft function is very closely associated with donor age, duration of patient's stay in ICU and the presence of abnormal graft appearance. The effect of increased donor age on the outcome of OLTx remains controversial^[7,8]. Previously the upper limit of donor age was 50 years. As gradual accumulation of experience of clinical OLTx, now some transplant centers elevate the upper limit of donor age to 65 years. But we suggest that the donor age should be limited to below 60 years, or allograft dysfunction or non-function would easily appear and increase mortality^[9]. When the appearance of the liver has changes in color, blunt edge and anomalous nodulae, it is necessary for frozen pathological examination before transplantation. Steatosis is the most important cause of PGN. The comparatively simple differentiating method is that white four-by being put into the container will turn into pale yellowish after several minutes and this will suggest that the degree of fat infiltrating liver tissue will be over 30%, however, pathological examination to evaluate the degree of fatty infiltration is the most reliable method. As to the hemodynamic stability of the donor, hypotension or the requirement of high-dose dopamine has been associated with nonfunction or delayed function, respectively. Although no obvious harmful effects of cardiopulmonary resuscitation on the early function of the liver allograft were demonstrated in this study, suboptimal perfusion of the liver and warm ischemic injury were strongly suggested. As to the abnormal appearance of the graft, little is known about the correlation between gross appearance and quality of the graft. Livers from donors with diabetes insipidus, who have been on vasopressin for a prolonged period of time, are often firm and suggest the presence of ischemic injury and liver allograft will be harder to touch. Since the use of vasopressin has been associated with a marked reduction in the blood flow to the

Table 3 Early graft function after orthotopic liver transplantation

Early graft function	Number of recipient problems		Total (%)
	No (%)	Yes ¹ (%)	
Good	21 (75)	1 (25)	22 (68.75)

CIT: cold ischemia time; T. Bil: total bilirubin; CPR: cardiopulmonary resuscitation.

liver, donors scheduled for liver procurement should stop vasopressin as soon as possible in order to minimize ischemic damage. Overhydration can distend the liver by an increase in central venous pressure and give a false impression as to the consistency of the liver. If the liver is distended from overhydration, the administration of intravenous diuretics can be used immediately.

As far as now, there have been two methods for procurement of liver allografts including aortic perfusion only (APO)^[10] and aortic and portal perfusion (APP). Due to shortage of donors, most American transplantation centers adopt multi-organ procurement, which means APO is the sole choice. The experience of Pittsburgh is that APO has no harm to allograft liver and its advantage is simple surgical procedure compared with APP^[11], meanwhile, superior mesenteric vein need not be exposed and therefore it reduces the separation and division of tissue. If RHA originates from superior mesenteric artery, the unexposure of superior mesenteric vein might avoid injuring aberrant right hepatic artery and ischemic injury of splenic organ due to arterial spasm by surgical procedure^[12-14].

The aberrant hepatic artery is very common; the aberrant rate was as high as 43.75% in our group. The right hepatic artery originating from SMA is the most common^[15]. In order to avoid injuring hepatic artery, it is very important to decide by touch whether or not there are pulses behind hepatoduodenal ligament before the abdominal aorta is clamped in the process of procurement of allograft liver. Even if there is no pulse, it could not exclude aberrant right hepatic artery. So routinary division of the right side of SMA can often protect aberrant right hepatic artery before dissection of hepatoduodenal ligament. Once there exist the injuries of aberrant hepatic arteries, several aspects should be noticed in the process of the reconstruction of hepatic arteries as follows: (1) the inner membrane of hepatic artery should not be dragged; (2) it is achieved with Carrel patch of the SMA to obviate a small caliber anastomosis; (3) whether the continuous suture will be used depends on operator's mastering of the technique of vascular anastomosis; (4) just before the sutures were tied, the reconstructed HA was allowed to distend by pulsatile infusion of cold solution while the distal HA was occluded digitally and such method can identify whether the reconstructed anastomosis has leakage and stricture, or thrombosis of HA will occur which could cause biliary tract complication^[16-19].

Although division of third hepatic hilum caused severe bleeding for two recipients in our group, this would not affect the early function of allograft liver. Hepatic artery thrombosis and multi-organ failure in earlier stage after transplantation caused poor and non-function for another two patients. Pittsburgh Transplant Center adopts the anastomosis between hepatic artery at the level of gastroduodenal artery in recipient and hepatic artery in donor, hepatic artery thrombosis in earlier stage after transplantation is associated with the technique of anastomosis. The simple differentiating method is to observe the pulse of hepatic artery after anastomosis, Doppler for hepatic artery the first day after liver transplantation is the optimal for finding thrombosis as soon as possible. Multi-organ failure often

accompanies the instability of systemic hemodynamics and the liver is much easier to be affected by ischemic-reperfusion injury, while the injury of the liver also worsens the multi-organ failure and this pernicious recycle can cause patients to die.

For the assessment of allograft viability in clinical OLTx, there is, to date, no practical and simple technique available that is discriminately predictive of allograft function before the actual transplant procedure. Primary graft non-function remains a major cause of mortality, and although the shortage of donor organs remains a major limiting factor in clinical liver transplantation^[20], still we should have a careful attitude toward the choice of liver allograft and take into serious account several predictive factors. If so, better therapeutic effect will be achieved.

Abstract

AIM: To study the levels of 5-fluorouracil (5-FU) in plasma, liver and tumor in patients with hepatocellular carcinoma after oral administration of 5'-deoxy-5-fluorouridine (5'-DFUR).

METHODS: Thirty-nine patients with hepatocellular carcinoma were treated with oral 5'-DFUR for more than 4 d before operation. The contents of 5-FU in plasma, liver and tumor were measured by high performance liquid chromatography (HPLC) and apoptosis of tumor cells was evaluated by *in-situ* TUNEL after resection of tumor.

RESULTS: The concentrations of 5-FU were 1.1 µg/mL, 5.6, 5.9, and 10.5 µg/g in plasma, the liver tissue, the center of tumor and the periphery of tumor, respectively. 5-FU concentration was significantly higher in the periphery of tumor than that in the liver tissue and the center of tumor (10.5 ± 1.6 µg/g vs 5.6 ± 0.8 µg/g, $t = 21.38$, $P < 0.05$; 10.5 ± 1.6 µg/g vs 5.9 ± 0.9 µg/g, $t = 20.07$, $P < 0.05$). 5-FU level was significantly lower in plasma than that in the liver and the tumor (1.1 ± 0.3 µg/mL vs 5.6 ± 0.8 µg/g, $t = 19.63$, $P < 0.05$; 1.1 ± 0.3 µg/mL vs 10.5 ± 1.6 µg/g, $t = 41.01$, $P < 0.05$). Apoptosis of tumor cells was significantly increased after oral 5'-DFUR compared to the control group without 5'-DFUR treatment.

CONCLUSION: There is a higher concentration of 5-FU distributed in the tumor compared with liver tissue and apoptosis of tumor cells is increased following oral 5'-DFUR compared with the control group. The results indicate that 5'-DFUR is hopeful as neo-adjuvant chemotherapy to prevent recurrence after resection of hepatocellular carcinoma.

Key words: Hepatocellular carcinoma; 5'-Deoxy-5-fluorouridine; 5-Fluorouracil; Apoptosis

INTRODUCTION

Hepatocellular carcinoma (HCC) remains one of the most common neoplasms in the world^[1,2]. 5'-Deoxy-5-fluorouridine (5'-DFUR) is an oral fluoropyrimidine derivative and it is converted to 5-fluorouracil (5-FU) by Pyrimidine nucleoside phosphorylase (PyNPase) which is expressed with higher level in tumor tissues compared with normal tissues^[3,4]. Oral 5-FU derivatives have shown comparable antitumor activity and long-term oral administration of low-dose has been considered as postoperative adjuvant chemotherapy after curative resection of the cancer to reduce recurrence and improve survival rate^[5-9]. The selective antitumor activity of 5'-DFUR is correlated with PyNPase activity in tumor^[10]. Although the activity of 5-FU in tumor is well recognized, resistance to this agent is frequently observed and remains its major limitation. It was reported that doxifluridine still showed antitumor activity to tumor cells which were resistant to 5-FU^[11].

The purpose of the present study was to investigate the impact of preoperative oral 5'-DFUR on distribution of 5-FU in plasma, liver and tumor and apoptosis of tumor cells in patients with hepatocellular carcinoma.

MATERIALS AND METHODS

Chemicals and reagents

5'-DFUR capsule (Furtulon) was produced by Shanghai Roche Pharmaceuticals Co. (Shanghai, China), and standard 5-FU was provided by Sigma Chemicals Co. (USA). Methyl-tert butyl ether, acetonitrile, methanol (HPLC grade) and potassium hydrogen phosphate (AR grade) were purchased from Peking Chemical Plant (Beijing, China).

Chromatographic conditions

HPLC system consisted of LC-10AT HPLC pump and SPD-10A Detector (SHIMADZU Co. Japan). The analytical column was Kromasil C₁₈ (5 µm 200 mm × 4.6 mm ID). The mobile phase consisted of acetonitrile, methanol, and 0.25 mol/L potassium hydrogen phosphate (1:4:5). The

flow rate was 1.0 mL/min and the wavelength was at 265 nm.

Collection of samples

Thirty-nine patients of 27 male and 12 female with hepatocellular carcinoma were included in this study. Their average age was 49.1 years and the diamters of tumors were from 5 to 7 cm. 5'-DFUR was administered orally and preoperatively (1 200 daily for more than 4 d before operation and 400 mg on the day of operation). The mean total dosage was 6.4 g. Blood sample and specimens of the normal liver tissue and the tumor tissue were collected 3-5 h after final administration. The liver and tumor tissues were cleaned by distilled water and blotted by filter paper. One gram tissue was weighed accurately and 4 mL distilled water was added to the container to crush the tissue. The blood samples and the crushed tissues were centrifuged, and 1 mL plasma or aqueous layer sample was then stored under -20 °C.

Extraction and determination of samples

Each 0.5 mL plasma or aqueous layer sample was added and mixed with 0.1 mL of potassium hydrogen phosphate (0.5 mol/L), followed by the addition of 5 mL methyl-tert butyl ether to each tube. The tube was then capped and shaken for 10 min on a shaker. The aqueous layer and the organic layer were separated by centrifugation at 3 000 r/min for 10 min. The aqueous layer was transferred to a clean test tube and evaporated to dryness under gentle stream of nitrogen at 50 °C. The residue was dissolved with 0.1 mL of mobile phase and vortexed. Then the sample was transferred into a micro-spin filter tube and was centrifuged at 3 000 r/min for 10 min. The filtrate was collected and the injection volume was 20 µL and the content of 5-FU was measured by high performance liquid chromatography (HPLC)^[12-14].

In vivo detection of apoptosis

TUNEL staining was used to detect DNA degradation *in situ* in the relatively late stage of apoptosis. Apoptotic cells were labeled by the TUNEL reaction using an *in situ* Cell Apoptosis Detection Kit. *In situ* Cell Apoptosis Detection Kits were purchased from Roche Diagnostics GmbH Co. in Germany. The detailed manipulation was conducted according to instructions for users. The procedure was performed following the instructions of the manufacturer and in reference of the previous observations^[15,16].

The positive cells were identified and analyzed based on morphological characteristics of apoptotic cells as previously described. Under the fluorescence microscopy, apoptotic cells manifested as brownish staining in the nuclei. Non-necrotic zone was selected in the tissue section and images were randomly selected. The positive cells were determined in at least five areas at ×400 magnification and divided into three categories as follows: (+) only sporadic positive cells were detected; (++) a cluster of apoptotic cells were observed; (+++) positive cells in a large scale or multi-cluster apoptotic cells were seen in representative tissue sections of each individual case. Twenty patients of HCC without oral 5'-DFUR treatment were included as the control group.

Statistical analysis

The data were expressed as mean±SD. Student's *t*-test was performed for statistical analysis. *P* value less than 0.05 was considered statistically significant.

RESULTS

Concentration of 5-FU in plasma, liver and tumor following oral administration of 5'-DFUR

The concentrations of 5-FU were 1.1 µg/mL, 5.6, 5.9, and 10.5 µg/g in plasma, the liver tissue, the center of tumor and the periphery of tumor, respectively. The 5-FU content was significantly higher in the periphery of tumor than that in the liver tissue and the center of tumor (*P*<0.05). Moreover, the 5-FU concentration was significantly lower in plasma than liver and tumor (*P*<0.05). However, the 5-FU level in the center of tumor was similar to that in the liver tissue (Table 1).

Table 1 5-FU concentrations in blood, liver and tumor after oral 5'-DFUR

Tissue	Level of 5-FU
Plasma (µg/mL)	1.1±0.3 ^a
Liver tissue (µg/g)	5.6±0.8
Central tissue of tumor (µg/g)	5.9±0.9
Periphery tissue of tumor (µg/g)	10.5±1.6 ^a

^a*P*<0.05 vs 5-FU concentration in liver tissue.

Apoptosis of the tumor cell demonstrated by TUNEL

Under the fluorescence microscope, apoptotic cells manifested as brownish staining in the nuclei. The degree of apoptosis was shown + in tissue sections of the control group in which sporadic positive cells were detected, and ++ in cases with oral 5'-DFUR in which clusters of apoptotic cells were seen (Figures 1A and B).

Figure 1 Apoptotic cancer cells detected by TUNEL method after oral administration of 5'-DFUR ×400. A: Sporadic apoptotic cells were detected; B: clusters of apoptotic cells were detected.

DISCUSSION

It is well known that hepatocellular carcinoma is one of the malignant tumors with poor chemosensitivity to anticancer agents^[17,18]. 5-FU is still the first choice for the chemotherapy of hepatocellular carcinoma^[19,20], because of its strong killing effects on the cancer cells. 5-FU can damage proliferating cells, reduce the tumor mass in size and prevent tumor

cells from spreading and metastasis. However, its usage is limited due to the rapid development of acquired resistance. The effects of 5-FU are not so satisfactory because 5-FU has a lower concentration in tumor tissue and relatively higher concentrations in blood after intravenous administration of 5-FU. Moreover, its side effects are serious and many patients are unable to tolerate.

5'-DFUR is a prodrug of 5-FU and it is converted to 5-FU by Pyrimidine nucleoside phosphorylase (PyNPase). PyNPase exists in all kinds of tumor tissues and its expression and activity in tumor tissue are higher than that in normal tissue^[3,4]. Nagata *et al.*^[21-24] reported that transfection of PyNPase gene into tumor cell can increase the sensitivity to 5'-DFUR, and thereby decreases the toxicity of the agent. In our study, it had been found that 5-FU level in tumor was 10 times higher than in plasma and 5-FU level was significantly higher in the periphery of tumor than in the liver tissue. The results suggested that more 5-FU was converted and accumulated within tumor tissue. This difference may be related to the higher PyNPase expression and activity in hepatocellular carcinoma. It had also been found that the 5-FU level was significantly higher in the periphery of tumor than the center of tumor. There was more 5-FU accumulated and converted in the periphery of tumor following oral 5'-DFUR administration. Oxygen, nutrition and growth factors were not equally distributed within the tumor tissue. Oxygen and nutrient of the central tumor tissue are supplied mainly by hepatic artery, and proliferation of the tumor in this region is slower and even partial necrosis appears. However, the periphery of tumor has effluent blood flow supplied by hepatic artery and portal vein, so the tumor cells can grow more rapidly. These results may indicate that large liver tumor is not sensitive to 5'-DFUR.

Oral 5'-DFUR is very convenient and its side effect is slight^[25]. The drug arrives in the liver firstly after being absorbed by the intestine. So most of 5'-DFUR can be converted to 5-FU in the liver or the liver tumor and accumulated in these tissues with higher concentration than that administered by iv approach. In this study, the 5-FU level in peripheral vein was only one-tenth of that in tumor tissue. 5-FU can be maintained at a certain level within the tumor tissue but not accumulated in the peripheral vein after regular oral administration of 5'-DFUR.

The expression and activity of PyNPase is higher in the tumor with vascular permeation and lymph node metastasis^[4,26,27]. Akao *et al.*^[28] reported that PyNPase activity was significantly higher in metastatic lymph node. Tazawa *et al.*^[29] found that 5'-DFUR could inhibit hepatic metastasis of tumor, which would be effective for the prophylactic treatment of metastatic disease. These indicate that PyNPase activity appears to be a new useful parameter for identifying both a poor prognosis and a highly malignant potential of tumor and 5'-DFUR is preferably sensitive in cancer patients with lymph node metastasis and vascular infiltration. 5'-DFUR is still effective to the tumor which is resistant to 5-FU therapy^[11]. Monden *et al.*^[30] found that vessel density and stage of tumor were correlated with expression of PyNPase which showed prognosis. 5'-DFUR not only is effective on primary tumor and metastatic lesion but also

suitable to postoperative prevention of tumor. Apoptosis of the tumor was enhanced after oral administration of 5'-DFUR. In this study, it was found that there were more apoptosis cells in the tumor after oral administration of 5'-DFUR.

In summary, our results showed that there was a higher concentration of 5-FU accumulated in the tumor tissue compared with liver tissue and apoptosis of the tumor cells was increased after oral administration of 5'-DFUR. 5'-DFUR is a hopeful agent for neo-adjuvant chemotherapy to prevent recurrence after resection of hepatocellular carcinoma.

Abstract

AIM: To examine the prevalence and prognostic significance of C-kit gene mutation and analysis the correlation of C-kit gene mutation and the clinicalpathologic parameters of GISTs.

METHODS: Eighty-two GISTs were studied for the mutation of C-kit gene by PCR-SSCP, DNA sequence. Statistical comparison were used to analysis the correlation of C-kit gene mutation and clinicalpathology, clinical behavior, recurrence.

RESULTS: (1) Mutation-positive and mutation-negative GISTs were 34 and 48, respectively; (2) Among these patients with C-kit mutation remained a significantly poor prognosis associated with 59% 3-year survival compared to those whose tumors did not; (3) Tumor size, PCNA index, mitotic cell number, presence of necrosis, microscopic invasion to adjacent tissues, recurrence and distant metastasis among mutation-positive and mutation-negative GISTs were significantly different.

CONCLUSION: C-kit mutation is a undoubtedly pivotal event in GIST and may be associated with poor prognosis. Evaluation of C-kit gene mutation may have both prognosis and therapeutic significances.

INTRODUCTION

Gastrointestinal stromal tumor (GIST) is designation for a major subset of mesenchymal tumors of the gastrointestinal tract. Their biological behavior is a persistent source of controversy. Concerning prognosis, various studies^[1-3] have endeavored in the establishment of clinicopathologic correlations, such as tumor size, location, mitotic cell count, proliferative activity, presence of necrosis, presence of hemorrhage, microscopic invasion to adjacent tissues, recurrence, distant metastasis, age, sex, cell type. Yet the criteria claimed to predict the biological behavior of GIST remains vague and do not even enable a confident discrimination between benign and malignant lesions. Discrimination of malignant GISTs based on an objectively defined factor would be of practical importance. In this study, we intend to contribute to this issue by examining the prevalence and prognostic significance of the above-mentioned parameters, C-kit expression and C-kit gene mutation, and analysis the correlation of C-kit gene mutation and the above-mentioned clinical parameters.

MATERIALS AND METHODS

Patients

During the period 1997-2001, 82 patients with primary mesenchymal tumors of the gastrointestinal tract underwent surgery at Changhai Hospital and were diagnosed as GISTs. Of these, 56 men and 26 women, the mean age of the GIST patients at the time of diagnosis was 53 years. The locations of the tumors were as follows: 3 in the esophagus, 42 in the stomach, 35 in the intestine, and 2 in the mesentery. According to the standard of Lewin's^[4], 82 cases were divided into 2 groups, 20 benign and 62 malignant GISTs. At the time of diagnosis, 16 were found microscopic invasion to mucous myometrium or placenta percreta, distant metastasis was found in 16 patients, 9 to the liver, 2 to bone, 1 to lung and 4 extensive metastasis; the remaining patients were free of distant metastasis. Thus, curative surgery was performed for 73 patients, and the patients with distant metastasis or peritoneal dissemination underwent only local resection. The mean follow-up period was 4.1 years, during the follow-up period, 18 patients suffered from recurrences, and 10 patients received reoperation for recurrences.

Immunohistochemistry

Paraffin sections (3 mm thick) of formalin-fixed tissues were used for conventional H&E staining and for immunohistochemistry. Rabbit polyclonal antibody against

human KIT and mouse monoclonal antibody against human PCNA were purchased from DAKO. Immunohistochemistry was performed using EnVision kit by two-step technique. PCNA index indicating the percentage of positive tumor nuclei was obtained by visual quantitative assessment of 100 tumor cells. Random fields were selected, excluding areas with excessive or scant immunostaining. Nuclear staining without cytoplasmic staining was considered a positive result. Negative result was set as “-”, PCNA index <10% +, PCNA index 10%-30%++, >30%+++.

PCR-SSCP

DNA was extracted from formalin-fixed, paraffin-embedded tissues using standard methods with proteinase K digested and phenol/chloroform purified. Exon11 of the C-kit gene was amplified by PCR using the following oligonucleotide primer pairs: sense primer 5'-aactcagcctgttctg-3'-antisense primer: 5'-gatctattttcccttctc-3'. PCR products were subjected to 8% non-denaturation polyacrylamide gel electrophoresis (aer:bis = 49:1) with 5% glycerin and silver nitrate staining.

DNA sequencing

PCR products that showed abnormal gel shift by PCR-SSCP were selected for sequencing after cloned into PMD18-T vector. The sequencing procedures were performed by Songon Co., Shanghai.

Statistical analysis

Eighty-two GISTs were divided into mutation-positive and mutation-negative subtypes according to C-kit gene detection. χ^2 test was used to analyze the correlation of C-kit mutation and clinicopathological and prognostic factors. Two-sided $P < 0.05$ were considered to represent statistical significance. The relative importance of various prognostic factors for the postoperative was analyzed with Cox's proportional hazard model. Logistic regression analysis with the forward stepwise method was used to compare the difference of survival curves between the C-kit mutation-positive and mutation-negative subtypes. The possible prognostic factors included age, sex, location of tumors, tumor size, cell type, microscopic invasion to neighboring structures, mitotic cell number, PCNA index, distant metastasis at the time of diagnosis, peritoneal dissemination at the time of surgery, recurrences during the follow-up period, presence of necrosis, presence of hemorrhage, presence of C-kit mutation and expression.

RESULTS

Immunohistochemistry

Immunohistochemical analyses revealed strong and diffuse C-kit expression in 80 of 82 cases. PCNA staining intensity varied from very weak to intensely strong and from finely granular to uniformly dark red-brown (Table 1).

Evaluation of mutations in exon11 of C-kit gene

Two alleles were observed for the normal PCR segments, fast and slow fragments were designated as A and B alleles, respectively. Comparing to normal cases, 34 (41.5%) malignant

GISTs showed abnormal gel shifts while no mutant bands were observed in benign GISTs. Abnormal gel shifts included multiple shift bands, monomorphic fragment or band shifting. Sequencing of abnormal bands revealed point mutation, deletion mutation and insertion deletion. Mutation-positive and mutation-negative GISTs were 34 and 48, respectively.

Survival analysis

Three-year survival rate was 77%(63/82) of 82 cases. Among these patients with C-kit mutation remained a significantly poor prognosis associated with 59% 3-year survival compared to those whose tumors did not. ($\chi^2 = 11.6464$, $P < 0.05$, Figure 1).

Figure 1 C-kit gene mutation and cumulative survival rate.

The relationship of C-kit mutation and clinicopathological marker

We examined whether the presence of C-kit mutation could be associated with clinicopathological features of GISTs (Table 1). Statistical analysis indicated that significant differences were detected with tumor size ($\chi^2 = 16.7950$, $P < 0.05$), PCNA index ($\chi^2 = 17.0990$, $P < 0.05$), mitotic cell number ($\chi^2 = 11.2327$, $P < 0.05$), presence of necrosis ($\chi^2 = 4.4036$, $P < 0.05$), microscopic invasion to adjacent tissues ($\chi^2 = 22.3912$, $P < 0.05$) between two terms. The age, sex, location of tumor, cell type, the presence of hemorrhage, and C-kit expression were independently related to the presence of C-kit mutation.

The correlation between C-kit mutation and prognostic factors

We also examined whether the presence of C-kit mutation was associated with the clinical outcome (Table 2). The mutation-positive GISTs showed more frequent recurrences ($\chi^2 = 16.333$, $P < 0.05$), distant metastasis ($\chi^2 = 12.9649$, $P < 0.05$) and higher mortality ($\chi^2 = 11.6464$, $P < 0.05$) than the mutation-negative GISTs. Of the patients with mutation-positive GIST, developed distant metastasis.

DISCUSSION

GISTs are the most common mesenchymal tumors of the human gastrointestinal tract which are enigmatic in terms of their line of differentiation or cell of origin and clinical behavior^[5]. Recently, many studies have shown that tumor size, location, mitotic cell count, cell type, proliferative

activity, presence of necrosis, presence of hemorrhage, microscopic invasion to adjacent tissues, recurrence, distant metastasis, as favorable factors of GIST. But histologic distinction of benign from malignant tumors is often difficult, and prediction of clinical outcome on the basis of histologic characteristics alone is not always reliable, many histologically malignant neoplasms were clinically benign. Moreover, some tumors had conflicting features of both benignancy and malignancy, and their malignant potential has been labeled uncertain or indeterminate. In recent years, C-kit protein expression and activated gene mutation have been found in GIST^[6-9], aggressive mastocytosis^[10], mast cell leukemia^[11], ANLL with/without mast cell involvement^[10], myeloproliferative disorders^[10], colon carcinoma^[12] and germ cell tumors^[13]. Dections of gene mutation have shown a good correlation with biologic behavior in such tumors and providing valuable adjunctive prognostic information. In this study, we examined whether the presence of mutation of C-kit gene is important as a prognostic factor of GIST and found it to indicate a significantly poorer prognosis.

First, we examined whether the presence of C-kit mutation could be associated with clinicopathological features of GISTs. Statistical analysis indicated that significant differences were detected with tumor size, PCNA index, mitotic cell number, presence of necrosis, microscopic invasion to adjacent tissues between mutation-positive and mutation-negative GISTs. While the age, sex, location of tumor, cell type, the presence of hemorrhage, and C-kit expression were independently related to the presence of C-kit mutation. This states that the mutation-positive GISTs were larger in size and showed more frequent invasion of adjacent tissues, the mutation-positive GISTs showed higher mitotic counts and PCNA index and more necrosis within the tumors histologically. Taken together, the mutation-positive GISTs had more malignant histological features than the mutation-negative GISTs. We also examined whether the presence of C-kit mutation was associated with the clinical outcome. The mutation-positive GISTs showed more frequent recurrences, distant metastasis and, higher mortality than the mutation-negative GISTs. There are at least possible two explanations for this : GIST may be classified into two subtypes, C-kit mutation-positive and mutation-negative GISTs mutation-positive GISTs showed more malignant features,; mutation-negative GISTs may acquire more malignant phenotype due to the addition of C-kit mutation.

Recently, gain-of-function mutations of the juxtramembrane domain of C-kit , including deletions or point mutations in exon11 were described in GIST^[14-18]. These mutations were shown to lead to spontaneous, ligand-independent tyrosine kinase activation. The stable transfection of murine lymphoid cells with the mutant C-kit complementary DNA was shown to induce malignant transformation, suggesting pathogenetic significance of such mutations. We have expanded these observations and found that the C-kit mutation in the exon11 predominantly occur in those GISTs that are histologically and clinically malignant while benign GISTs were not detected. This suggest that C-kit mutation in the exon11 may be an important pathogenetic mechanism of tumor malignant behavior. Moreover ,we found C-kit

mutations only in 60% of the malignant GISTs. This may suggest that additional pathogenetic mechanisms exist in other cases, or that mutations occur in alternative sites. Another study also showed correlation between the mutations and disease progression.

There is no effective therapy for unresectable or metastatic gastrointestinal stromal tumor, which is invariably fatal. STI571, a phenylaminopyrimidine derivative, is a small molecule that selectively inhibits the enzymatic activity of C-kit gene. Joensuu *et al.*^[19], found that inhibition by STI571 of the constitutively active mutant C-kit tyrosine kinase of gastrointestinal stromal tumors was an effective therapy for these tumors. There are two explanations for this: STI571 may be active in solid tumors that rely on the expression of C-kit, ABL, or platelet-derived growth factor receptor while GIST uniformly express C-kit; a tumor-specific C-kit mutation appears to be the chief cause of this neoplasm. Considering these findings, we conclude that C-kit mutation is a undoubtedly pivotal event in GIST and may be associated with poor prognosis. Evaluation of C-kit gene mutation may have both prognosis and therapeutic significances as the new tyrosine kinase inhibitor (STI571) treatments are available.

Abstract

AIM: To investigate the uptake of ^{99m}Tc -HYNIC-Tyr³-octreotide (^{99m}Tc -HYNIC-TOC) in human hepatocellular carcinoma (HCC), which can provide the localizable diagnosis in hepatic carcinoma.

METHODS: The expression of somatostatin receptor 2 (SSTR2) messenger RNA (mRNA) in human HCC cell line HepG₂ was examined by reverse transcriptase-polymerase chain reaction (RT-PCR). Uptake of ^{99m}Tc -HYNIC-TOC was evaluated in the human HCC implanted into BALB/c nude mice. ANMIS2000 nuclear medicine analysis system was used to calculate the ratio of ^{99m}Tc uptake between tumor tissue and vital organs.

RESULTS: We demonstrated the expression of SSTR2 mRNA in human HCC cell line HepG₂ by RT-PCR. The size of the RT-PCR products was 364 bp detected by sequence analysis of the human SSTR2 mRNA. Scintigraphy proved that ^{99m}Tc -HYNIC-TOC was uptaken in the tumor tissue, liver and kidney of the tumor-bearing mice.

CONCLUSION: Based on expression of the SSTR2 mRNA in human HCC, ^{99m}Tc -HYNIC-TOC can markedly bind with and be uptaken by human HCC tissues as compared with normal liver tissue. The significant retention of radionuclide in kidney and bladder is probably related to non-specific peptide uptake in the tubulus cells of kidney and possibly due to excretion by kidney. Our results show that localizable diagnosis and targeting radiotherapy with radionuclide-labeled somatostatin analog for HCC are of great value to be further studied.

INTRODUCTION

The role of somatostatin (SS) analogs in the tumor diagnostic and therapeutic applications has attracted the concern of the people. It has been widely reported about the growth suppressing effects of SS and its analogs on many tumors^[1-4]. To date, it is known that their suppressing effect on tumor cell proliferation is mediated by the somatostatin receptors (SSTRs) presented in the tumor constitution^[5]. Like most neuroendocrine tumors, adenocarcinomas originating in the breast, colon, or pancreatic tumor, as well as meningiomas, express SSTRs, and the majority of these tumors express the somatostatin receptor subtype 2 (SSTR2)^[6,7]. However, all five receptor subtypes (SSTR1-5) bind native SS with a high affinity, while octreotide, an SS analog, binds with a very high affinity only to subtype 2 (SSTR2) and shows a moderately high affinity for SSTR5^[8]. Overexpression of the SSTR2 in some tumors has made it possible to use SS-receptor scintigraphy with indium111 or technetium 99m-labeled octreotide for the visualization of SS receptor-positive cancers^[9,10]. In addition to tumor scintigraphy, a new application of these radiolabeled peptides is peptide receptor radionuclide therapy^[11,12].

It has been known that hepatocellular carcinoma (HCC) is a leading cause of cancer-related death. At present, surgical resection of malignant liver lesions offers the best outcome and the only hope of cure. The 5-year survival rate for selected patients undergoing surgical resection of primary HCC was 30%, with a median survival of 30 mo. However, approximately 90% of patients presenting with primary HCC have inoperable disease^[13]. These patients must rely largely on various forms of chemotherapy and radiotherapy^[14,15]. These treatments have at times shown promising response rates, symptom palliation and have occasionally down-staged hepatic tumors to allow surgical resection, but these treatment modalities have not improved 5-year survival rates, which remain in the order of 1%^[16]. The persisting poor survival among the vast majority of patients presenting with liver cancer has led to renewed interest in developing targeted radiotherapy with radiolabeled SS analogs as a

possible treatment option for patients with non-resectable liver cancer. However, it has not been known that HCC can uptake radiolabeled SS analogs. The aim of this study was to scintigraphically identify the localization of HCC in order to reveal a possible role of radiolabeled SS analogs in the treatment of HCC, and determine the target cell of receptor subtype selective radiolabeled SS analogs for targeting radiotherapy of HCC.

MATERIALS AND METHODS

Materials

All reagents and solvents were obtained from commercial sources and were used without further purification except HYNIC-[Tyr³]-octreotide (HYNIC-TOC). We applied hydrazinonicotinic acid (HYNIC) as the ligand for ^{99m}Tc. Labeling with ^{99m}Tc was performed using a co-ligand required to stabilize ^{99m}Tc bound to the hydrazino residue of the peptide conjugate. HYNIC-TOC was synthesized at the Medicine Isotope Research Center of Peking University. Na^{99m}TcO₄ was obtained from commercial ⁹⁹Mo/^{99m}Tc generator. The methods of HYNIC-TOC synthesis and ^{99m}Tc labeling were employed as previously described^[17,18]. Reaction solutions were tested for radiochemical purity by the C18-SepPak column of high-performance liquid chromatography immediately and up to 24 h after preparation. ^{99m}Tc of radioactive purity > 95% was bound to HYNIC-TOC.

RT-PCR and sequencing of products

The human HCC cell line HepG2 was assessed for the presence of somatostatin receptor subtypes (SSTR1-5) messenger RNA (mRNA) to confirm the presence of the target receptor subtype for ^{99m}Tc-HYNIC-Tyr³-octreotide (^{99m}Tc-HYNIC-TOC), especially SSTR2. The following primer pairs (Boya Co., Shanghai, China) were applied: for human SSTR1, sense (1 543-1 652) 5'-TCATCCTCGGCT-ATGCCAAC-3' and antisense (1 789-1 898) 5'-GCAGGTG-CCATTACGGAAGA-3'; for SSTR2, sense (359-378) 5'-CTGTGGATGGCATCAATCAG-3' and antisense (723-741) 5'-TCGGATTCCAGAGGACTTCA-3'; for SSTR3, sense (1 193-1 212) 5'-GCCTCTGCTACCTGCTCATC-3' and antisense (1 618-1 637) 5'-CCATCCTCCTCCTCC-TCATC-3'; for SSTR4, sense (480-499) 5'-CAGCGTGGC-CAAGCTCATCA-3' and antisense (962-981) 5'-GATCGG-CGGAAGTTGTCGGA-3'; for SSTR5, sense (205-224) 5'-GCCAAGATGAAGACCGTCAC-3' and antisense (668-887) 5'-AGCAGGTAGCACAGGCAGAT-3'; for β -actin, sense 5'-ACGTTATGGATGATGTATCGC-3' and antisense 5'-CTTAATGTCACGCACGATTTC-3'. RNA extraction and reverse transcription were performed according to the manufacturer's instructions. cDNA was amplified in a reaction mixture (total volume 20 μ L) comprising cDNA (transcribed from 12 μ g of total RNA), 2 μ L of 10 \times PCR buffer, 0.4 μ L of 10 mmol/L dNTP, and 1.5 μ L of 25 mmol/L MgCl₂, 10 pmol/L of each of sense and antisense primers, and 2.5 U of Taq DNA polymerase. Following an initial denaturing step at 94 °C for 5 min, the amplification program of 30 cycles, each cycle consisting of denaturation at 94 °C for 30 s, annealing at 60 °C for 20 s, and extension at 72 °C for 30 s, was

carried out by a Gene Amplification PCR system 2 400 (PE Corp., USA). The amplification was terminated with the final extension step at 72 °C for 10 min. The amplified products, subsequently, were electrophoresed and photographed on 15 g/L agarose gel stained with ethidium bromide. The final products were verified by sequencing in Boya Co. (Shanghai, China). β -actin specific primers were used to amplify the cDNA fragment as an internal standard.

Tumor cell inoculation and tumor growth assessment

The human HCC cell line HepG2 was from Clinical Medical Institute of Sir Run Run Shaw Hospital. The cells were grown in RPMI1640 (Gibco Co., USA) supplemented with 100 mL/L fetal bovine serum (Hangzhou Sijiqing Co., China) at 37 °C in a humidified atmosphere containing 50 mL/L CO₂ and 950 mL/L O₂. Subculturing was executed every 2-3 d and the cells grew well along the walls of culture tube. Then, the cells (2 \times 10⁶ cells/mouse) at logarithmic growth period were subcutaneously inoculated into right flank of BALB/c nude mice, aged 6-8 wk, weighing 18-20 g (purchased from Animal Center of Academy of Science, Shanghai, China). The total tumor load per mouse was approximately 1 cm³ at about 28 d post-injection. We took out the whole tumors, then, immediately put into saline containing 100 U/mL penicillin and streptomycin. Tumor pieces with a size 1-2 mm³ were made from the margins of the whole mass after winking the connective tissue around the mass. The mice were randomly divided into three groups in accordance with subcutaneous re-transplantation of tumor into right flanks (subcutaneous group) or *in situ* liver (intra-liver group), or without re-transplantation (control group). Each group consisted of three mice. The experiments were started at 21 d post re-implantation, when the size of tumor per mice was approximately 1 cm³.

In vivo imaging with ^{99m}Tc-HYNIC-TOC

Each mouse of tumor-bearing groups (subcutaneous group and intra-liver group) and control mice group received 100 μ Ci of ^{99m}Tc-HYNIC-TOC injected into the caudal vein under soluble pentobarbitone anesthesia. The mice were imaged at 2 and 4.5 h, respectively, after injection of ^{99m}Tc-HYNIC-TOC with mini-radioisotope gamma camera equipped with a pinhole collimator (Bingsong Corp., China). During imaging, the mice were maintained with a fixed band and positioned on dorsal recumbency with the legs extending from the body. The imaging analyses of ^{99m}Tc uptake in tumor tissue and vital organs were conducted using ANMIS 2000 nuclear medicine analysis system (Bingsong Corp.). Animals of the intra-liver group were killed after the second imaging session (4.5 h after injection of ^{99m}Tc-HYNIC-TOC) for examination of intra-liver tumor growth.

RESULTS

Expression and PCR products sequencing of SSTR2 mRNA in HCC cell line HepG2

PCR products of SSTRs were obtained for HepG2 cells. The size of the products corresponded to the predicted length of the synthesized cDNA fragment based on the position of the PCR primer. SSTR1-5 mRNAs were variably expressed in HepG2 cells. Expressions of SSTR1, SSTR2, and SSTR4 mRNA were found in HepG2 cells, respectively

(Figure 1), but those of SSTR3 and SSTR5 mRNAs were not observed. We identified that the product of SSTR2 mRNA was the specific fragment that we needed after performing sequencing and comparison with SSTRs mRNA rank of the GenBank^[19], it turned out to be a perfect coincidence with the fragment rank (Figure 2). The result showed that the amplification we executed was specific.

Figure 1 RT-PCR analysis for SSTR1-5 mRNA expression in HepG2. Lane m: marker; lane 1: SSTR1 (246 bp); lane 2: SSTR2 (384 bp); lane 3: SSTR3; lane 4: SSTR4 (502 bp); lane 5: SSTR5.

In vivo imaging with ^{99m}Tc-HYNIC-TOC

The gamma camera imagings of a representative mouse from the subcutaneous, intra-liver and control groups at 2 and 4.5 h after being injected with ^{99m}Tc- HYNIC-TOC are shown in Figure 3. These imagings showed visual accumulation of ^{99m}Tc-HYNIC-TOC detected in the tumor xenografts of mice (including subcutaneous group and intra-liver group). The retention of radioactivity in the kidney and excretion through the bladder were observed. The high-level uptake of radioactivity in the liver of tumor-bearing mice was also observed and compared with the control group. This tumor uptake was important to validate the dosing regimen that was used in therapy studies of liver cancer.

DISCUSSION

Radiolabeled SS analogs have brought new prospects to nuclear oncology for diagnosis and therapy of tumor. Due to their low molecular weight and high affinity to SSTRs, good tissue penetration properties, and being internalized

Figure 2 Sequencing of SSTR2 mRNA PCR products. The products were specifically amplified after the sequencing fragment was compared with human

SSTR2 of GenBank, and was a perfect coincidence with the fragment rank of human SSTR2 mRNA.

Figure 3 Scintigrams of mice at different times after injection of ^{99m}Tc-HYNIC-TOC. A and C: subcutaneous group at 2 and 3 h, respectively; B and D: intra-liver group at 2 and 4 h, respectively; E: subcutaneous group at 4.5 h, when the

bladder was emptied; F: control group at 2 h. The marked decrease in the liver (arrows) uptake was apparent in the control group mouse.

into the tumor cells after receptor binding^[20-22], they provide promising strategies for diagnosis and internal radionuclide therapy for various cancer types. Before radiolabeled, octreotide was employed in HCC, it has been studied with ¹²⁵I-[Tyr³]-octreotide for tumor diagnosis^[11]. However, some studies demonstrated that the SSTRs density in HCC was considerably lower than the receptor density found^[23,24], thus it has rarely been studied in the liver cancer. As radiotherapy of SS receptor-positive tumors with compounds such as ⁹⁰Y-labeled ones was applied, it is necessary to develop a new strategy for the treatment of liver cancer.

In this study, we evaluated the expression of SS receptor in human HCC cell line HepG2. The results showed that SSTR1, SSTR2 and SSTR4 were frequently expressed in human HCC, which was similar to previous reports^[25,26]. As the normal human liver does not express SSTR2 (predominant receptor subtype was SSTR1^[27]), the presence of SSTRs in HCC may be regarded as an overexpression of the receptors in this tumor. Like previous therapeutic experiments^[28], unlabeled octreotide was shown to bind with a high affinity to SSTR2, suggesting that the predominant receptor subtype was SSTR2. As to radiolabeled octreotide targeting therapy for HCC, the expression of SSTR2 in HCC is of high significance.

In scintigraphy experiment with ^{99m}Tc-HYNIC-TOC, the significant uptake of radionuclide by tumor xenografts in nude mice was found in both subcutaneous group and intra-liver group. And it was demonstrated that the hepatocarcinoma tissues had a fairly steady rate in uptaking ^{99m}Tc-HYNIC-TOC by the fact that there was still obvious radionuclide gathering at the tumor tissues at 4 h after administration. The results showed that the intensity of the signal was not as strong as for neuroendocrine tumor metastases. As a therapeutic tool, there are certainly potential clinical implications linked with the SS receptor expression in HCC.

The expression of some SS receptor subtypes was found in the liver and kidney as well^[24,29]. However, the physiological uptake of ^{99m}Tc-HYNIC-TOC in these organs was probably mainly due to some loss of technetium out of chelation (liver) and non-specific peptide uptake in the tubulus cells (kidney). Thus, in our receptor scintigram, the retention of radionuclide prominently in both kidney and bladder as well as the less uptake in liver, which was similar to previous reports^[30,31], was shown after injection of ^{99m}Tc-HYNIC-TOC. Because of the absence of SSTR2, the retention of technetium in the bladder, which was possibly due to the kidney excretion, almost vanished when bladder emptied (Figure 3E). Meanwhile, based on recent studies^[32-34], most of the radiolabeled octreotide, like our results, would accumulate in the kidney after glomerular filtration, followed by re-absorption into renal cells. It is necessary to take into consideration the induction of the kidney damage while performing targeting radiotherapy with radiolabeled octreotide.

In conclusion, HCC cell line HepG2 expresses SSTR2 mRNA. ^{99m}Tc-HYNIC-TOC, relying on the receptor mediation, can markedly bind with and be uptaken by human HCC tissues as compared to the normal liver tissue, which is probably mainly due to some loss of technetium

out of chelation. The significant retention of radionuclide in kidney and bladder is probably related to non-specific peptide uptake in the tubulus cells of kidney and possibly due to the excretion by kidney. This phenomenon has clued to potential radiation nephrotoxicity of the agents, which needs to be solved before a widespread application of targeting radiotherapy.

Abstract

AIM: To study the effects of He-Ne laser irradiation on experimental chronic atrophic gastritis (CAG) in rats.

METHODS: Sixty-three male adult Wistar rats were randomly divided into five groups including normal control group, model control group and three different dosages He-Ne laser groups. The chronic atrophic gastritis (CAG) model in rats was made by pouring medicine which was a kind of mixed liquor including 2% sodium salicylate and 30% alcohol down the throat for 8 wk to stimulate rat gastric mucosa, combining with irregular fasting and compulsive sporting as pathogenic factors; 3.36, 4.80, and 6.24 J/cm² doses of He-Ne laser were used, respectively for three different treatment groups, once a day for 20 d. The pH value of diluted gastric acid was determined by acidimeter, the histopathological changes such as the inflammatory degrees in gastric mucosa, the morphology and structure of parietal cells were observed, and the thickness of mucosa was measured by micrometer under optical microscope.

RESULTS: In model control group, the secretion of gastric acid was little, pathologic morphological changes in gastric mucosa such as thinner mucous, atrophic glands, notable inflammatory infiltration were found. After 3.36 J/cm² dose of He-Ne laser treatment for 20 d, the secretion of gastric acid was increased ($P < 0.05$), the thickness of gastric mucosa was significantly thicker than that in model control group ($P < 0.01$), the gastric mucosal inflammation cells were decreased ($P < 0.05$). Morphology, structure and volume of the parietal cells all recuperated or were closed to normal.

CONCLUSION: 3.36 J/cm² dose of He-Ne laser has a significant effect on CAG in rats.

INTRODUCTION

Chronic atrophic gastritis (CAG) is one of the most common digestive diseases worldwide^[1-4]. The patient's gastric mucosa atrophies, gastric sinus secret cells reduce, function is weakened, gastric acid secretion reduces, especially pathological changeable epithelium often contains intestine epithelium metaplasia and atypical hyperplasia, which are often seen as precancerous lesions of gastric carcinoma^[5-7]. To the author's knowledge, clinics still have no perfect and effective treatment projects^[8]. So we successfully established an animal model with CAG in rats^[9], used different radiation intensity of He-Ne laser to irradiate at the gastric projective area of rat with CAG, to study the therapeutic effects by examining changes of gastric acid and observing changes of pathologic histology in gastric mucosa.

MATERIALS AND METHODS

Animals

A total of 52 male adult Wistar rats weighing 180-230 g were purchased from Experimental Animal Center, Capital Medical University. They were housed in an air-conditioned room with 12 h dark/light cycle, and randomly divided into five groups: eight in normal control group, 11 in model control group, 11 in 3.36 J/cm² dose He-Ne laser group (small dose He-Ne laser group), 11 in 4.80 J/cm² dose He-Ne laser group (inside dose He-Ne laser group), 11 in 6.24 J/cm² dose He-Ne laser group (big dose He-Ne laser group). CAG model in rats were made by mixing 2% sodium salicylate and 30% alcohol and poured down their throats for 8 wk to stimulate their gastric mucosa, combined with irregular fasting and compulsive sporting.

He-Ne laser therapy

He-Ne laser therapy was carried out using the HJ-3DB He-Ne laser machine (wavelength 632.8 nm) which was made by Nanjing laser instrument factory, the He-Ne laser was amplified by convex lens, vertically radiated at the gastric projective area. The anterioposterior diameter of laser was 1 cm, its power density was 8 mW/cm². The following formed the course of treatment once a day for 20 d.

Small dose He-Ne laser treatment: irradiated 7 min each time, 3.36 J/cm² of dosage;

Inside dose He-Ne laser treatment: irradiated 10 min each time, 4.80 J/cm² of dosage;

Big dose He-Ne laser irradiation: irradiated 13 min each time, 6.24 J/cm² of dosage.

Process

The rats in each group were killed at the desired time-point. The animals were deprived of food but were offered enough water before being killed at 24 h. The rats were anesthetized with ether, the belly was opened immediately, cadre was ligature, the whole stomach was taken off, and the surface blood stains were washed by normal saline water, sucked dry with filter paper, then the gastric cavity was opened along greater curvature of stomach, flushed with distilled water, and the dilution gastric liquid (provided to measure the gastric acid pH value) was collected, then front and back gastric sinus and parts of stomach organized roughly into 3 mm×10 mm were taken in parallel with lesser curvature of stomach, fixed in neutral formalin, embedded in paraffin wax, 6 µm sections, stained with hematoxylin-eosin (HE) for pathological examination.

Determination of gastric acid

The rat's gastric acid (pH value) was determined five times for each example by acidimeter (PHS-3C) from Shanghai Instrument Factory, and took the average value as the pH value of this animal.

Pathology examinations

Take three sliced pieces for each example, and select three different visual fields for each slice such as the body of stomach, gastric sinus and the area of the body of stomach marked with gastric sinus. The whole gastric mucosa was observed under light microscope, which included the following aspects: (1) the immunity degree of the gastric mucosal ingluvitis cellular was divided into two grades such as negative (-) (no ingluvitis cells or some ingluvitis that jot spread at the gastric mucus) and positive (+) (more ingluvitis cell at the gastric mucosa or series of ingluvitis cells aggregated inside the mucus), counted the positive rate respectively by each visual field; (2) measured the thickness of the gastric mucosa with microscope, regarded µm as the unit, adopted the average of the mucosa thickness to show the reflection hyperplasia circumstance; (3) observed the parietal cell including the appearance, construction and arrangement.

Statistical analysis

Software SPSS 10.0 was used in the statistical analysis, parameters were expressed as mean±SD, and compared using One-way ANOVA analysis of variance, followed by χ^2 tests and differences were considered significant at $P<0.05$.

RESULTS

Gastric acid

The determination results of gastric acid showed that the secret function of gastric mucosa in model control rats was more decreased than that in both normal control group and small dose He-Ne laser group ($P<0.05$, Table 1).

Table 1 Detection of gastric results of pH value in Wistar rats

Group	<i>n</i>	pH value (mean±SD)
Normal control	6	3.72±1.02 ^a
Model control	7	5.86±1.45
Small dose He-Ne laser	7	4.43±1.18 ^a
Inside dose He-Ne laser	6	4.66±1.00
Big dose He-Ne laser	7	4.57±1.48

^a $P<0.05$ vs control group.

Pathological findings

The pathological histologies were observed under microscope. In normal control group, the gastric mucosa was thick, the epithelium was complete, only fell ingluvitis were spread, there was no obvious ingluvitis cellular immunity (Table 2). The parietal cells in normal control group were as follows: large volume, pyramid form, cell edge tactful, full, numerous, were arranged neatly and above 2/3 at a fundic gland (Figure 1A). In model control group, the gastric mucosa was thinner than that in normal control group ($P<0.01$), there were large quantities of immunity ingluvitis ($P<0.01$), most of the cells were lymphocytes and plasma cells. The parietal cells in model control group were as follows: volume sterigma, cell edge anomaly polygon, afterbirth syrup was wrinkled and arranged foul-up, intercellular space was enlarged, the ratio in syrup and nucleosidase increased the breadth of the gland antrum, and large quantity of cells were put through empty transformation (Figure 1B). In He-Ne laser groups, the gastric mucosa was thicker than that in model group ($P<0.01$), ingluvitis cells were less than that in model control group, particularly the small dose He-Ne laser group ($P<0.05$). The parietal cells in small dosage He-Ne laser

Table 2 Changes of gastric mucosa thickness and the observations of ingluvitis cellular immunity degree

Group	<i>n</i>	The thickness of gastric mucosa (µm) (mean±SD)	Ingluvitis cellular immunity degree			Ingluvitis edema	
			-	+	Positive rate (%)	Yes	No
Normal control	8	525.17±57.52 ^b	7	1	13 ^b		✓
Model control	11	387.21±51.60	1	10	91		✓
Small dose He-Ne laser	11	499.06±57.25 ^b	6	5	45 ^a		✓
Inside dose He-Ne laser	11	456.77±47.56 ^b	1	10	91	✓	
Big dose He-Ne laser	11	475.62±53.75 ^b	2	9	82	✓	

^a $P<0.05$, ^b $P<0.01$ vs model control group.

Figure 1 Pathology changes of parietal cells. **A:** parietal cells of gastric mucosa in normal control group (HE $\times 400$); **B:** parietal cells of gastric mucosa

in model control group (HE $\times 400$); **C:** parietal cells of gastric mucosa in small dose He-Ne laser group (HE $\times 400$).

group were as follows: cell appearance, volume and construction were all near to normal, and arranged neatly (Figure 1C). Besides, there was no obvious ingluvitis edema in normal control group, model control group and small dosage He-Ne laser group, but it was obvious in inside and large dose He-Ne laser groups, and the cells were transformed in the two groups.

DISCUSSION

The cause of disease and pathogenesis of chronic atrophic arthritis (CAG) are not yet completely clean, generally speaking, it is a synthesis factor with more effects and actions such as immunity, gall back streaming, pyloric infection, food, wine, smoke, and drugs^[2,8,9]. Research expressed that sodium salicylate could hurt gastric mucosa and enzyme could inhibit gastric cell growth^[10], alcohol could incite gastric mucosa. In our experiment, we poured a mixture of 2% sodium salicylate and 30% alcohol down the rat's throat for 8 wk, which could affect the natural cover and organize variety in gastric mucus, combined with fatigue from overwork, hunger and dissatisfaction in order to make the pathological changes of CAG appear on the gastric mucosa appear^[9]. Since the parietal cells reduced and degenerated, there was disorder both in gastric acid secretion and digestion enzyme weakness, the performance was a series of weak symptoms of the function of digestion and absorption such as the reduction of gastric acid secretion, diminishing of the gland and atrophy, and metaplasia of the intestinal epithelium^[9].

He-Ne laser, its characteristics such as 632.8 nm of wavelength, good directivity, high intensity, good monochromaticity, is a low-level laser^[11-14]. The low-level laser has some biology effects such as cell vitality^[15-18], phagocytosis^[19-21], immune responses^[22-25], but as far as its usage for the treatment of digestive disease, there were only few reports^[26-28]. On one hand, there was no difference between treating gastric ulcer through bark and by endoscope^[29]. On the other hand, external irradiation is easy, and patients can bear some pain with ease. We treated rats with CAG by external irradiation with He-Ne laser as amplified by a convex mirror, radiated at the gastric projective area. The results implied that the gastric acid secretion of the rats in CAG treated by He-Ne laser irradiation was increased, the best effect was on the animals treated by small dosage He-Ne laser. Some changes in gastric mucus such as thickness of gastric mucosa, alleviated

ingluvitis, and parietal cell hyperplasia were found in this experiment. We think the mechanism of He-Ne laser treated CAG in rats as follows: (1) partial microcirculation was ameliorated; (2) body immunity was enhanced; (3) the organized growth of gastric mucosa was promoted; (4) inflammation was eliminated. Moreover, in our experiment we found that three different dosages of He-Ne laser preceding the incitement to the rat in CAG, resulted in different effects. The best effect was the small dosage of He-Ne laser, the inside dose and the large dose were not as well as the small dose of He-Ne laser, which showed the dependence on dosage^[20,30,31]. Perhaps it is because the biology effect of He-Ne laser closely related to the action time, power density that organized He-Ne laser. Under the same power density (8 mW/cm²), different action time (small dose for 7 min, inside dose for 10 min, large dose for 13 min), produced different effects. These results showed that small dose He-Ne laser was a positive action, but large dose was an inhibitory action to incite lombricine organization^[32]. Besides, some damaged cells, individual swelling, afterbirth syrup degeneration and ingluvitis edema in the inside dose He-Ne laser group and the big dose He-Ne laser group were found in gastric mucus of rats under microscope. This may indicate the light dynamic damage of He-Ne laser. So we draw a further conclusion that big doses of He-Ne laser were deformative. In a word, the experiment showed that 3.36 J/cm² dose of He-Ne laser is a valid dose of external irradiation to incite life, it could promote the secretion of gastric acid and recover the function of gastric mucus to the CAG in rats.

In summary, 3.36 J/cm²/d dose of He-Ne laser irradiation is a well-tolerated, safe, and effective treatment in rats with CAG. The technique is easy, inexpensive, and of short duration^[25]. It is necessary to translate the outcome of this study into clinically relevant interventions by further studies which would develop a new way for the treatment of CAG.

Abstract

AIM: To study the expression of interferon-alpha/beta (IFN- α/β) receptor protein in liver of patients with hepatitis C virus (HCV)-related chronic liver disease and its clinical significance.

METHODS: A total of 181 patients with HCV-related chronic liver disease included 56 with HCV-related liver cirrhosis (LC) and 125 with chronic hepatitis C (CHC). CHC patients were treated with five megaunits of interferon- α 1b six times weekly for the first 2 weeks and then every other day for 22 wk. The patients were divided into interferon (IFN) treatment-responsive and non-responsive groups, but 36 patients lost follow-up shortly after receiving the treatment. The expression of IFN- α/β receptor (IFN- α/β R) protein in liver of all patients was determined with immunofluorescence.

RESULTS: In liver of patients with HCV-related chronic liver disease, the expression of IFN- α/β R protein in liver cell membrane was stronger than that in cytoplasm and more obvious in the surroundings of portal vein than in the surroundings of central vein. Moreover, it was poorly distributed in hepatic lobules. The weak positive, positive and strong positive expression of IFN- α/β R were 40% (50/125), 28% (35/125), 32% (40/125), respectively in CHC group, and 91.1% (51/56), 5.35% (3/56), and 3.56% (2/56), respectively in LC group. The positive and strong positive rates were higher in CHC group than in LC group ($P < 0.01$). In IFN treatment responsive group, 27.8% (10/36) showed weak positive expression; 72.2% (26/36) showed positive or strong positive expression. In the non-responsive group, 71.7% (38/53) showed weak positive expression; 28.3% (15/53) showed positive or strong positive expression. The expression of IFN- α/β R protein in liver was more obvious in IFN treatment responsive group than in non-responsive group.

CONCLUSION: Expression of IFN- α/β R protein in liver of

INTRODUCTION

Interferon (IFN) is effective in the treatment of chronic hepatitis C. It results in viral eradication and normalization of liver function in about 35-40% of the patients^[1-4]. The anti-virus mechanism of IFN is to transmit the signal to nuclei and to activate 2'-5' adenylic acid synthase and protein kinase after IFN molecule combines with IFN receptor, which then blocks the translations of virus protein and RNA. IFN receptor (IFN-R) is the initial protein for the chain reaction of IFN^[5]. Human interferon receptors are divided into type I IFN-R which can combine with IFN- α/β , and type II IFN-R which has specific sensitivity to IFN- γ . Furthermore, it has been proved that type II IFN-R is also sensitive to IFN- α/β to some extent^[6], meanwhile IFN- β and subtypes of IFN- α have high sensitivity to IFN-R^[7].

In this study, we determined the expression of IFN-R protein in liver of patients with HCV-related chronic liver disease and its clinical significance.

MATERIALS AND METHODS

Patients

A total of 181 patients were enrolled in this study, including 125 patients with chronic hepatitis C and 56 patients with HCV-related liver cirrhosis. All the patients were seropositive for HCV-RNA and underwent liver biopsy. None of the patient was infected with other hepatitis viruses. All the patients with chronic hepatitis C received IFN treatment. However, only 89 patients were evaluated for treatment response since 36 patients lost follow-up shortly after receiving the treatment. According to the response to IFN treatment, we studied the expression of IFN- α/β R protein in liver of 89 patients with chronic hepatitis C at least six months after IFN treatment.

IFN treatment

IFN treatment was standardized as follows. Five megaunits of IFN- α 1b was administrated to 89 patients with chronic hepatitis C by intramuscular injection six times weekly for the first 2 weeks and then every other day for 22 wk. The total dosage of IFN was 470 MU^[8]. The study followed the ethical guidelines of the Declaration of Helsinki and was approved by the institutional ethics committee. Informed consent was obtained from all patients before IFN treatment.

Appraisal of IFN treatment

According to the response to IFN, 89 patients with chronic hepatitis C who were seropositive for HCV-RNA and received IFN treatment were divided into responder group (36) and non-responder group (53). Responders were defined as patients who were seronegative for HCV-RNA with their serum alanine aminotransferase (ALT) decreased to the normal range for at least 6 mo after IFN treatment. The other patients were non-responders.

Histopathological evaluation

Liver biopsy specimens were defined by Knodell's pathologic classification. The degree of liver fibrosis was determined according to the criteria for staging fibrosis (F₀ to F₄), including F₀ (no fibrosis), F₁ (portal area fibrosis), F₂ (bridging fibrosis), F₃ (bridging fibrosis with lobule deformation), F₄ (cirrhosis). Inflammation activities were scored as follows: 1-3 points (mild hepatitis), 4-8 points (moderate hepatitis), 9-12 points (severe hepatitis).

Determination of IFN- α/β in liver

Making specimens with immunofluorescence technique

IFN- α/β in the liver was immunostained with an indirect immunofluorescence technique. The liver biopsy specimens were sampled during laparoscopy, fixed with fixatives, and frozen to make histological sections. The sections were incubated with non-marked antibody for 45 min at 37 °C, washed thrice in 0.15 mol/L pH7.6 phosphate buffered saline (PBS) for 3 min and once in 0.01 mol/L pH 7.6 PBS for 1 min, then incubated with anti-idiotypic antibody (AId) for 30-45 min at 37 °C and washed with PBS. The sections were dehydrated at room temperature and mounted in glycerol. We cloned the gene coding for the outside-membrane of IFN- α/β in Daudi's cells and immunized white rabbits with protein produced by the gene-transfected *E.coli* to get the first antibody (Amersham, Buckinghamshire, UK). The AId (Amersham, Buckinghamshire, UK) was an anti-rabbit-IgG class antibody labeled with fluorochrome. Negative control was serum of rabbits.

Criteria of fluoroimmunoassay

Intensity of fluorescence was standardized as follows (Figure 1): weak positive (+), positive (++) and strong positive (+++). If a minority of hepatocytes in the portal area were stained, it was defined as weak positive (+). The strong positive (+++) means almost all hepatocytes in the hepatic lobule were stained, and hepatocytes between the two grades were defined as positive (++)

Statistical analysis

Statistical significance of difference was determined by χ^2 -test.

RESULTS

Expression of IFN- α/β protein in liver

IFN- α/β protein was expressed in all the samples of HCV-related chronic liver disease, however the degree of expression varied. Expression of IFN- α/β protein in cell membrane was stronger than that in cytoplasm (Figure 2A). The expression of protein in the surroundings of the portal vein was stronger than that in the surroundings of the central vein. The protein was poorly distributed in hepatic lobules (Figure 2B). Almost all the IFN- α/β proteins expressing cells were hepatic parenchymal cells. However, IFN- α/β proteins were also expressed in part of interlobular cholangioepithelia (Figure 2C).

Expression of IFN- α/β protein in patients with chronic hepatitis C and HCV-related liver cirrhosis

Among the 125 patients with chronic hepatitis C, 40% (50/125) showed weak positive (+), 28% (35/125) showed positive (++) , 32% (40/125) showed strong positive (+++) expression of IFN- α/β protein. Among the 56 patients with HCV-related liver cirrhosis, 91.1% (51/56) showed weak positive (+), 5.35% (3/56) showed positive (++) , 3.56% (2/56) showed strong positive (+++) expression of IFN- α/β protein. The total frequency of positive and strong positive expression in chronic hepatitis C patients was much higher than that in patients with HCV-related liver cirrhosis ($P < 0.01$ Table 1).

cholangioepithelia (C).

Expression of IFN α / β R protein in liver of patients with chronic hepatitis C after IFN treatment

Six months after IFN treatment, the responders and non-responders were 36 and 53 respectively, and 27.8% (10/36) of the responders showed weak positive (+), and 72.2% (26/36) showed positive (++) or strong positive (+++) expression of the IFN α / β R protein; 71.7% (38/53) of non-responders showed weak positive (+), and 28.3% (15/53) showed positive (++) or strong positive (+++) expression of the IFN- α / β R protein. After the treatment, the total frequency of positive (++) and strong positive (+++) expression of the IFN- α / β R protein in responder group was much higher ($P < 0.05$) than that in non-responder group (Table 2).

Table 2 Effect of IFN and expression of IFN- α / β R protein

IFN treatment effect	n	Fluorescence intensity in cases, n (%)

Non-responders	53	38 (71.7)	15 (28.3)

^a $P < 0.05$ vs non-responders.

DISCUSSION

Isimura^[9] has proved that IFN R protein exists in liver by ELISA and reported that the expression degree of IFN- α R protein in cytoplasm is different. By immunohistochemical method and competitive polymerase chain reaction assay, Fujiwara *et al.*^[9], found that determination of the expression of IFN- α / β R protein is more useful than that of its mRNA. In this study, we found that expression of IFN- α / β R protein in cell membrane was stronger than that in cytoplasm by immunofluorescence assay. IFN- α / β R protein is a membrane receptor just like other cytoplasm receptors. Moreover, this study also found that the expression of IFN- α / β R protein in the surroundings of the portal vein was stronger than that in the central vein, and the protein was poorly distributed in hepatic lobules. This may be attributed to the following aspects. The blood stream in surrounding of the portal vein is more affluent, providing a good nutritional condition for virus infection which then induces the expression of IFN- α / β R. The expression intensity of IFN- α / β R protein varies in different chronic hepatic diseases. It is weaker in patients with HCV-related

liver cirrhosis than in patients with chronic C hepatitis. The reason may be that the bloodstream in patients with cirrhosis is not well-distributed and the blood supply becomes deficient due to various kinds of fibrosclerosis in hepatic lobules, and liver function and liver cell membrane are damaged because of hepatic cellular inflammation. Because of these factors, liver could not provide a good condition for the expression of IFN- α / β R protein in patients with cirrhosis. Defective expression of IFN- α / β R protein can reduce the intake of IFN, resulting in increased reproduction of virus and activity of hepatitis.

This study demonstrated that expression of IFN- α / β R protein had a close correlation with hepatic fibrosis. The majority of responders with chronic hepatitis C had a very strong expression of IFN- α / β R protein prior to the treatment, which coincides with other researches^[10-12]. The reasons are as follows. The infection of hepatitis virus C can induce expression of protein effectively^[13], since some patients with HCV-related chronic liver disease become very sensitive to IFN treatment. Expression of IFN- α / β R protein in liver in responsive cases is much stronger than that in non-responsive cases. That is to say, non-responsive reaction to the treatment may be caused by the defective expression of protein in patients with chronic hepatitis C. Although expression of IFN- α / β R protein in the responder group is stronger than that in non-responder group, the expression also exists in some non-responsive cases. On the contrary, expression of IFN- α / β R protein in some responsive cases is as weak as that in non-responsive cases. These inconsistencies are attributed to the following aspects. IFN- α / β R protein cannot represent all IFN R proteins involved in the anti-virus mechanism in chronic hepatitis C. The protein we studied is IFN- α / β R protein which could respond to IFN- α and IFN- β ^[7]. The protein plays a key role, in the anti-virus mechanism against HCV-related chronic disease. The combining activity of R proteins maybe changed in the responsive cases when IFN- α / β R protein is expressed. Among the responsive and non-responsive cases, some patients with severe chronic hepatitis C and cirrhosis were not sensitive to IFN treatment, and defective expression of IFN- α / β R protein in these patients was a major cause. It coincides with other studies^[14,15]. In conclusion, expression of IFN- α / β R protein in liver of patients with HCV-related chronic disease is likely involved in response to IFN treatment, the expression of IFN- α / β R protein may be useful in

predicting IFN therapeutic effect, and defective expression of IFN- α/β R protein in liver may result in resistance to IFN treatment in patients with HCV-related chronic liver disease.

Abstract

AIM: To study the surgical treatment effect and outcome of hepatocellular carcinoma (HCC) with bile duct tumor thrombi (BDTT).

METHODS: Fifty-three consecutive HCC patients with BDTT admitted in our department from July 1984 to December 2002 were reviewed retrospectively. The clinical data, diagnostic methods, surgical procedures and outcome of these patients were collected and analyzed.

RESULTS: One patient rejected surgical treatment, 6 cases underwent percutaneous transhepatic cholangial drainage (PTCD) for unresectable primary disease, and the other 46 cases underwent surgical operation. The postoperative mortality was 17.6%, and the morbidity was 32.6%. Serum total bilirubin levels of these patients with obstructive jaundice decreased gradually after surgery. The survival time of six cases who underwent PTCD ranged from 2 to 7 mo (median survival of 3.7 mo). The survival time of the patients who received surgery was as follows: 2 mo for one patient who underwent laparotomy, 5-46 mo (median survival of 23.5 mo, which was the longest survival in comparison with patients who underwent other procedures, $P = 0.0024$) for 17 cases who underwent hepatectomy, 5-17 mo (median survival of 10.0 mo) for 5 cases who underwent HACE, 3-9 mo (median survival of 6.1 mo) for 11 cases who underwent simple thrombectomy and biliary drainage, and 3-8 mo (median survival of 4.3 mo) for four cases who underwent simple biliary drainage.

CONCLUSION: Jaundice caused by BDTT in HCC patients is not a contraindication for surgery. Only curative resection can result in long-term survival. Early diagnosis and surgical treatment are the key points to prolong the survival of patients.

INTRODUCTION

Jaundice is present in 19-40% of patients with hepatocellular carcinoma (HCC) at the time of diagnosis and usually occurs in advanced stages of diseases. The etiology of jaundice is mainly due to diffuse tumor infiltration of liver parenchyma, progressive liver failure (advanced underlying cirrhosis) and hepatic hilar invasion^[1]. Obstructive jaundice caused by bile duct tumor thrombi (BDTT) arising from HCC is uncommon^[2,3]. Only 1-12% of HCC patients manifest obstructive jaundice as the initial manifestation^[4]. We have noticed this kind of obstructive jaundice caused by HCC with BDTT since 1980, and our initial report of HCC with BDTT was published in 1996^[5]. However, BDTT caused by HCC thrombus is often misdiagnosed as hilar cholangiocarcinoma, and has a particular mode of growth and clinical features. Herein, we report a total of 53 HCC patients with BDTT to make a better understanding of the nature of this disease.

MATERIALS AND METHODS

Patients

From July 1984 to December 2002, 53 consecutive HCC patients (47 males, 6 females, age range 20-69 years, mean age 48.2 ± 10.2 years) with BDTT were treated in our department. The common clinical manifestations included: jaundice, abdominal pain, poor appetite, abdominal distension, skin itch, clay-colored stools, etc. Eight cases had previous treatment in other hospitals before admission. Among them, four cases had recurrent HCC after hepatectomy, three received transcatheter arterial chemoembolization (TACE), and one underwent ³²P glass microspheres (³²P-GMS) internal radiotherapy thrice through hepatic artery cannulation and subcutaneous implantation of a drug pump.

Laboratory examination

The average level of serum total bilirubin was 311.9 ± 186.9 $\mu\text{mol/L}$ (range 20.3-776.6 $\mu\text{mol/L}$), ALT was 119 ± 82 IU/L (range 16-428 IU/L), ALP was 423 ± 241 IU/L (range 116-1 038 IU/L), $\gamma\text{-GT}$ was 410 ± 346 IU/L (range 98-1 637 IU/L), ALB was 37 ± 6 g/L (range 24-46 g/L). The hepatitis B surface antigen was positive in 35 cases (35/53, 66.0%). The hepatitis C antibody assay was positive in one case. The concentration of α -fetoprotein (AFP) was higher than

400 µg/L in 29 cases (29/53, 54.7%). Cirrhosis was found in 28 cases (28/53, 52.8%), ascites in 10 cases (10/53, 18.9%).

Imaging findings

Primary tumors and total BDTT in the common hepatic duct or the common bile duct (CBD) were detected by image investigations including ultrasonography (US), computed tomography (CT), endoscopic retrograde cholangiopancreatography and magnetic resonance cholangiopancreatography (MRCP). Three patients were misdiagnosed as cholangiocarcinoma, among them two cases underwent laparotomy and T-tube drainage in other hospitals, one case was found to have lung metastasis at the initial diagnosis.

Location and size of HCC and BDTT

No obvious primary liver tumor was found in seven cases, among them three cases were misdiagnosed as hilar cholangiocarcinoma (Figure 1). The diameter of the primary tumors ranged from 0.9 to 12 cm (mean value 5.0 ± 2.6 cm) in the remaining 46 cases. Of these, the diameter of the major tumor was larger than 10 cm in 6 cases, between 5 and 10 cm in 15 cases, less than 5 cm in 25 cases. Seventeen cases had multiple nodules, 29 had a single nodule. The tumors were involved in the right lobe ($n = 19$), the left lobe ($n = 13$), and the caudate lobe of liver ($n = 3$), the whole liver ($n = 11$). The tumor thrombi of CBD occurred in all cases. Thrombi coexisted in intrahepatic bile duct ($n = 38$), the right hepatic duct ($n = 5$), the left hepatic duct ($n = 4$), and the left and right hepatic ducts ($n = 6$). In addition, the tumor thrombi presented in the right branch ($n = 1$), and the left branch of portal vein ($n = 1$), the right branch of portal vein and the right hepatic vein ($n = 1$).

Statistical analysis

A database was established by SPSS 10.0 software. Data were expressed as mean \pm SD. Kaplan-Meier method and log-rank test were used for survival statistics. $P < 0.05$ was considered statistically significant.

RESULTS

Treatments

One patient refused surgery for other reasons. Fifty-two cases received treatments. Among them, six cases received non-surgical procedures including percutaneous transhepatic cholangio-drainage (PTCD, $n = 4$), biliary stent placement ($n = 2$). Forty-six cases underwent surgical operations including hepatectomy with thrombectomy and biliary drainage ($n = 21$), hepatic artery chemoembolization (HACE) for unresectable primary diseases and biliary drainage ($n = 5$), simple thrombectomy with biliary drainage ($n = 14$), and simple biliary drainage ($n = 4$). Among the 21 cases who underwent hepatectomy for their primary liver tumors, 2 cases underwent right hemihepatectomy, 2 left hemihepatectomy, 11 partial right lobectomy, 4 partial left lobectomy, 1 left hemihepatectomy with caudate lobectomy, 1 left hemihepatectomy with caudate lobectomy and segmentectomy. Simultaneously, one case underwent thrombectomy for the right branch thrombi of portal vein and the right hepatic vein thrombi via the transaction surfaces. Of the 14 cases

Figure 1 Location and size of HCC. **A:** Hilar obstruction indicating hilar cholangiocarcinoma (white arrow) shown by PTC. **B:** CBD tumor thrombi seen during intra-operation.

who underwent simple thrombectomy and biliary drainage, one underwent proper hepatic artery ligation (HAL), and the other right HAL at the same time.

Pathology

All the 53 cases were pathologically diagnosed as HCC by professional surgical pathologists. The BDTT consisted of tumor cells arranged like a nest of primary tumors, coexisting with red blood cells (RBC), leukocytes and necrotic tumor tissues.

Postoperative mortality and morbidity

Among the 46 patients who underwent operations, 8 died of hepatic failure postoperatively, the hospitalization mortality was 17.4% (8/46). One died 3 d after laparotomy, one died 26 d after simple thrombectomy with biliary drainage and right HAL, two died 7 and 45 d after simple thrombectomy with biliary drainage respectively, four died 7, 12, 15 and 38 d after hepatectomy with thrombectomy and biliary drainage respectively. Fifteen patients developed postoperative complications including liver function failure ($n = 8$), upper gastrointestinal hemorrhage ($n = 4$), pleural effusion ($n = 4$), serious coagulopathy ($n = 1$), intra-abdominal hemorrhage ($n = 1$), pleural hemorrhage ($n = 1$), biliary leakage ($n = 1$), subphrenic infection ($n = 1$), and lower limb venous thrombosis ($n = 1$). The postoperative morbidity was 32.6%. Of the six cases who received PTCD, one suffered from acute cholangitis, no death occurred.

Effect of treatment

The serum total bilirubin levels of these patients with obstructive jaundice decreased gradually. A total of 45 patients were followed up. One patient refused treatment and died 1 mo later. The survival time of six cases who underwent PTCD ranged from 2 to 7 mo (median survival of 3.7 mo). The survival time of the patients who received surgery was 2 mo for one patient who underwent laparotomy, 5-46 mo (median survival of 23.5 mo) for 17 cases who underwent hepatectomy, which was the longest survival compared to the patients who underwent other procedures (log-rank test, $P = 0.0024$), 5-17 mo (median survival of 10.0 mo) for 5 cases who underwent HACE, 3-9 mo (median survival of 6.1 mo) for 11 cases who underwent simple thrombectomy and biliary drainage, and 3-8 mo (median survival of 4.3 mo) for 4 cases who underwent simple biliary drainage.

DISCUSSION

BDTT derived from HCC is uncommon. However, bile duct invasion was commonly detected at necropsy in HCC patients with obstructive jaundice. In 1975, Lin *et al.*^[6], clinically classified such cases as “icteric type hepatoma”, which manifested as obstructive jaundice even at the early stage of tumors, and pointed out that its differential diagnosis was very difficult. In 1982, Kojiro *et al.*^[7], first described the clinical and pathological features of HCC invading the bile duct, and clarified that it was not equal to the portal vein thrombi (PVT), indicating the possibility of extensive dissemination in terms of severity of the disease. They considered that it was not necessarily a criterion of advanced disease. Actually, the rapid growth of the BDTT was rare and there was no report of BDTT extending to the duodenum. But BDTT could enlarge through blending with blood clotting and bile mucus, subsequently resulting in full obstruction of the biliary tract and obstructive jaundice.

The typical clinical features of BDTT were repeated episodes of cholangitis and fluctuating jaundice, which could be relieved by conservative treatment. For these manifestations, BDTT was often misdiagnosed as cholangiocarcinoma. Actually, in our series, three cases were misdiagnosed as hilar cholangiocarcinoma. In addition, it is essentially important to differ obstructive jaundice from hepatic jaundice caused by liver dysfunction due to extensive metastasis within the liver and underlying hepatitis and cirrhosis, because the later has no chance of surgery, but the former can gain a good outcome through operation and/or multi-modality treatment. We concluded that the following clues could help us differentiate BDTT from other types of jaundice. Patients had underlying hepatitis or liver cirrhosis, elevating serum AFP, and characteristic features of primary liver tumors presented in US and CT.

As to the imaging investigations, US is the most convenient and effective method to detect BDTT and intrahepatic primary tumors. Endoscopic sonography (EUS) can show a tumor thrombus with central echogenicity and a “nodule-in-nodule” pattern, which provides more accurate evidence for the diagnosis. Lee *et al.*^[8], reported a patient with a small HCC in caudate lobe and presence of obstructive jaundice. Preoperative EUS showed that it was tumor thrombi in CBD. In addition, intraoperative US could detect smaller or more deeply seated intrahepatic tumors. CT, MRI and MRCP could provide more information for us to know the extension of tumors and location of thrombi, and help us adopt proper treatment, in particular surgical procedure selection for patients. Intraoperative choledochoscopy and cholangiography can show the location of tumor thrombi and differentiate obstructions due to intraluminal mass, infiltrating ductal lesions or extrinsic mass compression. Jan and Chen^[9] reported 28 patients with obstructive jaundice as a result of floating tumor debris from ruptured tumors in CBD. Of these, 18 cases underwent choledochoscopy, and the tumor ruptured into right intrahepatic bile duct ($n = 9$), left intrahepatic bile duct ($n = 7$), and the confluence of the left and right hepatic ducts ($n = 2$). Hepatectomies were performed for four patients under the guide of choledochoscopy.

The size of primary tumors did not correlate with biliary metastasis^[10], and the primary liver tumors with obstructive

jaundice might be small and resectable. In our series, primary liver tumors were not detectable in seven cases. Twenty-five cases had tumors with a diameter of less than 5 cm, suggesting that obstructive jaundice is not a criterion of late-stage HCC and a contraindication for surgery necessarily^[11].

The managements of BDTT include hepatectomy, thrombectomy, biliary drainage, TACE, internal biliary stenting, radiotherapy, percutaneous transhepatic ethanol injection (PTEI), *etc.* Surgical resection has been the ideal treatment and the only way for patients to achieve a long-term survival^[12-14]. Most patients might have satisfactory palliation and opportunity for cure after surgery^[15]. The selection of surgical procedures was based on the nature and location of the main tumor and thrombi, severity of cirrhosis, associated biliary neoplastic strictures, the overall status of patients, and the experience of surgeons. If the condition of patients was good and the primary liver tumor was resectable, the primary tumor should be resected after thrombectomy. Even if it was only a palliative resection, it could increase the survival time. If no liver tumor was detected, biliary decompression and drainage should be performed through choledochotomy and thrombectomy. To the unresectable diseases, HAL and HACE might be beneficial to some selected cases^[16-19]. Shiomi *et al.*^[12], reviewed 132 patients with HCC who underwent hepatectomy between 1980 and 1999. Of these, 17 with BDTT underwent right hemihepatectomy, 1 caudate lobectomy, 11 right or left hemihepatectomy and 5 segmentectomy. Their 3- and 5-year survival rates were 47% and 28% respectively, and the median survival time was 2.3 years, similar to those achieved in 115 patients without BDTT. Fukuda *et al.*^[20], reported that after the patients with HCC and extrahepatic bile duct thrombi underwent tumor resection and HACE, the longest survival time of some patients reached 215 mo. In our 46 cases undergoing surgery, the postoperative mortality was 17.4%, and the morbidity was 32.6%. The survival time of the patients who underwent hepatectomy, thrombectomy and biliary drainage ranged from 5 to 46 mo with a median time of 23.5 mo. We concluded that the poor prognosis of these patients was due to the late diagnosis and obstructive jaundice that resulted in irreversible liver failure. In our study, one patient died 3 d after laparotomy, indicating that early diagnosis and surgical treatment are critically important to improve the prognosis of HCC patients.

BDTT is different from PVT. Complete removal of the later is sometimes difficult because portal vein provides the main blood supply for thrombi. However, it is easy to remove BDTT because most of thrombi do not adhere to the wall of bile duct tightly. Narita *et al.*^[21], reported one case of small HCC in the left lobe with bile duct thrombi, and they found that the thrombi just adhered to the mucosa of bile duct, rather than invaded submucosa. Primary tumor resection and thrombectomy may achieve satisfactory palliation and cure. However, active hemorrhage occurred during operation in some cases, this may be due to the continuity of BDTT with the main intrahepatic tumor or BDTT invading the bile duct wall. But bleeding could be easily controlled after primary tumor was removed. For patients with multiple and unresectable tumors or biliary hemorrhage, thrombectomy and T-tube drainage with HAL could control bleeding and

relieve jaundice, and subsequently improve liver function. The survival time of these patients may be prolonged.

PTCD and biliary stent placement could alleviate jaundice^[22,23]. TACE and PTEI could control the growth of tumors, improve the quality of life and survival rate after jaundice was relieved^[24-26]. Endoscopic biliary drainage (EBD) for unresectable HCC with obstructive jaundice remains controversial because of no benefit to survival. Matsueda *et al.*^[27], suggested that EBD was one of the effective treatments for patients with unresectable malignant biliary stenosis, and obstructive jaundice due to bile duct thrombi. However, EBD was often difficult in HCC patients with obstructive jaundice because of proximal biliary obstruction at the hilum, and multiple tumors diffusing in the whole liver. The decision to perform EBD should be based on the nature and location of thrombi, the condition of liver function, and the presence of PVT. In addition, endoscopic sphincterotomy could benefit the discharge of necrotic thrombi and further improvement of overall status, after endoscopic nasobiliary drainage resolved the obstruction^[28,29].

There is a considerable controversy over the role of transplantation in patients with HCC. Liver transplantation for HCC patients with BDTT is rare. Peng *et al.*^[30,31], have reported one patient who underwent piggyback orthotopic liver transplantation and survived for 27 mo. This suggests that selected HCC patients with BDTT may benefit from liver transplantation, but it needs to be studied further.

Abstract

Although in Crohn's disease post-operative recurrence is common, the determinants of disease recurrence remain speculative. The aim of this study was to examine factors affecting post-operative recurrence of Crohn's disease. A Medline-based literature review was carried out. The following factors were investigated: age at onset of disease, sex, family history of Crohn's disease, smoking, duration of Crohn's disease before surgery, prophylactic medical treatment (corticosteroids, 5-amino salicylic acid [5-ASA] and immunosuppressants), anatomical site of involvement, indication for surgery (perforating or non-perforating disease), length of resected bowel, anastomotic technique, presence of granuloma in the specimen, involvement of disease at the resection margin, blood transfusions and post-operative complications. Smoking significantly increases the risk of recurrence (risk is approximately twice as high), especially in women and heavy smokers. Quitting smoking reduces the post-operative recurrence rate. A number of studies have shown a higher risk when the duration of the disease before surgery was short. There were, however, different definitions of 'short' among the studies. Prophylactic corticosteroids therapy is not effective in reducing the post-operative recurrence. A number of randomized controlled trials offered evidence of the efficacy of 5-ASA (mesalazine) in reducing post-operative recurrence. Recently, the therapeutic efficacy of immunosuppressive drugs (azathioprine and 6-mercaptopurine) in the prevention of post-operative recurrence has been investigated and several studies have reported that these drugs might help prevent the recurrence. Further clinical trials would be necessary to evaluate the prophylactic efficacy of immunosuppressants. Several studies showed a higher recurrence rate in patients with perforating disease than in those with non-perforating disease. However, evidence for differing recurrence rates in perforating and non-perforating diseases is inconclusive. A number of retrospective studies reported that a stapled functional end-to-end anastomosis was associated with a lower recurrence rate compared with other types of anastomosis. However, prospective randomized studies

would be necessary to draw a definite conclusion. Many studies found no difference in the recurrence rates between patients with radical resection and non-radical resection. Therefore, minimal surgery including stricturoplasty has been justified in the management of Crohn's disease. In this review, the following factors do not seem to be predictive of post-operative recurrence: age at onset of disease, sex, family history of Crohn's disease, anatomical site of disease, length of resected bowel, presence of granuloma in the specimen, blood transfusions and post-operative complications. The most significant factor affecting post-operative recurrence of Crohn's disease is smoking. Smoking significantly increases the risk of recurrence. A short disease duration before surgery seems, albeit to a very minor degree, to be associated with a higher recurrence rate. 5-ASA has been shown with some degree of confidence to lead to a lower recurrence rate. The prophylactic efficacy of immunosuppressive drugs should be assessed in future. A wider anastomotic technique after resection may reduce the post-operative recurrence rate, though this should be investigated with prospective randomized controlled trials.

INTRODUCTION

Crohn's disease is a chronic inflammatory gastrointestinal disorder with an unpredictable clinical course characterized by the high incidence of recurrence. Nearly 80% of patients with Crohn's disease require surgery during their lifetime^[1]. Post-operative recurrence rates defined by clinical symptoms are 17-55% at 5 years, 32-76% at 10 years and 72-73% at 20 years^[2-14]. The rates of recurrence requiring re-operation are 11-32% at 5 years, 20-44% at 10 years and 46-55% at 20 years^[2-14]. Thus, the re-operation rate tends to steadily increase with time, reaching approximately 50% at 20 years after surgery. Although in Crohn's disease post-operative recurrence is common, the determinants of disease recurrence remain speculative. Several patients with Crohn's disease experience frequent recurrences while others have prolonged periods of remission after surgery.

Identifying risk factors for post-operative recurrence would be useful to spot patients at a high risk of future recurrence and to determine strategies for medical treatment after surgery. A number of factors have been evaluated as potentially influencing the recurrence rates after surgery for Crohn's disease^[14-39]: age at onset of disease, sex, family history of Crohn's disease, smoking, duration of Crohn's disease before surgery, prophylactic medical treatment (corticosteroids, 5-amino salicylic acid [5-ASA] and immunosuppressants), anatomical site of involvement, indication for surgery (perforating or non-perforating disease), length of resected bowel, anastomotic technique, presence of granuloma in the specimen, involvement of disease at the resection margin, blood transfusions and post-operative complications. A Medline-based literature review was carried out to examine factors affecting post-operative recurrence of Crohn's disease.

Age at onset of disease

Many studies examined the impact of age on the recurrence rate after surgery. Naturally, patients with early onset of disease seem to have a higher recurrence rate because of a longer follow-up duration. A younger age at onset of disease has been linked to a higher recurrence rate in several studies^[18,29,32-36] but not others^[17,20,21,26,28,30]. Thus, the reports about the importance of age have been conflicting and different studies have yielded contradictory results. In summary, age does not seem to be a definite predictive factor of post-operative recurrence.

Sex

A few studies have suggested that the sex of the patient influences the risk of recurrence after surgery, with slightly increased recurrence rates reported for both men^[37] and women^[32,38,39]. In many other studies, the recurrence rate was similar for both men and women^[15-17,20,21,26,27,29,30].

Family history of Crohn's disease

There have been only a few reports examining the relationship between family history of Crohn's disease and the recurrence rate after surgery^[17,35]. Chardavoyne *et al.*^[17], found family history of Crohn's disease did not influence the recurrence rate. Our recent study found that patients with a family history had a higher recurrence rate^[35].

Smoking

There has been increasing speculation as to the role of cigarette smoking in the pathogenesis of inflammatory bowel diseases, since smokers are over-represented in groups of patients with Crohn's disease and under-represented in patients with ulcerative colitis^[40-43]. Not only is smoking associated with an increased risk of developing Crohn's disease, but several studies have demonstrated a significantly increased risk of recurrence after surgery^[35,46-52]. Sutherland *et al.*^[46], reported that the 5- and 10-year recurrence rates were significantly higher in smokers (36% and 70%) than in non-smokers (20% and 41%; odds ratio, 2.1; $P = 0.007$). When patients were stratified by sex, the increased risk was more apparent in women (odds ratio, 4.2; 95% confidence interval [CI], 2.0-4.2) than in men (odds ratio,

1.5; 95%CI, 0.8-6.0). Lindberg *et al.*^[47], found that heavy smokers (>10 cigarettes/day) had an increased risk of operation at least once; odds ratios for heavy smokers compared with non-smokers after 5 and 10 years were 1.14 and 1.24, respectively ($P = 0.03$ and $P = 0.017$). The risk of further operations was even higher and after 10 years the odds ratio was 1.79 ($P = 0.015$). Cottone *et al.*^[24], conducted multivariate analyses to examine predictive factors for three types of recurrence (clinical [symptomatic], endoscopic and surgical [reoperation] recurrences) after surgery for Crohn's disease. They found that smoking was an independent significant factor for clinical recurrence (odds ratio, 1.46; 95%CI, 1.1-1.8), endoscopic recurrence (odds ratio, 2.2; 95%CI, 1.2-3.8) and surgical recurrence (odds ratio, 2.0; 95%CI, 1.2-2.3). Breuer-Katschinski *et al.*^[48], studied 346 patients with Crohn's disease and found that 73% of smokers and 39% of non-smokers required one or more operations. The 5- and 10-year recurrence rates were 43% and 64% for smokers, which were significantly higher than 26% and 33% for non-smokers (odds ratio, 3.1; $P < 0.00$). For the 5- and 10-year recurrence rates the relative risk estimates for smokers versus non-smokers were 3.1 (95%CI, 1.7 - 5.8) and 6.7 (95%CI, 2.7-6.8). When stratified by sex, the increased risk for the recurrence was recognized in both sexes. For the number of cigarettes smoked a dose-response effect was obvious in women. Timmer *et al.*^[49], found that at 48 wk after surgery for Crohn's disease, the relapse rate [Crohn's disease activity index (CDAI) > 150 or an increase of CDAI of > 60] was 30% in non-smokers compared with 53% in smokers (odds ratio, 2.1; $P = 0.02$). Ex-smokers did not have an increased risk; the relapse rate was 35%, which was similar to 30% in non-smokers. In my research in the UK^[50], after resection for ileocecal Crohn's disease the 5- and 10-year recurrence rates were 35% and 55% for smokers compared with 19% and 36% for non-smokers (odds ratio, 2.3; $P = 0.007$). When smokers were further divided into two sub-groups according to the number of cigarettes smoked per day, the cumulative recurrence rate was higher in heavy smokers (15 or >15 cigarettes/d) compared with mild smokers (<15 cigarettes/d). In my another study,^[51] after resection (colectomy and ileorectal anastomosis) for Crohn's colitis the 5-, 10- and 15-year recurrence rates were 25%, 46%, and 52% for smokers and 11%, 15%, and 18% for non-smokers (odds ratio, 3.0; $P = 0.005$). In the multivariate analyses, only smoking was an independent significant factor for poor outcome after surgery for Crohn's colitis. Our recent study^[35] examined the impact of quitting smoking on re-operation for recurrence after surgery for Crohn's disease. We found that patients who quit smoking were less likely to have undergone one, two and three re-operations for recurrence (odds ratio, 0.25; 95%CI, 0.15-0.41; odds ratio, 0.30; 95%CI, 0.16-0.57 and odds ratio, 0.25; 95%CI, 0.10-0.71). These data indicate that patients with Crohn's disease who stop smoking reduce the risk of re-operation for recurrence after surgery.^[35] In contrast, two studies failed to find significant correlations between smoking and the recurrence rate after surgery for Crohn's disease, though in those studies the number of patients included was small and the detailed data concerning smoking were not presented^[53,54]. In summary, smoking significantly increases the risk of recurrence after

surgery for Crohn's disease (risk is approximately twice as high), especially in women and heavy smokers. Quitting smoking is associated with a lower recurrence rate compared with that in smokers. Because many patients with Crohn's disease are unaware of the risks that smoking has on their disease^[55,56], education and encouragement of patients to stop smoking are necessary in the management of Crohn's disease^[55-59]. The mechanism of the effect of smoking on Crohn's disease is as yet unclear. Potentially important mechanisms include immune modulation, gut vascularity, gut mucous composition, gut permeability and perturbation in eicosanoid production^[40-45].

Duration of disease before surgery

An association between duration of disease before the first operation and early recurrence has been suggested previously^[15,17,23,28,33,38,60]. A number of studies have shown a higher risk with a short history of disease^[15,23,28,33,38,60]. In one prospective study, Poggioli *et al.*^[28], found that duration of disease less than 6 years prior to surgery was associated with higher the recurrence rates compared to patients with an illness of longer than 6 years prior to surgery. Another study^[17] found that recurrent disease was more likely to occur in patients with a duration of disease of between 3 and 10 years before surgery. Sachar *et al.*^[15], found significantly higher recurrence rates in patients with disease duration less than 10 years. This has not been universal and other groups have failed to find a relationship between pre-surgical disease duration and recurrence^[16,18-21,26,30]. Differences in the definition of 'short duration' hamper comparison among the studies. In our previous study^[60], we selected the arbitrary intervals of 1 year between the onset of disease and surgery, 1 and 10 years and more than 10 years and found that recurrent disease was significantly associated with short duration of disease prior to primary surgery. It is not clear why a short duration of disease prior to surgery emerges as such a powerful association with recurrent disease in our study. It may be that a short interval between diagnosis and primary surgery is indicative of a more aggressive disease phenotype. However, it would seem unreasonable to defer surgery in a symptomatic patient with a short history of disease, merely because of the potential risk of early recurrence.

Prophylactic medical treatment (corticosteroids, 5-ASA and immunosuppressants)

Many studies report that corticosteroids therapy is ineffective in reducing recurrence of Crohn's disease^[61-66]. Several randomized controlled trials have demonstrated that 5-ASA (mesalazine) is effective in reducing the frequency of post-operative recurrence and in decreasing the severity of the lesions^[67-69]. Caprilli *et al.*^[67], studied 110 patients operated on for Crohn's disease by the first intestinal resection. Patients were randomly allocated to receive mesalazine (2.4 g/d) or no treatment at all. The cumulative proportion of recurrence at 6, 12, and 24 mo was significantly lower in the mesalazine group than in untreated group ($P = 0.002$). At 24 mo the cumulative proportions of endoscopic recurrence were 0.52 and 0.85, respectively. At the same time, the cumulative proportions of symptomatic recurrence

were 0.18 and 0.41 ($P = 0.006$). The cumulative proportions of the severe recurrence was also significantly lower in the mesalazine group (0.17 *vs* 0.38; $P = 0.021$). It was estimated that 5-ASA prevents 39% of all recurrences and 55% of the severe recurrences. In a double-blind, multicenter clinical trial^[68], 87 patients were treated with 3 g/d mesalazine (Pentasa) or with placebo within 1 mo after surgery. Seventeen clinical relapses (seven in the mesalazine group) were recorded. After 12 mo, the endoscopic lesions were less frequent and less severe in the mesalazine group than were those in the placebo group ($P < 0.008$). The overall rate of severe recurrence (on endoscopy or radiological documentation) was 24% in the mesalazine group and 56% in the placebo group ($P < 0.004$). In another randomized controlled trial^[69], 163 patients who underwent a surgical resection were randomized to a treatment group (1.5 g mesalazine twice a day) or a placebo control group within 8 wk of surgery. The follow-up period was a maximum of 72 mo. The symptomatic recurrence rate in the treatment group was 31% (27 of 87) compared with 41% (31 of 76) in the control group ($P = 0.031$). The relative risk of developing recurrent disease was 0.628 (90%CI, 0.40-0.97) for those in the treatment group ($P = 0.039$) using an intention-to-treat analysis and 0.532 (90%CI, 0.32-0.87) using an efficacy analysis. The endoscopic and radiological rate of recurrence was also significantly decreased with relative risks of 0.654 (90%CI, 0.47-0.91) in the effectiveness analysis and 0.635 (90%CI, 0.44-0.91) in the efficacy analysis. These results^[67-69] suggest that high-dose (2.4-3.0 g/d) 5-ASA therapy early in the post-operative period may be the most effective regimen. A meta-analysis^[70] was conducted to assess the effectiveness of 5-ASA in maintaining remission of quiescent Crohn's disease. Fifteen randomized, controlled trials of 5-ASA maintenance therapy involving a total of 2 097 patients were selected for the analysis. Therapy with 5-ASA significantly reduced the risk of symptomatic relapse (pooled risk difference, -6.3%; 95%CI, -10.4% to -2.1%). The pooled risk difference was significant in the post-surgical setting (-13.1%; 95%CI, -21.8% to -4.5%) but not in the medical setting (-4.7%; 95%CI, -9.6% to 2.8%). Multivariate model predicts that the probability of symptomatic relapse significantly decreases with 5-ASA treatment, by increasing proportion of patients with ileal disease, with prolonged disease duration, and with surgically induced remission.

Immunosuppressive drugs (azathioprine and 6-mercaptopurine [6-MP]) are effective in the setting of steroid dependence and steroid resistance, as well as for the treatment of perianal and fistulizing Crohn's disease unresponsive to antibiotics^[64-66,71]. Recently, therapeutic efficacy of azathioprine and 6-MP in the prevention of post-operative recurrence in patients with Crohn's disease has been investigated. In a prospective, open-label, randomized study^[72], 142 patients received azathioprine [2 mg/(kg·d)] or mesalazine (3 g/d) for 24 mo. The risk of clinical relapse was comparable in the azathioprine and mesalazine groups. No difference was observed with respect to surgical relapse between the two groups. In a sub-group analysis, azathioprine was more effective than mesalazine in preventing clinical relapse in patients with previous intestinal resections (odds ratio, 4.83; 95%CI, 1.47-15.8). The study concluded that while

no difference was observed in the efficacy of azathioprine and mesalamine in preventing clinical and surgical relapses after conservative surgery, azathioprine is more effective in those patients who have undergone previous intestinal resection. In another randomized trial^[73], 131 patients received 6-MP (50 mg), mesalamine (3 g) or placebo daily. The clinical recurrence rates (intent to treat) at 24 mo were 50% (95%CI, 34-68%), 58% (95%CI, 41-75%) and 77% (95%CI, 61-91%) in patients receiving 6-MP, mesalamine and placebo, respectively. The endoscopic recurrence rates were 43% (95%CI, 28-63%), 63% (95%CI, 47-79%) and 64% (95%CI, 46-81%) and the radiographic recurrence rates were 33% (95%CI, 19-54%), 46% (95%CI, 29-66%) and 49% (95%CI, 30-72%), respectively. 6-MP was more effective than placebo ($P < 0.05$) in preventing the clinical and endoscopic recurrence. The study concluded that 6-MP (50 mg/d) may be considered as a maintenance therapy after ileocolonic resection for Crohn's disease. Thus, azathioprine and 6-MP might help prevent post-operative recurrence of Crohn's disease. However, further clinical trials would be necessary to evaluate the efficacy of immunosuppressants in preventing clinical relapse after surgery for Crohn's disease.

Anatomical site of involvement

Three main sites (small bowel, large bowel and ileocolonic region) of gastrointestinal involvement have been discussed as clinical patterns in Crohn's disease. A number of studies examined the impact of anatomical site of disease on the recurrence and reported the different results^[15-17,19,27-30]. The risk of recurrence was highest in patients with small bowel disease^[29,31,74] and ileocolonic disease^[27,30]. In one study^[17], patients with predominantly large bowel disease ($n = 56$) were found to have a higher rate of re-resection (45%) when compared with 32% in patients with small bowel involvement ($n = 94$) and with 35% in patients with both small and large bowel involvement ($n = 37$) ($P = 0.04$)^[17]. Other studies failed to find any significant impact of the site of disease on the recurrence rate^[15,16,19,28]. Thus, the use of 'anatomical site of involvement' as a factor for post-operative recurrence is of limited value in clinical practice.

Indication for surgery

Crohn's disease has two different clinical forms, a relatively aggressive 'perforating' type and a more indolent 'non-perforating' type. Greenstein *et al.*^[75], defined a perforating disease as acute free perforation, sub-acute perforation with abscess or chronic perforation with internal or external fistula from findings at laparotomy. This definition has been widely used in clinical practice. Several studies examined the relationship between the type of disease and post-operative recurrence. Aeberhard *et al.*^[76], found that the median interval between the first and second operation was 1.7 years for patients with perforating disease, which was significantly shorter than 13 years for patients with non-perforating disease. Lautenbach *et al.*^[77], studied 88 patients who had undergone at least two resections for Crohn's disease to elucidate predictors of early post-operative recurrence. A perforating indication for initial surgery ($P < 0.001$) was found to be an independent predictor of early post-operative

recurrence after initial surgery. The indication for initial surgery was predictive of the indication at a subsequent surgery for the recurrence ($P = 0.001$). The other study found that patients with fistulizing type of symptoms were at a high risk of early recurrence after surgery^[78]. In contrast, the postoperative recurrence rates were similar for patients with perforating and non-perforating diseases in other studies^[26-28,30,60,79,80]. Evidence for differing the recurrence rates in perforating and non-perforating diseases is inconclusive. There may be concordance between patients initially presenting with perforating *vs* non-perforating disease and the pattern of disease recurrence^[12,28,75,79]. However, McDonald *et al.*^[80], reported that patients were no more likely to have the same indication for surgery at the time of the second resection or the third resection compared with the initial resection.

Length of resected bowel

Several studies have suggested that the recurrence is more common after resection of a long length of diseased bowel^[37,81,82]. Other studies found that the length of resected small and large bowel made no difference to the rates of recurrence^[4,5,16,33]. Thus, the length of resected bowel does not seem to be a definite predictive factor of post-operative recurrence.

Anastomotic technique

The type of anastomosis following resection is one of the important issues in the surgical management of Crohn's disease. The fecal stream is implicated in anastomotic recurrence in Crohn's disease following bowel resection^[26]. Relative obstruction with stasis and bacterial overgrowth is also recognized contributory factors to recurrent Crohn's disease^[14,83]. Therefore, the stapled functional end-to-end technique may reduce the risk of obstruction at the anastomosis because of a wider anastomotic lumen. One retrospective study^[84] examined 27 patients who underwent conventional sutured end-to-end anastomosis and 42 who underwent stapled functional end-to-end anastomosis following bowel resection for Crohn's disease. In the stapled group, only one patient (2%) required re-operation for recurrence. By contrast, 14 patients (43%) in the sutured group required 15 further resections for recurrence. The median follow-up duration was 23 mo for the stapled group compared with 52 mo in the sutured group. Our retrospective study^[85] studied 45 patients who underwent stapled functional end-to-end anastomosis and 78 underwent conventional sutured end-to-end anastomosis. In the stapled group only one patient required re-operation for ileocolonic anastomotic recurrence compared with 26 in the sutured group. The cumulative 1-, 2- and 5-year ileocolonic recurrence rates requiring surgery in the stapled group were 0%, 0% and 3%, which were significantly lower than 5%, 11% and 24% in the sutured group ($P = 0.007$ by log-rank test). The median duration of follow-up was 34 mo in the stapled group compared with 92 mo in the sutured group ($P < 0.01$). A case-control comparative analysis of patients with Crohn's disease from two major inflammatory bowel disease centers (Mayo clinic and Birmingham) treated with wide-lumen stapled anastomosis ($n = 69$) and a matched (age and gender) group treated with conventional sutured end-to-end anastomosis

($n = 69$) was conducted^[86]. A total of 55 patients developed recurrent symptoms, 39 (57%) in the conventional sutured end-to-end anastomosis and 16 (24%) in the wide-lumen stapled anastomosis group. The median follow-up was 70 mo for the sutured group and 46 mo for the stapled group. After conventional sutured end-to-end anastomosis 18 re-operations were required and after wide-lumen stapled anastomosis three re-operations were necessary. The cumulative re-operation rate for anastomotic recurrence was significantly lower ($P = 0.017$ by log-rank test) for the wide-lumen stapled anastomosis group. One prospective study comparing the long-term results of stapled and hand-sewn anastomoses reported a lower recurrence rate after the stapled anastomosis^[87]. Thus, the stapled functional end-to-end anastomosis was associated with a lower incidence of post-operative anastomotic recurrence than the conventional sutured end-to-end anastomosis in the surgical management of Crohn's disease. Caprilli *et al.*^[26], reporting on prognostic factors for the recurrence of Crohn's disease in a multicenter study, found a trend towards a higher rate of endoscopic recurrence after end-to-end anastomosis compared to side-to-side or end-to-side anastomosis. Recent retrospective study^[88] compared the post-operative recurrence rate after a hand-sewn end-to-side or side-to-side isoperistaltic anastomosis ($n = 30$) and stapled functional end-to-end anastomosis ($n = 76$) and found that there were 5 recurrences (16.7%) in the hand-sewn group and 2 recurrences (2.6%) in the stapled group. The other study^[74] compared the recurrence rate after stapled side-to-side ileocolonic anastomosis ($n = 12$) to those after stapled end-to-side ($n = 36$) or hand-sewn side-to-side anastomosis ($n = 36$). The stapled side-to-side anastomosis group obtained a better symptom-free survival than the stapled end-to-side group ($P = 0.04$). In the stapled and hand-sewn side-to-side groups the re-operation rates were significantly lower than in the stapled end-to-side group ($P = 0.01$ and $P = 0.05$, respectively). A longer follow-up showed a significantly lower incidence of re-operation for recurrence in the stapled and hand-sewn side-to-side anastomosis compared to the stapled end-to-side anastomosis group. Thus, a wider anastomosis may delay the onset of the symptomatic recurrence and be associated with a lower early recurrence rate after resection for Crohn's disease. Furthermore, the incidence of complications after the stapled anastomosis is low and the procedures are quick and easy^[84-88]. Therefore, the stapled functional end-to-end anastomosis may be the anastomotic configuration of choice following resection for Crohn's disease. However, most of the previous studies were non-randomized trials. The follow-up duration was inevitably shorter and the number of patients was smaller in the stapled anastomosis group because the stapled technique has been introduced recently. Multicenter prospective randomized study with a larger number of patients and a longer follow-up duration would be needed to find an absolute evidence of difference between the stapled functional end-to-end anastomosis and the other types of anastomosis.

Presence of granuloma in the specimen

There are contradictory reports in the literature regarding the impact of identifiable granuloma in the resection specimen on the recurrence^[5,16,17,30,60,89-91]. Anselme *et al.*^[30], found that

granuloma in the specimen was significantly associated with the recurrence. Other authors^[89,90] reported a decreased rate of the recurrence in patients who had granulomas in their specimen. Some groups have shown that microscopic disease in the specimen increases the rate of anastomotic recurrence of ileocolonic Crohn's disease^[5,16,17,91].

Disease involvement at the line of resection

Several reports have reported that the wide resection of normal bowel uninvolved microscopically (radical resection) was associated with a lower recurrence rate than non-radical resection^[6,18,92,93]. However, many studies have shown no difference in the recurrence rates between patients with radical resection and non-radical resection^[17,21,30,60,82,94-96]. Fazio *et al.*^[95], carried out a randomized controlled trial to investigate the impact of resection margins on the recurrence of Crohn's disease in the small bowel. Patients who underwent ileocolonic resection for Crohn's disease ($n = 152$) were randomly assigned to two groups in which the proximal line of resection was 2 cm (limited resection) or 12 cm (extended resection) from the macroscopically involved area. Patients also were classified by whether the margin of resection was microscopically normal (category 1), contained non-specific changes (category 2), were suggestive but not diagnostic for Crohn's disease (category 3) or were diagnostic for Crohn's disease (category 4). The median follow-up time was 55.7 mo. Disease recurred in 29 patients: 25% of patients in the limited resection group and 18% of patients in the extended resection group. In 90 patients in category 1 with normal tissue, the recurrence occurred in 16, whereas in the 41 patients with some degree of microscopic involvement, the recurrence occurred in 13. The recurrence rates were 36% in category 2, 39% in category 3 and 21% in category 4. No group differences were statistically significant. The recurrence of Crohn's disease is unaffected by the width of the margin of resection from macroscopically involved bowel. Thus, the recurrence rates also do not increase when microscopic Crohn's disease is present at the resection margins. Therefore, extensive resection margins are unnecessary.

As the recurrence was independent of microscopic involvement of the resection margins in many studies^[17,21,30,60,82,94-96], there has been an increasing tendency toward minimal surgery in the treatment of Crohn's disease. Strictureplasty conserves bowel and minimizes the risk of developing the short bowel syndrome. Nowadays, strictureplasty has become an established surgical option in the management of obstructive Crohn's disease. It is particularly suitable for patients at a risk of short bowel syndrome^[97-104]. After strictureplasty the segment of inflamed bowel is left *in situ*, because the sutures are placed through the diseased bowel. However, the most recurrences after strictureplasty occur at non-strictureplasty sites and the recurrence rate at the strictureplasty sites has been reported to be only 2.8-3.7%^[98,100].

Blood transfusions

The immunosuppressive effect of blood transfusions may modify the progression of Crohn's disease. The effect of peri-operative blood transfusions on the recurrence of Crohn's disease was investigated in several studies^[105-112]. Williams and Hughes^[105] examined 60 patients with Crohn's

disease who underwent small bowel resection. Twenty-eight patients received blood transfusions. The patients who received peri-operative blood transfusions had a significantly lower recurrence rate. Five years after the bowel resection, the cumulative recurrence rate in transfused patients was 19% compared with 59% in controls. Peters *et al.*^[106] studied 79 patients with Crohn's disease who underwent intestinal resection. In 45 patients who received multiple red blood cell transfusions, the recurrence developed in 22% by 36 mo and the median time to the recurrence was 35 mo. In 34 patients who did not receive multiple transfusions, the recurrence was found in 44% by 36 mo and the median time to the recurrence was 20 mo ($P < 0.04$). The recurrence in patients with disease limited to the small bowel or to the colon was not significantly affected by the transfusion status. However, the recurrence developed in only 10% of multiply transfused patients with ileocolonic disease by 36 mo, whereas the recurrence developed in 45% of the patients who were not multiply transfused ($P = 0.057$). Gooszen and Silvis^[107] studied 148 patients with Crohn's disease, 62 males and 86 females (49 non-parous and 37 parous females). Eighty-seven patients received peri-operative blood transfusions. Overall, blood transfusions showed no effect on the recurrence. Peri-operative transfusions seemed to protect against recurrent disease after colonic resection. Transfusions had a beneficial effect in parous females ($P = 0.068$) and after correction for the type of operation this beneficial effect was significant ($P = 0.026$). After peri-operative blood transfusions parous females had a similar prognosis regarding the recurrent Crohn's disease to that of non-parous females and males. In contrast, other studies^[108-111] failed to find any significant effect of peri-operative blood transfusions on the post-operative recurrence of Crohn's disease. A recent pooled analysis studied 622 patients with a primary and complete resection of macroscopic disease^[112]. Three hundred thirty-one patients (53%) received blood in the peri-operative period and the mean follow-up duration was 72.8 mo. For the overall sample, the 5-year recurrence rates were 26.9% for the transfused group and 25.2% for the non-transfused ($P = 0.456$). When the data were stratified by age, gender, disease location and length of resection, no difference in the 5-year recurrence rates between transfused and non-transfused patients could be detected. This pooled analysis found no protective effect of blood transfusions on the post-operative recurrence of Crohn's disease.

Post-operative complications

Crohn's disease is frequently associated with possible risk factors for post-operative complications; intestinal obstruction, pre-existing septic complications, impaired nutritional status, chronic corticosteroid medication and the need for multiple anastomoses^[9,113]. There have been only a few reports about the relationship between the postoperative complications and recurrence rate^[25,28,74]. Poggioli *et al.*^[28] found no relationship, but Holzheimer *et al.*^[25] and Scarpa *et al.*^[74] reported that the development of post-operative complications was associated with a high recurrence rate.

DISCUSSION

Smoking significantly increased the risk of recurrence after

surgery for Crohn's disease, especially in women. The effect of smoking was dose-dependent. Giving up smoking was associated with a lower probability of recurrence compared with smokers. A short disease duration before surgery seems, albeit to a very limited extent, to be associated with a higher recurrence rate, though the definition of short duration is different depending on the study. A number of randomized controlled trials offer encouraging evidence of the efficacy of 5-ASA in reducing post-operative recurrence. Recent studies have reported that immunosuppressive drugs were useful in the prevention of post-operative recurrence. However, further clinical trials would be necessary to evaluate the efficacy of immunosuppressants. Several authors found that perforating disease was associated with a higher recurrence rate compared with non-perforating disease, though evidence for differing the recurrence rates in perforating and non-perforating diseases is inconclusive. A number of retrospective studies found that a stapled functional end-to-end anastomosis was associated with a lower recurrence rate compared with other anastomotic techniques. However, prospective randomized trials would be necessary to find an absolute evidence of difference between the stapled functional end-to-end anastomosis and the other types of anastomosis. The following factors were not predictive of post-operative recurrence: age at onset of disease, sex, family history of Crohn's disease, anatomical site of disease, length of resected bowel, presence of granuloma in the specimen, peri-operative blood transfusions and post-operative complications.

Abstract

AIM: To study the *in vitro* and *in vivo* antitumor effect of lidamycin (LDM) on hepatoma and the active moiety of its molecule.

METHODS: MTT assay was used to determine the growth inhibition of human hepatoma BEL-7402 cells, SMMC-7721 cells and mouse hepatoma H22 cells. The *in vivo* therapeutic effects of lidamycin and mitomycin C were determined by transplantable hepatoma 22 (H22) in mice and human hepatoma BEL-7402 xenografts in athymic mice.

RESULTS: In terms of IC_{50} values, the cytotoxicity of LDM was 10 000-fold more potent than that of mitomycin C (MMC) and adriamycin (ADM) in human hepatoma BEL-7402 cells and SMMC-7721 cells. LDM molecule consists of two moieties, an apoprotein (LDP) and an enediyne chromophore (LDC). In terms of IC_{50} values, the potency of LDC was similar to LDM. However, LDP was 10^5 -fold less potent than LDM and LDC to hepatoma cells. For mouse hepatoma H22 cells, the IC_{50} value of LDM was 0.025 nmol/L. Given by single intravenous injection at doses of 0.1, 0.05 and 0.025 mg/kg, LDM markedly suppressed the growth of hepatoma 22 in mice by 84.7%, 71.6% and 61.8%, respectively. The therapeutic indexes (TI) of LDM and MMC were 15 and 2.5, respectively. By 2 *iv.* injections in two experiments, the growth inhibition rates by LDM at doses of 0.1, 0.05, 0.025, 0.00625 and 0.0125 mg/kg were 88.8-89.5%, 81.1-82.5%, 71.2-74.9%, 52.3-59.575%, and 33.3-48.3%, respectively. In comparison, MMC at doses of 5, 2.5, and 1.25 mg/kg inhibited tumor growth by 69.7-73.6%, 54.0-56.5%, and 31.5-52.2%, respectively. Moreover, in human hepatoma BEL-7402 xenografts, the growth inhibition rates by LDM at doses of 0.05 mg/kg \times 2 and 0.025 mg/kg \times 2 were 68.7% and 27.2%, respectively. However, MMC at the dose of 1.25 mg/kg \times 2 showed an inhibition rate of 34.5%. The

inhibition rate of tumor growth by LDM was higher than that by MMC at the tolerated dose.

CONCLUSION: Both LDM and its chromophore LDC display extremely potent cytotoxicity to hepatoma cells. LDM shows a remarkable therapeutic efficacy against murine and human hepatomas *in vivo*.

INTRODUCTION

Lidamycin (LDM, also called C-1027), a macromolecular antitumor antibiotic produced by *Streptomyces globisporus* C-1027, can markedly inhibit the growth of transplantable tumors in mice including leukemia L1210, P388, sarcoma 180 and melanoma Harding-Passey^[1-4]. LDM consists of an apoprotein (LDP) of 10.5 ku and an enediyne chromophore (LDC) of 843 ku. These two parts of the molecule, connecting each other through non-covalent binding, can be dissociated^[5]. LDM can induce DNA damages including double-strand breaks, single-strand breaks and formation of abasic sites which is proved to be the major mechanism of the cytotoxicity of LDM. It is also reported that LDC can interact in DNA minor grooves and cleave double-helical DNA with a remarkable sequence-selectivity. The double-strand cleavage sites occurring predominantly at CTTT/AAAAG, ATAAT/ATTAT, CTTTA/TAAAG, CTCTT/AAGAG, and especially GTTAT/ATAAC, consist of nucleotide sequences with a two-nucleotide 3'-stagger of the cleaved residues^[6].

Recently, LDM has entered phase I clinical trials. In this study, we report the growth inhibition of various carcinoma cell lines by LDM, and the therapeutic efficacy of LDM against hepatoma in mice and human hepatoma xenografts in athymic mice.

MATERIALS AND METHODS

Materials

Highly purified LDM and LDP were prepared in our institute. MTT was obtained from Sigma Chemical Co. (St.

Louis, MO, USA). Mitomycin C (MMC) was purchased from Kyowa Hakkō Kogyo Co. Ltd. Adriamycin (ADM) was purchased from Zhejiang Hisun Pharmaceutical Co. Ltd., China.

Cell culture

Human hepatoma BEL-7402 cells, SMMC-7721 cells and murine hepatoma 22 cells were cultured at 37 °C with 50 ml/L CO₂ in RPMI-1640 medium supplemented with 10% heat-inactivated fetal bovine serum, penicillin G (100 U/mL) and streptomycin (100 µg/mL). All cell lines were passaged every 3 d and maintained in exponential growth to approximately 80% confluence for experiments.

Dissociation of LDM molecule

After 10 mg LDM was mixed with 5 mL methanol for 5 min at 4 °C, the mixture was placed at -20 °C and tossed for one time. LDC in the supernatant of reaction mixture was obtained by centrifugation of 16 000 *g* for 20 min at 4 °C. In order to extract LDC entirely, the operation was repeated three times.

MTT assay

Cells were detached by trypsinization, seeded at 3 000 cells/well in a 96-well plate (Costar, Cambridge, MA) over night. Then different concentrations of LDM were added and incubated for an additional 48 h. The effect on cell growth was examined by MTT assay. Briefly, 20 µL of MTT solution (5 mg/mL) was added to each well and incubated at 37 °C for 4 h. The supernatant was removed, and the MTT formazan formed by metabolically viable cells was dissolved in 150 µL of DMSO, and then monitored with a microplate reader (Bio-Rad) at a wavelength of 560 nm. Survival ratio was calculated according to the following formula:

$$\text{Survival ratio} = (A_{\text{test}} - A_{\text{blank}}) / (A_{\text{control}} - A_{\text{blank}}) \times 100\%$$

Animals and in vivo studies

Female Kunming mice weighting 20±2 g and BALB/c (nu/nu) athymic mice were obtained from the Institute of Experimental Animals, Chinese Academy of Medical Sciences (CAMS) and Peking Union Medical College (PUMC).

Therapeutic effects of LDM and MMC were assessed using murine hepatoma 22 models. Groups of 10 Kunming female mice were subcutaneously implanted with 1.5×10⁶ tumor cells. For experiment I, the drugs were administrated 24 h after tumor transplantation with single intravenous injection. For experiments I and II, the drugs were *iv* administrated 24 h and 7 d after tumor transplantation. PBS was used as control in each experiment. Animals were sacrificed on day 11 and tumor weights (*W*) were measured. Inhibition rate of tumor growth and therapeutic index were calculated respectively as follows:

$$\text{Inhibition (\%)} = ((W_{\text{control}} - W_{\text{treated}}) / W_{\text{control}}) \times 100$$

$$\text{Therapeutic index (TI)} = LD_{50} / ID_{50}$$

Therapeutic effect of LDM on human hepatoma BEL-7402 xenografts in athymic mice was assessed. Groups of six athymic female mice were subcutaneously implanted with hepatoma BEL-7402 tumor tissue fragments, 2 mm

in diameter, one for each mouse. LDM and MMC in PBS were administrated *iv* on d 3 and 10 after tumor implantation. PBS was used as control. Tumor volume (*V*) was measured twice a week using a caliper and calculated using the formula: $V \text{ (mm}^3\text{)} = 1/2ab^2$, where *a* and *b* represent the long diameter and perpendicular short diameter (mm) of the tumor, respectively.

Statistical analysis

Significant difference between two values was determined with Student's *t*-test. *P*<0.05 was considered statistically significant.

RESULTS

Cytotoxicity of LDM, MMC and ADM to hepatoma cells

As shown in Figures 1A and B, LDM displayed extremely potent cytotoxicity to hepatoma BEL-7402 and SMMC-7721 cells. In comparison, the cytotoxicity of LDM was much more potent than that of MMC and ADM. The IC₅₀ value of LDM, MMC and ADM was 0.0030, 152, and 51.7 nmol/L for BEL-7402 cells respectively, and 0.064, 1136.6, and 378 nmol/L for SMMC-7721 cells respectively. In terms of IC₅₀ values, the cytotoxicity of LDM to hepatoma cells was 10 000-fold more potent than that of MMC and ADM (Table 1). In addition, the growth inhibitory IC₅₀ value of LDM for mouse hepatoma 22 was 0.025 nmol/L by MTT assay (curve not shown).

cells (B) by LDM, LDC and LDP.

and LDP, on cell proliferation were evaluated with MTT assay. As shown in Figures 2A and B, LDM and its constituent LDC displayed extremely potent cytotoxicity to human

Table 1 Inhibition of proliferation by LDM, MMC, ADM and the LDM constituents LDC and LDP in hepatoma cells (mean±SD)

Drugs	IC ₅₀ (nmol/L)	
	BEL-7402	SMMC-7721
LDM	0.003±0.0006	0.064±0.013
MMC	152.0±27.3	1 136.6±72.2
ADM	51.7±6.5	378.0±39.6
LDC	0.0032±0.0005	0.0597±0.0064
LDP	2 896.0±345.5	1 896.0±354.0

LDM: lidamycin; LDC: LDM enediyne chromophore; LDP: LDM apoprotein; ADM: adriamycin, MMC: mitomycin C.

hepatoma BEL-7402 and SMMC-7721 cells. However, another constituent LDP was much less active to hepatoma cells. The IC₅₀ value of LDC on BEL-7402 and SMMC-7721 cells was 0.0032 and 0.0597 nmol/L, respectively. However, the growth inhibitory IC₅₀ value of LDP on BEL-7402 and SMMC-7721 cells was 2 896 and 1 896 nmol/L respectively. In terms of IC₅₀ values, the potency of LDC was similar to LDM, but LDP was 10⁵-fold less potent than LDM and LDC (Table 1).

Inhibitory effect of LDM and MMC on hepatoma 22 in mice

The *in vivo* therapeutic efficacy of LDM and MMC on the growth of murine hepatoma 22 (H22) in Kunming mice was investigated. As shown in Table 2, LDM and MMC inhibited the growth of hepatoma 22 tumors in a dose dependent manner. In experiment I, LDM with single *i.v.*

administration at the doses of 0.1, 0.05, 0.025, 0.0125, and 0.00625 mg/kg inhibited tumor growth by 84.7%, 71.6% and 61.8%, 60.6% and 40.8% ($P < 0.01$), respectively. Whereas, the inhibition rate of MMC at the doses of 5, 2.5, and 1.25 mg/kg was 58.9%, 49.9%, and 44.2%, respectively. The therapeutic index (TI) of LDM and MMC was 15 and 2.5, respectively. The therapeutic index of LDM was much higher than that of MMC. In experiments II and III, the drugs were administered on d 3 and 7. The growth inhibition rate by LDM was also higher than that of MMC. At doses used in these experiments, no body weight loss and other severe side-effects were observed, implying that LDM at tolerated doses displayed remarkable therapeutic efficacy.

Inhibition effect of LDM and MMC on the growth of human hepatoma BEL-7402 in athymic mice

For further *in vivo* evaluation, the athymic mice bearing BEL-7402 hepatoma xenografts were treated by injection of LDM and MMC into the tail vein for the first time 3 d after subcutaneous tumor inoculation. At that time the tumor diameters ranged from 2 to 4 mm. Then the drugs were administered for the second time on d 10. As shown in Figure 3, LDM significantly inhibited the growth of BEL-7402 tumors. According to the tumor volume on d 24 (Table 3), the inhibition rate by LDM at the doses of 0.05 and 0.025 mg/kg was 68.7% ($P < 0.05$) and 27.2%, respectively. MMC at the dose of 1.25 mg/kg inhibited tumor growth by 34.5%. LDM showed much higher efficacy against the growth of hepatoma xenografts.

Figure 3 Inhibitory effect of LDM and MMC on the growth of human hepatoma BEL-7402 xenografts in athymic mice.

DISCUSSION

Hepatoma progresses rapidly and has a poor prognosis.

Although the cause is not fully understood, there are several known risk factors, including over 40 years of age, male sex, cirrhosis, and exposure to hepatitis viruses (hepatitis B, C, D and G), *etc.* Although surgical operation could cure some patients with hepatoma, many patients with carcinomas are not good surgical candidates because of large tumor size, diminished liver function, or cirrhosis. Therefore, it is urgent to develop new drugs for the treatment of carcinoma.

It was reported that LDM strongly inhibits DNA synthesis in hepatoma BEL-7402 cells. In terms of effective concentration, LDM is over 1 000-fold potent than MMC or ADM. LDM also inhibits RNA synthesis in hepatoma BEL-7402 cells without affecting protein synthesis, blocks BEL-7402 cells at G₂/M phase^[7] and induces mitotic cell death of human hepatoma BEL-7402 cells^[8]. In the present study, LDM showed extreme cytotoxicity to hepatoma cells, including BEL-7402 SMMC-7721 and H22 cells *in vitro*. In our study, LDM displayed obvious tumor inhibition effect *in vivo*. The therapeutic efficacy of LDM was 6-fold higher than that of MMC. In addition, LDM showed potent anti-tumor effect on human hepatoma BEL-7402 xenografts in athymic mice in a dose dependent manner.

LDM has drawn much attention of researchers because of its potent anti-tumor effect, unique structure and action mechanism. Its apoprotein gene has been successfully cloned and nucleotide sequencing was determined^[9]. Recently, as an example of enediyne anti-tumor antibiotics, the biosynthetic genes of LDM have become a hot spot^[10]. In our studies on targeted anti-tumor drugs, LDM could act as a novel “effector moiety” to construct molecule-downsized and highly potent monoclonal antibody drugs. The downsized Fab'-LDM immunoconjugate is generated by chemical methods^[11], which shows potent anti-tumor effect both *in vitro* and *in vivo*. We have demonstrated in this study that LDC has a similar potency as intact LDM molecule. In contrast, its apoprotein LDP displays weak effect on tumor cells. Recently, an energized fusion protein, Fv-LDP-AE, has been prepared. The highly potent fusion protein is composed of Fv fragment of antibody, protein moiety of LDM molecule, and the active enediyne (AE) of lidamycin^[12]. The molecular weight of enediyne-energized fusion protein Fv-LDP-AE is only 38.7 ku, much smaller than the reported immunotoxin Fv-PE (67 ku). The method of preparing energized fusion protein Fv-LDP-AE may also provide a useful technical platform to construct scFv-based engineering and enediyne-energized fusion proteins specifically targeted to various cancers expressing different molecular markers.

In summary, both lidamycin and lidamycin chromophore have extremely potent cytotoxicity to liver cancer cells, and lidamycin shows remarkable therapeutic efficacy against murine transplantable hepatoma and human hepatoma xenografts.

Abstract

AIM: To identify the scFv antibody fragments specific for hepatocellular carcinoma by biopanning from a large human naive scFv phage display library.

METHODS: A large human naive scFv phage library was used to search for the specific targets by biopanning with the hepatocellular carcinoma cell line HepG2 for the positive-selecting and the normal liver cell line L02 for the counter-selecting. After three rounds of biopanning, individual scFv phages binding selectively to HepG2 cells were picked out. PCR was carried out for identification of the clones containing scFv gene sequence. The specific scFv phages were selected by ELISA and flow cytometry. DNA sequences of positive clones were analyzed by using Applied Biosystem Automated DNA sequencers 3730. The expression proteins of the specific scFv antibody fragments in *E.coli* HB2151 were purified by the affinity chromatography and detected by SDS-PAGE, Western blot and ELISA. The biological effect of the soluble antibody fragments on the HepG2 cells was investigated by observing the cell proliferation.

RESULTS: Two different positive clones were obtained and the functional variable sequences were identified. Their DNA sequences of the scFv antibody fragments were submitted to GenBank (accession nos: AY686498 and AY686499). The soluble scFv antibody fragments were successfully expressed in *E.coli* HB2151. The relative molecular mass of the expression products was about 36 ku, according to its predicted M_r value. The two soluble scFv antibody fragments also had specific binding activity and obvious growth inhibition properties to HepG2 cells.

CONCLUSION: The phage library biopanning permits identification of specific antibody fragments for hepatocellular

INTRODUCTION

Hepatocellular carcinoma is the third leading cause of cancer deaths in the world and the prognosis of patients remains poor. Immunotherapeutic strategies against cancer have been developed during the last 20 years. In this respect, mouse monoclonal antibodies against tumor marks have been used for tumor targeting and imaging^[1]. The use of murine monoclonal antibodies for therapy in humans has limitations because of the human anti-mouse antibody response. Moreover, whole antibodies are large molecules and have poor tumor penetration. Several advances made during the past years will probably facilitate the development of therapeutic antibodies^[2]. Indeed, a chimeric anti-CD20^[3] antibody and a humanized anti-HER2^[4] antibody have been approved by FDA for the treatment of non-Hodgkins lymphoma and metastatic breast cancer respectively. These successes indicate that immunotherapeutic modalities are effective^[5]. On the other hand, the antibody-mediated tumor immunotherapy has become critical parts of biotherapy and is used for the diagnosis of cancer and metastasis, fine staging, and decisions regarding therapeutic approaches^[6]. So, it is urgent to obtain new humanized antibody specific for tumor targeting, and it is the same state in the therapy of hepatocellular carcinoma^[7]. Phage libraries displaying antibody fragments provide the fastest route to obtain human antibody fragments^[8]. The advent of antibody fragment display on phage and the development of large ($>6 \times 10^9$ clones) phage display libraries^[9,10] offer a potential way of detecting new targets by biopanning using tumor cells and counter-selecting using non-tumor cells^[11-13]. Significant progress has been made using this method to screen the antibodies against cell surface antigens^[14-17]. Targeting with scFv antibody fragments may overcome some of the limitations of murine monoclonal antibodies, and provide greater targeting specificity^[18-20]. Here, we report the selection of scFv antibodies binding specifically to HepG2 cells by

using L02 as counter-selecting cells biopanning from a large human naive scFv phage library (Griffin. 1 library)^[21].

MATERIALS AND METHODS

Materials

The human naive scFv library (Griffin. 1 library) used in this study was a generous gift from Professor Winter, University of Cambridge, UK. *E. coli* TG1 (suppressor strain for propagation of phage particles), *E. coli* HB2151 (non-suppressor strain for expression of antibody fragments) and helper phage M13K07 were purchased from Pharmacia-Biotech. Mouse anti-M13 antibody was from Amersham. Goat anti-mouse IgG conjugated HRP was provided by Kirkegaard Perry Laboratories. Goat anti-mouse IgG conjugated with FITC was obtained from Zhongsheng, Beijing. 9E10 antibody, Ni-NTA, FACS were purchased from Santa Cruz Biotechnology, Qiagen, and BD, respectively.

Methods

Cell culture The hepatocellular carcinoma cell line HepG2 and liver cell line L02 were incubated in RPMI 1640 supplemented with 100 mL/L FBS at 37 °C with 50 mL/L CO₂.

Screening of scFv phages from phage library using whole cells An aliquot containing 1×10^{12} cfu from a large human scFv phage library was added to 1×10^6 L02 cells and mixed gently for 30 min at room temperature (RT). The phage-containing supernatant was used to resuspend a fresh pellet of 1×10^6 L02 cells and incubated for 30 min at RT, followed by pelleting the cells. Then, the resultant subtracted phage supernatant was incubated with 5×10^6 HepG2 cells for 1 h at RT with gentle mixing. The cell-bound phages were eluted with 0.5 mL of PBS containing 100 mmol/L citric acid (pH 2.2) for 10 min and neutralized with 0.5 mL of 1.0 mol/L Tris-HCl (pH 7.5). *E. coli* TG1 was infected with the eluted phages and plated on 2×TY agar containing 1% glucose and 100 µg/mL ampicillin. The resultant colonies were propagated and used to prepare phages. Biopanning was performed in triplicate using 1×10^{12} cfu.

FCM for polyclonal scFv phages The polyclonal scFv phages were blocked with 6% BSA in PBS. The blocked scFv-phage supernatants were added to parallel plates containing 1×10^5 HepG2 cells (1 h, 4 °C, gentle agitation). The cells were washed twice and centrifuged. Pellets were then resuspended in 100 µL of mouse anti-M13 antibody and incubated for 20 min at 4 °C. After being washed twice, the cells were resuspended in 100 µL of goat anti-mouse IgG conjugated with FITC and incubated for 20 min at 4 °C. After being washed thrice, the cells were analyzed by flow cytometry.

ELISA and FCM for monoclonal scFv phages *E. coli* TG1 was infected with the third round scFv phages and plated on 2×TY agar to obtain the monoclonal bacteria. PCR was carried out for identifying clones containing the scFv gene sequence. The clones containing scFv gene sequence were infected with helper phage to prepare monoclonal scFv phages. The ELISA for monoclonal scFv phages was performed as the FCM for polyclonal scFv phages described above.

After being washed the cells were resuspended in 100 µL of goat anti-mouse IgG conjugated with HRP instead of goat anti-mouse IgG conjugated with FITC, then incubated for 20 min at 4 °C. Cell pellets were resuspended in 100 µL of TMB reagents. The ELISA plates were read (A_{405} - A_{630}) and data were analyzed using a spreadsheet program (Microsoft Excel). Monoclonal scFv phages binding to HepG2 cells specifically were prepared for FCM.

Sequencing and analyzing of scFv DNA The positive monoclonal bacteria were isolated and sent to BoYa Shanghai Company for sequencing of DNA. The results of sequencing were Blast in GenBank and analyzed using IMGT/V-Quest software.

IMAC purification of soluble scFv antibody fragments Bacterial clones were cultured in 1 L of 2×TY, 100 µg/mL ampicillin, 0.1% glucose and induced with 1 mmol/L final concentration of IPTG for 20 h at 30 °C. The scFv antibody fragments were harvested from the periplasm and purified by IMAC of pentahistidine tag fused to the scFv fragments. The samples were dialyzed in PBS, filtered, concentrated and stored at 4 °C in about 1 mg/mL PBS.

Western blot Five micrograms of purified scFv antibody fragments was run on a 10% SDS-PAGE gel and transferred onto nitro-cellulose. Filters were blocked for 1 h at RT in 10% Marvel/PBS. The scFv antibody fragments were detected with the murine monoclonal antibody 9E10 followed by anti-mouse IgG horseradish peroxidase conjugate. Horseradish peroxidase was visualized with diaminobenzidine tablets in the presence of cobalt ions.

Cell ELISA for purified soluble scFv antibody fragments L02, HepG2, Hela, MCF-7 and K562 cell lines were selected for cell ELISA to identify the specificity of the purified soluble scFv antibody fragments binding to HepG2. The method of cell ELISA was the same as the monoclonal scFv-phage ELISA described above. The purified SLH04 or SLH10 was used as the first antibody, and antibody 9E10 was used as the second antibody.

Test of HepG2 cell proliferation A total of 10^4 HepG2 cells were cultured in a 24-well cell culture plate. Two wells were incubated with 500 µL of purified soluble scFv antibody fragments, SLH04 or SLH10. One well was incubated with 500 µL unrelated antibody, the other well was not treated with any antibody. Cells were cultured for a week and counted everyday.

RESULTS

Recovery rate of scFv-phage biopanning

An aliquot containing 1×10^{12} cfu scFv phage was selected on the HepG2 and L02 cell lines. The recovery rate of the third round biopanning was close to that of the second round indicating that positive clones were fully enriched (Table 1).

Table 1 Recovery rate of phage in each round of biopanning

Round	Input phage (cfu)	Eluted phage (cfu)	Recall rate (%)
1	1×10^{12}	1.9×10^8	1.9×10^{-6}
2	1×10^{12}	1.2×10^7	1.2×10^{-5}
3	1×10^{12}	1.5×10^7	1.5×10^{-5}

The recovery rate = eluted phage titer / input phage titer.

Selection of scFv phages

The selected and amplified polyclonal scFv phages were tested by FCM (Figure 1). The result also showed that positive clones were enriched well.

Figure 1 Result of polyclonal scFv phages by FCM (from left to right: purple -negative; green-1st round; red-2nd round; blue-3rd round).

After *E. coli* TG1 was infected with scFv phages of the third round and plated on 2×TY agar, 31 clones were isolated. PCR was carried out for identification of the clones combined with scFv gene sequence. Twelve positive clones were isolated to prepare monoclonal scFv phages. By ELISA, three scFv phages showed obviously higher binding activity in HepG2 cells according to the data of $A_{405}-A_{630}$ (Figure 2). By FCM, clones 4, 10 and 25 showed more extensive activity in HepG2 cells (Figure 3).

Figure 2 ELISA for monoclonal scFv phages.

Sequence of scFv DNA

The results of sequencing and Blast showed that clones 4 and 10 had homologous sequence of human immunoglobulin

Figure 3 FCM for monoclonal scFv phages.

in GenBank. The scFv DNA sequences were analyzed by IMGT/V-Quest software and submitted to GenBank (accession nos: AY686498 and AY686499). The region of CDR3 of VH was absent in clone 25 and the terminator codon was found in its open reading frame.

Result of IMAC purification

The scFv antibody fragments were harvested from the periplasm of 1 L *E. coli* HB2151 infected with positive phage SLH04 or SLH10 and the scFv antibody eluted effectively in PBS with 40 or 60 mmol/L imidazole by IMAC purification (Figure 4). SLH10 had the same result as SLH04 (data not shown).

Figure 4 SLH04 scFv antibody fragments eluted with different concentrations of imidazole. Lane 1: periplasm before eluting; lane 2: protein marker; lane 3, 4, 5, 6, 7, 8, 9, 10: elution washings at different imidazole concentrations, 200, 150, 100, 80, 60, 40, 20, 10 mmol/L, respectively.

Results of Western blot

Five micrograms of purified scFv antibody fragments was run on a 10% SDS-PAGE gel and transferred to nitro-cellulose and detected with the antibody 9E10 (Figure 5).

DISCUSSION

Antibodies displayed on phages are powerful tools for the identification of ligand specificity to targets of interest^[22]. Binding ligands from this library are usually selected by repetitive biopanning rounds usually performed on pure antigens on a solid phase^[23]. The isolation of antibodies for cellular receptors using whole cells as affinity matrix has a number of advantages. The receptors are likely to be in their native conformation compared to their purified one. Furthermore, a large number of known and novel surface antigens can be screened at the same time^[24,25]. In this respect, some investigators have selected a number of phage antibodies that bind to known and novel surface antigens using whole cells^[26,27].

In this study, two scFv antibody fragments were identified which could bind more extensively to HepG2 than to L02 cell line by biopanning of liver cells from a large naive antibody phage library. After three rounds of biopanning, the result indicated that positive clones were fully enriched. Then 12 monoclonal TG1 were picked out from the clones combined with scFv gene sequence. By

ELISA, seven of them showed no diversity binding to the two kinds of cells, two of them bound more extensively to L02 cells, three of them showed more extensive binding to HepG2 cells. The three clones were identified as the final positive clones at the end of biopanning. By sequencing and analyzing these three scFv DNA sequences, two clones were discovered having the right full open reading frame; the terminator codon was found in the open reading frame of clone 25 and its region of CDR3 of VH was absent and mutated. Probably this is why the affinity of binding to HepG2 showed no more specificity than the two other positive scFv antibody fragments. Blast in GenBank indicates that heavy chain of the scFv-04 belongs to IGHV2 family and its light chain belongs to Vk2 family, while the heavy chain of the scFv-10 belongs to IGHV1 family and its light chain belongs to Vλ3 family. Our data indicate that most soluble scFv antibody fragments are expressed in periplasm of the positive *E.coli* HB2151, few of them can be detected in bacterial supernatant. Therefore, we cannot obtain more soluble scFv antibodies purified from bacterial supernatant by IMAC as described previously^[28]. By cell ELISA the two soluble scFv antibody fragments showed higher ability to bind to HepG2 cells than to other cell lines, suggesting that scFv antibodies can bind to living HepG2 cells specifically. Furthermore, our data demonstrate that the two soluble scFv antibody fragments have growth inhibitory effects when cultured with HepG2 cells. Some antibodies have such biological effects on target cells because they are able to mimic the receptor-ligand interaction by triggering specific intracellular cascades of reactions, which eventually lead to biological signals such as inhibition of cell growth. In this regard, anti-transferrin receptor monoclonal antibody has the above characteristics^[29,30]. However, the fact that the transferrin receptor is expressed in most cell types makes these antibodies less interesting for cancer therapy. According to our results, the two scFv antibody fragments binding specifically to HepG2 cells can be used as target molecules in the treatment of hepatocellular carcinoma. Antibody phage biopanning method offers a potential application in the identification of human antibodies suitable for antitumor therapy^[31]. In summary, large human naive scFv antibody phage library is a useful tool for the selection of antibodies against antigens. The ability of the human scFv antibody fragments to bind to HepG2 cell surfaces will allow them to become a diagnostic and therapeutic reagent of HCC.

Abstract

AIM: Hydrogen sulfide (H_2S) is a prominent gaseous constituent of the gastrointestinal (GI) tract with known cytotoxic properties. Endogenous concentrations of H_2S are reported to range between 0.2-3.4 mmol/L in the GI tract of mice and humans. Considering such high levels we speculate that, at non-toxic concentrations, H_2S may interact with chemical agents and alter the response of colonic epithelium cells to such compounds. The GI tract is a major site for the absorption of phytochemical constituents such as isothiocyanates, flavonoids, and carotenoids, with each group having a role in the prevention of human diseases such as colon cancer. The chemopreventative properties of the phytochemical agent β -phenylethyl isothiocyanate (PEITC) are well recognized. However, little is currently known about the physiological or biochemical factors present in the GI tract that may influence the biological properties of ITCs. The current study was undertaken to determine the effects of H_2S on PEITC mediated apoptosis in colon cancer cells.

METHODS: Induction of apoptosis by PEITC in human colon cancer HCT116 cells was assessed using classic apoptotic markers namely SubG1 population analysis, caspase-3 like activity and nuclear fragmentation and condensation coupled with the MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrasodium bromide) viability assay and LDH leakage.

RESULTS: PEITC significantly induced apoptosis in HCT116 cells as assessed by SubG1 population formation, nuclear condensation, LDH leakage and caspase-3 activity after 24 h, these data being significant from control groups ($P < 0.01$). In contrast, co-treatment of cells with physiological concentrations of H_2S (0.1-1 mmol/L) prevented PEITC mediated apoptosis as assessed using the parameters

described.

CONCLUSION: PEITC effectively induced cell death in the human adenocarcinoma cell line HCT116 *in vitro* through classic apoptotic mechanisms. However, in the presence of H_2S , apoptosis was abolished. These data suggest that H_2S may play a significant role in the response of colonic epithelial cells to beneficial as well as toxic agents present within the GI tract.

INTRODUCTION

Cruciferous vegetables such as broccoli, watercress and Brussels sprouts are an important food source of phytochemicals known as glucosinolates (GSLs). Following tissue disruption GSLs can be converted by plant and/or enteric gut bacterial myrosinase to the organosulfur compounds isothiocyanates (ITCs)^[1,2]. Exposure to ITCs can reduce carcinogen induced tumor formation in a diverse range of organs such as lung, mammary gland, esophagus, liver and intestine^[3,4]. Supporting these findings are recent epidemiological studies showing that consumption of cruciferous vegetables, the primary source of ITCs in the human diet, can reduce cancer incidence in humans^[5,6]. Due to the promising chemopreventative properties of crucifers and ITCs, numerous reports have attempted to determine the mechanism(s) of action of ITC. ITCs can inhibit phase I enzymes^[7] and induce phase II detoxification enzymes^[8-12]. Moreover, the induction of apoptosis in target tissues and cancer cells has also been demonstrated. Previous investigations have shown that β -phenylethyl isothiocyanate (PEITC), benzyl isothiocyanate (BITC), allyl isothiocyanate (AITC) and sulforaphane (MSB) can induce apoptosis in both *in vitro* and *in vivo* situations^[13-19].

Considering the beneficial effects of ITC exposure in the diet, surprisingly few studies have placed much emphasis on endogenous or exogenous factors that may alter the beneficial properties of these phytochemical agents. To date, storage and cooking regimes, plant and bacterial myrosinase

activity and altered conversion of GSLs to non-bioactive nitriles have been shown to influence the response of host tissues and cells to ITCs^[20-24]. As ITCs are predominately absorbed along the gastrointestinal tract (GI) it is conceivable that the colonic environment may also contribute to the host's response to ITCs.

Hydrogen sulfide (H₂S) is a well known pungent gas and a prominent constituent present in the GI lumen. Exogenous sources show high toxicity towards the nervous, cardiovascular and respiratory systems in humans^[25]. The toxic effect of H₂S exposure are associated with its ability to bind reversibly to the heme site of cytochrome c aa3 site of cytochrome c oxidase thus inhibiting oxidative phosphorylation, although other mechanism(s) may also be involved. In addition, endogenous sites of H₂S production also exist in mammals^[26]. Catabolism of the amino acids L-cysteine and homocysteine by cystathionine- β -synthetase (CBS) generates appreciable levels of H₂S in the brain. CBS is highly expressed in the hippocampus and cerebellum and CBS knockout mice have no detectable amounts of H₂S in brain tissues. In contrast, H₂S is also formed from the same precursors by cystathionine- β -lyase (CSE) which is the predominant enzyme in the vasculature. In addition, mammalian cells may also be exposed to high levels of H₂S through the actions of enteric sulfate reducing bacteria in the GI tract^[27]. Recent studies have shown that H₂S concentrations in the large intestine of mice ranges between 0.2-1 mmol/L and are comparable to the concentration of H₂S in human feces (0.3-3.4 mmol/L)^[28,29]. Considering the high *in vivo* levels of H₂S it is plausible that such concentrations may directly affect the GI environment. Indeed, several clinical trials have shown a correlation between H₂S levels and the development of colorectal cancer and ulcerative colitis, such studies highlighting a potential deleterious effect of H₂S exposure^[30]. However, it is not currently known whether H₂S is the causative factor or a consequence of such diseases. In a more recent study Deplancke and Gaskins^[31] demonstrated that H₂S promotes cell cycle entry, MAPkinase activation, and cell proliferation in non-transformed intestinal IEC-18 cell *in vitro*. This data suggests a link between H₂S exposure and cell cycle dysregulation which perhaps contributes to colon cancer and ulcerative colitis development. However, considering the potential toxic effects of H₂S the GI tract has developed mechanism(s) to reduce the adverse effects of H₂S such as increased rhodanese expression and activity, detoxification via oxidation to thiosulfate and bicarbonate secretion^[32-34]. Therefore, H₂S production in health subjects may not lead to disease formation due to adequate protective mechanisms. Recent studies have shown that H₂S prevents glutamate induced oxidative stress in human neurons by stimulating glutathione biosynthesis^[35]. H₂S has also been shown to inhibit peroxynitrite, hydrogen peroxide and superoxide mediated cellular damage and death in neurons and myocytes by acting as an antioxidant^[36,37]. Likewise, organisms like *Saccharomyces cerevisiae* and deep sea hydrothermal vent *Archaea* use H₂S for the detoxification of methylmercury and heavy metal ion (Cu, Zn and Co) induced toxicity^[38,39], thus physiological concentrations in the human GI tract may protect colon cancer cells from undergoing apoptosis.

In view of the large quantities of H₂S in the GI tract we have systematically evaluated whether H₂S can alter the biological response of human colon cancer HCT116 cells to the chemopreventative agent PEITC. Such data may provide a novel insight as to how H₂S, at non-toxic concentrations, may act indirectly on colonic cells apoptosis.

MATERIALS AND METHODS

Cells and chemicals

Human colon cancer HCT116, HT29, SW480 and LS174T cell lines were purchased from the American Culture Collection (Rockville, MD). HCA-7 cells were kindly supplied by Susan. C. Kirkland, Royal Postgraduate Medical School, UK. β -Phenylethyl isothiocyanate, DMSO, ATP, SDS, penicillin and streptomycin were purchased from Sigma-Aldrich (St. Louis, MO, USA); MEM, trypsin and FBS from GIBCO BRL (Gaithersburg, MD, USA).

Cell culture

HCT116, HT29, HCA-7 and LS174T cells were cultured in complete DMEM (containing 100 mL/L FBS, 100 000 U/L penicillin, 100 mg/L streptomycin, pH 7.4) in 75-cm culture flasks at 37 °C in 50 mL/L CO₂. Similarly, SW480 cells were grown in RPMI 1640 medium under the above cell culture conditions.

Cell culture treatment

NaSH was used to generate readily controlled amounts of H₂S as it dissociates to Na⁺ and HS⁻ in solution, then HS⁻ associates with H⁺ to produce H₂S. We herein use the term H₂S to reflect the sum of the species H₂S, HS⁻ or S²⁻ present at physiological pH. PEITC was dissolved in DMSO to a final concentration of 100 mmol/L and adjusted to the required concentration by dilution in cell culture medium. All reagents were prepared fresh for each individual experiment.

Cell viability testing

Cell viability was determined using the MTT (3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyl tetrasodium bromide) viability assay as previously described^[40]. Activity of lactate dehydrogenase (LDH) in the medium was measured using an Abbott VP Biochemical Analyser with the test kit (Abbott Laboratories, Irving, TX, USA). The total LDH activity was determined by ultrasonication and assessed by expressing as percentage LDH leakage (LDH in medium/total LDH activity $\times 100$).

Detection of nuclear morphological changes and apoptosis

To assess apoptotic cell death morphologic changes in chromatin structure were detected by DAPI staining. Briefly, attached cells were harvested washed with PBS, and re-suspended in PBS prior to fixing with 700 mL/L ethanol for 15 min at room temperature. Cells were centrifuged, re-suspended in PBS and stained with 2 g/L DAPI in the dark for 5 min. Cell suspensions were mounted on glass slides and subjected to fluorescence microscopic examination using a Nikon photomicroscope (Thornwood, NY, USA). Apoptotic cells were identified by their morphology and by

the condensation and fragmentation of their nuclei.

DNA fragmentation in HCT116 cells was measured using propidium iodide staining followed by flow cytometry analysis as described^[41]. From each treatment 10 000 cells were analyzed using flow cytometry (Coulter Epics Elite ESP, Miami, FL, USA). Data was analyzed using WinMDI 2.7 software (Scripps Institute, La Jolla, CA, USA).

Measurement of caspase activity

Caspase-3 activity was determined spectrofluorometrically using the synthetic substrate Ac-DEVD-AFC respectively (BIOMOL Research Labs, Plymouth, PA, USA) as previously described^[42,43]. Cell homogenates were incubated with synthetic substrate 0.2 mmol/L at 37 °C/2 h. The fluorescence intensity of liberated AFC was monitored using a Tecan spectrofluor plus plate reader (USA) using an excitation wavelength of 400 nm and an emission wavelength of 505 nm.

Statistical analysis

All data are represented by three separate experiments. All experimental data consists of mean \pm SD unless otherwise stated and were analyzed by one-way ANOVA.

RESULTS

Evaluation of PEITC mediated reduction of colon cancer cell viability

Accumulating evidence has shown that cancer cells treated with PEITC undergo apoptosis by inducing mitochondrial dysfunction, sequential caspase activation, and MAPKinase mediated apoptotic signaling^[14,16]. To evaluate the cytotoxic effects of PEITC on the viability of colon cancer cells, we preferentially screened several commonly available cell lines namely colorectal carcinoma HCT116, and colorectal adenocarcinoma cell lines HT29, SW480, HCA-7 and LS174T cells, following 24h treatments with increased concentrations of PEITC. Cell viability was determined by MTT assay. All cells lines were responsive to PEITC treatment with viability decreasing in a concentration dependent manner (Figure 1).

Figure 1 (A) Concentration dependant loss of cell viability induced by PEITC in colon cancer cells as determined at 24 h using the MTT viability assay. Data are representative of three or more separate experiments (mean \pm SD).

Induction of apoptosis by PEITC

We next selected two cell lines for further study these being

the HCT116 and HT29 cell lines. Several key parameters that are known to be involved in PEITC induced apoptosis in HCT116 cells and HT29 cells were evaluated. Previous investigations have shown both HCT116 and HT29 cells are responsive to PEITC treatment, which we needed to reconfirm under our laboratory conditions^[14,44]. As represented in Figure 2, PEITC mediated a time and concentration dependant induction of caspase-3 like activity in HCT116 and HT29 cells. Caspase activity was determined by measurement of AFC fluorescence intensity derived from the catalytic cleavage of the substrate Ac-DEVD-AFC by endogenous caspase. The fluorescence intensity of treated over control cells, was used to determine the fold increase in caspase activity. Supporting a role of caspases in PEITC induced apoptosis was the inhibitory effects of the pharmacological caspase inhibitors Z-VAD-FMK (pan-caspase inhibitor), Ac-LEHD-CHO (caspase 9 inhibitor), and Ac-DEVD-CHO (caspase 3 inhibitor) on PEITC induced apoptosis. In both cell types tested all inhibitors reduced DNA fragmentation as determined by measurement of SubG1 populations by propidium iodide staining and LDH leakage (Figure 2).

Inhibition of PEITC mediated apoptosis by low molecular weight sulfur compounds

Because PEITC is absorbed along the GI tract we next evaluated whether hydrogen sulfide and other low molecular weight sulfur compounds could protect HCT116 cells from PEITC mediated apoptosis. Incubation of HCT116 cells with up to 1 mmol/L concentrations of hydrogen sulfide (H₂S) and its metabolic by-products sulfate (SO₄), sulfite (SO₃) and thiosulfate (S₂O₃²⁻) had no appreciable effects on cell viability as determined using the MTT assay and LDH leakage at 24 h (Figure 3). Co-treatment of individual sulfur compounds (SO₃, SO₄, S₂O₃²⁻) at 1 mmol/L concentrations failed to prevent the apoptotic effects of PEITC (40 μmol/L). In contrast, H₂S co-treatment but not pre-treatment inhibited PEITC induced apoptosis in a concentration dependant manner that was comparable to the low molecular weight thiol N-acetylcysteine (Figure 3). Associated with the inhibitory effects of both H₂S and NAC was a significant reduction in caspase activity (Figure 3D).

H₂S and NAC protect against BSO mediated sensitization of HCT116 cells to PEITC induced apoptosis

Intracellular depletion of glutathione (GSH) can be achieved using buthionine-S-sulfoximine (BSO), an inhibitor of the rate limiting enzyme required for GSH biosynthesis. BSO treatment sensitizes cells to apoptotic agents by reducing intracellular GSH levels. The sensitizing effects of combined treatment of PEITC and BSO in HCT116 cells were next investigated in the presence of H₂S and NAC. BSO at the concentration used had no appreciable effects on cell viability. Pre-treatment with 0.5 mmol/L BSO/24 h increased the apoptotic response of HCT116 cells to PEITC (40 μmol/L) as determined by the MTT assay and LDH leakage (Figure 4A). Indeed, BSO pre-treatment decreased cell viability by 83% and increased LDH leakage to 84.9% ($P<0.01$) in PEITC treated cells. Cellular protection was afforded by co-treatment with either H₂S or NAC (1 mmol/L). Moreover, evaluation of morphological

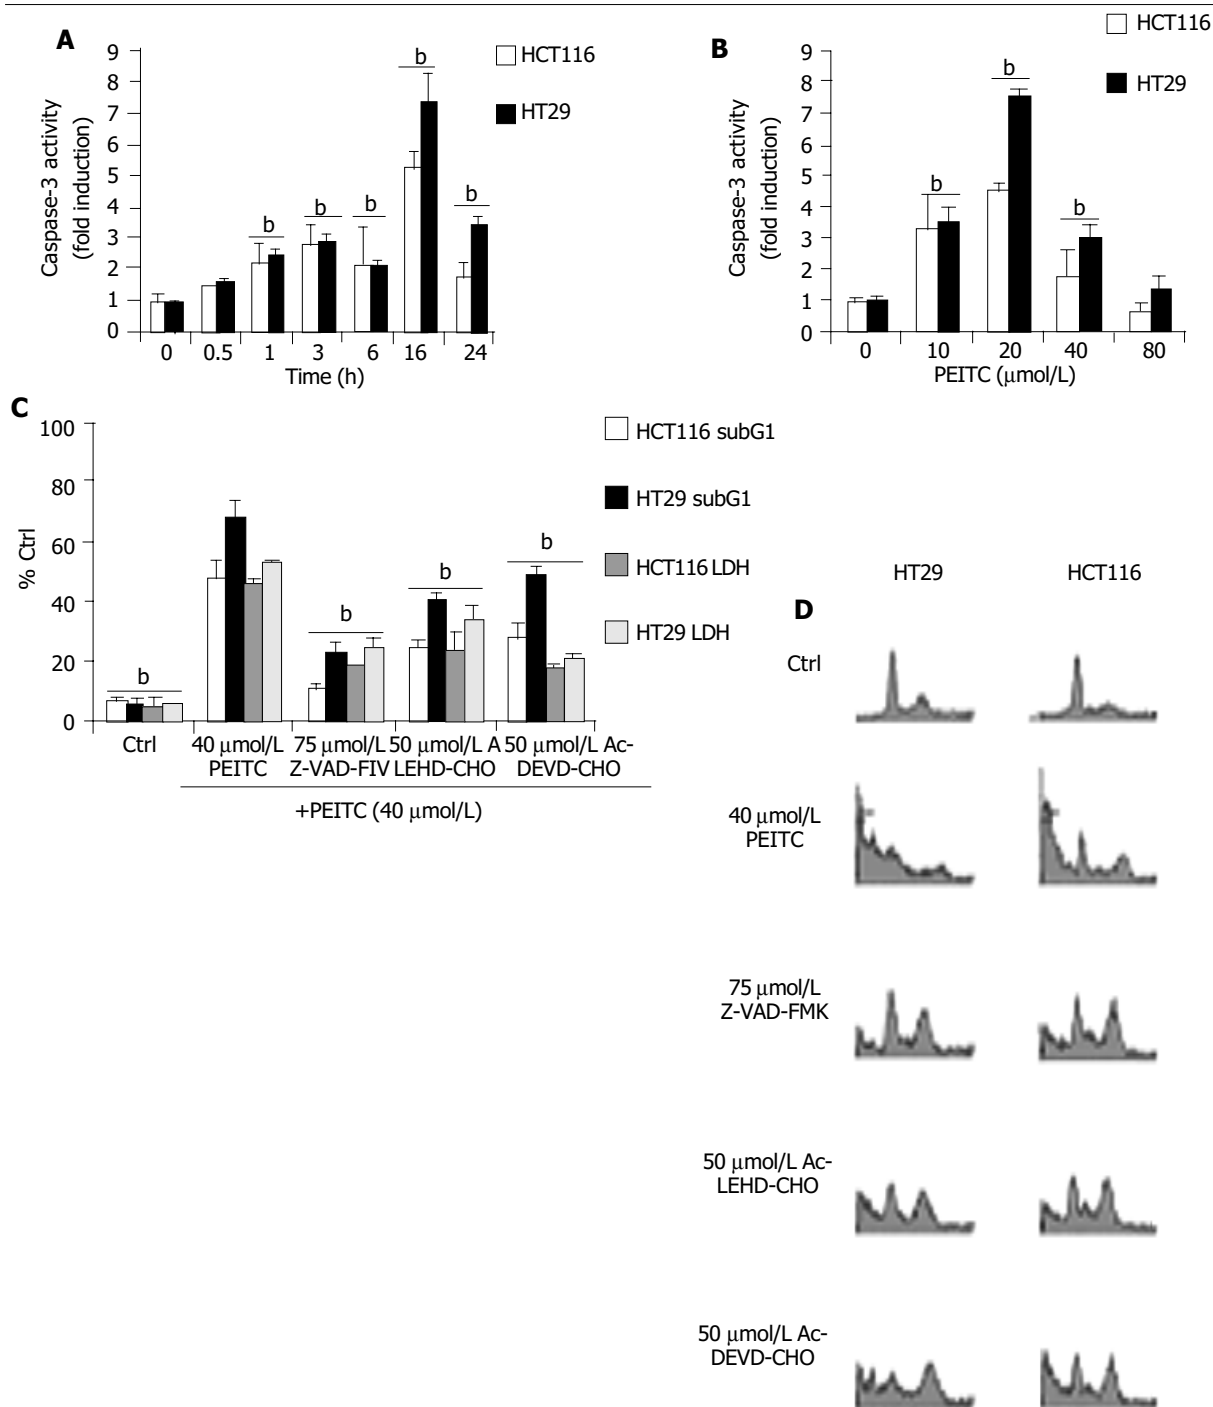

Figure 2 A: Time dependant Induction of caspase -3 activities in HCT116 and HT29 cells treated with 40 $\mu\text{mol/L}$ PEITC as determined at 0.5, 1, 3, 6, 16 and 24 h. B: Concentration dependant activation of caspase-3 as determined at 24 h after incubation with PEITC (10-80 $\mu\text{mol/L}$). C: Z-VAD-FMK, Ac-LEHD-CHO and Ac-DEVD-CHO inhibition on PEITC mediated apoptosis as determined at 24 h. ^b $P < 0.01$, significant difference compared to control groups. Cells were treated with individual caspase inhibitors for 1 h prior to the addition of 40 $\mu\text{mol/L}$ PEITC. SubG1 populations were determined by propidium iodide staining followed by

flow cytometry analysis as described in the materials and methods. ^b $P < 0.01$, comparing PEITC (alone) with control groups. D: Representative flow cytometry analysis of HCT116 and HT29 cells was used to determine the extent of DNA fragmentation in cells treated with PEITC (40 $\mu\text{mol/L}$) in the presence of caspase inhibitors. Data were determined by PI staining at 24 h. Figure shows representative example of at least 3 experiments. In each analysis, 10 000 events were recorded. ^b $P < 0.01$, PEITC (alone) vs control and caspase inhibitor treated groups.

and nuclear condensation also demonstrated that both H₂S and NAC prevent BSO mediated sensitization of HCT116 cells to PEITC.

DISCUSSION

In the present investigation we sought to examine whether

exogenous sources of the reductant H₂S could alter the response of human colon cancer cells to β -phenylethyl isothiocyanate induced apoptosis. PEITC is known to possess potent chemopreventative properties against carcinogen induced colon cancer in rodent models, perhaps mediated largely by the induction of carcinogen detoxification pathways, anti-inflammatory affects, and apoptosis^[8,11,18,19,45]. It is

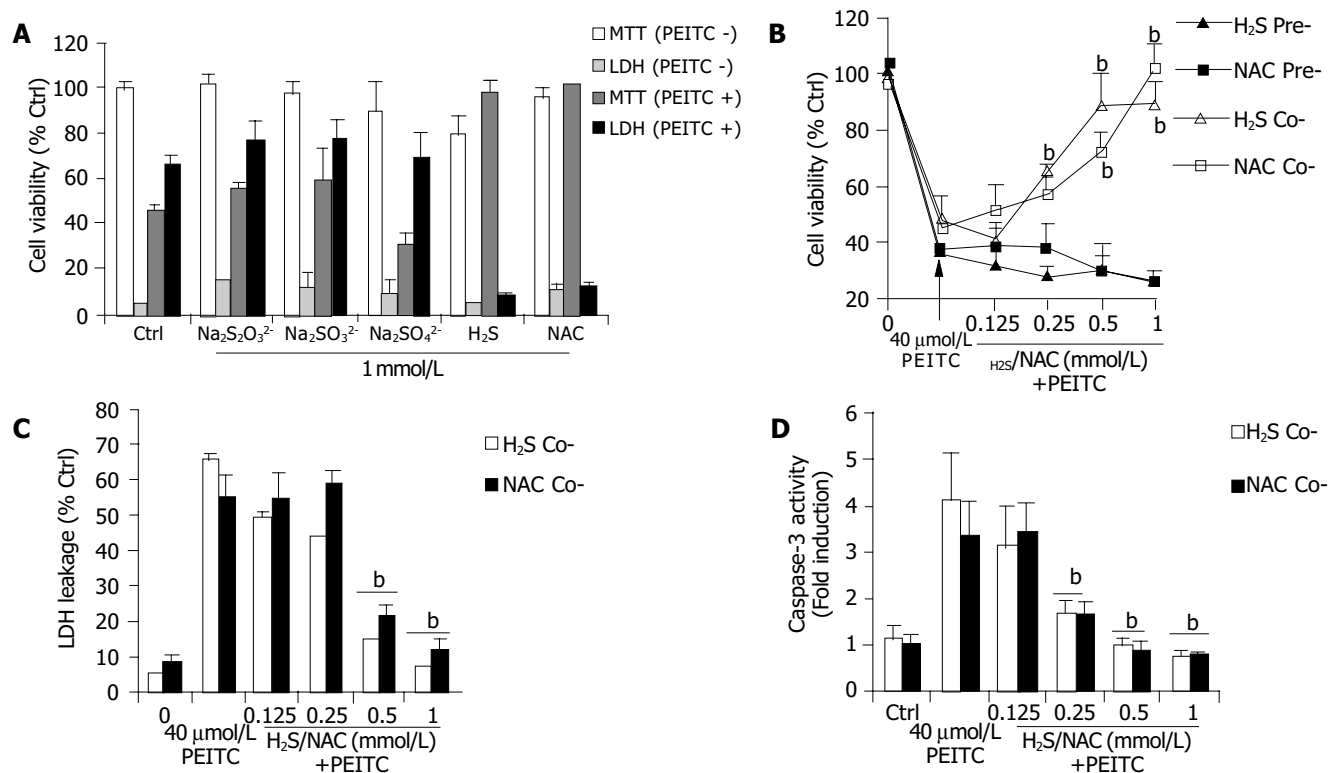

Figure 3 A: Effects of low molecular weight sulfur compounds on PEITC mediated loss of cell viability; B and C: Inhibition of PEITC mediated loss of cell viability in HCT116 cells following either co-treatment or pre-treatment (24 h) with H₂S or NAC (125 μmol-1 mmol/L) as determined by MTT or LDH leakage. Data are expressed as mean±SD, (n = 8); D: Co-treatment with either H₂S or

NAC (125 μmol-1 mmol/L) inhibits PEITC induced caspase-3 activity as determined at 16 h and Data are representative of 3 or more separate experiments conducted on separate occasions. mean±SD, ^bP<0.01 vs PEITC treated groups.

interesting to note, that previous investigations have shown that colon cancer cells are more sensitive to ITC mediated cytotoxicity than their detransformed counterparts. This property has been proposed to protect against the development of colorectal cancer by inhibiting the growth of transformed cell clones within the gastrointestinal mucosa^[46,47]. However, factors that may limit these beneficial effects have been largely unexplored.

The biological properties of ITCs, including PEITC, are predominantly mediated by the electrophilic central carbon atom of the isothiocyanate groups (R-N = C = S)^[48]. The NCS residue readily reacts with nucleophilic centers of deprotonated thiols such as those present on glutathione (GSH) and N-acetylcysteine (NAC) leading to the formation of N-substituted mono-dithiocarbamate conjugates. Such interactions alter the intracellular redox state and activate phase II detoxification enzymes or apoptotic signaling pathways.

Considering that sulfur metabolizing bacteria generate appreciable levels of the thiol H₂S in the GI tract, via metabolism of inorganic and organic sulfur compounds, we investigated whether H₂S could act in a similar manner to GSH or NAC in the detoxification of PEITC. Early work conducted by Zuman and Zahradnik^[49] demonstrated that organic ITCs can reversibly react with the hydrosulfide ion of H₂S forming N-mono-substituted dithiocarbamates, such findings supporting our hypothesis. However, whether these interactions could change the biological properties of PEITC, as well as other ITCs were not explored. H₂S

concentrations in the GI tract range between 0.2-1 mmol/L in mice and up to 3.4 mmol/L in human feces, therefore chemical interaction between H₂S and PEITC are highly plausible. On the basis of the chemical nature of H₂S and its similar biological characteristics to that of both GSH and NAC e.g. antioxidant properties and a deprotonated thiol group in aqueous solution, perhaps H₂S at physiological concentrations may impair the biological properties of electrophilic chemopreventive agents against colon cancer cells.

In our study, PEITC reduced colon cancer cell viability in a concentration manner in all cell lines studied (Figure 1). In addition, we also confirmed that the loss of cell viability in HT29 and HCT116 cells was due to the induction of apoptosis as assessed by nuclear fragmentation and condensation, LDH leakage, caspase-3 like activation and an increase in the SubG1 population (Figure 2). We next addressed using the HCT116 cell line whether H₂S could impair PEITC induced apoptosis. In each assay examined H₂S significantly reduced the apoptotic response of HCT116 cells to PEITC at concentrations well within the physiological reported levels (up to 3.4 mmol/L). Indeed, H₂S was almost as effective on a molar basis at inhibiting PEITC induced apoptosis as the antioxidant thiol N-acetylcysteine, a known inhibitor of PEITC intracellular up-take^[12]. We assume that the mechanism of inhibition by H₂S is similar to NAC, although this requires further study.

Understanding the mechanisms by which PEITC mediates apoptosis and factors that may influence its *in vivo* efficacy is of considerable importance as PEITC mediated

Figure 4 Inhibition of PEITC mediated loss in cell viability in GSH depleted cells following pre-treatment with 0.5 mmol/L BSO for 24 h. Both H₂S and NAC inhibited PEITC induced loss of cell viability in concentration dependent manner as determined using the MTT assay (A) and (B) LDH leakage. (C) Respective

photographs and DAPI stained cells showing cell morphological changes and nuclear condensation. Data are representative of 3 or more separate experiments conducted on separate occasions. mean±SD, ^b*P*<0.01 vs PEITC treated to control groups.

apoptosis is thought to contribute to its chemopreventative effects. In particular, extensive induction in apoptosis by PEITC has been observed in cell culture studies and rodent models of colon cancer. Similarly, an inverse correlation between ITC exposure and a reduction in colon cancer prevalence has been demonstrated in some epidemiological studies. Whether elevated levels of H₂S observed in colon cancer and ulcerative colitis impair chemopreventative or chemotherapeutic drug induced anti-inflammatory and apoptotic effects of has yet to be demonstrated.

In summary, our data reports for the first time that physiological concentrations of H₂S can inhibit the apoptotic effects of the chemopreventative agent PEITC. It is possible based on our data that changes in H₂S levels along the GI tract may influence the extent of PEITC mediated apoptosis *in vivo*. The potential interaction of H₂S with other dietary constituents as well as chemotherapeutic drugs requires further study.

Abstract

AIM: To ascertain the adequacy of the microsatellite instability (MSI) as a prognostic indicator by assessing MSI status of patients with double primary gastric and colorectal cancer (DPGCC).

METHODS: Sixteen patients were studied, all of whom exhibited sporadic DPGCC, and had no family history of hereditary non-polyposis colorectal cancer, according to the Amsterdam criteria. A total of 32 cancers from 16 DPGCC patients, and 216 single primary CRC, were assessed for MSI in 5 microsatellite loci, BAT25, BAT26, D2S123, D5S346, and D17S250.

RESULTS: MSI was observed in 6 (37.5%) of 16 GC and 4 (25.0%) of 16 CRC. Thirty tumors (13.9%) out of 216 single primary CRC and one tumor (16.7%) out of 6 double primary CRC were found to be microsatellite unstable. Of the 6 GC with MSI in DPGCC, 5 (31.3%) were MSI-high and one (6.3%) was MSI-low. In 5 of 16 DPGCC patients, the cancer recurred in or adjacent to the anastomosis or metastasized to the kidney or lung. The MSI-high DPGCC cases were associated with a younger age of onset (47.5 years *vs* 62.5 years), higher frequency of lymph node metastasis (100% *vs* 25%), and advanced Dukes stage (C, 100% *vs* 41.7%), as well as a higher frequency of recurrence or metastasis (100% *vs* 8.3%). Only recurrence or metastasis showed statistical significance by Fisher's exact test.

CONCLUSION: Our data suggest that MSI may play an important role in the development of DPGCC, and that it may be used clinically as a molecular predictive marker

INTRODUCTION

Gastric cancers (GC) and colorectal cancers (CRC) are common neoplasms in Korea and Japan. Almost 5% of GC and CRC patients develop other primary gastrointestinal (GI) cancers, either synchronously or metachronously^[1]. GC is the most prevalent extra CRC among multiple primary GI cancers involving CRC in Korea and Japan^[2,3]. The determination of high-risk groups of patients with multiple primary cancers involving the GI tract is important for clinical management, especially with regard to the prediction of patient's prognoses^[4]. The most well-known example of multiple primary cancers is hereditary non-polyposis colorectal cancer (HNPCC), an autosomally dominant hereditary syndrome which is caused by germline mutations in mismatch repair genes, including hMSH2, hMLH1, hPMS1, hPMS2, and hMSH6. Ninety percent of HNPCCs exhibit microsatellite instability (MSI)^[5]. MSI has also been observed in approximately 15-30% of single sporadic GC^[6,7] and in 10-15% of single sporadic CRC^[8,9]. Germline mutations of MLH1 and MSH2 occur at approximately equal frequencies in HNPCC, whereas virtually all sporadic MSI-high cancers develop due to epigenetic silencing of the MLH1 promoter through somatic hypermethylation^[10-13]. MSI may impart a favorable prognosis in colorectal, gastric, pancreatic, and probably esophageal cancers, but a poor prognosis in non-small cell lung cancer^[14].

Some reports have suggested the contribution of MSI in double primary cancers involving both the colorectum and stomach in the same patient^[4,15-17]. According to these reports, MSI is an indicator of increased cancer susceptibility in these double primary gastric and colorectal cancer (DPGCC) patients and genetic instability may play an important role in the development of these cancers. However, little remains known regarding the prognostic role of MSI in DPGCC, although a number of previous studies

have focused on the etiology or carcinogenic mechanisms of DPGCC. Therefore, we examined MSI status in patients with DPGCC in order to ascertain the adequacy of MSI as a prognostic indicator.

MATERIALS AND METHODS

Patients

Sixteen patients with sporadic DPGCC were studied. None of these cases had any family history of the HNPCC, according to the Amsterdam criteria for HNPCC. All patients underwent curative resections of both stomach and large bowel with tumor-free resection margins at the Department of Surgery, Samsung Medical Center, between January, 1994 and December, 2002, with the exception of one (case 12). Clinicopathological features are summarized in Table 1. Ages ranged from 35 to 76 (58.8 ± 10.1) years. Patients with synchronous DPGCC were defined as cases diagnosed with a secondary cancer that was detected within 6 mo of the detection of primary cancer, and those with metachronous DPGCC were defined as cases diagnosed with a secondary cancer detected more than 6 mo later, as previously described^[15,18]. Our study included 12 cases of synchronous (75.0%) and 4 cases of metachronous (25.0%) DPGCC. In one out of the 4 metachronous cases, the initial cancer was GC; in the remaining 3, it was CRC. The average ages of patients with synchronous and metachronous DPGCC were the same as the mean, 58.8 years. In cases of GC, 10 were found to be intestinal type (62.5%), and 6 cases were diffuse type (37.5%). Four cases were early type (25.0%), and 12 cases were advanced type (75.0%). No lymph node metastasis was detected in any of the cases of GC, and all cases were at stage I. In cases of CRC, six (37.5%) were located at the left-side of the colon or in the rectum. Four cases exhibited mucinous differentiation (25.0%) and 12 cases evidenced moderate tubular differentiation (75.0%). Nine cases (56.3%) of CRC exhibited lymph node metastasis, and 14 (87.5%) were at an advanced

stage (Dukes B or C).

Two hundred and sixteen single primary CRC, and 6 double primary CRC, were analyzed for MSI for the comparison in the current study for DPGCC.

We followed the recurrence and survival of 16 patients with DPGCC for at least 18 mo.

DNA extraction and MSI analysis

Microdissection was performed by an expert pathologist in this field using 10- μ m-thick hematoxylin-stained tissue sections in order to reduce contamination from other cellular DNA components. DNA was extracted from formalin-fixed, paraffin-embedded archival specimens of tumors and matched normal tissues, using the DNeasy Tissue kit (Qiagen, Hilden, Germany).

Five primers from independent genomic sites, including two mononucleotide repeat microsatellites (BAT25 and BAT26) and three dinucleotide repeat microsatellites (D2S123, D5S346 and D17S250), all of which were recommended by the National Cancer Institute workshop, were used in this study. Forward primers were synthesized with a fluorescent tag (FAM and NED) on the 5' end, and were purified by standard high-performance liquid chromatography. One hundred nanograms of DNA was amplified in a 20 μ L reaction solution, which containing 2 μ L of 10 \times buffer (Roche, Mannheim, Germany), 1.75–3 mmol/L $MgCl_2$, 0.4 μ mol/L primer pairs, 250 μ mol/L deoxynucleoside triphosphate, and 2.5 units of DNA polymerase (Roche, Mannheim, Germany). Amplifications were performed using a 2 min initial denaturation at 94 $^{\circ}C$, followed by 30 cycles of 45 s at 94 $^{\circ}C$, 45 s at 55 $^{\circ}C$, and 45 s at 72 $^{\circ}C$, and 5 min final extension at 72 $^{\circ}C$. The fluorescence-labeled PCR products were electrophoresed on an Applied Biosystems 3100 automated DNA sequencer (Applied Biosystems, Foster, USA), and the fluorescent signals from the differently-sized alleles were recorded and analyzed using Genescan software (version 2.7; Applied Biosystems).

C, cecum; AC, ascending colon; TC, transverse colon; DC, descending colon; SC, sigmoid colon; R, rectum.

Statistical analysis

Either Fisher's exact tests or Mann-Whitney tests were used to analyze variations in MSI status between various parameters. *P* values of less than 0.05 were considered statistically significant. Specialized statistical assistance was warranted by the small number of samples.

RESULTS

A total of 32 cancers from 16 Korean DPGCC patients and 216 single primary CRC cases were assessed for MSI, for 5 microsatellite loci. MSI results are summarized in Table 2. MSI was observed in six (37.5%) of 16 GC and 4 (25.0%) of 16 CRC in DPGCC patients (Figure 1). Thirty (13.9%) tumors of 216 single primary CRCs and one (16.7%) tumor of 6 double primary CRCs were found to be microsatellite unstable. Of the 6 GC with MSI in DPGCC, 5 (31.3%) were MSI-high and one (6.3%) was MSI-low. All CRC with MSI were MSI-high. There was an increasing tendency of MSI detected, with the lowest probability in single primary CRC, followed by double primary CRC, CRC of DPGCC, and GC of DPGCC. Two of six patients with MSI (33.3%) exhibited heterogeneity in terms of microsatellite alterations. For example, one lesion exhibited the MSI phenotype, but the other lesion in the same patient proved uninformative. One MSI in double primary CRC showed homogeneity with regard to MSI-high status.

Five patients of 16 DPGCC exhibited recurrence, either in or adjacent to the anastomosis or metastasis to different organs, such as the kidney or lung (Table 2). Case 1 exhibited recurrence of GC, 21 mo after the initial diagnosis, and recurrence of CRC 22 mo, after the initial diagnosis, both occurring at the anastomosis site. Case 2 exhibited metastatic GC in the right kidney, 88 mo after initial diagnosis. Case 3 exhibited an ampulla of Vater cancer at the time of initial diagnosis. Case 4 exhibited a recurrent CRC in another colonic segment (initial, cecum; recurred, transverse colon)

10 mo after the initial diagnosis. Case 16 exhibited metastatic CRC in the left lung 67 mo after the initial diagnosis.

The MSI-high DPGCC was associated with a younger age of onset (47.5 years *vs* 62.5 years), a higher frequency of lymph node metastasis (100% *vs* 25%), advanced Dukes stage (C, 100% *vs* 41.7%), and higher frequency of recurrence or metastasis (100% *vs* 8.3%) (Table 3). Only recurrence or metastasis showed statistical significance, with *P* values of less than 0.005, by Fisher's exact test.

Figure 1 Typical results of microsatellite instability (MSI) of tumors. **A:** Abnormal MSI peaks (arrows) of gastric cancer from case 4; **B:** Abnormal MSI peaks (arrows) of colonic cancer from case 2 (upper row: normal tissue, middle row: cancer tissue, lower row: upper row + middle row).

- Dukes A : B : C	0 : 0 : 4	2 : 5 : 5	NS
Recurrence, metastasis, or other organ malignancy	100%	8.3%	<0.005

NS: not significant.

DISCUSSION

MSI has been suggested to play an important role in the development of multiple primary cancers of the gastrointestinal tract. Thus, MSI appears to be useful in screening for the detection of a high-risk group for secondary primary cancer in some patients with sporadic single gastric and colorectal cancers, because it is rapid and inexpensive.

MSI has been observed in approximately 15-30% of single sporadic gastric cancers^[6,7] and 10-15% of single sporadic colorectal cancers^[8,9]. Our results regarding MSI rate in double primary CRC and single sporadic CRC, were not radically different from the results of other investigators. In our study, MSI was observed in 31.3%, 25.0%, 16.7%, and 13.9% of GC in patients with DPGCC, CRC of patients with DPGCC, double primary CRC, and single primary CRC, respectively. This indicates that genetic instability may play an important role in the development of multiple primary cancers of the GI tract. MSI has been observed more frequently in multiple GI cancer patients than in those with single primary gastric or colorectal cancers, as demonstrated in previous reports^[3,4]. Concordant MSI rate, and MSI-high status in both cancers, has been reported 17.7-25.0% of DPGCC^[3,15]. Our result is very similar to these. Yamashita *et al.*^[4], reported that MSI-high status was seen more frequently in the same organ group, especially in multiple GC patients, than in different organ groups, and lesions from different organ groups tended to show MSI-low or stable phenotype. Thus, MSI in multiple GI cancers containing GC appears to be relatively common, and may play an important role in multi-organ carcinogenesis.

The relationship between MSI of DPGCC and patient prognosis or clinicopathological features remains unclear. Kim *et al.*^[3], reported that MSI-positive CRC was characterized by fungating tumor gross, poor or mucinous differentiation, and rare nodal metastasis. MSI-positive GC was characterized by intestinal type, smaller size, and rare nodal spread. They were unable to explain discrepancies in size and differentiation between CRC and GC. According to our result, the clinicopathological features of GC were basically the same concordantly MSI-positive GC as was observed in other cases of DPGCC. Studied cases were usually intestinal type,

and at a relatively early stage. Differences, in general, were seen in the age and the clinicopathological features of CRC. Concordantly MSI-positive CRC was associated with younger age, larger tumor size, more frequent nodal metastasis, higher stage, and more frequent recurrence and distant metastasis. Our results were also different from others. Ohtani *et al.*^[15], reported that concordantly MSI-positive CRC was usually associated with better prognosis. There were no dead patients found, among 5 concordantly MSI-positive DPGCC, and 4 dead patients (26.7%) among the 15 remaining cases. However, no explanation was given in their report regarding about the causes of death. In our results, we found no cancer-related or natural deaths in the studied cases. Ikeda *et al.*^[19], compared the prognosis of patients with DPGCC with patients with single cancer, and reported that the former was better than the latter. One explanation for this difference in prognosis may be that DPGCC is often discovered at an early stage. According to our results, the stage of DPGCC was more advanced in concordantly MSI-positive DPGCC. Thus, we suggested that the prognosis of patients with DPGCC appears to be dependent on stage.

Interestingly, there have been no reports regarding the recurrence or late metastasis in patients with DPGCC. We followed the hospital course of all studied cases. Case 1 was a unique example of cancer recurrence in patients with concordantly MSI-positive DPGCC. This patient had mucosa-confined early gastric cancer and Dukes C CRC in the transverse colon synchronously, and underwent curative resection for both organs with ample resection margins. However, both tumors recurred at the anastomosis sites, 21 and 22 mo after the initial diagnosis. Case 2 was also very unique. He had submucosa-confined early gastric cancer and Dukes C CRC in the ascending colon synchronously, and underwent curative resection for both organs with ample resection margins. The patient then had an uneventful history for 7 years. However, renal metastasis of previous early gastric cancer was found 88 mo after the initial diagnosis. Cases 4 and 16 were examples of recurrence and late distant metastasis of advanced-stage CRC. Recent studies have revealed the significance of MSI in gastric carcinogenesis. Kashiwagi *et al.*^[20], reported that MSI in the gastric biopsy specimens of chronic gastritis patients may predict the risk of progression to adenoma and well-differentiated adenocarcinoma. Kim *et al.*^[21], reported that gastric carcinomas arising from adenomas are frequently associated with MSI. These data, and ours, suggest that MSI might play an important role in the early phase of carcinogenesis, and is, therefore, related to the delayed development of recurrent disease. Less clear is the role of and mechanisms underlying MSI-low status. In our study, only one MSI-low was found.

Due to its rarity, the meaning of MSI in DPGCC, whether concordantly-positive or not, is still a topic which warrants future investigation. Our data suggest that MSI may play an important role in the development of DPGCC, and that it may be used clinically as a molecular marker for the prediction of recurrence or late metastasis of DPGCC.

Abstract

AIM: To enhance the radiosensitivity of human colon cancer cells by docetaxel.

METHODS: Immunoliposomal docetaxel was prepared by coupling monoclonal antibody against carcinoembryonic antigen to cyanuric chloride at the PEG terminus of liposome. LoVo adenocarcinoma cell line was treated with immunoliposomal docetaxel or/and irradiation. MTT colorimetric assay was used to estimate cytotoxicity of immunoliposomal docetaxel and radiotoxicity. Cell cycle redistribution and apoptosis were determined with flow cytometry. Survivin expression in LoVo cells was verified by immunohistochemistry. D801 morphologic analysis system was used to semi-quantify immunohistochemical staining of survivin.

RESULTS: Cytotoxicity was induced by immunoliposomal docetaxel alone in a dose-dependent manner. Immunoliposomal docetaxel yielded a cytotoxicity effect at a low dose of 2 nmol/L. With a single dose irradiation, the relative surviving fraction of LoVo cells showed a dose-dependent response, but there were no significant changes as radiation delivered from 4 to 8 Gy. Compared with liposomal docetaxel or single dose irradiation, strongly radiopotentiating effects of immunoliposomal docetaxel on LoVo cells were observed. A low dose of immunoliposomal docetaxel could yield sufficient radiosensitivity. Immunoliposomal docetaxel were achieved both specificity of the conjugated antibody and drug radiosensitization. Combined with radiation, immunoliposomal docetaxel significantly increased the percentage of G₂/M cells and induced apoptosis, but significantly decreased the percentage of cells in G₂/G₁ and S phase by comparison with liposomal docetaxel. Immunohistochemical analysis showed that the brown

stained survivin was mainly in cytoplasm of LoVo cells. Semi-quantitative analysis of the survivin immunostaining showed that the expression of survivin in LoVo cells under irradiation with immunoliposomal docetaxel was significantly decreased.

CONCLUSION: Immunoliposomal docetaxel is strongly effective for target radiosensitization in LoVo colon carcinoma cells, and may offer the potential to improve local radiotherapy.

INTRODUCTION

Colorectal cancer is one of the most common malignant diseases in the world^[1-3]. In the treatment of colorectal cancer, local recurrence is a major problem. To improve the overall survival and reduce the local recurrence rate after surgery, additional radiotherapy is given either preoperatively or postoperatively^[4-7]. Docetaxel has substantial radiosensitizing properties for malignant tumors. It inhibits microtubule disassembly and interferes with mitotic spindle function to block cells at G₂/M, the most radiosensitive phase of cell cycle^[8,9].

Conventional radiosensitizers alone are limited by side effects due to their poor selectivity for tumors. Monoclonal antibody specific tumor antigen makes them possible to enhance the selectivity by a targeted delivery approach^[10,11]. Radiation induces apoptosis of neoplastic cells. The extent of radiation-induced apoptosis correlates closely with radiosensitivity^[12,13]. Apoptosis is regulated by activators and inhibitors in signal transduction pathways. In this study, we attempted to investigate the radiosensitization of colon carcinomas targeting with docetaxel liposome conjugated antibody specific for carcinoembryonic antigen (CEA). The aim of this study was to selectively deliver of docetaxel and to enhance the radiation sensitivity of human colon cancer cells. In order to increase radiotherapy effects on local tumors and to improve the quality of life and overall survival, radiosensitizers should be delivered into the tumor.

This workshop considered a new approach by use of targeted radiosensitizers to improve radiotherapy.

MATERIALS AND METHODS

Chemical and biological materials

Cholesterol, and soy phosphatidylcholine were purchased from Shanghai Chemical Agent company. 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), cyanuric chloride, O-(2-aminoethyl) polyethylene glycol 3000, N,N-diisopropylethylamine, dimethyl sulfoxide (DMSO), 1,2-dipalmitoyl-sn-glycero-3-phosphoethanolamine (DPPE) were purchased from Sigma. Docetaxel was kindly supplied by Jiangsu Hengrui Medicine Co. Monoclonal antibody specific for CEA was purchased from Beijing Zhongshan Biotechnology Co. Immunocytochemical detection kit was from Wuhan Boster Biological Technology Co.

Preparation of immunoliposomal docetaxel

Immunoliposomal docetaxel was prepared according to the method described by Bendas^[14-17] with minor modifications. Briefly, a 2-fold molar of N, N-diisopropylethylamine and a 3-fold molar cyanuric chloride were added to chloroform solution of DPPE, mixed for 12 h, then DPPE-cyanuric chloride was isolated. DPPE-PEG-OH was prepared by adding a 1-fold molar aminopolyethylene glycol 3000 and a 2-fold molar of N,N-diisopropylethylamine to DPPE-cyanuric chloride. PEG terminus was activated by reaction with 1-fold molar of cyanuric chloride in addition to a 2-fold molar of N,N-diisopropylethylamine. DPPE-cyanuric chloride (cyanur-PEG-PE) was synthesized.

Liposomal docetaxel was prepared with soy phosphatidylcholine cholesterol 2:1 (molar ratio), cyanur-PEG-PE (0.5 mmol/L), docetaxel (1 μ mol/L). Multilamellar vesicles were extruded through a 200 nm polycarbonate membrane. Antibody conjugated with docetaxel liposomes: anti-CEA-antibody molar ratio of 1 000:1 was prepared in 0.15 mol/L NaCl (pH 8.8). Unbound antibodies were separated by gel permeation chromatography using Sepharose 4B.

Cell culture

LoVo cells, the CEA-expressing human colon adenocarcinoma cell line, were maintained in Dulbecco's modified Eagle's medium supplemented with 10% heat-inactivated fetal calf serum, 100 μ g/mL streptomycin, 100 units/mL penicillin. The population doubling time was approximately 30 h. LoVo cells were grown at 37 °C in a humidified atmosphere of 50 mL/L CO₂.

Treatment with immunoliposomal docetaxel and irradiation

LoVo cells (5×10^3) were plated onto 96-well plates or 6-well plates. Before the administration of appropriate doses of immunoliposomal docetaxel or radiation, cells were plated for 24 h to allow attachment. LoVo cells were incubated with different concentrations of immunoliposomal docetaxel or liposomal docetaxel as equivalent docetaxel doses of 1 nmol/L, 2 nmol/L, 10 nmol/L, 100 nmol/L and 1 000 nmol/L for 2 h at 37 °C. After washing thrice with culture medium, the cells with or without radiation were

incubated for 24 h or 48 h at 37 °C. Cells were X-irradiated at 0, 2, 4, 6 and 8 Gy respectively. Irradiation was performed with 6-MV photons generated by a Philips SL-75 linear accelerator at a dose rate of 1.3 Gy/min. In the combined treatment modality studies, the treated cells were incubated for 24 h before radiation treatment. All doses were delivered without interruption and with the same focus-target distance.

MTT assay

LoVo cells were treated with various concentrations of immunoliposomal docetaxel, and some were exposed to radiation. To measure cell proliferation, the colorimetric method based on MTT assay was used^[18,19]. Cells were stained with MTT (50 mg/mL) and incubated for 4 h at 37 °C in a humidified atmosphere of 50 mL/L CO₂. Then the cells were lysed in DMSO, and the solutions were read in a Bio-Tek spectrophotometer at 570 nm. The production of formazan crystals, and the intensity of color after their dissolution, were proportional to the number of viable cells.

Flow cytometric analysis

At the end of each treatment, LoVo cells were harvested with 0.5 g/L trypsin and 0.2 g/L EDTA. Cells were fixed in 2 mL of 70% cold ethanol at 4 °C for 2 h, centrifuged, washed twice with phosphate buffered saline (PBS), and resuspended in 0.5 mL propidium iodide (PI)/RNase A solution. The mixed cells were incubated in the dark at room temperature for 10 min. The fluorescence emission of stained cells was measured with a Becton Dickinson flow cytometer. The number of cells and DNA content were detected by flow cytometry, the fraction of cells in each phase of cell cycle was analyzed. Apoptotic cells were determined by the hypodiploid peak.

Immunohistochemistry

Streptavidin-biotin peroxidase complex technique was used for staining cells. The treated LoVo cells were harvested and plated on slides. The cells were fixed in 95% aqueous alcohol. The endogenous peroxidase activity was blocked by a 3% solution of hydrogen peroxide in methanol for 30 min. Cells were immunostained using monoclonal antibody against human survivin for 1 h at 37 °C. After three further washes with PBS, a second biotinylated rabbit anti-mouse antibody was applied for 1 h at room temperature. Following extensive washes with PBS, color development was demonstrated with diaminobenzidine tetrahydrochloride chromagen. The slides were lightly counterstained with hematoxylin. Stained cells were examined using light microscopy and photographed. JD801 morphologic analysis system for color-image measurement was used to semi-quantify immunohistochemical staining of survivin.

RESULTS

Determination of the cytotoxicity of immunoliposomal docetaxel to LoVo cells

To determine the cytotoxicity of immunoliposomal docetaxel to human colon cancer cells, LoVo cells were treated with various concentrations of immunoliposomal docetaxel for 24 or 48 h. Relative survival data for LoVo

cells are shown in Figure 1. Under the treatment with 2 nmol/(L • d) immunoliposomal docetaxel for 24 h, survival was decreased 12% as compared with 1 nmol/L a immunoliposomal docetaxel. The results for Figure 1 also indicate that LoVo cells were more sensitive to immunoliposomal docetaxel treatment in 24 h than for 48 h. The cytotoxicity was induced by immunoliposomal docetaxel alone in a dose-dependent manner. The immunoliposomal docetaxel yielded a cytotoxicity effect at a low dose of 2 nmol/L.

Figure 1 Cytotoxicity of immunoliposomal docetaxel to LoVo cells.

Radiotoxicity to LoVo cells

LoVo cells received a series of test doses of radiation, ranging from 2 to 8 Gy. The radiotoxicity generated is shown in Figure 2. At the doses of 4 to 8 Gy, the reaction to irradiation appeared less pronounced.

Figure 2 Radiotoxicity to LoVo cells irradiated with single doses.

Target radiopotentiating effect of immunoliposomal docetaxel

To examine whether immunoliposomal docetaxel could target LoVo cells and reveal radiopotentiating effect, these cells were treated with immunoliposomal docetaxel and liposomal docetaxel, respectively, then irradiated at the dose of 2 Gy radiation doses. The control cells were irradiated alone. Using MTT assay, the relative surviving fractions were obtained. The results in Figure 3 showed that immunoliposomal docetaxel was strongly radiopotentiated in LoVo cells, compared with the effects of liposomal docetaxel or single irradiation ($P < 0.05$). No significant

radiopotentiating effects were found after treatment with liposomal docetaxel.

Figure 3 Target radiopotentiating effects of docetaxel immunoliposomes on LoVo cells.

Cell cycle effects

To determine whether immunoliposomal docetaxel in combination with radiation could increase cellular sensitivity to radiation through cell cycle redistribution, we analyzed the LoVo cells by flow cytometry. After treatment with immunoliposomal docetaxel or liposomal docetaxel, all cells were irradiated at 2 Gy. The response of LoVo cell cycle to radiation is shown in Figure 4. Compared to treatment with liposomal docetaxel, the percentage of G_2/M cells treated with immunoliposomal docetaxel was significantly increased ($P < 0.01$), but the percentages of cells both in G_2/G_1 phase and in S phase were decreased significantly ($P < 0.05$). Apoptosis was also monitored by flow cytometry (Figure 4). Apoptosis was significantly increased in LoVo cells due to the combined effects of immunoliposomal docetaxel and radiation.

Figure 4 Combined of effect immunoliposomal docetaxel and radiation on cell cycle distribution and apoptosis.

Immunohistochemical analysis of survivin

Survivin expression in LoVo cells after irradiation and treatment with immunoliposomal docetaxel was verified by immunocytochemistry. Survivin was positively stained with anti-survivin monoclonal antibody. Representative results are shown in Figure 5.

Figure 5 Expression of survivin in LoVo cells.

Semiquantitative assessment of survivin staining

Positive staining of survivin was mainly present as diffuse cytoplasmic staining with variable intensity. Integral optical density of survivin was detected semiquantitatively by immunohistochemical staining combined with image analysis. For density measurement, color-images were directly analyzed using D801 morphologic analysis system. The semiquantitative data reported here were directly comparable to image analysis data. Survivin expression in LoVo cells after irradiation and treatment with immunoliposomal docetaxel was significantly decreased in comparison to treatment with liposomal docetaxel ($P < 0.001$, Figure 6).

Figure 6 Survivin expression in LoVo cells were determined by quantitative image analysis.

DISCUSSION

Docetaxel plays an important role in the treatment of human malignancies, particularly ovarian and breast cancer^[17,18]. It inhibits mitotic progression and induces programmed cell death^[19]. For systemic toxicity of docetaxel, the optimal usage is the targeted delivery.

Liposome is used as a potential vector for targeted delivery of radiosensitizers^[20]. Liposome is a phospholipid bilayer membrane-bound vesicle capable of encapsulating a wide variety of substances either within their lipid membrane or their central aqueous core. Liposome incorporates polyethylene glycol components and has a prolonged circulation half-life. Liposomal doxorubicin is understanding clinical phase II pilot study in patients with inoperable squamous cell cancer of the head and neck^[21].

Maruyama *et al.*^[22], introduced a PEG-PE derived lipid with a terminal maleimide group for the reaction with thiolated antibodies. Allen *et al.*^[23], synthesized a thiol-reactive PEG anchor for reaction with maleimide-containing antibodies. The terminal coupled antibody shows an increased target binding ability compared with conventional immunoliposomes^[24]. A drawback of these coupling procedures is the need of derivation for the attachment of antibody. Two reagents are needed to activate PEG-derivatives with carboxy groups. In this study, a new liposomal membrane anchor was introduced for the covalent attachment of antibody to liposomes. Anti-CEA-antibody is simply and rapidly coupled to cyanuric chloride at the PEG terminus of liposome without previous derivatization.

Immunoliposomal docetaxel may be an attractive strategy for target radiopotential because it can radiosensitize LoVo cells. Docetaxel is targeted by specific anti-CEA-antibody. Our study demonstrate that docetaxel conjugated to a monoclonal antibody specific for CEA tumor-associated antigen could exert efficient and specific cytotoxicity to CEA-expressing LoVo cells. Immunoliposomal docetaxel alone showed dose-dependent cytotoxicity to LoVo cells. Furthermore, anti-CEA-antibody enhanced the target effects of docetaxel and led to radiosensitization.

Immunoliposomal docetaxel achieved both specificity of the conjugated antibody and drug radiosensitization. Using a low dose of immunoliposomal docetaxel could yield sufficient radiosensitization. Radiation combined with immunoliposomal docetaxel caused a significant increase in the population of G₂/M cells. One of the mechanisms may correlate to the effects of docetaxel such as interfering with normal microtubule function, blocking cells in G₂/M, and enhancing the sensitivity to apoptosis^[25,26]. The presence of arrest in G₂/M did not seem to be a sufficient condition to enhance radiation sensitivity. Redistribution of cell cycle due to radiosensitization induced by immunoliposomal docetaxel was observed. Increased apoptosis may have a potential correlation to increased radiosensitivity.

Furthermore, apoptosis may be regulated by a complex balance in signal transduction pathways between apoptosis-activating factors, such as p53 and bax, and antiapoptotic factors, such as the bcl-2 family and inhibitor of apoptosis protein (IAP) family^[27]. Survivin, a newly identified member in IAP family, is a strong apoptosis inhibitor. It can be found during fetal development and in colorectal cancer^[28]. Expression of survivin may confer a certain degree of radioresistance to rectal cancer cells^[29-31]. In the present study, we attempted to find a relationship between the expression of survivin and radiation-induced apoptosis.

Immunohistochemistry examination showed that survivin was mainly in cytoplasm of LoVo cells. Moreover, semiquantitative analysis of the immunohistochemical staining of survivin indicated that a low survivin expression was associated with a significantly higher radiosensitivity after treatment with immunoliposomal docetaxel combined with irradiation. LoVo cells were radiosensitized significantly by decreased expression of survivin. The alteration of survivin expression in LoVo cells may partially explain the enhanced apoptosis and radiation sensitivity.

In conclusion, immunoliposomal docetaxel is strongly

effective for target radiosensitizing in LoVo colon carcinoma cells, and may offer the potential to improve local radiotherapy.

Abstract

AIM: To study the effect of caffeic acid phenethyl ester (CAPE) on proliferation, cell cycle, apoptosis and expression of β -catenin in cultured human colorectal cancer (CRC) cell line HCT116.

METHODS: HCT116 cells were treated with CAPE at serial concentrations of 80, 40, 20, 10, 5, 2.5 mg/L. The proliferative status of HCT116 cells was measured by using methabenzthiazuron (MTT) assay. Cell cycle was analyzed by using flow cytometry (FCM) with propidium iodide (PI) labeling method. The rate of apoptosis was detected by using FCM with annexin V-FITC and PI double labeling method. β -catenin levels were determined by Western blotting. β -catenin localization in HCT116 was determined by indirect immunofluorescence.

RESULTS: After HCT116 cells were exposed to CAPE (80, 40, 20, 10, 5, and 2.5 mg/L) for 24, 48, 72, 96 h, CAPE displayed a strong growth inhibitory effect in a dose- and time-dependent manner against HCT116 cells. FCM analysis showed that the ratio of G_0/G_1 phase cells increased, S phase ratio decreased and apoptosis rate increased after HCT116 cells were exposed to CAPE (10, 5, and 2.5 mg/L) for 24 h. CAPE treatment was associated with decreased cytoplasmic β -catenin, nuclear β -catenin and a concurrent increase in β -catenin protein expression at cell-cell junctions.

CONCLUSION: CAPE could inhibit HCT116 cell proliferation and induce cell cycle arrest and apoptosis. Decreased β -catenin protein expression may mediate the anti-proliferative effects of CAPE.

INTRODUCTION

Colorectal cancer (CRC) is one of the most common human malignancies, and is the fourth leading cause of cancer deaths. The incidence tends to increase in China. Aberrant WNT pathway signaling is an early progression event in 90% of colorectal cancers. It occurs through mutations mainly of APC and less often of CTNNB1 (encoding β -catenin) or AXIN2 (encoding axin-2, also known as conductin). Activation of WNT signaling leads to inhibition of GSK-3 β activity, resulting in accumulation of cytoplasmic (signaling) β -catenin, which becomes available to bind the TCF/LEF family of transcription factors and to induce target gene expression^[1]. Dysregulation of WNT signaling and hence β -catenin expression is believed to be central to the early stages of sporadic colorectal carcinogenesis in human beings^[2]. Therefore, control of β -catenin and/or control of downstream TCF target gene expression represents an ideal target for CRC chemoprevention. Caffeic acid phenethyl ester (CAPE), an active component of propolis, has many biological and pharmacological activities including antioxidant, anti-inflammation, antiviral action, anticancer effect, *etc.*^[3-7]. It also inhibited the development of azoxymethane-induced aberrant crypts in the colon of rats^[8]. Thus, we investigated the effects of CAPE on proliferation, cell cycle, apoptosis and expression of β -catenin in the cultured human colorectal cancer (CRC) cell line HCT116.

MATERIALS AND METHODS

Drugs and reagents

CAPE, dimethyl sulphoxide (DMSO), PI and MTT were purchased from Sigma-Aldrich (USA). RPMI-1640 medium was purchased from Hyclone. Mouse monoclonal anti-human β -catenin antibody was obtained from Sigma-Aldrich (USA). FITC and horseradish peroxidase-conjugated secondary antibody were obtained from Pierce Biotechnology (USA). Annexin-V and PI double staining kit was purchased from Roche (USA). CAPE was prepared as 80 g/L stock solutions in DMSO. Control flasks or plates contained DMSO at an equivalent dilution to that in cultures containing CAPE.

Cell culture

The human CRC cell line HCT116 was purchased from the American Type Culture Collection (ATCC). The cells were cultured in RPMI1640 medium (pH 7.2-7.4) supplemented with penicillin G (100 U/mL), streptomycin (100 U/mL) and 10% fetal calf serum (FCS) at 37 °C in a 50 mL/L CO₂ humidified atmosphere. Cells were routinely sub-cultured using 2.5 g/L trypsin/ethylenedinitrile tetraacetic acid (EDTA) solution (obtained from Sigma).

MTT assay for determination of cell growth

The logarithmically growing HCT116 cells were plated at a density of 4×10^3 cells/well into a 96-well plate. After 24 h, cells were treated with CAPE at various concentrations (80, 40, 20, 10, 5, and 2.5 mg/L) for 24, 48, 72, and 96 h. Control wells were treated with 0.1% DMSO alone. Then, 20 μ L MTT (5 g/L) was added to each well and incubated for an additional 4 h, and then culture media were discarded followed by addition of 0.15 mL DMSO and vibrated for 10 min. The absorbance was measured at 490 nm using a model 550 microplate reader. The inhibitory rates (IR) were calculated as follows: $IR (\%) = (1 - \text{absorbance of the treated wells}) / (\text{absorbance of the control wells}) \times 100\%$. The 50% inhibitory concentration (IC₅₀) value was determined using a CalcuSyn software.

Analysis of cellular DNA content by flow cytometry

The cells were grown at 50–60% confluence in T75 flasks, serum-starved for 24 h and then treated with a range of CAPE (10, 5, and 2.5 mg/L) for 24 h. At the end of the treatment, the floating cells were collected by centrifugation, whereas adherent cells were harvested by trypsin-EDTA solution to produce a single cell suspension. The cells were then pelleted by centrifugation and washed twice with PBS. Then, the cell pellets were suspended in 0.5 mL PBS and fixed in 5 mL ice-cold 70% ethanol at 4 °C. The fixed cells were spun by centrifugation and the pellets were washed with PBS. After resuspension with 1 mL PBS, the cells were incubated with RNase A (20 mg/L) and PI (50 mg/L) and shaken for 1 h at 37 °C in the dark. The stained cells were analyzed using a FACScan flow cytometer in combination with BD lysis II software (Becton Dickinson).

Assessment of apoptosis by annexin-V and PI double-staining flow cytometry

The cells were treated and harvested as above. Annexin-V and PI double staining kit (Roche) was used to assess apoptosis, then cells were immediately analyzed by flow cytometry. Early apoptotic cells were localized in the lower right quadrant of a dot-plot graph using annexin-V-fluorescein *vs* PI.

TUNEL assay for determination of apoptotic cells

Cells grown on glass coverslips were treated for 24 h with CAPE (10, 5, and 2.5 mg/L) or an equivalent dilution of DMSO, under standard culture conditions as described above. Cells were fixed immediately in 4% formaldehydum polymerisatum at 20 °C for 60 min and washed twice in PBS. Apoptosis of HCT-116 cells was evaluated by using an *in situ* cell death detection kit (Roche Co. Ltd, Germany). Monolayers were treated with proteinase K and then 0.3%

H₂O₂, labeled with fluorescein dUTP in a humidified box for 1 h at 37 °C. The cells were then combined with POD-horseradish peroxidase, colorized with diaminobenzidine tetrahydrochloride (DAB). Controls consisted of omission of fluorescein dUTP. Cells were visualized under a light microscope.

Western blot analysis

Cells were seeded into flasks and grown to 50-60% confluence for 24 h. The cells were then placed in serum-free medium with or without CAPE (10, 5, and 2.5 mg/L) for a period of 24 and 48 h. In the end, the attached cells and floating cells were extracted in lysis buffer using standard methods. Western blot was carried out using standard techniques. Briefly, equal amounts of proteins in each sample were resolved in 10% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and the proteins transferred onto PVDF membranes. After blocking with non-fat dried milk, the membranes were incubated with the appropriate dilution of primary antibody (mouse monoclonal anti-human β -catenin antibody). The membranes were then incubated with a horseradish peroxidase-conjugated secondary antibody. The proteins were detected by an enhanced chemiluminescence detection system, and light emission was captured on Kodak X-ray films.

Indirect immunofluorescence

Cells grown on glass coverslips were treated for 24 and 48 h with CAPE (10, 5, and 2.5 mg/L) or an equivalent dilution of DMSO, under standard culture conditions as described above. Cells were fixed in 100% methanol at -20 °C for 10 min and washed twice in PBS. Monolayers were incubated with primary antibody (mouse monoclonal anti-human β -catenin antibody) in PBS plus 10 g/L dried skimmed milk powder overnight at 4 °C. Omission of the respective primary antibody was used as a negative control. Monolayers were incubated with FITC-conjugated secondary antibody in 1% dried skimmed milk in PBS for 30 min at 37 °C. Confocal microscopy was performed using a Leica TCS SP laser scanning confocal microscope.

Statistical analysis

Data were expressed as mean \pm SD. Analysis of data was performed using one-way ANOVA. $P < 0.05$ was considered statistically significant.

RESULTS

Effect of CAPE on cell proliferation

HCT116 cells were treated with CAPE at various concentrations for 1-4 d, and the cell viability was determined as described above by MTT assay. As shown in Figure 1, CAPE inhibited the growth of HCT116 cells in a dose- and time-dependent manner. The IC₅₀ value for CAPE at 24, 48, 72, 96 h after treatment was 22.45, 12.07, 6.47, 5.36 mg/L, respectively.

Effect of CAPE on apoptosis

After HCT116 cells were exposed to CAPE (10, 5, and 2.5 mg/L) for 24 h, annexin-V and PI double-staining FCM analysis showed that the apoptosis rates were $25.5 \pm 3.3\%$,

Figure 1 Effect of CAPE on HCT116 cell proliferation.

16.6±0.6%, 10.2±0.7%, respectively, which were significantly higher than control (5.5±0.9%) ($P<0.01$). CAPE induced apoptosis in a concentration-dependent manner in HCT116 cells (Figures 2 and 3). TUNEL assay showed that the apoptosis cells were significantly increased in a concentration-dependent manner in HCT116 cells (Figure 4).

Figure 2 Effect of CAPE on HCT116 cell apoptosis rates.

Figure 3 Annexin-V and PI double-staining FCM of HCT116 cells following 24 h incubation with (A) control, (B) 2.5 mg/L CAPE, (C) 5.0 mg/L CAPE, (D) 10 mg/L CAPE.

Effect of CAPE on cell cycle parameters

After HCT116 cells were exposed to CAPE (10, 5, and 2.5 mg/L) for 24 h, FCM analysis showed that the

Figure 4 TUNEL assay of HCT116 cells following 24 h incubation with (A) 2.5 mg/L CAPE, (B) 10 mg/L CAPE.

proportion of cells in G_0/G_1 phase increased, the proportion of cells in S phase decreased in a concentration-dependent manner (Table 1, Figure 5).

β -Catenin expression during CAPE treatment

After HCT116 cells were exposed to CAPE (10, 5, and 2.5 mg/L) for 24 and 48 h, Western blot analysis showed that CAPE treatment was associated with a concentration-dependent decrease in β -catenin protein expression in HCT116 cells (Figure 6).

Indirect immunofluorescence studies of β -catenin localization in HCT116 cells revealed that CAPE treatment was associated with decreased cytoplasmic β -catenin, nuclear β -catenin and a concurrent increase in β -catenin protein expression at cell-cell junctions (Figure 7) compared with cells treated with DMSO alone.

Table 1 Effect of CAPE on HCT116 cell cycle parameters

CAPE (mg/L)	G_0/G_1	G_2/M	S
0	0.40±0.04	0.15±0.04	0.45±0.08
2.5	0.52±0.06	0.16±0.05	0.32±0.02
5	0.56±0.01 ^b	0.15±0.01	0.29±0.01 ^a
10	0.60±0.01 ^b	0.15±0.05	0.25±0.04 ^a

^a $P<0.05$, ^b $P<0.01$ vs control.

DISCUSSION

Polyphenolic compounds derived from natural products are well known to have various beneficial effects namely anti-tumor^[9,10], anti-inflammatory and antioxidant properties^[11,12]. CAPE is also a phenolic compound and an active component of honeybee propolis^[13,14]. Several investigators have demonstrated that CAPE has anti-proliferative effect, apoptosis-inducing effect against various tumor cell lines^[3-7,15] and an

Figure 5 Flow cytometry of HCT116 cells following 24 h incubation with (A)

control, (B) 2.5 mg/L CAPE, (C) 5.0 mg/L CAPE, (D) 10 mg/L CAPE.

Figure 6 Western blot analysis of β -catenin protein expression in HCT116 cells following 24 h (Lanes 1-4) and 48 h (Lanes 5-8) incubation with different concentrations of CAPE. Lanes 1-4: control, 2.5 mg/L CAPE, 5.0 mg/L CAPE, 10 mg/L CAPE; Lanes 5-8: control, 2.5 mg/L CAPE, 5.0 mg/L CAPE, 10 mg/L CAPE.

Figure 7 Indirect immunofluorescence analysis of β -catenin protein expression in HCT116 cells following 48 h incubation with (A) control, (B) 10 mg/L CAPE.

antioxidant effect by lipoxygenase inhibition^[16]. Also, dietary intake of CAPE decreased tumor formation and expression of the oncoprotein catenin in the enterocytes of the Min/+ mouse^[17]. In the present study, we investigated the effect of CAPE on the proliferation, cell cycle and apoptosis of CRC HCT116 cells. Our data demonstrated that CAPE treatment was associated with a strong inhibition of proliferation in a dose- and time-dependent manner, along with induction

of G₀/G₁ arrest and apoptosis in HCT116 cells. Similar to our findings, CAPE entered HL-60 cells very quickly and then inhibited their survival in a concentration- and time-dependent manner. CAPE induced characteristic DNA fragmentation and morphological changes typical of apoptosis in these cells^[4].

To investigate the mechanism of the anti-proliferative effects of CAPE on HCT116 cells, we studied the effect of CAPE on the expression of β -catenin, a multifunctional protein, responsible for the transduction of WNT mediated signals as well as for cell-cell adhesion^[18,19]. The signaling function of β -catenin is particularly important in colon cancer in which activation of β -catenin, as a result of mutations in APC or stabilizing mutations in the N-terminal region of β -catenin, is common^[20]. Activating mutations of β -catenin are also common in many other cancers^[21]. β -catenin signaling promotes the G₁ to S-phase transition, inhibits anoikis and allows cells to progress into S-phase after radiation damage^[22]. WNT-1 signaling also inhibits apoptosis by activation of β -catenin/TCF-mediated transcription^[23] and β -catenin signaling plays an important role in the growth of colon cancer cells^[24].

In our study, Western blot analysis showed that CAPE treatment was associated with a concentration-dependent decrease in β -catenin protein expression in HCT116 cells. The immunofluorescence data suggest that downregulation of β -catenin protein measured by Western blot analysis following CAPE treatment was associated with decreased cytoplasmic β -catenin, nuclear β -catenin and a concurrent increase in β -catenin protein expression at cell-cell junctions. Multiple molecular mechanisms seem to be involved in the tumor suppressive effects of CAPE. Recently, it is reported that CAPE induced apoptosis via Fas signal activation in human breast cancer MCF-7 cells^[25]. Moreover, tumor suppressor protein p53 and p38 MAPK play a prominent role in the

CAPE-induced apoptotic cell death which might contribute to the antitumor effects of CAPE in C6 glioma cells^[26].

In summary, we have identified that CAPE could inhibit HCT116 cell proliferation and induce cell cycle arrest and apoptosis. Decreased β -catenin protein expression may mediate the anti-proliferative effects of CAPE. The present findings may help to explain some features of CAPE-mediated chemoprevention. Future experiments will tell which β -catenin-related downstream genes may be affected by CAPE and whether CAPE may play a role in chemoprevention strategies.

Abstract

AIM: Ribavirin (RBV) shows a strong antiviral effect on hepatitis C virus when used in combination with interferon. However, RBV-induced anemia is a major problem in this therapy. It would be of great clinical importance to ameliorate the anemia without reducing the RBV dose. We report here that, Ninjinyoeito (NYT), a herbal medicine can reduce the RBV-induced anemia.

METHODS: Twenty-three patients with chronic hepatitis C were treated with interferon alpha 2b plus RBV with (NYT group) or without (control group) NYT by a randomized selection. Eighteen patients completed the treatment schedule, and hemato-biochemical and virological effects were evaluated.

RESULTS: There was no significant difference in biochemical and virological responses between the two groups. However, anemia was significantly reduced in the NYT group compared with the control group. The maximal decrease of Hb in the NYT group (2.59 ± 1.10 g/dL) was significantly ($P = 0.026$) smaller than that in the control group (3.71 ± 0.97 g/dL). There was no significant difference in serum glutathione peroxidase activity, serum RBV concentration, and Th1/Th2 balance between the two groups. There was no specific adverse effect in NYT administration.

CONCLUSION: These results suggest that NYT could be used as a supportive remedy to reduce the RBV-induced anemia in the treatment of chronic hepatitis C.

INTRODUCTION

Chronic hepatitis C often gradually progresses to cirrhosis, and hepatocellular carcinoma develops especially in advanced hepatic fibrosis^[1]. Recently, ribavirin (RBV) has been used in combination with pegylated interferon (IFN) as the most effective antiviral therapy^[2]. However, RBV-induced anemia is the major dose-limiting factor in the combined therapy of RBV and IFN products^[3]. The pathogenesis of RBV-induced anemia is reported to be the destruction of erythrocytes due to the retention of RBV inside the erythrocytes because there is no RBV dephosphorylase in erythrocytes^[4], possibly leading to the oxidative damage to the erythrocytic membrane. When anemia is progressive, the dose of RBV is usually reduced, and even the IFN-RBV therapy itself might be stopped in case of severe anemia. If we could prevent or at least reduce RBV-induced anemia to some extent, patients would receive a sufficient amount of RBV and could show a favorable virological response. There have been only a few reports on the attempt to ameliorate the RBV-induced anemia^[5,6].

Ninjinyoeito (NYT), a herbal medicinal formula, shows antiviral action on hepatitis C virus (HCV)^[7], as well as antioxidant^[8], immunomodulatory^[9], and hematopoietic^[10-12] effects. We speculated that the antioxidant effect of NYT could protect the erythrocytic membrane from the RBV-induced hemolysis and that NYT would promote erythropoiesis in response to the RBV-induced anemia.

In this report, we aimed to elucidate a beneficial effect of NYT on the RBV-induced anemia by conducting a randomized controlled trial.

MATERIALS AND METHODS

Patients

Patients with chronic hepatitis C were selected for the treatment protocol with the following criteria: serum levels of HCV-RNA more than 100 kIU/mL by RT-PCR (or more than 1 Meq/mL by a branched DNA probe assay) in naive patients, or ineffective or recurrent after the interferon monotherapy. Patients were excluded due to the following criteria: pregnant women, allergic to interferon, administration of a herbal medicine "Shosaikoto", severe heart failure, chronic renal failure, and past history of depression. Twenty-

three patients with chronic hepatitis C were enrolled into this study. Seventeen were male and six were female. The mean age of the patients was 51.1 (range 26-74). The diagnosis was confirmed histologically with liver biopsy in 13 patients. The other patients were diagnosed by hematological, biochemical, and virological findings.

Treatment protocol

Interferon-alpha 2b (Intron A®, Schering-Plough, Kenilworth, NJ, USA) and RBV (Rebetol®, Schering-Plough) were used as antiviral agents as previously described^[6,7]. In principle, interferon-alpha 2b (IFN) was administered intramuscularly 6 d a week for 2 wk at a dose of 10 MU, then thrice a week for 22 wk at the same dose. RBV was administered orally for 24 wk at a dose of 800 mg per day when the patient had a body weight over 60 kg, and at a dose of 600 mg when under 60 kg. Ninjinyoeito extract granules (NYT, Chinese name: Renshen-yangrong-tang, TJ-108, Tsumura & Co., Tokyo, Japan), including 6.0 g of NYT extract, was administered orally for 24 wk at a dose of 9 g per day. The patients were assigned into two groups in a random selection (Figure 1). The NYT group was treated with the three agents (IFN, RBV, and NYT), and the control group was treated with the two agents (IFN and RBV). No specific drugs were administered after the 24-wk treatment. A written informed consent was obtained from all the patients enrolled. Criteria for dose-down or stopping of the IFN and RBV were as follows: criteria by hemoglobin (Hb): dose-down of RBV from 800 to 600 mg or from 600 to 400 mg/d without the change of IFN dose when Hb less than 10 g/dL; administration of both IFN and RBV were stopped when Hb less than 8.5 g/dL; criteria by WBC and platelet counts: dose down of IFN without the change of RBV dose when WBC counts were less than 1 500/ μ L or platelet counts were 50 000/ μ L; administration of both IFN and RBV were stopped when WBC counts were less than 1 000/ μ L or platelet counts were 25 000/ μ L. Other criteria for dose-down or discontinuation of treatment included subjective symptoms such as anorexia, general malaise, or depressive tendency.

Figure 1 Study design.

Blood sampling and laboratory tests

Approximately 20 mL of blood was taken from the patients before treatment and again at 2, 4, 8, 12, and 24 wk after the start of treatment, and 24 wk after the end of treatment.

Hematological, biochemical, and virological tests were performed.

HCV-RNA assay and HCV serotypes

Serum HCV-RNA was detected with an Amplicor HCV test (Roche Diagnostics, Tokyo, Japan), and was quantified using an Amplicor HCV Monitor test, version 2.0, Roche Diagnostics). Serotypes of HCV were determined using an enzyme immunoassay (Genotyping EIA, International Reagents, Kobe, Japan). Sustained virological response (SVR) was considered to be obtained when the serum HCV-RNA was negative and serum ALT was within normal limits at 24 wk from the end of the IFN/RBV treatment.

Determination of ribavirin concentration

RBV concentration was determined in 18 patients, using high performance liquid chromatography (HPLC, SRL, Tokyo, Japan). Two-hundred microliters of serum was applied to HPLC after deproteination. The range of this assay system was from 50 to 20 000 ng/mL.

Determination of serum erythropoietin concentration

Serum levels of erythropoietin concentration were determined in eight male patients at wk 0 and 4 (four patients from each group), using radioimmunoassay (SRL, Inc., Tokyo, Japan). The eight patients were selected because their sera were available and it was considered to be adequate to compare the male patients only instead of mixing a few female patients.

Measurement of Th1/Th2 balance

The Th1/Th2 balance as a marker for cellular immunological response was assayed using the flow cytometry-based "Fastimmune Cytokine System" (Beckton Dickinson Biosciences, San Jose, CA, USA). Briefly, the blood was collected in sodium heparin, and was activated with ionomycin (IM), Brefeldin-A (BFA), and phorbol 12-myristate 13 acetate (PMA). After lysing and permeabilization, intracellular staining with fluorescent-conjugated monoclonal antibodies against cytokines was done. The two-color interferon- γ /interleukin-4 staining (Fastimmune system, Beckton Dickinson Biosciences) was utilized. Laser flow cytometer (FACS Caliber, Beckton Dickinson Biosciences) was used for analysis.

Glutathione peroxidase assay

Glutathione peroxidase activity as an antioxidant activity was determined using the Glutathione Peroxidase Assay kit (Cayman Chemical Company, Ann Arbor, MI, USA).

Statistical analysis

The software package Statmate III (Atms, Tokyo, Japan) was used for statistical analysis. The two-tailed Mann-Whitney *U* test was used to assess the significance of difference between the various laboratory test items such as Hb. The Fisher's exact test was used for the comparison of antiviral effects between the two groups. Multiple regression analysis was performed for the analysis on the factors influencing the anemia. All data were expressed as the mean \pm SD. A *P* value less than 0.05 was considered to be statistically significant.

RESULTS

Enrollment and follow-up of the registered patients

Patients were treated with IFN plus RBV either with ($n = 13$) or without ($n = 10$) NYT. Eighteen patients (nine patients in each group) completed the 24-wk treatment. There were five patients who dropped out due to anorexia and general malaise in three cases (all in the control group) and due to social problems in two cases (one case in each group). There was no significant difference between the NYT and control groups in age, gender, body weight, serum ALT levels, Hb levels, HCV-RNA levels before treatment, and HCV serotypes (Table 1). During the course of treatment, the dose of RBV was stopped in 1 patient, but not reduced in any of the remaining 9 patients in the NYT group, whereas it was reduced due to anemia in 2 of 13 patients, resulting in stopping of RBV in 4 patients in the control group ($P = 0.45$).

Table 1 Patients' characteristics before therapy

	NYT	Control	<i>P</i>
Age (yr)	46.3±14.3	54.9±10.3	0.113
Gender (M/F)	9/1	8/5	0.123
Body weight (kg)	65.2±9.8	60.6±9.1	0.291
ALT (U/L)	74.9±38.2	58.1±25.1	0.457
Hb (g/dL)	14.3±1.4	14.0±1.6	0.709
HCV RNA (kIU/mL)	553.5±315.0	637.6±314.0	0.673
HCV serotype (1/2)	8/2	9/4	0.377

Biochemical and virological responses

There was no significant difference in RBV concentrations at wk 4 between the two groups. In the intention-to-treat analysis as in Table 2, serum ALT levels were within normal limits in 7 of 10 (70.0%) patients in the NYT group whereas they were normal in 6 of 13 (46.2%) patients in the control group at the end of the IFN/RBV treatment ($P = 0.253$). At the same time point, HCV-RNA turned negative in 8 of 10 (80.0%) patients in the NYT group whereas it was negative in 7 of 13 (53.8%) patients in the control group ($P = 0.192$). At 6 mo after the NYT/RBV treatment, serum ALT levels were within normal limits in 8 of 10 (80.0%) patients in the NYT group while they were within normal limits in 4 of 13 (30.8%) patients in the control group ($P = 0.489$). Sustained virological response (SVR) was obtained in 4 of 10 (40.0%) patients in the NYT group whereas it was seen in 4 of 13 (30.8%) in the control group ($P = 0.645$). In patients with serotype 1, SVR was obtained in 3 of 8 (37.5%) patients in the NYT group and 1 of 9 (11.1%) patients in the control group ($P = 0.311$), whereas in patients with serotype 2, SVR was recognized in 2 of 2 (100%) in the NYT group and 3 of 4 (75%) in the control group ($P = 0.316$).

Table 2 Virological and biochemical results

	NYT (%)	Control (%)	<i>P</i>
Enrolled cases	10	13	
Normal ALT at the end of therapy	7 (70.0)	6 (46.2)	0.253
Negative HCV RNA at the end of therapy	8 (80.0)	7 (53.8)	0.192
Normal ALT 6 mo after therapy	8 (80.0)	4 (30.8)	0.489
Negative HCV RNA 6 mo after therapy	4 (40.0)	4 (30.8)	0.645

Hematological changes

We analyzed the hematological changes in the 18 patients who received the IFN/RBV treatment for more than 4 wk. As shown in Table 3 and Figure 2, the maximal decrease of Hb in the NYT group (2.59 ± 1.10 g/dL) was significantly ($P = 0.026$) smaller than that in the control group (3.71 ± 0.97 g/dL). The minimal Hb during the treatment in the NYT group (11.66 ± 1.78 g/dL) tended to be higher than that in the control group (10.10 ± 1.08 g/dL, $P = 0.079$). Maximal decrease of erythrocytes in the NYT group ($868\,000 \pm 474\,000/\mu\text{L}$) tended to be smaller than that ($1\,244\,000 \pm 419\,000/\mu\text{L}$) in the control group ($P = 0.178$). As shown in Table 1, there were some differences, although not significant, in age, gender, and body weight, which might influence the grade of anemia. We performed a multivariate analysis using the multiple regression method. Backward stepwise regression was performed, and a P value greater than 0.20 was used for a variable removal, and the NYT administration and serum creatinine were picked up. The final linear regression model selected only the NYT administration as a significant variable ($P = 0.0042$) influencing maximal hemoglobin decrease (Table 4). There were no significant differences in the WBC or platelet (Plts) counts between the two groups.

Table 3 Hematological and immunological results

	NYT	Control	<i>P</i>
max Δ RBC ($\times 10^9$)	868±474	1,244±419	0.178
max Δ Hb (g/dL)	2.59±1.10	3.71±0.97	0.026
min Hb (g/dL)	11.66±1.78	10.10±1.08	0.079
WBC (wk 24)	3,444±1731	3,204±1143	0.894
Plts (wk 24, $\times 10^9$)	14.69±5.52	12.77±4.22	0.709
Th1 (wk 4, %)	27.29±11.6	30.20±8.66	0.480
Th2 (wk 4, %)	2.77±1.06	2.30±1.09	0.232
Th1/Th2 (wk 4)	10.89±5.68	15.48±6.87	0.130
GPx [wk 4, nmol/(min · mL)]	76.41±31.79	78.96±31.96	0.522

GPx: glutathione peroxidase.

Table 4 Multiple regression analysis

Variable	Parameter estimate	Standard error	<i>P</i>
Intercept	-1.61742	1.12391	0.1707
NYT administration	1.47645	0.43746	0.0042
Serum creatinine (wk 0)	-3.05400	1.57891	0.0722

Maximal hemoglobin decrease = $1.477 \times [\text{NYT administration}] - 3.054 \times [\text{serum creatinine at wk 0}] - 1.617$ (NYT administration: the NYT group, 1; the control group, 2) Adjusted R square: 0.3923.

Changes in serum erythropoietin concentrations

Serum levels of erythropoietin were determined in eight male patients at wk 0 and 4 (four patients from each group), and there was no significant difference in the increase of erythropoietin from wk 0 to wk 4 between the two groups (38.4 ± 21.6 ng/mL in the NYT group *vs* 45.2 ± 30.3 ng/mL in the control group, $P = 0.885$).

Changes in the Th1/Th2 balance

There were no significant changes in Th1, Th2, or the Th1/Th2 ratio in either group during the observation period in

Table 5 Comparison of NYT and other drugs which were reported to be effective for RBV-induced anemia

	Action	Mechanisms	Indication for anemia in health insurance system of Japan	Form	Adverse reactions	Daily cost (yen)
NYT	Promotion of erythropoiesis, protection of erythrocytic membrane, improvement of erythrocytic deformability	Activation of immature erythroid cells, antioxidant effect	Anemia in general,	Granule	Abdominal discomfort (frequency unknown)	227.7
EPA	Increase in erythrocyte deformability	Increase in EPA content in erythrocytic membrane phospholipids	None	Capsule	Jaundice, gynecomastia (frequency unknown), hemorrhagic tendency, liver injury (<0.1%)	353.4
EPO	Increase in erythropoiesis	Stimulation of stem cell differentiation to erythroid cells	Renal anemia	Vial for injection	Thromboembolism, cerebral hemorrhage, shock (frequency unknown), high blood pressure, liver injury (0.1-5%)	1 643 (750 IU)

each group, and there were no significant differences in these cellular immunological markers between the two groups at any time point. Table 3 shows the results at wk 4.

Changes in glutathione peroxidase activity

There were no significant changes in glutathione peroxidase activity during the observation period, and there was no significant difference in this activity between the two groups at any time point. Table 3 shows the results at wk 4.

DISCUSSION

In this study, we elucidated, for the first time, the anemia-ameliorating effect of NYT in the IFN/RBV treatment for chronic hepatitis C in a randomized controlled trial. Although NYT possesses a hematopoietic action^[10-12], we speculate that anemia-reducing effect of NYT was derived from its anti-oxidant^[8] and stabilizing actions on the erythrocytic membrane, ameliorating the hemolytic anemia. NYT is reported to show an anti-HCV action^[7], but NYT did not affect the anti-viral effect of IFN/RBV therapy in this study. If we can reduce the grade of anemia and discontinuation of therapy, it would lead to the increase in number of patients with SVR.

As mentioned above, NYT is reported to have the following effects: hematopoietic^[10-12], antioxidant^[8], hepatocyte-protective^[13], Th1/Th2 balancing^[9], and direct anti-HCV^[7]. NYT has been used in the treatment of asthenic or fatigued patients, especially after operation or severe infectious diseases^[14]. NYT is effective for various signs

and symptoms, including anemia, general malaise, anorexia, night sweating, sensation of cold in the extremities, cough, and insomnia^[14]. These effects have been analyzed and verified in the theory of Traditional Chinese Medicine. From the viewpoint of hepatitis treatment, these effects of NYT are suitable for ameliorating the adverse effects of IFN (general malaise, anorexia, and psychiatric problems) and that of RBV (anemia). The dose of NYT was 9.0 g/d in this study, which is a normal dose in Japan.

The precise mechanisms of RBV-induced anemia are unknown, but several reports^[3,4] suggest that the accumulation of phosphorylated RBV in erythrocytes due to the lack of dephosphorylase in erythrocytes impairs the deformability of erythrocytes. The accumulated RBV may affect the antioxidant defense mechanisms of the erythrocytic membrane. These changes in erythrocytes would lead to the extravascular destruction of erythrocytes (hemolysis). Since NYT has an antioxidant action, it may show a beneficial effect on the erythrocytic membrane. Although NYT would not affect the accumulated RBV inside the erythrocyte, NYT might improve erythrocytic deformability in a different manner, like other herbal medicines with common components. Therefore, the reasons why NYT ameliorates RBV-induced anemia might include the protection of erythrocytic membrane, the improvement of erythrocytic deformability, and erythropoiesis (Figure 3).

Previous reports showed that erythropoietin^[5] and eicosapentaenoic acid^[6] can be effective against RBV-induced anemia. In the prospective, double-blind, randomized controlled study by Afdhal *et al.*, in 185 patients^[5], erythropoietin (EPO) was administered after anemia

**Figure 2** Effect of Ninjinyoeito on the RBV-induced anemia.**Figure 3** Speculated mechanisms of Ninjinyoeito's beneficial effect on RBV-induced anemia.

developed, and the mean Hb increase was 2.2 ± 1.3 g/dL, which was significantly greater than 0.1 ± 1.0 g/dL in the placebo group. However, the use of EPO would be expensive and would not address the solution of hemolysis. In the uncontrolled, pilot study by Ide *et al.*, in six patients^[6], eicosapentaenoic acid (EPA) was also administered after the development of anemia, and the mean Hb significantly increased from 10.8 to 11.4 g/dL in 1 mo. The effect of EPA seems to be marginal, and it was tested in a pilot study and would need a randomized trial. EPA improves erythrocyte deformability and increases EPA content in erythrocytic membrane phospholipids^[6]. Table 5 summarizes the comparison among NYT, EPO, and EPA from the viewpoints of effectiveness, adverse reactions, and cost-benefits. EPO is expensive, with more adverse effects, but most effective. NYT is economical, with little adverse reaction. EPA seems to be intermediate between the above two drugs.

In our study, NYT was administered from the beginning of IFN/RBV treatment, and we cannot simply compare the results between the above-mentioned studies and ours. We would like to test whether NYT improves the RBV-induced anemia after it occurs, or whether pretreatment with NYT prevents the anemia.

Erythropoietin response is reported to be subnormal in the IFN/RBV treatment. Although NYT has a bone marrow-stimulatory action via enhancing colony stimulating factors^[11], there was no significant difference in the endogenous erythropoietin response between the NYT and control groups in our study. Therefore, NYT might ameliorate RBV-induced anemia, not by stimulating hematopoiesis, but by reducing hemolysis. We measured serum glutathione peroxidase activity before and after the IFN/RBV therapy with or without NYT. There was no significant change both in time course and between the NYT and control groups. But, according to the previous reports^[8,13] it is likely that NYT may exert its protective effect on the erythrocytic membrane by antioxidative action and membrane stabilization. Serum antioxidant markers other than glutathione peroxidase might reveal the effect of NYT.

Regarding the combination therapy of IFN and herbal medicines, Shosaikoto (SST, Shao-chaihu-tang) is prohibited for use in combination with IFN because this combination is reported to increase the risk of interstitial pneumonia. The herbal component *Scutellariae radix* alone does not cause interstitial pneumonia, but when used in combination with other herbal components, some unknown factors causing interstitial pneumonia are considered to be expressed. NYT does not contain five of the seven medicinal herbs used in SST, including *Scutellariae radix*. Interstitial pneumonia or any other adverse reactions in relation to NYT use were not found in this study. Since NYT was used safely in the IFN/RBV therapy, NYT could be used in combination with PEG-IFN+RBV for 48 wk, which is considered as the most effective anti-HCV therapy^[2]. This current worldwide standard was not available during the period of this study in Japan.

In conclusion, NYT ameliorated the RBV-induced anemia in RCT. NYT did not show any stronger antiviral effect on HCV, but it was used safely without any adverse reaction in the combination treatment with IFN/RBV. These results

provide good evidence for the effect of the herbal medicine NYT. It is suggested that NYT can be used as a supportive drug for IFN/RBV therapy for chronic hepatitis C. Active mechanisms are to be elucidated and these results would be verified in additional studies with more patients.

Abstract

AIM: To construct a random peptide phage display library and search for peptides that specifically bind to the PreS region of hepatitis B virus (HBV).

METHODS: A phage display vector, pFuse8, based on the gene 8 product (pVIII) of M13 phage was made and used to construct a random peptide library. *E.coli* derived thioredoxin-PreS was purified with Thio-bond beads, and exploited as the bait protein for library screening. Five rounds of bio-panning were performed. The PreS-binding specificities of enriched phages were characterized with phage ELISA assay.

RESULTS: A phage display vector was successfully constructed as demonstrated to present a pVIII fused HBV PreS1 epitope on the phage surface with a high efficiency. A cysteine confined random peptide library was constructed containing independent clones exceeding 5×10^8 clone forming unit (CFU). A pool of phages showing a PreS-binding specificity was obtained after the screening against thio-PreS with an enrichment of approximately 400 times. Five phages with high PreS-binding specificities were selected and characterized. Sequences of the peptides displayed on these phages were determined.

CONCLUSION: A phage library has been constructed, with random peptides displaying as pVIII-fusion proteins. Specific PreS-binding peptides have been obtained, which may be useful for developing antivirals against HBV infection.

INTRODUCTION

The attachment to hepatocytes by hepatitis B virus (HBV) during infection has long been proposed to be a potential target for antiviral intervention. It is thought that molecules specifically binding to HBV particles may interfere with viral attachment and hence reduce or block subsequent infection^[1-3]. Ideally, these molecules should mimic the structural elements of a cell surface HBV receptor. Unfortunately, although a few host proteins have been demonstrated to interact with HBV particles or viral surface antigens, such a cell surface HBV receptor remains elusive^[4-8]. Consequently, our knowledge on the molecular events leading to HBV attachment to hepatocytes is very limited. One longstanding notion is the role of HBV PreS region in mediating HBV attachment to the putative receptor on hepatocytes^[8-11]. Specifically, the aa 21-47 segment within the PreS1 domain is believed to be essential for this process^[11]. It is noteworthy that other important functions of the PreS region have also been reported, for example, in the assembly and budding of HBV virion^[12-14]. Therefore, the PreS region has become a potential target for screening antivirals against HBV infection.

Strategies for ligands discovery are usually based on procedures for assembling a large number of compounds to produce a diverse array of molecules, followed by a screening process against targets of interest. Among various technologies for ligand discovery, phage display has evolved into one of the main approaches for obtaining lead molecules^[15,16]. Filamentous phage M13 has a rather simple architecture composed of five different structure proteins. The product of gene 8 (pVIII) is a major capsid protein. There are approximately 2 700 pVIII molecules all over a phage particle, while other structural proteins are located at the tail of the phage particle with only a few copies of each^[17]. Thus, by fusing with pVIII, hundreds or thousands of ligands can theoretically be displayed on the surface of the phage particle, which should help strengthen its interaction with a target^[15,16]. Thus, pVIII fusion protein based phage display will offer a greater chance to find mildly binding ligands.

In this study, we have constructed a structurally constrained phage display library in which random peptides are displayed

as N-terminal fusions to pVIII and confined in a loop by a pair of flanking cysteine residues^[15,18,19]. Recombinant thio-PreS protein was used as target in screening for the PreS-binding peptides. A pool of phages showing PreS-binding specificity was obtained with an enrichment factor of approximately 400. Phages with high PreS-binding specificities were selected and characterized. Sequences of the peptides displayed on five of PreS-binding phages were determined.

MATERIALS AND METHODS

Materials

The pCANTAB5E vector, T7 DNA sequencing kit, and HRP-conjugated M13 specific monoclonal antibody (anti-M13 mAb) are products of Amersham Pharmacia Biotech (Piscataway, USA). XL1-blue F' *E. coli* strain and helper phage VCSM13 were purchased from Stratagene (La Jolla, USA). PreS1 specific mAb 125E11 has been previously described^[20,21]. Maxisorp F16 module (Nunc, Denmark) was used for protein coating. Thiobond™ affinity resin and the thioredoxin specific mAb (anti-thio) were from Invitrogen (Carlsbad, USA). Recombinant enterokinase (rEK) was purchased from Novagen (Madison, USA).

Construction of random peptide phage display library

pCANTAB5E was utilized as the parental vector for constructing a pVIII fusion protein display vector. The coding sequence for M13 pVIII was amplified with specific primers (pVIII-forward: 5'-TAAGGATCCGGTGGTGCT-GAGGGTGACGATCCCGC-3', pVIII-reverse: 5'-AGGAATTCATGTACCGTAACACTG-3') using the VCSM13 genome as template. PCR product was digested with *Bam*HI and *Eco*RI, and inserted into the same sites in pCANTAB5E, replacing the original gene 3. The resulted vector was named pFuse8 (Figure 1A). To construct pFuse8-E that encodes a PreS1 epitope fused with pVIII (Figure 1A), annealed oligonucleotides (sense: 5'-CAGCAATGGCAGGC AGCCTGAACCCTAGCTGGGATGGTGGCGGAGGATCCG-3', antisense: 5'-AATTCGGATCTCCGCCACC ATCCAGCTAGGGTTCAGGCTGCCTGCCATTGCTGGCT-3', the epitope coding sequence is underlined) were ligated to pFuse8 digested with *Sfi*I and *Bam*HI.

For the construction of peptide library, antisense oligonucleotides containing random nucleotides (5'-ATTGCGGATCCACACC(MNN)₃GCA(MNN)₇ACA(MNN)₃GCCTGCTGCCATTGCTGC-3', N = A, T, C or G; M = A or C) was synthesized (Invitrogen). A complementary primer (5'-CAGCAA TGGCAGCAGGC-3') was annealed to the 3' end of the long oligonucleotides, followed by the fill-in reaction with the Klenow polymerase to generate the double-stranded DNA. The DNA duplex was then digested with *Bam*HI and ligated into pFuse8 cut with *Sfi*I and *Bam*HI. The ligation mixture was used to transform XL1-blue F' competent cells by electroporation. The phage library was established by co-infection of helper phage VCSM13 (MOI, 10:1) to the transformed cells as previously described^[22]. Complexity of the library was estimated according to the number of independent transformed clones.

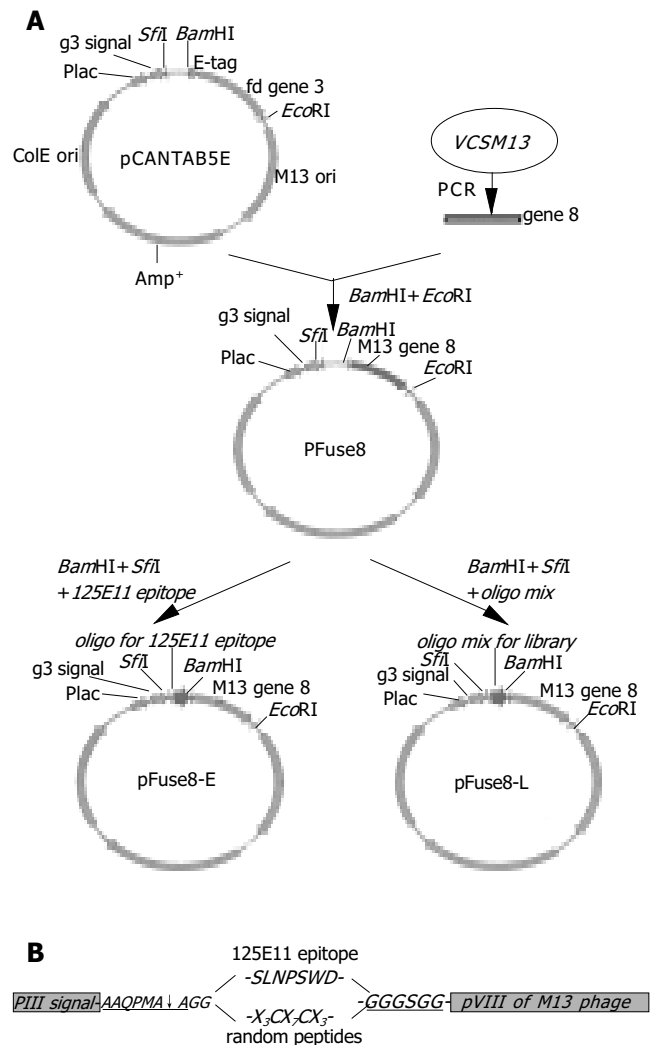

Figure 1 Diagram of library construction. **A:** a schematic representation of the steps in the construction of the phagemid encoding the pVIII fusion protein. pCANTAB5E, a pIII displaying vector; pFuse8, the vector harboring gene 8 coding sequence in place of gene 3; pFuse8-E, the coding sequence for a specific epitope recognized by the 125E11 mAb is inserted into pFuse8; pFuse8-L, the coding sequences for random peptides are inserted into pFuse8; **B:** Inserted sequences in pFuse8-E and pFuse8-L after translation. SLNPSWD is the specific epitope recognized by the 125E11 mAb. In pFuse8-L, the epitope is replaced with X3CX7CX3.

DNA sequencing

Phagemid pool of randomly picked-up clones from the library was prepared with SV minipreps kit (Promega). DNA sequencing was performed with T7 DNA sequencing kit according to the manufacturer's instruction.

Preparation of PreS fusion protein

Prokaryotic expression plasmid pThioHisA-PreS was constructed for the synthesis of thioredoxin fused PreS (thio-PreS) in *E. coli*^[23]. An affinity purification for the expression product was performed with Thiobond™ beads according to the manufacturer's instruction.

Library screening

Totally 10¹¹ phages were mixed with 30 μL of the thio-PreS bound Thiobond™ beads and incubated on a rotating wheel for 10 min. After washing with PBS containing 0.05% Tween

20 for four times, the beads were treated with 1 unit of rEK at 30 °C for 6 h. Phages binding specifically to the PreS region were supposed to detach off the beads. Eluted phages in the collected supernatant were subject to propagation in XL1-blue F' cells, followed by VSCM13 co-infection to produce a phage pool for next round of panning^[22]. A total of five rounds of selection were performed.

Western blot

Western blot of thio-PreS was performed according to a standard method^[24]. Thio-PreS coupled on resins with or without rEK treatment were boiled and separated on SDS-PAGE, and transferred to nitrocellulose filters. Anti-thio mAb (1:1 000) was used as the primary antibody for the detection. Blots were developed using the ECL method with HRP-labeled rabbit anti-mouse Ig (1:2 000, DaKo, USA).

Phage ELISA

Phage ELISA was carried out as described previously^[22]. Purified thio-PreS proteins (1 µg/well) were immobilized on the microwells in PBS buffer overnight. Phages propagated from infected XL1-blue F' cells were precipitated by 0.1 volume of PEG8000/NaCl (20% PEG8000, 3 mol/L NaCl), resuspended in PBS buffer and applied to thio-PreS coated wells, followed by an incubation at room temperature for 1 hour. An HRP-labeled anti-M13 mAb (1:1 000) was used for the detection of bound phages.

Virus capture assay

For capturing HBV virions, each microwell was coated with 10¹¹ phages in carbonate buffer (pH 9.5) at 4 °C overnight. After blocking with 1% BSA at 37 °C for 2 h, cultured medium of HepG2.2.15^[25] that contains HBV particles was added and incubated for 1 h at 37 °C, followed by a washing process with PBS buffer containing 0.05% Tween 20. An HRP-conjugated anti-HBs antibody was used to detect the captured HBV particles according to the manufacturer's protocol (Sino-American Biotech, Shanghai).

RESULTS

Construction of pVIII based phage display vector

To construct the vector pFuse8, M13 gene 8 was amplified using the genomic DNA of VSCM13 phage as template. The PCR product was inserted into pCANTAB5E to replace the coding sequence of gene 3 and the E-tag (Figure 1A). The inserted gene 8 is located downstream to a leader signal sequence of gene 3, which is used to direct the pVIII fusion protein to the surface of the phage particle. In the phagemid pFuse8-E as shown in Figure 1B, a spacer between the leader signal and gene 8 encodes an in-frame peptide AAQPMAG-SLNPSWD-GGSGG. The first part of the peptide (AAQPMAG) is a recognition sequence of the *peB* signal peptidase^[26]. The 7-amino acids in the middle of this peptide represents an epitope within the HBV PreS1 domain that is recognized by the 125E11 mAb (unpublished data), providing a molecular marker for detection of phage display. The ensuing glycine tether is used to link the peptide to pVIII, increasing the flexibility of the peptide.

Phages were generated by co-infection of the pFuse8-E transformed XL1-blue F' cells with helper phage VSCM13.

The displayed 125E11 epitope was readily detected by phage ELISA in a dose dependent manner with the immobilized 125E11 mAb but not with an irrelevant mAb (anti-HBs) (Figure 2). As shown in Figure 2, the *lac* promoter employed in the vector was somewhat leaky so that pVIII-fused epitope could be easily detected even without IPTG induction^[27].

Figure 2 Surface display of the epitope recognized by 125E11. The SLNPSWD epitope displayed on the surface of the phage particle was detected by phage ELISA. The circles indicate the phages that bind 125E11 coated wells. Triangles represent phages captured by an irrelevant mAb (anti-HBs). The synthesis of pVIII fusion proteins with or without IPTG induction is denoted as white or black, respectively.

Construction of structure-confined random peptide phage display library

Structure-confined random peptide library has the advantage to present peptides in a fixed loop so that their conformations are relatively rigid^[18,19]. In this study, random peptides fused with pVIII assume a form of X₃CX₂CX₃, where X stands for any amino acids. Two cysteine residues flank the 7 random amino acids in the middle. Under a non-reducing environment in the periplasm of *E. coli*, these cysteine residues may spontaneously form a disulfide bond that constrains the conformation of the displayed peptide^[18,19]. The oligonucleotides mixture coding for the random peptides was inserted into the pFuse8 vector (pFuse8-L, Figure 1A). The resulting library had the size of about 5.0×10⁸ independent clones that represented a great complexity. The random property of the library was verified by DNA sequence analysis. As shown in Figure 3, in the region coding for the random peptides, all four kinds of nucleotides are equally distributed at the first two positions of the triplet codons, while T or G varies at the third position, indicating a sufficient diversity of the library.

Screening for PreS-binding peptides

The PreS region of HBV, when synthesized alone in *E. coli*, is vulnerable to degradation and largely insoluble. To overcome these problems, the PreS region was fused with the C-terminus of thioredoxin (Figure 4A), which has dramatically enhanced both the stability and the solubility of the PreS region (Figure 4B). An enterokinase site located at the junction between the PreS region and the thioredoxin tag (Figure 4A) facilitates the release of the PreS region by digestion with rEK, leaving the thioredoxin tag on the affinity matrix (Figure 4C). Thus, the PreS-binding phages could be

Figure 3 Diversity of the constructed library. In the region coding for the random peptides, four kinds of nucleotides are equally distributed at the first two loci of the triplet codons, while T or G varies at the last. Oligonucleotides for cysteine confined random peptides (5'-GCAGCAGGC-(NNS)3-TGT(NNS)7-TGC(NNS)3-GGTGGTGA-3', N = A, T, C or G; S = A or C) are shown.

Lane 1, the *E. coli* lysate without IPTG induction; lane 2, the soluble lysate after IPTG induction, thio-PreS of 33 ku is indicated with a triangle; lane 3, the purified thio-PreS; **C**: Western blot with the anti-thio mAb. Lane 1, thio-PreS coupled to the Thiobond™ beads; lane 2, thio-PreS coupled beads treated in the absence of rEK; lane 3, thio-PreS coupled beads treated in the presence of rEK.

dissociated from the resin and enriched. It was expected that cleavage by rEK might decrease a nonspecific enrichment of phages binding to the thioredoxin tag. It is noteworthy that the degradation of the free PreS region should not influence the recovery of the PreS-binding phages.

A total of five rounds of screening were performed.

As shown in Table 1, the PreS-binding phages were greatly enriched as evidenced by a steadily rising enrichment factor (EF, phage eluted/phage applied). An approximately 400-fold of enrichment (EF_{5th}/EF_{1st}) was achieved as estimated by the titer of the phages after the screening. The pool of phages from the final round of selection bound to the thio-PreS immobilized wells specifically in a dose-dependent manner, in sharp contrast to the original pool of phages before selection (Figure 5). A much weaker noise was noticed with the thioredoxin immobilized wells serving as a control, indicating that the thioredoxin-binding phages were also selected, though they might only be a small minority.

Characterization of the PreS-binding phages

The specificity of the phages with regard to PreS-binding was further characterized by virus capture assay. When coated on microplate wells, the pool of phages from each round of selection was tested for their abilities to capture HBV virions from the cultured medium of HepG2.2.15. The binding capacity to HBV virions increased greatly after the final round of selection (Figure 6), suggesting that the PreS-binding phages were truly selected. Phages from the final round of selection were picked for a further analysis. The specificities of these phages with regard to PreS-binding were analyzed with phage ELISA assay. Phages with a strong binding capacity to thioredoxin were considered nonspecific and discarded (data not shown). The corresponding phagemids of five of the PreS-binding phages were subjected to DNA sequencing. Amino acid sequences of the potential PreS-binding peptides were deduced (Figure 7).

DISCUSSION

The filamentous phage display system, whereby the expressed peptides are displayed as fusions to phage coat proteins, has been effective in the discovery of ligands^[15,16]. Commonly exploited strategy is the surface display of N-terminus fusions to the minor coat protein pIII (product of phage gene 3). It represents a low-valent surface display, as only three to five copies of pIII are present at the tail of the phage particle, providing a selection platform for an interaction with a high affinity^[15]. In our work, a pVIII fusion protein based vector was successfully constructed, and proved to work well in peptide displaying. Since pVIII is a major coat protein with thousands of molecules on a single phage, thus pVIII fusion protein based phage display will offer a greater chance to find mildly or weakly binding ligands. As PreS-binding peptides are concerned, the pVIII fusion protein based system may be a better choice than the pIII fusion protein based system. It is supposed that the affinity of the HBV virion to its putative receptor on hepatocytes may not be strong, because an ensuing intracellular event of dissociation may occur closely after the penetration of the viral particle during the infection.

Linear oligopeptides likely present various solution conformations that may be quite different from the structure in the native or bound forms of a protein. It has been demonstrated that the structurally active region in native protein may be mimicked by cyclic amino acid sequences of constrained peptides displayed on the phage surface^[15,18,19]. A pair of flanked cysteine residues was adopted to confine the random peptides in the middle by presumably forming

an intra-molecular disulfide bond that provides a more defined scaffold when folded in the periplasmic environment of *E. coli*. In this study, we have constructed a conformation

constrained random peptide phage display library and performed the screening with this library, in the hope that potential peptides with more defined conformations may better fulfill the structural features required for PreS-binding. On the other hand, such a conformation-constrained library has its weaknesses. It is likely that during the interaction process between PreS and a potential peptide, both partners may exert their influences on each other so that the conformation of the potential peptide adjusts to better bind PreS. In such a situation, the peptide with a constrained conformation may be too rigid to accommodate itself upon binding PreS, which will probably result in a reduced binding affinity.

During the life cycle of HBV, the PreS region of the large surface antigen (LHBs) plays a crucial role in virion assembly and budding as well as in viral attachment to hepatocytes^[8-12,28,29]. Given the pivotal role of the PreS region in HBV life cycle, the specific PreS-binding ligands are expected to be useful as inhibitors to block viral entry to hepatocytes, or to interfere with the process of virion assembly in HBV infected cells. Similar ideas have been pursued widely in the field of HIV research and proved to be a potential way for antiviral drug development^[30,31]. Moreover, studies on the PreS-binding peptides will likely provide helpful information about the interaction between HBV virion and hepatocytes that may aid the identification of a yet-to-be-found receptor of HBV.

The binding capacity of the pool of phages to HBV virions increased greatly after the final round of selection. Thus, the thio-PreS fusion protein was proved to be an 10 effective bait protein that might mimic the conformation adopted by the PreS region in the native virions. In addition, the affinity screening for the PreS-binding phages represents a promising approach for discovering HBV binding ligands. Several peptides encoded by the phagemids of five of the PreS-binding phages were determined. No consensus sequence or conserved amino acids were found in these five peptides. Therefore, these peptides likely bind to different fragments of the PreS region. On the other hand, sequences of more PreS-binding peptides need to be determined and the binding properties of the PreS-binding peptides await further investigations, which are currently on the way.

Abstract

AIM: Eph receptor tyrosine kinases and their membrane bound receptor-like ligands, the ephrins, represent a bi-directional cell-cell contact signaling system that directs epithelial movements in development. The meaning of this system in the adult human gut is unknown. We investigated the Eph/ephrin mRNA expression in the intestinal epithelium of healthy controls and patients with inflammatory bowel disease (IBD).

METHODS: mRNA expression profiles of all Eph/ephrin family members in normal small intestine and colon were established by real-time RT-PCR. In addition, differential expression in IBD was investigated by cDNA array technology, and validated by both real-time RT-PCR and immunohistochemistry. Potential effects of enhanced EphB/ephrin-B signaling were analyzed in an *in vitro* IEC-6 cell scratch wound model.

RESULTS: Human adult intestinal mucosa exhibits a complex pattern of Eph receptors and ephrins. Beside the known prominent co-expression of EphA2 and ephrinA1, we found abundantly co-expressed EphB2 and ephrin-B1/2. Interestingly, cDNA array data, validated by real-time PCR and immunohistochemistry, showed upregulation of ephrin-B2 in both perilesional and lesional intestinal epithelial cells of IBD patients, suggesting a role in epithelial homeostasis. Stimulation of ephrin-B signaling in ephrin-

B1/2 expressing rat IEC-6-cells with recombinant EphB1-Fc resulted in a significant dose-dependent acceleration of wound closure. Furthermore, fluorescence microscopy showed that EphB1-Fc induced coordinated migration of wound edge cells is associated with enhanced formation of lamellipodial protrusions into the wound, increased actin stress fiber assembly and production of laminin at the wound edge.

CONCLUSION: EphB/ephrin-B signaling might represent a novel protective mechanism that promotes intestinal epithelial wound healing, with potential impact on epithelial restitution in IBD.

INTRODUCTION

The rapid resealing of the intestinal surface partly relies on the highly adaptive ability of epithelial wound-edge cells to rapidly form pseudopodial protrusions, reorganize the cytoskeleton, and migrate into a wound defect in a coordinated manner^[1-3]. In the intestine, the fast epithelial healing is particularly important considering the necessity to protect the host with a one-cell-layer epithelium against a considerable microbial threat and exposure to a multitude of immunogenic and toxic factors^[1]. Since epithelial integrity is critically linked to the prevention and healing of inflammatory bowel disease (IBD), the investigation of wound closure modifying factors has attracted a lot of attention in this field. Growth factors (EGF, TGF- β , HGF, KGF, IGF), trefoil peptides, cytokines (IL-1 β , IL2), nutrients (SCFA, polyamines), and matrix components (laminin) are among the best studied contributors to epithelial restitution^[1,4].

In contrast to those established soluble co-factors, the Eph receptor tyrosine kinases (RTKs), and their membrane-

bound receptor-like ligands, the ephrins, specifically direct collaborative cell movements by direct cell-cell signaling^[5,6]. Based on their sequence homology, structure, and binding affinity, the Eph-RTKs and ephrins are divided into two subclasses, A and B. With few exceptions, the two classes (A and B) of Eph-RTKs exhibit a differential affinity for the distinct A- and B-subsets of ephrins. In contrast to humoral signaling systems, the ligands in this system are membrane-bound. A-ephrins are tethered to the outer leaflet of the plasma membrane by virtue of a glycosylphosphatidylinositol (GPI) anchor, whereas, B-ephrins are transmembrane proteins^[7,8]. With the discovery that ephrins can by themselves induce a “reverse” cellular signaling response by exhibiting receptor-like functions, it is apparent that the Eph-RTK/ephrin interactions represent a cell-cell signaling system that is capable of mediating a bidirectional response in both the ligand and the receptor-bearing cell^[9]. The generated juxtacrine signals organize the coordinated movement of cells during development, e.g. in axonal guidance, remodelling of blood vessels, and formation of epithelial surfaces^[10–13]. It has also been demonstrated that the differential expression of ephrin ligands and Eph-RTKs along the crypt-villus axis determines the correct positioning and allocation of the proliferating versus differentiating compartment during development of crypts in the small intestine^[14]. Disruption of those genes leads to intermingling between both of these compartments.

While the meaning of Eph-RTKs/ephrins in embryonic morphogenesis has been well established, their physiologic role in adult tissues is unknown. However, recent data indicate a possible role in tissue repair and maintenance^[15]. EphA2/ephrin-A1 signaling, previously termed epithelial cell kinase (Eck) and protein B61, has already been suggested to be involved in the homeostasis of the intestinal barrier in adults^[16]. Since cytokines such as IL-1 β , IL-2 and TGF- β can modulate the steady-state levels of the expression of EphA2/ephrin-A1 *in vitro*, a role in inflammatory bowel disease (IBD) is possible^[16]. Therefore, we investigated the full repertoire of Eph-RTKs and ephrins in the gut epithelium and possible differential expression in IBDs. Furthermore, possible consequences of the observed changes for the intestinal wound closure capacity were evaluated.

MATERIALS AND METHODS

Tissue specimens and RNA isolation

The corresponding protocols for the study have been accepted by the local ethics committee and biopsies were taken after informed consent of the patients. For establishing of an Eph-RTK/ephrin mRNA expression profile of the normal human gut, total mucosa biopsies were obtained from normal colon ($n = 5$, ages ranged from 28 to 75 years). Normal small intestine mRNAs ($n = 5$, ages ranged from 20 to 61 years) were purchased from Clontech (BD Biosciences, Palo Alto, USA). For each tissue, the RNAs were pooled to avoid bias due to potential interindividual differences.

Affymetrix[®] HGU133A and HGU133B GeneChip array data, recently published by our collaborators, indicated possible differential expression of some Eph-RTK/ephrin family members^[17]. In that array analysis, samples had been

collected from resected terminal ileum and colon of control subjects ($n = 4$, ages ranged from 52 to 60 years), Morbus Crohn (MC) patients ($n = 4$, ages ranged from 23 to 43 years), and Colitis ulcerosa (CU) patients ($n = 4$, ages ranged from 20 to 57 years). The material was obtained from non-inflamed regions at least 10 cm distant from visibly inflamed areas to avoid bias due to inflammatory cells. From the same cohort of patients, individual (not pooled) RNAs were available for real-time RT-PCR based validation of selected genes in this study.

For low density array analysis, biopsies were used provided by the core facility “primary cells and tissues” of the Regensburg-SFB585 (German interdisciplinary research initiative on “immune functions in the gut”; <http://www.uniregensburg.de/Einrichtungen/Klinikum/SFB>). To control the sampling process, sets of six biopsies were taken from each patient or control subjects from identical sites. One of those biopsies was archived and paraffin-embedded for histopathological analysis by an expert pathologist (F.B.). The remaining biopsies were used for research purposes in this set of experiments. Bias due to stromal and inflammatory cells was avoided by preparation of intestinal epithelial cells (IECs). In brief, five needle-head sized biopsies were sampled in 10 mL HBSS/2 mmol/L EDTA buffer. Epithelial cells and crypts were detached by vigorous shaking at 37 °C for 15 min at 225 r/min. After vortexing for a few seconds, the remaining parts of the biopsies were manually removed. Crypts and cells were then spun down by short centrifugation and resolved directly into 350 μ L RLT buffer (RNeasy, Qiagen, Hildesheim, Germany). Due to this IEC preparation, IBD biopsies could be investigated from actively inflamed sites in this series. Four control samples (ages ranged from 22 to 66 years), seven MC samples (ages ranged from 33 to 48 years) and four CU samples (ages ranged from 28 to 62 years) were included.

For all samples, RNA extraction was performed according to the manufacturer’s protocol (RNeasy Mini Kit, Qiagen, Hilden, Germany). RNA quality was assessed with the 6000 Nano LabChip[®] using an Agilent 2100 bioanalyzer (Agilent Technologies, Palo Alto, USA) and quantified spectrophotometrically following standard protocols.

Real-time fluorescence RT-PCR

Real-time TaqMan[®] RT-PCR (PE Applied Biosystems, Darmstadt, Germany) was performed on a ABI Prism 7900 HT Sequence Detection System as previously published^[15,18]. Briefly, cDNA was synthesized using the Reverse Transcription Kit from Promega (Madison, USA) according to the manufacturer’s protocol. Probes and primers for TaqMan[®] analysis were designed on the basis of gene-specific nonhomologous DNA sequence of the corresponding members^[15]. The standard curve method was used for the quantification of the relative amounts of gene expression products. This method provides unitless normalized expression values that can be used for direct comparison of the relative amounts of target mRNA in different samples. All reactions were performed as triplicates.

Low density arrays

Due to limited representation of the Eph-RTK/ephrin

family on the Affymetrix® HGU 133 A/B chips, we established a custom low density array comprising 91 important RTKs, including the complete family of Eph-RTKs/ephrins and a selection of other receptor and non-receptor tyrosine kinases. The selection of non-Eph-RTKs was based on a current review on kinase signaling^[19]. The detailed list of genes can be requested from the authors.

The low density arrays were prepared as follows. 50-mer amino modified oligonucleotide probes were arrayed onto CodeLink™ Slides (Amersham Biosciences) using a conventional Pin-and-Ring™ spotter (Affymetrix) in a controlled environment (20 °C and 65-75% humidity). Optimal sequences of the 50mer probes (two for each gene) were determined by a MWG Biotech proprietary software (MWG Biotech, Ebersberg, Germany). The 2×91 oligonucleotides were spotted together with 9 reference oligos (mwghuman10K #11000-#11008) in linear pattern with 4 replicates each, resulting in a total number of 955 spots per slide. Labeled cRNA was synthesized from total RNA using Cy3-UTP (Amersham Biosciences) in accordance with the linear RNA amplification procedures described in the MWG Array-Application Guide. The cRNA was applied onto the microarray surface using 120 µL Gene Frames® (ABgene) and hybridized for 16 h at 42 °C. For data analysis, the microarrays were scanned at 10 micron resolution and analyzed using the program ScanAlyze (M. Eisen; available at <http://rana.lbl.gov/EisenSoftware.htm>). Areas of the array with obvious bad signals were manually flagged and excluded from subsequent analyses. A linear normalization method was used, assuming that most of the genes represented on an array show the same expression profile. Expression ratios were then calculated and further evaluated using the Significance Analysis of Microarrays (SAM) algorithm^[20]. The SAM calculates the false discovery rate (FDR) as an estimate of the percentage of false positive genes, i.e. genes identified as differentially expressed by chance. Two-class unpaired analysis was applied to compare MC and CU samples to the control samples, separately. Identical FDRs were used to compare the significance of the regulated genes in MC *vs* control and CU *vs* control expression patterns.

Immunohistochemistry

For immunohistochemical staining of ephrin-B2 the anti-ephrin-B2 antibody (Santa Cruz, CA, USA) was used in a dilution of 1:75. Sections of intestinal tissue were boiled (10 min) in citrate buffer for antigen retrieval. Isotype matched antibody controls were run in parallel. The remaining staining procedure according to the ABC-technique followed standard protocols. Ten control sections of healthy individuals (ages ranged from 43 to 78 years), 10 cases of CU (ages ranged from 26 to 80 years), and 10 cases of MC (ages ranged from 21 to 49 years) were analyzed.

IEC-6 in vitro scratch wound assays

To evaluate possible consequences of enhanced ephrin-B dependent signaling effects on wound closure of intestinal cells, not transformed rat IEC-6 cells were chosen as a model. IEC-6 cells are able to close monolayer scratch

wounds within a timeframe assuring that closure is a function of migration competence of the cells at the wound margin rather than proliferation^[21]. In our hands, both HT29 cells and CaCo2 cells failed to fulfil this criterion. Briefly, the IEC-6 cells were seeded into six-wells and grown to confluence in Dulbecco's MEM (Biochrom AG, Berlin, Germany) supplemented with 5% fetal calf serum (FCS) (PAN Biotech, Aldenbach, Germany). After reaching confluence, the cells were fed with starving medium (0.1% FCS) and small scratch-wounds (-1 mm width) were produced with a cell scraper drawn over the surface of the monolayer along a ruler. The cells were stimulated with varying concentrations of recombinant rat EphB1-Fc Chimera (R&D Systems, Minneapolis, USA). The used doses ranged from 0.05 µg/mL (~0.33 nmol/L) to 5 µg/mL (~33 nmol/L). For control experiments, recombinant human IgG-Fc (R&D Systems) was used. Wound closure was monitored at 0, 6, and 24 h after wounding. Images of the wounds were taken by a digital camera on top of the cell culture microscope from exactly the same position at various time points (100× magnification). The closure of the wounds was assessed by calculating the difference between the initial wound area and the remaining wound area at a certain time point. Wound area calculations were performed using the publicly available J-Image software of the NCBI (Bethesda, MA, USA). For each condition, four wounded areas were analyzed in parallel, and all experiments were repeated twice.

Immunofluorescence microscopy of wound margins

Cells were plated on fibronectin coated glass cover slips and grown for 16 h in Dulbecco's MEM plus 5% FCS. Cells were starved for one night with 0.1% FCS medium, then the monolayer was wounded by a cell scraper and stimulated with recombinant EphB1-Fc (5 µg/mL) or IgG-Fc (5 µg/mL) as control for 6 h. For actin staining, cells were fixed with 4% paraformaldehyde for 5 min at room temperature and permeabilized with 0.1% Triton-X 100 for 5 min. The cells were then incubated for 30 min with rhodamine-conjugated phalloidine (1:100) (Chemicon, Temecula, CA, USA) as recommended by the supplier. Each experimental condition was performed on eight replicate cover slips. For detection of wound edge deposits of laminin an affinity purified laminin specific antibody L9393 from Sigma (St. Louis, MS, USA) and FITC labeled secondary goat anti-rabbit antibody (Vector, Burlingame, USA) were used. Images were taken on a Leitz microscope equipped with a fluorescence lamp and appropriate filters. Cells were photographed at 400× magnification.

Immunoblotting

To demonstrate the ability of the recombinant rat EphB1-Fc (R&D Systems) used to bind and potentially activate ephrin-B2 in IEC-6 cells, immunoprecipitation of ephrin-B2 was performed using the Seize™ Classic Mammalian Immunoprecipitation Kit (Pierce, Rockford, USA). Ephrin-B2 protein was precipitated using this recombinant rat EphB1-Fc. Precipitates were analyzed by SDS-PAGE and blotted according to standard protocols. For detection of ephrin-B2, a polyclonal anti-ephrin-B2 antibody (Santa Cruz) was used.

Figure 1 Expression profile of Eph-RTKs and ephrins in normal human mucosa of the small intestine ($n = 5$) and colon ($n = 5$) assessed by real time TaqMan® RT-PCR. The CT-values allow a relative quantification of the mRNA expression

of the single members. Low CT-values indicate a high expression level and vice versa. The arrows indicate marked expression of the family members EphA2, ephrin-A1, EphB2, and ephrin-B1/2.

Statistical analysis

Non-parametric testing was performed (Mann-Whitney test) for comparing the mean values in the wound closure experiments. Significance was indicated by a $P < 0.05$.

RESULTS

Intestinal mucosa expresses a broad gut-specific spectrum of Eph-RTKs and ephrins

The role of Eph-RTKs and ephrins is well defined in developmental biology. However, the expression and function in adult tissues is only marginally known, yet. Therefore, we established a profile of the expression of the members of this family in the small intestine and colon from normal control individuals. For this purpose, a library of real time TaqMan® RT-PCR probes and primers was employed that was recently established in our lab^[15]. The results are shown in Figure 1. Small intestine and colon mucosa exhibit the presence of a broad spectrum of A- and B-class Eph receptors and ephrins with some organotypic differences of the expression profiles. Ephrin-A1 (formerly protein B61) and ephrin-B1/2 are the most abundantly expressed ligands. On the receptor site, EphA2 (formerly epithelial cell kinase, Eck) and EphB2 are the most abundantly expressed receptors.

Ephrin-B2 is upregulated in mucosa samples from IBD patients

A recently published gene array analysis (Affymetrix® platform) of pooled IBD samples and control patients produced detectable signals only for a minor fraction of Eph-RTKs and ephrins (EphA2, ephrin-A1, EphB2, EphB4 and ephrin-B1/2)^[17]. Interestingly, these were almost exactly the most abundantly expressed genes of this family in our real-time RT-PCR profile (Figure 1).

That array analysis had further revealed an up-regulation of ephrin-B2 (2.4-fold in the small intestine and 1.5-fold in the colon) in perilesional, not inflamed mucosa of MC patients^[17]. In this study, we validated those observations in the same cohort of patients. For this purpose, we used our established TaqMan® probe and primer set for ephrin-B2. In these experiments, the individual (not pooled) samples of all 4 well characterized cases of MC, CU and controls were analyzed (Figure 2). A significant up-regulation of ephrin-B2 could be confirmed in the individual MC patients

both in the small intestine and in the colon samples. The individual probes of the CU patients also showed a significant up-regulation in the colon samples. In contrast, a 0.5-fold downregulation of EphB4 in the colon of CU patients, as indicated by previous Affymetrix® array analysis^[17], did not reach significance in the real-time RT-PCR validation.

Figure 2 Differential gene expression of Eph-RTKs and ephrins in the mucosa of IBD patients (TaqMan® RT-PCR validation of Affymetrix® cDNA array results^[17]). Individual RNAs from perilesional total mucosa biopsies (ileum terminale and colon) of 4 control subjects, 4 MC patients and 4 CU patients were analyzed. Real-time RT-PCR confirmed significant up-regulation of ephrin-B2 in MC patients (ileum and colon) and CU (colon). Differential expression of EphB4, as suggested by the Affymetrix® array data, was not significant. The relative expression values were calculated according to the standard curve method of the TaqMan® protocol (Applied Biosystems, Darmstadt, Germany) by normalization with a housekeeper gene (18S rRNA) and are therefore unitless (for details, see^[15]). ^a $P < 0.05$ vs normal.

Low density arrays confirm the up-regulation of ephrin-B2 in intestinal epithelial cells (IECs) prepared from lesional IBD biopsies

Since RT-PCR suggested a much more diversified presence of Eph-RTKs and ephrins in gut mucosa than it was detectable by the HGU 133 A/B chip generation, we employed low density 50 mer oligonucleotide technology based on protocols developed by MWG (MWG Biotech, Ebersberg, Germany). To further substantiate the specificity of the results for the epithelial compartment, in this series of experiments the IECs were isolated from sets of biopsies of controls and lesional inflamed mucosa biopsies of MC patients and CU patients, respectively.

SAM (significance analysis of microarray data) analysis revealed that ephrin-B2 reached the highest significance score

Figure 3 Immunohistochemistry of ephrin-B2 from biopsies of normal colon and lesional colon in IBD. (A-C: normal colon; D, F: MC; E: CU). A-C: ephrin-B2 expression shows a physiologic gradient along the crypt-axis in normal epithelium of the colon, i.e. the maximum staining is found in the luminal,

terminally differentiated epithelium of normal colon mucosa. D-F: In MC and CU this gradient is disturbed, i.e. strong ectopic expression in the deep parts of the crypts can be observed. C and F represent cross sections of the deep part of a crypt.

in MC patients among 16 further genes with significant scores at an estimated false positive rate of 5%. This is consistent with the previous Affymetrix[®] array analysis^[17] and our real time RT-PCR data (Figure 2). Interestingly, with this 50 mer low density chip further Eph-RTKs and ephrins produced measurable signals and were identified as potentially regulated in the (lesional) intestinal epithelium of MC patients (ephrin-A5, EphB1, EphB4). Moreover, FGFR-3, INSR, NGFR, PDGFR- β were among the candidate genes, growth factor receptors that have already been linked to epithelial healing, proliferation and many other aspects of IBD-physiology^[22]. In contrast, no significantly regulated genes were observed in the CU group.

Immunohistochemistry confirms up-regulation and ectopic epithelial expression of ephrin-B2 in lesional IBD biopsies

Immunohistochemistry revealed that ephrin-B2 is expressed most prominently in the upper parts of the crypts in normal mucosa of the human colon, i.e. the most intense expression is found in the terminally differentiated epithelium at the luminal surface. Apparently, there is a gradient along the crypt-axis with decreasing expression in the deeper parts of the crypts. In contrast, in inflamed MC samples a strong staining of the entire epithelium was observed from the basis to the top of the crypts with an obvious loss of this gradient (Figure 3). In CU samples, this distortion of ephrin-B2 expression was also seen in some samples, but not as consistent as in MC.

IEC-6 in vitro scratch wound assays indicate an enhanced wound closure upon stimulating the ephrin-B reverse signaling pathway

Since both array analysis and quantitative RT-PCR data suggested up-regulation of ephrin-B2 in lesional and perilesional intestinal epithelium of MC patients, we investigated possible functional consequences of intensified reverse ephrin-B signaling in an intestinal epithelial model cell line. Not transformed rat intestinal IEC-6 cells were chosen for two reasons: (1) Constitutive expression of the ligand ephrin-B2 and the receptor EphB2 in this cell line could be confirmed by quantitative RT-PCR, immunocytochemistry (data not shown) and immunoblotting (Figure 4); (2) IEC-6 cells exhibit a basal wound closure competence *in vitro*, which exceeded the competence of human intestinal cancer cell lines (HT-29, CaCo-2, SW-480) tested in our lab.

Figure 4 Immunoprecipitation of ephrin-B2 with EphB1-Fc demonstrates that the recombinant rat EphB1-Fc binds to ephrin-B2 (42 ku), and ephrin-B2 is constitutively expressed by rat IEC-6 cells. Ephrin-B2 transfected B16 melanoma cells served as positive control.

Wounded monolayers of IEC-6 cells were treated with recombinant rat EphB1-Fc for stimulation of ephrin-B dependent pathways. As shown in Figure 5, a dose-dependent acceleration of wound closure by stimulation with EphB1 could be observed after 6 and 24 h ($P < 0.05$). Interestingly, maximal effects were already obtained with 0.05 $\mu\text{g/mL}$ ($\sim 0.33 \text{ nmol/L}$) concentration of EphB1-Fc. Higher concentrations slightly decreased the wound closure activity. Control experiments were performed with equal amounts of IgG-Fc.

Stimulating the ephrin-B reverse signaling pathways in IEC-6 cells induces cellular responses indicating enhanced wound closure capacity

As shown in Figure 6, starved unstimulated IEC-6 cells exhibit only a limited wound closure activity 6 h after wounding (Figure 6A). In contrast, the EphB1-Fc stimulated cells already show signs of organized motile activity forming multiple archipelago-like sheets of cells stretching into the denuded area (Figure 6B). Notably, asymmetric lamellipodial protrusions are formed by those wound-edge cells. Further cytoskeletal correlations of inducible wound-edge activities can be demonstrated by actin staining with phalloidin. The unstimulated cells show a rounded morphology with less polymerized actin bundles (Figure 6C). The EphB1-Fc exposed cells show a stretched-out, bizarre morphology and apparent assembly of stress fibers. The spike-structures may reflect increased focal adhesion assembly (Figure 6D). Furthermore, the enhanced wound closure of the stimulated cells is also accompanied by

Figure 5 IEC-6 *in vitro* scratch wound assays indicate an enhanced wound closure activity upon stimulation with EphB1-Fc. IEC-6 cell monolayers were wounded in a standardized manner using a cell scraper, and relative wound

closure was monitored after 6 h and 24 h. Subnanomolar doses of EphB1-Fc (0.05 µg/mL–0.33 nmol/L) significantly enhanced the wound closure ($^aP < 0.05$). Higher doses did not further increase this effect.

increased deposition of laminin as a provisional basal membrane at the wound edge (Figure 6E, F).

DISCUSSION

This study demonstrates a complex spectrum of Eph-RTK and ephrin expression in the normal human adult intestinal mucosa. This suggests that Eph-RTKs and ephrins may contribute to tissue maintenance throughout life, in addition to their well-established roles in development^[23]. Consistent with a previous study by Podolsky and co-workers^[16], we found EphA2 and ephrin-A1 among the most prominently expressed family members both in the small intestine and colon. To the best of our knowledge, this is the first study showing a concurrent prominent co-expression of EphB2 and ephrin-B1/2 in normal human intestine. Other family members revealed a less abundant expression. This gut ‘signature’ is unique among other normal tissues in humans^[15]. In addition, this study reports a differential regulation of ephrin-B2 in the intestinal epithelium of MC patients. In the light of recent insights into the function of ephrin-B2, its upregulation suggests a possible ephrin-B2-dependent modulation of cytoskeletal dynamics and migration competence of epithelial cells in IBD. The multi-modal

interaction of ephrin-B2 with downstream effectors of the cytoskeleton such as focal adhesion kinase (FAK) and cdc42 has been recently demonstrated^[24].

Therefore, we addressed possible functional effects of an enhanced EphB/ephrin-B-dependent exchange of intercellular signals on epithelial repair processes. The stimulation of rat IEC-6 cells with recombinant ephrin-B2-binding EphB1-Fc receptors effectively enhanced their wound closure competence at doses below 1 nmol/L. Consistent with this ‘repair phenotype’, EphB1-Fc stimulation induced a concerted migratory response of wound-edge cells. This was documented by early archipelagolike movements at the wound-edge associated with increased stress-fiber polymerization and adoption of a stretched-out morphology with multiple wound-oriented lamellipodia. Furthermore, the increased deposition of laminin provides a new basement for integrin-dependent anchorage and survival of the cells^[25]. Although the IEC-6 model suggests mechanisms in favor of enhanced wound healing, any conclusions regarding the *in vivo* situation have to be drawn with caution. As shown by immunohistochemistry of MC lesions, the physiologic expression gradients extending from the basis of the intestinal crypts to the apical epithelium are apparently lost in MC epithelia. This graded expression

Figure 6 Stimulation of IEC-6 cells with EphB1-Fc induces subcellular responses compatible with enhanced wound closure capacity. Compared to the non-stimulated control (A), recombinant EphB1-Fc stimulated cells produce an organized migratory activity forming multiple archipelago-like sheets of cells stretching into the denuded area already 6 h after stimulation. In addition, asymmetric lamellipodia are seen (arrow). (B). Staining of actin with phalloidin

shows a rounded morphology with less polymerized actin bundles in unstimulated cells (C), whereas EphB1-Fc stimulated cells display a stretched-out, bizarre morphology and apparent assembly of abundant stress fibers. Spike-like protrusions may correspond to focal adhesion assembly (arrows) (D). EphB1-Fc also induces an increased deposition of laminin as a provisional basal membrane at the wound edge (F) (arrows) compared to control cells (E).

is tightly regulated by β -catenin and TCF, and has been shown to be responsible for the spatial separation of the proliferative and differentiated epithelial compartment along the crypt-villus axis during development^[14]. Since the expression gradient may be the driving principle of organized cell replacement, from the base to the top along the crypt-villus axis, this ectopic expression in MC could also be deleterious. Finally, the upregulation of ephrin-B2 does not necessarily mean enhanced ephrin-B2-dependent signaling in the epithelium, since counteracting mechanisms (e.g. phosphatases such as FAP-1 and PTP-BL) may be up-regulated as well^[26].

Extrapolations on *in vivo* effects of single family members are also hampered by the complexity involved. Members of this largest class of Eph-RTKs in humans can evolve seemingly disparate effects depending on the cellular system and the relative balance of A *vs* B receptors and ligands. For instance, Lawrenson *et al.*, have reported that ephrin-A5, also in our list of upregulated candidate genes in MC epithelium, can induce de-adhesion of EphA3 expressing 293T and melanoma cells^[27]. The contrary has been reported for CaCo2 cells^[16]. With PC-3 prostate cancer cells transfected with EphA2, stimulation with ephrin-A1 resulted in an inhibition of cell adhesion and spreading on laminin and fibronectin^[28]. EphA2 is also linked with the p53 tumor-suppressor protein family and can induce apoptosis^[29]. In contrast, ephrin-B/EphB-interaction can promote integrin-mediated cell attachment in embryonic kidney cells^[30], endothelial cells^[31], platelets^[23] and P19 cells^[32]. Obviously, the composition and fine-tuned balance of expressed individual members of this large family is a critical

point and might contribute to the movement of intestinal cells along the crypt-villus axis^[14], or from the wound margin to the center of epithelial defects.

Nevertheless, therapeutically it could be very interesting to strengthen the effects of the protective members and to weaken the effects of the counteracting members in this system, since our study demonstrates that nM doses can provoke significant effects on wound healing in the IEC-6 cell model. With the discovery of defined peptides that activate or specifically block selected molecules of this family^[33], a differentiated biological targeting of this delicately balanced system is possible in the near future. Since T-cell homing and interferon- γ production are also dependent on their Eph-RTK/ephrin environment, strategies could evolve that both regain the epithelial homeostasis and attenuate immunologic responses in IBD patients.

We conclude that the EphB/ephrin-B induced pathways should be placed on the list of targets for future molecular therapies trying to intervene with neomorphogenic pathways in IBD epithelia. However, the specifics of such interventions like potential interactions with the immune system, and the function of numerous partly counteracting family members, have to be better understood first.

Abstract

AIM: To assess the effects of ulcerogenic agents on actin cytoskeleton and cell motility and the contribution of oxidative stress.

METHODS: Rat gastric mucosal cell monolayers were cultured on coverslips. The cells were exposed, with or without allopurinol (2 mmol/L), for 15 min to ethanol (10-150 mL/L), ASA (1-20 mmol/L) or taurocholate (1-20 mmol/L), then the cells were processed for actin and vinculin staining. Cell migration after wounding was also measured.

RESULTS: Exposure to 10 mL/L ethanol caused divergence of zonula adherens-associated actin bundles of adjacent cells and decreased rate of migration. These actions were opposed by xanthine oxidase inhibitor allopurinol. Exposure to 50 mL/L ethanol induced degradation and divergence of zonula adherens-associated vinculin from adjacent cells, which was, again, partially reverted by allopurinol. With 1 mmol/L ASA actin filaments became shorter and thicker. However, higher concentrations (10, 20 mmol/L) of ASA returned microfilaments thinner and longer, and decreased rate of migration. Zonula adherens-associated actin bundles were moderately distorted with 10 mmol/L ASA and with 10 mmol/L taurocholate. Exposure to taurocholate provoked changes resembling those of ASA. Taurocholate 5-20 mmol/L decreased the rate of migration dose dependently. The effects of ASA and taurocholate were not prevented by allopurinol.

CONCLUSION: All ulcerogenic agents decreased the rate of migration dose dependently and induced divergence of zonula adherens-associated actin bundles of adjacent cells.

INTRODUCTION

The gastric mucosa is frequently exposed to different exogenous and endogenous ulcerative agents, such as ethanol, aspirin and taurocholate. These agents have been extensively investigated with methods, including biochemistry, morphology, electrophysiology, tissue permeability, *etc.*, but the cellular mechanisms of injury are still poorly defined.

In digestive epithelia actin cytoskeleton is involved, for example, in organization of cytoplasm, maintenance of cell shape, generation and maintenance of epithelial polarity and in migration. The cytoplasm of epithelial cell is spatially and temporally organized by microfilaments, microtubules and intermediate filaments, which form a lattice-like intracellular meshwork^[1,2].

The actin cytoskeleton is highly conserved in eukaryotic cells, including more than 70 categorized types of actin-binding proteins^[3]. The human actin family includes α -, β -, and γ -actin, which share most of their amino acid sequences. The actin filaments are formed by polymerization of actin monomers. The polymeric actins are assembled into a filamentous network, which is regulated by actin-binding proteins. These proteins regulate, for example, polymerization, cross linking, nucleation and branching, anchoring, capping, membrane interaction, cell-extracellular matrix interaction, cell-cell interaction and contractility of actin filaments^[4]. The actin filaments are bundled together by various actin cross-linking proteins to form complex three-dimensional structures. The filaments are extensively branched near the plasma membrane, focal adhesions, and adherens and tight junctions.

Arp2/3 complex is involved in this branching^[5].

Different components of the cytoskeleton are tightly involved in cell motility^[6]. Actin based cell motility has several important tasks in epithelial cell functions, such as in secretory vesicle movement and cell migration during wound healing^[7]. The cell migration starts with lamellipodia extension and formation of new focal adhesions, followed by the contraction of the cell body and detachment of the tail. Rho guanosine triphosphatases have a key role in regulating different phases of migration. Rac1 seems to be involved in initiation of migration^[8] and in stimulation of lamellipodium extension^[9], while Rho seems to contribute mainly to cell body contraction^[6].

Epithelial cells have specialized mechanisms to enable cell-cell and cell-extracellular matrix adhesions. These connections are formed by transmembrane proteins, which bind to extracellular matrix or adjacent cells with their extracellular domains, while the intracellular domains bind to intracellular cytoskeleton via cytoplasmic adaptor proteins, many of which interact with the actin cytoskeleton^[10]. Integrins mediate cellular adhesion to the extracellular matrix. They are linked to the actin cytoskeleton in focal adhesion complexes, which include a multitude of proteins, such as vinculin, talin, paxillin and calpain. These focal adhesions are involved in regulation of the cell migration and proliferation. The classical E-cadherins mediate Ca²⁺ dependent cell-cell adhesion through their extracellular Ca²⁺ binding repeats, while their cytoplasmic part binds to the actin cytoskeleton via β - and α -catenin. This complex is associated with a variety of other proteins, including vinculin, α -actinin, and paxillin. Zonula adherens is an E-cadherin based belt-like adherent junction just below the tight junctions encircling the epithelial cells adhered to each other. Along the cytoplasmic side of the zonula adherens runs a contractile bundle of actin filaments, which are associated to zonula adherens with a set of intracellular proteins, such as α -catenin, vinculin, α -actinin and plakoglobin. Vinculin is a large protein with multiple binding sites to different adhesion related proteins, including actin, α -actinin, talin, paxillin, VASP, ponsin, vinexin and PKC^[11,12]. Vinculin is thought to mediate the linkage between actin cytoskeleton and cadherins or integrins in cell-cell or cell-extracellular matrix adhesions. Recently vinculin has been shown to transiently associate with arp2/3 complex in the nascent focal complexes in the leading edge^[13], possibly linking cellular protrusion and adhesion to extracellular matrix. Ethanol is known to cause oxidative stress in rat hepatocytes and in gastric mucosal cells^[14,15]. Oxidative stress can cause various effects in the cell, such as oxidation and fragmentation of cellular proteins, peroxidations of membrane lipids, fragmentation of DNA and mitochondrial damage. Among the very early effects of oxidative stress might be disruption of the cytoskeleton^[16].

The aim of the present study was to characterize the effects of different ulcerogenic agents on actin cytoskeleton, cell adhesion molecules and cell migration, and to investigate the possible role of oxidative stress in the cellular injury induced by them. This was accomplished by confocal and normal fluorescence imaging of actin and vinculin during exposure of the epithelial cells to the ulcerogenic agents. We also measured the rate of cell migration during exposure to the ulcerogenic agents to assess the functional state of

the cytoskeleton. We further studied the possible role of reactive oxygen species in epithelial injury by inhibiting endogenous intracellular generation of superoxide radicals from purines with a xanthine oxidase inhibitor, allopurinol.

MATERIALS AND METHODS

Immortal rat gastric mucosal cells (RGM-1, Riken Cell Bank, Riken, Japan)^[17] were cultured on coverslips to confluent monolayers at 37 °C in humidified atmosphere containing 50 mL/L CO₂ in air. The medium used was an equal mixture of Ham's F12 and Dulbeccos's MEM supplemented with inactivated 200 mL/L fetal bovine serum, 100 U/mL penicillin, 100 µg/mL streptomycin and 0.125 µg/mL amphotericin.

The cells were exposed for 15 min to the following ulcerogenic agents: ethanol (10-150 mL/L), acetylsalicylic acid (ASA, 1-20 mmol/L) and taurocholate (1-20 mmol/L) at 37 °C. In allopurinol experiments the samples were treated with 2 mmol/L allopurinol 24 h before and during the exposure of the ulcerogenic agent. Thereafter the cells were fixed with 35 mL/L paraformaldehyde in PBS for 15-20 min at room temperature and stained as described below.

Actin filaments and focal adhesion plaques were stained with phallotoxins conjugated to Alexa 488 fluorophore (Molecular Probes, A-12379). After fixation the cells were washed three times for 5-10 min with PBS at room temperature, permeabilized with 1 mL/L Triton-X, 1 mL/L bovine serum albumin in PBS and washed again three times for 5-10 min in PBS. Thereafter, the samples were incubated for 30-60 min in PBS with 80 mL/L bovine serum albumin and washed three times for 5-10 min with PBS and incubated overnight with the mouse monoclonal anti-vinculin (10 µg/mL, with 10 mL/L bovine serum albumin). The samples were washed three times for 5-10 min with PBS and were incubated with secondary antibody goat anti-mouse Alexa 568 (10 µg/mL) and Alexa 488 phalloidin (1:1 000) with 1 mL/L bovine serum albumin in PBS for 30 min at room temperature. Thereafter, the samples were washed three times for 5-10 min with PBS and mounted with DABCO containing mounting media. Confocal fluorescence microscopy was performed with a Leica TCS SP2 confocal microscope and normal fluorescence microscopy with an Olympus IX50 microscope.

Cell migration assay

RGM cells were cultured to confluency on plastic culture dishes as described above. In allopurinol series the confluent monolayers were treated with allopurinol after and 24 h before wounding. Artificial round-shaped wounds were created in the cell monolayer with a silicon tip, where after control (water) or ulcerogenic agents were added. The migration distance of the cells at the wound edge was measured during the next 6 h at 2 h intervals by measuring the change in cell free area. The rate of migration was calculated from the change of cell free area measured at 0 and 6 h, as described previously^[18].

Statistical analysis

The results are expressed as mean \pm 95% confidence intervals.

Student's unpaired *t*-test was used for statistical analysis of the raw data. *P* values less than 0.05 were considered as statistically significant.

RESULTS

Ethanol

In control cells, actin filaments were thin, showing branched actin networks and zonula adherens-associated actin bundles near the cell-cell contact sites (Figures 1 and 2). Exposure to 10 mL/L (vol/vol) ethanol for 15 min (Figure 1) did not cause any apparent changes in actin cytoskeleton. Increasing the ethanol concentration to 50 mL/L caused moderate degradation and irregularity in the actin filament organization. These changes became more prominent with 100 mL/L ethanol, displaying almost complete degradation of the actin filaments. Exposure to 150 mL/L ethanol for 15 min provoked detachment of the cells from each other (Figure 1). The damage of the actin filaments was severe, and in some microscopic fields only shadows of cells and nuclei remained visible.

In control cultures, the zonula adherens-associated actin bundles were normally seen as continuous belt-like accumulations between the cells, and the actin belts of adjacent

cells could not be distinguished from each other. Exposure to 10 mL/L ethanol caused actin belts of adjacent cells to diverge from each other and the gap between them was widened with increasing ethanol concentrations (20-50 mL/L, Figure 2). Treatment with allopurinol (2 mmol/L), which acts as an inhibitor of xanthine oxidase and inhibits production of intracellular reactive oxidative species, prevented completely the divergence of actin belts in cells exposed to 10 mL/L ethanol and partially in cells exposed to 20 mL/L ethanol, but not in cells exposed to 50 mL/L ethanol.

In control cultures, vinculin was visible at the focal adhesions as well as in the zonula adherens between the adjacent cells. The zonula adherens-associated vinculin of adjacent cells could not be distinguished. Exposure to 10-20 mL/L ethanol did not change the distribution of vinculin, but 50 mL/L ethanol exposure caused degradation and divergence of zonula adherens-associated vinculin staining. Allopurinol treatment moderately attenuated this change (Figure 3).

Exposure to 10 mL/L ethanol decreased the rate of migration during the first six hours after wounding (27 ± 3 and 17 ± 2 $\mu\text{m}/\text{h}$ for control and ethanol experiments, respectively; $P < 0.001$, $n = 20$, Figure 4). This decrease in

Figure 1 Effects of different doses of ethanol (ETOH), acetylsalicylic acid (ASA)

and taurocholate (TC) on actin filaments of RGM rat gastric surface epithelial cells.

Figure 2 Effects of different doses of ethanol (ETOH), acetylsalicylic acid (ASA) and taurocholate (TC) on the zonula adherens-associated belt-like actin bundles

in RGM cells and their modulation by allopurinol (2 mmol/L) treatment. Arrows indicate perturbations in the actin belt organization.

migration was partially abolished by allopurinol pretreatment (17 ± 2 and 23 ± 2 $\mu\text{m}/\text{h}$ for ethanol and ethanol+allopurinol experiments, respectively; $P = 0.025$, $n = 20$). Allopurinol treatment alone had no effect on the rate of migration (27 ± 3 and 27 ± 2 $\mu\text{m}/\text{h}$ for control and allopurinol experiments, respectively). The migration distances are shown in Figure 4. With higher ethanol concentrations the rate of migration

was further decreased (to 7 ± 3 $\mu\text{m}/\text{h}$ with 30 mL/L ethanol) and even numerically reversed (to -17 ± 13 $\mu\text{m}/\text{h}$ with 50 mL/L ethanol), indicating enlarging of the wound, possibly due to a direct toxic effect of ethanol and/or to overall cell shrinkage in the monolayer caused by ethanol. At these higher concentrations of ethanol (30-50 mL/L) allopurinol did not prevent the ethanol promoted decrease in migration.

Figure 3 Effects of different doses of ethanol (ETOH), acetylsalicylic acid (ASA) and taurocholate (TC) on vinculin distribution in RGM cells and their modulation

by allopurinol (2 mmol/L) treatment. Arrows indicate perturbations in vinculin organization.

Acetylsalicylic acid (ASA)

After 15 min exposure to 1 mmol/L ASA, the actin filaments were contracted and became shorter and thicker, but no signs of cell detachment from each other were visible. However, with higher concentrations of ASA (10 and 20 mmol/L) the microfilaments became thinner and longer again, but failed to resume their original size and shape. Increasing ASA concentration to 20 mmol/L detached the cells partially from each other, which was manifested also as a divergence of the zonula adherens-associated actin bundles of adjacent cells (Figure 1). Also degradation of the actin filaments was visible.

Exposure to 1-5 mmol/L ASA had no effect on the zonula adherens-associated belt-like actin bundles. Exposure to 10 mmol/L ASA moderately distorted these actin belts and this was not prevented with allopurinol treatment (Figure 2).

Exposure to 1-10 mmol/L ASA had no effect on vinculin distribution (Figure 3). Likewise, exposure to 1-5 mmol/L ASA had no effect on the rate of migration, but exposure to 10 mmol/L ASA retarded migration after wounding from 16.8 ± 0.5 to 13.7 ± 1.2 $\mu\text{m}/\text{h}$ ($P = 0.008$, $n = 6$).

Taurocholate

Following exposure to low concentrations of taurocholate (1 and 5 mmol/L) the actin filaments were contracted, becoming shorter and thicker than in controls. These effects became more conspicuous with increasing concentrations of taurocholate (Figure 1). In fact, taurocholate caused similar changes as was seen with low concentrations of ASA, but the alterations were of lesser degree. Exposure to 1-5 mmol/L taurocholate did not cause any change in the zonula adherens-associated actin bundles, but 10 mmol/L

Figure 4 Effect of ethanol on cellular migration distance, with and without allopurinol treatment. Ethanol significantly reduced the migrated distance. Allopurinol partially abolished the ethanol promoted inhibition of cell migration.

taurocholate showed a moderate perturbation of these belts, which was not prevented by allopurinol treatment (Figure 2). Exposure to taurocholate (1-10 mmol/L) had no effect on vinculin distribution (Figure 3).

Exposure to 1 mmol/L taurocholate had no effect on the rate of migration after wounding, but 5-20 mmol/L taurocholate retarded migration dose dependently (migration speed 16.8 ± 0.6 , 14.5 ± 0.8 ($P = 0.01$), 12.7 ± 0.4 ($P < 0.001$) and 1.6 ± 0.8 ($P < 0.001$) $\mu\text{m}/\text{h}$ for 0 mmol/L (control), 5, 10 and 20 mmol/L taurocholate, respectively; P values are given in comparison with control, $n = 6$).

DISCUSSION

The gastric mucosa is normally exposed to a large number of ulcerogenic compounds, including ethanol, ASA (aspirin) and bile salts. The effects of these agents on cell cytoskeleton have not been thoroughly studied. In the healing of superficial gastric mucosal lesions, intact actin cytoskeleton is essential for cell migration and survival. The normal wound healing process in gastric mucosa is initiated by epithelial restitution whereby the surviving epithelial cells around wound edge migrate over the injured area to cover it with a flattened neo-epithelium. The migrating cells form lamellipodia and vinculin, RhoA and Rac are strongly expressed along the wound edge^[19]. Ulcerogenic agents can profoundly modulate this healing process.

Ethanol promotes narrowing of lamellipodia as well as retards cell migration and inhibits cellular proliferation after wounding in rabbit gastric mucosa^[20,21]. Exposure to 50-100 mL/L ethanol causes extensive disorganization and fragmentation of the actin cytoskeleton leading to its complete collapse in an intestinal epithelial cell line^[22,23]. We have previously shown that 50 mL/L luminal ethanol causes the opening of basolateral potassium channels leading to cell volume shrinkage^[24]. In the present work we demonstrated that the same concentration of ethanol affects also various components of the cytoskeleton. The changes in the structure and arrangement of the cytoskeleton are in line with cell shrinkage and the consequent increase in the gaps between the cells. Since an intact cytoskeleton is of utmost importance for the epithelial integrity and function, these minor changes may be the first manifestations of the ethanol-induced damage to the epithelial cells. At 100 mL/L ethanol concentration,

there was an extensive distortion of the actin cytoskeletal network, and even stronger ethanol (150 mL/L) caused severe damage to the cells with complete degradation of all actin filaments.

The zonula adherens-associated belt-like actin bundles of adjacent cells were diverged from each other already during exposure to a rather low (10 mL/L) concentration of ethanol. This divergence was prevented with 2 mmol/L allopurinol treatment. Allopurinol is a cell membrane permeable xanthine oxidase inhibitor, which blocks endogenous intracellular enzymatic generation of superoxide radicals from purines. This suggests that superoxide radicals are involved in ethanol induced divergence of the actin belts. Ethanol also perturbed the distribution of the zonula adherens junction-associated protein, vinculin, but only after exposure to 50 mL/L ethanol. Further, this change was moderately opposed by allopurinol treatment. The damage in zonula adherens-associated vinculin became apparent only with higher ethanol concentrations than was needed for changes in zonula adherens-associated actin bundles, which suggests that the changes in the actin belts might precede the zonula adherens junction damage. Allopurinol also opposed the ethanol provoked decrease in cell migration after artificial monolayer wounding, a further indication of the involvement of superoxide radicals in ethanol induced cytoskeletal damage.

The above findings suggest that oxidative stress might underlie the observed ethanol induced changes in actin cytoskeleton. Epithelial cells exposed to ethanol increase superoxide production^[25] and superoxide dismutase activity is decreased in rat stomach exposed to pure ethanol^[26]. Also, oxidative stress and mitochondrial damage precede death in gastric mucosal cells exposed to ethanol^[15]. The number of propidium iodide positive cells, indicating loss of cell viability, was increased following exposure to 50 mL/L ethanol and ethanol caused mitochondrial cell membrane depolarization and mitochondrial permeability transition, indicating mitochondrial dysfunction^[15].

It has been suggested, that NSAIDs, including ASA, damage gastrointestinal tract both by direct local effects and by systemic inhibition of prostaglandin synthesis. Davenport first demonstrated that ASA diffuses into the gastric mucosa as an undissociated molecule leading to disruption of the gastric mucosal barrier and backdiffusion of luminal acid into the mucosa, which, in turn, leads, presumably via generation of an inflammatory cascade, to break-down of the mucosal tissue^[27]. Although prostaglandins contribute to cell migration in several cell types^[28,29], addition of exogenous prostaglandins or inhibition of endogenous prostaglandin synthesis had no effect on gastric epithelial cell migration^[18]. On the other hand, NSAIDs may directly retard cell migration and decrease actin staining in gastric epithelial cell (RGM1) monolayer^[30].

The present results with ASA are well in accordance with our earlier finding that ASA causes major cell shape deformations in *Necturus* gastric antrum (unpublished results). The shrinkage of actin cytoskeleton probably contributes to cell-cell detachment, which was shown to occur at higher ASA concentrations. ASA decreased migration at 10 mmol/L concentration and degradation of actin filaments was visible

at 20 mmol/L ASA concentration. Zonula adherens-associated actin bundles were moderately damaged with 10 mmol/L ASA and this was not affected by allopurinol treatment, suggesting a mechanism different from ethanol-induced divergence of these actin bundles.

To our knowledge there is very little information about the actions of ASA on cellular actin cytoskeleton in the gastric epithelium. Electrophysiological measurements have shown that there is a slight initial increase in transepithelial resistance following exposure to 10 mmol/L ASA (at pH 3), which is, however, due to increase in apical cell membrane resistance. However, during more prolonged exposure to ASA the transepithelial resistance decreased, which might be a consequence of tight junction disruption, widening of intercellular space and/or loosening of cell-cell adhesions^[31]. The changes in the zonula adherens-associated actin bundles observed in the present study might contribute to the previously observed decrease in transepithelial resistance.

In earlier studies bile salts have been shown to retard wound restitution and repair in cultured rabbit gastric epithelial cells^[32]. In the present study, taurocholate caused similar effects in cell migration reducing it dose dependently in concentrations of 5 mmol/L and higher. The mechanism of taurocholate induced decrease in migration speed is still unclear, but bile salts are known to increase intracellular calcium levels^[33,34] and this might have an effect on cellular migration.

Taurocholate is known to interact with cell membranes and as a lipophilic compound it may diffuse into the cell membranes increasing its permeability to extracellular agents^[35]. Taurocholate may also act as a detergent dissolving cell membrane phospholipids eventually breaking up the cell membrane^[36]. Apical cell membrane resistance was decreased significantly with 10 mmol/L taurocholate in *Necturus antrum*^[31], suggesting that cell membranes may be the main target in taurocholate induced cellular damage. Zonula adherens associated actin bundles were moderately damaged with 10 mmol/L taurocholate, but this was not affected by allopurinol treatment suggesting, again, a mechanism different from ethanol induced damage. Previously, it has been shown that bile salts induce depolarization of mitochondrial membrane potential, which might be due to disturbed oxidative phosphorylation in mitochondria^[37]. In the present study, the possible oxidative damage was not prevented with allopurinol exposure, suggesting that xanthine oxidase is not involved in taurocholate-induced cellular injury.

In conclusion, our results show that deformations of the actin cytoskeleton are involved in the epithelial cell damage caused by the three ulcerogenic agents tested. Reactive oxidative species seems to underlie ethanol, but not ASA or taurocholate, induced cytoskeletal damage.

Abstract

AIM: Irritable bowel syndrome (IBS) is a common disorder and many patients fail to find adequate relief from conventional therapies for their symptoms. This study tests the claim that acupuncture is effective for a majority of these patients.

METHODS: A prospective, blinded, sham acupuncture-controlled trial of traditional Chinese acupuncture was performed at a single postgraduate teaching hospital in Europe. Sixty patients with well-established IBS were recruited. The blinded comparator was sham acupuncture administered by the second of two acupuncturists who alone was aware of the randomization, and who otherwise followed the prescription of the first. The primary endpoint was a defined fall in the symptom score at 13 wk (by intention to treat). The prior expectation was a 30% placebo response, and a response rate of 70% from acupuncture, for which the study was adequately powered.

RESULTS: Patients in treated and sham groups improved significantly during the study-mean improvement in scores being equal (minus 1.9) and significant for both ($P < 0.05$; one-tailed t test). There was a small numeric but non-significant difference between the response rate in patients receiving acupuncture (40.7%) and sham treatment (31.2%). Several secondary end-points marginally favored active treatment, but an improved symptom score of any degree of magnitude occurred more often with sham therapy (65.6% vs 59.2%). For no criterion was statistical significance approached.

CONCLUSION: Traditional Chinese acupuncture is relatively ineffective in IBS in the European hospital setting, and the magnitude of any effect appears insufficient to warrant investment in acupuncture services.

INTRODUCTION

Acupuncture has been utilized for a variety of conditions, by up to 19% of the European population, and with as many as 12 million treatments per year in the USA^[1]. Gastrointestinal problems are addressed^[2], and in addition to publications in the traditional Chinese medicine (TCM) literature there has been support in more mainstream journals^[3,4]. Not all reviewers have been so positive however^[5]. Irritable bowel syndrome (IBS) is common, and many patients fail to find adequate relief from conventional therapies. It is claimed that acupuncture is effective for a majority of patients with IBS, but there are few data to support this. Case reports do not adequately address the large placebo response in this condition, the often substantial inter-subject variability in response, nor the differing systems of nomenclature in acupuncture. The US NIH consensus did not include IBS amongst 12 conditions for which it found evidence favoring acupuncture^[4]. The only paper specific to acupuncture in IBS that we have found is a pilot study of seven patients, which recorded improvements in bloating and general well-being^[6]. A complex Austrian study in which acupuncture or sham acupuncture (inter alia) was used for irritable colon demonstrated benefit at 1 mo (43.7% vs 26.7% relief; $P < 0.01$)^[7]. However, the definition of response, the nature of the randomization, and the mechanism of blinding are unclear. Evidence in favor of acupuncture for IBS cannot be considered definite.

Previous attempts to assess the placebo response in acupuncture therapy have been criticized. Orthodox clinician-scientists object to poor blinding, while acupuncturists argue that attempts to blind therapy negate the diagnostic and therapeutic process, and confound the individualization of the chosen regime necessary for the TCM paradigm. The present study addresses a single hypothesis and tackles the issues of methodology in a novel and creative fashion.

MATERIALS AND METHODS

Patients and consent

Patients were selected by personal approach in the St Mark's Hospital clinics. Eligibility required a confident clinical diagnosis of IBS and age of over 16 years. Patients were to

satisfy the Rome criteria^[8] and the Manning criteria^[9]. The Rome II criteria^[10] became available during the study; their fulfillment was noted but not required. Patients were to have had symptoms for at least 3 mo and to have failed to respond to standard therapies including: increased dietary fiber, reduction of lactose-containing foods, antispasmodics, simple laxatives (in those with predominant constipation), and opioids (in those with predominant diarrhea). Other physical disease was required to be absent or inactive. Formal psychiatric disease was an exclusion criterion. Patients were not permitted to use psychotropic drugs during the study period unless these had been commenced at least 3 mo before recruitment and were maintained at static dose throughout. Potentially fertile women were required to use effective contraception.

Normality of routine hematology, renal, hepatic and thyroid biochemistry, and of inflammatory markers was required. All subjects had a normal sigmoidoscopic examination within 3 mo of entry. Those over 40 years of age were required to have had colonoscopy, or flexible sigmoidoscopy and barium enema within 2 years of entry. All were given an information leaflet and were required to provide written informed consent.

Study methodology

The study was a double blind, sham-controlled trial of TCM acupuncture therapy. Two acupuncturists, fully trained in traditional Chinese acupuncture and accredited to the British Acupuncture Council, were responsible for the active and sham interventions. Recruited patients were allocated according to computer-generated random numbers concealed in sealed envelopes. Ten treatments were administered, at approximately 1-wk intervals.

Technical aspects of active and sham acupuncture

The first acupuncturist was the “diagnosing acupuncturist” (DA), whom the patient saw for the initial consultation, and before and after each treatment. A full case history was taken by the DA, together with tongue and pulse examination, to arrive at an individual diagnosis in accordance with the principles of TCM, with an additional lesser emphasis on Five Element Acupuncture^[11–14]. Although all patients in the study had IBS, this corresponded to a wide range of TCM patterns, making individual diagnosis essential. Dietary and lifestyle advice (important in treatment according to TCM principles) was given to all patients by the DA, who then selected acupuncture points.

The second “treating acupuncturist” (TA) opened the randomization envelope, and for the duration of the study remained the only individual aware of treatment allocation. The TA carried out the treatment—either according to instructions issued by the DA or using sham points, depending on the randomization.

In TCM meridian-based acupuncture the aim is to manipulate or remove blocking of the “Qi”. A variety of needling techniques is necessary, both to achieve requisite ‘deqi’ or ‘needling sensation’, and, subsequently, a range of therapeutic effects. Eight to sixteen needles were inserted at 4–8 specified acupuncture sites, bilaterally, in each session. Needles were left in place momentarily, or for up to 25 min,

depending on the desired effect. For active patients the TA implemented the instructions of the DA, including the needle technique, and the length of time of their retention.

‘Sham’ acupuncture points were chosen from three different areas on the body (the anterior thigh distally, the posterior thigh, and the lateral aspect of the lower back), which do not correspond to recognized acupuncture points and are deemed to have no therapeutic value. These were varied to some degree each week as in genuine treatment, including variation in needle technique and length of time of retention. No deqi needling sensation was sought or obtained at sham points.

Sterile single-use ‘Carbo’ brand needles were used (mostly 0.22 mm×25 mm, some 0.25 mm×40 mm). Insertion may be uncomfortable but is not normally painful (less discomfort than venepuncture). Needles were generally well tolerated, and were gently stimulated, as required, by the acupuncturist during treatment.

Moxibustion (therapeutic burning of the herb *Artemisia vulgaris*) is integral to the practice of traditional Chinese acupuncture, but was not used during the study, although there were a number of patients for whom it was considered indicated. This reflected hospital fire regulations and added difficulties with blinding.

The DA re-examined the patients’ pulses at the end of every session, as pulse changes during treatment are considered important indicators of efficacy. On the basis of these, and the verbal, pulse and tongue feedback at the start of the next session, the DA varied the emphasis on different treatment principles and the choice of acupuncture points prescribed for the next treatment.

Outcome measures and data analysis

Patients completed weekly symptom diaries, supplemented by psychological and quality of life scales at entry and at 12th wk (or prior exit). Therapeutic effects were judged from the diaries and questionnaires, and by physician assessment. The symptom diary is based on the Bristol scale^[15] and has been previously validated^[16]. It employs eight Likert scales relating to abdominal symptomatology and their interference with activities (Appendix), and permits the compilation of a numerical (non-linear) global “symptom score” between 0 and 30. Patients also completed the Hospital Anxiety and Depression (HAD) scale^[17], and the EuroQol^[18] quality of life questionnaire.

The principal outcome measure was a change in the symptom score. A reduction of four is considered indicative of a clinically useful response, and was expected from sham or placebo therapy in approximately 30% of eligible patients. Acupuncturists expect to obtain a useful response in around 70% of patients with IBS (informal enquiries of several practitioners), with the proviso that limitations imposed by the experimental protocol might reduce this a little.

Secondary outcome measures included assessment by one of the blinded investigators at the end of the study period, which made a simple categorization of patient status as “improved”, “unchanged” or “worse”. Secondary outcomes also included changes on the HAD and EuroQol instruments. As the principal objective is to reduce symptomatology and to improve quality of life, the patients’ perceptions of

these are the outcomes of critical interest to them. The end-points recorded are comparable to those utilized in respected studies of this condition.

Statistical calculations for 60 subjects provided for a study with 60% power to demonstrate a 30% numerical (not relative) difference between the two groups, if a placebo response of 30% is assumed. Results were analyzed by intention to treat.

Apart from the hospital notes all data were retained anonymously. The study complied with the requirements of the Declaration of Helsinki (1996 modification), the British Data Protection Act (1984), the International Conference on Harmonization Tripartite Guideline for Good Clinical Practice, and had approval from the Harrow Research Ethics Committee.

Patients

Sixty patients (40 female) were recruited; one female withdrew after recruitment but before randomization. Results are therefore recorded for 59 individuals (Table 1). Twenty-eight patients were allocated to acupuncturist A as the DA and to acupuncturist B as the TA, with the converse in the other 31. There was a good balancing of the two groups: for no parameter was there a statistically significant difference at study entry (Table 1).

Role of sponsors: None in either design of the study or in the writing of the report.

Table 1 Patient characteristics at study entry

	Acupuncture group	Sham group
Number	27	32
Number female	16	23
Mean age (yr)	43.0	44.4
Age range (yr)	19–67	17–79
Predominant symptom		
Pain	11	10
Bloating	7	11
Diarrhea	7	9
Constipation	2	2
Mean symptom score	13.5	13.1
Mean anxiety score (HAD)	10.2	11.2
Mean depression score (HAD)	5.8	6.8
Mean EuroQol LAS score (%)	59	64

HAD = hospital anxiety and depression scale. LAS = linear analog scale.

RESULTS

The mean global symptom score in the acupuncture-treated patients fell from 13.5 ± 4.51 to 11.6 ± 5.13 , and in the sham group from 13.1 ± 4.30 to 11.2 ± 4.17 ($P < 0.05$ for one-tailed t test for the improvements in both study groups) (Figure 1). A reduction in symptom score was observed in 16 acupuncture subjects (59.2%), and by at least four points in 11 (40.7%). The equivalent figures for the sham group were 21 (65.6%) and 10 (31.2%). The differences between sham and actively treated groups did not approach statistical significance.

The blinded clinician considered 13 of the acupuncture group (48.1%) improved, compared to 10 of the sham group (31.2%) (NS). These were predominantly the same patients who considered themselves improved (reduction in symptom score of four or more). Similar proportions in the two groups were considered to have deteriorated or had withdrawn (18.5% *vs* 21.9%; NS).

For those with pain predominance at enrollment the median score of 13 remained at 13 in the actively treated group, and fell from 15 to 10 in the sham group; for bloating the equivalent figures were 14 to 9, and 14 to 11; for diarrhea 11 to 8 compared to 11 to 10.5; and for constipation 16 to 15 *vs* 11 to 8.

There were no significant differences between the HAD scores for the sham and active groups, but a slightly higher proportion of the sham-treated group had anxiety scores in the “probable” (≥ 12) range (47% *vs* 41%). The response rate (drop of ≥ 4 symptom points) was 27% in the subset of anxious patients receiving sham treatment and 54% in those on active therapy (NS).

The EuroQol score rose slightly (improvement) in the actively treated (59.4–64.6%) and the sham treated (64.6–65.6%); neither change was significant. There was no correlation between initial EuroQol score and the likelihood of a response.

Acupuncturist A (as TA) treated 31 patients, of whom 19 were allocated to sham therapy. Their mean score of 13.6 ± 4.84 fell to 12.3 ± 4.56 ; the score fell by ≥ 4 in 7 (36.8%). In the 12 patients who received active acupuncture the mean score fell from 14.3 ± 4.68 to 11.6 ± 6.69 , with a fall of ≥ 4 in 6 (50%). Acupuncturist B (as TA) treated 28 patients of whom 13 were allocated to sham; the score fell by ≥ 4 in 3 (23.1%) of these. In the 15 patients randomized

Figure 1 Change in the global symptom score from entry to 13 wk. The upper panel shows the individual values for the actively treated patients and the lower

panel those for sham-treated patients.

to active acupuncture a “qualifying” fall in score occurred in 5 (33.3%). Overall 41.9% of patients “diagnosed” by acupuncturist B and “treated” by acupuncturist A responded with a qualifying fall in score, compared to 28.6% of those with the acupuncturists filling the alternative roles (NS).

Adverse events and non-completing patients

No direct adverse events were elicited. One patient was commenced on antidepressants after psychiatric consultation, and another on beta-blockers for anxiety. Six other patients failed to complete the study period. Of these eight withdrawals, five belonged to the acupuncture group and three to sham. These patients have been included in the above analyses by intention to treat. If the principal outcome measure is applied only to those completing the intended therapy the results are unchanged: the mean symptom score at completion of the acupuncture course was 11.4 compared to 10.9 in the sham group (NS).

DISCUSSION

As expected there was a response to TCM acupuncture and to sham treatment. The number of responding patients in the sham group and the magnitude of the responses were in line with our prior expectations (31.2% good responders compared to an anticipated 30% placebo response). The study group is therefore likely to be generally representative. Formal acupuncture failed to elicit significant advantage (40.7% responders). There were several areas in which numeric advantage lay with acupuncture, including the clinician’s assessment and the proportion achieving at least a four point reduction in symptom score, but sham therapy had the numeric advantage if responses of any degree of magnitude are included (65.6% *vs* 59.2%). There was no obvious trend according to predominant symptom at study entry, but initial anxiety possibly predicts a better response.

The inference that TCM acupuncture is of very limited value in IBS is supported by the absence of positive data in the literature, its absence from the conclusions of the NIH consensus^[4], and from a small study which showed no effect on colonic motility in constipation^[19]. We are confident that our sham technique was performed with retention of complete blinding of the DA, the gastroenterologist and the patient. This necessarily unblinded nature of the treating acupuncturist clearly had important effects on the two practitioners concerned, who felt uncomfortable “deliberately denying” the patient, a therapy in which they had confidence. It is possible that this proved a confounding factor. The close similarity of the outcome from sham therapy to that expected from placebo suggests that neither positive nor negative effects predominate. In consequence, it is not clear that anything would have been gained by the use of sham needles, as has been advocated^[20], since while this strategy has the potential to conceal sham administration from the TA it may unblind the patient. It is acknowledged that the use of sham needling probably elicits important physiological effects (such as increased endorphin activation), but the absence of an obvious difference in response rate in our sham group from that anticipated from “other” placebos indicates that the effect is not one of lasting clinical consequence.

The combination of acupuncturist B as diagnostician with acupuncturist A as acupuncturist appeared “better” than the converse. This was probably a direct consequence of the individualization of therapy (by the TA as well as that planned by the DA), but represents a post hoc and non-significant observation. We deliberately chose to permit both acupuncturists to engage in therapy so as to increase the generalizability of the study, hence avoiding results dependent on the consequences of a unique pairing of practitioners.

The outcome may have included systematic bias against acupuncture. The specific dietary and lifestyle advice considered important to TCM was given to all patients regardless of randomization. It is unlikely that this was a major influence as the sham response was closely similar to that expected for placebo. The proscription of moxibustion would be expected to have placed the actively treated group at a disadvantage compared to those treated outside the study context. However, this technique cannot easily be a practical proposition in health service premises in which fire regulations and the presence of smoke detectors are ubiquitous. The third factor potentially disadvantageous to acupuncture therapy was the impossibility of completely individualized therapy in a formal trial, and perhaps adverse influences from other constraints of the hospital environment. This drawback was considered carefully during the devising of the study and felt to be an acceptable compromise between Western scientific method and traditional Chinese practice. The possibility that simplified acupuncture as delivered by Western-medicine-trained acupuncturists might have given a different result is intriguing and may warrant further study.

The study was underpowered to demonstrate a small benefit, but it was of sufficient size to confirm the large difference that was anticipated. If such an effect has been missed by the present study it is our opinion that it is of insufficient clinical relevance to justify de novo investment in provision of acupuncture services to hospital patients with IBS.

ACKNOWLEDGMENTS

We are also grateful for the support of our research nurses, to the clinicians who referred patients to us, and to the patients themselves. We greatly appreciate the very useful comments of Dr. Andrew Thillainayagam, MD, FRCP (medically trained acupuncturist), on an earlier draft of the manuscript.

Abstract

AIM: To investigate the effects of adeno-associated virus (AAV) mediated expression of human interferon- γ for gene therapy in experimental hepatic fibrosis *in vitro* and *in vivo*.

METHODS: We constructed the recombinant AAV encoding human INF- γ (rAAV- INF- γ) and took the primary rat hepatic stellate cells and carbon tetrachloride induced rats as the experimental hepatic fibrosis model *in vitro* and *in vivo*. Immunocytochemistry analysis was used to reveal the expression of α -SMA, the marker protein expressed in hepatic stellate cells. The mRNA expression of TGF- β , TIMP-1, and MMP-13 were analyzed by RT-PCR method. *In vivo* study, the hydroxyproline content in liver and serum AST, ALT were also detected.

RESULTS: *In vitro* study, AAV vector could mediated efficient expression of human INF- γ , which inhibit the activation of hepatic stellate cells, decrease the expression of α -SMA and mRNA of TIMP-1, TGF- β , with the MMP-13 unchanged. *In vivo* study, the histological examination revealed that rAAV- INF- γ could inhibit the progression of the hepatic fibrosis. In the rAAV-INF- γ induced group, the hydroxyproline content and serum AST, ALT level were decreased to 177 ± 28 μ g/g wet liver, 668.5 ± 140.0 , 458.4 ± 123.5 U/L, compare with the fibrosis control group 236 ± 31 μ g/g wet liver, $1\ 019.1 \pm 276.3$, 770.5 ± 154.3 U/L, respectively ($P < 0.01$). mRNA expression of TIMP-1 in the rAAV-INF- γ induced rat liver was decreased while no significant change was observed in TGF- β and MMP-13.

CONCLUSION: All these results indicated that rAAV-INF- γ has potential effects for gene therapy of hepatic fibrosis, which could inhibit the progression of hepatic fibrosis.

INTRODUCTION

Liver fibrosis is a very common disease in China and other countries, it is a wound-healing response to chronic liver injury, results from viral hepatitis, ethanol and drug abuse, which if persistent can lead to cirrhosis or liver failure. The main feature of the fibrosis is the increased deposition of extracellular matrix (ECM) caused by activated hepatic stellate cells (HSCs, Ito cells or fat-storing cells)^[1,2].

In normal liver, HSCs undergo the quiescent state, contain retinoid lipid droplets and synthesize low levels of matrix proteins. But, as a result of liver injury, HSCs are in the process of activation, proliferate and transform to myofibroblast like cells. Activated HSCs are characterized by loss of retinoid, appearance of α -smooth muscle actin (α -SMA) and procollagen I, III, which are known to be the primary source of excess ECM deposited in liver fibrosis^[3-5]. Meanwhile, the balance between generation and degradation of ECM is broken, cytokines and proteases secreted by hepatocytes, Kupffer cells and leukocytes make up a complicated pathways enhance the activation of HSCs^[6,7]. Some growth factors such as transforming growth factor- β (TGF- β) is enhanced in both availability and activity, stimulate the transcription of procollagen, fibronectin and other ECM genes. Also effect of the matrix metalloproteinase (MMP-13), the key enzyme in the degradation of ECM, is decreased by over expression of its inhibitor, the tissue inhibitors of matrix metalloproteinase (TIMP-1). Furthermore, the accumulation of ECM in turn increase not only the number of HSCs but also their capacity to synthesize the matrix proteins, which ultimately results in cirrhosis^[1,3,5].

The interferons (INFs) are a family of cytokines with several crucial biological functions, such as antiviral and immunomodulatory activities, which have first been used in the treatment of chronic hepatitis. Among the INFs, INF- α and INF- β (INF type I) are widely used to treat hepatitis C virus (HCV) infection in clinics, whereas INF- γ (INF type II) has a 10-100 fold lower specific antiviral activity than

INF type I, but 100-10 000 times more immunomodulatory activities^[8,9]. Recently, more and more studies have shown that INF- γ could inhibit the proliferation and activation of HSCs, thus prevent the production of ECM and decrease the expression of procollagen and other cytokines^[10-12]. However the serum elimination half-life of INF- γ is only 2-3 h^[12]. To make the therapeutic concentration in target organ, administration of INF- γ through a subcutaneous route may results in a much higher level of INF- γ in the serum, which could cause the adverse effects of flu-like symptoms, leucopenia and mental depression^[13].

Therefore, vector mediated local INF- γ expression in the liver could expand the clinical use of INF- γ in hepatic fibrosis. In this study, the AAV was introduced as the delivery vector for gene therapy. AAV is a number of small single stranded DNA viruses of the genus *Dependovirus* in the Parvoviridae family. Not only is AAV non-pathogenic and of minimal immune responses, but it could also infect both dividing and terminally-differentiated cells with high efficiency, expressing the transgene for at least 6 mo. Moreover it has a broad range of host cells and tissues^[14-18]. We constructed the recombinant AAV coding human INF- γ and examined its potential effects for gene therapy of hepatic fibrosis *in vitro* and *in vivo*.

MATERIALS AND METHODS

Generation of recombinant AAV virion

The plasmid of AAV vector, rAAV-eGFP and packaging helper plasmids pAd, pAAD are kindly provided by Prof Rui-An Xu (University of Hong Kong, Genome Research Center). The recombinant plasmid rAAV-INF- γ contains a hybrid of the cytomegalovirus immediate-early enhancer and the chicken β -actin/rabbit β -globin promoter (CAG), inserted with the reporter gene, a 511bp *EcoRI/XhoI* fragment of complementary DNA (cDNA) encoding full-length human INF- γ . Also the woodchuck hepatitis B virus post-transcriptional regulatory element is inserted to boost expression levels (Figure 1).

Figure 1 Structure of recombinant plasmid AAV-INF- γ . Human INF- γ cDNA obtained from RT-PCR was cloned into AAV plasmid, which contains a CAG promoter, WPRE enhancer and BGH polyA.

To generate the rAAV virions, we cotransfect the recombinant plasmid AAV-INF- γ or AAV-eGFP and two packaging helper plasmids into HEK 293 cells (ATCC CRL 1573) by

calcium phosphate precipitate. The cells were harvested 60 h after transfection and lysed by incubating with 5 g/L deoxycholate in the presence of 50 U/mL benzonase (Sigma, St. Louis, MO, USA), then isolated the recombinant AAV particles by using heparin affinity column chromatography (Amersham, HiTrap). The titles of the rAAV-INF- γ and rAAV-eGFP preparations were determined by AAV Titration ELISA kit (Progen). The virions were stored at -80 °C before experimental use.

Primary cell culture of rat HSCs

Primary rat HSCs were extracted from Sprague-Dawley rat (450-550 g, Animal Center of China Pharmaceutical University, Nanjing, China) liver by sequential *in situ* perfusion with collagenase and pronase followed by density gradient centrifugation and then cultured in 20% FBS DMEM, maintained in a humidified 50 mL/L CO₂ incubator at 37 °C^[19,20]. Experiments described in this study were performed on HSCs between the second and ninth serial passages with highly activated cells as tested. HSCs were cultured in 10 cm culture plates at a density of 2×10^4 cells/cm². After changing the medium, HSCs were maintained in presence or absence of rAAV-INF- γ and rAAV-eGFP at 5×10^4 v.g./cell for 72 h, meanwhile collect the medium every 12 h to analysis the expression of human INF- γ by ELISA. Then HSCs were in preparation for RNA isolation and immunocytochemistry analysis.

ELISA assay of INF- γ

We used the ELISA kit (R&D systems) to quantitative determine the expression of human INF- γ in the cell culture supernatant. The antibody specific for human INF- γ has been pre-coated onto a microplate. Pipette the samples into the wells, any present INF- γ was bound by the immobilized antibody. Then washed away the unbound substances, an enzyme-linked antibody was added to the wells. After washing any unbound antibody-enzyme reagent, a substrate solution was added to the wells and color developed in proportion to the amount of INF- γ bound in the initial step. Finally, stop the reaction and determined the optical density of each well at 540 or 570 nm within 30 min.

Immunocytochemistry

HSCs were washed with PBS and fixed in the slides with 40 g/L phosphate buffered paraformaldehyde (PFA) at 4 °C for 20 min. Then eliminated endogenous peroxidase activity by adding 30 mL/L H₂O₂ in PBS at room temperature for 30 min to permeabilized and blocked with goat serum blocking solution at room temperature for 1 h. After blocking, cells were incubated with primary antibody, anti- α -SMA (diluted 1:200 in PBS, Sigma) at 4 °C overnight. Washed the slides thrice in PBS, incubated the cells with secondary antibody biotinylated anti-mouse IgG from goat for 30 min, washed five times and added the solution of avidin-biotin peroxidase. Incubating for 30 min, the cells were then stained with DAB (3,3'-diaminobenzidine tetrahydrochloride, Sigma) peroxidase substrate solution-brown and counterstained with hematoxylin (Sigma). Finally, dehydrate the slides, clear in xylene and coverslip with permanent mounting medium.

RNA extraction and RT-PCR

Total RNA was extracted from HSCs and snap-frozen liver tissue using TRIzol Reagent (Gibco BRL) according to the method of Chomczynski and Sacchi^[21]. Then 4 μ g RNA of each sample was used for cDNA synthesis using a RevertAid First Strand cDNA Synthesis Kit (Fermentas). The amplification was carried out with 1 μ L of synthesized cDNA in a 50 μ L PCR mixture containing 20 pmol of a primer pair, 1.5 mmol/L MgCl₂, 0.2 mmol/L dNTPs and 1 U of recombinant Taq DNA polymerase. In total, 30 cycles of the reaction were carried out at 95 °C for 1 min, 57 °C for 1 min and 72 °C for 2 min. The PCR products were electrophoresed on a 20 g/L agarose gel and stained with ethidium bromide. The primers used in this study are listed in Table 1. The density of the band was analyzed using a BIO-RAD Gel Doc 2 000 densitometer.

Animal model of hepatic fibrosis

Hepatic fibrosis was induced in male Sprague-Dawley rats (140-150 g) by carbon tetrachloride (CCl₄) administration^[22]. Animals were maintained on standard chow and water. A total of 48 rats administered 500 mL/L CCl₄ dissolved in olive oil at a dose of 1 mL CCl₄/kg body weight twice weekly (every Monday and Thursday) via gastrogavage for 8 wk. One group of six rats received olive oil as control. This method reproducibly results in early fibrosis within 3-4 wk, and advanced fibrosis by 6-8 wk^[23]. After 3 wk, six rats of CCl₄ treated and untreated group were killed for examination of hepatic fibrosis development. After 6 wk, the remaining model rats were injected via the hepatic portal vein with a single infusion of 500 μ L of either saline ($n = 8$), 3×10^{11} v.g./mL rAAV-INF- γ ($n = 8$), and 3×10^{11} v.g./mL rAAV-eGFP ($n = 8$). After 8 wk, all the rats were killed and the liver were fixed in 40 g/L PFA for histological examination or snap-frozen in liquid nitrogen in preparation for measurement of hydroxyproline and RNA isolation. Also the blood samples were taken immediately before the rats were sacrificed for biochemical analysis.

Histological examination

For light-microscopic examination, the fixed liver specimens were embedded in paraffin. Sections were cut at a thickness of 4 μ m and stained with hematoxylin-eosin for routine examination.

Measurement of hydroxyproline content

The liver tissue was finely minced and then homogenized in nine volumes of ice-cold PBS, hydrolyzed in HCl and the hydroxyproline content was determined by the method of Sakaida *et al.*^[24], with minor modifications.

Measurement of AST and ALT

Blood was collected from femoral artery, allow the samples to clot for 30 min before centrifugation for 10 min at 1 000 r/min. Remove serum for aspartate aminotransferase (AST) and alanine aminotransferase (ALT) determination.

Statistical analysis

The data presented are the mean \pm SD of each group. A statistical analysis was performed using the Student's *t* test, $P < 0.05$ was considered to be statistically significant.

RESULTS

Effect of recombinant AAV-INF- γ on the primary cultured HSCs

Freshly isolated HSCs could emit blue-green fluorescence, which is easily quenched, stimulated by radiation of 328 nm laser source. Five days after isolation, HSCs exhibited expanded cytoplasmic processes and enlarged nuclei corresponding to the intermediate stage of the activation process. After 10 d culture, HSCs could undergo a totally activated process.

To confirm that AAV-INF- γ was transcriptional active, total RNA of infected HSCs was isolated and examined by RT-PCR analysis. Human INF- γ mRNA transcripts were detected in HSCs infected with rAAV-INF- γ , but undetectable in sham-infected or rAAV-eGFP infected HSCs (Figure 2A). Also the expression and secretion of human INF- γ was next evaluated by ELISA. In the group of rAAV-eGFP infected HSCs, 24 h after infection, human INF- γ expression was 265 ± 67 pg/mL in the supernatant and its level reaches the peak value, $1\ 211 \pm 178$ pg/mL at 60 h after infection (Figure 2B).

Because α -SMA is the marker protein of activated HSCs, the immunocytochemistry examination was introduced to evaluate the effects of rAAV-INF- γ on activated HSCs. The results revealed that the expression of α -SMA was suppressed by supplementation with rAAV-INF- γ (Figure 3A-D).

Additionally, INF- γ has a notable feature of immunomodulatory activity, which could affect the cytokines and proteases expression in HSCs. The mRNA expression of TGF- β , MMP-13 and TIMP-1 between the activated HSCs and HSCs infected with rAAV-eGFP and rAAV-INF- γ were examined by RT-PCR method (Figure 4A). There was no significant difference in the mRNA expression between the untreated and rAAV-eGFP infected HSCs. But the levels of TGF- β and TIMP-1 mRNA were decreased in the rAAV-INF- γ infected HSCs, with an unchanged expression in MMP-13 in contrast to those two groups of HSCs (Figure 4 B).

Histology of CCl₄ induced hepatic fibrosis and AAV-INF- γ treatment

Histological analysis confirmed that CCl₄ could cause the

Table 1 Primer pairs for RT-PCR used in this study

Gene	Forward primer	Reverse primer
INF- γ	5'-CCGCTCGAGATGAAATATACAAGTTATATC-3'	5'-CGGAATCTTACTGGGATGCTCTTCGACC-3'
TGF- β	5'-CTTCAGCTCCACAGAGAAGAACTGC-3'	5'-CACGATCATGTTGGACAACCTGCTCC-3'

MMP-13	5'-TGACTATGCGTGGCTGGAA-3'	5'-AAGCTGAAATCTTGCCCTTGA-3'
GAPDH	5'-GTCAACGGATTGGCTCGTATT-3'	5'-AGTCTTCTGGGTGGCAGTGAT-3'

Figure 2 The expression of INF- γ in rAAV-INF- γ infected HSCs. **A:** RT-PCR analysis of INF- γ expression in rAAV-INF- γ infected HSCs. The untreated and rAAV-eGFP infected HSCs did not show any PCR band; **B:** Time course of the INF- γ expression in the HSC supernatants after rAAV-INF- γ infection. (Data are mean \pm SD, $n = 6$).

hepatic fibrosis. After 3 wk, the mature collagen fibrils bridging vascular structures were obviously presented in the CCl₄ treated group, showing a early stage of hepatic fibrosis (Figures 5 A and B). At the end of 8 wk, the saline and rAAV-eGFP treated model group revealed cirrhotic-like structural patterns: fibrous connective tissue components

in Glisson's sheath, pseudolobule formations and formation of fibrotic septa and thickened reticulin fibers joining central areas. In contrast, the rat liver that received rAAV-INF- γ showed only light bridging fibrosis and diminished fibrosis in both the periportal and centrilobular liver (Figures 5C-E).

Hydroxyproline content in liver

In collagen, 13.4% of total amino acid is hydroxyproline, whereas little content in elastin and inexistence in other proteins. So hydroxyproline content could reflect the collagen content in connective tissue. Determination of hydroxyproline content in different groups of rat liver confirmed the histological studies that hydroxyproline content in the rAAV-INF- γ treated group was significantly reduced to 177 ± 28 μ g/g wet liver, compare with the fibrosis control group 236 ± 31 μ g/g wet liver (Table 2).

Measurement of AST and ALT

The serum AST and ALT levels in the group of rats treated with CCl₄/saline and CCl₄/rAAV-eGFP were $1\,019.1 \pm 276.3$, 770.5 ± 154.3 U/L and 985.4 ± 241.6 , 727.2 ± 175.0 U/L, respectively. No significant difference was observed between those two groups. In contrast to the CCl₄/saline control group, the serum AST and ALT level of CCl₄/rAAV-INF- γ treated rats were reduced to 668.5 ± 140.0 , 458.4 ± 123.5 U/L, suggesting that the INF- γ gene expression inhibited the hepatic toxicity caused by CCl₄ (Table 2).

mRNA expression of TGF- β , TIMP-1, and MMP-13 in the liver

The mRNA expression of TGF- β , MMP-13 and TIMP-1 between the control group and the group induced with rAAV-INF- γ were analyzed by RT-PCR method (Figure 6A). There was a similar result between the *in vivo* and *in vitro*

study, with one difference that mRNA expression of TGF- β were unchanged in three groups of rat liver (Figure 6B).

DISCUSSION

Liver fibrosis is reversible, whereas cirrhosis, the end stage consequence of fibrosis, is generally irreversible. Thus, efforts

to understand fibrosis may focus primarily on events that lead to the early accumulation of ECM in hopes of identifying therapeutic targets to slow its progression^[25,26]. Endogenous INF- γ is a lymphokine produced by natural killer cells and T lymphocytes, which plays a central role in the control of the immune response. It is also known for its regulatory effects on collagen synthesis. Tissue repair is characterized

Table 2 Serum markers of hepatic fibrosis and damage

	Number	Hydroxyproline ($\mu\text{g/g}$ wet liver)	AST (U/L)	ALT (U/L)
No treatment	6	96 \pm 11	76.3 \pm 6.3	53.0 \pm 6.9
CCl ₄ (3 wk)	6	162 \pm 14	561.2 \pm 81.4	358.0 \pm 85.4
CCl ₄ /Saline	8	236 \pm 31	1 019.1 \pm 276.3	770.5 \pm 154.3
CCl ₄ /rAAV-eGFP	8	249 \pm 37	985.4 \pm 241.6	727.2 \pm 175.0
CCl ₄ /rAAV-INF- γ	8	177 \pm 28 ¹	668.5 \pm 140.0 ²	458.4 \pm 123.5 ³

Hydroxyproline content and serum AST, ALT are shown with mean \pm SD for each group. There are no significant differences between group of CCl₄/saline and CCl₄/rAAV-eGFP in all three markers. The group of CCl₄/rAAV-INF- γ vs CCl₄/saline: ¹ $P = 0.0015$; ² $P = 0.0064$; ³ $P = 0.0032$.

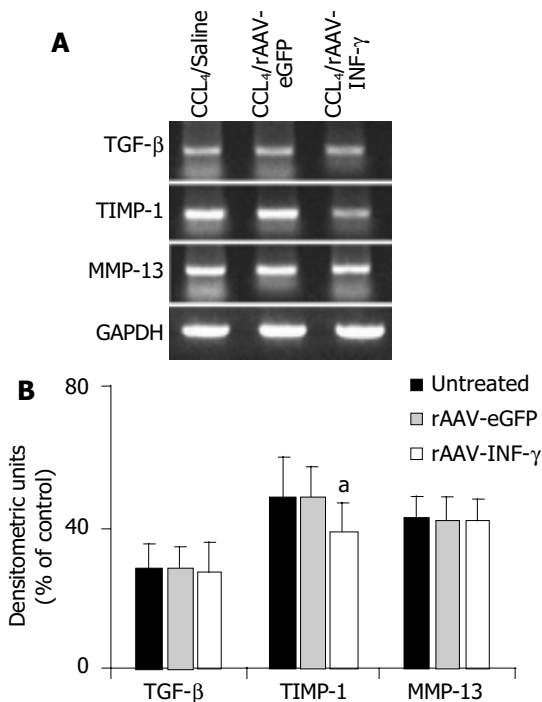

Figure 6 The mRNA expression of fibrosis related cytokines and proteases in different group of rat liver. **A:** mRNA expressions of TGF- β , MMP-13 and TIMP-1 in the rat liver were examined by RT-PCR method; **B:** Densitometric units were calculated by dividing the density of individual bands by that of GAPDH. by infiltration of inflammatory, immune and mesenchymal cells in injured areas accompanied by release of cytokines, followed proliferation of mesenchymal cells involved in synthesis and deposition of collagen. The effects of INF- γ on collagen production have been the objects of a number of studies suggest that INF- γ acts as an endogenous mediator reducing collagen synthesis^[27,28].

In this study, rAAV-INF- γ could infect the primary cultured HSCs effectively. The expression of INF- γ reached the peak level, 1 211 \pm 178 pg/ml, at 60 h after infection with 5 \times 10⁴ v.g./cell rAAV-INF- γ . α -SMA expression and mRNA of TGF- β , TIMP-1 were down regulated with the expression of INF- γ , attenuated the HSCs activation and proliferation *in vitro*. Also, rAAV-INF- γ could inhibit the development of experimental hepatic fibrosis induced by CCl₄ administration *in vivo*, though it seemed hard to reverse it. The histology results revealed that hepatic fibrosis rats treated with rAAV-INF- γ showed light fibrosis compared with the control groups. In the rAAV-INF- γ induced group,

the hydroxyproline content and serum AST, ALT level were decreased to 177 \pm 28 $\mu\text{g/g}$ wet liver, 668.5 \pm 140.0, 458.4 \pm 123.5 U/L, compare with the fibrosis control group 236 \pm 31 $\mu\text{g/g}$ wet liver, 1 019.1 \pm 276.3, 770.5 \pm 154.3 U/L, respectively ($P < 0.01$). mRNA expression of TIMP-1 in the rAAV-INF- γ induced rat liver was decreased while no significant change was observed in TGF- β and MMP-13.

There is a difference between *in vitro* and *in vivo* study, expression of TGF- β mRNA was inhibited in HSCs infected with rAAV-INF- γ , but keeps unchanged in AAV-INF- γ treated rat liver compare with the control group. TGF- β is the important mediator involved in the transdifferentiation of HSCs from quiescent to activated phenotypes and biosynthesis of collagens type I, resulting in production of ECM^[29]. In liver, Kupffer cells are another main source of TGF- β besides HSCs. Since INF- γ could also activate macrophages including Kupffer cells, the total effect of INF- γ in liver does not change the mRNA expression of TGF- β ^[30]. Thus the protein production and receptor expression of TGF- β should be investigated to make a more elaborate description of the change about TGF- β modulated by INF- γ .

The majority of clinical use of INF- γ up to date has been conducted with subcutaneous route of purified recombinant INF- γ protein. The cost of standard INF- γ regimen is very expensive that limits its access to the patients. So gene therapy appears to be the more powerful strategy than other forms in gene therapy of hepatic fibrosis. Potential advantages of gene therapy are sustained expression of transgene and highly localized delivery within a single injection. The advantages of localized vector delivery are obvious because it can induce a high level of transgenic proteins *in situ* to achieve potential efficient activity and reduce adverse effects compared with systemic delivery. In recent studies, several gene delivery systems were reported for gene therapy targeting the liver disease. Adenoviruses are the vectors used most commonly for gene therapy, but its effective host immune response and the toxic/anaphylactic reaction limits its clinical use^[31-32]. Protzer *et al.*^[33] demonstrated that INF gene transfer by the hepatitis B virus vector efficiently suppressed wild-type virus infection, however the gene transfer efficiency in the liver is comparatively low. Compare with those two vectors, AAV vectors have little immunogenicity and far higher transfer efficiency. Furthermore, AAV vectors can mediate the long-term *in vivo* expression in host cells, with persistent expression up to 6 mo^[18,34,35]. Actually, the human clinical trials for cystic fibrosis and for hemophilia B have been enrolling patients

since 1996 and 1999, respectively, via recombinant AAV vectors. While comprehensive reviews exist of the current scope of clinical conditions for AAV vectors are being developed, it is likely that clinical trials involving delivery to the liver will commence in the near future^[15].

Taking all these results together, rAAV-INF- γ has potential effects for gene therapy of hepatic fibrosis. We believe that this system could now be applied in clinical trials, though we must continue to explore critical pre-clinical evaluation of risks in the age of clinical trials.

Abstract

AIM: This study investigated the mechanisms of protection afforded by the proton pump inhibitor lansoprazole against gastric injury induced by different non-steroidal anti-inflammatory drugs (NSAIDs) in rats.

METHODS: Male Sprague-Dawley rats were orally treated with indomethacin (100 $\mu\text{mol/kg}$), diclofenac (60 $\mu\text{mol/kg}$), piroxicam (150 $\mu\text{mol/kg}$) or ketoprofen (150 $\mu\text{mol/kg}$). Thirty minutes before NSAIDs, animals were orally treated with lansoprazole 18 or 90 $\mu\text{mol/kg}$. Four hours after the end of treatments, the following parameters were assessed: gastric mucosal PGE₂, malondialdehyde (MDA), myeloperoxidase (MPO) or non-proteinic sulfhydryl compounds (GSH) levels; reverse transcription-polymerase chain reaction (RT-PCR) of mucosal COX-2 mRNA; gastric acid secretion in pylorus-ligated animals; *in vitro* effects of lansoprazole (1-300 $\mu\text{mol/L}$) on the oxidation of low density lipoproteins (LDLs) induced by copper sulphate.

RESULTS: All NSAIDs elicited mucosal necrotic lesions which were associated with neutrophil infiltration and reduction of PGE₂ levels. Increments of MPO and MDA contents, as well as a decrease in GSH levels were detected in the gastric mucosa of indomethacin- or piroxicam-treated animals. Indomethacin enhanced mucosal cyclooxygenase-2 expression, while not affecting cyclooxygenase-1. At the oral dose of 18 $\mu\text{mol/kg}$ lansoprazole partly counteracted diclofenac-induced mucosal damage, whereas at 90 $\mu\text{mol/kg}$ it markedly prevented injuries evoked by all test NSAIDs. Lansoprazole at 90 $\mu\text{mol/kg}$ reversed also the effects of NSAIDs on

MPO, MDA and GSH mucosal contents, without interfering with the decrease in PGE₂ levels or indomethacin-induced cyclooxygenase-2 expression. However, both lansoprazole doses markedly inhibited acid secretion in pylorus-ligated rats. Lansoprazole concentration-dependently reduced the oxidation of LDLs *in vitro*.

CONCLUSION: These results suggest that, besides the inhibition of acid secretion, lansoprazole protection against NSAID-induced gastric damage depends on a reduction in mucosal oxidative injury, which is also responsible for an increment of sulfhydryl radical bioavailability. It is also suggested that lansoprazole does not influence the down-regulation of gastric prostaglandin production associated with NSAID treatment.

INTRODUCTION

Non-steroidal anti-inflammatory drugs (NSAIDs) are among the most commonly prescribed drugs due to their high efficacy in the treatment of pain, fever and inflammation. However, the use of these drugs is associated with the occurrence of adverse digestive effects, consisting most notably of gastric erosions, ulceration, bleeding and perforation^[1]. It is widely accepted that both the beneficial and detrimental effects of NSAIDs are attributable to their ability to inhibit prostaglandin synthesis through a direct blockade of cyclooxygenase (COX)^[2]. In particular, the sequelae of suppressed prostaglandin production, which may contribute to the pathogenesis of gastroduodenal ulceration, include a decrease in mucus synthesis and secretion of mucus, an inhibition of bicarbonate secretion, a reduction of mucosal blood flow, an alteration of microvascular structure and an increase in acid and pepsinogen secretion^[1,3].

The pathogenesis of NSAID-induced gastrointestinal

damage may also depend on prostaglandin-independent mechanisms, such as uncoupling of oxidative phosphorylation, alterations of mucosal cell turnover as well as neutrophil activation followed by enhanced endothelial adhesion^[1,4]. These mechanisms, in combination with those related to prostaglandin suppression, lead to microvessel occlusion and subsequent hyperproduction of reactive oxygen metabolites. Such substances are then able to induce oxidative tissue injury which seems to play a prominent role in the development of mucosal ulceration caused by NSAIDs^[3,5].

The impairment of mucosal defence allows gastric acid to cause injury. Therefore, gastric acid is regarded as a pivotal step in the pathogenesis of gastroduodenal ulceration, and acid suppression is viewed as a main option in the treatment of NSAID-induced mucosal damage^[6]. For these reasons, proton pump inhibitors (PPIs), including lansoprazole and other related compounds, have been investigated in clinical studies in patients under treatment with NSAIDs, and proven to be effective in both prevention and healing of NSAID-induced gastric lesions^[7]. Indeed, PPIs can markedly reduce gastric acidity through the blockade of H⁺, K⁺-ATPase, the enzyme responsible for the final step in the secretion of hydrochloric acid by parietal cells^[8]. However, there is also evidence to suggest that these drugs can activate gastric protective mechanisms independent of acid reduction^[9,10]. For instance, in previous studies omeprazole and lansoprazole prevented gastric injury elicited by acidified ethanol or hemorrhagic shock through an enhancement of mucosal defence^[9].

At present, a large variety of endogenous factors, including prostaglandins, growth factors, digestive hormones, sensory peptides, nitric oxide, and sulfhydryl compounds, has been implicated in the mechanisms through which gastric mucosa counteracts ulcerative stimuli^[11], and some of these factors have been proposed to account for the gastroprotective effects of PPIs^[9,10]. Nevertheless, the possible contribution of acid-independent mechanisms to the protective effects of these drugs against NSAID-induced gastric injury remains to be clarified. Overall, the present study was designed to: (1) examine the influence of lansoprazole on gastric mucosal damage induced by different NSAIDs; (2) evaluate to what extent factors and mechanisms related to gastric mucosal defence are involved in the protective actions of lansoprazole; (3) assess whether lansoprazole is endowed with direct antioxidant properties.

MATERIALS AND METHODS

Animals and experimental design

Albino male Wistar rats, with 200–220 g body weight, were used throughout the study. They were fed standard laboratory chow and tap water *ad libitum* and were not used for at least one week after their delivery to the laboratory. The animals were housed, four in a cage, in temperature-controlled rooms on a 12-h light cycle at 22–24 °C and 50–60% relative humidity. They were deprived of food 24 h before the experiment. However, free access to water *ad libitum* was allowed until 1 h before the beginning of experiments. Experiments were performed in accordance with the provisions of the European Community (EC)

Council Directive 86-609, recognized and adopted by the Italian Government.

In experiments on gastroprotection, lansoprazole (18 or 90 µmol/kg) or its vehicle was administered by intragastric gavage. The following NSAIDs, which are associated with moderate to high levels of risk for gastric injury in clinical settings^[4], were then administered by intragastric gavage at doses known to induce gastric lesions in rats: indomethacin (100 µmol/kg^[12]), diclofenac (60 µmol/kg^[13]), piroxicam (150 µmol/kg^[14]), and ketoprofen (150 µmol/kg^[15]). In all cases, a 30 min interval was allowed between lansoprazole and NSAID administration. Four hours after treatment with NSAIDs, the animals were sacrificed by cervical dislocation, their stomachs were rapidly removed and processed for the evaluation of the following parameters: (1) histomorphometric analysis of gastric mucosal damage; (2) quantitative estimation of mucosal inflammatory activity; (3) assay of malondialdehyde (MDA), non-proteinic sulfhydryl compounds and prostaglandin E₂ (PGE₂) in the mucosal layer; (4) assessment of mucosal expression of COX isoforms (COX-1, COX-2).

In an additional set of experiments, the effects of lansoprazole (18 or 90 µmol/kg) or its vehicle were assayed on gastric acid secretion in rats subjected to pylorus ligation. Dose levels of lansoprazole were selected on the basis of previous studies in rat models of gastric injury, showing that this PPI exerted maximal protective actions at 90 µmol/kg^[9].

Animals subjected to NSAID-induced gastric mucosal damage

Histomorphometric evaluation of gastric mucosal damage The histomorphometric estimation of gastric mucosal damage was carried out as previously described^[16]. Briefly, the stomach was opened along the greater curvature, gently washed with saline (154 mmol/L NaCl), pinned upon a cork plate with the mucosal surface turned upwards, and fixed in 10% formalin buffered with phosphate for 24 h at 4 °C. Each stomach was dissected in parallel strips perpendicular to the lesser curvature at a distance of 2 mm. The strips from each stomach were sequentially placed on a glass slide and oriented with the side of each strip distal to the pylorus upwards. A solution of melted 3% agar was gently poured on the strips and quickly cooled at 4 °C to induce solidification. The agar block was then removed from the glass slide, dehydrated, and embedded in paraffin wax. Three micrometers thick paraffin sections were cut using a microtome and stained with hematoxylin and eosin. Sections were examined by light microscopy and the length of both total and damaged mucosa was evaluated by means of a micrometric scale. The lesion index was estimated as the length fraction of damaged mucosa over the total length of mucosa, and expressed in percentage values.

Determination of mucosal myeloperoxidase content Myeloperoxidase (MPO) was assayed as previously reported by Pacheco *et al.*^[17], and assumed as a quantitative index to estimate the degree of mucosal infiltration by polymorphonuclear cells elicited by treatment with test NSAIDs. Briefly, specimens of mucosa were rapidly scraped from the underlying tissue layers of gastric wall using two glass slides kept cold on ice. Mucosal samples (300 mg) were homogenized 3 times (30 s each) at 4 °C with a polytron homogenizer (Cole Parmer Homogenizer, Vernon Hills,

IL, USA) in 1 mL of ice-cold 50 mmol/L phosphate buffer (pH 6.0) containing 0.5% of hexadecyltrimethylammonium bromide to prevent the pseudoperoxidase activity of hemoglobin as well as to solubilize membrane-bound MPO. The homogenate was sonicated for 10 s, frozen-thawed 3 times and spun by centrifugation for 20 min at 18 000 *g*. The supernatant was then recovered and used for determination of MPO concentration by means of enzyme-linked immunosorbent assay (ELISA) (Bioxytech, Oxis International Inc., Portland, OR, USA). All samples were assayed within 2 d after collection. The results were expressed as ng of MPO per 100 mg of gastric mucosa.

Quantitative evaluation of mucosal oxidative damage

MDA concentrations in samples of gastric mucosa were determined to obtain quantitative estimations of membrane lipid peroxidation evoked by test NSAIDs. For this purpose, specimens of mucosa were scraped from the underlying tissue layers of gastric wall using two glass slides kept cold on ice. The mucosa was weighed, minced by forceps, homogenized in 2 mL of cold buffer (Tris-HCl 20 mmol/L, pH 7.4) using a polytron homogenizer (Cole Parmer Homogenizer), and spun by centrifugation at 1 500 *g* for 10 min at 4 °C. Aliquots of supernatants were then used for subsequent assay procedures. Mucosal MDA concentrations were estimated by colorimetric assay (Calbiochem-Novabiochem Corporation, San Diego, CA, USA), and the results were expressed as nmol of MDA per milligram of gastric mucosa.

Assay of sulfhydryl compounds in gastric mucosa The concentrations of reduced glutathione (GSH) in specimens of gastric mucosa were determined to estimate the tissue content of non-proteinic sulfhydryl compounds^[18]. For this purpose, samples of mucosa were scraped from the underlying layers of gastric wall using two glass slides kept cold on ice. The scraped mucosa was weighed, minced by forceps, homogenized in 2 mL of cold buffer [0.4 mol/L 2-(N-morpholino)-ethanesulfonic acid, 0.1 mol/L phosphate, and 2 mmol/L ethylenediaminetetraacetic acid (EDTA), pH 6] using a polytron homogenizer (Cole Parmer Homogenizer), and spun by centrifugation at 10 000 *r/min* for 15 min at 4 °C. Aliquots of supernatants were deproteinized by a solution containing 1.25 mol/L metaphosphoric acid and 4 mol/L triethanolamine, to avoid interferences due to particulate components or proteinic sulfhydryl groups, and then used for the subsequent assay procedures. Gastric mucosal levels of GSH were determined by enzyme colorimetric assay (Cayman Chemicals, Ann Arbor, MI, USA), and the results were expressed as nmol of GSH per milligram of gastric mucosa.

Assay of PGE₂ in gastric mucosa

Enzyme immunoassay of PGE₂ in gastric mucosa was performed by means of a commercial kit (Cayman Chemical Company, Ann Arbor, MI, USA). Briefly, specimens of mucosa were rapidly scraped from the underlying tissue layers of gastric wall using two glass slides kept cold on ice. The mucosa was weighed, minced by forceps, and homogenized in 1 mL of cold phosphate buffer (PBS 0.1 mol/L, pH 7.4, containing 1 mmol/L EDTA and 10 µmol/L indomethacin) per gram of tissue using a polytron

homogenizer (Cole Parmer Homogenizer, Vernon Hills, IL, USA). The resulting homogenate was added with an equal volume of absolute ethanol, and stirred with vortex. After 5-min incubation at room temperature, the homogenate was spun by centrifugation at 1 500 *r/min* for 10 min at 4 °C. The supernatant was added with 1 mol/L HCl until pH 4. Before the assay, samples were subjected to purification by means of superclean LC-18 SPE columns (Sigma Co., St. Louis, MO, USA). For this purpose, 0.5 mL of sample was added to 2 mL of ethanol and vortexed. After incubation at room temperature for 5 min, the sample was spun by centrifugation at 3 000 *r/min* for 10 min. The supernatant was then removed and applied to the LC-18 SPE column which was previously activated with 5 mL of methanol and then with 5 mL of ultrapure water. The column was subsequently washed with 5 mL of ultrapure water and 5 mL of hexane. PGE₂ was then eluted with 5 mL of ethyl acetate containing 1% methanol. The eluted ethyl acetate fractions were collected and evaporated to dryness with nitrogen. Aliquots were then used for subsequent enzyme immunoassay. PGE₂ concentration was expressed as nanogram per gram of mucosal tissue.

Western blot assay of COX-1 and COX-2 in gastric mucosa

Specimens of mucosa were scraped from the underlying tissue layers of gastric wall using two glass slides kept cold on ice. Mucosal samples were weighed and homogenized in lysis buffer containing: HEPES 10 mmol/L, NaCl 30 mmol/L, EDTA 0.2 mmol/L, phenylmethylsulfonyl fluoride 2 mmol/L, leupeptin 10 µg/mL, aprotinin 10 µg/mL, sodium fluoride 1 mmol/L, sodium orthovanadate 1 mmol/L, glycerol 2%, MgCl₂ 0.3 mmol/L, and Triton-X 100 1%, using the polytron homogenizer. Mucosal homogenates were spun by centrifugation at 20 000 *g* for 15 min at 4 °C, and the resulting supernatants were then separated from pellets and stored at -80 °C. Protein concentration was determined in each sample by the Bradford method (Protein Assay kit, Bio-Rad, Hercules, CA, USA). To perform Western blot analysis of COX-1 and COX-2, equivalent amounts of protein lysates (50 µg) were separated by electrophoresis on sodium dodecylsulfate polyacrylamide gel (8%) and transferred onto a nitrocellulose membrane. The blots were then blocked overnight with 5% non-fat dried milk in phosphate buffered saline, and incubated overnight at room temperature with goat polyclonal antiserum raised against rat COX-1 or COX-2 (dilution 1:1 000). After repeated washings with 0.1% Tween-20 in Tris-buffered saline, a peroxidase-conjugated rabbit anti-goat antibody (dilution 1:10 000) was added for 1 h at room temperature. After repeated washings with 0.1% Tween-20 in Tris-buffered saline, the immunoreactive bands were visualized by enhanced chemiluminescence (ECL, Amersham Biosciences Europe GmbH, Cologno Monzese, Italy). The relative expression of COX-1 or COX-2 was quantified by densitometric analysis with NIH Image computer program (Scion Corporation, USA).

Animals subjected to pylorus ligation

Pylorus ligation was carried out as previously described^[19]. Briefly, during a short anesthesia with diethyl ether, the

abdomen was opened by a midline laparotomy and the duodenum was exteriorized. Then, lansoprazole (18 or 90 $\mu\text{mol/kg}$) or its vehicle was directly injected into the distal portion of duodenum by means of a 25-gauge needle, the pylorus was ligated, the abdominal incision was closed with clips, and the animals were allowed to recover from anesthesia for 10 min. Two hours after pylorus ligation, the esophageal-gastric junction was ligated, and the whole stomach was excised. The gastric content was emptied, carefully collected in graduated centrifuge tubes, and spun by centrifugation at 3 000 r/min for 10 min. Samples with more than 0.5 mL of sediment were discarded. The level of acidity was measured by automatic potentiometric titration to pH 7.0 with 0.01 mol/L NaOH, using an Autotitrator pH Meter PHM82 (Radiometer, Copenhagen, Denmark), and evaluated as H^+ output. The effect of lansoprazole was expressed as $\mu\text{EqH}^+ / 2 \text{ h}$.

In vitro assay of antioxidant activity of lansoprazole

To evaluate whether lansoprazole is endowed with direct antioxidant properties, the drug was incubated in a reaction mixture where human native low density lipoproteins (LDLs) were subjected to oxidation upon exposure to CuSO_4 at 37 °C for 120 min, in accordance with a standardized method^[20]. Lansoprazole was assayed at concentrations ranging from 1 to 300 $\mu\text{mol/L}$. The reaction mixture consisted of 2 mL of a phosphate buffer (10 mmol/L $\text{KH}_2\text{PO}_4/\text{K}_2\text{HPO}_4$, pH 5.3) containing LDLs 150 $\mu\text{g/mL}$ and CuSO_4 1 $\mu\text{mol/L}$. At the end of incubation, the oxidative reaction was stopped by addition of butyldihydroxytoluene 0.5 mol/L in acetonitrile, and the extent of LDL oxidation was estimated by measurement of 8-iso-prostaglandin $\text{F}_{2\alpha}$ (8-iso-PGF $_{2\alpha}$) concentrations. For this purpose, 100- μL aliquots of the reaction mixture were used to assay 8-iso-PGF $_{2\alpha}$ by means of a commercial kit for competitive enzyme-linked immunoassay (Cayman Chemicals, Ann Arbor, MI, USA). The results were expressed as pg of 8-iso-PGF $_{2\alpha}$ per mL.

Statistical analysis

The results are given as mean \pm SE. The statistical significance of data was evaluated by one-way analysis of variance (ANOVA) followed by *post hoc* analysis by Student-Newman-Keuls test, and *P* values lower than 0.05 were considered significant; “n” indicates the number of experiments. All statistical procedures were performed by personal computer programs. **Drugs** The following drugs and reagents were used: indomethacin, ketoprofen, diclofenac, piroxicam, human native low density lipoproteins, butyldihydroxytoluene, HEPES, EDTA, phenylmethylsulphonyl fluoride, leupeptin, aprotinin, sodium orthovanadate, glycerol, Triton-X, Tween-20, sodium dodecylsulfate, hexadecyltrimethylammonium bromide (Sigma Chemicals Co., St. Louis, MO, USA); lansoprazole (kindly provided by Takeda Italia Farmaceutici, Rome, Italy); diethyl ether (Mallinckrodt Baker BV, Deventer, The Netherlands); polyacrylamide (Bio-Rad, Hercules, CA, USA); goat anti-rat COX-1 and COX-2 antibodies, peroxidase-conjugated rabbit anti-goat antibody (Santa Cruz Biotechnology Inc., Santa Cruz, CA, USA). Other reagents were of analytical grade. Lansoprazole and

test NSAIDs were suspended in 1% methocel and administered in a volume of 0.5 mL.

RESULTS

Animals subjected to NSAID-induced gastric mucosal damage

Effects of lansoprazole on gastric mucosal damage induced by NSAIDs Intragastric administration of test NSAIDs caused various degrees of macroscopically evident mucosal damage (not shown). Histological examination of gastric sections showed that treatment with test NSAIDs elicited necrotic mucosal lesions associated with widespread areas of infiltration by polymorphonuclear cells in the upper part of the submucosal layer and the lower part of mucosa (Figure 1). Histomorphometric analysis of gastric tissue revealed negligible lesions of surface epithelium in control animals, as well as those receiving lansoprazole alone, with a total damage accounting for $(0.27 \pm 0.12)\%$ (control), $(0.18 \pm 0.11)\%$ (lansoprazole 18 $\mu\text{mol/kg}$) and $(0.09 \pm 0.03)\%$ (lansoprazole 90 $\mu\text{mol/kg}$). By contrast, in animals treated with indomethacin, diclofenac, piroxicam or ketoprofen, histomorphometry displayed a necrotic damage affecting $(6.38 \pm 0.32)\%$, $(4.48 \pm 0.26)\%$, $(6.43 \pm 0.54)\%$, and $(5.62 \pm 0.39)\%$ of gastric mucosa, respectively (Figure 2). Under these conditions, pretreatment with lansoprazole (90 $\mu\text{mol/kg}$) caused marked reductions of NSAID-induced gastric mucosal injury (Figure 2), which was associated with a concomitant decrease in the degree of infiltration by polymorphonuclear cells (Figure 1). When assayed at the dose of 18 $\mu\text{mol/kg}$, lansoprazole exerted a slight influence on NSAID-induced mucosal damage, achieving a level of statistical significance only in animals exposed to diclofenac (Figure 2).

Figure 1 H&E-stained sections of rat gastric mucosa. A, treatment with indomethacin 100 $\mu\text{mol/kg}$; A: severe lesion with necrosis of gastric mucosa; B: several polymorphonuclear cells can be detected (arrows); C and D: Rats treated with lansoprazole 90 $\mu\text{mol/kg}$ plus indomethacin 100 $\mu\text{mol/kg}$; C: less severe lesion with lysis of mucosal cells; D: few polymorphonuclear cells can be evidenced (arrows). A and C: original magnification 100x; bar = 150 μm . B and D: original magnification 170x; bar = 60 μm .

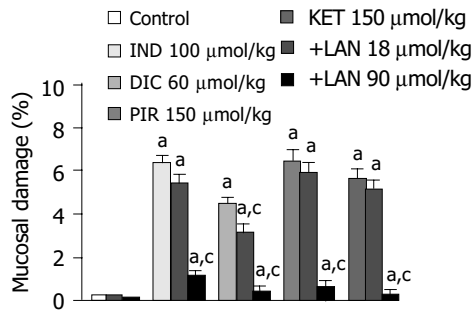

Figure 2 Histomorphometric evaluation of gastric mucosal damage in rats subjected to intragastric administration of indomethacin (IND, 100 μmol/kg), diclofenac (DIC, 60 μmol/kg), piroxicam (PIR, 150 μmol/kg) or ketoprofen (KET, 150 μmol/kg) either alone or in the presence of lansoprazole (LAN, 18 and 90 μmol/kg). Each column indicates the mean value obtained from 6-8 animals±SE (vertical lines). **P*<0.05 vs control values; ^c*P*<0.05 between the respective values obtained in animals treated with a test NSAID alone.

Assay of MPO, MDA, and GSH in gastric mucosa

MPO levels in the gastric mucosa of control animals were 3.57 ± 0.78 ng/100 mg, and this value was not significantly affected by treatment with lansoprazole alone (90 nmol/kg). In this set of experiments, indomethacin, and piroxicam induced marked increments of mucosal MPO concentrations (+116.8% and +131.1%, respectively), which no longer occurred after pretreatment of animals with lansoprazole (Figure 3A).

MDA levels in the gastric mucosa of control rats were 5.6 ± 1.4 nmol/mg tissue. Lansoprazole alone (90 μmol/kg) did not influence basal MDA concentrations. Treatment with indomethacin or piroxicam caused a significant increase in mucosal MDA concentrations (+148.2% and +112.5%, respectively), and pretreatment with lansoprazole significantly prevented the tissue accumulation of MDA promoted by test NSAIDs (Figure 3B).

In control animals, mucosal GSH levels reached 0.064 ± 0.006 nmol/mg. Under these conditions, lansoprazole alone (90 μmol/kg) did not significantly affect the mucosal concentration of endogenous sulfhydryl compounds. Treatment with indomethacin or piroxicam elicited a significant reduction of mucosal GSH levels (-70.3% and -79.7%, respectively). However, the decrease in gastric GSH concentration caused

by test NSAIDs no longer occurred upon pretreatment of animals with lansoprazole (Figure 3C).

Assay of PGE2 in gastric mucosa

Basal PGE2 levels in the gastric mucosa of control animals accounted for 151.9 ± 13.3 ng/g, this value being not significantly affected by administration of lansoprazole alone (90 μmol/kg). All test NSAIDs caused a significant reduction in mucosal PGE2 levels. Marked inhibitory effects were observed in animals treated with indomethacin, piroxicam and ketoprofen (-74.8%, -79% and -86.6%, respectively), whereas a moderate inhibitory action could be detected in diclofenac-treated rats (-48.4%). Pretreatment with lansoprazole did not significantly interfere with the inhibitory actions of test NSAIDs on mucosal PGE2 production (Figure 4).

Figure 4 PGE2 levels in the gastric mucosa of rats treated with indomethacin (IND, 100 μmol/kg), diclofenac (DIC, 60 μmol/kg), piroxicam (PIR, 150 μmol/kg) or ketoprofen (KET, 150 μmol/kg), either alone or in the presence of lansoprazole (LAN, 90 μmol/kg). Each column represents the mean value obtained from 6 to 8 animals±SE (vertical lines). **P*<0.05 vs control values; ^c*P*<0.05 between the respective values obtained in animals treated with a test NSAID alone.

Western blot assay of COX-1 and COX-2 in gastric mucosa

The protein expression of COX isoforms was evaluated by Western blot analysis of gastric mucosal samples obtained from animals subjected to vehicle, indomethacin, lansoprazole or lansoprazole plus indomethacin administration. Western blot assay revealed the expression of both COX-1 and COX-2 in the gastric mucosa of control animals as well as in

Figure 3 MPO (A), MDA (B) and GSH (C) levels in the gastric mucosa of rats treated with indomethacin (IND, 100 μmol/kg) or piroxicam (PIR, 150 μmol/kg), either alone or in the presence of lansoprazole (LAN, 90 μmol/kg). Each column

represents the mean value obtained from 7 to 10 animals±SE. **P*<0.05 vs control values; ^c*P*<0.05 between the respective values obtained in animals treated with indomethacin or piroxicam alone.

rats treated with lansoprazole alone (90 $\mu\text{mol/kg}$) (Figure 5). The densitometric analysis of immunoreactive bands showed that the relative expression of COX-1 or COX-2, in the presence of lansoprazole, did not differ significantly from that estimated in control animals. Treatment with indomethacin was followed by a marked enhancement of COX-2, but not COX-1, expression in the gastric mucosa. A similar effect was exerted by indomethacin upon pretreatment of animals with lansoprazole (Figure 5).

Figure 5 Western blot analysis of COX-1 and COX-2 protein expression in gastric mucosal lysates obtained from animals treated with indomethacin (IND), lansoprazole (LAN, 90 $\mu\text{mol/kg}$) or lansoprazole plus indomethacin (LAN+IND). ^a $P < 0.05$ vs the control values (CON).

Figure 6 Rats subjected to pylorus ligation. Effect of lansoprazole (LAN, 18 and 90 $\mu\text{mol/kg}$) on gastric acid secretion. Each column represents the mean value obtained from six experiments \pm SE (vertical lines). ^a $P < 0.05$ vs the control values.

Animals subjected to pylorus ligation

In control animals subjected to pylorus ligation for 2 h and pretreated with lansoprazole vehicle the gastric acid output accounted for $153.7 \pm 5.8 \mu\text{EqH}^+ / 2 \text{ h}$ ($n = 6$). The administration of lansoprazole (18 or 90 $\mu\text{mol/kg}$) at the time of pylorus ligation caused a significant decrease in acidity (-81.4% and -93.1%, respectively; Figure 6).

In vitro assay of antioxidant activity of lansoprazole

In control experiments, 8-iso-PGF₂ α generation promoted by CuSO₄-induced oxidation of LDLs accounted for $1261.3 \pm 113.7 \text{ pg/mL}$. When the oxidative reaction was carried out in the presence of increasing concentrations of lansoprazole (1-300 $\mu\text{mol/L}$), the production of 8-iso-PGF₂ α underwent a progressive decrease. Under these conditions, the antioxidant activity of lansoprazole achieved a significant level at 3 $\mu\text{mol/L}$ (-17%), and a maximal effect could be detected at the concentration of 100 $\mu\text{mol/L}$ (-85.9%, Figure 7).

DISCUSSION

It is currently acknowledged that the ability of PPIs to prevent NSAID-associated gastric ulcers in clinical settings results from their inhibition of acid secretion^[1]. However, several lines of evidence indicate that acid-independent mechanisms may contribute to the antiulcer actions of PPIs^[9,10]. In the present study, the protective properties of lansoprazole were examined in a rat model of mucosal injury evoked by NSAIDs associated with high risk of adverse digestive events in clinical practice^[4]. The histomorphometric analysis of gastric sections showed that the damaging effects of test NSAIDs were prevented by lansoprazole, and evidence was also obtained that the ability to interfere with the oxidative and inflammatory injuries evoked by NSAID treatment plays a relevant role in the gastroprotective action of this benzimidazole derivative.

NSAIDs assayed in the present investigation elicited areas of mucosal necrosis which were associated with destruction of glandular architecture, submucosal edema, and extensive infiltration by polymorphonuclear cells. This pattern of gastric damage was also characterized by a marked

Figure 7 8-Iso-PGF₂ α levels generated *in vitro* upon oxidation of native LDLs by CuSO₄, either in the absence (C, control) or in the presence of increasing concentrations of lansoprazole (LAN). Each column represents the mean value obtained from 5-6 experiments \pm SE (vertical lines). ^a $P < 0.05$ vs the control values.

increase in mucosal MPO levels, regarded as a reliable marker of tissue neutrophil infiltration, which occurred together with an increment of mucosal MDA content and a decrease in GSH concentration. MDA is an end product resulting from peroxidation of polyunsaturated fatty acids and related esters within cell membranes, and the measurement of this substance represents a suitable index of oxidative tissue injury^[21]. On the other hand, sulfhydryl compounds are involved in the maintenance of gastric integrity, particularly when reactive oxygen species are implicated in the pathophysiology of tissue damage^[22,23]. Indeed, GSH participates in many aspects of oxidative metabolism, including the neutralization of hydroperoxides and the maintenance of the physiological sulfhydryl status of proteins^[23,24]. Overall, the present findings are consistent with previous evidence indicating that NSAIDs, acting through both local and systemic mechanisms, promote ischemic and inflammatory alterations which result in gastric neutrophil infiltration, release of oxygen metabolites, and cell membrane peroxidation^[1,3]. In particular, focal ischemia, characterized by neutrophil adherence to vascular endothelium, capillary congestion and intravascular fibrin deposition, has been recognized as an early event in the pathogenesis of NSAID-induced gastric oxidative injury, and these alterations are further amplified by subsequent tissue infiltration with polymorphonuclear cells, the activation of which causes a massive release of reactive oxygen radicals and other inflammatory mediators responsible for epithelial damage^[1,25]. In these respects, rat models, as that adopted in the present study, can be regarded as predictive of NSAID-induced gastric alterations occurring in clinical settings, since gastric erosions elicited by aspirin in healthy volunteers were accompanied by marked increments of mucosal MPO activity and lipid peroxidation^[5].

It is recognized that acid secretion can facilitate or exacerbate the damage to gastric mucosa evoked by exogenous agents, including NSAIDs, and acid suppression is then regarded as the main target of most pharmacological treatments designed to prevent or heal gastric ulcers^[26]. However, NSAID-induced ulcers result mainly from alterations of protective mechanisms, and some arguments suggest that acid secretion may not represent a pivotal step in the pathophysiology of NSAID gastropathy^[1,3]. For instance, achlorhydria does not protect patients against upper digestive ulcers during NSAID use^[27], and H₂ receptor antagonists appear to be scarcely effective in preventing NSAID-associated gastric ulcers under both experimental and clinical conditions^[28]. In the present study, NSAID-induced gastric lesions were extensively prevented by lansoprazole 90 µmol/kg, whereas rather weak effects were detected with 18 µmol/kg, a dose shown to ensure a marked blockade of acid secretion in pylorus-ligated rats. On these bases, it can be proposed that acid-independent mechanisms concur with inhibition of acid secretion for gastric protection afforded by lansoprazole against NSAIDs. In particular, since in our experiments lansoprazole prevented mucosal MDA generation elicited by test NSAIDs, it is conceivable that this drug is endowed with antioxidant properties accounting for its gastroprotective actions.

At least two mechanisms can be advocated to explain

the defence exerted by lansoprazole against gastric oxidative damage associated with NSAID treatment, as this drug might directly scavenge reactive oxygen species or interfere with the oxidative metabolism arising from the activation of polymorphonuclear cells. To address this issue, we carried out a series of experiments on an *in vitro* model, and evidence was obtained that lansoprazole directly protects native LDLs from copper-induced oxidation. These results agree with the experiments performed by Lapenna *et al.*^[29], where omeprazole was shown to significantly scavenge hypochlorous acid as well as to inhibit iron- and copper-driven oxidative reactions in appropriate *in vitro* systems. When taking into account indirect antioxidant mechanisms, it is important to consider that the increased output of free oxygen radicals, arising from activated polymorphonuclear cells, requires the acidification of phagolysosomes, and that such a process is accomplished by a proton pump which is fully susceptible to blockade by benzimidazole derivatives^[30,31]. Indeed, omeprazole blocked the oxidative burst of isolated polymorphonuclear cells^[30,32]. In addition, lansoprazole inhibited the output of free oxygen radicals from neutrophils activated by *Helicobacter pylori*^[33], and counteracted the increase in plasma levels of peroxidized lipids in patients with duodenal ulcer^[34]. Overall, it can be proposed that lansoprazole, acting via both direct and indirect antioxidant mechanisms, protects the gastric mucosa against oxidative injury caused by NSAID-induced focal ischemia and neutrophil activation.

Sulfhydryl radicals take a significant part in mechanisms deputed to the defence of tissues against oxidative injury, and there is evidence to suggest that sulfhydryl donor drugs can afford protection against gastric mucosal injuries elicited by various necrotizing agents, stress or ischemia^[22]. Adequate levels of sulfhydryl compounds appear also to be an important requirement for prevention of NSAID-induced gastropathy, since previous reports showed that a mucosal depletion of endogenous sulfhydryl radicals contributed to the pathogenesis of gastric lesions evoked by different NSAIDs^[14,15], and GSH concentrations were significantly decreased in mucosal bioptic specimens obtained from patients with NSAID-induced gastric bleeding^[35]. Consistent with these observations, in the present study animals treated with indomethacin or piroxicam displayed a marked reduction in mucosal GSH levels, and in both cases the decreasing action could be reversed by pretreatment with lansoprazole. The latter finding can be interpreted in light of the antioxidant properties of lansoprazole, through which this drug is expected to preserve mucosal sulfhydryl compounds from the excess of gastric scavenging activity required to counteract NSAID-induced oxidation, and therefore it is likely that an increased bioavailability of endogenous sulfhydryls plays a significant role in the prevention afforded by lansoprazole against gastropathy associated with NSAID therapy. In keeping with this view, lansoprazole was previously shown to interfere with the decrease in mucosal GSH concentrations in a rat model of gastric necrosis and oxidative injury caused by intraluminal application of acidified ethanol^[36].

The implication of prostaglandins in the antiulcer effects of PPIs is currently debated. In previous studies in rat

models, single-dose administration of lansoprazole did not influence gastric prostaglandin production^[36,37]. Furthermore, omeprazole failed to affect the release of prostaglandins from cultured gastric mucosal cells^[38]. More recently, Tsuji *et al.*^[10], observed that, after a treatment course of 14 d, lansoprazole promoted a gastrin-dependent increment of both gastric COX-2 expression and PGE2 concentration in rats. In the present study, a series of experiments was designed to evaluate PGE2 levels and the expression of COX isoforms in the gastric mucosa. PGE2 mucosal concentrations were consistently decreased after administration of test-NSAID, as expected, but such inhibitory effects were not influenced by pretreatment with lansoprazole. Moreover, indomethacin enhanced the mucosal expression of COX-2, but not COX-1, in line with previous findings^[39], whereas the expression of both isoforms was not modulated by lansoprazole neither in the absence nor in the presence of indomethacin. Therefore, lansoprazole does not appear to exert positive influences on gastric PGE2 levels, at least upon blockade of COX isoforms by NSAID treatment. In agreement with these observations, omeprazole prevented indomethacin-induced gastric ulcers in rabbits, without interfering with the concomitant decrease in mucosal PGE2 formation^[40].

In conclusion, the present results support the view that, besides the inhibition of acid secretion, the protective effects exerted by lansoprazole against NSAID-induced gastric damage can be ascribed to a reduction of gastric oxidative injury, which is also responsible for an increased bioavailability of mucosal sulfhydryl compounds. It is also suggested that lansoprazole does not exert any modulator influence on the down-regulation of gastric prostaglandin formation associated with NSAID treatment.

Abstract

AIM: This report gives a comprehensive overview of ultrasonography of splenic abnormalities. Certain ultrasonic features are also discussed with pathologic correlation.

METHODS: We review the typical ultrasonic characteristics of a wide range of splenic lesions, illustrating them with images obtained in our institution from 2000 to 2003. One hundred and three patients (47 men, 56 women), with a mean age of 54 years (range 9-92 years), were found to have an abnormal ultrasonic pattern of spleen.

RESULTS: We describe the ultrasonic features of various splenic lesions such as accessory spleen, splenomegaly, cysts, cavernous hemangiomas, lymphomas, abscesses, metastatic tumors, splenic infarctions, hematomas, and rupture, based on traditional gray-scale and color Doppler sonography.

CONCLUSION: Ultrasound is a widely available, noninvasive, and useful means of diagnosing splenic abnormalities. A combination of ultrasonic characteristics and clinical data may provide an accurate diagnosis. If the US appearance alone is not enough, US may also be used to guide biopsy of suspicious lesions.

INTRODUCTION

By structure and function, the spleen resembles two separate organs combined in one. On the one hand, it is an organ of the immune system, with the white pulp involved in the maturation of lymphocytes and plasma cells and in the generation of antibodies. On the other hand, it has a phagocytic role, with the red pulp removing particulate matter from the blood and participating in the destruction of senescent red blood cells. In early life the red pulp also plays a role in hematopoiesis and the storage and sequestration of blood. The length of the spleen is variable, averaging 11 cm^[1]. The weight varies from 50 to 300 g, with an average of 150 g. The normal adult spleen decreases in size with age^[2]. The normal appearance of the parenchyma on ultrasound (US) is very homogeneous and uniform, with an echogenicity slightly greater than that of normal hepatic parenchyma. In comparison with other solid abdominal organs, the spleen is relatively rarely the primary site affected by disease. By contrast to the widely studied lesions of the liver, the US appearance of disease in the spleen is rather nonspecific. An understanding of the history and associated symptoms may help narrow the differential diagnosis. The ability of US to detect focal or diffuse splenic lesions depends on numerous factors: spleen size; size, number, and echogenicity of focal lesions; and ancillary adjacent findings.

MATERIALS AND METHODS

Ultrasonographic data of abdominal imaging with a diagnosis of splenic abnormalities from 2000 to 2003 at Mackay Memorial Hospital were reviewed retrospectively. In this period, 103 patients (47 men, 56 women), with a mean age of 54 years (range 9-92 years), were found to have an abnormal US pattern of spleen (exclusion of splenomegaly in patients with cirrhosis and thalassemia) from about 100 000 US evaluations. The indications for patient to undergo abdominal US were abdominal pain referred from emergency room in 13% of evaluations, abdominal relating symptoms referred from ordinary wards or intensive care units in 11% of evaluations, screening of viral hepatitis, abnormal liver function, liver cirrhosis, hepatoma or other malignancy referred from out-patient departments in 76% of evaluations. The spleen was scanned by a real time ultrasound using a 3.5 to 6 MHz transducer and color Doppler imaging was applied in some cases. The final diagnosis of each lesion in our patients was determined by pathologic, bacteriology examination or clinical history and serial imaging study.

RESULTS

These 103 splenic abnormalities were accessory spleen in 5

patients, true cysts in 22 and pseudocysts in 9 patients, splenic calcification and Gamna-Gandy bodies in 10 patients, cavernous hemangiomas in 15 patients, abscesses in 8 patients, lymphomas in 8 patients, metastatic tumors in 5 patients, splenic infarctions in 10 patients, hematomas and rupture in 11 patients.

Diseases of the spleen

Congenital abnormalities Some congenital anomalies of the spleen are common, such as splenic lobulation and accessory spleen, while other conditions are rare, such as wandering spleen^[3] and polysplenia^[4]. Failure of fusion of splenic tissue results in the formation of an accessory spleen. US appearances usually present as a homogenous, less than 4 cm round contour near the hilum and an echogenicity identical to that of adjacent spleen. Pathologic processes affecting the spleen also affect the accessory spleen, indicating that they have the same developmental origin (Figure 1). An intrapancreatic or intrahepatic accessory spleen is a homogenous mass in the parenchyma of the pancreas or liver that may mimic a neoplastic lesion^[5,6]. As it poses no danger, accurate diagnosis is necessary to avoid unnecessary treatment. The diagnosis of ectopic splenic tissue is best made by technetium-99m colloid scintigraphy^[7].

Figure 1 There is a homogenous, round contour near the hilum, identified as an accessory spleen (AS) in a 62-year-old female. One anechoic cyst is noted within the accessory spleen. The pathologic process affecting the spleen (small cyst) also affects the accessory spleen (large cyst).

Splenomegaly and portal hypertension As the spleen is an irregularly shaped organ, no completely satisfactory technique has been developed to measure the volume accurately. Estimating the volume with the formula $0.524 \times W \times T \times (ML + CCL) / 2$ (where ML = maximum length, W = width, T = thickness, and CCL = craniocaudal length) provides better overall accuracy^[8]. The differential diagnosis for splenomegaly includes infection, portal hypertension, storage disorders, blood dyscrasias, and neoplasm. Mild splenomegaly can be seen in infections and portal hypertension. Moderate splenomegaly suggests leukemia, lymphoma, or infectious mononucleosis. Massive splenomegaly is seen in myelofibrosis or chronic myeloid leukemia. The presence of portosystemic collateral vessels, ascites, and cirrhosis of the liver indicates portal hypertension^[9]. The presence of space-occupying lesions within an enlarged

spleen suggests lymphoma, metastases, or abscesses.

Splenic calcification and Gamna-Gandy bodies Foci of hemosiderin and calcium deposits in the splenic parenchyma secondary to intraparenchymal hemorrhage are called Gamna-Gandy bodies (Figure 2). They are commonly seen in patients with liver cirrhosis and portal hypertension and are also found in patients with splenic vein thrombosis, hemolytic anemia, hemochromatosis, or trauma^[10]. Echogenic foci with acoustic shadowing indicating calcification are found in chronic granulomatous infections such as tuberculosis, hamartomas, sickle cell disease^[11] and trauma.

Figure 2 Multiple tiny calcified spots involving almost the entire spleen are found in a 58-year-old female with liver cirrhosis, called Gamna-Gandy bodies.

Splenic cysts Splenic cysts are rarely seen, but they are still probably the commonest splenic lesions. They are much less common than those arising in the kidney, liver, or ovary. They can be true cysts, pseudocysts, or hydatid cysts. The true cyst, also known as an epidermoid cyst, is defined by the presence of an inner endothelial lining. Pseudocysts that lack such a lining are usually secondary to old trauma, a resolved infection, or infarction. Hydatid cysts are formed by the larval stage of the dog tapeworm *Echinococcus granulosus*. Simple cysts pose less diagnostic problems if they have the classic ultrasonic features of being anechoic and thin-walled with posterior echo enhancement. Splenic cysts usually are located completely within the spleen, thus differing from hepatic or renal cysts which may have an exophytic component. Infection or hemorrhage may cause debris and echogenic contents within thick-walled pseudocysts (Figure 3). Brightly foci with acoustic shadow due to calcification within the wall is also a correlative US feature to pseudocysts. A rare complication of pancreatic pseudocyst may be erosion into the adjacent spleen, where it mimics a huge simple splenic cyst (Figure 4). Rupture of an intrasplenic pancreatic pseudocyst can result in massive hemoperitoneum. Miele stated that internal septa are more frequent in true cysts while parietal calcifications are typical of pseudocysts^[12]. However, the final diagnosis is made histologically.

Splenic abscess A splenic abscess is a collection of pus, most commonly caused by hematogenous spread of infection from elsewhere. Intravenous drug abusers are predominantly affected. Other causes include penetrating wounds or

complications of a hematoma resulting from infarction or trauma. A pyogenic abscess is typically hypoechoic and often has thick, irregular walls. Other findings include gas, progressive enlargement of the lesion, subcapsular extension and collections of extracapsular fluid^[13]. If gas has formed within the abscess, hyperechogenicity with distal dirty shadowing can be seen. Through transmission indicates the cystic nature of an abscess even when it contains echogenic material. Color Doppler examination may reveal hypervascularity in the thick wall. The clinical triad suggestive of splenic abscess consists of fever, left upper quadrant pain, and leukocytosis. The typical triad was seen in 44% of patients in one series of 34 cases^[14]. Although splenic abscess is rare, there is a high mortality if diagnosis and treatment are delayed. Percutaneous drainage of a single abscess and splenectomy for multiple abscesses are recommended. Fine-needle aspiration is useful when an abscess is suspected, as this may confirm the diagnosis as well allowing culture of the pathogen. In the series noted above, multiple or gas-containing abscesses had a poor prognosis^[14].

Figure 3 A pseudocyst cyst of the spleen after trauma reveals debris or echogenic contents within the thick wall (arrows) in a 60-year-old female.

Figure 4 Pancreatic pseudocyst eroding into the adjacent spleen and mimicking a huge splenic simple cyst was noted after an episode of acute alcoholic pancreatitis in a 32-year-old male patient.

Hemangioma A hemangioma is characterized by a proliferation of blood-filled spaces lined and separated by endothelium. Cavernous hemangiomas are the most common solid benign lesion seen in the spleen and are found

incidentally. The US appearance varies widely from a predominately solid to mixed to a pure cystic lesion. Hemangiomas usually have a periphery and a hypoechoic center with a through transmission character similar to cavernous hemangioma of the liver. Color Doppler may show blood flow within the solid portions. Atypical features are commoner in larger lesions and include heterogeneous echogenicity with hypoechoic areas due to necrosis, hemorrhage, and thrombosis (Figure 5). Rarely, hemangiomas may be large or multiple and can involve the whole spleen (Figure 6). The most frequent complications are rupture and bleeding. Although up to 14% of patients in autopsy series have been reported to have splenic hemangiomas^[2], but they are less frequently identified on imaging.

Figure 5 An atypical hemangioma can have mixed echogenicity with a dominant cystic portion. Mild through transmission points to the cystic nature of the hemangioma.

Figure 6 Large and multiple hemangiomas occupy the entire spleen. The hypoechoic areas shown in Figure 5 are filled with blood clots and thrombosis. The 48-year-old male received splenectomy due to LUQ pain caused by venous thrombosis in spleen.

Lymphoma Primary malignant tumors of the spleen are uncommon, with primary lymphoma and angiosarcoma being the most frequently reported. Splenomegaly is a frequent finding in lymphoma, but a normal sized spleen does not exclude the diagnosis^[15]. The US patterns correspond to the three macroscopic morphologies: (1) infiltrative and diffuse, (2) miliary and nodular, and (3) focal

and cyst-like (Figure 7)^[16]. In cyst-like lymphoma, the appearance of a distinct boundary is an important clue in distinguishing lymphoma from cyst^[17]. Indistinct boundary echo pattern indicated splenic lymphomas. Hodgkin and non-Hodgkin lymphoma can not be distinguished by the US appearance.

Metastatic tumor Metastatic involvement of the spleen is very uncommon, usually seen in patients with widespread, terminal malignant disease. The most frequent metastases arise from lymphoma and melanoma, followed by carcinoma of the ovary, breast, lung, and stomach in decreasing order of frequency^[2]. Target lesions with a hypoechoic halo suggest metastasis (Figure 8). This appearance is said to be a sign of aggressive behavior, but other authors have postulated that it is due to necrosis or hemorrhage. Miliary tuberculosis, atypical mycobacteria, and *pneumocystis carinii*, especially in immunocompromised patients, can also result in multiple hypoechoic focal lesions^[18]. These should be differentiated from splenic metastases.

Splenic infarction Infarction can result from either occlusion of the splenic artery or venous thrombosis in the splenic sinusoids. Splenic infarction is typically seen in patients prone to embolic phenomena or, more recently, as a complication of transcatheter arterial embolization of a hepatoma. In splenic vein thrombosis, the entire spleen may be involved, resulting in massive splenomegaly. US typically show a peripheral, wedge-shaped region of hypoechogenicity

(Figure 9). Color Doppler imaging may show a lack of perfusion; however, the presence of flow within a lesion does not exclude the diagnosis because the embolus may subsequently lyse. Splenic infarcts may initially be large and then become small and echogenic as fibrosis occurs.

Hematoma and rupture The spleen, liver, and kidney are the three intraperitoneal organs most commonly injured by blunt trauma. If the capsule of the injured spleen remains intact, an intraparenchymal or subcapsular hematoma (Figure 10) may result. Echogenicity of a hematoma depends on the stage at which the scan was performed. Fresh blood is liquid and initially echo-free but over the course of several days becomes more echogenic and thus more difficult to identify. Free fluid in the left upper quadrant is strongly suggestive of splenic injury, which must be excluded in such a case^[19]. Less frequently, a splenic laceration or rupture is identified as a blood-filled cleft with capsular rupture. (Figures 11 and 12).

Biopsy procedures In many cases, pathologic confirmation is necessary to provide a definitive diagnosis. The traditional dry cytologic aspiration is relatively safe but provides only a small sample. Siniluoto *et al.* reported false-negative results for malignancy is about 31% of biopsies using a 22-gauge fine needle aspiration technique^[20]. Core-needle biopsies with and 18 or 20-gauge cutting-biopsy needle may increase the diagnostic accuracy by obtaining a sufficiently large

Figure 7 An enlarged spleen (A) demonstrates a diffusely coarse echotexture with several mixed echoic lesions (B) in a 58-year-old male patient.

Figure 9 A peripheral wedge-shaped hypoechoic region (arrows) was noted at the upper pole of spleen from an infarction after transcatheter arterial embolization in a 45-year-old male with hepatoma.

Figure 8 Splenic metastasis from a lung carcinoma in a 68-year-old male is seen as a hypoechoic mass with a target sign.

Figure 10 A subcapsular crescent-shaped hypoechoic lesion is noted at the upper pole of spleen.

specimen. And Katsumi *et al.*^[21], reported the safety of this procedure in four cases. All procedures should be carefully planned in advance to avoid hitting the intestine, pancreas, kidneys or pleura as the needle is advanced. Color Doppler imaging helps avoid passing the needle through a large vessel. Endoscopic ultrasound-guided fine needle aspiration may be used in if the lesion is adjacent to the hilum or too small for a CT- or US-guided biopsy. A linear echo endoscope and 22-gauge needles are used to obtain specimens for cytology^[22]. To avoid unnecessary morbidity and mortality, laparotomy and splenectomy for pathologic confirmation should be used only when absolutely required.

Figure 11 Several linear hypoechoic foci and a subcapsular fluid accumulation are noted in a spleen. Loss of the normal architecture was seen after a traffic accident in a 38-year-old male.

Figure 12 A splenic laceration and rupture (in Figure 11) is identified as a blood-filled cleft (lower arrow) and capsular rupture (upper arrow) on contrast CT.

DISCUSSION

Because splenic abnormalities are relatively rare, the clinician is unlikely to be as familiar with them as with those of the liver. Although some of the experience gained with hepatic US is useful in examining the spleen, there are some differences that must be noted. The classic US finding of posterior echo enhancement suggesting a cyst in the liver or kidney is noted in only 25% of splenic cysts according to Ishida^[17] and in our experience (6/22) as well. While the reason for this discrepancy is not known for sure, Ishida suggested it might relate to differences in the acoustic patterns of the parenchyma of the two organs^[17]. Splenic

cysts are reportedly located completely within the spleen, and we have never found one of 28 cases that extends outside the capsule. Because the spleen is closely surrounded by other organs, it might be difficult for an exophytic cyst to develop. Another difference is that cystic portions occur more commonly and prominently in splenic hemangiomas compared with liver hemangiomas, which are more likely to be solid, in contrast with the variable appearance of hemangiomas in the spleen.

While there have been to differentiate benign from malignant focal lesions in the spleen based on US appearance, the results have been disappointing. There is too much overlap between the echo patterns^[23]. Therefore, US should be supplemented with other diagnostic techniques in such cases. However, certain criteria have been proposed that are at least suggestive. For example, malignant lesions are more likely to be multifocal, as with metastatic lesions, or to be diffuse and ill defined because of rapid growth. A soft tissue lesion associated with calcification usually indicates a long term process. Gas in the parenchyma usually originates from bacterial infection and indicates benign disease. Wan *et al.* said that solitary lesions with an anechoic pattern or echogenic foci with gas or calcification are more likely benign, while multifocal or diffuse solid lesions associated with a target sign or extrasplenic abdominal masses are suggestive of malignancy^[24].

Over the past decade, great efforts have been made to improve both tissue harmonic imaging and contrast sonography. The former is a gray-scale imaging technique that uses information from harmonic signals generated by non-linear propagation. This minimizes artifacts from the body, side lobe, and scatter and thus improves the signal-to-noise ratio. Contrast imaging uses gas microbubbles^[25], which has dramatically extended the ability of liver US to assess blood flow in a tumor^[26]. Preliminary experience with this modality has produced spleen-specific enhancement^[27]. Thorelius *et al.* suggested that contrast enhanced sonography might be useful in the detection of lesions in which blood flow is reduced such as infarctions, hematomas, necrotic tissue, and non-vascular cysts in the spleen^[28].

In conclusion, US is a widely available, noninvasive, and useful means of diagnosing splenic abnormalities. A combination of ultrasonic characteristics and clinical data may provide an accurate diagnosis, particularly for such disorders as hemangiomas, splenomegaly secondary to portal hypertension, simple cysts, malignant lesions with a target sign, or lesions associated with other obvious intra-abdominal pathology. In many cases, pathologic confirmation is necessary to make a definitive diagnosis. Fine needle aspiration, core-needle cutting biopsy, and endoscopic ultrasound-guided fine needle aspiration have been developed to assist diagnosis.

Abstract

AIM: To systematically evaluate the efficacy of H₂-receptor antagonists (H₂RAs) and proton pump inhibitors in healing erosive esophagitis (EE).

METHODS: A meta-analysis was performed. A literature search was conducted in PubMed, Medline, Embase, and Cochrane databases to include randomized controlled head-to-head comparative trials evaluating the efficacy of H₂RAs or proton pump inhibitors in healing EE. Relative risk (RR) and 95% confidence interval (CI) were calculated under a random-effects model.

RESULTS: RRs of cumulative healing rates for each comparison at 8 wk were: high dose *vs* standard dose H₂RAs, 1.17 (95%CI, 1.02-1.33); standard dose proton pump inhibitors *vs* standard dose H₂RAs, 1.59 (95%CI, 1.44-1.75); standard dose other proton pump inhibitors *vs* standard dose omeprazole, 1.06 (95%CI, 0.98-1.06). Proton pump inhibitors produced consistently greater healing rates than H₂RAs of all doses across all grades of esophagitis, including patients refractory to H₂RAs. Healing rates achieved with standard dose omeprazole were similar to those with other proton pump inhibitors in all grades of esophagitis.

CONCLUSION: H₂RAs are less effective for treating patients with erosive esophagitis, especially in those with severe forms of esophagitis. Standard dose proton pump inhibitors are significantly more effective than H₂RAs in healing esophagitis of all grades. Proton pump inhibitors given at

INTRODUCTION

Gastro-esophageal reflux disease (GERD) is one of the most common chronic conditions affecting 20-40% of adult populations and has a major adverse impact on the quality of life^[1-3]. About 40-60% of patients with symptoms of GERD may have substantial injury of esophageal mucosa ranging from mild inflammation and erythema to various grades of erosions. The major complications of GERD are esophageal ulcer and bleeding, esophageal stricture, and Barrett's esophagus^[1-4].

Reflux esophagitis is generally considered to be the result of prolonged and repeated exposure of the distal esophageal mucosa to acidic gastric contents^[5,6]. It is increasingly clear that the key to reducing symptoms and to healing erosive esophagitis is to decrease the duration of exposure to the acidic refluxate. Acid-suppressing drugs that have been used to treat GERD include H₂-receptor antagonist (H₂RAs) and proton pump inhibitors. The efficacy of medical treatment depends on the ability to increase and maintain the intragastric and intra-esophageal pH above 4.0 over the 24-h period^[7,8]. H₂RAs are limited in their ability to inhibit postprandial gastric acid secretion and are ineffective in controlling reflux symptoms and healing esophagitis^[9,10]. In contrast to H₂RA, proton pump inhibitors block the final step of acid secretion, resulting in a profound and long-lasting acid suppression regardless of the stimulus^[11,12]. Results from 33 randomized clinical trials with over 3 000 patients showed that symptomatic relief could be anticipated in 83% of proton pump inhibitors-treated patients compared with 60% of patients receiving H₂RAs. Similarly, esophagitis was healed in 78% and 50%

of patients treated with proton pump inhibitors and H₂RAs, respectively^[13]. Previously there have been several systematic reviews and meta-analyses of clinical trials assessing the effects of medical treatments for erosive esophagitis^[14-17]. Chiba and colleagues^[14], and Caro and colleagues^[15] compared the effectiveness of proton pump inhibitors and H₂RAs in the healing of esophagitis, whereas the comparative efficacy among proton pump inhibitors was analyzed by Sharma *et al.*^[16], and Edwards *et al.*^[17]. However, comparison of the effects between treatments with proton pump inhibitors and H₂RAs in patients with esophagitis has been difficult because of the difference in the study design. For example, studies included in the previous meta-analyses were not all head-to-head comparative trials^[14,15]. The overall estimates of healing rate calculated by one-step pooling from different pairs of comparatives, may produce bias due to the ignorance of study differences such as sample size and differential difference in effect sizes. In addition, healing of esophagitis is significantly influenced by the initial grade of esophagitis, with healing rate being lower for the severe form of esophagitis than for the mild form of esophagitis^[18-20]. However, no meta-analysis has been published to systematically evaluate the impact of the initial grading of esophagitis on esophagitis healing rates in head-to-head comparative trials. Therefore, the objectives of the current study were firstly to evaluate any difference in healing erosive esophagitis between proton pump inhibitors and H₂RAs in head-to-head comparative trials, and secondly to estimate the impact of baseline grade of esophagitis on esophagitis healing rates.

MATERIALS AND METHODS

Literature search

A computerized literature search was performed in the PubMed, Medline, Embase and Cochrane databases for clinical trials published in English up to May 2004 with the following MeSH terms and/or text words in various combinations: gastroesophageal reflux, GERD, GORD, esophagitis, and healing, as well as the name of each respective drug (H₂-receptor antagonists: cimetidine, ranitidine, famotidine, nizatidine, roxatidine; proton pump inhibitors: omeprazole, lansoprazole, pantoprazole, rabeprazole, esomeprazole). The title and abstract of all potentially relevant studies were screened for their relevance before retrieval of full articles. Full articles were also scrutinized for relevance if the title and abstract were ambiguous. Fully recursive searches were performed from the reference list of all retrieved articles to ensure a complete and comprehensive search of the published literature. All searches were conducted independently by at least two reviewers.

Study selection

The inclusion criteria were as follows: (1) Randomized, controlled clinical trials in adults with an endoscopically confirmed diagnosis of GERD. (2) Two or more treatment arms: high dose *vs* standard dose H₂RA, or an H₂RA *vs* a proton pump inhibitor, or a proton pump inhibitor *vs* a proton pump inhibitor. (3) Healing of esophagitis was documented by endoscopy. (4) Studies with explicit information about the number of patients treated in each group, drug

dosage and schedule, and healing rate of esophagitis.

We excluded studies that only assessed symptom relief without endoscopic documentation of esophagitis healing. Also excluded were studies dealing only with relapsed or recurrent esophagitis, studies of pediatric patients, duplicate publications or studies published only in abstract form, or those focusing on pharmacokinetics and pharmacodynamics. Combination treatments such as an anti-secretory agent and a prokinetic drug were also excluded.

Data extraction

Data was extracted from each study independently and entered into a computerized database. Differences were resolved by discussion to reach consensus between the reviewers. The information retrieved covered country of study, study design, characteristics of population, grading of esophagitis, treatment regimen, number of patients treated, evaluated and healed, and confounding variables such as alcohol use, cigarette smoking, and caffeine use, where applicable. Healing data, up to 12 wk were extracted for both intention-to-treat (ITT) and per-protocol (PP) analyses. Data on healing based on the initial grade of esophagitis were also extracted, if applicable. In studies where only per-protocol healing rates were reported, we calculated the ITT healing rates based on the initial randomized number of patients. Articles that did not specify the type of analysis were assumed to report per-protocol data.

Quality assessment

Study quality was assessed by a series of validity criteria, including study design, level of blinding, method of randomization, patient selection, baseline characteristics, severity of esophagitis, definition of healing, compliance, and analysis by intention to treat criteria. Discrepancies in quality assessment were resolved by consensus among the authors. No quality score was assigned to any study to avoid possible introduction of subjectivity by the authors.

Statistical analysis

The data were grouped as follows: high dose *vs* standard dose H₂RAs; proton pump inhibitors *vs* H₂RAs, or one proton pump inhibitor *vs* another proton pump inhibitor. We defined standard dose of each drug as: ranitidine 300 mg/d, famotidine 40 mg/d, nizatidine 300 mg/d, cimetidine 800 mg/d, omeprazole 20 mg/d, lansoprazole 30 mg/d, pantoprazole 40 mg/d, rabeprazole 20 mg/d, esomeprazole 40 mg/d. The newer proton pump inhibitors include lansoprazole, pantoprazole, rabeprazole and esomeprazole.

The outcomes considered were healing rates of esophagitis for each group at different time points (2, 4, 6, 8, and 12 wk), based on initial grade of esophagitis, if applicable. Healing rate was calculated by pooling raw data from qualified studies within each group. These data were then expressed as a healing-time curve that plotted the cumulative percentage of patients healed *vs* the end point in weeks.

Relative risk (RR) and 95% confidence interval (CI), under a random-effects model^[21], were calculated using raw data of the selected studies at specified time points (2, 4, 6, 8, and 12 wk). The potential effect of publication bias was assessed using a funnel plot suggested by Egger *et al.*^[22].

Statistical heterogeneity between studies was assessed using the Q value calculated from the Mantel-Haenszel method. In the presence of statistical heterogeneity, we searched for the sources of any possible clinically important heterogeneity, i.e., methodological or biological heterogeneity. We did not simply exclude outliers on the basis of statistical test of heterogeneity. Furthermore, to test the robustness of the analysis, we performed sensitivity analyses to evaluate whether exclusion of a single study substantially altered the result of the summary estimate.

All analyses were carried out using EasyMa software for meta-analysis written by M Cucherat, Lyon, France (EasyMa, 2001).

RESULTS

Study characteristics

We identified a total of 485 citations with the computerized search. Screening of the title and abstract of the citations identified 72 potentially relevant studies for full article retrieval. Of these, 52 studies met the inclusion criteria^[19,20,23-72], and 20 studies were subsequently excluded for the following reasons: 17 were not head-to-head comparative studies^[73-89], 1 duplicate publication^[90], 1 without raw data^[91], and 1 with a confusing treatment allocation^[92]. The manual search of the reference list of the retrieved articles did not yield any additional studies. Of the 52 studies, the majority were double blind studies (51/52, 98.1%). Ten (19.2%) compared high dose H₂RA with standard dose H₂RA^[23-32], 26 (50.0%) compared a proton pump inhibitor with an H₂RA^[33-57,71], and 16 (30.8%) compared a proton pump inhibitor with another proton pump inhibitor^[19,20,58-70,72]. Only 25 (48.1%) reported raw healing data by the initial grade of esophagitis^[19,20,23,24,30,32,35,38,43-47,49,52,53,55-58,60,61,69-71].

The proportion of patients with a smoking history was reported in 61.5% of studies, alcohol consumption was reported in 48.1% of studies. The initial grade of esophagitis was reported in 58% studies. However, only 48.1% studies provided raw data on healing by the initial grade of esophagitis.

Healing of esophagitis

High dose H₂RAs vs standard dose H₂RAs Ten studies involving 27 treatment arms compared high dose ($n = 2041$ patients) with standard dose H₂RAs ($n = 1967$ patients)^[23-32]. Table 1 summarizes the pooled healing rates of esophagitis in patients treated with high dose H₂RAs *vs* standard dose H₂RAs. Statistical significance was achieved at 4, 8 and 12 wk,

indicating that high dose H₂RAs healed significantly more esophagitis than did standard dose H₂RAs (Table 1).

No comparative study reported data on the healing of esophagitis at 2 wk. Only one study^[29] reported healing rates at 3 wk, of 17.2% (29/169) for high dose H₂RAs and 19.6% (33/168) for standard dose H₂RAs (RR 0.87, 95%CI 0.56-1.37) (Table 1).

Proton pump inhibitors vs H₂RAs There were 14 studies with 28 treatment arms comparing standard dose proton pump inhibitors ($n = 861$ patients) with standard dose H₂RAs ($n = 752$ patients)^[33-45,71]. The pooled healing rates achieved with the standard dose proton pump inhibitors were superior to that of H₂RAs at all given time points (Table 2). Similar findings were observed when the comparison was made between high dose H₂RAs ($n = 234$ patients) and the standard dose proton pump inhibitors ($n = 237$ patients)^[50,51] (Table 2).

Three studies compared low dose proton pump inhibitors ($n = 279$ patients) with standard dose H₂RAs ($n = 276$ patients) for healing esophagitis^[52,53,71]. The pooled healing rates of the low dose proton pump inhibitors were higher than that of the standard dose H₂RAs at both 4 and 8 wk (Table 2).

Omeprazole 20 mg daily vs other proton pump inhibitors

Eleven studies with 23 treatment arms reported comparative results on the healing of esophagitis between omeprazole 20 mg daily ($n = 3\ 137$ patients) and other proton pump inhibitors at standard doses ($n = 3\ 397$ patients)^[20,59-68]. No significant difference in the healing rate was observed between omeprazole 20 mg daily and other proton pump inhibitors at 2-8 wk (Table 3).

The esophagitis healing time curves are depicted in Figures 1-3. As shown in Figure 1, high dose H₂RA achieved higher healing rates than standard dose H₂RA. However, the healing rate achieved with standard dose proton pump inhibitors at 2 wk was even higher than that of H₂RAs at wk 8 (63.4% *vs* 52.0%), suggesting that proton pump inhibitors healed esophagitis significantly faster than did H₂RAs (Figure 2). Similar healing rates were also observed when the newer proton pump inhibitors were compared with omeprazole 20 mg daily (Figure 3).

Refractory esophagitis

Refractory esophagitis was defined as treatment failure with a standard dose of H₂RAs given for at least 12 wk^[55-57]. Three studies compared the effectiveness of proton pump inhibitors with ranitidine for the treatment of refractory esophagitis^[55-57] (Table 4). Two of them reported that lansoprazole 30 mg daily achieved significantly higher healing

other study indicated that treatment with high dose omeprazole (40 mg/d) in patients refractory to H₂RA therapy significantly improved esophagitis healing when compared to high dose ranitidine (600 mg/d) (RR 3.69, 95%CI 2.30-5.90 at 4 wk; and RR2.03, 95%CI 1.54-2.67 at 8 wk)^[57].

Healing by initial grade of esophagitis

Twenty-five studies^[19,20,23,24,30,32,35,38,43-47,49,52,53,55-58,60,61,69-71] with 54 treatment arms provided raw data on healing by the initial grade of esophagitis (Tables 5-7). Because data by intention-to-treat analysis were not available from the majority of trials, the healing rate by per-protocol analysis was therefore used.

When the healing rate was adjusted according to the initial severity of esophagitis, no significant differences in the healing rates was observed when patients with the severe

Ome: omeprazole; Lan: lansoprazole; Ran: ranitidine; o.d.: once daily in the morning; b.d.: twice daily; h.d.: high dose; sd: standard dose. ¹This study did not report cumulative healing rate at 8 wk. All patients' endpoint was at 8 wk. The decreased healing rate at 8 wk for ranitidine group may be due to subsequent relapse of esophagitis.

form of esophagitis (\geq grade III) were treated with either high dose or standard dose H₂RAs. However, a significant difference was observed for patients with grade II esophagitis at 4 wk (Table 5). No patients with grade IV esophagitis were included in any of the studies comparing high dose with standard dose H₂RAs.

Proton pump inhibitors achieved consistently and significantly higher healing rates than H₂RAs across all grades

of esophagitis, irrespective of the dose and duration of treatment (Table 6). With a wide range of CI, the superiority of proton pump inhibitors over H₂RAs was even greater when the initial grade of esophagitis was considered in studies of patients with refractory esophagitis (Table 6) despite that one study reported the same effects on grade I esophagitis at 12 wk, when omeprazole 40 mg daily was compared with ranitidine 300 mg daily^[47]. The healing rates

were similar between omeprazole and the newer proton pump inhibitors across all grades of esophagitis (Table 7).

Testing for between-study heterogeneity and sensitivity analyses

In the comparison of the healing rates achieved with omeprazole and the newer proton pump inhibitors, a significant heterogeneity was found at 4 and 8 wk ($P < 0.001$). However, no further heterogeneity ($P = 0.43$ at 4 wk, and $P = 0.92$ at 8 wk) was found after exclusion of the studies from Kahrilas *et al.*^[67], and Richter *et al.*^[68], suggesting that the heterogeneity was caused by these two studies. Further scrutiny of these two studies revealed that *Helicobacter pylori* (*H. pylori*) positive patients were excluded in both studies, whereas other studies

did not use *H. pylori* status as an exclusion criterion. No additional confounding factors such as the study design, level of blinding and compliance of patients were identified. Sensitivity analysis showed no difference in the healing rates of erosive esophagitis between omeprazole and the newer proton pump inhibitors (RR 1.00, 95% CI 0.96-1.04 at 4 wk; and RR 0.99, 95% CI 0.97-1.02) when the data from the two studies were excluded. There was no evidence of heterogeneity in any other comparisons.

Publication bias

Tests for publication bias were assessed with funnel plots using RRs against the sample size of each study. Due to the inadequacy of the number of studies in each comparison,

funnel plots did not demonstrate strong patterns. Therefore, figures are not shown.

DISCUSSION

There have been a few systematic reviews and meta-analyses summarizing the effect of medical treatments for reflux esophagitis^[14-17]. However, most of them suffered from methodological flaws. The current study was the first attempt to systematically evaluate the effects of antisecretory agents in healing esophagitis based on head-to-head comparative trials. We believe that analysis of comparative trials provides more robust results than that obtained from simple pooling of results from non-comparative trials because no stratification was used in the latter form of analysis. We found that high dose H₂RAs was superior to standard dose H₂RAs in healing erosive esophagitis at wk 4, 8, and 12, and proton pump inhibitors achieved significantly higher healing rates of esophagitis than did H₂RAs, irrespective of dose and treatment duration. However, no statistically significant difference in healing rates was observed between standard dose omeprazole and the newer proton pump inhibitors after 4 and 8 wk of treatment.

The difference in the rate of healing esophagitis between proton pump inhibitors and H₂RAs can also be expressed as a healing-time curve for the ease of comparison^[14]. Using this method, we have shown that proton pump inhibitors healed esophagitis at a rate approximately twice that of H₂RAs at all time points and the healing rate achieved at 2 wk with proton pump inhibitors was greater than that obtained with H₂RAs at 8 wk. This is consistent with the findings from previous meta-analyses using a different study design^[14-17].

H₂RAs are less effective for healing esophagitis because they cannot effectively inhibit meal-stimulated acid secretion^[9,10]. Moreover, tolerance may occur to H₂RAs, resulting in a significant decrease in their anti-secretory effect^[93,94]. Therefore, patients with reflux esophagitis often require high dose H₂RAs to maintain an intragastric pH above the critical threshold of 4.0 to achieve satisfactory symptom relief and remission of esophagitis^[7,8]. Proton pump inhibitors have been proved to be effective in suppressing gastric acid secretion throughout the 24-h period, including meal-stimulated acid production^[95,96]. So far, tolerance to proton pump inhibitors has not been reported in the literature even after long-term treatment.

The severity of esophagitis is a good predictor of a successful treatment^[97]. In this analysis, we have shown that high dose H₂RAs achieved a significantly better healing rate of esophagitis than standard dose H₂RAs. However, this difference disappeared when the results were adjusted by the initial grade of esophagitis except for the comparison at 4 wk when high dose H₂RAs healed 10% more esophagitis (Table 5). A possible explanation for the rapid loss of superiority of anti-secretory effect of high dose H₂RAs over standard dose H₂RAs after 4 wk could be due to the subsequent development of tolerance to the continuous use of H₂RAs^[93,94].

Our study has confirmed that proton pump inhibitors were significantly more effective than H₂RAs in healing erosive esophagitis across all grades. In patients with mild

forms of esophagitis (grades I and II), the healing rate achieved with proton pump inhibitors was significantly higher than that with H₂RAs (100.0% *vs* 64.0% for grade I, and 93.3% *vs* 55.5% for grade II) at 8 wk (Table 6). This suggested that, even in patients with the mild form of esophagitis, H₂RAs is a less effective treatment compared to proton pump inhibitors. The difference was even greater in patients with grade III/IV esophagitis. The healing rate achieved with proton pump inhibitors at 8 wk was 59.6%, but only 17.6% with H₂RAs (Table 6). In patients refractory to H₂RAs, proton pump inhibitors healed 50.0% and 62.1% of grade IV esophagitis after 4 and 8 wk of treatment, respectively (Table 4). Thus, proton pump inhibitors are significantly more effective than H₂RAs for treating all grades of esophagitis, including patients refractory to H₂RAs.

It is known that individual proton pump inhibitors differ with respect to the onset of action and duration of effect because of the variability in their bioavailability. Although omeprazole has a relative lower bioavailability than other proton pump inhibitors^[98-100], which may contribute to the late onset of symptom relief, this has not been translated into a disadvantage in healing rate of esophagitis of all grades when compared with the newer proton pump inhibitors according to the results of this analysis.

A statistically significant heterogeneity was found in the overall analysis comparing the efficacy of healing esophagitis among different proton pump inhibitors. Two studies identified to have contributed to the heterogeneity, compared esomeprazole to omeprazole and excluded patients with *H. pylori* infection in their analyses^[67,68]. Although a higher healing rate of reflux esophagitis has been observed in patients with *H. pylori* infection compared to uninfected patients when treated with proton pump inhibitors^[101,102], there is no evidence that esomeprazole would work better on *H. pylori* negative patients. Therefore, there might in fact be real difference in efficacy between esomeprazole and omeprazole, because esomeprazole is the enantiomer of omeprazole and the active compound is the achiral cyclic sulfenamide. Comparing 40 mg of esomeprazole with 20 mg of omeprazole would be more or less the same, as comparing double dose of omeprazole^[103]. More data are needed to further confirm the presumption.

There are several limitations in this meta-analysis. Firstly, the quality of a meta-analysis, in general is dependent on the quality of original studies, particularly the study design and reporting. To correct reporting bias from original studies is difficult and requires collaboration of investigators involved. Because of the practical difficulties, such as lapse in time between the time of publication and the time of this analysis, we did not contact investigators for raw data or clarification of unclear presentation. Secondly, three different esophagitis grading systems were used in the individual studies, which might have confounded the results of analyses. Huang *et al.*, previously reported that there is a systematic difference in healing rates between studies using Hetzel-Dent scoring system and those using Savary-Miller system^[104]. Therefore, we considered that the impact of different esophagitis scoring systems on the analysis of esophagitis healing rates deserves a systematic evaluation in its own right. This warrants an immediate consensus of using a

standard esophagitis scoring system among investigators so that a truly meaningful comparison of the efficacy of different drugs can be made. Thirdly, the stratified analysis by the initial grade of esophagitis may also be biased because per-protocol data were used in the analysis. Fourthly, we excluded meeting abstracts and non-English publications for technical reasons such as inadequate reporting of outcomes in meeting abstracts and no resources for translation of non-English articles. This might have introduced selection bias. To estimate the magnitude of possible impact, we searched the literature and identified six articles published in non-English literature, but with an English abstract^[18,105-109]. Four studies compared a standard dose proton pump inhibitor with an H₂RA, one between two H₂RAs and one between two different doses of cimetidine. The conclusions of these trials are consistent with those of this meta-analysis. Therefore, we believe that the inclusion of non-English studies would not change the conclusions of this analysis. Fifthly, relief of reflux symptoms is another important aspect in the management of patients with GERD. However, the large variability in measuring and reporting symptom data in the literature prohibited us from conducting a reliable meta-analysis of the effects of antisecretory agents on relieving reflux symptoms. This requires an urgent attention to establishing a standard instrument for the assessment of symptom response in patients with GERD.

In conclusion, this meta-analysis of comparative trials clearly identifies that H₂RAs are not effective treatment for patients with esophagitis of all grades irrespective of dose. Proton pump inhibitors are significantly more effective than H₂RAs for healing esophagitis of all grades including those refractory to H₂RAs. No significant differences in healing esophagitis exist among standard dose of different proton pump inhibitors. Therefore, proton pump inhibitors should be used for patients with esophagitis of all grades.

ACKNOWLEDGMENT

Abstract

AIM: This paper aims to develop a data-based semi-quantitative food frequency questionnaire (SQFFQ) covering both urban and rural areas in the Chaoshan region of Guangdong Province, China, for the investigation of relationships between food intake and lifestyle-related diseases among middle-aged Chinese.

METHODS: We recruited 417 subjects from the general population and performed an assessment of the diet, using a 3-d weighed dietary record survey. We employed contribution analysis (CA) and multiple regression analysis (MRA) to select food items covering up to a 90% contribution and a 0.90 R^2 , respectively. The total number of food items consumed was 523 (443 in the urban and 417 in the rural population) and the intake of 29 nutrients was calculated according to the actual consumption by foods/recipes.

RESULTS: The CA selected 233, 194, and 183 foods/recipes for the combined, the urban and the rural areas, respectively, and then 196, 157, and 160 were chosen by the MRA. Finally, 125 foods/recipes were selected for the final questionnaire. The frequencies were classified into eight categories and standard portion sizes were also calculated.

CONCLUSION: For adoption of the area-specific SQFFQ, validity and reproducibility tests are now planned to determine how the combined SQFFQ performs in actual assessment of disease risk and benefit.

INTRODUCTION

Lifestyle is the most important environmental factor related to chronic diseases such as cardiovascular diseases, diabetes and cancer^[1-5], now the major causes of death in the developed countries and also increasing their impact in the developing world^[6]. While genetic factors are also of interest in terms of etiology, from the viewpoint of disease prevention, environmental factors are more important, because they are controllable and thus targetable for health promotion. Unlike smoking, which only does harm to health^[7], the diet has two profiles: appropriate intake is necessary for life, but excessive intake or imbalance may be deleterious. The investigation of reliable internal associations between food intake and health/diseases requires sufficient and accurate information on diet intake.

Increasing interest in relationships between long-term dietary intake and the occurrence of chronic disease has thus stimulated the development of evaluation methods to assess dietary factors among large groups of individuals. As a relatively new but efficient method, the semi-quantitative food frequency questionnaire (SQFFQ) has become widely used worldwide, especially in the US and European countries^[8,9]. Compared with other approaches, the SQFFQ has the following advantages: (1) it is simple and convenient to implement; (2) it has the ability to provide food information over a relatively long time period; (3) it can be applied with focuses on specific age groups^[10]. At present, the SQFFQ is therefore the best tool to obtain information for investigation of the relationship between the diet and health or disease.

Recently, the economic status in China has greatly

improved, but a nationwide survey of food and nutrient intake in the country has revealed that geographical variations between urban and rural areas still exist in most regions. This variation demands the development of an appropriate SQFFQ covering both urban and rural populations to investigate the association between dietary factors and cancer risk, cases naturally being recruited from both areas. To develop a feasible combined SQFFQ, we here conducted a survey of food and nutrient intake using a 3-d weighed dietary record method (WDR) in urban and rural areas of Chaoshan.

MATERIALS AND METHODS

The Chaoshan region, including Shantou, Chaozhou and Jieyang cities, is located in the east of Guangdong Province of China, with a population of approximately 10 million. People here still retain their own language and traditional culture. We have demonstrated that Nan'ao county in Chaoshan has the highest incidence and mortality rates of esophageal cancer in all China^[11]. We here selected Chaozhou and Jieyang areas, including Nan'ao county, as representative of the countryside, and Shantou as representative of the new city.

Study subjects

We initially recruited 520 healthy residents aged 30-55 years for participation in our investigation, but only 417 (200 males and 217 females) completed the 3-d WDR survey (70 in Chaozhou, 247 in Shantou and 100 in Nan'ao). The remainder dropped out because of their busy schedules or difficulties in recording. The fraction of sampling for the whole region was 41 per million.

Part juniors in the Chaozhou Normal College, staff of the Shantou Disease Preventive and Control Center, the Director General of the Nan'ao Board of Health and some doctors of Nan'ao Hospitals joined in our research team and were responsible for making contact with the subjects. Supervisors examined the completeness and accuracy of the information from the survey.

Dietary assessment

A 3-d WDR (2 weekdays and 1 weekend day) was performed from December 2002 to August 2003, with a 24-h recall method also used as a supplement. Foods/recipes were individually weighed and recorded for their raw weights before cooking, except with cooked foods bought from markets. The completeness and accuracy of information were also reviewed by the research nutritionists.

Nutrients of interest

The nutrients of interest comprised 29 items: energy, protein, fat, carbohydrates, crude fiber, retinol, carotene, vitamin C, vitamin E, folic acid, sodium, potassium, magnesium, calcium, iron, zinc, copper, selenium, phosphorus, saturated fatty acids (SFA), mono-unsaturated fatty acids (MUFA), poly-unsaturated fatty acids (PUFA), oleic acid, linoleic acid, arachidonic acid, linolenic acid, eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA) and cholesterol.

Selection of foods/recipes

Nutrient intake was calculated by multiplying the food intake

(grams) by the nutrient content per gram of food listed in the China Food Composition 2002, compiled by the Institute of Nutrition and Food Safety, China CDC^[12]. Where necessary we also used data from the Japanese Standard Tables of Food Composition, 5th revised edition^[13] for the nutrient content of foods which were not listed in the China Food Composition.

The selection of food items for developing the SQFFQ was performed using the same procedure as adopted by Tokudome and his colleagues^[14]. At first, contribution analysis (CA) was performed for all nutrients of interest^[14-16], and each food item was listed according to the intake amount of nutrient. We selected food/recipe items with up to a 90% cumulative contribution. Then, multiple regression analysis (MRA) was carried out by adopting the total intake of specific nutrient as the dependent variable and overall amounts of this nutrient from the selected food/recipe items by CA as the independent variables for 417 individuals and secondly choosing foods/recipes with up to a 0.90 cumulative square of the multiple correlation coefficient^[14,16]. Finally, we determined food items for the SQFFQ both by CA and MRA. Some food items with up to 0.90 R^2 but very small % contribution were excluded, because they may be marginal for total nutrient intake. The foods contributing less than three nutrients, with relatively small % contributions, were also excluded. The statistical package SPSS for Windows 10.0 (SPSS Inc., Chicago, IL, USA) was employed for the data analysis.

Intake frequency

The food intake frequencies in SQFFQ were classified into seven categories: almost never; 1-3 times per month; 1-2 times per week; 3-4 times per week; 5-6 times per week; 1-2 times per day; and 3 times per day or more.

Portion size

The standard portion size of each food item per meal was determined using the mean amount, typical/standard value or the natural unit. Portion size in SQFFQ was divided into six categories: none, 0.5, 0.75, 1.0, 1.5, 2.0 or more. As estimation of condiment and oil consumption per meal was difficult, four categories were employed: none, less than normal, normal and more than normal. The normal intake was determined as the mean amount in the 3-d WDR, and allocation to less or more than normal was estimated with reference to the standard deviation. We also took pictures of the most representative foods with a standard portion size and made a food model booklet for standardization of the intake amount.

RESULTS

Characteristics of the subjects studied

Table 1 shows the characteristics of the investigated subjects. The mean age was slightly older for the rural than the urban subjects in both genders. Although the mean height was not different, the mean weight and BMI in urban males were larger than those in their rural counterparts, with statistical significance. This was not the case for females.

Intake of energy and selected nutrients

Table 2 shows mean intake and standard deviations for energy,

Table 1 Characteristics of the investigated subjects

	Males		<i>P</i>	Females		<i>P</i>
	Rural <i>n</i> = 115	Urban <i>n</i> = 102		Rural <i>n</i> = 102	Urban <i>n</i> = 98

protein, fat, carbohydrate and other nutrients. Geographical variation of energy and major nutrient intake was not apparent in either sex, except for greater intake of crude fiber in urban males. Urban males and females consumed more vitamin E, MUFA, PUFA, oleic acid, and linoleic acid than rural subjects. In males, urban subjects consumed more cholesterol, carotene, retinol, folic acid, calcium, potassium and linolenic acid, whereas rural subjects had greater intakes of sodium, DHA and EPA. In females, rural subjects took more zinc and manganese.

We compared the consumption of each nutrient with the Recommended Nutrient Intake (RNI) for the first and second degree of work in China^[17]. The energy consumption in our urban and rural males was similar to RNI, but with females the values were high. The consumption of protein and fat in both genders of urban and rural areas was higher than the RNI, especially for fat, but that for carbohydrate was relatively low.

Selection of food items

The total number of food/recipe items consumed by all subjects over 3 d was 523 (443 and 417 in the urban and rural cases, respectively). The numbers of food items with up to 90% cumulative contribution for 29 nutrients were 233, 194, and 183 in the combined, urban and rural areas, and those for up to 0.9 cumulative *R*² were 196, 157, and 160, respectively. Then, we combined several food items with similar nutrient contents. Finally, we selected 125 food items for a combined SQFFQ. Alcohol beverages were not included in them, because the number of regular drinkers was very small. However, liquor and beer were intentionally added in this SQFFQ, because they are important dietary factors involved in the risk of diabetes and cancer^[4,5].

The number of food items selected for each nutrient by CA and MRA are listed in Table 3. The mean numbers by CA were 58, 46, and 48 for the combined, the urban and

the rural cases, respectively, as compared with 30, 14, and 72 with the MRA.

List of food items

The percentage contributions of the top five foods/recipes for energy, protein, fat and carbohydrate for rural, urban

and combined areas are listed in Tables 4 and 5. Rice was the most important food source for energy, protein and carbohydrate intake, accounting for more than one-third of the energy, followed by peanut oil, pork, mixed oil, and lard, this being similar in both urban and rural areas. One-fourth of protein and more than two-thirds of carbohydrates

Table 4 Percentage contributions of the top five foods for energy and protein

Energy						Protein					
Rural		Urban		Combined		Rural		Urban		Combined	
Rice	45.8	Rice	38.2	Rice	41.9	Rice	28.6	Rice	23.6	Rice	25.7

Table 5 Percentage contribution of the top five foods for fat and carbohydrate

Fat						Carbohydrate					
Rural		Urban		Combined		Rural		Urban		Combined	
Peanut oil	21.7	Peanut oil	24.2	Peanut oil	22.9	Rice	70.4	Rice	67.5	Rice	70.4
Pork	20.2	Mixed oil	17.6	Pork	17.4	Noodle	3.2	Noodle	3.3	Noodle	3.2
Mixed oil	13.3	Pork	15.7	Mixed oil	15.6	Bread	2.3	Bread	3.0	Bread	2.3
Lard	13.1	Lard	11.0	Lard	11.0	Rice noodles	1.7	Rice noodles	2.1	Rice noodles	1.7
Pork chops	3.7	Pork chops	3.6	Pork chops	3.6	White sugar	1.6	White sugar	1.9	White sugar	1.6

were also contributed by rice. Peanut oil supplied more than one-fifth of fats, followed by pork, mixed oil, lard, pig chops and rice according to the CA. As for energy, the combined, urban and rural data also demonstrated almost have the same ranking for protein, fat and carbohydrate.

According to the category of the China Food Composition 2002, the 125 foods/recipes listed in the SQFFQ comprised: cereals (11 items), legumes (6), fresh legumes (3), vegetables (13), melons and nightshade (5), cauliflower (1), roots (7), fruits (11), meats (11), poultry (5), milk (2), eggs (3), pickles (4), marine products (16), mushrooms (5), nuts (2), cakes (3), condiments (6), oils (3) and beverages (8).

Nutrition coverage in the SQFFQ

Table 6 shows the percentage coverage of 29 nutrients by the SQFFQ. The selected food items covered 17, 19, and 16 nutrients with up to 90% of the total intake for the rural, urban and combined SQFFQ, and the lowest coverage percentage of the combined SQFFQ was still 82.7%, for linolenic acid.

DISCUSSION

The present study showed that variation in nutrient consumption between urban and rural subjects in the Chaoshan area was small, and the selected food items for the rural and urban SQFFQs were similar, covered all 29 nutrients with acceptable

percentage values. The present results thus revealed that development of a combined SQFFQ for rural and urban populations is feasible.

The nationwide survey of China held in 1992 showed the national average energy intake to be higher in urban than in rural areas, especially in those with middle and high incomes^[18]. Recent economic improvement may have reduced the variation in diet between rural and urban populations, and increased the amount of nutrient intake in both, but especially in rural individuals. The total energy intake in males was 2.4% higher in the present urban area and 21.0% higher in the rural area than those in the representative urban and rural areas of the same province by nationwide survey. The mean intakes of major nutrients in the present study were 6.4% higher in the urban area and 25.9% higher in the rural area for protein; 15.6% higher and 70.6% higher for fat; 2.1% lower and 1.0% higher for carbohydrate; and 31.9% higher and 15.9% higher for crude fiber, compared with the respective figures from the nationwide survey. The present urban population took more unsaturated fatty acid from vegetables, and the rural population took more animal fat, although geographical variation in total fat intake was not apparent.

Here we chose the 3-d WDR method as the “gold standard” rather than others to develop a SQFFQ for Chaoshan area, because it is the most efficient method for collecting dietary information at present. To decrease the

influence of seasonal variation on food survey, we conducted the survey in three seasons of winter, spring and summer, because there is no major climatic difference between the fall and winter. Although the sample size was relatively small, the number of subjects appeared sufficient from previous studies to develop SQFFQs, including the ones conducted in China^[14,19,20].

We used the two contrasting methods of CA and MRA to select representative food items for stable food intake. Each method has its own particular advantages and disadvantages^[13,14]. The former approach is based on the absolute food and nutrient intake and is especially suitable for investigation of the associations between absolute nutrient intake and disease risk. The latter, in contrast, is based on variance of nutrient intake, and is efficient for categorizing individuals. Therefore, the combination of the two methods for food selection should provide a more suitable SQFFQ for the assessment of food and nutrient intake.

We selected 125 food items, including alcoholic beverages, for the combined SQFFQ. Most were frequently consumed by the local inhabitants. Although the coverage rates of all 29 nutrients were over 80%, the potential for overestimation or underestimation does exist, because of

the incompleteness of the composition table, and the exclusion of food items, such as some marine products, in the selection for the SQFFQ.

We have already developed data-based SQFFQs in Jiangsu, in the central coastal region of China, and Chongqing, more than 1 000 km west inland from Jiangsu, using a standardized method developed in Japan^[14]. We compared the top three food items of three SQFFQs developed in Jiangsu^[19], Chongqing^[20] and the present study area, Chaoshan, more than 1 000 km south of Jiangsu, according to the percentage contribution for energy, protein, fat and carbohydrate by the urban and rural area (Table 7). Most items were shared in common, except for fat. These comparisons suggest the possibility to developing a common SQFFQ to assess and compare dietary factors impacting on cancer by the standardized method^[21].

In summary, in the present investigation we clarified common intake of foods and 29 nutrients in urban and rural areas of Chaoshan, Guangdong Province, China, for adoption in an area-specific SQFFQ. Validity and reproducibility tests^[22–24] are now planned to determine how the combined SQFFQ performs in the actual assessment of disease risk and benefit.

INTRODUCTION

Hepatitis C virus (HCV) infection is increasingly recognized as a major health care problem throughout the world. Approximately 85% of individuals infected with HCV will develop chronic HCV infection^[1,2]. Identified risk factors for HCV infection include intravenous drug use, exposure to infected blood/blood products, and intranasal drug use^[3]. Surveys of HCV infection among IDU have reported prevalence rates as high as 70-90%^[4-6] among habitual injectors. High risk sexual activity (multiple sexual partners), history of sexually transmitted disease, tattooing, and skin piercing have also been suggested to be associated with increased risk for HCV; however, study results have been contradictory^[7].

Whereas the overall seroprevalence of HCV among Iranian blood donors has been estimated to be 0.12%^[8] the prevalence of HCV has been shown to be as high as 45% in populations of incarcerated IV drug users^[9]. HCV seroprevalence among prison inmates varies markedly from country to country^[10,11]. Worldwide hepatitis C data similarly report significant prevalence figures in high risk populations ranging from 30% to 50%, with intravenous drug use being the predominant risk factor^[12-15]. High risk populations are individuals most at risk for hepatitis C, including those medically underserved, have a history of IV drug injection and high-risk behaviors. A dramatic growth in the number of prisoners associated with high-risk behaviors and high rates of community re-entry emphasizes the need for detection and treatment of hepatitis C virus infection in this unique group.

This study could be of particular interest, as in comparison with worldwide hepatitis C data, the seroprevalence of hepatitis C infection among Iranian general population is low. However, recent studies in Iran has shown that the level of hepatitis C infection among Iranian prisoners is as high as HCV seroprevalence in incarcerated population of countries with high prevalence of HCV infection in their general population.

MATERIALS AND METHODS

This study was carried out in the central prison of Hamedan (one of the largest penal institutions in Iran), from mid-June to mid-September 2002. The study protocol conforms to the ethical guideline of the 1975 Declaration of Helsinki, as revised in 1983. The sample was selected by drawing the numbered individual prison files, available to investigators,

Abstract

AIM: Recent studies in Iran has shown that prevalence of hepatitis C virus (HCV) infection among Iranian prisoners is high, in spite of low HCV seroprevalence in general population.

METHODS: This study was carried out in the central prison of Hamedan - Iran, in year 2002. Inmates were interviewed using a standard questionnaire including demographic, imprisonment history and HCV-related risk behaviors items. Thereafter, the sera drawn from the participants were tested for anti-HIV and anti-HCV antibodies.

RESULTS: A total number of 427 drug abuser inmates participated in our study. Three hundred and ninety-seven (93%) were men and 30 (7%) were women. Total number of IV drug abusers (IDA) and non-IV drug abusers (NIDA) was 149 (34.9%) and 278 (65.1%), respectively. The overall rate of antibody positivity among inmates was 0.9% for HIV and 30% for HCV. Of all IDAs, 31.5% and of NIDAs, 29.1% had serological evidence of HCV infection.

CONCLUSION: The seroprevalence of HCV infection among drug abuser prisoners in comparison with the general population in Iran, is very high (30% *vs* in italics 0.2%). Our results indicate the importance of policies to prevent transmission of HCV infection during and following incarceration.

Alizadeh AHM, Alavian SM, Jafari K, Yazdi N. Prevalence of hepatitis C virus infection and its related risk factors in drug abuser prisoners in Hamedan - Iran. *World J Gastroenterol*

in intervals determined by a random number generator. There were 427 drug abuser inmates in our study. Participation in this study was voluntary and confidentiality was guaranteed. All inmates were counseled about the study and they were required to provide signed informed consent. Thereafter, inmates were interviewed using a standard questionnaire including demographic items, specific questions relative to their imprisonment history and HCV-related risk behaviors such as intravenous drugs abuse, having received blood and/or blood products, tattoos, body piercing, sexual activity, and history of sexually transmitted diseases.

Physical examination was performed on all participants and afterward 8 mL of blood was taken. The sera were tested for anti-HIV and anti-HCV antibodies by using an enzyme-linked immunosorbent assay (ELISA) 3rd generation (for anti-HCV antibodies we used HCV 3.0 ELISA Test System with Enhanced SAvE; ORTHO®, Raritan, NJ, USA). All anti-HCV Ab positive sera were retested, using recombinant immunoblot assay (RIBA) 2nd generation (HCV Blot 3.0; Genelabs® Diagnostics, Singapore) as a complementary test. Patients with both ELISA and RIBA positive reports were considered to be infected with HCV.

Microsoft Access 2000 database software was used (Microsoft Corp., Redmond, WA, USA). Basic descriptive statistics were performed using SPSS for Windows (version 11.0; SPSS Inc., Chicago, IL, USA) software. Risk factors prevalences were generated using data from all consented study participants. Standard χ^2 and χ^2 trend tests were performed to assess the univariate relationship of demographic and behavioral variables and HCV seroprevalence. Univariate ORs were computed with 95% confidence intervals (CIs) for each risk factor.

RESULTS

A total number of 427 drug abuser inmates participated in

our study. Three hundred and ninety-seven (93%) were men and 30 (7%) were women. Total number of IV drug abusers (IDA) was 149 (34.9%). The remaining 278 individuals (65.1%) were non-IV drug abusers (NIDA). Demographic characteristics of drug abuser inmates are depicted in Table 1.

The overall rate of antibody positivity among inmates for HIV was 0.9% (4/427) and for HCV was 30% (128/427). Of all IDAs, 31.5% (47/149) had serological evidence of HCV infection and in NIDAs seropositivity for HCV was 29.1% (81/278). There were no significant statistical differences for HCV seropositivity between the two groups.

About HIV infection in the two groups, only one inmate (out of 149, 0.67%) was seropositive for HIV in IDA group and in NIDA we found three inmates with anti-HIV antibodies (3/278, 1.07%). Because the number of HIV infected participants was small, no statistical comparisons were conducted. Among three HIV positive individuals, all were male and their ages were between 30 and 49 (mean 37.5), one was IV drug abuser for 36 mo, one reported history of tattoos and one had received blood transfusion, they spent 2-26 mo in prison.

As shown in Table 1, the pattern of HCV antibody prevalence differed within each demographic characteristic.

The mean \pm SD of participants was 37.9 ± 9.7 (range 15-77 years old). Most participants belonged to 30-39 years old age group (34.7%) and HCV seropositivity in ≤ 20 years and 40-49 years old age group was highest (40% and 31.6%, respectively; $P = 0.70$).

None of the inmates had high risk job (health-care related) be infected by HCV or HIV. 42.6% of HCV seropositive participants were labourers and 41% had private business, 8.2% were farmers, 6.6% housekeepers, and 1.6% were unemployed (no significant difference, $P = 0.4$).

As depicted in Table 2, we studied the association between some behavioral characteristics and HCV seropositivity. The

¹Hepatitis C Virus. ²Basis of numbers and %s may be slightly smaller due to missing values. ³Odds ratio, 95% confidence interval. ⁴Sexually transmitted disease.

seroprevalence of HCV was associated with duration of imprisonment ($P = 0.02$). Remarkably, 100% of the individuals who reported 108-119 mo of imprisonment were infected with HCV.

DISCUSSION

High risk populations are individuals most at risk of contracting hepatitis C, including those who come from medically underserved and minority communities and /or have a history of IV drug injection, alcohol abuse, and multiple sex partners^[16]. IV drug abusing remains the predominant mode of HCV transmission risk in prison systems^[17].

In this study we evaluated the seroprevalence of HCV and HIV among drug abuser inmates (IV drug abusers (IDA) and non-IV drug abusers (NIDA)). Prevalence of HCV antibody positivity among all participants was 30%. HCV seroprevalence in IDA and NIDA groups was 31.5% and 29.1%, respectively, and confirms the high prevalence of

blood borne disease in those with imprisonment history^[18-20]. Different studies have estimated the seroprevalence of HCV antibody among the general population (blood donors, mostly) to be about 0.16-6% world-wide^[8,21-24]. In high risk population in comparison to the general population, IV drug abusing, sharing needles and tattooing may increase risk status.

We found only one published similar investigation on Iranian prisoners. In Zali *et al.* study^[9], the seroprevalence of HCV among IDAs was 45%. In the studies on prisoners of Australia, Brazil, France, India, Ireland, UK and United States the HCV seroprevalence were about 38%, 6.3%, 30%, 16%, 37%, 30%, and 41%, respectively^[25-28,10,12,13]. According to other investigations worldwide, hepatitis C antibody positivity prevalence in high risk ranges from 31% to 50%, while intravenous drug abuse is the predominant risk factor^[11,29-33].

Limited available data indicate the majority of HCV infections are acquired before incarceration^[16]. Blood serum evaluations among 265 male prison inmates in Maryland

(USA) revealed a hepatitis C prevalence of 38% at intake^[34].

In our study, the overall rate of HIV antibody among prisoners was 0.9% (4/427). In IDA and NIDA groups, we found 0.67% and 1.07% positive HIV antibodies. The HCV prevalence rate in our study was higher than HIV prevalence. However, the findings are in accordance with those in many countries - including Germany, Nederland, Switzerland and Australia^[35,36]. In Iran we have no similar investigation on HIV seroprevalence of prisoners in comparison with our results.

Prevalence of antibodies of HIV in Irish and Brazilian prisoners was 2% and 3.2%, respectively^[13,26]. The HIV prevalence reported in prison studies from other developed countries is similar^[37-40].

Some limitations of our study should be considered. As with any convenience sample, this study had the limitation of being a self-selected group and may not be a representative of all Iranian prisoners. In addition, because of religious beliefs and security problems of prisons, many individuals could not respond properly to the questions containing sex behavior characteristics. Therefore we excluded the sex behavior related risk factors from statistical analysis. Because of financial problems we couldn't perform PCR on our samples.

In our investigation we studied some risk factors related to HCV and HIV infection. Participants who had spent more time in prison, however, and those who had history of hospitalization were significantly more likely to be positive for antibodies to HCV. Being in prison in Iran may be an independent risk factor for hepatitis C infection. We found no statistical association between HCV and other risk factors and there was no significant difference in HCV seropositivity prevalence between IV drug abusers and non IV drug abusers recommending the possibility of some other unknown etiologic factors. The high percentage of HCV positive cases with no apparent risk factor further emphasizes the need for further investigation on the routes of transmission and other factors, which have not yet been concerned. It should be noted that in some investigations, there were considerable numbers of HCV infected cases with no apparent risk factors, depicting the complex nature of HCV transmission^[41-45].

Although the inmates participating in this study cannot be considered representative of all prisoners in Iran, the results obtained have important implications for penal and public health administrators, indicating the importance of policies to prevent transmission of these infections during and following incarceration. These policies must include primary concern on not only identification of those most at risk but also on provision of appropriate treatment^[8,12,16,26]. Specific harm-reduction strategies directed toward preventative education and counselling are also crucial. In addition, testing programs in prisons, which should be seen as an opportunity to improve the health outcome of those infected and prevent further transmission of infectious agents^[46-48].

There are few studies involving large multicentre sampling that provided epidemiological aspects of HCV infection among prison inmates in Iran. In conclusion, prospective studies with meticulous assessment of confounding risk factors are required to assess the potential risk factors of HCV and HIV infections in prisons of Iran, effectively.

Abstract

AIM: To explore a novel mechanism for tumor necrosis factor-related apoptosis-inducing ligand (TRAIL), upregulation of CD4⁺ and CD8⁺ T lymphocytes participating in the pathophysiological process of chronic hepatitis B (CHB).

METHODS: The levels of serum soluble TRAIL (sTRAIL), serum IFN- γ and membrane-bound TRAIL expression on peripheral leucocytes from 58 CHB patients were examined by ELISA and flow cytometry respectively. The levels of TRAIL were compared with the baseline levels of 17 healthy controls, and correlation analysis was performed between ALT, TBIL, PT, morphological change in hepatic tissues, and serum IFN- γ .

RESULTS: The results showed that TRAIL levels on membranes of CD4⁺, CD8⁺ T cells in CHB patients were much higher than those in healthy controls ($P < 0.001$), and were correlated with serum TBIL ($r = 0.354$, $P = 0.008$ for CD4⁺ and $r = 0.522$, $P = 0.000$ for CD8⁺, respectively), ALT ($r = 0.393$, $P = 0.003$ for CD8⁺), PT ($r = 0.385$, $P = 0.004$ for CD8⁺) and serum IFN- γ level ($r = 0.302$, $P = 0.011$ for CD4⁺ and $r = 0.307$, $P = 0.009$ for CD8⁺). On the contrary to membrane-bound TRAIL expression, serum level of sTRAIL was not correlated with that of TBIL and PT, though it was higher than that of the normal population and was positively correlated with serum HBeAg expression ($r = 0.695$, $P = 0.001$).

CONCLUSION: The expression level of TRAIL on the membrane of lymphocytes was upregulated and associated with the liver injury in CHB patients. These findings suggest that upregulation of TRAIL expression may be induced by virus antigen and inflammatory cytokine IFN- γ .

INTRODUCTION

The TNF- α and Fas systems as well as the perforin/granzyme system have been implicated in hepatocyte apoptotic processes in viral hepatitis. Tumor necrosis factor-related apoptosis-inducing ligand (TRAIL), a type II transmembrane protein^[1], is a recently identified member of the TNF family and is capable of inducing apoptosis in virus-infected cells. This suggests that TRAIL may play an important role in HBV immunopathology. Human CD4⁺ T cell clones exhibit TRAIL-mediated cytotoxicity against certain target cells^[2], indicating that TRAIL constitutes an additional pathway of T cell-mediated cytotoxicity. The aim of this study was to study a possible novel mechanism for TRAIL upregulation of CD4⁺ and CD8⁺ T lymphocytes participating in the pathophysiological process of chronic hepatitis B (CHB).

MATERIALS AND METHODS

Patients

Fifty-eight patients seropositive for HBV marker (HBsAg) for more than 6 mo were the subjects of this study. Thirty were seropositive for HBV DNA, and all were negative for other hepatitis virus and HIV markers in sera. None had received any antiviral therapy or immunotherapy in the preceding 6 mo. They were classified into four groups^[3]: 13 cases with mild chronic hepatitis (CH1), 14 cases with moderate chronic hepatitis (CH2-3), 15 with liver cirrhosis (LC) and 16 with chronic severe hepatitis (CSH). Seventeen healthy laboratory workers negative for HBsAg and normal in liver functions were assessed at the same time and served as controls. The demographic data of all participants are summarized in Table 1. Serum specimens for antibody to HAV, HCV, HDV, HEV, as well as antibody to HIV were tested by enzyme immunoassay. Immunoassay for the *in vitro* qualitative determination of serum HBsAg and HBeAg was tested on Roche Elecsys immunoassay analyzers, HBV DNA was assayed by quantitative PCR.

Leukocyte and flow cytometry

Citrated blood samples were obtained. Aliquots of 100 μ L

were incubated for 15 min with 20 μ L antibody against TRAIL-PE (eBioscience, Clone number RIK-2), CD4-FITC, CD8-FITC, or isotype control (CALTAG, USA) at room temperature. After labeling with the antibody, leukocyte suspensions were washed and erythrocytes were lysed using FACS brand lysing solution (Becton Dickinson, USA). Washed cells were resuspended in 300 μ L of PBS and analyzed. FACS scan flow cytometer (Becton Dickinson, USA) and cell quest software were used for acquisition and analysis of the data. Populations of lymphocytes were identified from forward and side scatter characteristics on dot plot profiles and were analyzed for fluorescence intensity using fixed defined gate. At least 10 000 cells per sample were acquired.

ELISA

Serum specimens collected were stored at -80°C , and IFN- γ and soluble TRAIL (sTRAIL) protein levels were determined using immunoassay kit according to manufacturer's specifications.

Statistical analysis

Statistically significant differences among groups of patients were determined by ANOVA, correlation coefficients were determined by Pearson (two-tailed) using SPSS10.0 software, and P values ≤ 0.05 were considered as significant.

RESULTS

Changes of serum soluble TRAIL and modulation of membrane-bound TRAIL expression on peripheral T lymphocytes in chronic hepatitis

The results showed that TRAIL levels in membranes of

CD4 $^{+}$ and CD8 $^{+}$ T lymphocytes and the serum levels of sTRAIL in CHB patients were much higher than those in healthy controls ($P < 0.001$). Membrane-bound TRAIL expression was shown to correlate with the activity of viral hepatitis, that of CD4 $^{+}$ and CD8 $^{+}$ T lymphocytes correlated with serum TBIL ($r = 0.354$, $P = 0.008$ for TRAIL of CD4 $^{+}$ *vs* TBIL and $r = 0.522$, $P = 0.000$ for TRAIL of CD8 $^{+}$ *vs* TBIL) and that of CD8 $^{+}$ T lymphocytes was correlated with serum ALT ($r = 0.393$, $P = 0.003$), and PT ($r = 0.385$, $P = 0.004$). A positive relationship between serum IFN- γ level and the degree of TRAIL antigen expressions of CD4 $^{+}$ and CD8 $^{+}$ T lymphocytes ($r = 0.302$, $P = 0.011$ for TRAIL of CD4 $^{+}$ *vs* IFN- γ ; $r = 0.307$, $P = 0.009$ for TRAIL of CD8 $^{+}$ *vs* IFN- γ) was shown. Serum level of sTRAIL was not correlated with TBIL and PT, though it was higher than that in normal population. The related results are shown in Table 2.

Positive correlation between liver histological findings and membrane-bound TRAIL expression

In 30 samples from 58 HBV patients, with the aggravation of liver inflammation grade, membrane-bound TRAIL expression in peripheral T lymphocytes in chronic hepatitis was upregulated. There was a positive correlation between the inflammation grade and level of TRAIL antigen expression ($r = 0.677$, $P < 0.01$). Statistical analysis is shown in Table 3.

Positive correlation between serum IFN- γ level and membrane-bound TRAIL expression

The serum level of IFN- γ in patients with CHB was 24.04 ± 19.03 pg/mL for CH1, 76.02 ± 84.35 pg/mL for

CH2-3, 81.81±63.11 pg/mL for CSH. There was a positive relationship between serum levels of IFN- γ and TRAIL antigen expression in CD4⁺T ($r = 0.302$, $P = 0.011$) and CD8⁺T ($r = 0.307$, $P = 0.009$). No relationship between serum levels of IFN- γ and sTRAIL was found.

DISCUSSION

In this paper, a possible novel mechanism for TRAIL upregulation of CD4⁺, CD8⁺ T lymphocytes participating in the pathophysiological process of CHB was studied in patients with CHB. HBV is the main etiologic agent for viral hepatitis. Cytotoxic T lymphocytes (CTLs) recognize viral peptides, which have been intracellularly processed and expressed on cell surface of hepatocytes in conjunction with MHC class I molecules. CTL-induced immunological tissue destruction is one of the hallmarks of liver injury in viral hepatitis. Apoptosis is now recognized to play a significant role in the pathogenesis. Different pathways, which include the Fas and TNF- α system as well as the perforin/granzyme system, have been implicated in hepatocyte apoptotic processes^[4]. Fas has been shown to be correlated with the activity of viral hepatitis^[5], and Fas expression can be induced either by virus-specific protein expression or by inflammatory cytokines such as interleukin-1. Activated CTLs express FasL and induce hepatocyte apoptosis via Fas signaling cascades. TNF-R1 expression has also been shown to be enhanced in HBV, and the increased production of TNF- α has been demonstrated in peripheral blood mononuclear cells in hepatitis B. Additionally, HBx has been shown to sensitize cultured and transfected hepatocytes to TNF- α -induced apoptosis^[6]. In contrast to Fas and TNF- α signaling, the potential hepatotoxicity of TRAIL is still controversial, especially its ability to induce hepatocyte apoptosis. A recombinant soluble version of TRAIL ligand fused to a trimerizing leucine zipper failed to induce hepatotoxicity in mice^[7], whereas a polyhistidine-tagged recombinant soluble form of TRAIL was reported to induce apoptosis in cultured human hepatocytes^[8]. Because of the rapid dedifferentiation of cultured hepatocytes, it is difficult to extrapolate these experiments to *in vivo* condition. Furthermore, these discrepancies may be attributed to the different TRAIL agonists. Although there is expression of TRAIL receptors 1 and 2 mRNA in human liver, a more recent report^[9] demonstrated that TRAIL-R2 protein was minimally expressed in human hepatocytes and a specific TRAIL-R2 agonist did not induce apoptosis in cultured human hepatocytes. Therefore, TRAIL signaling seems to play a less important role in pathophysiological process of hepatocyte apoptosis than Fas or TNF- α . In this paper we

found that even serum sTRAIL in healthy individuals is very high, which also supports this theory. However, since TRAIL-R expression can be induced, for example, by DNA damage or by bile acid^[10,11], it is also possible that hepatocyte sensitivity to TRAIL may increase in disease states. Viral infection triggering sensitivity to TRAIL-mediated apoptosis has been reported. Yoon *et al.*^[4], have recently observed that in HBV-transfected HepG2 cells, TRAIL-R1 expression level was higher than in their parent cell line, HepG2 cells. Moreover, the HBV-transfected cells were more sensitive to TRAIL-induced apoptosis than the untransfected ones, and this sensitization was reduced by anti-viral treatment. Our group also demonstrated that in HBV-transfected HepG2 cells, TRAIL expression level was higher than in their parent cell line (unpublished data). Mundt *et al.*^[12], also reported that HBV-mediated acute liver failure resulted in upregulation of protein expression of TRAIL and TRAIL receptors, thereby activating the TRAIL-specific death pathway in HBV-infected hepatocytes. Our study is the first report that membrane-bound TRAIL expression on peripheral T lymphocytes in CHB was upregulated and was correlated with the activity of viral hepatitis. Serum level of sTRAIL was not correlated with TBIL and PT, and same results were also reported by Janssen *et al.*^[13]. It suggested that serum level of sTRAIL was unable to accurately reflect the severity of disease.

Recently it was reported that the expression level of sTRAIL was positively correlated with the level of HBeAg. Furthermore, we found that there existed a positive correlation between the degree of TRAIL antigen expression and serum levels of IFN- γ . The IFN-induced gene family is now known to comprise the death ligand TRAIL, the dsRNA-dependent protein kinase, interferon regulatory factors and the promyelocytic leukemia gene, all of which have been reported to be the mediators of cell death^[14]. Our study suggests that interaction of TRAIL signaling and IFN- γ participates in the pathophysiological process in CHB patients.

TRAIL expression in liver tissues, especially in lymphocytes needs to be analyzed further.

Abstract

AIM: To prepare and identify specific anti-mouse caspase-12 hammerhead ribozymes *in vitro*, in order to select a more effective ribozyme against mouse caspase-12 as a potential tool to rescue cells from endoplasmic reticulum stress induced apoptosis.

METHODS: Two hammerhead ribozymes directed separately against 138 and 218 site of nucleotide of mouse caspase-12 mRNA were designed by computer software, and their DNA sequences were synthesized. The synthesized ribozymes were cloned into an eukaryotic expression vector-neo^rpBSKU6 and embedded in U6 SnRNA context for further study. Mouse caspase-12 gene segment was cloned into PGEM-T vector under the control of T7 RNA polymerase promoter (containing gene sequence from positions nt 41 to nt 894) as target. *In vitro* transcription both the ribozymes and target utilize T7 promoter. The target was labeled with [α -³²P]UTP, while ribozymes were not labeled. After gel purification the RNAs were dissolved in RNase free water. Ribozyme and target were incubated for 90 min at 37 °C in reaction buffer (40 mmol/L Tris-HCL, pH 7.5, 10 mmol/L Mg²⁺). Molar ratio of ribozyme vs target was 30:1. Samples were analyzed on 6% PAGE (containing 8 mol/L urea).

RESULTS: Both caspase-12 and ribozyme gene sequences were successfully cloned into expression vector confirmed by sequencing. Ribozymes and caspase-12 mRNA were obtained by *in vitro* transcription. Cleavage experiment showed that in a physiological similar condition (37 °C, pH 7.5), Rz138 and Rz218 both cleaved targets at predicted sites, for Rz138 the cleavage efficiency was about 100%, for Rz218 the value was 36.66%.

CONCLUSION: Rz138 prepared *in vitro* can site specific

INTRODUCTION

Apoptosis plays an important role in the pathogenesis of liver diseases^[1]. Activation of death receptors and mitochondrial damage are well-described common apoptotic pathways. Recently, a novel pathway via endoplasmic reticulum (ER) stress was reported^[2]. Following studies have demonstrated that many liver diseases are associated with ER stress, including nonalcoholic steatohepatitis, cholestasis, alcohol induced liver diseases, and viral hepatitis^[3-5].

Among the death-specific enzymes in apoptosis is a family of cystein-dependent aspartate-specific proteases known as caspases^[6]. Activation of caspases is a central mechanism in the apoptotic cell death process^[7].

Caspase-12 resides in the endoplasmic reticulum and is specifically involved in the apoptosis that results from ER stress, Apoptosis triggered through pathways that do not involve the ER, such as serum deprivation or Fas-activation, do not result in activation of caspase-12. Cells isolated from transgenic mice that lack intact caspase-12 protein were more resistant to ER stress-induced apoptosis than wild type cells^[2].

Caspases are central to both normal programmed cell death and injury-dependent apoptosis, so any therapy that manipulates caspase activity must take into account the possible effects on tissue homeostasis. In this regard, caspase-12 seems to have a strong advantage as a target over other caspases. In contrast to other caspase knockouts, caspase-12 deficient mice have no noticeable developmental or behavioral defects, and have a normal incidence of tumors^[2]. So caspase-12 may be a promising target for treating ER stress associated diseases with few side effect.

Until now, no specific caspase-12 inhibitors are available. Ribozymes (Rz) are RNA molecules with enzymatic activity

that can associate with a larger target RNA by base-pairing to cleave a specific phosphodiester bond^[2,8]. In the past years, ribozyme-mediated gene inhibition has been demonstrated for many examples in cell lines. Selective downregulation of a particular caspase by ribozyme provides an alternative approach to rescue cells from apoptosis^[9-11].

Catalytic cleavage of caspase-12 mRNA by ribozyme may block ER stress induced apoptotic pathway, thus protect liver cells from apoptosis. In the present study, ribozymes were designed and synthesized against the sequences of caspase-12 mRNA which cleave at nucleotide positions 138 and 218 respectively. Also mutant ribozymes were synthesized for future study. Transcription and cleavage reaction were performed *in vitro* to determine the activity of ribozymes designed and assess the potential value of them against caspase-12 mediated apoptosis.

MATERIALS AND METHODS

Material

PGEM-T vector kit, transcription kit, TRIzol kit, and T4 DNA ligase were purchased from Promega Company. RT-PCR kit, Restriction endonucleases were purchased from TaKaRa Company. [α -³²P]UTP was the product of Amersham Biosciences UK. E coli DH5 α and eukaryotic expression vector-neo^rpBSKU6 for ribozyme were kind gifts from Dr. YouXin Jin. The PCR primers and ribozyme gene sequences were synthesized in the Beckman Oligo-1000 DNA synthesizer.

Methods

Cloning of Caspase-12 cDNA Mouse caspase-12 mRNA gene sequence was obtained from online Genbank of NCBI (GI: 2094805). Total RNA of fresh mouse liver tissue was extracted using Trizol kit. The up stream primer for RT-PCR amplification of caspase-12 gene segment was F: 5'-TCT AGA CCA GGA GGA CAC ATG AAA GA-3' (41-60 bp), the 5' extension underlined is *Xba*I site, the downstream primer was R: 5'-GGA TCC TCT CAG ACT CCG ACA GTT AG-3' (894-875 bp), the 5' extension underlined is *Bam*HI site. PCR product contained gene sequence from position nt 41 to nt 894 with *Xba*I site ahead and *Bam*HI site behind. Purified PCR product were inserted into pGEM-T vector through A-T pairing under the control of T7 RNA polymerase promoter. The recombinants were transfected into competent JM109 E Coli cells for blue/white screening on LB plate. The selected clone containing Caspase-12 cDNA was confirmed by sequencing and named pCaspase-12.

Ribozyme Construction The hammerhead ribozymes were designed according to the computer software compiled by Professor Chen Nong-An (Shanghai Institute of Biochemistry of the Chinese Academy of Science). The specificity of ribozymes designed for mouse caspase-12 mRNA were determined by sequence analysis with other RNA sequences of mouse cells in NCBI GenBank using blastn. The sequences of the two ribozymes are shown in Table 1. G in the catalytic core for active ribozyme, A for inactive ribozyme. The inactive ribozymes allow binding to the target RNA, but lack cleavage ability^[12]. Oligonucleotides

encoding Rz138 and Rz218 were designed to generate *Xba*I/*Bam*HI ends upon annealing and were ligated with the *Bam*HI and *Xba*I digested neo^rpBSKU6 plasmid embedded in U6 SnRNA context containing U6 SnRNA promoter/enhancer and terminator. The reconstructed plasmids were named pRz138, pRz138m(mutant), pRz218, pRz218m respectively according to the confirmation of DNA sequencing, and the reconstructed Rz plasmids were prepared for further *in vivo* study.

Table 1 Ribozyme sequence

	5' binding arm	Catalytic core	3' binding arm
Rz138	5' TCCATTAA	CT(G/A)ATGAGTCCGT GAGGACGAA	ACATTCTT 3'
Rz218	5' TCTCTAAG	CT(G/A)ATGAGTCCGT GAGGACGAA	AGTTCTC 3'

In vitro transcription of ribozymes and target RNA

In vitro transcription were prepared according to the supplier (Promega). Both the ribozymes and substrate were transcribed with T7 RNA polymerase. Transcription of target RNA started with an additional 46 nt derived from the vector and terminated just at the end of *Bam*HI linearized pCaspase-12. The total length was 910 nt. Substrate transcription was performed in 20 μ L volume in the presence of 1 μ L [α -³²P]UTP (10 uci/ μ L), while ribozymes were not labeled with isotope. Ribozyme templates were produced by PCR, primers were complementary to the flanking U6 sequence adjacent to the embedded ribozyme, T7 promoter was pulsed to the F primer 5'-TCT AGA GTA ATA CGA CTC ACT ATA GGG C CTT CGG CAG CAC ATA TAC-3', the underlined sequence represents T7 promoter. Primer R was 5'-TAT GGA ACG CTT CAG GAT-3'. PCR products were purified by 12 g/L agarose gel electrophoresis as templates for transcription. The products of transcription were purified with 6% denaturing polyacrylamide gels (PAGE), the bands were cut off from the gel and soaked in NES (0.5 mol/L NH₄Ac, 1 mmol/L EDTA, 0.1% SDS) at 45 °C overnight. After centrifuge, the supernatant were precipitated by ethanol and 3 mol/L sodium acetate, washed twice by 75% ethanol, then dissolved in RNase free water. The [α -³²P]UTP labeled substrate was counted in a Beckman-LS 6500 counter^[13]. As many studies show that inactive mutant ribozymes have no cleavage activity^[12,14,15], we preferred to use the normal Rz *in vitro* study.

Identification of ribozyme activity by cleavage reaction

The molar quantity of target RNA was estimated according to the cpm value combined with the UTP number in the RNA. Rz molar concentration was estimated according to the spectrophotometric A_{260} value. Ribozyme and substrate were incubated for 90 min at 37 °C in reaction buffer (40 mmol/L Tris-HCl, pH 7.5, 10 mmol/L Mg²⁺). Molar ratio of ribozyme versus substrate was 30:1. Samples were analyzed on 6% PAGE (containing 8 mol/L urea). The cleavage efficiency [CE] was calculated from cpm values of the bands of undigested substrate (S) and product (P) separated from denaturing PAGE. CE = [P/(P+S)]•100%.

RESULTS

Transcription of caspase-12 cDNA fragment

RT-PCR amplified caspase-12 cDNA segment was separated by 1.2% agarose gel and stained with ethidium bromide. The length of product containing restriction endonuclease site was 866bp. (Figure 1).

Purified caspase-12 PCR product was inserted into pGEM-T vector by A-T base pairing. After blue/white screening on LB plate and DNA sequencing, pCaspase-12 was confirmed. Then, *Bam*HI linearized pCaspase-12 was used as transcription template. The length of transcribed target RNA as shown in Figure 2 was 910 nt.

Figure 1 Agarose gel electrophoresis of caspase-12 RT-PCR product. Lane 1: DL 2000 DNA Marker; lane 2: The 866 bp caspase-12 gene segment produced by RT-PCR.

Figure 2 *In vitro* transcription product of caspase-12 segment, separated by 6% PAGE, the transcript was 910 nt.

Transcription of ribozymes

The length of Rz templates for transcription produced by PCR were about 100 bp (Figure 3). Transcription products were also purified through 6% PAGE, using upper ultraviolet to determine the position of the bands. The bands were excised and dissolved in RNase free water and reserved under -20 °C.

Figure 3 Agarose gel electrophoresis of PCR amplified ribozyme templates. Lane 1: DL 2000 DNA Marker; lane 2: Rz138 template produced by PCR; lane 3: Rz218 template produced by PCR.

Cleavage *in vitro*

As shown in Figure 4A, The length of target RNA transcribed from *Bam*HI linearized pCaspase-12, which contains the mouse caspase-12 cDNA segment, should be 910 nt, and the expected fragments cleaved by Rz138 *in vitro* should be 150 nt and 760 nt. Rz218 cleavage would generate 230 nt and 680 nt. The cleavage result showed that at a 30:1 ribozyme-to-target ratio, both Rz138 and Rz218 cleaved target at the predicted sites which were consistent with our design and proved to be correct (Figure 4B). The cleavage efficiency of Rz138 was about 100%, while 36.66% for Rz218.

Figure 4 *In vitro* Cleavage of mouse caspase-12 mRNA by ribozymes. **A:** The length of caspase-12 segment transcribed from *Bam*HI linearized pCaspase-12 which contains the mouse caspase-12 gene segment, and its anticipated cleavage products. **B:** The results of cleavage reaction by PAGE electrophoresis. Lane 1: Rz138 cleavage result; lane 2: Rz218 cleavage result; lane 3: control (control contains all other components except ribozyme.).

DISCUSSION

Apoptosis is essential to development of multicellular organisms as well as to physiologic cell turn over. Excessive apoptosis may contribute to organ injury^[16]. A novel apoptotic pathway via ER stress was recently testified in mouse. Prolonged ER stress leads to cell death and is linked to the pathogenesis of some neurodegenerative disorders. ER stress also plays an important role in several liver diseases^[3-5,17]. Activation of caspase-12 from procaspase-12 is specifically induced by insult to the ER, ER stress triggers a specific cascade involving caspase-12,-9,-3. Although it was reported that human caspase-12 may have no significant effect on apoptotic sensitivity^[18,19], many evidences show that functional caspase-12 exists in many human cell types and is associated with ER stress induced apoptosis.^[20-22] It was knowing that cells lack of intact caspase-12 protein were more resistant to ER stress-induced apoptosis than wild type cells. Inhibition of caspase-12 expression by ribozyme may block ER stress induced apoptotic pathway, thus protect liver cells from apoptosis.

The ribozymes are divided into two groups: small ribozymes and large ribozymes. Small ribozymes, approximately those less than 100 nucleotides, include the

hammerhead ribozyme, hairpin ribozyme, and hepatitis delta virus ribozyme. Large ribozymes contain ribonuclease P RNA and group I and group II introns. Hammerhead ribozyme is simple in structure with high turnover in cleavage reaction. The activity of the hammerhead ribozyme is significant higher than that of all other ribozymes *in vitro*. It's being widely used to inhibit endogenous gene expression of basic biochemical pathways such as angiogenesis and apoptosis. It's the first to be approved to use in clinical trial^[23]. It contains a tripartite structure consisting of a central catalytic core that is flanked on both sides by two antisense side arms that can form base pairs with the RNA substrate, thus providing the sequence specificity of the endonuclease action. Sequences 5' to the catalytic domain form helix I and sequences 3' to it form helix III when complexed with the target RNA^[24].

Ribozyme used as molecular tool for specific inhibition of gene translation is affected by many factors including the mRNA secondary structures and target accessibility. Our studies show that computer aided energy minimization algorithms predicted regions in mouse caspase-12 mRNA are accessible to ribozyme cleavage. The cleavage reaction revealed that Rz138 and Rz218 prepared *in vitro* possessed perfect specific catalytic cleavage activity. Rz138 has an excellent cleavage efficiency. The results were consistent with our designed. This finding made it worthy to do further study on the cleavage activity of these ribozymes *in vivo* and to develop them as a therapeutic nucleic acid drug in the future. Considering that the *in vitro* activity does not represent exactly the efficiency of a ribozyme in degrading the target mRNA in intact cells, we've cloned the two ribozymes in eukaryotic expression vector for further study *in vivo*.

Abstract

AIM: To investigate the radiation response of various human tumor cells and normal liver cells.

METHODS: Cell lines of human hepatoma cells (SMMC-7721), liver cells (L02), melanoma cells (A375) and cervical tumor (HeLa) were irradiated with ^{60}Co γ -rays. Cell survive was documented by a colony assay. Chromatid breaks were measured by counting the number of chromatid breaks and isochromatid breaks immediately after prematurely chromosome condensed by Calyculin-A.

RESULTS: Linear quadratic survival curve was observed in all of four cell lines, and dose-dependent increase in radiation-induced chromatid and isochromatid breaks were observed in GB2B phase. Among these four cell lines, A375 was most sensitive to radiation, while, L02 had the lowest radiosensitivity. For normal liver cells, chromatid breaks were easy to be repaired, isochromatid breaks were difficult to be repaired.

CONCLUSION: The results suggest that the γ -rays induced chromatid breaks can be possibly used as a good predictor of radiosensitivity, also, unrejoined isochromatid breaks probably tightly related with cell cancerization.

INTRODUCTION

Liver cancer is one kind of malignancy tumor with the highest incidence and clinical risk, especially popular in China. As till now, radiotherapy is the most acceptable and effective method. Low LET (Linear energy transfer) rays, such as X-ray, γ -ray, were often used. Radiobiologists aim to develop an assay or a combinative assay to predict the radiation response of human cancers. Precise prediction of response to radiation could provide the basis for selecting and designing clinical treatment project.

Colony assay or growth assay has the good correlation with the radiation response^[1-5]. But as a routine predictive assay, it will take at least 2 or 3 weeks to form the clone, is unlikely to be used for clinical diagnosis and treatment.

The PCC (premature chromosome condensation) technique is very useful for measuring the radiation-induced chromatin breaks in all of the cell cycles^[6-9], especially in G_2 phase. In the present study, we investigated the G_2 phase radiosensitivity of human hepatoma cells and normal liver cells, compared with other two type of human malignancy tumors. The results showed that the radiosensitivity of normal liver cells is lowest among these four cell lines, suggest that in the course of liver cancer radiotherapy, liver cells will less injured than hepatoma cells and other two tumor cell lines when absorbed same dose of radiation.

MATERIALS AND METHODS

Cell culture and irradiation

Four cell lines (From CCTCC) were grown in RPMI-1640 medium supplemented with 10% fetal calf serum at 37 °C in 50 mL/L CO_2 , additional 0.25 U/mL insulin was added into the L02 culture medium.

Exponentially growing cells were irradiated with γ -rays generated by ^{60}Co source with a dose rate 0.2 Gy/min at Lanzhou medicine college, dose range was from 0 to 8 Gy.

Chromosome preparation

Calyculin-A (BIOMOL America) was used as the PCC inducer, which was dissolved in 100% ethanol as 1 mmol/L stock solution; 50 nmol/L of Calyculin-A was added to the cell cultures before irradiation to score the initial chromatid breaks. Then, cells were incubated for a further 30 min at 37 °C in 50 mL/L CO_2 . Chromosome spreads were then harvested by swelling cells in 75 mmol/L KCl for 20 min at 37 °C and fixed with Carnoy's fixation. A final wash and fixation in the same fixative was completed before dropping

cells onto a glass slide and hot humidity drying.

Chromosome was stained with 5% Giemsa for 20 min. More than 40 G_2 phase cells were scored for each dose point according to the standard criteria^[10]. Briefly, chromatid discontinuing, misalignment of the distal to the lesion, or a non-stained region longer than the chromatid width was classified as a break. Isochromatid breaks were scored two breaks. The total chromatid breaks were calculated by summing the production of chromatid and isochromatid breaks. The process of kinetic repair of damaged chromosome by PCC technique was same as initial ones.

RESULTS

G_2 PCC chromosome spreads

Calyculin A is a phosphatase inhibitor, can effectively induce the cells into G_2 phase by very little time. It is easy to detect the chromosome damage using PCC technique. Figure 1 shows the G_2 PCC chromosome spreads of L02 cell lines exposed to 8 Gy of γ -rays and SMMC-7721 cell lines of 0.5 Gy.

Figure 1 G_2 phase prematurely condensed chromosome spreads. **A:** SMMC-7721 cells after exposed to the γ -rays of 0.5 Gy; **B:** L02 cells after exposed to the γ -rays of 8 Gy. Arrows show the chromatid breaks, arrowheads show the isochromatid breaks.

Survival curves

Colony assay is a routine method for analyzing the cell survival fraction. Classical model of cell survival curve after exposed to low LET rays, such as X-ray, γ -ray, was linear quadratic. In present study, four cell lines' fitted survival curve were well agreement with the linear quadratic model. Figure 2 shows the detail of it.

Figure 2 Cell survival curve after exposed to γ -rays. All of four cell lines have a linear quadratic survival curve, which were good agreement with classical model.

Initial chromatid and isochromatid breaks after irradiated with γ -rays in G_2 phase

Figures 3A and B express the chromatid and isochromatid breaks of four cell lines after irradiated with various absorbed dose. Though some inter-exchanges or inner-exchanges exist in chromosome spreads, its number was rare. We only observed the main chromosome break type, i.e., chromatid and isochromatid breaks. Chromatid and isochromatid breaks linearly increased with the dose increase of these four cell lines, the number of chromatid breaks was much more than that of isochromatid breaks at each dose point.

Figure 3 G_2 chromosome breaks at various absorbed dose. **A:** chromatid breaks; **B:** isochromatid breaks.

Kinetic repair of chromosome breaks of L02 cells in 48 h of post-irradiation time

Figures 4 and 5 show the unrejoined chromatid breaks/cell/Gy at 0, 24, and 48 h. In this kinetic process, almost

Figure 4 Correlation between chromatid breaks and absorbed dose at 0, 24, and 48 h after exposed to radiation.

50% chromatid breaks got repaired, for isochromatid ones, just 15% got repaired at most. Also we can see, during 24-48 h, both of these two type breaks were nearly the same level, i.e., from 2.16 to 1.93 breaks/cell/Gy for chromatid breaks, from 0.476 to 0.48 breaks/cell/Gy for isochromatid ones. However, from 0 to 24 h these values were 2.95-2.16 breaks/cell/Gy, 0.502-0.476 breaks/cell/Gy, respectively. Compared with chromatid breaks, isochromatid breaks nearly keep the original state within 48 h after exposed to radiation. This is to say, at the early 24 h after exposure, chromosome repair process finished.

Figure 5 Kinetic repair of chromosome breakages within 48 h after L02 cell line was exposed to γ -rays. The chromatid breaks plus 46 (number of normal human chromosomes) make this change remarkably.

DISCUSSION

Liver cancer is of high risk and mortality. Besides the surgical excision, radiotherapy is the main method after the discovery of X-rays. Before radiotherapy, prompt and exact detection of radiosensitivity of target cells is of great importance.

Many researchers have reported a linear-quadratic cell survival curve in various cell lines irradiated by X-rays, γ -rays, also, linear relationship between chromosome breaks and absorbed dose was discovered^[5,8,9,11-15]. With the introduction of the premature chromosome condensation technique^[16-18], it is easy to study initial radiation-induced chromosome damage (Figure 1).

In the present study, fitted cell survival curve of four cell lines were linear quadratic (Figure 2), which were consistent with previous studies^[8-9]. Among these four cell lines, survival fraction of L02 was highest, A375 was lowest after absorbed same dose of radiation, suggested that human normal liver cells was of much higher resistance to γ -rays than human hepatoma cells, melanoma cells and cervical tumor cells. Radiation injury mainly resulted from oxidative free radicals, reductive glycogens synthesized in liver cells which interact with free radicals reduce the radiation injury.

Linear relationship was found between dose and the chromatid breaks after the cells were exposed to ^{60}Co γ -rays in this study (Figure 3). This relationship has proved by previous studies^[5,8,14,19,20]. An increased production of chromatid breaks induced by X-ray irradiation has been reported by Durante^[21-23], an increased production of isochromatid breaks produced by exposure to X-ray was also reported by Kawata^[8,9]. It suggested that with the higher

dose, the electrons which hit the target-chromosome increased, so, the production increased. While, the absolutely production increase of isochromatid breaks was smaller than that of chromatid breaks. Kawata *et al.*^[8], has reported that after low LET irradiation, the chromatid breaks dominated, while for high LET rays, such as heavy ions, isochromatid breaks dominated, suggesting that most isochromatid breaks resulted from two separate breaks on sister chromatids induced by independent electron tracks. For low LET rays, it can not deposit enough energy during unit range to penetrate sister chromatids meantime, so, most breaks were chromatid ones.

Since normal liver cells were more radioresistant to γ -rays than other three kind of cancer cells, study the kinetic repair of chromosome damage of L02 cells has the essentiality. Data^[4,9,15,16] showed that these irradiation could induce the chromosome damage, the damage will probably result in cancerization. Correct and effective repair of injured chromosome is very important to stop cancerization course. Figures 4 and 5 show the correlation between chromatid breaks and dose at 0, 24 and 48 h after radiation. In the present study, at each time point, chromatid breaks and isochromatid breaks were increased linearly with the dose, and the absolute number of chromatid breaks was much more than that of isochromatid ones, this phenomenon was described by Kawata *et al.*^[8]; Suzuki *et al.*^[15], reported that this repairing process occurred during the early 10 h after irradiation. This means in the early 24 h, most of any kind of cells end their spontaneous repair process if they are injured. After 24 h, without any artificial factors, injured and normal cells will be stable and continue synthesizing, mitosing, and so on.

Though the radiotherapy by using common irradiation such as γ -ray is very effective, we could not neglect the side-effect which largely reduce the curative effect due to the injury of normal tissue. Heavy ions have the good biophysics characteristics such as Bragg peak of dose distribution which result in the lowest side scatter, higher RBE (relative biological effect) and lower OER (oxygen enhancement ratio). Present study will enrich the essential data for the Heavy-Ion-Radiotherapy project in the Institute of Modern Physics, Chinese academy of Sciences when the national great engineering HIRFL-CSR (heavy ion research facility of Lanzhou-cooling restore cycle) complete at 2005.

Abstract

AIM: To study the genetic alterations and their association with clinicopathological characteristics of hepatocellular carcinoma (HCC), and to find the tumor related DNA fragments.

METHODS: DNA isolated from tumors and corresponding noncancerous liver tissues of 56 HCC patients was amplified by random amplified polymorphic DNA (RAPD) with 10 random 10-mer arbitrary primers. The RAPD bands showing obvious differences in tumor tissue DNA corresponding to that of normal tissue were separated, purified, cloned and sequenced. DNA sequences were analyzed and compared with GenBank data.

RESULTS: A total of 56 cases of HCC were demonstrated to have genetic alterations, which were detected by at least one primer. The detectability of genetic alterations ranged from 20% to 70% in each case, and 17.9% to 50% in each primer. Serum HBV infection, tumor size, histological grade, tumor capsule, as well as tumor intrahepatic metastasis, might be correlated with genetic alterations on certain primers. A band with a higher intensity of 480 bp or so amplified fragments in tumor DNA relative to normal DNA could be seen in 27 of 56 tumor samples using primer 4. Sequence analysis of these fragments showed 91% homology with *Homo sapiens* double homeobox protein DUX10 gene.

CONCLUSION: Genetic alterations are a frequent event in HCC, and tumor related DNA fragments have been found in this study, which may be associated with hepatocarcinogenesis. RAPD is an effective method for the identification and analysis of genetic alterations in HCC, and may provide new information for further evaluating the molecular

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common cancers worldwide and a leading cause of death in many countries, mainly in Asia and Africa^[1]. It is commonly associated with chronic hepatitis B virus (HBV) and hepatitis C virus (HCV) infections, with chronic exposure to mycotoxin, aflatoxin B1 (AFB1), and is a complication of alcoholic cirrhosis^[2]. The development of HCC is a multistep process associated with multiple genetic alterations, including the genetic alteration of cancer cells^[3,4]. In the past several years, many molecular genetic studies have been extensively performed to clarify the molecular events related with initiation, development and progression of human cancers^[4-7]. Like other cancers, a variety of genetic changes have frequently been found in HCC^[8-13], including p53 mutations^[1,14], loss of heterozygosity (LOH) on chromosome arms 1p, 4q, 5q, 6q, 8p, 10q, 11p, 16p, 16q, 22q^[7-12]. Microsatellite instability has also been recognized in some HCCs^[12,15-17]. However, no information on genetic alterations in the entire genome of HCC is available.

The random amplified polymorphic DNA (RAPD) method is a DNA fingerprinting technique based on polymerase chain reaction (PCR) amplification of random fragments of genomic DNA with single short primers of arbitrary nucleotide sequences^[18]. Unlike the microsatellite instability analysis which can only detect specific microsatellite loci, the RAPD method can simply and rapidly detect genetic alterations in the entire genome without knowledge of specific DNA sequence information^[19]. The RAPD method is a powerful tool for population and pedigree analysis, phylogenetic studies, and bacterial strain identification^[20]. Recently, the RAPD method was used as a means for identifying the genetic alterations in human tumors and revealed that genetic

alterations occurred frequently in lung cancer^[21], squamous cell carcinoma of the head and neck^[22], brain tumor^[23], ovarian cancer^[24], breast cancer^[25], or human aberrant crypt foci and colon cancer^[26]. In the present study, genetic alterations in HCC were investigated using RAPD in order to determine the relationship between the frequency of genetic alterations and the clinicopathological characteristics of HCC, and to find the tumor related DNA fragments.

MATERIALS AND METHODS

Patients and samples

Fifty-six liver cancer tissues were obtained from surgically resected samples in Eastern Hepatobiliary Surgery Hospital, Second Military Medical University. All patients did not receive any prior treatment. All specimens were confirmed with histopathological examination. This study included 43 men and 13 women. The age ranged from 29 years to 78 years. Thirty-five of fifty-six patients had serum AFP ≥ 20 $\mu\text{g/L}$. There were 39 cases with positive HBsAg. Twelve cases had small (≤ 3 cm) and 44 were advanced (>3 cm) HCCs. Tumor differentiation was graded according to WHO criteria (2000). Twenty HCCs were well differentiated, 28 were moderately differentiated and 8 were poorly differentiated. Of the 56 patients, 45 had evidence of intrahepatic metastasis (portal vein invasion and/or intrahepatic dissemination). Forty-seven HCCs were detected accompanied with liver cirrhosis.

DNA extraction

Fresh samples were obtained, immediately frozen in liquid nitrogen and stored at -70°C until analysis. A microdissection technique with a cryostat was used to separate tumor cells from corresponding noncancerous liver tissues. Genomic DNA was extracted from carcinoma tissues and corresponding noncancerous liver tissues using the standard phenol/chloroform extraction and ethanol precipitation method^[24]. The concentration of DNA was determined with both spectrophotometric and fluorometric methods.

RAPD analysis

For RAPD analysis, 10 arbitrary 10-mer primers were used. These primers were designed, referred to sequences reported previously^[19-25] and synthesized commercially. The sequences of these primers were:

- P1, 5'-CCGGCTACGG-3';
- P2, 5'-CAGGCCCTTC-3';
- P3, 5'-TACGGACACG-3';
- P4, 5'-AGCTTCAGGG-3';
- P5, 5'-AGGCATTCCC-3';
- P6, 5'-GGTCTGAACC-3';
- P7, 5'-TAGGCTCACG-3';
- P8, 5'-ACGGTACACT-3';
- P9, 5'-GTCCTCAACG-3';
- P10, 5'-CTTCACCCGA-3'

In a total volume of 25 μL , 50 ng of genomic DNA extracted from carcinoma tissues or corresponding noncancerous liver tissues was amplified in 10 mmol/L Tris-HCl (pH 8.3), 1.5 mmol/L MgCl_2 , 200 $\mu\text{mol/L}$ each of dNTP, 0.4 $\mu\text{mol/L}$ of each arbitrary primer, and 1.0 units of

AmpliTaq Gold DNA polymerase (Perkin-Elmer, Norwalk, CT). Forty cycles of denaturation (at 94°C for 30 s), annealing (at $36-40^\circ\text{C}$ for 1 min), and extension (at 72°C for 2 min) were carried out in a DNA thermocycler (Biomettr). Five microliters of the PCR products mixed with loading buffer was loaded in 1.5% agarose gels and electrophoresed with 100 V for 1 h. The gels were stained with ethidium bromide (0.5 mg/mL) and visualized under UV light.

Loss or gain of band(s) and clearly detectable changes in intensity were scored. Scoring was done by two independent observers. A change of band intensities was defined as an increase or decrease of the signal intensity by 50% in the tumor DNA compared to normal DNA by gray scanning with an EDAS290 digital camera system (Kodak) and image analysis with the PDQuest 6.2 software (Bio-Rad).

Cloning and sequencing of RAPD-PCR amplified products

The amplified 480 bp or so fragments from HCC DNA using the primer P4 were excised from the agarose gel and purified. The purified DNAs were reamplified with the primer P4 using the same concentration of reaction mixture constituents and the PCR cycle conditions as described above. The PCR products were analyzed on agarose gels to confirm their size and purity. The reamplified 480 bp DNA fragments were cloned using the TA cloning kit (Invitrogen, Carlsbad, CA, USA) following the protocol provided by the manufacturer. Restriction analysis of the recombinant plasmid DNA prepared by the alkaline lysis purification method was carried out to determine the appropriate insert size^[27-29]. The pure clone amplified DNA insert was sequenced with an automated DNA sequencer through the MegaBACE-500 capillary array electrophoresis instrument in our department. Sequences obtained from our clones were compared with the known sequences in the GenBank database using the BLASTn and BLASTx programs.

Statistical analysis

The relationship between the frequency of genetic alterations and clinicopathological features was assessed by using the χ^2 test, $P < 0.05$ was considered statistically significant.

RESULTS

Genetic alterations in HCC

We examined 56 HCC tissues and corresponding noncancerous liver tissues using the RAPD method to detect the genetic alterations in HCC. Our results indicated that RAPD-PCR was an effective tool for identifying genetic alterations in cancer tissues. All the cases of HCC were demonstrated to have genetic alterations in at least one of ten primers. The incidence of genetic alterations ranged from 20% to 70% in each case, and 17.9% (15/56) to 50% (28/56) in each primer. The primer with the highest frequency of genetic alteration was P4. Genetic alterations were identified as band loss, gain, intensity change and shift in the tumor DNA lane as compared to the paired normal DNA lane (Figure 1A).

Correlation with clinicopathological characteristics

The correlation between the frequency of genetic alterations and clinicopathological features in HCC is shown in Table 1.

Table 1 Correlation between clinicopathological features and genetic alterations in hepatocellular carcinoma

Clinicopathological features		No.	P1	P2	P3	P4	P5	P6	P7	P8	P9	P10

^a $P < 0.05$, ^b $P < 0.01$, χ^2 test.**Figure 1** RAPD-PCR analysis of hepatocellular carcinoma. Corresponding noncancerous liver tissue DNA (N), and tumor DNA (T) were amplified by PCR with obvious primers and electrophoresed in agarose gels. **A:** Genetic alterations identified as band loss, gain, shift and intensity change in the tumor DNA lane as compared to the paired normal DNA lane; **B:** Amplified 480 bp fragments from HCC DNA using the primer P4, the 1.5 kb ladder was used as a marker (M).

No significant correlation was observed between the genetic alterations and serum AFP concentration, HBV infection, tumor size, cirrhosis, histological grade, tumor capsule, as well as tumor intrahepatic metastasis. As to the primers, the frequencies of genetic alterations on primer P1, P4, P8 and P10 were significantly higher in patients with positive HBsAg than in those with negative HBsAg ($P < 0.01$). Genetic alterations on P3 were more frequent in tumors less than 3 cm in size ($P < 0.05$ or $P < 0.01$). Genetic alterations on P1 and P4 were more frequent in poorly or moderately differentiated tumors than in well-differentiated tumors ($P < 0.01$ and $P < 0.05$), but genetic alterations on P3 were

more frequent in well-differentiated tumors than in poorly or moderately differentiated tumors ($P < 0.05$). Genetic alterations on P3 were significantly higher in patients without intact tumor capsules than in those with intact capsules ($P < 0.01$). Genetic alterations on P4 were more frequently detected in tumors with intrahepatic metastasis than in those without. Similarly, genetic alterations on P3 were significantly lower in patients with intrahepatic metastasis than in those without ($P < 0.01$).

Cloning and sequencing of amplified differential fragments from P4, sequence homology search

The amplified 480 bp fragments from HCC DNA using the primer P4 were separated on the agarose gels, excised, eluted, and reamplified with the same primer (Figure 1B). After analysis of the PCR products on an agarose gel to confirm their size and purity, these amplified DNA products were cloned using the TA cloning kit. After confirmation of positively cloned DNA by hybridization with the purified RAPD-amplified fragments, sequences were obtained from several clones and compared with known sequences in GenBank. Figure 2 shows the electropherograms from sequencing with amplified 476 bp fragments using P4 primer. The followings were the nucleotide sequences of the fragments: TCCCCGCGATGGCCCTCCTGACAGCT-TCGGACAGCACCCACCCTGCAGAAGCACATTAAC-AGGAATGACGAAGGAGACTCCTTTGGAACC-CGAGCCAAAGCGAGGCCCTGAGAGCCTGCT-TTGAGCAAACCATAGCCGGGTATCGCCACAAGAG-AATGGCTGGCCAGGCCATCGGCATTCCAG-AACCCAGGGTCCAGATTTGGTTTCAGAAATGAGA-GGTCACGCCAGCTGAGGCAGCACCGGCCGCGGA-ATCTCGCCCTGGCCTGGGAGACGCGGCCAGCAA-GAAGGCAGGTGAAAGTGGACCGCCGTCACCAGATCC-CAGACCGCCCTGCTCCTCCGAGCCTTTGAGAA-

BLAST analysis revealed that there were significant matches of the 480 bp or so RAPD fragments with any known gene in this database either at the DNA level or its corresponding amino acid sequence. The tumor-specific P4 amplified 476-bp fragment sequences showed 92% homology with homo sapiens 3 BAC RP11-413E6 (Roswell Park Cancer Institute Human BAC Library, accession number AC108724.4) from nt 84 643 to nt 84 168, and with human DNA sequence clones RP11-298A19 on chromosome 22 (accession number AL592170.21) from nt 84717 to nt 842981, and 91% homology with homo sapiens double homeobox protein DUX10 gene from nt 316 to nt 788 (accession number Ay044051.1), and with homo sapien putative proteins and FSHD region gene 2 protein (HSA10-FRG2) genes (accession number AY028079.1) from nt 118 939 to nt 119 411.

DISCUSSION

The RAPD method, a PCR-based method for nucleic acid fingerprinting, was originally reported by Williams *et al.*^[18], and it is thought to be suitable for investigation of genetic alterations. RAPD-PCR multiple bands amplified with arbitrary primers could generate a complex DNA fingerprint that can detect qualitative (structural) and quantitative (aneuploid) genetic differences between normal and tumor cell genomes. Mutations can affect the fingerprint by altering the distance between the two primers, the ability of the primer to anneal, and the relative amounts of target amplification^[19]. In the present study, we identified genetic alterations in HCC at the level of ethidium bromide stained agarose gels. Genetic alterations indicating distance band shift or band loss/gain were observed. Mutations occurred at the primer-template interaction sites resulted in the loss or gain of a band, and mutations occurred between the primer-template interaction sites, such as deletions or insertions, resulted in a mobility shift of bands. However, single base situations between two primers could not be detected by this method. In addition to these qualitative alterations, we also observed decrease or increase in the relative intensities of the bands in tumor DNA compared to those in normal tissue DNA. Allelic losses due to their linkage to suppressor genes, might result in decrease of band intensities, and gene amplification or chromosomal aneuploidy might result in increase of band intensities. Furthermore, we found a significant correlation between the instability of certain primers and HBV infection, tumor size, cirrhosis, histological grade, tumor capsule, as well as tumor intrahepatic metastasis at some primers. These results suggest that the high frequency of genetic alterations identified by the RAPD method may be involved in the malignant potential of HCC.

Since this method permits the direct cloning and characterization of amplified DNA bands which represent genetic alterations specific in HCC genome during tumor progression, further research in this direction will find out new genes contributing to progression in liver cancer. The

most important finding in the present study is that a band with a higher intensity of 480 bp or so amplified fragments in tumor DNA relative to normal DNA could be seen in 27 and 56 tumor samples using primer 4. An enhancement of the signal intensity of amplified DNA fragments may be related to localized overamplification of that gene locus in the genome, or could result from changes at the chromosome level, such as trisomy or tetrasomy. These events could play an important role in the development of HCC or they could occur during the clonal expansion of genetically unstable tumor cells. Sequence analysis of the fragments showed 92% homology with homo sapiens 3 BAC RP11-413E6 (Roswell Park Cancer Institute Human BAC Library) complete sequence, and with human DNA sequences from clone RP11-298A19 on chromosome 22, complete sequence. Also the fragment sequences showed 91% homology with homo sapiens double homeobox protein DUX10 gene, and with homo sapiens putative protein and FSHD region gene 2 protein (HSA10-FRG2) genes. Homeobox protein genes comprise a large and essential family of developmental regulators that are vital for all aspects of growth and differentiation. Although many studies have reported their deregulated expression in cancer, few studies have established direct functional roles for homeobox genes in carcinogenesis^[30]. Our data suggest that homeobox protein gene family members are activated as an important pathway in hepatocarcinogenesis.

In summary, genetic alterations are a frequent event in HCC. Furthermore, serum AFP concentration, HBV infection, tumor size, histological grade, tumor capsule, as well as tumor intrahepatic metastasis, may be correlated with allelic losses with certain primers. A band with a higher intensity of 480 bp or so amplified fragments in tumor DNA relative to normal DNA can be seen tumor samples and sequence analysis of the fragments can show 91% homology with homo sapiens double homeobox protein DUX10 gene. The RAPD method is an effective tool for the identification and analysis of genetic alterations in HCC tissues and it may provide some new information about the molecular mechanism of hepatocarcinogenesis.

Abstract

AIM: To evaluate the association between *Chlamydia pneumoniae* (*Cpn*) infection and primary biliary cirrhosis (PBC).

METHODS: *Cpn* IgG and IgM were determined by enzyme-linked immunosorbent assay (ELISA) in 41 well-established PBC patients and two race-matched control groups (post-hepatitis cirrhosis, $n = 70$; healthy controls, $n = 57$).

RESULTS: The mean level and seroprevalence of *Cpn* IgG in PBC group and post-hepatitis cirrhosis (PHC) group were significantly higher than those in healthy controls (46.8 ± 43.4 RU/mL, 49.5 ± 45.2 RU/mL vs 28.3 ± 32.7 RU/mL; 68.3%, 71.4%, 42.1%, respectively; $P < 0.05$). There was a remarkably elevated seroprevalence of *Cpn* IgM in patients with PBC (22.0%) compared to the PHC and healthy control (HC) groups. For the PBC patients versus the HCs, the odds ratios (ORs) of the presence of *Cpn* IgG and IgM were 2.7 (95% CI 0.9-6.1) and 5.1 (95% CI 1.4-18.5), respectively. Though there was no correlation in the level of *Cpn* IgG with total IgG in sera of patients with PBC ($r = -0.857$, $P = 0.344 > 0.05$), *Cpn* IgM was related with the abnormally high concentrations of total IgM in PBC group.

CONCLUSION: The results of this study do not support the hypothesis that infection with *Chlamydia pneumoniae* may be a triggering agent or even a causative agent in PBC, but suggest that *Chlamydia pneumoniae* infection probably contributes to the high level of IgM present in most patients with PBC.

INTRODUCTION

PBC is a chronic inflammatory process that mainly affects the medium-sized intrahepatic bile ducts, leads to chronic cholestasis, and often develops to cirrhosis and liver failure that requires liver transplantation. This disease is characterized by the presence of anti-mitochondrial autoantibodies and is considered as an autoimmune disease. However, its exact mechanism of pathogenesis and etiology remains elusive. Several studies have demonstrated cross-reactivity at both B-cell and T-cell levels between autoantigen-pyruvate dehydrogenase complex (PDC) and polypeptides derived from the sequences of potential pathogens^[1,2]. It is suggested that molecular mimicry between pathogen and self-antigen might result in tolerance breakdown. A good deal of evidence suggests an infectious component in the development of PBC, and to date, some bacteria and viruses have been found to be linked to with the disease^[3-5]. Nevertheless, so far no microbiological agent has been confirmed in PBC, though the possibility of a pathophysiological role for some viral or bacterial micro-organisms has not been excluded. It was reported that infection with the respiratory bacterium *Cpn* might be a triggering agent or even a causative agent in PBC^[6]. If that is the case, antibiotic treatment could be effective. We attempted to confirm these findings serologically by designing a case-control study, to assess whether PBC patients had any serologic evidence of *Cpn*, and to evaluate the correlation of *Cpn* infection with PBC by testing the levels of serum antibodies IgG and IgM against *Cpn* in Chinese patients with PBC.

MATERIALS AND METHODS

Patients

A total of 211 subjects, recruited in 2002 and 2003, were divided into three groups. Patient groups involved 41 Chinese patients with well-established PBC from Eastern China including Zhejiang, Jiangsu and Shanghai, who met

the following diagnostic criteria for PBC recommended by the American Association for the Study of Liver Diseases (AASLD)^[7]: (1) presence of cholestatic liver disease manifestations including jaundice, fatigue and pruritus with abnormally high levels of cholestatic parameters such as ALP, serum bilirubin and γ -GT; (2) absence of biliary obstruction as confirmed by ultrasonography, computed tomography, or endoscopic cholangiography; (3) serum positive AMA titre $\geq 1:40$. Information of each patient was obtained at the first visit. The ratio of male to female in the study was about 1:6 (6/35). The average age of the patients was 52.5 years (range: 29-87 years). All patients showed AMA positive and anti-M2 was detectable in 35 PBC patients (85.4%). Two groups of race-matched control individuals with no known cardiac disease were selected on the basis of similar age and sex. A control group consisted of 70 Chinese patients with PHC. The third control group included 57 healthy subjects for estimating the prevalence of *Cpn* antibodies in the general population.

Testing of *Cpn* antibodies

The sera were tested at dilution of 1:101 for *Cpn* specific IgG and IgM antibodies with ELISA kits (Euroimmun, Luebeck, Germany), according to the manufacturer's instructions. The coated antigens in the wells contained all relevant antigens localized in the outer membrane of HEp-2 cells infected with the "CDC/CWL-029" strain of *Cpn*. The outer membrane is composed of lipopolysaccharide (LPS) and numerous proteins (outer membrane proteins, OMPs). IgG antibodies against *Cpn* were quantitated with three calibration sera at concentrations of 2, 20, and 200 RU/mL. IgM antibodies were quantified by calculating a certain ratio against the calibration serum. If the ratio ≥ 1 , the serum was defined as positive; if the ratios < 1.0 , the serum was defined as negative.

Clinical laboratory tests

Quantitative measurements of IgG and IgM were analyzed on sera of all PBC patients with a Dade-Behring nephelometer. Anti-mitochondrial autoantibodies (AMA) were tested by indirect immunofluorescence (Euroimmun, Luebeck, Germany). Anti-M2 antibody was tested by immunoblotting assay using a humanized M2 trimer as antigen source.

Statistical analysis

All statistical analyses were performed with SPSS for Windows 10.0. The frequencies of antibodies were processed by χ^2 test or Fisher's exact test. The *t*-test was used for the comparison of group means. $P < 0.05$ was considered statistically significant. Odds ratios (ORs) were calculated with exact 95% confidence intervals (CIs).

RESULTS

The mean level of *Cpn* IgG in PBC and PHC groups (46.8 ± 43.4 , 49.5 ± 45.2 RU/mL, respectively) was much higher than that in the HC group (28.3 ± 32.7 RU/mL), and there was no statistical difference between the two groups ($P < 0.05$). According to the cut-off value of 20 RU/mL recommended by the kits, the frequency of *Cpn* IgG in PBC,

PHC, and HC groups was 28/41 (68.3%), 50/70 (71.4%) and 24/57 (42.1%), respectively. The positive rate of *Cpn* IgG in PBC and PHC groups was different from that in HC group ($P = 0.02$ and 0.001 respectively as shown in Figure 1). In contrast, the proportion of IgM positive samples in the PBC group (22.0%, 9/41) was much higher than that in the control groups (PHC, 7.1%; HC, 5.3%), and this difference was statistically significant ($P = 0.023$ for PBC *vs* PHC and 0.013 for PBC *vs* HC). Compared to the healthy controls, the ORs of the presence of *Cpn* IgG and IgM antibodies in the PBC patients were 2.7 (95%CI: 0.9-6.1) and 5.1 (95%CI: 1.4-18.5) respectively.

Twenty-eight of the forty-one (68.3%) patients had high total IgG and IgM levels and 22 of the 28 PBC patients were *Cpn* IgG positive (78.6%), but there was no difference in total IgG level between *Cpn* IgG positive and negative patients ($P = 0.275$). However, the correlation between *Cpn* IgG level and sera total IgG was statistically insignificant ($r = -0.857$, $P = 0.344$). Nine of the twenty-eight (32.1%) patients with increased IgM level were *Cpn* IgM positive. *Cpn* IgM was related to abnormally high level of total IgM. Anti-mitochondrial antibodies were found in all the 41 PBC patients, 35 cases (85.4%) of them were M2 autoantibodies positive. Between *Cpn* IgM positive and negative PBC patients, no significant differences were found in age, age at onset, disease duration and other laboratory parameters including ALP, γ GT, serum bilirubin and bile acids.

Figure 1 Proportion of patients positive for *Cpn* IgG and IgM. ^a $P < 0.05$ vs HC group ^c $P < 0.05$ vs PHC and HC group.

DISCUSSION

Cpn is a common cause of community acquired acute respiratory infection with a seroprevalence rate of over 50% adults in many countries. It has been shown that *Cpn* may play a potential role in autoimmune diseases such as atherosclerosis^[8], multiple sclerosis^[9] and even primary sclerosing cholangitis^[10] that is also an autoimmune cholangitis. The presence of *Cpn* antigen and RNA in biopsies from patients with autoimmune diseases suggests that *Cpn* antigen may trigger an immune response through molecular mimicry^[11,12]. The role of *Cpn* in the etiology of autoimmunity is however controversial.

It was found that in periportal and lobular hepatocytes of liver tissues from patients with PBC, *Cpn* antigens are present instead of *C. trachomatis* by immunohistochemical

staining^[6], suggesting that *Cpn* infection is closely related with PBC. High level of *Cpn* IgG is an important marker for previous infection whereas IgM reactivity represents acute infection. In this study, up to 68.3% PBC patients were infected with *Cpn*. Though their prevalence and mean level of *Cpn* IgG were higher than healthy controls, no difference was seen compared to PHC patients. Therefore, it is difficult to conclude that *Cpn* infection is the cause of PBC or the result of chronic liver diseases.

Abnormally high level of serum IgM is one of the serological characteristics of PBC. However, the reasons for high level of IgM and the nature of IgM remain unclear. In our study, 70% PBC patients had a high level of IgM and about one third of them were *Cpn* IgM positive, indicating that increased serum IgM in PBC patients is closely related to *Cpn* IgM and *Cpn* infection may be one of the factors for abnormally high level of IgM in PBC patients.

Recently, studies with animal model of experimental allergic encephalitis (EAE) indicate that *Cpn* infection increases the severity of EAE that can be attenuated with anti-infective therapy, and that infection of the central nervous system with *Cpn* can amplify the autoreactive pool of lymphocytes and regulate the expression of autoimmune diseases^[13,14]. Though we did not find any difference between patients with or without acute *Cpn* infection in clinical features and biochemical parameters, including ALP, AST and GGT, *Cpn* may secrete high immunogenic substrates or provide an inflammatory microenvironment to enhance the self-reactivity of pathogenic T lymphocytes. How *Cpn* infection acts on the process of PBC remains to be clarified in future studies.

In conclusion, the results of this study do not support the hypothesis that infection with *Cpn* may be a triggering agent or even a causative agent at least in Chinese patients with PBC, but suggest that *Cpn* infection may contribute to the high level of IgM present in most PBC patients.

Abstract

A healthy 31-years-old man presented with a three-year history of abdominal discomfort. Radiological examinations revealed multifocal tumoral lesions in the spleen. The patient underwent splenectomy for differential diagnosis and treatment. During the operation, in addition to the splenic masses, there were also multiple milimetric purpuric-like lesions on the colonic serosal surfaces adjacent to the splenic hilum. One of them was excised. Histologic examination showed hemangiopericytoma of the spleen and cavernous hemangioma of the adjacent colon. This is the first report showing the close association of these two distinct lesions with vascular origin in the literature. Despite not having any apparent evidence, there may be a sequential relationship between the hemangiopericytoma of the spleen and cavernous hemangiomas.

<http://www.wjgnet.com/1007-9327/11/4111.asp>

INTRODUCTION

Hemangiopericytoma is a perivascular tumor originating from pericytes located along capillaries and venules^[1]. Tumor may be benign or malign in behavior. It is most common in the lower extremity, also occurs in the pelvic retroperitoneum or other sites^[2]. Hemangiopericytoma of the spleen is a rare tumor and so far only eight patients have been reported in the

literature. It tends to occur at adult ages, but can be diagnosed in childhood^[3]. There is not any specific symptom or sign of the disease. There may be single^[3-6] or multifocal^[3,7-9] tumors in the spleen. On the other hand, cavernous hemangioma is a benign vascular tumor consisting of dilated blood vessels. In the present case, interestingly, in addition to the splenic hemangiopericytoma there were multiple cavernous hemangiomas on the adjacent colonic serosal surfaces. There may be a sequential, rather than co-incidental, relationship between the two distinct pathologies. We report a case of multifocal hemangiopericytoma of the spleen and cavernous hemangiomatosis of the adjacent colonic serosa.

CASE REPORT

A healthy 31-years-old man presented with a three-year history of early satiety and abdominal discomfort. He had no history of weight loss. Physical and laboratory examinations were normal. Gastroendoscopy showed no pathologic finding. Abdominal ultrasonography revealed suspicious nodular lesions in the spleen. Computed tomography and magnetic resonance imaging showed hypervascular and hypodense masses located in the splenic hilum (Figure 1). Maximum size of the masses was 4 cm in diameter.

The patient underwent splenectomy for suspicion of primary or secondary splenic malignancy. During the operation, there were three exophytic nodular lesions in the splenic hilum. In addition, there were also multiple small lesions dark-red in color and 4-5 mm in diameter, resembling to the purpuric lesions macroscopically, on the serosal surface of the splenic flexura of the colon and descending colon. One of them was excised.

Histopathological findings

Spleen was 10 cm×8 cm×7 cm in diameter and weighted 200 g and there were three masses located in the splenic hilum. The gross appearance of the masses showed colour exchange into grayish-brown with a maximum diameter of 3 cm. Tumors were unencapsulated and their borders were irregular. On microscopical examination, there was a tumoral tissue consisting of slightly pleomorphic, atypical cells which were ovoid or spindle in shape. Tumor cells were widespread around the capillary vessels and had fusiform nuclei with prominent nucleolus and eosinophilic cytoplasm (Figures 2 A and B). Mitotic activity was not observed. Tumoral cells were stained positively with CD34 and Vimentin, but negatively with lysozyme, cytokeratin, smooth muscle actin, S-100, factor 8-related antigen, desmin, HMB-45, CD117 and epithelial membrane antigen immunohistochemically. This lesion was reported as hemangiopericytoma.

Figure 1 CT and MR images of splenic hemangiopericytoma. **A** and **B**: Enhanced computed tomography scan showing high-density masses located

in the spleen. **C** and **D**: T1-weighted abdominal magnetic resonance images showing multifocal hypervascular lesions in the spleen.

Figure 2 **A**: Spindle-shaped cells of hemangiopericytoma with eosinophilic cytoplasm around the capillary vessels in the spleen (HE $\times 40$); **B**: (HE $\times 200$);

C: Dilated vessels of the cavernous hemangioma of the colonic serosa (HE $\times 40$).

On histologic examination of the lesion excised from the serosal surface of the splenic colon flexura, there was a tumoral tissue consisting of dilated blood vessels with flattened endothelium and their lumens were containing erythrocytes (Figure 2C). This lesion was reported as cavernous hemangioma.

Immunohistochemistry of the both specimens (hemangiopericytoma and cavernous hemangioma) did not display vascular endothelial growth factor (VEGF) expression.

The patient had an uneventful recovery and discharged on postoperative d 5. He did not take any additional therapy and has been disease free for 36 mo of follow-up.

DISCUSSION

Despite the advances in imaging techniques, differential

diagnosis and management of the splenic hemangiopericytoma may be problematic because of the rarity of the disease. In the present case, ultrasonography, computed tomography, magnetic resonance imaging techniques were inconclusive. In most of the cases, splenectomy seems to be necessary for establishing prompt histologic diagnosis and providing initial treatment of the disease.

Multiple millimetric cavernous hemangiomas of the serosal surfaces of the colon is a rare condition and also splenic hemangiopericytoma is rare. These two distinct tumoral lesions were in the same region, multiple and all three masses in the splenic hilum were growing as exophytic tumors. We hypothesized that there may be triggering substances, which were secreted locally from the tumoral cells, leading paracrine stimulation of the some inducible receptor positive cells in the adjacent tissue. These inducible

potential cells had proliferated and developed vascular neoplasia by the effect of these substances. Similarly it has been reported that VEGF may play a role in the pathogenesis of vascular lesions such as cerebral cavernous malformations^[10] or cerebral hemangiopericytomas^[11]. However VEGF reactivity was negative in both of cavernous hemangioma and splenic hemangiopericytoma in the present case. On the other hand, another substance or mechanism that are not yet clear may play a role in the genesis of this association. We believe that presence of two distinct lesions in the same region was not a co-existence. It may be sequential rather than co-incidental.

Hallen^[6] reported that it was difficult to decide whether the splenic hemangiopericytoma was benign or malignant. They also reported that presence of multifocal tumors and mitoses may be an indicator of poor prognosis. In the present case, there were multifocal tumors but mitotic activity was not observed on the histologic examination. Despite multicentric lesions, recurrence has not been described for 36 mo follow-up. Therefore, we think that microscopic features, especially presence of mitosis, may be more important than the presence of multifocal tumors in predicting malign tumor behavior.

In conclusion, splenic hemangiopericytoma and cavernous hemangiomas can be found in the same region and there may be a sequential relationship between these tumoral lesions.

Abstract

We report on a 26-year-old man who presented with severe jaundice and elevated serum liver enzyme activities after having received a dose of Twinrix®. In his past medical history, jaundice or abnormal liver function tests were never recorded. Following admission, an elevated immunoglobulin G level and antinuclear antibodies at a titer of 320 with a homogenous pattern were found. Histology of a liver biopsy showed marked bridging liver fibrosis and a chronic inflammation, compatible with autoimmune hepatitis. Treatment was started with budesonide and ursodeoxycholic acid, and led to complete normalization of the pathological liver function tests. We believe that Twinrix® led to an acute exacerbation of an unrecognized autoimmune hepatitis in our patient. The pathogenesis remains to be clarified. It is tempting to speculate that inactivated hepatitis A virus and/or recombinant surface antigen of the hepatitis B virus - as seen in patients with chronic hepatitis C and unrecognized autoimmune hepatitis who were treated with interferon alpha-might have been responsible for disease exacerbation.

INTRODUCTION

Autoimmune hepatitis (AIH) is a chronic immunity-mediated inflammatory liver disease and is characterized by a marked female preponderance, hypergammaglobulinemia, non-tissue specific autoantibodies and a characteristic good response to immunosuppressive treatment. Without treatment AIH progresses to liver cirrhosis, and in 50% of patients advanced liver fibrosis or complete cirrhosis is already present at the

time of diagnosis. Patients usually present with variable unspecific symptoms. In a significant number of patients, the presentation of AIH may be acute or fulminant mimicking acute viral hepatitis^[1]. We wish to report on a young male patient, who presented with severe acute exacerbation of a previously unrecognized AIH after the third dose of Twinrix®.

CASE REPORT

A 26-year-old Caucasian man presented in August 2003 with severe jaundice associated with elevated serum liver enzyme activities after having received the third dose of Twinrix®. The first dose was given five months ago, in March 2003, and the second in April 2003. The past medical history of the patient was unremarkable and jaundice or abnormal liver function tests were previously unknown. He denied any alcohol intake or drug (ab)use, and had not been exposed to any blood products. No family history of liver diseases was given. The physical examination showed a moderately enlarged liver without stigmata of chronic liver disease. Blood tests showed elevated alanine aminotransferase (ALT) with 50.4 $\mu\text{mol/s.L}$ (reference interval 0.17-0.60 $\mu\text{mol/s.L}$), aspartate aminotransferase (AST) with 33.2 $\mu\text{mol/s.L}$ (reference interval <0.17-0.60 $\mu\text{mol/s.L}$), and serum bilirubin with 17.2 mg/dL (reference interval <1.1 mg/dL), while the γ -globulin fraction was with 23.3% only slightly elevated. Full blood count, creatinine, urea and electrolytes were within the normal limits. Serological tests for viral hepatitis, including hepatitis A, B, and C viruses, and human herpes viruses were all negative. There was no evidence of a metabolic liver disease or biliary obstruction. Because serum liver function tests did not improve on follow-up (Figure 1), a percutaneous liver biopsy was taken in November 2003 (see below). A month later the patient was referred to our University Hospital for further evaluation. On admission, serum ALT was raising again (16.40 $\mu\text{mol/s.L}$). Additionally, we found elevated immunoglobulin G fraction with 22.70 g/L (reference interval 9-16 g/L) and antinuclear antibodies at a titer of 320 with homogenous immunofluorescence pattern suggestive of AIH. The liver biopsy was re-examined using paraffin sections stained with hematoxylin and eosin (H&E), periodic-acid Schiff (PAS) reagent with and without diastase pretreatment, Masson's trichrome stain, reticulin stain, and iron stain. Histologically, marked bridging fibrosis was noted (Figure 2A). A moderate chronic inflammatory infiltrate with few scattered eosinophils was found in the septa, an interface hepatitis was noted and small, partly confluent necroinflammatory foci were present in the parenchyma (Figures 2B and C). A pathological iron deposition or diastase-resistant PAS-positive globuli indicating α 1-antitrypsin deficiency, were not found. The histopathological

findings were compatible with advanced AIH. The patients was then treated with budesonide (Budenofalk®), 3 mg tiw and ursodeoxycholic acid (Ursofalk®), 250 mg tiw, which resulted in complete normalization of the liver function tests (Figure 1). The excellent response to immunosuppressive therapy further supports the diagnosis of AIH.

Figure 1 Changes of alanine aminotransferase activity and serum bilirubin level on follow-up and during the therapy with budesonide and ursodeoxycholic acid.

Figure 2 A liver biopsy obtained 3 mo after the first clinical presentation of the patient showed marked bridging fibrosis (A). A moderate chronic inflammatory infiltrate with few scattered eosinophils was found in the septa (B), and an interface hepatitis was also noted (C). The histopathological findings were compatible with AIH. Masson trichrome stain (A) and H&E-stain (B and C). Original magnifications 100x (A and B) and 200x (C).

DISCUSSION

Hepatitis A and B viruses (HAV and HBV) are responsible for considerable morbidity and mortality^[2]. Twinrix® is a sterile suspension of inactivated HAV and recombinant surface antigen of the HBV (rHBsAg) and used for active immunization^[3]. Vaccination with rHBsAg has been reported to be associated with the development of autoimmune diseases, especially with rheumatoid arthritis^[4]. Some patients with vaccination-induced rheumatoid arthritis share the common HLA DR3 and DR4 haplotypes (DRB*0301, *0401)^[4]. Evidence exists that AIH has also a specific genetic background including HLA A1, B8 and DR3 or DR4 alleles. The majority of patients with AIH was reported to be either

DRB3*0101 or DRB4*0401 positive^[1,5].

AIH was reported repeatedly to manifest after viral infections. Some reports suggested that HAV might induce AIH in genetically susceptible persons^[6,7], and protracted HAV infection was strongly associated with HLA-DRB*1301, which is a marker for AIH in pediatric patients^[8]. The activation of an anti-HBsAg response was, however, not sufficient to induce AIH in an HBV envelope transgenic mouse model^[9]. In our patient, who had a previously unrecognized, clinically silent AIH with advanced liver fibrosis, the exposure to Twinrix® led to the development of severe jaundice and an acute, clinically overt exacerbation of chronic liver disease. No other case of AIH after vaccination has been reported yet. Postmarketing studies occasionally described on jaundice and acute hepatitis after the use of Havrix® and abnormal liver function tests using Engerix-B®^[3]. Moreover, vaccination was never reported to lead to chronic liver disease. The pathogenesis of acute exacerbation of this previously clinically silent AIH remains to be clarified. Inactivated HAV and/or rHBsAg are not known to be hepatotoxins, therefore, an intrinsic hepatotoxic effect is highly unlikely. Rather, Twinrix® probably caused an idiosyncratic reaction, i.e. hypersensitivity. Several drugs can cause chronic hepatitis, biochemically, serologically, and histologically almost indistinguishable from AIH and have been named drug-induced AIH^[10].

In view of the advanced liver fibrosis in our patient, and the relatively recent immunization with Twinrix®, we believe that our patient already suffered from AIH. Drug-induced AIH usually have a long and variable latency period until clinical presentation and was not observed in our patient. Similarly, patients with chronic hepatitis C receiving interferon alpha^[11] may also experience an acute exacerbation of AIH. This further supports our assumption that in our patient Twinrix® caused an acute exacerbation rather than an induction of AIH in a previously healthy liver. The therapy with the local active corticosteroid, budesonide, resulted in complete remission of the disease which-based also on our clinical experiences-represents an effective treatment of AIH^[12].

Abstract

We report a case of the rare solid-pseudopapillary tumor of the pancreas. In contrast to other pancreatic tumors, the solid-pseudopapillary tumor has a favorable prognosis. The 60-year-old female patient we report on here was treated by left pancreatic resection combined with splenectomy for a non-metastasizing tumor of the pancreas. A solid-pseudopapillary tumor was found on histology. The patient had no signs of metastases at present. Since a microscopically invasive tumor growth is assumed, oncologically curative resection should be preferred vs the less radical enucleation. The rare solid-pseudopapillary tumor of the pancreas has a good prognosis after successful oncological resection.

Eder F, Schulz HU, Röcken C, Lippert H. Solid-pseudopapillary tumor of the pancreatic tail. *World J Gastroenterol* 2005; 11(26): 4117-4119

<http://www.wjgnet.com/1007-9327/11/4117.asp>

INTRODUCTION

Solid-pseudopapillary tumor of the pancreas is a rare condition. In the literature, about 300 cases have been reported. This tumor was first described in 1959^[1]. It is also known under the term FRANTZ tumor, named after the author who first described this tumor, which has also been referred to as solid cystic tumor; papillary epithelial neoplasia; solid and papillary epithelial neoplasia; or papillary epithelial tumor. In 1996, this tumor was included in the WHO classification of pancreatic tumors^[2]. The origin of the solid-pseudopapillary tumor has not yet been clarified. It is discussed to originate either from ductal epithelium^{3-6]}, acinar cells^[7-11], or from endocrine cells^[12,13]. Another hypothesis is that this tumor arises

from pluripotent embryonic cells of the pancreas^[12,14,15] or from ridges/ovarian anlage related cells, which were attached to the pancreatic tissue during early embryogenesis^[16,17].

Solid-pseudopapillary tumor of the pancreas has a tendency to predominantly affect young women aged between 25 and 35 years^[4,8,14,18-22]. Age is reported to range from 8^[15] to 70 years^[3]. However, a relationship to oral contraception has not been proven^[8]. This tumor rarely affects men^[23-26] and is characterized by a long asymptomatic course and unspecific symptoms. Therefore, it is not uncommon that solid-pseudopapillary tumor is detected only when it has reached a remarkable size (8-10 cm)^[4,10]. Even a tumor size of 20 cm in diameter has been reported^[27].

One feature of this tumor is its low malignant potential. Although the liver is found to be the site mostly affected by metastases, these are only rarely seen^[15,23,27,28]. Furthermore, there are only few reports about invasive growth^[3,4]. Survival time has been reported to reach up to 21 years^[1].

Here, we report on a 60-year-old woman, who was found to suffer from a non-metastasizing solid-pseudopapillary tumor of the pancreatic tail. Curative resection was performed.

CASE REPORT

A 60-year-old Caucasian woman attended her GP for recurring headache. An X-ray of the spine showed calcifications projecting onto the left upper kidney. Ultrasound and CT-scan of the abdomen showed a polycystic tumor in the tail of the pancreas, which measured approximately 14 cm in maximum diameter.

After the patient was referred to a general hospital a biopsy for cytology was obtained using endoscopic ultrasonography and provided suspicion of a malignant tumor. MRT of the abdomen showed a lesion, which was incompatible with a benign tumor or pseudocyst, and raised suspicion of a cystadenocarcinoma of the pancreas. Finally the patient was referred to our University. The past medical history of the patient included uncomplicated deliveries of four children, no abortions or miscarriages. No history was given suggestive of chronic pancreatitis. The family and social history gave no evidence of a familial cancer syndrome. On admission the patient was mobile, orientated in time, place and person, afebrile and normotonic. Palpation of the abdomen revealed a mild dull pain in the left upper abdomen.

Blood tests showed mild hypercholesterolemia and normal LFT, U&E, and FBC. The tumormarkers CEA, CA19-9 and CA125 were normal. X-ray of the chest and ECG were normal.

A laparotomy was performed and the a tumor of the pancreatic tail explored. No metastases were found. The preparation of the tumor showed a brown colored and good separated growth. A distal pancreatectomy combined

with splenectomy was indicated and deperformed. The pancreatic resection margin was free of cancer as demonstrated by frozen section.

Ten days later the patient was discharged from our University hospital without any postoperative complications. The patient is followed up in our tumor dispensaire.

The pancreatic tumor measured 14 cm in greatest diameter and was located in the pancreatic tail. The cut surface was yellow in color with hemorrhages (Figure 1A).

Histologically, the tumor was encapsulated by a fibrous pseudocapsule and characterized by extensive old necroses, large hyalin scars, cholesterol crystals surrounded by foreign body giant cells and calcifications. After extensive sampling small areas of preserved tumor were found under the fibrous capsule. The tumor tissue exhibits a solid monomorphic pattern with small polyhedral cells lining fibrovascular stalks (Figure 1C). A pseudopapillary pattern was noted in areas with regressive changes (Figure 1B). Perineural invasion, angioinvasion, or deep invasion were not found. Immunohistochemistry with antibodies directed against alpha-1-antitrypsin (Figure 1D), neuron-specific enolase, and CEA showed immunostaining of tumor cells. Immunostaining was not observed with antibodies directed against pancytokeratin (AE1/AE3), CK 8, CK18, chromogranin A, synaptophysin, S-100, and alpha-fetoprotein.

The histological and immunohistochemical findings were in keeping with the diagnosis of a solid-pseudopapillary tumor of the pancreas.

DISCUSSION

Although the vast majority of patients with a solid pseudo-papillary tumor of the pancreas are young women, our patient, affected by this lesion, was already 60 years old. In 85-90% of the patients the prognosis of the tumor is excellent^[16]. Some authors^[15,21] described an aggressive growth of the tumor in older patients. Our observations are not in accordance with them. A 53-year-old woman with a solid-pseudopapillary tumor of the pancreatic head treated by radical partial pancreaticoduodenectomy in 1998 is still tumor free at present.

Owing to the slow growth of solid-pseudopapillary tumors, typical early symptoms are lacking. These are only found in conjunction with a higher number of local displacements. In our case, the patient consulted her doctor because of recurrent headache. She never had suffered from epigastric or abdominal pain. In order to investigate putative causes for recurrent headache, X-rays were taken from the spine and calcifications were noted projecting onto the left upper kidney. A tumor of the pancreatic tail was found on ultrasound and CT-scan of the abdomen. In general, owing to the lack of symptoms, a diagnosis of these tumors is possible only when their diameter is in the range of 12-14 cm. There seems to be no correlation between tumor size and behavior^[23]. Venous invasion, degree of nuclear atypia, mitotic count and large necrotic clusters are considered histological markers of an increased potential of malignancy^[23]. A further criterion is the nuclear DNA-ploidy grade. Kamei and

Figure 1 cross section of the pancreatic tumor showed a yellow tumor with hemorrhages (A); bar indicates 1 cm. The tumor tissue exhibits a solid monomorphic pattern with a pseudopapillary pattern in areas with regressive changes (B) and

small polyhedral cells lining fibrovascular stalks (C). The tumor cells were immunoreactive for alpha-1-antitrypsin (D). Hematoxylin and eosin (B and C), anti-alpha-1-antitrypsin (D); Original magnification: x100 (B), x200 (C), x400 (D).

Nishihara^[23] demonstrated aneuploidy in patients with metastases, whereas patients without any sign of malignancy showed diploidy. However, this issue is controversially discussed in the literature. In any case, patients exhibiting these markers should be subject to particularly critical surveillance. Opposite to our patient, a complete fibrous capsule always be found in these tumors^[23]. Capsular invasions have been described^[3] and typically the preserved tumor tissue is found in the periphery, as shown here. Furthermore, tumors may infiltrate into both the sane pancreatic parenchyma and peripancreatic adipose tissue^[19]. Therefore, resection according to oncological criteria should be preferred over “radical enucleation”^[11] and/or local excision^[20]. In addition, since the tumor is confined to the organ or develops metastases only at later time points, radical surgery of a solid-pseudopapillary tumor of the pancreas could be curative.

In conclusion, the patient bearing a solid-pseudopapillary tumor of the pancreas has a good prognosis if the tumor is resected completely, shows no histological evidence of malignancy and demonstrates a diploid population of tumor cells in DNA analysis.

Abstract

Diagnosis of hepatocellular carcinoma (HCC), a common digestive malignancy, remains a challenge. The aim of this study was to evaluate the feasibility of performing laparoscopy and laparoscopic ultrasound with local anesthesia as a diagnostic procedure in HCC. Laparoscopy and laparoscopic ultrasound with local anesthesia was performed in the gastrointestinal endoscopy unit in three patients diagnosed of HCC. Endoscopy staged diffuse liver disease. Laparoscopic ultrasonography identified all liver tumors not visible during endoscopy and guided needle biopsy in one case. No complications happened. In conclusion, laparoscopy and laparoscopic ultrasound, performed as a minimally invasive diagnostic procedure can be a safe and very promising tool in planning therapy of HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the most common primary liver cancer^[1]. Nevertheless, less than a third of patients are candidate to radical treatments^[2]. Besides the low hepatic reserve of usual underlying cirrhosis, one of the explanations of these poor results are the limited accuracy and discrepancies between the imaging techniques in the discovering and staging of neoplasm^[3,4]. There is a common agreement that the most accurate diagnostic method is operative assessment with ultrasound^[5,6]. But this approach

bears an unacceptable morbidity and mortality precluding its general use.

Laparoscopy, initially introduced in gastroenterology, affords an excellent view of the intra-abdominal organs, although the inner part is not accessible to inspection^[7]. In the mid-1980's pilot studies described laparoscopic ultrasound that combined the advantages of a visual assessment of peritoneal cavity and all the organs, specifically the liver, with the high resolution of intraoperative ultrasound examination^[8-10]. More recently, with the incorporation of laparoscopic surgery into the practice of general surgery, it has been shown that this procedure optimizes staging in hepatic malignancy^[11-14]. However, surgical laparoscopic ultrasound typically performed under general anesthesia exposes patients to certain risks and increases costs. So, laparoscopy with ultrasound scanning, performed under local anesthesia could be a safer procedure providing meaningful information.

Our initial experience using diagnostic laparoscopy and laparoscopic ultrasound with local anesthesia is shown.

CASE REPORT

Laparoscopy with laparoscopic ultrasound procedures was performed in three consecutive patients diagnosed of HCC. The procedures were performed with local anesthesia in the gastrointestinal endoscopy unit. Oxygen saturation and heart rate were automatically monitored. After puncturing in the left upper quadrant of the abdomen, near the umbilicus, with a multihole 21-gauge needle, pneumoperitoneum with oxygen insufflation was established. Then, two 11-mm laparoscopic trocars were inserted. The first one was inserted through the pneumoperitoneum puncture site. Then, a frontal high-resolution video laparoscope (*Olympus GTV-S6*, Olympus Optical Co., Ltd, Japan) was introduced into the cannula, performing an initial endoscopic exploration of the peritoneal cavity. Another trocar was positioned to introduce the ultrasonic probe making a choice between the right paraumbilical region and the right inferior quadrant in accordance with abdominal characteristics. The laparoscopic ultrasonography was performed using ultrasonographic equipment (*Olympus IU-E1*, Olympus Optical Co., Ltd, Japan) that included a linear 7.5 MHz, 9.9 mm in diameter, orientable-tip probe (*Olympus MH-300*, Olympus Optical Co., Ltd, Japan) placed in contact with liver capsule. All probe manipulations during ultrasound scanning were guided by direct eye vision. The liver was systematically scanned at its front, upper (diaphragmatic), and lateral surfaces by moving the probe. For the left lobe

exploration of the liver, the probe was transferred to the epigastric port. The parenchyma, hepatic and portal veins were then carefully scanned, by using advancement-withdrawal maneuvers, lateral movements, sweeping and rotating the probe over the liver surface, in an attempt to identify the segmental anatomy. Duration of procedure ranged between 60 and 90 min. Recovery monitoring was performed for 15 min in gastrointestinal suite. Patients were then admitted for 22-h observation and later discharged.

Case 1

A 69-year-old male patient with previous chronic C hepatitis was diagnosed after abdominal ultrasonography and biopsy of HCC. Ultrasonography and abdominal computed tomography showed one tumor, 36 mm in diameter, located in the right lobe (segment V) (Figure 1). Laparoscopic examination demonstrated liver cirrhosis without tumor in surface (Figure 2A). Laparoscopic sonogram described the neoplastic deposit that was impossible to endoscopically visualize (Figure 2B). No other tumors were discovered inside the liver. Two grams of magnesium metamisole were intravenously administered at the end of procedure. Some days later, laparotomy with intraoperative ultrasonography was carried out with no additional findings, and then a surgical atypical hepatectomy was performed. Postoperative was unremarkable and patient has remained without recurrence for 21 mo.

Figure 2 A: Endoscopic liver image of cirrhosis. Ultrasonic probe is placed in contact to a fibrotic depressed whitish area near the gallbladder; B: Laparoscopic sonogram revealing a tumor under liver surface.

Case 2

A 51-year-old male diagnosed of alcoholic and viral C liver cirrhosis with portal hypertension developed ascites. He had a history of a hemangioma in both liver lobes. Former abdominal ultrasonography and computed tomography discovered a new 16-mm nodule whose biopsy diagnosed a HCC (Figure 3). Laparoscopy showed liver cirrhosis with portal hypertension and ascites (Figure 4A), whereas laparoscopic ultrasonography confirmed previous conventional radiological findings (Figure 4B). No analgesic drugs were required. Although the patient was selected for resection at that moment, during laparotomy unresectability was determined after discovering malignant diaphragm implant, and then radio-frequency treatment was carried out. The patient, in Child-Pugh B functional stage, refused liver transplantation and no antitumoral therapy was given.

Figure 3 Sonogram showing a 16-mm hypoechoic hepatic nodule in segment IV, histologically diagnosed of HCC.

Figure 4 A: Laparoscopy displaying the left lobe of the liver with medium-sized nodules and without evidences of neoplasm; B: The endoscopic sonogram confirming the intrahepatic presence of uninodular HCC.

Case 3

A 59-year-old male with prior history of 140 g/d of ethanol intake started with right hypocondrium pain. After abdominal sonogram, computed tomography scans and abnormal serum α -fetoprotein (2 440 ng/mL) a diagnosis of HCC was made (Figure 5). There were 4 tumors in right lobe, ranging from 1 to 7 cm in diameter. On laparoscopy chronic non-cirrhotic liver disease without neoplasm on surface was discovered (Figure 6A). Laparoscopic ultrasonography showed all the lesions. Sonographically guided biopsy gave a confirmatory result of HCC (Figure 6B). Non-neoplastic tissue obtained at

laparoscopy revealed an alcoholic hepatitis with fibrosis but without cirrhosis. Magnesium metimazole (2 g) combined with atropine (1 mg) were intravenously given during the procedure. Twenty months later the patient is alive in a consumptive state.

Figure 5 Sonogram revealing a hypo-isoechoic tumor in the center of the right lobe of the liver.

Figure 6 A: Upper aspect of right lobe of the liver. The surface is not perfectly smooth owing to the presence of alternately reddish areas slightly elevated with respect to lighter colored ones; B: Laparoscopic sonogram showing a very well defined tumor near a vascular structure.

DISCUSSION

Staging surgical laparoscopy with laparoscopic ultrasound, has been reported in the last several years as an important tool in the diagnostic approach to hepatobiliary and pancreatic malignancy, avoiding unnecessary laparotomy in up to 46% of patients^[11-14]. In HCC, surgical laparoscopy with laparoscopic ultrasound also optimizes patient selection for curative hepatic resection, discovering unresectable disease in as much as 63% of cases^[15-17].

Some years ago, Ido *et al.*, reported in Japan^[18] that laparoscopic ultrasound performed with local anesthesia diagnosed new nodular lesions in 64 out of 186 patients (34%). Twenty-eight nodules in 23 of the 186 patients (12%) were identified as HCC after biopsy. During the follow-up other 10 lesions, which had initially described as noncarcinomatous nodules, were diagnosed as HCC. So, laparoscopic ultrasonography discovered new HCC nodules in 17% of patients, defining multicentric neoplasm and avoiding unnecessary open surgery.

In our patients, laparoscopy with laparoscopic ultrasound was successfully performed in the gastrointestinal endoscopy

unit. There were no complications related to procedure that was done just under local anesthesia with non-narcotic analgesic drugs. So, this type of diagnostic laparoscopy seems as safe as standard laparoscopy^[7]. Endoscopic findings were liver cirrhosis in two cases (one with portal hypertension and ascites) and chronic liver disease without cirrhosis in the other one. There were no tumors on the liver surface. Extrahepatic, including peritoneal, spread was not detected.

Laparoscopic ultrasonography confirmed location and number of lesions diagnosed by conventional imaging. In particular, ultrasonographic pictures had similar characteristics to those of transparietal sonography, but with higher quality and definition. In the patient lacking previous histologic diagnosis, the tumor was biopsied with laparoscopic ultrasound guidance, achieving a definitive confirmation of hepatocellular carcinoma.

In conclusion, our preliminary experience suggests that laparoscopy with laparoscopic ultrasonography carried out with local anesthesia in a nearly ambulatory setting could be a safe, effective and relatively simple procedure in staging of HCC and optimizing patient selection for liver resection or transplantation. The procedure, that is well tolerated and carried out with minimal drug therapy, may be cost-effective for HCC diagnostic assessment. Ultrasonography, providing the image of interior of the liver and guiding puncture, increased sensitivity to laparoscopic procedure. On the other hand, endoscopic examination diagnosed in one case a non-cirrhotic liver, later confirmed after biopsy, finding that is associated with a better chance of hepatectomy and survival. Staging was correct in all cases except one wherein diaphragm infiltration was not detected at endoscopic study. The visual assessment of some areas, as dorsal surface of the right lobe, is still difficult and led to this false negative result. This problem could probably be overcome employing an orientable-tip device. Besides, this technique could be also useful in detection and ultrasonography-guided biopsy of lesions not accessible to conventional diagnostic approach. Consequently, this procedure, which may be a powerful tool in the management of HCC, must be extensively evaluated.

ACKNOWLEDGMENT

The authors thank Olympus España (Medical Europa) for the ultrasonographic equipment used in this study.

TO THE EDITOR

Although the incidence of gastric cancer has declined somewhat in recent years, it remains one of the most common cancers worldwide^[1], and is the most common cancer in East Asian countries such as Korea and Japan^[2]. In terms of the genetics of gastric cancer, mutations in *CDH1* (*E-cadherin*) have been associated with hereditary diffuse gastric cancer (HDGC). The first germline mutation in *CDH1* was reported in a large Maori HDGC family^[1], with subsequent corroborations in Western and Asian HDGC families^[3-5]. *CDH1* mutations are believed to be associated with up to 50% of HDGC families^[5], but have not been linked with sporadic or intestinal types of gastric cancer^[5]. Interestingly, the observed *CDH1* germline mutations differ between Western and Asian countries; the mutation frequencies are higher in Western countries, with predominately truncating germline mutations observed, whereas only a few different missense mutations have been reported in Asian countries^[6]. This ethnic difference and the low frequencies of *CDH1* germline mutation in Asian populations prompted researchers to seek other susceptibility gene for Asian familial gastric cancer (FGC)^[2,7]. We found a *MET* germline mutation in a FGC patient suffering from a diffuse type of gastric cancer^[2], and another group reported a *MET* germline mutation in a gastric cancer patient without detailed family history information^[7]. These *MET* germline mutations were also found in Korean gastric cancer patients, but the overall *MET* mutation frequencies seem to be low

(1%^[7] and 5%^[2]), suggesting that while *MET* germline mutations may be causative in Korean or Asian gastric cancer patients, they likely do not play a major role in the development of FGC. Thus, no major FGC-related susceptibility gene has been identified in Asian countries to date.

The *TP53* tumor suppressor gene is known to cause Li-Fraumeni Syndrome (LFS), a rare hereditary clustering of malignancies including sarcoma, breast cancer, brain tumor, leukemia and adrenocortical carcinoma (Table 1)^[8]. Along with these five major cancers, LFS has also been associated with a wider range of tumors, such as melanoma, Wilms' tumor, lung, gastric, and pancreatic carcinoma^[8]. The definition of LFS includes a proband diagnosed with sarcoma before 45 years of age, a first-degree relative with cancer before this same age, and another first-or second-degree relative in the lineage with any cancer before this age or sarcoma at any age^[9]. *TP53* germline mutations have been reported in around 80% of LFS and 40% of Li-Fraumeni-like (LFL) syndrome patients^[8].

Recently, Keller *et al.*, reported a *TP53* germline mutation in one German FGC patient^[10]. They further performed mutational screening of *CDH1* and *TP53* in 35 FGC patients, which led to identification of two *CDH1* (one frameshift and one missense) and one *TP53* (missense) germline mutation (1 out of 34, for a 3% mutation frequency in *TP53*; only the proband was available for analysis). This novel report of a *TP53* germline mutation in one FGC patient suggested that *TP53* might play a role in the development of FGC. Based on this, Keller *et al.*, recommended that the *TP53* gene should be included in genetic screening of FGC patients with a suspected genetic predisposition for the disease.

Very recently, Oliveira *et al.*, reported a *TP53* germline mutation in 1 out of 10 screened FGC families from Portugal, which also has a high incidence of gastric cancer^[11]. Interestingly, the Portuguese family with the *TP53* germline mutation had a family history of both FGC (three gastric cancer members) and atypical LFS (one pancreatic cancer patient and one colon cancer patient). This family had previously been described as a Li-Fraumeni kindred^[12]. Based on these results, Oliveira *et al.*, reiterated the suggestion of Keller *et al.*, that families with an excess of gastric cancer should be considered for *TP53* mutation screening. These two reports differ from two previous studies of Japanese FGC families, in which no *TP53* germline mutations were identified^[13,14].

In our lab, we screened the entire coding region of *TP53* in probands from 23 Korean FGC families. We identified a nonsense (E287X) *TP53* germline mutation in 1 (SNU-G2)

Table 1 Definition of Li-Fraumeni syndrome and familial gastric cancer subtypes (familial gastric cancer, hereditary diffuse gastric cancer, and familial intestinal gastric cancer)

	Hereditary cancer	Definition	Reference
1	Li-Fraumeni syndrome (LFS)	A proband with a sarcoma under 45 yr Plus 1st degree relative under 45 yr with any cancer Plus an additional 1 st or 2 nd degree relative in the same lineage with any cancer aged under 45 yr or sarcoma at any age	8
2	Familial gastric cancer (FGC)	At least two gastric cancer patients within 1 st degree relatives and one patient diagnosed before the age of 50	6
2-(1)	Hereditary diffuse gastric cancer (HDGC)	(1) Two or more diffuse gastric cancer patients in 1 st or 2 nd degree relatives, with at least one diagnosed before the age of 50 (2) Three or more diffuse gastric cancer patients in 1 st or 2 nd degree relatives, independently of age of onset	15
2-(2)	Familial intestinal gastric cancer (FIGC)	At least three relatives should have intestinal gastric cancer and one of them should be a 1 st degree relative of the other two Plus at least two successive generations should be affected plus in one of the relatives, gastric cancer should be diagnosed before the age of 50	15

Criteria for countries with high incidence of gastric cancer.

out of the 23 screened individuals^[6]. The E287X *TP53* mutation segregated with the cancer phenotype in family members from whom DNA samples were available. As there were seven individuals in this family affected with gastric cancer, we initially believed that *TP53* might be a new candidate gene for FGC. However, a thorough clinical investigation revealed that two members of this family were afflicted with brain tumors, seven with gastric cancers, two with sarcomas and one with both gastric cancer and a sarcoma. This family history is compatible with both FGC and LFS. Thus, it is highly probable that the identified *TP53* germline mutation in our family (and perhaps those investigated in the other papers) is associated with LFS regardless of FGC history.

Based on this observation, we examined the pedigree in which Keller *et al.*^[10], identified their *TP53* germline mutation. This family included three gastric cancer patients, 1 individual who died of leukemia at age 17, one individual who died of liver carcinoma at age 34, and two individuals (younger brothers of the proband) for whom the causes of death were not listed. Although this family history satisfies the criteria for FGC, the family cannot be excluded from meeting the LFS criteria^[8,9]. Indeed, if this family was listed as including one sarcoma patient, the family history could satisfy the classical LFS criteria^[8,9].

Thus, the three recent papers^[6,10,11] appear to indicate that germline mutations in *TP53* likely do not contribute significantly to the development of FGC, but are instead associated with LFS, which may be accompanied by FGC in countries with high gastric cancer incidences. As there is presently insufficient clinical data to assess the incidence and prevalence of LFS in countries with high gastric cancer incidence rates, these results are very important for directing the genetic screening and counseling of FGC families. As suggested by Keller *et al.*^[10], and Oliveira *et al.*^[11], *TP53* mutation screening should be performed in FGC families with LFS-related cancers, whether or not the mutation is causative of FGC or only LFS. In addition, further work

will be warranted to determine more clearly whether or not *TP53* contributes to the development of FGC with LFS-related clinical symptoms.

Joseph B. Kirsner, *Evolution of our understanding of inflammatory bowel diseases: From the mystical to the cellular and now the molecular.*

*'Science (IBD) is moving but slowly, slowly creeping on from point to point'.
Alfred Lord Tennyson (1809-1892)*

It is of interest in an era of increasing biomedical sophistication to recall that a relatively short time ago, early in the 20th century, 'simple' ulcerative colitis was an obscure 'medical curiosity' emerging slowly from an unknown past. Crohn's disease was yet unidentified as a separate entity although careful review of the IBD literature documented its early presence, masquerading as 'intestinal tuberculosis'. Into the 1930s, the etiology and pathogenesis of ulcerative colitis and Crohn's disease were unknown, and investigative hypotheses were scarce. Therapeutic resources were limited and treatment was primitive. At a time of limited biomedical knowledge and minimal clinical awareness, unsubstantiated views prevailed, including 'vague reactions to foods' (sugar, margarine, corn flakes), deficiency of a 'protective factor' in pig intestine, and psychiatric disease.

The position of inflammatory bowel diseases in the medical world today is vastly different. Ulcerative colitis and Crohn's disease are now recognized worldwide, are frequent subjects at medical meetings and increasingly provide the focus of important clinical and laboratory research. Indeed, few diseases in gastroenterology present as varied an array of investigative opportunities. This dramatic change began in the mid-20th century with the increasing support of biomedical research and the

subsequent growth of the basic sciences, highlighted by the adiscoveries of sulfonamides in the 1930s, antibiotics in the 1940s, and ACTH and adrenocorticosteroids in the 1950s. The entry of young physicians into gastroenterology during the 1930s and 1940s, trained in the rigors of basic research and controlled clinical study, contributed to this advance. Progress accelerated following the establishment of the General Medicine Study Section of the National Institutes of Health in 1956, which subsequently provided a major source for support of research in gastroenterology, the growth of academic medicine, and the establishment of the Crohn's and Colitis Foundation of America. By the 1970s, sufficient new clinical and scientific information on IBD had been accumulated to justify a comprehensive publication on ulcerative colitis and Crohn's disease, the 1975 1st Edition of *Inflammatory Bowel Diseases*, a volume of approximately 400 pages, with contributions from 25 authors. Subsequent editions of *Inflammatory Bowel Diseases*, appearing approximately every five years, documented the increasing depth and sophistication of clinical and scientific knowledge of ulcerative colitis and Crohn's disease. The 3rd Edition of *Inflammatory Bowel Diseases* in 1985, involving 44 authorities, had doubled in size and included chapters on the nature of intestinal defenses, the M cell, early information on immunologic and genetic aspects of ulcerative colitis and Crohn's disease, as well as advances in the pathology, radiology and endoscopy of IBD, and its improving medical and surgical treatment. Psychiatric and other early 20th century hypotheses had been replaced by concepts based in the disciplines of epidemiology, microbiology, immunology and genetics.

Into the 1990s, with more investigators involved, knowledge of the inflammatory bowel diseases increased exponentially. Etiologic possibilities, as outlined by R Balfour Sartor, now were more definitive, including persistent pathogenic microbial infection, enhanced intestinal mucosal permeability, 'dysbiosis' or the altered balance of protective bacteria *vs* aggressive commensals, and 'dysregulated' immune responses, leading to loss of oral tolerance to commensal bacteria and aggressive cellular activation. Academically based IBD centers generated more focused research and controlled therapeutic trials. IBD research in the laboratory had advanced from the study of tissues and epithelial cells to cellular biology and cellular constituents. Chapters now included the biologic nature of the IBD tissue reactions, the gut mucosal immune system and more advanced immunological and genetic mechanisms. Ulcerative colitis and Crohn's disease had become features of national and international medical meetings attracting large audiences.

The 1999 5th Edition included more than 70 authorities

submitting increasingly diverse chapters on epithelial cell function in health and disease (including heat shock proteins, and trefoil peptides), cytokines, chemokines, growth factors, eicosanoids and other bioactive molecules in clinical IBD and experimental intestinal inflammation, leukocyte-endothelial interactions, altered intestinal neuromuscular function, and the nature of oral tolerance. Genetic studies had identified susceptibility loci for ulcerative colitis and, most importantly, a locus (now identified as NOD-2) on chromosome 16 for Crohn's disease, particularly involving the ileum, the first gene linked with susceptibility to Crohn's disease. Transgenic and recombinatorial science now facilitated the creation of a variety of experimental animal models seeking to approximate human IBD, thereby enabling the more comprehensive study of intestinal tissue injury. The molecular nature of inflammation now became a prime area of investigation, with therapeutic dividends. After one hundred years of intermittent immunologic research led to the identification of tumor necrosis factor (TNF), an antibody to TNF proved to be a highly effective treatment, though not a cure, for Crohn's disease. Newly recognized bioactive molecules, IL-1, IL-2R, CAMS, addressins, defensins, flagellins, granulysins, selectins, claudins, annexins, guanylyns, laminins, intimins, aquaporins, and microsins now filled the IBD literature. Into the 21st century, additional bioactive molecules relevant to intestinal inflammation were identified at a rapid pace: adaptins, fibrillarins, syndecan-1, stromelysin, integrins, galanin-1, tropomyosin, fibroblast growth factor, epidermal growth factor, permeability-enhancing factor, neurotrophins, survivins, ubiquitins and zonulins.

The many pro-inflammatory and immunoregulation molecules, countless cytokines, and other biological substances, generated a series of novel biologic therapeutic agents (CP571, IDEC-131, OPC 6535, LDP02, CDP870 J695), creating a formidable, if not intimidating, array of terms and pathways for the IBD physician and investigator alike. How do these molecules relate to IBD and to each other? Where are the signaling mechanisms and pathways determining their coordinated action? Are they different in ulcerative colitis and Crohn's disease? Does NF κ B have both pro-inflammatory and anti-inflammatory actions, also involving trace elements (boron, selenium, vanadium, zinc)? Are there other dominant pro-inflammatory molecules analogous to TNF which can be successfully blocked? What is the possible role of the Peyer's patch microenvironment in the regulation of T cell function? Since the intestinal bacterial flora play a critical role in the pathogenesis of IBD, what might be the abnormalities in the commensal mucosal flora or the defects in the intestinal epithelium barrier leading to chronic intestinal inflammation? The role of human regulatory T cells? The 5q31 cytokine gene cluster? The role of the M cell in the entry of protective or detrimental antigens? The pivotal regulatory role of AP₂₀ in intestinal inflammation? The role of the intestinal epithelial barrier in the development of intestinal immunity? The possibility of increasing the production of local secretory IgA antibodies as a protection against bacterial infection and inflammation? The possible involvement of nitric oxide in the inflammatory responses and immune reaction of

IBD? The possible role of maternal immunologic memory in predisposing children to IBD and the genetic regulation of the intestinal epithelium? Important clinical issues similarly await resolution: the nature of the environment associated with urban industrialization and its relationship to IBD; and the role of today's 'hygienic home environment' in the vulnerability to IBD among children? Jewell and his colleagues recently have pointed out 'the importance of NOD-2/CARD 15 and the HLA region in determining clinical subgroups of Crohn's disease, which may provide the initial basis for the construction of a molecular classification of Crohn's disease.'

The discovery of new therapeutic approaches, in addition to currently available methotrexate, cyclosporine, antimicrobial compounds, thalidomide, and the adhesion molecule inhibitor heparin, including: growth factors, anti NF κ B transcriptional agents, the prostaglandin receptor EP4, anti-A4 integrin antibody, inhibitors of stress-activated MAP kinases, antisense oligonucleotides vasoactive intestinal polypeptide and heterologous hemopoietic stem-cell transplantation. Sartor has raised the possibility of more effective local treatment of IBD via 'targeted delivery of biologically active immunosuppressive molecules by recombinant bacteria colonizing mucosal surfaces.' More immediately available microenvironmental approaches include the resurrection of 'old' treatment probiotics, live microbial food ingredients (lactobacilli, bifidobacteria species) and prebiotics (germinated barley and nonabsorbed carbohydrates) and their newly recognized actions: production of antimicrobials and short chain fatty acids, inhibition of microbial adherence to the intestinal epithelium and restoration of normal intestinal permeability. In classic Karl Popper fashion, the expanding IBD research has generated many new important IBD questions and new research opportunities, necessitating a new IBD 'road map.' Despite the extraordinary progress in scientific information, more fundamental knowledge awaits discovery as the pace and the dimensions of IBD research continue to increase.

The impressive scientific advances in IBD, illuminating fundamental biologic and physiologic aspects of intestinal function, accentuate the importance of the 6th Edition of *Kirsner's Inflammatory Bowel Diseases*, and also defines its purpose: to clarify the new intestinal biology, its relevance to the clinical situation, and provide a launching pad for the remarkable advances towards etiology and the cure of IBD yet to come. *Kirsner's Inflammatory Bowel Diseases*-6th Edition, provides the currently indispensable 'road map' guiding IBD physicians and scientists through the multi-complex IBD labyrinth. Co-editors, Dr. R Balfour Sartor, Professor of Medicine, Microbiology and Immunology at the University of North Carolina, and Dr. William J Sandborn, Professor of Medicine at the Mayo Clinic, have assembled a superb panel of national and international authorities and a 'cutting edge' array of IBD scientific and clinical topics. This book, *Kirsner's Inflammatory Bowel Diseases*, since 1975, has played a vital part in assembling and expertly analyzing for the medical world the increasing 'basic' science and the expanding clinical information and will continue this important role, befitting the status of *Kirsner's Inflammatory Bowel Diseases* as 'the best book in the IBD field.'

Sarto RB, Sandborn WJ. Kirsner's inflammatory bowel disease. *World J Gastroenterol* 2005; 11(26): 4129
<http://www.wjgnet.com/1007-9327/11/4129.asp>

Very few medical textbooks have so thoroughly dominated, and even defined a field, as has *Inflammatory Bowel Diseases* by Joe Kirsner. Originally co-edited with Roy Shorter of Mayo Clinic, this book, beginning with its first edition in 1975, encapsulated the science and art of caring for patients with Crohn's disease and ulcerative colitis. Thus it is with considerable respect, and indeed some awe and trepidation, that we eagerly embraced the opportunity to assume the editorship of this preeminent textbook and the obligation to transition it to reflect the changing, increasingly complex pathophysiology and treatment of these diseases.

Our editorial principle has been 'evolution, not revolution', in an effort to maintain the unique character of the original book while advancing its format and scope to encompass the important recent developments in basic and clinical investigation and to emphasize translational areas. We added multiple new chapters, including clinical pharmacology, epithelial/immune and epithelial/bacterial interactions, T lymphocyte dysregulation, T lymphocyte trafficking, fibrogenesis, serology and laboratory markers of disease activity, assessment of disease activity and clinical trial design, pouchitis, and pharmacoeconomics, and split genetics and colon cancer into basic and clinical components. In the process of changing the character of the contents, 30 new primary authors have contributed chapters. These authors are a blend of established thought leaders and younger investigators who have brought new concepts to the field, but all authors share the common characteristics of having

a global perspective and being the premier investigator in their respective field. We thank the individual authors for their considerable efforts to create concise yet authoritative chapters and for their good humor in our exhortations to meet deadlines and to make suggested alterations. This adherence to deadlines and the timely production schedule by Elsevier have resulted in the most current textbook on IBD, with a lapse of only 7 mo from final submission to publication. Thus, recent trends in treatment and the latest concepts in pathogenesis are reflected in this book.

The cover encapsulates the evolving concepts of applying new insights into the pathogenesis of ulcerative colitis and Crohn's disease to their diagnosis and treatment. This book discusses the interactions between mucosal innate and acquired immune responses and between enteric commensal microflora and environmental triggers that lead to disease in genetically susceptible hosts. Novel mechanisms of diagnosis provide earlier and more precise diagnosis of disease, and novel biologic treatments bring new opportunities to induce a remission, and hopefully maintain disease quiescence. The individual chapters collectively develop the theme of genetic and molecular heterogeneity that results in distinct phenotypes of disease. The sub-classification of both Crohn's disease and ulcerative colitis should define clinically relevant populations of patients that selectively and predictably respond to individual therapeutic agents, resulting in highly effective and minimal cost treatment. Ultimately, preclinical diagnosis will lead to a way to prevent onset of clinical disease and associated complications in genetically susceptible individuals.

Finally, we must thank our family members, especially Em and Kenna, who have encouraged and supported this undertaking and in the process have endured many lonely weekends and holidays as the task was completed. We dedicate this book to these family members; to Joe Kirsner, for his guidance and confidence in our ability to continue his superb tradition, to our colleagues, fellows and students who provide continued stimulation and important questions; to the authors for their eloquent and comprehensive contributions; to the publishers for their strong support and professional production; and to the patients who have entered the clinical studies which have advanced our knowledge of the pathogenesis, epidemiology, diagnosis, and treatment of these disease. We hope that our readers will profit by this collective experience and make suggestions to improve future editions.

Abstract

Gastric carcinoma remains a common disease worldwide with a dismal prognosis. Therefore, it represents a very important health problem. It occurs with a high incidence in Asia and is one of the leading causes of cancer death in the world. Although the incidence and mortality of gastric carcinoma are decreasing in many countries, gastric cancer still represents the second most frequent malignancies in the world and the fourth in Europe. The 5-year survival rate of gastric carcinoma is low. The etiology and pathogenesis are not yet fully known. The study of gastric cancer is important in clinical medicine as well as in public health. Over the past 15 years, integrated research in molecular pathology has clarified the details of genetic and epigenetic abnormalities of cancer-related genes in the course of the development and progression of gastric cancer. Gastric cancer, as all cancers, is the end result of the interplay of many risk factors as well as protective factors. Although epidemiological evidence indicates that environmental factors play a major role in gastric carcinogenesis, the role of immunological, genetic, and immunogenetic factors are thought to contribute to the pathogenesis of gastric carcinoma. Among the environmental factors, diet and *Helicobacter pylori* are more amenable to intervention aimed at the prevention of gastric cancer. The aim of the present paper is to review and include the most recent published evidence to demonstrate that only a multidisciplinary approach will lead to the advancement of the pathogenesis and prevention of gastric cancer. On the immunogenetic research it is clear that evidence is accumulating to suggest that a genetic profile favoring the proinflammatory response increases the risk of gastric carcinoma.

Key words: Gastric cancer; *H pylori*; Immunogenetics; IL-1; Diet; Trefoil regulation; gp130

Shang J, Peña AS. Multidisciplinary approach to understand the pathogenesis of gastric cancer. *World J Gastroenterol* 2005; 11(27): 4131-4139
<http://www.wjgnet.com/1007-9327/11/4131.asp>

DISEASE DEFINITION AND CLASSIFICATION

The stomach wall is divided into three major areas: fundus, corpus, or body, and antrum and it has five layers: the inner lining (the mucosa) contains glands. Underneath is the submucosa; then is the layer of muscle; next is the subserosa. The outer layer is the serosa. Gastric cancers are malignancies arising in any part of stomach. Most gastric cancers arise in the antrum, the distal third of the stomach. The predominant site of gastric cancer occurrence has changed over the last 30 years^[1-6]. A large number of tumors involving the proximal stomach and gastro-esophageal junction have been found. The lesser curvature of the stomach is more frequently involved than the greater curvature.

Several different types of cancer can occur in the stomach. Adenocarcinoma, which starts in the glandular cells, is the most common cancer of the digestive tract and histology accounts for 90-95% of all gastric malignancies. It can spread to nearby lymph nodes (LN) and other areas of the body, such as the liver, pancreas, colon, lung, and ovaries. Other types of malignancy in the stomach are sarcoma arising from the cells of the muscle layer, and more common, lymphoma arising in the B and T cells of the lamina propria. The latter two types of malignancies have different prognosis and require different management than adenocarcinoma.

In this review we will concentrate in adenocarcinoma of the stomach mainly because other types have rarely been reported^[7,8].

Several classification systems are used for gastric cancer. Borrmann types, developed by Borrmann in 1923, identify five different types. This tissue classification of gastric cancer is characterized by the shape of the tumor on gastric mucosa and its pervading style in gastric wall.

Lauren developed the DIO system of the histomorphological classification, which assumes two main biological groups: diffuse gastric cancer (D) and intestinal gastric cancer (I), and other (O)^[9,10]. The former two groups account for 90% of all stomach cancers. The intestinal type is well differentiated and characterized by polypoid or fungating

lesions that may ulcerate centrally. Many evidences show that this type is strongly associated with *Helicobacter pylori* (*H. pylori*), and usually arises on a backdrop of chronic gastritis, gastric atrophy, and intestinal metaplasia^[11]. Clinically, the latter is present with diffuse thickening of the stomach wall, rather than a discernible mass. A genetic predisposition is presumed in young patients with a diffuse type of gastric cancer, in contrast to the intestinal type associated with older age^[12,13]. The intestinal type of adenocarcinoma has a better prognosis than the diffuse variant, most of which have spread beyond the confines of the stomach at the time of diagnosis. As with other cancers, stage is the most important determinant of outcome^[14].

According to the standard of WHO, the cellular classification in gastric carcinoma has these subtypes: papillary adenocarcinoma, tubular adenocarcinoma, mucinous adenocarcinoma, signet-ring cell carcinoma, squamous cell carcinoma, adenoacanthoma, undifferentiated carcinoma, unclassified carcinoma and carcinoid tumor.

The Fifth International Union Against Cancer tumor node metastasis (UICC TNM) classification, which was published in 1997, based on the number of metastatic LN, has proved to be a reliable and objective method as the principal assessing the extent and severity of disease and determining the prognosis of cancer patients^[15]. The new TNM classification not only is an objective, simple and reproducible system, but also a significant prognostic index for gastric cancer superior to the old classification. The new TNM classification represents a prognostic factor equally powerful to the old classification. Especially, the new N-classification is superior to the old N-classification in terms of the homogeneity of each N group^[16,17].

X-ray examination after taking barium meal may eventually contribute to detecting delayed gastric emptying quantitatively and indicates the degree of tumor infiltration. Similarly and more accurately, spiral CT is of help in the identification of the gross type, invasion to serous layer and adjacent organs of gastric cancer in its stage of progression. The CT scan is also valuable in detecting metastatic as hepatic, splenic, and abdominal apart from the involvement of LN near the lesion. Enhanced dynamic CT scan plays a significant role in the diagnosis of gastric carcinoma; early enhancing phase scanning is the technique of choice nowadays for demonstrating tumor lesions. Sophisticated scanning technique is mandatory in improving the diagnostic accuracy of gastric carcinoma^[18,19].

The ultrasound examination of stomach so far has been still a difficult technique that requires expertise. It can be used to observe the infiltration of the tumor into the lower layer of the mucous membrane. Endoscopic ultrasonography is very accurate in assessing the depth of tumor infiltration and the lymph node metastasis. It also can be used to determine the progress and prognosis of gastric carcinoma^[20].

DISEASE CHARACTERISTICS

Precancerous lesions of stomach

Six different pathological disorders have been described as increasing the risk for malignancy in the stomach. The following processes have been implicated as precancerous lesions.

Chronic atrophic gastritis There is evidence from animal model that nitrosamine plays a role in developing malignancy. Achlorhydria in atrophic gastritis allows bacterial colonization of the stomach, most extremely in places where overgrowth may cause nitrate reduction and transform the nitrate, which exist in many foods to potentially develop carcinogenic N-nitroso compounds^[21]. This occurs more often in antrum gastritis with intestinal metaplasia and non-typical proliferation. The course of gastritis is rather long and gastric cancer is believed to develop slowly over many years. Some patients present dyspepsia, vague abdominal fullness (after meal), irregular pain, belching, nausea, and vomiting, but not specific. Severe cardiac gastritis may produce glossitis and anemia.

Gastric polyps Familial adenomatous polyps are associated with upper gastrointestinal adenomas and adenocarcinoma. Based on Nakamura's classification^[22,23], hyperplastic polyps were further classified into the following subtypes: the foveolar epithelial type, fundic glandular hyperplastic type, and pyloric glandular hyperplastic type. It was found that atypical hyperplastic foci usually appear in the foveolar epithelial subtype, indicating a close relationship to cancer. This finding suggests that the subclassification of hyperplastic gastric polyp has a higher practical value in clinical application^[24].

Gastric ulcer Some gastric cancers are considered to transform from gastric ulcers, but with a low rate, 1-5% in China. Cancerous degeneration of ulcer was small and the epithelial regeneration at the ulcer's edge and benign fusion of the muscularis mucosa with the muscularis propria were very common. The cancerous tissue extending to node metastasis was rare. Therefore, the cancerous tissue down to the submucosa was found at the margin but not at the base of the ulcer. These patients should be thought seriously, specially if they are more than 45 years old, the symptoms of gastric ulcer are persistent 1 mo after treatment. These findings that conform well to Hauser's criteria blood test are positive. These results suggest that multiple biopsies should be taken from the edge of chronic ulcers. The most distinct feature of malignant ulcer was the lack of cancerous infiltration and muscular residue in the scar tissue of ulcer base. The existence of this type of ulcer clinically and pathomorphologically supports the viewpoint that gastric cancer ulcer can undergo malignant change^[25].

Cancer of gastric remnant Patients after gastrectomy have more opportunity to get vicious tumor than normal people, and the course from remnant stomach to gastric cancer is nearly 15-30 years. Refluxing of intragastric and bile after gastrectomy became the base of gastritis. Furthermore the pH is increased and is beneficial to the abnormal proliferation of cell, carcinogen such as nitrite transfer to nitrosamine. Bile salt, a carcinogen, sometimes can lead to cancer.

Cholecystitis It was found that both the content of various kinds of biliary acid salt and pH value of gastric juice were much higher in patients with gastric cancer, gastric ulcer, and chronic atrophic gastritis than in normal controls. Bile acid salt is known to be harmful to gastric mucosa and the damage becomes more severe with the increase of bile acid salt concentration and prolongation of exposure. Therefore,

our results suggest that the bile acid salt in the gastric juice is one of the carcinogenic factors^[26].

Pernicious anemia Pernicious anemia can lead to atrophic gastritis and is well known to be associated with gastric cancer. Pernicious anemia and autoimmune disease in general is rare in Chinese patients. There are few reports of pernicious anemia in Chinese patients and does not play a significant role as a predisposing cause of gastric cancer in China^[27,28].

Gastric schistosomiasis Gastric carcinoma has been found arising from schistosomiasis in the epidemic area of south China and this chronic inflammation has been linked to development of gastric cancer in this area of China^[29].

Early gastric cancer

The designation early gastric cancer (EGC) refers to a gastric carcinoma, which does not infiltrate beyond the submucosa. This definition is not influenced by absence or presence of metastases or by the diameter of the tumor. The 5-year survival of EGC is 90% or more. The diagnosis can regularly be made if, in the case of persistent vague upper abdominal complaints, an optimal radiological examination of the stomach is done. At even the slightest radiological suspicion, or if complaints persist in spite of negative radiological findings, gastroscopic examination and multiple-aimed biopsies should follow. Attention should be focused on the gastric angular incisure, antrum and lesser curvature to perform site-directed biopsy. Final diagnosis depended on the pathological diagnosis of the biopsy material. Pathologic diagnosis would be correct, provided the biopsy material was taken from the proper site^[30,31].

An investigation from Liaoning Province reported pathological characteristics of EGC in Chinese patients. The peak age of the patients was between 50 and 59 years. The incidence in female before 50 years was higher than that in male but reverse after this age. The most common site was in lower part of the stomach. Highly differentiated carcinomas were more frequently found in those cancer foci of no larger than 0.5 cm in diameter. More signet ring cell carcinomas were found. Lymphatic metastasis was more in type IIc+III and the least in type I. Comparing with the Japanese cases, it was found that the peak age of EGC patients in Japanese was 10 years older than that in Chinese patients and most of the tumor occurred in middle part of the stomach. Type III and mucinous adenocarcinoma was hardly found^[32].

The recurrence rate was higher in submucosal tumors than in mucosal tumors, in lymphatic and vascular vessel invasion-positive cases than in negative cases, in synchronous multiple gastric cancer than in solitary tumors, in tumors of 1.5 cm or more in diameter than in tumors of less than 1.5 cm. The rate of hematogenic metastasis to the liver or lung was 45.5%, and the recurrence in the residual stomach was 27.3% and in lymph node was 27.3%^[33].

Advanced gastric cancer

Because of the elusive nature of gastric disorders, gastric cancer usually is advanced when symptoms first appear. There are several characteristic routes by which gastric carcinoma will progress and metastasize: (1) by extension

and infiltration along the mucosal surface and stomach wall or lymphatic vessels, (2) via lymphatic or vascular embolism, probably to regional LN, (3) by direct extension into adjacent structures such as the pancreas, liver, or esophagus, and (4) by blood-borne spread. The pattern of metastatic spread of gastric cancer correlates with the size and the location of tumor. Lesions of the distal portion of the stomach usually metastasize to infra-pyloric, inferior gastric, and celiac LN. Tumors in the proximal portion often metastasize to pancreatic, pericardial, and gastric LN. With advanced gastric cancer, involvement of the left supraclavicular nodes may occur. Distant metastatic sites are the lung, adrenal glands, bone, liver, pancreas, and peritoneal cavity^[34].

Clinical syndromes

In the early stage, GC seldom showed significant symptoms, some of which are common to other, less serious gastrointestinal disorders (bloating, gas, and a sense of fullness). Some degrees of dysplasia occur, appetite loss, heartburn, vague abdominal fullness, flatus, excessive belching, and breath odor, mild or severe, were similar as in the presentation of chronic gastritis or gastric ulcer previously reported. Soon afterwards the difficulty in swallowing, particularly difficulty that increases over time, nausea and vomiting, abdominal pain and weight loss were on the rise. In the late stage some patients might vomit blood; have blood in the stools or black stools, tiredness due to anemia, abdominal pain and weight loss are aggravated, a decline in general health.

As other malignancies, early detection, early diagnosis, and early treatment remain the key to improve the survival of patients with resected cancer of the gastric cardia. Why residual tumor left at the resection edge and the presence of tumor thrombi do not influence survival needs to be further studied.

EPIDEMIOLOGY

The epidemiology of gastric cancer involves many features, since there are significant geographical, ethnical, and cultural factors influencing the prevalence of GC. It is more frequent in the developing world than in the developed world, more common in Asia than in Europe, and more in Latin America than in North America and Africa^[35]. Stomach cancer in China has distinct geographically different distribution. The morbidity in urban areas is higher than in rural areas, giving a difference of 1.9 times^[36]. According to an investigation between 1989 and 1999, in Linqu County of China, no reduction in GC mortality was observed in the highest risk population worldwide^[37].

The most recent estimates indicate that gastric cancer is the second most common cancer in the world after lung cancer. It represents 11% of all cancers in men and 7% of all cancers in women. In developing countries, lung cancer ranks first, representing 13% of all cancers and gastric cancer second (12%). In developed countries gastric cancer ranks fifth, representing 7% of all cancers, three-fourth of which occur in Asia. About 80% of the cases diagnosed in Asia occur in China and Japan. Steady decline in the rates of gastric cancer has been observed everywhere in the last few decades. However, the total number of new cases

diagnosed worldwide is increasing mainly because of increasing and aging of the population. It was estimated that there were 700 000 new cases in 1980, 755 000 in 1985, 900 000 in 1990, 1 013 000 in 1995, and 1 000 000 in 2000. This indicates that the impact of gastric cancer in public health is not decreasing^[4].

ETIOLOGY

Gastric cancer, of all cancers, is the end result of the interplay of many risk factors as well as protective factors. Genetic and environmental factors are likely to play a role in the etiology of the disease. Several factors are suspected to play a role in gastric carcinogenesis, including the effects of diet, exogenous chemicals, intragastric synthesis of carcinogens, genetic factors, infectious agents, and pathological conditions in the stomach (such as gastritis). According to Correa, there is evidence from pathology and epidemiology studies that gastric carcinogenesis develops with the following sequential stages: chronic gastritis; atrophy; intestinal metaplasia; and dysplasia. The initial stages of gastritis and atrophy have been linked to excessive salt intake and infection with *H pylori*^[38].

Environmental factors and gene polymorphisms involved in the susceptibility of gastric cancer

Several epidemiological evidences indicate that environmental factors play an important role in gastric carcinogenesis. The fact that immigrants exhibit incidence rates similar to those of their country of origin has led researchers to accept exogenous influences such as environment and diet. The investigation from China showed that the risk factors of gastric cancer were living in high incidence area for a long period, low economic income, low consumption of fresh vegetables and fruits and animal protein, high intake of sweet potato and ink fish and salted meat, eating and drinking too much at one meal and mental injury, and a family history of gastric cancer. High intake of grains and low intake of animal fat and proteins appear to be associated with a decreased risk. Diets rich in vitamins A and C are associated with low risk for gastric cancer. Controversy exists over the role of nitrates found in soil-grown foods, drinking water, and prepared foods. Because refrigeration and a high intake of ascorbic acid inhibit the formation of nitrates, it is postulated that the presence of these factors may account for decreasing gastric cancer. Neither smoking tobacco nor drinking alcohol has been demonstrated to increase the risk of gastric carcinoma^[32,39-44].

H pylori

Gastric carcinogenesis is a multistep and multifactorial process beginning with *H pylori*-associated gastritis in most cases. *H pylori* infection, together with other environmental factors and individual susceptibility, determine the final risk for the development of gastric cancer. The discovery of *H pylori* in the early 1980s has proved a turning point in understanding the pathogenicity of this malignancy. *H pylori* infection is common worldwide and about half of the human population believed to be infected. But only a small fraction of infected individuals develop gastric cancer.

Additional factors must be involved in the progression toward cancer^[45,46,50].

H pylori are highly host-adapted bacterial pathogens that establish a chronic infection in the human stomach and have no known animal or environmental reservoirs. It shows a high degree of genetic heterogeneity due to mutations and frequent recombination. In the past, specific genes have been identified which are associated with bacterial virulence. These genes (e.g., *vacA*, cytotoxin associated gene A (*cagA*), and *iceA*) have been studied individually, and distinct genotypes have been defined. There is accumulating evidence that the different genotypes of *H pylori* show a particular geographic distribution^[51]. *H pylori* strains containing the *cagA* protein are associated with more severe disease and harbor a 40-kb pathogenicity island (PAI) induce NF- κ B activation and interleukin (IL)-8 secretion in gastric epithelial cells. *H pylori* changes the expression of genes encoding growth factors and cytokine/chemokines and their receptors, apoptosis proteins, transcription factors, and metalloprotease-disintegrin proteins, and tissue inhibitors of metalloproteinases^[47].

H pylori stimulate endothelial cells to upregulate adhesion molecule expression and to increase the production of neutrophil-recruiting chemokines. The PAI encodes a bacterial type IV secretory system that secretes and translocates the *cagA* protein into host cells, where it is phosphorylated by a host-cell kinase and causes morphological changes. Innocenti *et al.*, found that several, but not all, *H pylori* strains are able to activate endothelial cells to express the adhesion molecules VCAM-1, ICAM-1, and E-selectin and to secrete neutrophil-recruiting chemokines, and therefore contribute to tissue damage and ulcer formation^[48,49]. Among people infected with *H pylori*, the virulence of the infecting strain is a major determinant which develops disease. Strains producing vacuolating cytotoxin activity are more commonly isolated from people with peptic ulcers than without. The gene encoding the toxin, *vacA*, varies between strains, especially in its signal sequence and mid regions. *vacA* genotype influence cytotoxin activity, and signal sequence type correlates closely with peptic ulceration. Infection with strains possessing *cagA* is more common among people with peptic ulceration or gastric adenocarcinoma than without. *CagA*+ *H pylori* infection is more closely associated with gastric cancers and peptic ulcers than *cagA*-infection. Because *cagA*+ infection may be associated with the development of atrophic gastritis, *cagA* infection is believed to be a risk factor for intestinal-type gastric cancer. But Deguchi *et al.*, reported that *cagA* infection is also associated with diffuse-type gastric cancer in Japan. They also found that all p53 alteration were in *H pylori*-positive gastric cancer and their mutations were more frequent in the *cagA* group, although the correlation between p53 mutation and *H pylori* infection did not reach statistical significance. p53 abnormality was clinically correlated with prognostic factors (e.g., tumor size, depth, lymph node metastasis) of gastric cancer. These findings indicated that *cagA*+ *H pylori* infection might have an important role in the development of gastric cancer with p53 mutation^[52].

The p53 tumor suppressor gene, located on chromosome

17p13, is one of the most commonly mutated genes in all types of human cancer. p53 codon 72, which produces variant proteins with an arginine (Arg) or proline (Pro), has been reported to be associated with cancers of the lung, esophagus, and cervix. Recently, studies in Japan suggested that the Pro/Pro genotype at p53 codon 72 contributes to susceptibility of diffuse-type gastric cancer patient with *H. pylori*-CG^[53]. The mutation of p53 and inactivation of p21WAF1 and p16 play an important role in carcinogenesis of stomach. However, *H. pylori* infection was not associated with the abnormal expression of these three genes in China^[54].

Human Chk1 and Chk2 are DNA damage-activated protein kinases that function as downstream mediators of ataxia-telangiectasia mutated, which are involved in G₂/M cell-cycle arrest. A study from Japan found a significant correlation between the levels of expression of Chk1 and p53 proteins in gastric carcinomas. Chk2 might be important in the checkpoint function in human gastric carcinomas with p53 mutation^[56]. Mutations of an oncogene, K-ras, may be involved in the early stage of carcinogenesis of the intestinal types. The incidence of K-ras mutations in gastric cancer is only 10%. However, by histological classifications, the incidence of K-ras mutation was more frequent in intestinal types than in diffuse types of gastric adenocarcinoma. In addition, K-ras mutations in *H. pylori*-associated chronic gastritis were significantly more frequent in gastric cancer patients than in cancer-free patients (50% *vs* 3.7%, $P = 0.037$)^[57].

No evidence for the involvement of antigastric antibodies in the stimulation of apoptosis was found. Therefore, host factors may be at least as important as bacterial factors in determining gastric mucosal responses to *H. pylori*^[55].

Interleukin gene polymorphisms and gastric cancer

The presence of *H. pylori* in gastric antrum is, in most cases, associated with mucosal inflammatory changes consisting of infiltration of a large number of polymorphonuclear and mononuclear phagocytes. *H. pylori* reside in the mucus layer overlying the epithelium and do not invade epithelial cells. However, accumulating evidence indicates that gastric infection with *H. pylori* induces the expression of several proinflammatory cytokines, including IL-1 β , IL-6, IL-8, IL-18 and TNF- α in gastric mucosa.

IL-1 β is a potent proinflammatory cytokine and powerful inhibitor of gastric acid secretion that is upregulated in the presence of *H. pylori* and is important in initiating and amplifying the inflammatory response to this infection. El-Omar *et al.*, reported that gene polymorphisms in the interleukin gene family of cytokines (IL-1 β -31C, IL-1 β -511T, and IL-1RN*2 alleles) are associated with an increased risk of both hypochlorhydria, in *H. pylori* negative infected first-degree relatives of gastric carcinoma^[58,59]. A study from Portugal supported the hypothesis that host genetic factors that affect IL-1 gene determine why some individuals infected with *H. pylori* develop gastric cancer while others do not^[60,61]. The polymorphism of promoter region -31C/T of IL-1 β gene and the polymorphism of IL-1RN genes 1/2 and 2/2 are associated with the susceptibility of gastric cancer in Chinese. Carrying -31T

allele increases the risk of gastric cancer. Polymorphism of IL-1RN and IL-1 β gene may be used as indicators of susceptibility of gastric carcinogenesis^[62]. A study from Japan investigated the polymorphism of -511 T-to-C located in the IL-1 β gene. According to these authors in view of the results for the IM or CAG without *H. pylori* group, the presence of the C allele may also indicate a risk of mucosal atrophy of the stomach in the Japanese population^[63].

Serum levels of IL-8 and nitrogen monoxide (NO) are correlated with CagA+*H. pylori* strain infection. Combined detection of serum level of IL-8, NO, and HP-CagA will contribute to the early diagnosis of precancerous lesion in the stomach^[64]. Secretion of IL-8 by gastric epithelial cell upon *H. pylori* infection is dependent on activation of NF- κ B^[65].

IL-18 is a recently identified cytokine (originally termed interferon γ -inducing factor) and is related to the IL-1 family both structurally and functionally. Recently research has showed that IL-18 was increased in a variety of human inflammatory conditions, including Crohn's disease, rheumatoid arthritis, and tuberculoid leprosy with pleiotropic immunomodulatory functions. It has been found that IL-18 mRNA expression was greater in *H. pylori*-positive than in *H. pylori*-negative patients with normal mucosa. But mature IL-18 protein and active caspase-1 p20 are present in mucosa of both *H. pylori*-infected and -uninfected subjects. The presence of the mature form of IL-18 in both normal and gastric mucosa suggests that gastric IL-18 has an important role in promoting local production of interferon-N and cell-mediated responses in the gastric mucosa^[47].

H. pylori induces the production of tumor necrosis factor- α (TNF- α), which is closely related to epithelial injury. TNF- α plays a crucial role in host defense against infection, but a high concentration of TNF- α may cause severe pathology. The gene for TNF- α is located within the class III region of the major histocompatibility complex, which is a highly polymorphic region. The most common exchanges are G to A transitions in the TNF- α promoter at positions -308 (-308A) and -238 (-238A), and these genetic changes have been reported to influence TNF- α concentrations. It is possible that increased TNF- α concentrations, as a result of -308A polymorphism, alter the immune response, which confers susceptibility to gastric disease with *H. pylori*-cagA subtype infection^[66]. In a study in Spain, these results suggest that TNF and LTA gene polymorphisms are related to the development of gastric and duodenal ulcer and may determine disease outcome in *H. pylori* infection^[67].

Wu *et al.*, have reported that no association was noted between gastric cancer and the distribution of IL-1 and TNF- α genotypes in Taiwanese Chinese. Logistic regression analysis revealed that *H. pylori* infection, cigarette smoking, and IL-10 genotype are independent risks for gastric cancer in the Taiwanese. Similar studies should be carried out in different populations and as Wu *et al.*, have correctly performed the risk of genotypes should be adjusted with confounding environmental risks^[68].

Genetic polymorphisms of some metabolizing enzymes

Environmental genotoxic chemical agents arising from the

diet, smoking, and air pollution are responsible for carcinogenesis in humans. It is generally accepted that the majority of carcinogenic chemical do not produce their biological effects *per se*, but require metabolic activation by host enzymes: phase I enzymes including cytochrome P450 enzyme and phase II enzymes including epoxide hydroxylase, *N*-acetyltransferase 2 (NAT2), and glutathione *S*-transferase (GSTs). Genetic polymorphisms have been recently shown in many of these enzymes, indicating that there are genetic differences among individuals in the ability to metabolize chemicals. Such genetic polymorphisms may affect the individual susceptibility to chemical carcinogenesis. From this point of view, the relationship between the genetic polymorphisms and carcinogenicity has been extensively examined to determine which polymorphic enzymes are highly associated with the susceptibility to cancers. Japanese researchers suggested that a combination of GSTM1 and NAT2 decreases the risk of gastric cancer in Japanese patients^[69]. A population-based case-control study in China suggested that the GSTP1 genotype seems not to be associated with the risk of gastric cancer and chronic gastritis in a high-risk Chinese population^[70]. The polymorphic genes of cytochrome P450, CYP2A6, and CYP2E1 have been implicated in increased susceptibility to certain malignancies. The CYP2A6 deletion was associated with gastric adenocarcinoma among Japanese population^[72].

KILLER/death receptor DR5

The KILLER/death receptor DR5 has been identified as a potent inducer of apoptosis, and mapped to chromosome 8p21-22, showing frequent allelic loss in gastric cancer. As stated before, the p53-induced apoptosis is an important biological process to prevent the development of cancer, and is mediated in part by expression of KILLER/DR5 only in cells with wild-type p53 protein, but not in those lacking p53 function. A report from Japan suspected that inactivation of KILLER/DR5 caused by mutations of KILLER/DR5 may be one of the possible escaping mechanisms against KILLER/DR5-mediated apoptosis and that inactivating mutation of KILLER/DR5 may contribute to the promotion or progression of a subset of gastric cancers^[71]. In Japan, another cancer registry-based study found that the incidence of gastric cancer was increased up to 5-fold in male relatives of early-onset prostate cancer patients. Currently unknown genes might contribute to the observed link between prostate and gastric cancer^[73].

E-cadherin

E-cadherin is a member of the cadherin family of calcium-dependent cell adhesion molecules. These molecules are localized in lateral cell-cell contacts of the epithelial cells and regulate the process of homophilic/homotypic adhesion between epithelial cells and play a role as a tumor suppressor gene. E-cadherin associates with α -catenin, β -catenin, and γ -catenin to form a complex that is essential for cell-cell communication and cell adhesion. Indeed, abnormal E-cadherin expression (characterized by loss, reduced, and/or cytoplasmic expression) has been observed in several types of carcinoma, and is frequently associated with poor differentiated/undifferentiated carcinomas and/or invasive

tumors. A co-operative study among Portugal, Germany, and Belgium reported that E-cadherin inactivation is significantly related with the diffuse histotype in gastric carcinoma, not only in "pure" diffuse carcinomas but also in the diffuse component of mixed tumors, β -catenin mRNA levels are increased in the vast majority of intestinal-type gastric cancers and this overexpression is independent of *H pylori* infection^[74,75].

Trefoil regulation, gp130, and gastric cancer

For a long time it was believed that the stomach and the intestine respond differently to inflammation. The immunological system of the stomach appears less fully developed than the intestine. This in part is due to the fact that nature has given the stomach a mechanism to protect itself with the production of hydrochloric acid and therefore an environment where only special bacteria, such as *H pylori* can survive. The intestine on the contrary is full of bacteria; however, seemingly ends in unrelated diseases. Inflammatory bowel disease and gastric cancer share in common an origin in chronic inflammation. An important and interesting finding that has arisen from research in mice with a "knock-in" mutation abrogating the Src-homology tyrosine phosphatase 2 (SHP2)-Ras-ERK signaling that developed gastric adenomas by 3 mo of age. Mice with a mutation eliminating the STAT1/3 signaling gp130 (Delta STAT)) showed impaired colonic mucosal wound healing^[76]. As stated in an editorial in Nature Medicine^[77], given the close interplay between the immune response and epithelial cells, it is not surprising that perturbations in signaling of immune system mediators play a key role in disease of the gut. It is the gp130 receptor, which binds the IL-6 family (IL-6 and IL-11) of cytokines that serve as an inflammation intersection between the stomach and the intestine. The homodimers of gp130, a transmembrane receptor β -chain, contain two discrete functional modules which signal through SHP-2/Erk and STAT1/3 that are responsible for the different behavior exhibited by the stomach and the intestine in response to inflammation. To understand the pathogenesis, it is necessary to understand the function of other family of genes called the trefoil factor (TFF) family that intimately appear to work with the gp130 molecule. Suemori *et al.*^[78], discovered in 1991 a group of small proteins designated intestinal trefoil factor. These authors demonstrated that it is primarily expressed and secreted onto the intestinal surface by goblet cells, suggesting that it may be an important component of intrinsic mechanisms for defending mucosal integrity. They are upregulated around areas of epithelial damage, ulceration, and neoplasia^[79].

IL-1 and IL-6 overexpression in chronic gastritis may lead to mucosal damage and gastric carcinogenesis through transcriptional repression of TFF1 and TFF2^[80]. TFF1 knockout mice developed multiple gastric adenomas and carcinomas, suggesting that TFF1 is a gastric-specific tumor-suppressor gene^[81]. The gp130 directly regulates the TFF genes. The trefoils are key downstream targets of the SHP2/Erk and STAT signaling pathways. The data also add to TFF1's credibility as a gastric-specific tumor-suppressor gene and TFF3's as a mediator of intestinal homeostasis. The hyperproliferative lesions was observed in the stomachs

of gp130 arise as a result of enhanced STAT3 activity in the absence of a counter-acting signal from the SHP2-Ras-Erk pathway rather than from the complete absence of (IL-6 and IL-11-mediated) gp130 signaling. IL-6 is likely to have an important role in the initial phase of intestinal wound healing. Furthermore, endogenous IL-11, unlike pharmacologically administered IL-11, seemed to have negligible effects on the intestinal epithelium.

In conclusion, although the incidence of gastric cancer is decreasing in some parts of the world, it still takes a significant toll among the inhabitants of Japan, China, Chile, Finland, Poland, Austria, Yugoslavia, and Costa Rica. The key to prevention of cancer of stomach lies in dietary intake. It is important to consume a balanced diet high in fresh fruits and vegetables and moderate amount of animal protein and fats. Salted, smoked, and pickled foods should be consumed in low quantities.

Screening and early detection programs are very useful. If detected at an early stage and treated aggressively, gastric cancer can be cured. As with all other forms of gastrointestinal cancers, gastric cancer is insidious in its onset and development. It usually infiltrates rapidly and can be disseminated throughout the body before overt signs of cancer are manifested. Overall 5-year survival rates are reported to range from about 8% to 16%. Gastric cancer mimics several other gastrointestinal maladies and diseases such as polyps, ulcers, dyspepsia, and gastritis. Some of the most difficult aspects of prevention and early detection are informing and motivating people at risk for the development of gastric cancer to seek medical attention for chronic "stomach problems". Inappropriate use of home remedies, self-medication, and misdiagnosis are major hurdles to overcome.

Abstract

AIM: To assess long-term effects of *Helicobacter pylori* (*H pylori*) eradication on antral G cell morphology and function in patients with and without duodenal ulcer (DU).

METHODS: Consecutive dyspeptic patients referred to the endoscopy entered the study. Out of 39 *H pylori* positive patients, 8 had DU (*H pylori* +DU) and 31 gastritis (*H pylori* +G). Control groups consisted of 11 uninfected dyspeptic patients (CG1) and 7 healthy volunteers (CG2). Basal plasma gastrin (PGL), antral tissue gastrin concentrations (ATGC), immunohistochemical and electron microscopic characteristics of G cells were determined, prior to and 6 mo after therapy.

RESULTS: We demonstrated elevated PGL in infected patients compared to uninfected controls prior to therapy. Elevated PGL were registered in all *H pylori*+patients (*H pylori* +DU: 106.78 ± 22.72 pg/mL, *H pylori* +G: 74.95 ± 15.63 , CG1: 68.59 ± 17.97 , CG2: 39.24 ± 5.59 pg/mL, $P < 0.01$). Successful eradication (e) therapy in *H pylori*+patients lead to significant decrease in PGL (*H pylori*+DU: 59.93 ± 9.40 and *H pylori* +Ge: 42.36 ± 10.28 pg/mL, $P < 0.001$). ATGC at the beginning of the study were similar in infected and uninfected patients and eradication therapy lead to significant decrease in ATGC in *H pylori* +gastritis, but not in DU patients. In the *H pylori* +DU patients, the mean number of antral G cells was significantly lower in comparison with all other groups ($P < 0.01$), but after successful eradication was close to normal values found in controls. By contrast, G cell number and volume density were significantly decreased ($P < 0.01$) in *H pylori* +Ge group after successful eradication therapy (294 ± 32 and 0.31 ± 0.02 , respectively), in comparison to values before eradication

(416 ± 40 and 0.48 ± 0.09). No significant change of the G cell/total endocrine cell ratio was observed during the 6 mo of follow up in any of the groups. A reversible increase in G cell secretory function was seen in all infected individuals, demonstrated by a more prominent secretory apparatus. However, differences between DU and gastritis group were identified.

CONCLUSION: *H pylori* infection induces antral G cell hyperfunction resulting in increased gastrin synthesis and secretion. After eradication therapy complete morphological and functional recovery is observed in patients with gastritis. In the DU patients some other factors unrelated to the *H pylori* infection influence antral G cell morphology and function.

INTRODUCTION

Helicobacter pylori (*H pylori*) causes chronic active type B gastritis and is involved in the pathogenesis of peptic ulcer disease (PUD) and gastric cancer^[1]. PUD symptoms were almost immediately attributed to the presence of *H pylori* infection, however a positive correlation between the infection and non-ulcer dyspepsia (NUD) was acknowledged only after the results of meta-analysis^[2]. NUD should be considered in dyspeptic patients when symptoms persist for at least a month and endoscopy reveals neither peptic ulcer nor signs of gastric cancer^[3].

Gastrin is a secretory product of antral and duodenal G cells. Two main forms of gastrin (gastrin-17 and -34) are present in the circulation. About 95% of antral gastrin is gastrin-17^[3,4]. Stimuli for gastrin secretion are well identified and include food intake, presence of digested amino acids in the lumen, cholinergic stimuli, and antral alkalization^[3,4].

Although elevated serum gastrin levels are frequently observed in individuals with chronic *H pylori* infection^[5-7], its pathophysiological significance in gastric mucosal inflammation remains unclear. Gastrin is capable of

up-regulating CXC chemokines in gastric epithelial cells and therefore may contribute to the progression of the inflammatory process in the stomach^[8]. Chronic hypergastrinemia is also associated with gastric argiophil cell hyperplasia in rats and humans and carcinoid tumor in Mongolian gerbils^[9]. In the antrum of *H pylori* infected gerbils and humans enhanced apoptosis is an early and transient cell cycle event whilst epithelial cell proliferation peaks later and is related to increased gastrin levels. Based on these findings it was suggested that gastrin-dependent mechanism might be responsible for epithelial cell growth in *H pylori* colonized gastric mucosa^[10,11]. It can be assumed that restored antral G cell function after *H pylori* eradication resulting in lower basal and meal-stimulated gastrin release would be a desirable event in both chronic gastritis and PUD. Most studies conducted so far focused on the effects of *H pylori* infection on gastric endocrine cells in patients with duodenal ulcer and came to different conclusions^[5,6]. There have been few reports concerning G cell morphology^[12-14] and/or gastrin secretion^[7] in patients with gastritis.

The aim of our study was to investigate changes in antral G cell morphology and function in dyspeptic patients with *H pylori* infection and its possible restoration in course of eradication therapy.

MATERIALS AND METHODS

Patients

We conducted an outpatient based prospective study in the Clinic for Gastroenterology and Hepatology, Clinical Center of Serbia, lasting for 6 mo after patients completed eradication therapy. Fifty consecutive dyspeptic patients referred to the endoscopy and seven healthy asymptomatic volunteers entered the study. Out of 39 *H pylori* positive patients had 31 histological signs of gastritis- *H pylori* +G and 8 DU- *H pylori* +DU. Control group 1 (CG1) consisted of 11 *H pylori* negative dyspeptic patients while 7 healthy asymptomatic volunteers were assigned to the control group 2 (CG2). All patients gave informed consent and the study protocol was approved by the local Ethics Committee. Mean age was 48 ± 15 years (28 males and 22 females), 21 were smokers and 21 had personal history of PUD. Exclusion criteria were in concordance with the recommendations from European *H pylori* Study Group^[15]. *H pylori* infection was diagnosed by rapid urease test (RUT), histology and serology. A patient was defined as *H pylori* positive if histology and at least one of the other applied diagnostic methods were positive.

Diagnostic methods

Routine endoscopy and biopsy samples Upper endoscopy was performed before therapy in all dyspeptic patients and repeated 6 mo after appropriate therapy. In healthy volunteers (CG2) endoscopy was performed only once. During endoscopy antral biopsy specimens, intended for routine histology, RUT test, determination of tissue gastrin levels, immunohistochemistry and electron microscopy were taken.

***H pylori* serology** Blood samples were taken from the patients after endoscopic examination and sera were

separated by centrifugation and stored at -20°C until analyzed. The concentration of anti- *H pylori* IgG antibodies was analyzed using the Pyloriset EIA-G IIITM (Orion Diagnostica, Finland), according to the manufacturers' instructions.

Therapy A triple eradication therapy consisting of omeprazole 20 mg twice a day (bid), amoxicillin 1 000 mg b.i.d. and metronidazole 500 mg b.i.d. was administered for 7 d in patients with *H pylori* infection. In uninfected patients, symptomatic therapy consisting of antacids, H_2 antagonists or proton pump inhibitors (PPIs) was prescribed for 2 wks. In the course of *H pylori* eradication, the disappearance of spiral bacteria from antral and corpus gastric mucosa, according to a negative RUT and histological examination, were observed.

Histological assessment Biopsies from antral and corpus mucosa were stained using hematoxylin- eosin and modified Giemsa staining procedure. Biopsy specimens were assessed according to the Sydney System^[16,17] by a single, experienced pathologist who was blinded to the clinical presentation, endoscopic data and RUT results of the patient.

Assessment of plasma and tissue gastrin levels

Plasma preparation Full blood samples for estimating fasting plasma gastrin levels were placed in ice/chilled tubes (5 mL) containing EDTA (2 mg) and proteinase inhibitor (Trasylol, 2 500 KIU). Plasma was extracted using standard procedure and stored below -70°C until further analysis.

Tissue extract preparation Each antral mucosa biopsy was washed with saline solution, measured and placed in to the tube together with 1 mL of distilled water. Gastrin extraction was performed in water bath on 95°C for 10 min, supernatant collected and after cooling stored below -70°C until further analysis.

Radioimmunoassay procedure (RIA) Plasma and tissue gastrin was determined under basal conditions using RIA protocol provided by Affiniti (UK) with rabbit antihuman gastrin-17 antiserum. Final dilutions were for plasma 1:100 000 and for the tissue 1:500 000. Intra-assay and inter-assay coefficients were 9.0 and 8.4 respectively. Sensitivity of the method was 1 pmol/L.

Evaluation of antral G cells

Immunohistochemistry Two antral biopsies from each patient were used for immunohistochemistry and light microscopic morphometry. These were fixed with 10% buffered formalin and embedded in paraffin in the usual manner. Only well-oriented antral mucosa biopsies that allowed assessment of the full mucosal thickness were studied. The sections were stained with different immunohistochemical methods in order to identify antral gastrin-producing cells and evaluate the ratio of antral G cells/all antral endocrine cells. Immunohistochemical staining for G cells was performed using rabbit anti human gastrin-17 (1:300 dilution, Code No A0568, DAKO A/S, Denmark) and peroxidase-labeled streptavidin biotin method (DAKO LSAB+/HRP, DAKO A/S, Denmark). In addition, sections were double immunostained with both polyclonal antibody to gastrin mentioned above and mAb to synaptophysin (1:50 dilution, Code No. A0010,

DAKO A/S, Denmark), using DAKO EnVision[®] double stain system (Code No. K1395). For double immunostaining, antisynaptophysin antibody was applied first with DAB as a chromogen, followed by antigastrin-17 antibody as the second antibody, with AEC as a chromogen. Negative controls were conjugated with normal horse serum^[18].

Routine electron microscopy The biopsy specimens of antral mucosa were immediately placed in a mixture of 2% glutaraldehyde in 0.2 mol/L sodium cacodylate buffer, pH 7.4, and fixed in the same fixative for 20 h at 4 °C. After postfixation for 1 h in 1% osmium tetroxide in cacodylate buffer, the specimens were dehydrated in graded ethanol and embedded in Epon 812[®], with mucosa surface perpendicular to the cutting surface. The blocks were sectioned with an LKB ultratome II. Ultra thin sections were double-stained with uranyl acetate and lead-citrate before examination in an Opton 109 electron microscope.

Morphometric analysis of G cells detected by immunohistochemistry Three 5-μm thick immunostained sections of antral mucosa at intervals of 50 μm were analyzed. Weibel multipurpose test system containing 42 points and 21 lines was used for evaluation of volume density and number of G cells^[19,20]. The total number of G cells per mm² of antral mucosa, as well as, ratio of antral G/total antral endocrine cells was calculated by examination of single or double immunostained sections. All sections were examined randomly by two histologists.

Morphometric analysis of G cells detected by electron microscopy G cells were identified as described previously^[21]. Morphometric analysis was performed using the methods described previously^[19,20]. Cell profile areas were estimated by drawings of G-cells using Camera Lucida attached to a Reichert microscope and analyzed with an image analyzing system (MOP 3 Video plan; Carl Zeiss)^[19,20].

Statistical analysis

Each time mean and SD was calculated for results presentation. A two sample paired or unpaired Student's *t*-test and Wilcoxon rank sum test and ANOVA were used. A *P* value less than 0.05 was considered significant.

RESULTS

Clinical data

Clinical and demographic characteristics of the patients are shown in Table 1. Out of 39 *H. pylori*-positive patients

eradication therapy was successful in 32 (82.1%). In all DU patients the infection was successfully treated, together with 24 patients with gastritis (*H. pylori* +Ge). In seven patients with gastritis eradication therapy failed (*H. pylori* +Gne). No significant difference in demographic and clinical data between *H. pylori*+Gne and *H. pylori*+Ge patients was observed.

Basal plasma gastrin levels (PGL)

Basal plasma gastrin-17 levels were compared between groups of patients at the beginning of the study. These findings are shown in Figure 1. PGL in *H. pylori*+DU patients were significantly higher at the beginning of the study than in any other group of patients irrespective of the presence of infection (*H. pylori* +DU: 106.78±22.72 pg/mL vs *H. pylori* +Ge: 74.95±15.63, *H. pylori*+Gne: 74.21±10.99, CG1: 68.59±17.97 and CG2: 39.24±5.59 pg/mL, *P*<0.001). Healthy asymptomatic controls (CG2) had significantly lower plasma gastrin levels than all other dyspeptic patients (*P*<0.01). After 6 mo, statistically significant decrease of PGL were observed in all successfully eradicated patients (*H. pylori*+DU: 59.93±9.40 and *H. pylori*+Ge: 42.36±10.28 pg/mL, *P*<0.001). However, no significant change was seen in other groups (*H. pylori*+Gne: 76.81±19.54 and CG1: 58.29±17.97 pg/mL, *P*>0.05).

Basal tissue gastrin concentrations

At the beginning of the study there was no significant difference ($P>0.05$) in antral tissue gastrin concentrations (ATGC) between groups of infected (*H pylori*+Ge: 0.23 ± 0.05 , *H pylori*+Gne: 0.23 ± 0.05 , *H pylori*+DU: 0.24 ± 0.03 pg/g wet weight) and uninfected patients (CG1: 0.22 ± 0.04 and CG2: 0.24 ± 0.03 pg/g wet weight). After successful eradication therapy significant decrease in ATGC was observed only in *H pylori*+Ge group (0.20 ± 0.05 pg/g wet weight, $P<0.05$), while in *H pylori*+DU group no significant change was observed (0.22 ± 0.04 pg/wet weight, $P>0.05$). ATGC in the *H pylori*+Gne and CG1 did not change significantly (0.26 ± 0.07 and 0.26 ± 0.06 pg/g wet weight, respectively, $P>0.05$). These findings are seen in Figure 2.

Antral G cell number

Antral G cell number was expressed as number of identified G cells per mm² of antral mucosa, G cell volume density (%) and a ratio of antral G/total antral endocrine cell count (Table 2). Antral G cell number remained unchanged after

6 mo of follow-up in *H pylori*+Gne (405 ± 32 vs 432 ± 18), CG1 (413 ± 61 vs 428 ± 80) and CG2 (426 ± 57) patients. In the *H pylori*+DU patients mean number of antral G cells per mm² of mucosa was lower at the beginning of the study (292 ± 20) than in any other group analyzed ($P<0.01$). At the end of the follow-up and after successful eradication of *H pylori* infection number of antral G cells identified in DU patients was increased (400 ± 32) and comparable to both control groups (CG1 and CG2). By contrast, in patients with gastritis successful treatment lead to a decrease in both antral G cell number (416 ± 40 vs 294 ± 32 , $P<0.01$) and volume density (0.48 ± 0.09 vs 0.31 ± 0.02 , $P<0.01$), as seen in Figure 3. However, no significant change of the G cell/ total endocrine cell ratio was observed during the 6 mo of follow up in any of the groups, including *H pylori* +Ge group (Figure 4).

changes in antral G cell morphology in all *H pylori*+patients. Namely, more prominent endoplasmatic reticulum (Figure 6B) and Golgi apparatus together with an increase in number and volume density of cytoplasmic granules (Figure 6A) were identified in all *H pylori* infected individuals. Antral G cells of *H pylori*+DU patients, however, exhibited some specific features, such as increased cell profile surface and increased mean diameter of cytoplasmic granules. It was

also found that G cells in DU patients, in comparison with healthy controls, have an increased proportion of dense core granules. In *H pylori*+Ge patients more granules per profile and higher volumen density, but similar diameter of secretory granules was identified when compared to the CG1 patients.

After successful eradication all those alterations were normalized and G cell ultrastructurally resembled to those found in CG2 group, with the exception of the diameter and volume density of cytoplasmic granules that remained higher in the *H pylori* +DU patients.

Figure 4 Synaptophysin and gastrin double immunostaining in pyloric gland of *H pylori*-associated gastritis before (A) and after (B) eradication therapy. DAKO EnVision double stain method; DAB is chromogen for G cells and aminoethylcarbazole (AEC) is chromogen for synaptophysin containing endocrine cells. x20 (A) and x10 (B). G cells (red)/ other endocrine cells (brown) ratio is equal before (A) and after (B) succesful eradication of *H pylori* infection.

Figure 5 Electron micrographs of gastrin producing cells from healthy persons antral mucosa. Normal ultrastructure is characterized by the presence of numerous secretory granules of different electron density. Uranyl acetate, lead citrate; x8 400 (A) and x12 680 (B).

Figure 6 Electron micrographs of gastrin producing cells from *H pylori* infected individuals with gastritis (A) and duodenal ulcer (B) before eradication therapy. Uranyl acetate, lead citrate; x8 400 (both A and B). Note that total number of granules is higher than in controls and that dense core granules are more numerous in *H pylori*-patient with gastritis (A). Endoplasmatic reticulum is very prominent in *H pylori*-patient with duodenal ulcer.

DISCUSSION

In our study, eradication therapy was successful in 82% (32/39) of all *H pylori* infected patients, all DU (100%, 8/8), and 77% of patients (24/31) with gastritis that accords with previously proposed acceptable eradication rate of approximately 80%^[2,22]. Eradication rate in our study is in line with results obtained with this eradication protocol that is, according to the literature, ranging from 53-81%^[23,24].

It is well known that *H pylori* leads to chronic gastritis and affects gastric acid secretion in virtually all infected individuals. The underlying mechanism responsible for changes in gastric acid secretion in *H pylori* infected individuals is not completely explained, however it is probably a result of impaired gastrin and somatostatin secretion and elevated proinflammatory cytokines in the infected gastric mucosa^[8,22,25]. Gastrin secretion and morphofunctional features of antral G cells in patients with *H pylori* infection and gastritis or DU was scarcely studied using a comparative study, before and after eradication of the infection.

In the present study, healthy asymptomatic individuals (CG2) had significantly lower plasma gastrin levels than all dyspeptic patients. Higher gastrin concentrations were registered in the plasma of *H pylori* infected individuals, both with gastritis and especially when duodenal ulcer was found on endoscopy. After 6 mo, significant decrease in plasma gastrin levels was registered in all successfully eradicated patients. However, no significant change was seen in other groups, including noneradicated patients with gastritis (*H pylori*+Gne) and dyspeptic patients without *H pylori* infection (CG1).

Higher basal plasma gastrin levels in *H pylori* infected patients and animals compared to the uninfected controls were previously reported by different authors^[3-6,10,25]. Our results showed that in infected patients with DU have significantly higher plasma levels of gastrin-17 when compared to *H pylori*-patients with gastritis, as was previously demonstrated both in adults by Kamada *et al.*^[26], and in children by Kato *et al.*^[27], but opposed to the results of other studies^[14]. After successful eradication of *H pylori* infection, plasma gastrin levels decreased markedly in both DU and gastritis patients, as demonstrated previously in adults^[1,26,28-30] and pediatric patients^[27,31] by other authors.

This change was not observed in non-eradicated patients and uninfected dyspeptic controls, implicating that decrease in plasma gastrin is directly related to the eradication of the bacterium from the stomach.

Antral tissue gastrin concentrations at the beginning of our study were similar in both infected (DU and gastritis group) and uninfected patients, as in other studies^[31,32]. Successful eradication therapy lead to a significant decrease in antral tissue gastrin concentrations in patients with gastritis, as seen in other studies^[33], but not in DU patients.

Immunohistochemical and ultrastructural examination of G cell morphology at the beginning of the study revealed significantly lower antral G cell number in *H pylori*+DU patients compared to all the other groups. However, after successful eradication antral G cell number was close to values observed in controls (both CG1 and CG2). By contrast, successful eradication therapy lead to a decrease in G cell number in the antrum of infected patients with gastritis. On the other hand no significant change in gastrin/total endocrine cell ratio was observed during the 6 mo of follow up, neither in infected nor uninfected patients.

Majority of authors agree that there is no significant difference in antral G cell number in infected and uninfected patients before therapy^[12,26,28,31,32]. Yacoub *et al.*, in a similar study, did not find differences in antral G, D, and EC cell densities and G/D, G/EC and D/EC cell ratios in DU patients^[13] compared to controls. On the other hand, a study by Chamouard *et al.*^[34], showed significantly lower number of antral G cells in DU patients, that is in agreement with the results of our study. The decrease in antral G cell number in subjects with DU (that can also correspond to the degranulation of very active gastrin-producing cells resulting in profound hypergastrinemia) could be related to the fact that the number of bacteria and/or severity of antral gastritis is greater in DU patients. Other possible explanation could be related to differences in *H pylori* strains that colonize the antrum of patients with DU. Namely, we previously reported that in Serbia and Montenegro there is high seroprevalence of *cagA*-positive *H pylori* strains in dyspeptic patients with and without peptic ulcer, while *VacA*-positive strains are more closely related to peptic ulcer disease^[35]. However, Gaider *et al.*, found *CagA*+ strains in 78% patients with *H pylori* infection and DU and described the absence of *CagA*+strains in individuals with antral G-cell hyperplasia^[36].

Based on the ultrastructural findings, we propose that in the *H pylori* +DU patients strongly stimulated remaining antral G cells, as a result of a compensatory mechanism, develop a strong synthetic and secretory phenotype before eradication therapy. In addition, after successful eradication all ultrastructural alterations registered in *H pylori*+DU patients were normalized to appearance expected in control group, excluding cytoplasmic granules volume density and their diameter which retained some higher values, but the observed difference was not statistically significant in comparison to values in healthy subjects. These findings suggest that remaining alterations in G cell morphology in DU should be attributed to an unknown host factor.

After successful *H pylori* eradication in dyspeptic patients with gastritis both unchanged^[35] and decreased^[31] antral G cell number was reported, that is consistent with

our results where eradication therapy lead to a decrease in antral G cell number.

Ultrastructural examinations in *H pylori*+ patients with gastritis at the beginning of the study revealed similar, but less prominent subcellular alterations of G cell morphology detected the DU patients. We confirmed in our study, previously reported, increased cytoplasmic cell granule index in patients with *H pylori*-related gastritis using electron microscopy and immunohistochemical examination of antral G cells^[12]. After successful eradication, all detected alterations were reversed and antral G cells had morphological features similar to those in healthy controls. This is consistent with the findings of Sugamata *et al.*^[14], demonstrating the reversibility of antral G cell morphology changes after elimination of the infection.

We identified total antral endocrine cell population and calculated number of G cells using double immunostaining for both synaptophysin and gastrin. Synaptophysin was considered an adequate pan-neuroendocrine marker based on the distribution background in the human antrum, while its importance in the other parts of gastrointestinal tract remains limited. The co-localization study revealed that synaptophysin immunoreactivity occurred in virtually all antral gastrin, somatostatin and serotonin-producing cells^[38]. In the antrum, proportion G cells accounts for 40% of all endocrine cells^[9], as described in all of our examined groups of patients and healthy controls. The fact that the antral G cells/total endocrine cell ratio remained unchanged after eradication of *H pylori* implicates that other gastric endocrine cell types disturbances are related with the presence of the infection. This finding is important for the understanding of the potential important role of other endocrine cell types and their interactive, functional relationship in gastric regulatory physiology in gastritis and peptic ulcer disease associated with *H pylori* infection. Namely, previous studies reported the increase in basal and gastrin-stimulated somatostatin-containing (D) cell activity in the early phase (4-8 wks) after *H pylori* eradication in gastric ulcers^[22] and gastritis^[39], suggesting that both antral G and D cell morphology and function should be considered in the gastric mucosal response to the presence of *H pylori* infection. Decreased antral D cell number in patients with *H pylori*-related chronic gastritis might be one of the reasons for the existing hypergastrinemia^[12].

Possible mechanisms responsible for hypergastrinemia in *H pylori* associated gastritis or duodenal ulcer could be different. Some recent studies indicated that ypergastrinemia related to *H pylori* infection is associated with enhanced activity of platelet activating factor (PAF) produced locally, in the affected gastric mucosa and higher expression of nuclear factor kappaB (NF-kappaB)^[40,41]. PAF may contribute to the hypergastrinemia of *H pylori* infection by stimulating gastrin release from G cells involving influx of extracellular calcium via L-type channels and activation of protein kinase C^[40]. NF-kappaB activation is considered crucial event in the production of proinflammatory molecules in *H pylori*-associated gastritis. In the uninflamed stomach, NF-kappaB was highly expressed and active in a subset of epithelial cells, which were identified as predominantly G cells. In accordance with this activity, antral

mucosa of infected individuals expressed high levels of the NF-kappaB target cytokine TNF-alpha, a well-documented stimulator of gastrin production. In patients with *H pylori*-associated gastritis, NF-kappaB activity was markedly enhanced and activation occurred preferentially in the epithelial cells^[41]. In addition, treatment of cultured canine antral G-cells with *H pylori* constituents enhances subsequent basal and bombesin-stimulated gastrin release suggesting that direct contact between *H pylori* and G-cells in the gastric antrum may be responsible for the hypergastrinemia seen in the infected individuals^[42].

In conclusion, it may be concluded that in *H pylori* infected patients with chronic gastritis, changes in morphology and function of antral G cell are completely reversible and attributable exclusively to the presence of the bacterium in the gastric mucosa. However, duodenal ulcer formation in infected individuals is partly attributable to the presence of the infection, but host factors are of importance as well, since more profound alterations are observed and a certain extent of antral G cell hyperfunction, resulting in prolonged hypergastrinemia, is detected. Further investigations are needed in order to identify relevant host characteristics leading to the ulcer formation including gene polymorphisms of proinflammatory cytokines involved in the control of gastric acid secretion.

Abstract

AIM: Ghrelin is an endogenous ligand for the growth hormone secretagogue receptor, and it plays a role in stimulating the growth hormone secretion, food intake, body weight gain and gastric motility. Eradication of *Helicobacter pylori* (*H pylori*) was shown to be associated with increase of the body weight. On the other hand, *H pylori* infection evokes the release of gastric IL-1 β . The present study was designed to investigate the involvement of the gastric IL-1 signal in the ghrelin dynamics in *H pylori*-colonized mice.

METHODS: Twelve-week-old female IL-1-receptor type 1-homozygous-knockout mice (IL-1R1^{-/-}) and their wild-type littermates (WT) were orally inoculated with *H pylori* (Hp group), while other cohorts received oral inoculation of culture medium (Cont group). Thirteen weeks after the inoculation, the mice were examined. The plasma and stomach ghrelin levels and the gastric preproghrelin mRNA were measured.

RESULTS: Although the WT mice with *H pylori* infection showed a significantly decreased body weight as compared with that of the animals without *H pylori* infection, *H pylori* infection did not influence the body weight of the IL-1R1-knockout (IL-1R1^{-/-}) mice. In the *H pylori*-infected IL-1R1^{-/-} mice, the total and active ghrelin levels in the plasma were significantly increased, and the gastric ghrelin level was decreased. No significant differences were noted in the gastric preproghrelin mRNA expression.

CONCLUSION: Ghrelin secretion triggered by *H pylori* infection might be suppressed by IL-1 β , the release of

INTRODUCTION

Ghrelin, an endogenous ligand for the growth hormone secretagogue receptor (GHS-R), stimulates growth hormone (GH) release from cultured pituitary cells in a dose-dependent manner^[1], and is produced and secreted from the A-like cells found mainly in the oxyntic glands of the gastric fundus^[2]. Ghrelin is now known to play a role in not only GH release, but also in controlling the appetite and body weight. Since both parenterally and intracerebro-ventricularly administered ghrelin have been shown to stimulate food intake and increase the body weight of mice and rats with free access to food, even those animals with GH deficiency^[3,4], the control of appetite and body weight may be independent of GH release. Ghrelin, a 28-amino-acid peptide, is activated when its third serine residue is acylated by n-octanoic acid, and GHS-R is responsive to the first four or five residues including the octanoylated serine residue of the whole ghrelin peptide^[5]. GHS-R has been shown to be present in the pituitary, hypothalamus, adrenal glands, thyroid, pancreas, myocardium, spleen and testes^[1,6-8]. Ghrelin stimulates the expression of both NPY and AGRP mRNA in the hypothalamus. The central orexigenic effect of ghrelin is mediated by the NPY/AGRP-expressing neurons in the hypothalamus^[3,9-11]. On the other hand, ghrelin has also been reported to suppress vagal afferent activity^[2]. The peripheral orexigenic effect of ghrelin may be mediated, at least in part, by its suppressive effect on the vagal afferent activity.

IL-1 β is a pro-inflammatory cytokine that mediates the cachectic process by stimulating the expression and release of leptin^[12] and/or by mimicking the effect on the hypothalamus of excessive negative-feedback signaling from

leptin^[13]. Cachexia is a condition characterized by wasting, emaciation, feebleness and inanition. It was recently reported that the levels of both ghrelin peptide and ghrelin mRNA in the stomach were up-regulated in a mouse model of cancer cachexia^[14]. In cachectic mice with increased plasma levels of IL-1 β , the plasma concentrations of ghrelin also increased with the progression of cachexia^[15]. This result suggests that a close relationship might exist between the ghrelin dynamics and the cachectic process mediated by IL-1. IL-1 β is an anorexigenic substance, just like CCK, leptin, gastrin-related protein and bombesin, and antagonizes the actions of ghrelin. Asakawa *et al.*, reported that parenterally administered IL-1 β decreased NPY mRNA expression in the hypothalamus and preproghrelin mRNA expression in the stomach, and that intraperitoneally administered ghrelin inhibited the severity of IL-1 β -induced anorexia.

Helicobacter pylori (*H pylori*) infection is known to be a major pathogenetic factor in the development of gastritis, peptic ulcer disease and gastric malignancy^[16,17]. Attachment of *H pylori* to the gastric mucosa induces inflammation, which is associated with the release of various cytokines, including IL-1 β ^[18]. Although the importance of the anorexigenic effect of IL-1 β in cases with *H pylori* infection has not yet been clarified, it has been observed clinically that *H pylori* eradication is often followed by improvement of some nutritional parameters, such as the body weight and the serum levels of total cholesterol, total protein and albumin^[19]. We recently reported that *H pylori* infection could modify the plasma and gastric ghrelin dynamics in Mongolian gerbils^[20]. In humans, however, *H pylori* infection has been reported not to be associated with any changes of the plasma ghrelin levels^[21,22], although eradication of *H pylori* has been shown by some to be associated with increases of the plasma ghrelin levels^[23]. Therefore, regulation of the ghrelin dynamics and its influence on the body weight control in cases with *H pylori* infection still remains to be clarified.

We designed the present study to investigate the role of the gastric IL-1 signal in the regulation of the ghrelin dynamics and its influence on the body weight control under in cases with *H pylori* infection.

MATERIALS AND METHODS

Animal procedures

All experiments and procedures carried out on the animals were approved by the Keio University Animal Research Committee (No. 023009). Twelve-week-old, specific-pathogen-free female interleukin-1 (IL-1)-receptor type 1-homozygous-knockout mice (IL-1R1^{-/-}) on a C57BL/6 background (The Jackson Lab., Bar Harbor, ME, USA) and their wild-type cohorts as controls (WT) were used for the study. The Sydney Strain of *H pylori* (SS1) was grown from frozen stocks at 37 °C under microaerobic conditions for 24–36 h in lysed horse-blood agar supplemented with antibiotics, harvested in Brucella broth, and administered to the mice immediately after being harvested. Six IL-1R1^{-/-} mice and five WT mice were orally inoculated with *H pylori* (1.5 \times 10⁸ CFU/mL, 0.5 mL), while another six IL-1R1^{-/-} mice and five WT mice were orally inoculated with the culture medium alone as control. A week later, each animal

was inoculated again with the aforementioned bacterial strain. Thirteen weeks after the first inoculation, all the mice were examined under ether anesthesia. The mice were then deprived of food for 17 h before being killed. The body weight of each mouse was measured just before the examination.

Confirmation of Infection

H pylori infection was diagnosed by determining the number of CFUs in a microaerobic bacterial culture. Briefly, the diluted homogenates of the stomachs were plated on to Brucella agar plates containing 10% horse blood, 2.5 μ g/mL amphotericin B, 9 μ g/mL vancomycin, 0.32 μ g/mL polymyxin B, 5 μ g/mL trimethoprim, and 50 μ g/mL 2, 3, 5-triphenyl-tetrazolium chloride. The plates were then incubated at 37 °C in a microaerobic atmosphere for 7 d^[24]. All of the *H pylori* inoculated animals were confirmed as *H pylori* positive by this procedure in the present study.

Measurement of plasma ghrelin levels

Whole-blood samples were obtained from the right ventricle in tubes containing EDTA-2Na (1 mg/mL blood) and aprotinin (500 kIU/mL blood). The tubes were centrifuged and the plasma samples were stored at -80 °C.

Plasma total ghrelin was measured using the Desacyl-Ghrelin ELISA Kit (Mitsubishi Kagaku Medical, Inc., Ibaraki, Japan), and plasma active ghrelin was measured using the Active Ghrelin ELISA Kit (Mitsubishi Kagaku Medical, Inc., Ibaraki, Japan). Total ghrelin, i.e., active plus inactive ghrelin, was measured using an antibody directed against the C-terminal end (residues 1 to 11) of ghrelin, while an antibody directed against the N-terminal end of ghrelin (residues 13 to 28) was used for the measurement of active ghrelin. The plasma samples were placed in testing wells coated with the ghrelin antibodies. Then, the plate with the wells was incubated for 2 h at room temperature. After incubation, the samples were washed and diluted HRP was added to the wells. The plate was then incubated again for 1 h at room temperature. The samples were washed and substrate solution was added to the wells. The plate was incubated for a further 30 min at room temperature under shade conditions. After the reaction, a reagent was added to stop the reaction, and the absorbance of each well was measured at 450 nm.

Measurement of myeloperoxidase activity

Immediately after the mice were sacrificed, the stomachs of the animals were removed and opened along the greater curvature. Tissue samples of the gastric mucosa were collected in tubes containing PBS and protease inhibitors (100 μ mol/L phenylmethylsulfonyl fluoride, 10 μ g/mL aprotinin) and sonicated over ice in 30 consecutive 0.5 s bursts at 0.5 s intervals, at a power setting of 150 W (VCX 50; Sonics and Materials, Inc., Newton, CT, USA). The total protein content in the homogenates was measured by modified Lowry's method^[25], as described by Smith *et al.*^[26].

Myeloperoxidase (MPO) activity, as an index of tissue-associated neutrophil accumulation, was determined by a modification of Grisham *et al.*'s method^[27]. Aliquots containing 100 μ L of the mucosal homogenates were

centrifuged at 8 000 r/min for 15 min at 4 °C to separate the pellets of insoluble cellular debris. The pellets were rehomogenized in an equal volume of 0.05 mol/L potassium phosphate buffer (pH 5.4) containing 0.5%-hexadecyltrimethylammonium bromide. The samples were then centrifuged at 8 000 r/min for 15 min at 4 °C and the supernatants were reserved. The MPO activity in the supernatants was assessed by measuring the H₂O₂-dependent oxidation of 3, 3', 5, 5'-tetramethylbenzidine. One unit of enzyme activity was defined as the amount of MPO that caused a change in the absorbance of 1.0/min at 655 nm, at 25 °C.

Measurement of the gastric ghrelin levels

Fresh whole-anterior-wall specimens of the glandular stomach were frozen immediately after collection in liquid nitrogen and stored at -80 °C. Each sample was boiled for five min in a 10-fold volume of water to inactivate the intrinsic proteases. The solution was adjusted to 1N acetic acid by addition of 180 microliter acetic acid after cooling, and the tissue was homogenized. The supernatant was lyophilized and subjected to RIA to measure the ghrelin level. The extraction efficiency of tissue ghrelin was more than 95%.

Two RIA techniques were used for measuring ghrelin, as described previously^[28]. Briefly, ghrelin levels were measured using two polyclonal rabbit antibodies raised against an N terminal (1-11) (Gly1-Lys11) or C terminal (13-28) (Gln13-Arg28) fragment of rat ghrelin. Two tracer ligands were synthesized: [Tyr29]-rat ghrelin for antirat ghrelin (1-11) antiserum and [Tyr12]-rat ghrelin [13-28] for antirat ghrelin [13-28] antiserum. The RIA incubation mixtures containing 100 µL of either standard ghrelin or unknown samples containing 200 µL of antiserum diluted in RIA buffer containing 0.5% normal rabbit serum, were initially incubated for 12 h. Then, the mixture was incubated for 36 h after the addition of 100 µL of ¹²⁵I labeled tracer (15 000 cpm). Antirabbit IgG goat serum (100 µL) was added followed by incubation for an additional 24 h. Free and bound tracers were then separated by centrifugation at 3 000 r/min for 30 min. Following aspiration of the supernatant, the radioactivity in the pellet was quantified using a gamma counter (ARC-600; Aloka, Tokyo, Japan). All assays were performed at 4 °C. The antirat ghrelin (1-11) antiserum specifically recognized the n-octanoylated form of rat ghrelin, but not the des-acyl form. The antirat ghrelin (13-28) antiserum recognized both the acylated and des-acyl forms of rat ghrelin equally efficiently. Both antisera were equally cross-reactive with human and gerbil ghrelin, and did not recognize the other enteric peptides. The respective intra- and interassay coefficients of variation for the N terminal RIA were 3% and 6%, and for the C terminal RIA were 6% and 9%.

Measurement of the preproghrelin mRNA expression level in the stomach

Total RNA was extracted from the stomach of the mice using the RNeasy Mini Kit (Qiagen). A TaqMan quantitative real-time RT-PCR was performed to detect preproghrelin mRNA and GAPDH mRNA using the ABI PRISM 7700 sequence detection system (PE Applied Biosystems)^[29].

The following primers were used to amplify preproghrelin mRNA: forward-ghrelin (5'-GGA ATC CAA GAA GCC ACC AGC-3'), reverse-ghrelin (5'-GCT CCT GAC AGC TTG ATG CCA-3'), and Taqman-ghrelin (5'-FAM-AAC TGC AGC CAC GAG CTC TGG AAG GC-TAMRA-3'). The following primers were used to amplify GAPDH mRNA as the internal control: forward primer (5'-TTC AAC GGC ACA GTC AAG GC-3'), reverse primer (5'-GCC TTC TCC ATG GTG GTG AAG-3'), and Taqman probe (5'-FAM-CCC ATC ACC ATC TTC CAG GAG CGA GA-TAMRA-3').

The preproghrelin mRNA expression levels were normalized using the GAPDH mRNA expression levels.

Statistical analysis

All the data were expressed as the mean±SE. The data were analyzed using one-way analysis of variance, followed by Scheffe's multiple comparison tests. A value of *P*<0.05 was considered to denote statistical significance.

RESULTS

Among the WT mice, the *H. pylori*-infected mice showed a significantly reduced body weight as compared to the uninfected and control mice (*P*<0.001). Although the basic body weight of the IL-1R1^{-/-} mice was lower than that of the WT mice, no further reduction of the body weight of these mice was observed after *H. pylori* infection (Table 1).

H. pylori infection increased the MPO activity in the gastric mucosa in both the WT (*P*<0.01) and IL-1R1^{-/-} (*P*<0.01) mice, although in the IL-1R1^{-/-} mice, the increase was significantly less marked (*P*<0.05) (Figure 1).

Table 1 Body weight of the mice at the time of the examination

Wild type mice (g)		IL-1R1 ^{-/-} mice (g)	
Not-infected	Infected	Not-infected	Infected
26.0±0.71	22.1±0.54 ^b	23.4±0.51	23.1±0.34

Among the wild-type mice, the body weight of *H. pylori*-infected mice (*n* = 4) was lower than that of the uninfected mice (*n* = 5); on the other hand, among the IL-1R1^{-/-} mice, no significant difference in the body weight was noted between the infected (*n* = 6) and uninfected (*n* = 6) mice. ^b*P*<0.001 vs the uninfected mice.

Figure 1 Myeloperoxidase (MPO) activity in the stomach. Both wild-type (filled column: *n* = 4) and IL-1R1^{-/-} (spotted filled column: *n* = 6) mice with *H. pylori* infection showed increased MPO activity as compared with the uninfected wild-type (clear column: *n* = 5) and IL-1R1^{-/-} (spotted clear column: *n* = 5). ^a*P*<0.05 vs the wild-type mice, ^b*P*<0.001, ^d*P*<0.01 vs the uninfected mice.

Among the WT mice, the *H pylori*-infected animals showed no significant increase of the plasma total ghrelin levels as compared to the uninfected and control mice. In the case of the IL-1R1^{-/-} mice, although simple lack of the IL-1 signal did not affect the plasma total ghrelin dynamics, *H pylori* infection of these mice was associated with a marked increase of the plasma total ghrelin levels ($P < 0.05$; compared with the uninfected mice, $P < 0.001$; compared with the wild-type mice) (Figure 2).

The same tendency was shown for the plasma active ghrelin dynamics. Among the WT mice, the *H pylori*-infected mice showed a tendency towards increase in the plasma active ghrelin levels as compared to the uninfected and control mice, but the increase was not statistically significant. On the other hand, in the IL-1R1^{-/-} mice, while a simple lack of the IL-1 signal did not affect the plasma active ghrelin dynamics, *H pylori* infection of these animals was associated with a marked increase of the plasma active ghrelin levels ($P < 0.01$; compared with the uninfected mice, $P < 0.05$; compared with the wild-type mice) (Figure 3).

Figure 2 The total ghrelin levels in the plasma. Although neither simple lack of the IL-1 signal (spotted clear column: $n = 4$) nor *H pylori* infection alone (filled column: $n = 4$) was associated with any changes in the total plasma ghrelin levels as compared with the levels in the uninfected wild-type mice (clear column: $n = 5$), *H pylori* infection induced a marked increase of the total plasma ghrelin levels in the IL-1R1^{-/-} mice (spotted filled column: $n = 6$). ^a $P < 0.05$ vs the uninfected mice. ^b $P < 0.001$ vs the wild-type mice.

Figure 3 The active ghrelin levels in the plasma. Neither simple lack of the IL-1 signal (spotted clear column: $n = 6$) nor *H pylori* infection alone (filled column: $n = 3$) was associated with any changes in the total plasma ghrelin levels as compared with the levels in the uninfected wild-type mice (clear column: $n = 5$). *H pylori* infection induced a marked increase of the plasma active ghrelin levels in the IL-1R1^{-/-} mice (spotted filled column: $n = 6$). ^a $P < 0.05$ vs the wild-type mice; ^b $P < 0.01$ vs the uninfected mice.

In contrast to the effects of *H pylori* on the plasma ghrelin dynamics, the ghrelin levels in the stomach, both total and active, were significantly decreased in the *H pylori*-infected IL-1R1^{-/-} mice ($P < 0.05$) (Figure 4A and B), indicating that ghrelin is secreted into the blood from its stores in the stomach.

Preproghrelin mRNA expression, evaluated in comparison with the expression of GAPDH mRNA, was not modified by either *H pylori* infection or lack of the IL-1 signal, or both (Figure 5). These results suggest that the stomach ghrelin stores were not replenished after ghrelin secretion into the blood.

Figure 4 The gastric (A: total, B: active) ghrelin levels. Although neither a simple lack of the IL-1 signal (spotted clear column: (A) $n = 5$, (B) $n = 5$) nor *H pylori* infection alone (filled column: (A) $n = 5$, (B) $n = 5$) was associated with any changes in the gastric ghrelin levels as compared with the levels in the uninfected wild-type mice (clear column: (A) $n = 5$, (B) $n = 5$), *H pylori* infection induced a marked decrease of the a) total and b) active gastric ghrelin levels in the IL-1R1^{-/-} mice (spotted filled column: (A) $n = 6$, (B) $n = 5$). ^a $P < 0.05$ vs the uninfected mice; ^c $P < 0.05$ vs the wild-type mice.

Figure 5 Preproghrelin mRNA levels in the gastric mucosa. No significant differences were observed among the uninfected wild-type mice (clear column: $n = 5$), uninfected IL-1R1^{-/-} mice (spotted clear column: $n = 6$), *H pylori*-infected wild-type mice (filled column: $n = 5$) and *H pylori*-infected IL-1R1^{-/-} mice (spotted filled column: $n = 6$).

DISCUSSION

It is widely known that *H. pylori* infection is associated with loss of body weight. In the present study, although *H. pylori*-infected wild-type (WT) mice showed body weight loss, no such weight loss was observed in IL-1R1^{-/-} mice with *H. pylori* infection (Table 1). On the other hand, although an increase in the level of gastric mucosal neutrophil accumulation was noted in both WT and IL-1R1^{-/-} mice with *H. pylori* infection, the neutrophil accumulation was significantly less marked in *H. pylori*-infected IL-1R1^{-/-} mice than in *H. pylori*-infected WT mice (Figure 1), indicating that the lack of the IL-1 signal could affect the regulatory mechanisms of both body weight and gastric mucosal inflammation.

It has previously been reported that the administration of lipopolysaccharide (LPS) is associated with a reduction in the plasma levels of ghrelin^[30, 31] and increase in the plasma levels of IL-1 β ^[31]. According to the study by Burgess *et al.*^[32], while intracerebroventricular administration of LPS greatly reduced the food intake in WT mice, no such effect was observed in mice deficient in the IL-1 β -converting enzyme. In addition, as mentioned above, it has been reported that injection of IL-1 β was followed by a decrease in the gastric preproghrelin mRNA expression^[9]. These results suggest that the anorexigenic effect of LPS may be mediated by IL-1 β and ghrelin, a downstream molecule in the cascade. The production of IL-1 β might be enhanced by LPS and the release of ghrelin might be suppressed by IL-1 β .

We recently reported from a study in Mongolian gerbils, that the plasma levels of ghrelin are enhanced for a restricted period after *H. pylori* inoculation^[20]. In the present study, while the plasma levels of ghrelin showed no significant increase in the WT mice with *H. pylori* infection, the levels were significantly elevated in IL-1R1^{-/-} mice with *H. pylori* infection (Figure 2, 3), indicating that IL-1 may suppress ghrelin secretion, as mentioned above. As in Mongolian gerbils, *H. pylori* infection also stimulates ghrelin secretion in mice, but the secretion is suppressed by IL-1 β , a mediator whose production is also enhanced by *H. pylori* infection. Therefore, in IL-1-signal-deficient mice with *H. pylori* infection, ghrelin production and release into the blood occurs unopposed by the inhibitory action of IL-1 on these processes.

Contrary to the observations on the ghrelin dynamics, the gastric expression of leptin mRNA, one of the important anorexigenic peptides produced by adipocytes, is significantly increased by *H. pylori* infection^[33]; expression of this mRNA is also significantly enhanced by IL-1 administration^[12]. The central pathway of appetite control by ghrelin is reported to be mediated by neuropeptide Y (NPY)-expressing neurons in the hypothalamus. Ghrelin increases the activity of NPY-expressing neurons, and hence food intake^[9, 10]. The same NPY-expressing neurons in the hypothalamus have also been reported to be involved in the suppression of appetite by leptin. Leptin decreases the mRNA expression of NPY in the neurons of the hypothalamus^[11], thereby suppressing food intake and causing loss of body weight^[3, 11]. The effects of ghrelin and leptin are considered to be competitively regulated by the hypothalamic NPY-expressing neurons.

Thus, in the WT mice, *H. pylori* infection stimulates both

ghrelin secretion and IL-1 β release, but excessive ghrelin secretion is suppressed by IL-1 β , whereas leptin secretion, also stimulated by *H. pylori*, is promoted by IL-1 β . The competitive actions of ghrelin and leptin in the hypothalamic NPY-expressing neurons result in a decrease of the appetite and body weight of WT mice with *H. pylori* infection. On the other hand, in the *H. pylori*-infected IL-1R1^{-/-} mice, the inhibitory effect of the IL-1 signal on ghrelin secretion is absent, and the enhanced ghrelin secretion combined with the enhanced leptin secretion might result in a dominant effect of ghrelin on the appetite control, and body weight loss does not become manifest in these animals.

While the secretion of stored gastric ghrelin is affected by *H. pylori*, the gastric preproghrelin mRNA expression was not significantly enhanced by *H. pylori* infection in the present study (Figure 5). While in Mongolian gerbils, *H. pylori* infection was associated with increased plasma ghrelin levels and decreased gastric ghrelin and preproghrelin mRNA expression^[20], the infection in mice had no significant effect on any of the above three parameters. According to Asakawa *et al.*^[9], IL-1 administration reduced gastric preproghrelin mRNA expression; this may be the reason why the IL-1-receptor-knockout mice in the present study did not show any changes of the gastric preproghrelin mRNA expression. Thus, there may be species differences in the hormone dynamics and their reactivity to stimulation, such as in the event of *H. pylori* infection.

In conclusion, ghrelin secretion triggered by *H. pylori* infection might be suppressed by IL-1 β , resulting in body weight loss of the infected mice.

Abstract

AIM: To investigate the effects of leptin (1-20 µg/kg) on acidified ethanol (AE)- and indomethacin (Indo)-induced gastric lesions in rats and compare it with ranitidine, lansoprazole, and omeprazole and to determine its mechanisms of actions.

METHODS: Gastric ulcers, which were approximately 1 mm in width, formed in the glandular portion of the gastric mucosa produced by oral administration of either AE or Indo were taken as ulcer index. The inhibitory effect of subcutaneous administration of leptin, two proton pump inhibitors (PPIs) lansoprazole and omeprazole, or H₂-receptor antagonist ranitidine 30 min before AE or Indo was evaluated. A radioimmunoassay was used to determine the PGE₂ concentration in the homogenate of the glandular portion of the stomach. We performed histological study of the glandular stomach for the evaluation of total, acidic, and sulfated mucus content.

RESULTS: Subcutaneous administration of leptin, two PPIs lansoprazole and omeprazole or H₂-receptor antagonist ranitidine 30 min before AE or Indo produced a dose-dependent and reproducible inhibition of gastric ulcers (GUs). This inhibition was found to be more potent than other antagonists used. In *N*⁶-nitro L-arginine methyl ester (L-NAME)-pretreated animals, the ulcer prevention ability of leptin in AE-induced ulcer was significantly reduced, compared to rats without L-NAME pretreatment. However, the ulcer prevention ability of leptin was not altered by L-NAME treatment in Indo-induced ulcers. Leptin produced a dose-dependent increase in PGE₂ level in the gastric glandular tissues. Leptin also increased mucus secretion.

CONCLUSION: The results of the present study show that leptin inhibits GU formation by AE or Indo in a dose-dependent and reproducible manner in rats. The results

INTRODUCTION

Peptic ulcer is caused by a break in the mucosal integrity, close to the acid-secreting areas of the gastrointestinal tract. It is a disease that was characterized by remissions and exacerbations before the era of gastric acid secretion modifying drugs or *Helicobacter pylori* (*H. pylori*). It is often located in the stomach (gastric ulcer, GU), in the proximal duodenum (duodenal ulcer), rarely in the esophagus, jejunum (distal to a gastrojejunal anastomosis) or the Meckel's diverticulum, containing ectopic gastric mucosa. Development of a peptic ulcer depends on the balance between the known aggressive factors and mucosal defense mechanisms. Some of the aggressive factors are gastric acid^[1,2], bile salts, abnormal motility^[3], pepsin, use of nonsteroidal anti-inflammatory drugs (NSAID)^[4], infection with micro-organisms (*H. pylori*, herpes simplex and others). Mucus secretion, gastroduodenal bicarbonate production^[5], prostaglandin synthesis^[6], cholecystokinin and somatostatin^[7], cellular regeneration, and normal tissue microcirculation protect against ulcer formation.

Leptin, a 167-amino acid peptide hormone, is secreted by the adipocytes into the circulation, lowers the body weight by decreasing appetite and increasing energy expenditure^[8-10]. It has also been found to be present in the gastric mucosa^[11], and this has been thought to control food intake in man. Another way of interpreting the presence of leptin in the gastric mucosa is to invoke its ability to function as a mucosal defense factor in the stomach. Indeed, a Polish group of workers showed recently that leptin has a gastro-protective effect in rats^[12]. Much more recently, a Turkish group of workers showed that leptin has a gastro-protective effect on mucosal injury induced by ischemia reperfusion^[13]. To date, there is a dearth of information in the literature about the mechanism by which leptin prevents ulcer formation in the stomach. Thus, the primary aim of this project was to investigate the effect of leptin on PGE₂ synthesis on ulcer formation by

indomethacin (Indo), a NSAID, or acidified ethanol (AE) in rats. The second aim was to study the role of leptin in relation to other established anti-ulcer agents, such as ranitidine^[14] and PPIs^[15] on peptic ulcer prevention in rats.

MATERIALS AND METHODS

The following drugs and chemicals were used for the experiments: absolute alcohol (BDH, Poole, UK), hydrochloric acid (BDH), lansoprazole (Sigma, St. Louis, MO, USA), omeprazole (Astra, Uppsala, Sweden), Indo (Sigma, UK), L-NAME (Sigma, UK) and high sensitivity prostaglandin E₂ Chemiluminescence Enzyme Immunoassay Kit (Assay Designs Inc., MI, USA). Leptin was a generous gift from Amgen Inc., USA. All solutions were freshly prepared and diluted in normal saline.

Experimental protocols

Wistar rats weighing 200–250 g were fasted for 18 h in wire mesh cages to avoid coprophagy. The animals were deprived of food but had free access to water *ad libitum*. The temperature of the animal room was maintained at 22±2 °C and a 12–12 h dark-light cycle was maintained. All animals used for the study had an ethical clearance from the Animal Users' Committee of the Faculty of Medicine, United Arab Emirates University.

Indomethacin-induced ulceration and effect of leptin treatment

Indo (30 mg/kg) was administered orally to induce GUs in 18-h fasted Wistar rats. Gastric lesions were formed 6 h after Indo administration. The rats were divided into different groups of six animals each and Indo was given to each animal 30 min after administering leptin (1–50 µg/kg, subcutaneously) or normal saline (1 mL/kg, subcutaneously), and the animals were killed 6 h later by cervical dislocation and exsanguinations. The abdomen was incised, the stomach removed and cut open along the greater curvature and rinsed with water to remove any adherent food particles and mucus. The opened stomach was spread on a sheet of cork so as to have a clear macroscopic view of the gastric mucosa. The total lengths of the hemorrhagic lesions, which were approximately 1 mm in width formed in the glandular portion of the gastric mucosa, were taken as ulcer index. An observer unaware of the drug treatments confirmed the ulcer index. The percentage reduction of the ulcer index in the drug-treated groups was calculated from the saline-treated groups.

Indomethacin-induced ulceration: comparison of leptin with ranitidine

The ability of different doses of leptin (1–50 µg/kg) and a fixed dose of ranitidine (50 mg/kg), all administered subcutaneously, to prevent the formation of Indo-induced GU was studied. The rats were killed 6 h after administering Indo by cervical dislocation and exsanguinations. The abdomen was incised and the stomach removed and the ulcer index was determined as described above. The reduction of the ulcer in the drug-treated groups was calculated as a percentage of the ulcer index in the saline-treated group.

Indomethacin-induced ulceration: comparison of leptin with two proton pump inhibitors

In another experiment, 10 mg/kg each of lansoprazole and

omeprazole, or 10 µg/kg of leptin was administered 30 min before the animals received Indo orally. The rest of the experiment and determination of the ulcer index were performed as described earlier.

Acidified ethanol-induced ulceration and effect of leptin treatment

AE was administered orally to induce GUs in rats. We used 60% ethanol in 150 mmol/L HCl as an ulcerogenic agent, based on earlier observation that ethanol 50% and above caused a reproducible model of gastric damage^[16,17]. Gastric lesions were formed 1 h after administering AE. The rats were divided into different groups of six animals each and each group received either saline (1 mL/kg) or leptin (1–20 µg/kg), subcutaneously. Thirty minutes later, AE was given orally to each animal at a dose of 1 mL per rat and the animals were killed 1 h later by cervical dislocation and exsanguinations. The ulcer index was determined as described above.

Leptin ulcer prevention ability in indomethacin pre-treated rats

In order to study the influence of prostaglandin on the cytoprotective activity of leptin, Indo was administered at a dose of 10 mg/kg subcutaneously (a dose, which inhibits prostaglandin synthesis, but does not induce gastric ulceration) to one group of animals followed by subcutaneous administration of leptin (10 µg/kg), 30 min later. AE was given to each animal 30 min after drug administration and the animals were killed 1 h later. The stomachs were subsequently removed to measure the ulcer index as described earlier.

Leptin ulcer prevention ability in L-NAME pre-treated rats

In another group of animals, N^G-nitro L-arginine methyl ester (L-NAME, 25 mg/kg), an inhibitor of nitric oxide synthase activity, was administered subcutaneously 15 min before giving leptin (10 µg/kg, subcutaneously). AE was given orally 30 min later and the animals were killed 1 h after ethanol administration to determine the ulcer index. In another group of L-NAME-pretreated animals, Indo was given orally instead of AE to induce ulcers, and the animals were killed 6 h later to determine the ulcer index.

Effect of leptin on prostaglandin E₂ (PGE₂) levels in the gastric mucosa

The glandular portion of the control and leptin-treated rat stomachs were homogenized in 1.5 mL of Tris buffer (50 mmol/L; pH 7.5) containing 10 µg/mL Indo to prevent further cyclo-oxygenase activity at 0 °C. The tissue homogenate was acidified by addition of 2 mmol/L HCl to a pH of 3.5, and allowed to settle at 4 °C for 15 min before centrifuging the samples in a microcentrifuge at 1 000 r/min for 5 min to remove the tissue debris. The supernatant was harvested and stored at -20 °C until assayed, usually within 24 h. A radioimmunoassay was used to determine the PGE₂ concentration in the supernatant according to the instructions of the manufacturer (Assay Designs Inc., MI, USA). The assay is based on the competitive binding technique by which PGE₂ present in a sample competes with a fixed amount of alkaline phosphatase-labeled PGE₂ for sites on a mouse mAb. During incubation, the mouse mAb is bound to the

goat anti-mouse antibody coated onto the microtiter well plate. Following a wash to remove excess conjugate and unbound sample, a substrate solution is added to the wells to determine the bound enzyme activity. Immediately following the color development, the luminescence is read in a luminometer. The intensity of the color is inversely proportional to the concentration of PGE_2 in the sample. A standard curve was constructed from a series of known concentrations of PGE_2 solution provided by the kit manufacturer, and the PGE_2 concentrations of the unknown samples were determined by interpolation.

Determination of mucus in glandular mucosa

We performed histological study of the glandular stomach for the evaluation of total, acidic, and sulfated mucus content. Cross-sectional areas of the portion of the gland stained red by periodic acid Schiff (PAS) were measured to give the total glycoprotein present in the gastric pits. The Alcian Blue (AB) method at pH 1 was used to measure the sulfated macromolecular content in the gastric pits, whereas at pH 2.5 were used to measure the total acidic mucus content.

The glandular portion of the stomach was fixed in Zamboni fixative overnight. Smaller pieces cut from the glandular portion was dehydrated with ethanol and embedded in paraffin. Two series of sections (6 $\mu\text{mol/L}$ thick) were made by cutting the block in a plane perpendicular to the mucosal surface. Sections, after being deparaffinized

and hydrated to distilled water and placed in acetic acid solution, were stained with PAS and/or AB (pH 2.5 and 1). They were serially dehydrated in 95% ethyl alcohol, absolute alcohol, and xylene and mounted in resinous medium. The sections were evaluated in a randomized blinded fashion by a histologist who was unaware of the experimental protocol.

Statistical analysis

All results were expressed as mean \pm SE. Ulcer index obtained for test drugs and saline controls were compared using one-way ANOVA. A two-tailed P value <0.05 was considered significant.

RESULTS

Indo caused a marked ulceration of the stomach in those rats given normal saline (Figures 1A-D). Figure shows hemorrhagic lesions on the glandular area of the rat stomach caused by AE (A) and Indo (C) in the absence (A and C) and presence (B and D) of 10 $\mu\text{g/kg}$ leptin. A significant inhibition of the hemorrhagic lesions due to the leptin treatment was evident. When the animals were treated with leptin (1-50 $\mu\text{g/kg}$), there was a dose-dependent increase of the ulcer prevention ability of leptin, against Indo and formed a plateau at a dose of 20 $\mu\text{g/kg}$ leptin. The ulcer index at each of the leptin concentrations from 5-50 $\mu\text{g/kg}$ was significantly less ($P<0.05$) than the ulcer index in normal saline-treated rats (Figure 2A).

Figure 2B reveals the degree of preventing Indo-induced

Figure 1 Photomicrograph of macroscopic appearance of the glandular mucosa, showing the effect of AE (A) and Indo (C) in the absence (A and C) and presence

of 10 $\mu\text{g/kg}$ dose of leptin (B and D). These photographs are typical of six such tissues.

Figure 2 A: The ulcer indices of saline and different concentrations of leptin (1-50 $\mu\text{g/kg}$) against Indo. Each value is a mean \pm SE. Asterisks indicate significant difference when compared to saline control (^a $P<0.05$, ^b $P<0.01$); **B:** The degree of prevention of Indo-induced ulcerations after treatment with different doses of

lansoprazole and omeprazole (each used at 1-10 mg/kg), leptin (10 $\mu\text{g/kg}$) and ranitidine (50 mg/kg). Each value is a mean \pm SE. Asterisks indicate significant difference (^d $P<0.001$) when compared to saline control.

ulcerations when the animals were treated with lansoprazole and omeprazole, each used at a dose of 1, 2, 5, and 10 mg/kg. There was a profound inhibition of ulcer formation at 10 mg/kg of both lansoprazole and omeprazole. The difference between the drug-treated group (lansoprazole or omeprazole at 2-10 mg/kg) and the saline-treated group was significant ($P<0.001$); with lansoprazole showing a slightly more powerful inhibition than omeprazole but the difference between them was not statistically significant. The leptin ulcer inhibition at 10 μ g/kg dosage was significantly less ($P<0.001$) than that achieved with lansoprazole or omeprazole, each administered at 10 mg/kg (1 000 times the dose of leptin used; Figure 2B). When the rats were treated with 50 mg/kg of ranitidine (5 000 times the dose of leptin), the ulcer prevention activity was significantly higher ($P<0.001$) than that achieved with 10 μ g/kg leptin (Figure 2B).

When the animals were treated with increasing doses of leptin (1-10 μ g/kg), lansoprazole (1-20 mg/kg) and omeprazole (0.5-10 mg/kg) 30 min before they received AE, there was a dose-dependent inhibition of ulcer formation by leptin and each of the PPIs (Figure 3).

Figure 3 The effect of increasing doses of leptin (1-10 μ g/kg), lansoprazole (1-10 mg/kg), and omeprazole (0.5-10 mg/kg) on AE-induced ulceration in rats. Each value is a mean \pm SE. Asterisks indicate significant difference, $^aP<0.05$, $^bP<0.001$ vs controls.

Leptin (10 μ g/kg) produced a significant ($P<0.001$) inhibition of Indo-induced ulcers in L-NAME-pretreated animals, which was not statistically significantly different from the ulcer index for leptin in animals without L-NAME pretreatment (Figure 4).

Leptin caused a profound ulcer inhibition, which was significantly greater ($P<0.001$) for 10 μ g/kg of leptin than saline-treated controls when AE was used to induce gastric ulceration in Indo-pretreated animals (Figure 5). When ulcer induction was performed with AE in L-NAME-pretreated rats, there was a significantly greater degree ($P<0.001$) of GU inhibition by leptin than saline-treated controls (Figure 5). However, the inhibition by leptin of AE-induced ulcer formation was significantly less ($P<0.001$) in the presence of L-NAME than in its absence (Figure 5). Injection of increasing doses of leptin to the animals before AE led to increasing degrees of peptic ulcer prevention and higher tissue concentrations of PGE₂ (Figure 6). Leptin increased

Figure 4 The ulcer prevention ability of leptin (10 μ g/kg), when Indo was used to induce ulcer in L-NAME-pretreated animals. Each value is a mean \pm SE. Asterisks indicate significant difference, $^bP<0.001$ vs controls.

Figure 5 The ulcer prevention ability of leptin (10 μ g/kg), in AE-induced ulcer after Indo or L-NAME pretreatment. Each value is a mean \pm SE. Asterisks indicate significant difference, $^bP<0.001$ vs controls. $^dP<0.001$ shows the significant difference in the effect of leptin on saline-treated and L-NAME-pretreated rats.

Figure 6 The effect of increasing doses of leptin (1-10 μ g/kg) on AE-induced ulcer and prostaglandin E₂ levels in the gastric glandular mucosa in rats. Each value is a mean \pm SE. $^bP<0.01$, $^dP<0.001$ indicate significant difference in percentage ulcer index compared to AE-treated rats taken as 100%. $^fP<0.01$ shows the significant difference in the level of prostaglandin E₂ compared to AE-treated rats taken as 100%.

mucus secretion (Figures 7D, F) and prevented injury to the epithelial layer (Figures 7A-C) thus showing the involvement of mucus as the mechanism of gastroprotection.

DISCUSSION

Leptin is a peptide that is produced by the adipocytes and it

Figure 7 Gastric mucosal layer of rats stained with PAS showing (A) normal epithelium from control rats; (B) damaged epithelium (●) and (C) repaired epithelium after leptin treatment. Lower panel shows the AB (pH 1.0) staining

regulates the function of the satiety center in the hypothalamus^[8]. Although it has also been found in the stomach^[11] its function in the stomach is not clear. In this study, we investigated the property of leptin as an ulcer-preventing agent in an experimental animal model. Our results showed that exogenous leptin demonstrated profound ulcer prevention ability in rats when their gastric mucosa was exposed to ulcer-inducing agents, such as Indo and AE. Exogenous administration of leptin increased the leptin levels in the blood plasma, fundus, and antrum of the stomach^[18,19]. The basal leptin concentration did not prevent by itself the ulcerogenic effect of Indo or AE. However, exogenously administered leptin prevented this effect indicating a pharmacological action of leptin.

Indo is a well-known ulcerogenic agent. In this study, Indo produced hemorrhagic lesions in the gastric mucosa 6 h after its ingestion, which is in accord with previous reports^[20-23]. In Indo-induced ulceration, the ulcer prevention ability of leptin was dose-dependent, reaching a maximum at 10 μ g/kg. No further increase was observed when the leptin dose was doubled. Indeed, its ulcer prevention ability was reduced at a higher leptin dose of 50 μ g/kg. This phenomenon may be explained by an increase in gastric acid secretion that was observed in this study (unpublished data). At this dosage, the leptin ulcer prevention ability was significantly less ($P < 0.05$) than that achieved with ranitidine, which was used at 50 mg/kg, 5 000 times the dose of leptin. However, the ulcer prevention ability of leptin at 10 μ g/kg compares well with that of omeprazole or lansoprazole, each used at 10 mg/kg, 1 000 times the dose at which leptin was employed.

AE, a well-known ulcerogenic agent, was used in the study to produce gastric mucosal damage by causing areas

of focal hyperemia and hemorrhage^[22,24,25]. Moreover, intragastric ethanol increases vascular permeability and vascular damage in capillaries near the luminal surface and not in the deeper muscularis mucosa that might indicate a role for impaired blood flow in the production of AE-induced gastric lesions. Leptin demonstrated a profound ulcer prevention ability, which compared well with that of each of the PPIs, lansoprazole and omeprazole, when AE was employed as an ulcerogenic agent. This is in line with previous reports^[12] that leptin has gastro-protective effect on the gastric mucosal injury induced by topical application of 75% ethanol.

It was interesting to note that the leptin ulcer prevention ability was slightly greater in AE- than in Indo-induced ulceration, although it did not reach statistical level of significance. This may be due to the fact that the AE-induced ulcers are formed superficially at the epithelial layer unlike that induced by Indo, which affects the deeper layer, the submucosa. This profound effect of inhibiting AE-induced ulcer formation by leptin was maintained, even when the animals were pretreated with low dose of Indo. However, a competition in the production of gastric mucosal PGE₂ between Indo (inhibition) and leptin (stimulation) cannot be ruled out. In AE-induced ulceration, evaluation of the effect of leptin on gastric tissue prostaglandin synthesis revealed a dose-dependent increase of gastric mucosal PGE₂ concentration^[26]. This finding suggests that leptin might act in part via the cyclo-oxygenase pathway in preventing ulcer formation. Furthermore our findings that leptin stimulated mucus secretion support the notion that this peptide acted by stimulating PGE₂ production. It has been reported previously that PGE₂ stimulates mucus secretion^[26-28]. In contrast to our results Brzozowski *et al.*^[12], reported that

prostaglandins are not involved in the gastro-protective effect of leptin. The contradictory finding observed in our present results could be due to methodological differences in inducing ulcer.

The influence of leptin-induced histamine release, which has a protective effect on the gastric mucosa, was reported by several workers^[13,29]. Morimoto *et al.*^[29], have reported that histamine release in the hypothalamus was significantly increased by leptin administration. Erkasap *et al.*^[13], have reported that leptin exerts a cytoprotective effect by increasing gastric tissue histamine content which in turn maintain the gastric mucosal blood flow, thereby suggesting that histamine is involved in the prevention of ischemia reperfusion-induced gastric mucosal injury. Goiot *et al.*^[30], reported that the co-existence of leptin and STAT-3 proteins in antral cells provide evidence for the involvement of leptin in the control of gastric secretions. Konturek *et al.*^[31], have investigated the effect of leptin on gastric acid secretion using *H. pylori*-positive and -negative patients and reported that gastric meal- and CCK-induced leptin is capable of inhibiting basal and meal stimulated gastric H⁺ secretion in *H. pylori*-positive patients. But in *H. pylori*-negative patients the release of leptin was reduced in response to CCK and meal. We have shown that subcutaneous administration of low doses of leptin (1-50 µg/kg) potentiates the gastric acid stimulating effect of dimaprit, an H₂ receptor agonist, and pentagastrin, a gastrin receptor agonist, in anaesthetized rats (results not shown). The variation in our results and those of others may be due to the methodological approach towards the evaluation of leptin effect. Taken together our data and those of Azuma *et al.*^[32], Morimoto *et al.*^[29], Erkasap *et al.*^[13], and Konturek *et al.*^[19], suggested that, in addition to the local effect of leptin, a generalized effect of leptin could not be ruled out.

Pretreatment of the animals with L-NAME (25 mg/kg, subcutaneously), an inhibitor of the nitric oxide synthase, before AE-induced gastric ulcerations, reduced the peptic ulcer prevention ability of leptin (10 µg/kg) significantly. However, it did not blot it out completely. This finding suggests that the peptic ulcer prevention ability of leptin does not depend solely on the nitric oxide pathway. This again is in line with the observation of Brzozowski *et al.*^[12], that L-NAME reduced the ulcer-preventing ability of leptin against AE. Brzozowski *et al.*^[33], have also investigated the effect of centrally and intraperitoneally administered leptin and reported that its gastro-protective action, accompanied by increased gastric blood flow and increased plasma gastrin levels, depends on vagal activity and involves hyperemia mediated by NO.

Our results may have consequences for the clinical practice. Based on our data, one would want to recommend the use of leptin subcutaneously in a pilot study in humans, in order to assess its efficacy as an ulcer prevention drug in patients in the intensive care unit, who are prone to develop stress ulcers^[34] during the course of their treatment. Another potential area for its use is among patients with active rheumatoid arthritis^[35] who need to use NSAID for their inflammatory joint disease. This is mainly because the existing epidemiological data support a causal relationship between NSAID use and the development of clinically

important ulcer disease or its complications, including upper GI bleeding.

In conclusion, we have shown that leptin, at low doses (1-10 µg/kg), has ulcer prevention ability, which is comparable to that of ranitidine, an H₂-receptor antagonist or omeprazole and lansoprazole. The ulcer prevention ability of leptin varies according to the ulcerogenic agent used. It is more effective in inhibiting AE-induced than Indo-induced ulcers. The ulcer prevention ability of leptin in AE-induced ulcer involves the cyclooxygenase and the nitric oxide pathways, whereas it acts only via the cyclooxygenase pathway in preventing Indo-induced ulcers.

ACKNOWLEDGMENTS

We would like to thank Amgen Inc., USA, for kindly donating the leptin, which was used in this study. We would also like to thank Dr. Eric Mensah-Brown for his help in studying the photomicrographs and Mr. Naseer Omar for assisting in animal experiments and Dr. Edward Adeyemi who passed away at the end of the year 2004.

Abstract

AIM: To investigate the ability of a genetically altered embryonic stem (ES) cell line to generate insulin-producing cells *in vitro* following transfer of the Nkx2.2 gene.

METHODS: Hamster Nkx2.2 genes were transferred into mouse ES cells. Parental and Nkx2.2-transfected ES cells were initiated toward differentiation in embryoid body (EB) culture for 5 d and the resulting EBs were transferred to an attached culture system. Dithizone (DTZ), a zinc-chelating agent known to selectively stain pancreatic beta cells, was used to detect insulin-producing cells. The outgrowths were incubated in DTZ solution (final concentration, 100 µg/mL) for 15 min before being examined microscopically. Gene expression of the endocrine pancreatic markers was also analyzed by RT-PCR. In addition, insulin production was determined immunohistochemically and its secretion was examined using an ELISA.

RESULTS: DTZ-stained cellular clusters appeared after approximately 14 d in the culture of Nkx2.2-transfected ES cells (Nkx-ES cells), which was as much as 2 wk earlier, than those in the culture of parental ES cells (wt-ES). The frequency of DTZ-positive cells among total cultured cells on day 28 accounted for approximately 1.0% and 0.1% of the Nkx-ES- and wt-ES-derived EB outgrowths, respectively. The DTZ-positive cellular clusters were found to be immunoreactive to insulin, while the gene expressions of pancreatic-duodenal homeobox 1 (PDX1), proinsulin 1 and proinsulin 2 were observed in the cultures that contained DTZ-positive cellular clusters. Insulin secretion was also confirmed by ELISA, whereas glucose-dependent secretion was not demonstrated.

CONCLUSION: Nkx2.2-transfected ES cells showed an

INTRODUCTION

It has been proposed that approximately 150 million people worldwide have diabetes mellitus, which may double by 2025, and 5-10% of those suffer from type 1 diabetes, for which injections of insulin are unavoidable. Transplantation of pancreatic islets for type 1 diabetes is a promising therapeutic strategy^[1], however, an inadequate supply of donor islets is a major obstacle. Thus, embryonic stem (ES) cells are being considered as a potential source for generating insulin-producing cells. ES cells come from clonal cell lines derived from the inner cell mass of developing blastocysts^[2,3], and are able to proliferate *in vitro* and have shown a capacity to differentiate into a broad spectrum of derivatives of all three embryonic germ layers including hematopoietic cells, cardiomyocytes, smooth muscle cells, neurons, hepatocytes, and insulin-producing cells^[4-10]. We recently reported the appearance of the islet-like cellular clusters containing insulin-producing cells in embryoid body (EB) outgrowth cultures with the use of a zinc-chelating substance, dithizone (DTZ)^[11]. However, the development of islet-like cellular clusters was found in only a small portion of the EB outgrowths and required long-term cultures of more than 3 wk.

Nkx2.2 and Nkx6.1 are NK-homeodomain genes expressed in early pancreatic progenitor cells as well as neurogenin-3 (Ngn3)-expressing islet precursor cells, and are considered to be β -cell competence factors^[12-14]. Nkx2.2 mutants completely lack insulin expression^[14], while Nkx6.1 mutants show a less dramatic impaired differentiation of β -cells^[15]. Further, Nkx2.2 expression lasts for a longer period of time in differentiated islet cells. These findings suggest that Nkx2.2 is a critical transcription factor in early pancreatic endocrine development and the following differentiation into pancreatic β -cells.

In the present study, we generated Nkx2.2-expressing

cell lines by transfection of the Nkx2.2 gene into undifferentiated ES cells, and investigated their ability to differentiate into insulin-producing cells in EB outgrowth cultures. We found that insulin-producing cells appeared as much as 2 wk earlier in the EB outgrowths derived from Nkx2.2-transfected ES (Nkx-ES) cells than in those from parental ES (wt-ES) cells. Further, the frequency of insulin-producing cells on culture d 28 was approximately 1% in the Nkx-ES-derived EB outgrowths, a 10-fold greater efficiency as compared to that on the wt-ES-derived EB outgrowths. These results suggest that Nkx2.2 acts to promote the differentiation of ES cells into insulin-producing cells.

MATERIALS AND METHODS

Murine ES cell lines

We utilized a mouse ES cell line, EB3 (129/SvJ mouse ES cells, a kind gift from Dr. Hitoshi Niwa, RIKEN Center for Developmental Biology, Kobe, Japan)^[15], which was a subline derived from E14tg2a ES cells^[16] and carried the blasticidin S-resistant selection marker gene driven by the Oct-3/4 promoter (active under undifferentiated status)^[17]. Undifferentiated EB3 cells were maintained on gelatin-coated dishes without feeder cells in the maintenance medium, which was knockout-DMEM medium (Gibco-BRL) supplemented with 10% fetal bovine serum (FBS; GIBCO/BRL), 0.1 mmol/L of 2-mercaptoethanol (Sigma), 10 mmol/L of non-essential amino acids (GIBCO/BRL), L-glutamine, and 1 000 U/mL of leukemia inhibitory factor (LIF; GIBCO/BRL).

Generation of Nkx2.2-expressing ES (Nkx-ES) cells

The hamster Nkx2.2 gene was obtained from the plasmid pBAT12.shNkx2.2 (kindly provided by Dr. M. German, University of California, San Francisco). The cDNA was inserted into the BstXI-stuffer site of the expression vector pPyCAGIRESzeocinpA^[18]. The constructed plasmid pPyCAGIRESzeocinpA-Nkx2.2 contained the zeocin resistance gene driven by the chicken β -actin promoter. The Nkx2.2 vector (20 μ g) was transfected using a lipofection method with lipofectAmine (GIBCO/BRL). Transfected ES cells were selected by growth in the presence of 20 μ g/mL of zeocin, and three clones expressing Nkx2.2 (Nkx-ES) were established. Undifferentiated Nkx-ES cells were maintained in the same manner as undifferentiated wt-ES cells.

EB outgrowths with non-selective differentiation

The method used for the EB outgrowths has been previously described^[11]. Briefly, undifferentiated ES cells were dissociated into single-cell suspensions and then cultured in hanging drops to induce embryoid body (EB) formation at an initial cell density of 500 cells per drop (20 μ L) of ES cell-medium in the absence of LIF. After 5 d in a hanging drop culture, the resulting EBs were plated in plastic 30-mm gelatin-coated dishes (five EBs per dish), and then allowed to attach and form outgrowth cultures. A half amount of culture medium was replenished with new medium every 2 d. The culture medium used was the maintenance medium lacking LIF and known differentiation-inducing factors.

Throughout the whole culture, no growth factors or cytokines including insulin were added to the culture medium.

Dithizone (DTZ)-staining

A DTZ (Merck, Whitehouse Station, NJ, USA) stock solution was prepared with 50 mg of DTZ in 5 mL of dimethylsulfoxide (DMSO) and stored briefly at -15 °C. The staining solution was filtered through a 0.2 μ m nylon filter and then used as a DTZ working solution. *In vitro* DTZ staining was performed by adding 10 μ L of the stock solution to 1 mL of culture medium, then the culture dishes were incubated at 37 °C for 15 min in the DTZ solution. After the dishes were rinsed thrice with HBSS, clusters stained crimson red were examined using a stereomicroscope. After examination, the dishes were refilled with DMEM containing 10% FBS. Although the stain completely disappeared from the cells after 5 h, the cultures that had not been treated with DTZ were used for RT-PCR and insulin secretion studies to avoid the influence of the treatment. In some experiments, the number of DTZ-stained cells in the cultures was determined by counting crimson red cells after trypsinization following DTZ stain.

RT-PCR

Total RNA was extracted from the cells using TRIzol (GIBCO/BRL). DNase-treated total RNA was used for the first-strand cDNA. This reaction was performed using M-MLV Reverse Transcriptase (Promega) and Random Primer (Takara Bio Inc.), following the protocols of the manufacturers. cDNA samples were subjected to PCR amplification with specific primers under linear conditions in order to reflect the original amount of the specific transcript. The cycling parameters were as follows: denaturation at 94 °C for 1 min, annealing at 52-60 °C for 1 min (depending on the primer), elongation at 72 °C for 1 min (35 cycles), and a final extension for 20 min at 72 °C. The PCR primers and the lengths of the amplified products were as follows: β -actin (TGAAGTGGCTGACTGCTGTG and CATCCTTGGCCTCAGCATAG, 174 bp); pro-insulin 1 (GTTGGTGCACCTTCCTACCCCTG and GTAGAGGGAGCAGATGCTGGTG, 300 bp); pro-insulin 2 (GTGGATGCGCTTCCTGCCCCTG and GTAGAGGGAGCAGATGCTGGTG, 300 bp); PDX1 (GGCCACACAGCTCTACAAGG and TTCCACTTCATGCGACGGTT, 582 bp); and mouse-nkx2.2 (TGACCAACACAAAGACGGGGT and GCACGTTTCATCTTGTAGCGA, 650 bp). A set of mouse-nkx2.2 primers was used for the detection of hamster Nkx2.2.

Immunocytochemistry

Cells in culture dishes were fixed with 4% paraformaldehyde in phosphate-buffered solution and immunocytochemistry was carried out using a standard protocol. As the primary antibody for Nkx2.2, mouse anti-chick Nkx2.2 mAb (Hybridoma Bank, University of Iowa) was used at a dilution of 1:40. For detection of the primary antibody, a biotinylated anti-mouse antibody, ABC kit (VECTASTAIN Elite ABC KIT), and DAB (Dojindo; Kumamoto, Japan) were utilized according to the manufacturers' instructions.

For detection of the primary antibody, a fluorescent labeled secondary antibody, goat anti-guinea pig IgG conjugated with fluorescein-5-isothiocyanate (Cappel 57000, ICN Pharmaceuticals, Inc., OH, USA), was utilized according to the manufacturer's instructions. All nuclei were stained with DAPI (Dojindo; Kumamoto, Japan).

Insulin detection assay

Cells in the culture dishes were washed thrice with PBS and pre-incubated in Krebs Ringer bicarbonate buffer (KRBB) containing 2.8 mmol/L of glucose for 1 h, then placed in 1 000 μ L of KRBB with 2.8 mmol/L of glucose for 2 h. Next, the supernatant was collected and the dishes were rinsed thrice with PBS, after which the cells were re-incubated with KRBB containing 25.5 mmol/L of glucose for 2 h. Subsequently, conditioned medium samples were collected, and insulin levels were measured using an enzyme immunoassay (Mouse Insulin ELISA TMB Kit AKRIN-011T, Shibayagi Co., Ltd. Gunma, Japan) that detects mouse insulin in a range between 156 and 10 000 pg/mL with no cross-reactivity to C-peptide.

RESULTS

Establishment of Nkx2.2-expressing ES cell lines

ES cells were transfected with the Nkx2.2 expression vector and selected with zeocin. Three stable clones at a time were obtained and screened for Nkx2.2 expression by RT-PCR and three clones with a high expression of Nkx2.2 were finally selected (Figure 1A). Subsequently, immunocytochemistry showed that all three clones expressed Nkx2.2 protein (Figure 1B). Each Nkx-ES clone demonstrated similar results in the following experiments, thus representative results from only clone 3 are shown.

Figure 1 Expression of Nkx2.2 in parental (wt-ES cells) and Nkx2.2-transfected ES cells (Nkx-ES cells). **A:** Nkx-ES cells, but not wt-ES cells, expressed Nkx2.2 mRNA; **B:** Nkx2.2 protein was mainly observed in the nuclei of Nkx-ES cells. Original magnification, $\times 200$.

Early appearance of DTZ-stained cells in EB outgrowths

DTZ, a zinc-chelating agent, is known to selectively stain pancreatic β -cells crimson red^[19-21] and we previously demonstrated that DTZ stain could also be applied for the detection of ES-derived insulin-producing cells. Figure 2 shows the outline of the EB outgrowth culture and results of DTZ-staining. DTZ-positive cellular clusters appeared as much as 2 wk earlier in the EB outgrowths derived from Nkx-ES cells. On d 14, DTZ-positive cells were already present in the EB outgrowths derived from Nkx-ES cells (Figure 2D), whereas they were absent in those from wt-ES cells (Figure 2A). On d 21, distinct DTZ-positive cellular clusters were observed in the Nkx-ES-derived EB outgrowths (Figure 2E), while they were obscure in the differentiating wt-ES cultures (Figure 2B). In the wt-ES-derived EB outgrowths, DTZ-positive cellular clusters became distinct on d 28 (Figure 2C). The appearance of DTZ-positive clusters on d 28 in Nkx-ES-derived EB outgrowths was quite similar to that seen on d 21 (Figures 2E and F).

DTZ-stained clusters that appeared in Nkx-ES-derived EB outgrowths were frequently larger than those in wt-ES-derived EB outgrowths. To estimate the frequency of the emerged DTZ-stained cells in the cultures, the number of DTZ-stained red cells was directly counted under a microscope after trypsinization following the treatment with DTZ. The percentages of DTZ-stained cells among total cells on day 28 were $1.0 \pm 0.2\%$ of the Nkx-ES-derivatives and less than 0.1% of the wt-ES-derivatives.

Gene expression and immunohistochemistry of differentiating EB outgrowths

Pdx 1, a key transcriptional factor of pancreatic differentiation, was faintly detected in Nkx-ES cells and completely absent in wt-ES cells on d 0. Thereafter, Pdx 1 was expressed in all EB outgrowths on d 14, 21, and 28 as well as in isolated mouse islets. In contrast, Nkx2.2 was not detected on d 14, faintly detected on d 21, and clearly detected on d 28 in the differentiating wt-ES cells. In addition, pro-insulin 1 and 2 were detected on d 14 in the Nkx-ES-derived EB outgrowths, though not until d 28 in the wt-ES-derived EB outgrowths. To confirm the expression of insulin protein, we performed an immunohistochemistry examination in parallel with the DTZ-stain examination (Figure 3B). Immunoreactivity against insulin was found to coincide with the DTZ-stained culture areas within the EB outgrowths. In Nkx-ES-derived EB outgrowths, insulin-immunoreactivity was detected as early as on d 14, whereas it did not become positive until d 28 in the wt-ES-derived EB outgrowths. No immunoreactivity was found on d 14 or 21 in the wt-ES-derived EB outgrowths.

Insulin secretion

EB outgrowths on d 28 were used for the detection of released insulin. Insulin concentrations in culture media of wt-ES-derived EB outgrowths incubated with 2.8 and 25 mmol/L of glucose were 163 ± 38 and 191 ± 31 pg/mL, respectively, while those in media of Nkx-ES-derived EB outgrowths were 525 ± 132 and 660 ± 171 pg/mL with 25.5 mmol/L of glucose, respectively. Glucose-dependent insulin secretion was not observed in wt-ES- or Nkx-ES-

Figure 2 A-F: Early appearance of insulin-producing cells in EB outgrowths. An outline of the culture processes and results of DTZ-staining are shown. Scale

bar represents 100 μm in length.

Insulin-immunoreactivity was examined in the EB outgrowths with DTZ-staining. Scale bars represent 100 μm in length.

derived EB outgrowth cultures, whereas secreted insulin was detected in the Nkx-ES-derived EB outgrowth cultures, in amounts several times greater than in the wt-ES-derived EB outgrowth cultures.

DISCUSSION

The homeodomain transcription factor Nkx2.2 is one of the key transcription factors in pancreatic β -cell differentiation and expressed throughout all development periods, as well as broadly in the initial pancreatic precursor population, and in Ngn3-expressing islet progenitor cells and differentiated islet cells^[12,13,22]. Mice homozygous for a null mutation of Nkx2.2 develop severe hyperglycemia leading to death shortly after birth, because of the lack of insulin-producing β -cells^[14], and show a variety of functional defects in the islet cells that produce endocrine hormones other than insulin. In the present study, we examined genetically altered ES cells after transfection of the Nkx2.2 gene to determine their ability to differentiate into insulin-producing cells *in vitro*.

To assess the effect of the exogenous Nkx2.2 transgene on generation of insulin-producing ES-derived cells, we considered that an EB-based 1-step culture protocol^[11,15,23] that supported natural differentiation of ES cells would be better than an EB-based multi-step protocol^[24] that directed an oriented differentiation of ES cells toward pancreatic cell lineages using serum-free culture followed by a combination of growth factors. Since a promoted induction of insulin-producing cells was expected, a less efficient differentiation protocol was better suited to demonstrate the promoted action than a more sophisticated and efficient protocol. In addition, some investigators have speculated that the insulin-immuno-positive nature of cultured cells derived in an EB-based multi-step method is due to the incorporation of insulin from the culture medium^[25,26], while it is also suspected that such insulin-incorporated cells are apoptotic. Therefore, in the present study, EBs are simply allowed to attach and grow in gelatin-coated dishes in media containing FCS without growth factors, including insulin.

Since the emergence of insulin-producing cells among the simple EB outgrowths was expected to be rare, we used DTZ to locate those that produced insulin. DTZ is a zinc-binding substance, and known to stain crimson red the pancreatic islets from such animals, as mice, dogs and pigs, as well as those from human beings^[19-21]. We previously reported that DTZ-stained cellular clusters appeared in EB outgrowths and that the clusters demonstrated characteristics similar to pancreatic islets^[11]. In the present study, DTZ-stained cellular clusters appeared 2 wk earlier in the Nkx-ES-derived EB outgrowths, as compared to the wt-ES-derived EB outgrowths. Those cellular clusters were immunopositive for insulin and the presence of secreted insulin was confirmed by ELISA. Further, in addition to an early emergence, an increased frequency of DTZ-stained cells was also observed in the Nkx-ES-derived EB outgrowths. These results suggest that the fate of differentiating cells was favorably affected toward the generation of insulin-producing cells.

In spite of our success, the DTZ-positive cellular fraction still accounted for only 1% of the differentiated Nkx-ES cells. To achieve a more efficient generation of insulin-

producing cells from ES cells *in vitro*, controlled regulation of other transcriptional factors that are involved in pancreatic β -cell differentiation might be necessary. Indeed, a highly efficient production of insulin-producing cells from ES cells has been reported by the expression of exogenously transfected pdx-1, pax 4, or Nkx6.1^[27-29].

The precise mechanisms by which Nkx-ES cells promote the induction of insulin-producing cells is unknown, thus sequential analyses of a number of transcription factors that are involved in pancreatic β -cell differentiation must be examined in differentiating Nkx-ES cells. Although we have not performed such an analysis, an important finding to investigate is the early expression of insulin seen in the present differentiating Nkx-ES cells. Nkx2.2 expression preceded insulin expression in differentiating wt-ES cells (Figure 3A), which has also been seen in the pancreatic β -cell development^[30]. Therefore, Nkx-ES cells may directly skip to that process following Nkx2.2 expression. Glucose-dependent insulin secretion was not observed in the cultures of ES-derived insulin-secreting cells, which we considered may have been due to the high concentration of glucose present in the culture media, in which the ES cells were allowed to differentiate until the insulin detection assay.

In summary, we generated gene-engineered Nkx2.2-expressing ES cells and demonstrated their ability to induce insulin-producing cells *in vitro*. Our results show that gene-engineered ES may be a useful source of insulin-producing cells.

Abstract

AIM: To build up the research models of hepatic fibrosis in mice.

METHODS: Inbred wild-type FVB/N mice were either treated with alpha-naphthyl-isothiocyanate (ANIT), allyl alcohol (AA), carbon tetrachloride (CCl₄), 3,5-diethoxycarbonyl-1,4-dihydrocollidine (DDC), and silica, or subjected to common bile duct ligation (CBDL) to induce hepatic injury. Liver biopsies were performed every 4 wk to evaluate hepatic fibrosis over a period of 6 mo. Cumulative cirrhosis and survival curves were constructed by life table method and compared with Wilcoxon test.

RESULTS: Under the dosages used, there was neither mortality nor cirrhosis in AA and silica-treated groups. DDC and ANIT caused cirrhosis within 4-12 and 12-24 wk, respectively. Both showed significantly faster cirrhosis induction at high dosages without significant alteration of survival. The duration for cirrhosis induction by CCl₄ ranged from 4 to 20 wk, mainly dependent upon the dosage. However, the increase in CCl₄ dosage significantly worsened survival. Intraperitoneal CCl₄ administration resulted in better survival in comparison with gavage administration at high dosage, but not at medium and low dosages. After CBDL, all the mice developed liver cirrhosis within 4-8 wk and then died by the end of 16 wk.

CONCLUSION: CBDL and administrations of ANIT, CCl₄, and DDC ensured liver cirrhosis. CBDL required the least amount of time in cirrhosis induction, but caused shortened lives of mice. It was followed by DDC and ANIT administration with favorable survival. As for CCl₄, the speed of cirrhosis induction and the mouse survival depended upon the dosages and the administration route.

INTRODUCTION

Being the final outcome of chronic liver damage regardless of the underlying etiologies, hepatic fibrosis demands thorough study. The studies of hepatic fibrosis rely upon the availability of animal models. Although no experimental model exactly reproduces human liver fibrosis by etiologies, animal models serve to improve our understanding of pathogenetic mechanisms of liver fibrosis. In view of the cost-effectiveness in inducing hepatic injuries, hepatotoxin administration and common bile duct ligation (CBDL) were considered as useful methods^[1].

In recent years, advances in molecular biology have helped to generate a transgenic mouse model of liver fibrosis^[2]. This represents a new form of perturbation analysis whereby selective expression of novel or altered genes are used to perturb a complex system so that the information about the changes during development, functioning and malfunctioning can be deduced^[3]. This approach potentially allows development of animal models with liver fibrosis that are inducible and genetically similar to that of man. A reliable and reproducible model of hepatic fibrosis in wild-type control mice will aid to unveil the pathologic mechanisms deduced from genetic and molecular approaches. However, informative data of mouse hepatic fibrosis generated in the laboratory remained lacking in the literature because rats had long been the most common animal model for studying hepatic fibrosis induced by various chemical or surgical hepatic injuries^[1]. Since different animal models display distinct characteristics in the nature of pathogenesis of fibrosis or cirrhosis, the data acquired from rats could not apply to mice without bias^[4-8]. This urged us to set up a mouse model of hepatic fibrosis using CBDL or the administration of various hepatotoxins including alpha-naphthyl-isothiocyanate (ANIT)^[9,10], silica^[11], carbon tetrachloride (CCl₄)^[12-14], 3,5-diethoxycarbonyl-1,4-dihydrocollidine (DDC)^[15,16], and allyl alcohol (AA)^[17-19]. This study mainly focused on the strain of FVB/N inbred mice, which have been widely used to generate a variety of transgenic lines owing to their high reproduction rate and easy access in microinjection^[20,21].

MATERIALS AND METHODS

Mice

Inbred FVB/N mice (8-10 wk old) were obtained from the National Laboratory Animal Center (Taipei, Taiwan). All animals received care as outlined in the "Guides for the Care and Use of Laboratory Animals" prepared by the Committee of Animal Research, Chang Gung Memorial Hospital. Mice were supplied with food and water and exposed to a 12-h light-dark cycle. Ten mice (five males and five females) composed a group to which surgical CBDL or a hepatotoxin via intraperitoneal (IP) or oral gavage (OG) administration at the same dosage was given during a period of 6 mo.

Methods to induce hepatic injuries

ANIT (Sigma Chemical Co., St. Louis, MO, USA) ANIT was dissolved in corn oil and administered via IP or OG route, respectively. For each route of administration, there were three subgroups according to the maintenance dose as follows: 25 mg/kg (low dosage), 50 mg/kg (medium dosage) and 125 mg/kg (high dosage). After a single loading dose of 100 mg/kg, the maintenance doses were given twice a week. Additionally, there was a modified method of OG administration with a single loading dose of 100 mg/kg and subsequent maintenance doses of 50 mg/kg for the 1st and 2nd mo, 75 mg/kg for the 3rd and 4th mo, and 100 mg/kg for the 5th and 6th mo.

AA (Sigma Chemical Co.) AA was prepared in double distilled water and administered via OG route for five subgroups according to the dosages as follows: 0.2, 0.4, 0.6, 0.8, and 1.0 mmol/kg twice a week.

CCl₄ (Sigma Chemical Co.) The mice were fed via OG or IP route with CCl₄ (density = 1.594 kg/L) diluted in double distilled water. As for each route of administration, they were further subgrouped into three according to the maintenance doses as follows: 0.8 g/kg (low dosage), 1.6 g/kg (medium dosage) and 2.0 g/kg (high dosage). After a single loading dose of 2.4 g/kg, the maintenance doses were then administered twice a week.

DDC (Sigma Chemical Co.) The mice were fed via OG with DDC in corn oil twice a week. They were subgrouped by four different dosages as follows: 0.25, 0.5, 2.5, and 5 mg. In addition, 0.1% DDC contained diet (Purina Mills TestDiet, St. Louis, MO, USA) was used as the 5th subgroup.

Silica (US Silica Company, Berkeley Springs, WV, USA) Silica was dissolved in Dulbecco's modified eagle media and given subcutaneously at the dose of 3.5 g/kg, or intraperitoneally at the dose of 1.6 g/kg twice a week.

CBDL The surgical procedure was performed under sterile conditions. The mice were anesthetized with isoflurane. Midline laparotomy was performed for exploring the hepatic hilum and identifying CBD. Under the dissecting microscope, CBD was then isolated, doubly ligated and transected between two ligatures.

Liver biopsy

Liver biopsy demanded survival procedures and sterile techniques. After anesthesia with isoflurane, midline laparotomy was performed to expose the mouse liver. A liver block sized 0.5 cm in diameter was taken and then the cut surface was sutured for hemostasis. Serial biopsy was

performed monthly (per 4 wk) for each mouse till cirrhosis was well documented by histopathology. At the first liver biopsy, ascites, and intra-abdominal adhesion were examined and recorded.

Histopathology

Mouse livers from biopsies were fixed in 10% neutral buffered formaldehyde solution and embedded in paraffin. Sections, 4 μ m in thickness, were stained with hematoxylin and eosin. Fatty change of hepatocytes was recorded when hepatocytes showed fat accumulation, balloon-like swelling or formation of fat cysts. For liver necrosis, there were the disorganization of liver cell cords, homogeneous cytoplasm, pyknotic nuclei and periportal infiltration of inflammatory cells. Fibrosis was defined as the presence of fibrous scarring band in the liver parenchyma by Mason's trichrome collagen stain. Once the irregular zones of fibrosis developed and surrounded the remaining parenchymal tissues to display a pattern of nodularity under microscope, cirrhosis was diagnosed.

Statistical analysis

For survival and cirrhosis rate analyses, life table method was used. The length of time intervals used in this study was 4 wk. Any mouse which died, or whose liver was pathologically documented to be cirrhotic was considered to have experienced an event. When a mouse died before cirrhosis was confirmed at cirrhosis rate analysis, it was counted as a withdrawal and treated the same way as cases lost to follow-up. Plots were constructed with weeks after inducing liver injury vs survival or cirrhosis rate. The Wilcoxon test was employed to compare the curves. Differences were regarded as significant if a *P* value was less than 0.05.

RESULTS

Mouse survival

During the period of 6 mo, none of the 260 mice enrolled in this study died of the procedures for CBDL, liver biopsy or administration of hepatotoxins. There was no mortality case in the AA and silica groups. As for the other groups, 71 mice died in the course of this study. Among the 71 deaths, 20 occurred before cirrhosis could be histopathologically confirmed (pre-cirrhotic) and the remaining 51 after cirrhosis was found (post-cirrhotic). Nineteen of the 20 pre-cirrhotic deaths occurred in the CCl₄ group. As for the post-cirrhotic deaths, there were 4 in the ANIT group, 26 in the CCl₄ group, 11 in the DDC group and 10 in the CBDL group. The case numbers of mortality in each subgroup were listed in Table 1. Mortality had been found in all the CCl₄ subgroups, ranging from 40% to 100%. In the DDC group, mortality was mainly post-cirrhotic, and seen in 2.5 and 5 mg and 0.1% diet subgroup. All the mice in CBDL group had post-cirrhotic death by the end of 16 wk. The overall comparison for the survival curves in the ANIT and DDC groups could not reach any statistical significance (*P* = 0.0823 and 0.1227, respectively), whereas there was a significant difference in the CCl₄ subgroup (*P* < 0.0001). Pairwise comparisons for survival curves of the six CCl₄ subgroups showed that the

low dosage (IP0.8 and OG0.8) was significantly better than the medium dosage (IP1.6 and OG1.6, Figure 1, $P = 0.0010$ – 0.0317), and the medium dosage was also superior to the high dosage (IP2.0 and OG2.0, Figure 1, $P = 0.0002$ – 0.0044). Considering the administration routes, IP route compared favorably in survival with OG route at the high dosage ($P = 0.0221$), but not at the medium and low dosages ($P = 0.7899$ and 0.5902 , respectively).

Table 1 Case number of pre-cirrhotic and post-cirrhotic deaths

	Pre-cirrhotic death	Post-cirrhotic death
ANIT OG 25 mg/kg	0	0
ANIT OG 50 mg/kg	0	0
ANIT OG 125 mg/kg	0	3
ANIT IP 25 mg/kg	0	0
ANIT IP 50 mg/kg	0	0
ANIT IP 125 mg/kg	1	0
ANIT modified	0	1
AA OG from 0.2 to 1.0 mmol/kg	0	0
CCl ₄ OG 0.8 g/kg	0	5
CCl ₄ OG 1.6 g/kg	2	7
CCl ₄ OG 2.0 g/kg	5	5
CCl ₄ IP 0.8 g/kg	4	0
CCl ₄ IP 1.6 g/kg	6	1
CCl ₄ IP 2.0 g/kg	2	8
DDC OG 0.25 mg	0	0
DDC OG 0.5 mg	0	1
DDC OG 2.5 mg	0	3
DDC OG 5 mg	0	4
DDC 0.1% diet	0	3
Silica (SC 3.5 g/kg or IP 1.6 g/kg)	0/0	0/0
CBDL	0	10

OG: Oral gavage; IP: intraperitoneal; SC: subcutaneous.

Figure 1 Survival curves of six CCl₄ subgroups are shown. The number immediately behind the IP or OG indicates the dosage of CCl₄ used in g/kg.

Ascites and intraabdominal adhesion

Ascites was universally found at laparotomy when the hepatotoxins were administered via IP route. In the CBDL group, there were only three mice presenting with ascites at the subsequent laparotomy. Intraabdominal adhesion existed in over 50 % of cases (ranging from 50% to 100%) when IP route or CBDL was used. Additionally, granuloma-like masses were intraperitoneally identified in all the cases of silica IP subgroup and in nine cases of ANIT IP subgroups

(two for 25 mg/kg, one for 50 mg/kg and six for 125 mg/kg).

Histopathology

The case numbers of histopathological findings in each subgroup were listed in Table 2. Fatty change was seen mainly in the ANIT and CCl₄ groups, and sporadically in the AA group (1 for 0.8 mmol/kg and 2 for 1.0 mmol/kg). Bile lakes were the common findings in the DDC and CBDL groups. Liver necrosis and fibrosis were demonstrated almost in all the cases of the ANIT, CCl₄, DDC, and CBDL groups, two cases of the AA group (one for 0.8 mmol/kg and the other for 1.0 mmol/kg), but none of the silica group. The necrosis and fibrosis were detected at the first or second liver biopsy (4–8 wk after liver injury). Liver fibrosis in the two mice from the AA group did not progress to cirrhosis by the end of this study. Cirrhotic nodules could be identified in 30 mice (42.9%) of ANIT group ($n = 70$), 32 mice (53.3%) of CCl₄ group ($n = 60$), 39 mice (78.0%) of DDC group ($n = 50$) and all the mice (100%) of CBDL group ($n = 10$). DDC subgroup with higher dosages (2.5 and 5 mg) and 0.1% diet could substantially reach 100% successful rate of cirrhosis induction as seen in the CBDL group.

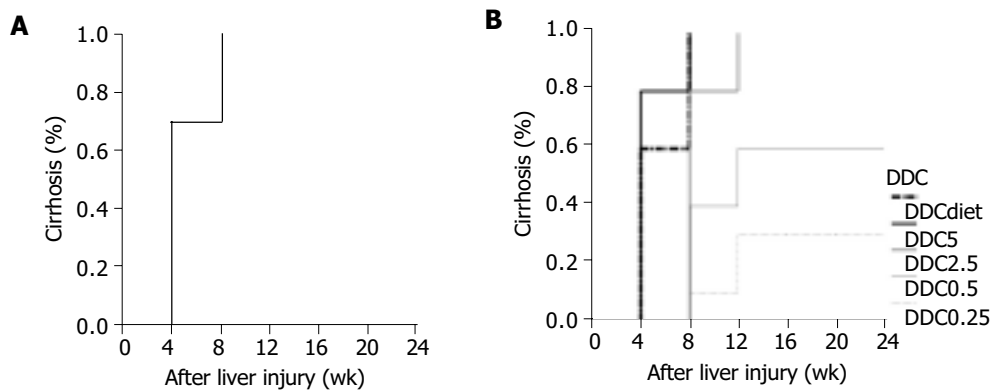

Durations required for cirrhosis induction

Results from life table analysis for the durations were presented in the curves with weeks after inducing liver injury *vs* cirrhosis rate. CBDL represented a rapid method to induce liver cirrhosis with 70–100% of successful rate within 4–8 wk (Figure 2A). DDC caused liver cirrhosis within 4–12 wk (Figure 2B). Statistical analysis revealed that the lower the DDC dosage, the longer the time spent by DDC in inducing cirrhosis among 0.5, 2.5 and 5 mg subgroups (DDC0.5 *vs* DDC2.5, $P = 0.0387$ and DDC2.5 *vs* DDC5, $P = 0.0004$). There was no significant difference between 0.25 and 0.5 mg DDC subgroups ($P = 0.1311$). DDC 0.1% diet required significantly less time to induce cirrhosis than DDC 0.25 mg ($P = 0.0001$), 0.5 mg ($P = 0.0008$) and 2.5 mg ($P = 0.0032$), but was not significantly different from 5 mg subgroups ($P = 0.3415$). As for CCl₄, the duration for inducing cirrhosis was quite variable, ranging from 4 to 20 wk (Figure 3A). The IP and OG high dosages (2.0 g/kg) of CCl₄ spent significantly less time in cirrhosis induction than IP and OG low dosages (0.8 g/kg) of CCl₄ ($P = 0.0005$ – 0.0209). There was no difference of the cirrhosis curves between IP and OG administrations at the high ($P = 0.1760$) and low ($P = 0.1661$) dosages, whereas OG administration compared favorably in cirrhosis induction than IP administration at the medium dosage (1.6 g/kg) of CCl₄ ($P = 0.0060$). The OG medium dosage (OG1.6) had no significant difference from the high dosage ($P = 0.1852$ for OG2.0 and $P = 0.7241$ for IP2.0), and the IP medium dosage (IP1.6) had no significant difference from the low dosage ($P = 0.8822$ for OG0.8 and $P = 0.1514$ for IP0.8). Cirrhosis caused by ANIT did not show up until 12–24 wk (Figure 3B). The high dosage of ANIT significantly spent less time in cirrhosis induction than the medium ($P = 0.0002$ – 0.0263) and low dosages ($P = 0.0002$ – 0.0027), whereas the medium dosage could not be significantly superior to the low dosage ($P = 0.0904$ – 1.0000). At the same ANIT dosage used, there was no significant difference of cirrhosis curves between OG and

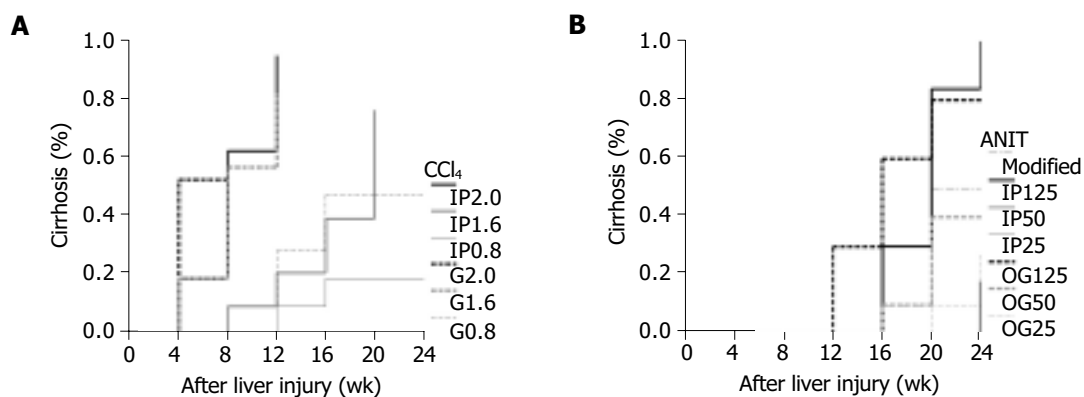

Table 2 Histopathological changes after inducing liver injuries

OG: oral gavage; IP: intraperitoneal; SC: subcutaneous. ¹1 for 0.8 mmol/kg and 2 for 1.0 mmol/kg; ²1 for 0.8 mmol/kg and 1 for 1.0 mmol/kg.

**Figure 2** Cirrhosis rates of CBDL and DDC groups. **A:** The cirrhosis curve for CBDL group is shown; **B:** The cirrhosis curves for 5 DDC subgroups are

shown. The number immediately behind DDC indicates its dosage used in mg per mouse. DDC diet represents 0.1% DDC contained diet.

**Figure 3** Cirrhosis rates of CCl₄ and ANIT groups. **A:** The cirrhosis curves for six CCl₄ subgroups are shown. The number immediately behind the IP or OG indicates the dosage of CCl₄ used in g/kg; **B:** The cirrhosis curves for seven

ANIT subgroups are shown. The number immediately behind the IP or OG indicates the dosage of ANIT used in mg/kg.

IP administrations ($P = 0.2444$ for high dosage, $P = 0.0904$ for medium dosage, and $P = 0.5032$ for low dosage). The modified method for ANIT administration compared

favorably in cirrhosis induction only with IP low dosage and IP medium dosage ($P = 0.0349$, for both), but poorly with OG high dosage ($P = 0.0303$).

DISCUSSION

In this 6-mo study of experimental cirrhosis induction, AA and silica were ineffective in inducing liver fibrosis let alone cirrhosis. AA administration in the drinking water (50 ppm equivalent to 0.08–0.11 mmol/kg per d) for 15 wk has no effect on the histopathological examination of rat livers^[19]. Moreover, IP injection of AA in rats only produced variable periportal liver necrosis predominantly at 6–12 h, followed by restitutive proliferation of periportal necrosis to repopulate the necrotic zone. Eventually, the liver architecture was essentially restored by 1 wk^[18]. It indicated that AA merely induced short-term toxicity in rats. Although we had observed liver necrosis and fibrosis in two mice with OG administration of 0.8 and 1.0 mmol/kg AA, this liver damage was transient and insufficient to result in cirrhosis. It suggested that rats and FVB/N mice had similar hepatotoxic resistance to AA. As for silica, subcutaneous or IP administration was reported to cause liver fibrosis and cirrhosis in nude mice at 12 mo and in (C57BL/6×BALB/c) F₁ mice at 18 mo^[22]. Thus, a 6-mo duration might not be long enough for silica to cause hepatic injury with subsequent fibrosis and cirrhosis in FVB/N mice. As a result, a longer-term administration of silica might be required for inducing liver cirrhosis in FVB/N mice. A major drawback with silica administration was the granuloma formation at the injection site. This might be of concern to subsequent laparotomy for liver biopsy when the IP route is used.

The IP or OG administration of ANIT, CCl₄ or DDC could effectively lead to liver fibrosis within 4–8 wk. All the liver fibrosis in mice did not always progress to microscopic cirrhotic nodules by the end of 24 wk. It suggested that restitutive response of mice to the injuries by those hepatotoxins sometimes restore liver architecture. ANIT has been used for years to study cholangiolitic hepatotoxicity in laboratory animals^[9,10]. This study showed that ANIT usually led to mouse cirrhosis within 12–24 wk after administration. Mortality was only seen in the subgroups with high dosage and modified administration. However, there was no significant difference among the survival curves of all the ANIT subgroups. The high dosage of ANIT could more rapidly induce liver cirrhosis than the medium or low dosage. At the same dosage of ANIT, it made no significant difference between IP and OG administrations in cirrhosis induction. The modified method by gradual increase of ANIT dosage could not substantially provide any benefit in cirrhosis induction in this study. Overall, ANIT model required a longer period for the formation of cirrhosis. This might provide more time for researchers to investigate the progression of liver fibrosis.

CCl₄ has been used extensively for decades to induce liver injury in various experimental models to elucidate the mechanisms behind hepatotoxicity^[23]. Also, it was commonly used as a hepatotoxic agent in transgenic mice to evaluate liver fibrosis and cirrhosis on the basis of the selective expression of some novel or altered genes^[13,14,24]. We experienced that the major problem in association with the use of CCl₄ to induce liver fibrosis or cirrhosis had been the high mortality rates of mice, accounting for 40–100 % in those subgroups. Animals might die before or after cirrhosis was found. The higher CCl₄ dosage was associated with the worse survival

curve. The duration required for cirrhosis induction by CCl₄ was quite variable, ranging from 4 to 20 wk, mainly depending upon the dosage. The high dosage (2.0 g/kg) of CCl₄ could rapidly cause liver cirrhosis within 4–12 wk, but led to poor survival. Under the circumstances, IP administration will be suggested since IP route posed better survival than OG route only at the high dosage of CCl₄. The low dosage (0.8 g/kg) of CCl₄ required 12–24 wk to successfully induce cirrhosis. At the low dosage, it was shown that the administration routes had no influence on the survival and the cirrhosis induction. At the medium dosage (1.6 g/kg) of CCl₄, OG administration was more rapid to induce cirrhosis than IP administration, but did not significantly differ in survival curves from IP administration. Nevertheless, the high mortality rate along with the use of CCl₄ must be taken into consideration since it will prematurely terminate the sequential studies or observations of liver fibrosis or cirrhosis. Furthermore, CCl₄ might not be an ideal solvent for investigating hepatocarcinoma since liver carcinogenesis might be due to the genotoxic chemical carcinogen effect of CCl₄ itself as well as CCl₄-induced liver cirrhosis^[25,26].

DDC did not result in pre-cirrhotic death, but tended to lead to post-cirrhotic death at higher dosage (2.5 and 5 mg) and 0.1% DDC diet. The overall comparison for all survival curves of those DDC subgroups led to the insignificant difference. It took about 4–12 wk for DDC to successfully induce cirrhosis. Except 0.25 mg DDC subgroup, the successful rate of cirrhosis induction was quite satisfactory. The higher the dosage of DDC we used, the lesser the time we needed to induce cirrhosis. DDC 0.1% diet could not be superior to 5 mg DDC subgroup in cirrhosis induction. A major concern of DDC use was the high proportion of bile lake formation. This might cause some biases in observing the relationship between cirrhosis and its sequelae.

CBDL represented a rapid and consistent method to induce liver fibrosis and cirrhosis. Hepatocellular injuries were caused by cholestasis, leading to liver dysfunction, promoting fibrogenesis and ultimately resulting in liver failure and death. All the mice with CBDL rapidly progressed to cirrhosis within 4–8 wk after operation, and died by the end of 16 wk. The rapid progression to cirrhosis and death by CBDL might limit its application in chronic fibrosis studies and make it difficult to carry out a long-term investigation of liver cirrhosis. A major technical problem was the reversibility of histological changes due to recanalization of bile ducts^[1]. In our tested animals, the bile ducts remained totally obstructed till their death in view of bile lakes at final pathology and the coloration of peritoneum and auricle. The successful obstruction by CBDL might be due to the fact that CBD was doubly ligated and transected between two ligatures^[27]. Besides, intraabdominal adhesion could be an obstacle for subsequent survival laparotomy to study CBDL livers.

In summary, CBDL and hepatotoxins of ANIT, CCl₄ and DDC could be effective in causing liver fibrosis of mice. CBDL rapidly and irreversibly led to liver fibrosis and subsequently to cirrhosis within 4–8 wk, but inevitably caused mortality by the end of 16 wk. As a result, CBDL was suitable for creating a mouse model for the short-term study of liver fibrogenesis. Although CCl₄ had been commonly used for inducing liver fibrosis and cirrhosis, the duration

required for cirrhosis induction varied (4-20 wk) and mainly depended upon the dosage. It could be used in mice for studying both acute and chronic liver fibrogenesis. A major drawback in association with CCL₄ use was a relatively high mortality. DDC could effectively induce cirrhosis within 4-12 wk. The time required for cirrhosis induction by DDC was quite similar to that of CBDL, but the survival experience was better in the DDC group. ANIT slowly induced liver cirrhosis in mice. The duration from initial liver inflammatory damage to cirrhosis formation by ANIT was more than 12 wk after administration. Thus, ANIT was quite a good toxin for a long-term study of fibrosis progression into cirrhosis.

Abstract

AIM: To investigate the effect of tetramethylpyrazine (TMP), an active compound from *Ligustium Wollichii Franchet*, on electrolyte transport across the distal colon of rodents and the mechanism involved.

METHODS: The short-circuit current (I_{sc}) technique in conjunction with pharmacological agents and specific inhibitors were used in analyzing the electrolyte transport across the distal colon of rodents. The underlying cellular signaling mechanism was investigated by radioimmunoassay analysis (RIA) and a special mouse model of cystic fibrosis.

RESULTS: TMP stimulated a concentration-dependent rise in I_{sc} , which was dependent on both Cl^- and HCO_3^- , and inhibited by apical application of diphenylamine-2,2'-dicarboxylic acid (DPC) and glibenclamide, but resistant to 4,4'-diisothiocyanatostilbene-2,2'-disulfonic acid disodium salt hydrate (DIDS). Removal of Na^+ from basolateral solution almost completely abolished the I_{sc} response to TMP, but it was insensitive to apical Na^+ replacement or apical Na^+ channel blocker, amiloride. Pretreatment of colonic mucosa with BAPTA-AM, a membrane-permeable selective Ca^{2+} chelator, did not significantly alter the TMP-induced I_{sc} . No additive effect of forskolin and 3-isobutyl-1-methylxanthine (IBMX) was observed on the TMP-induced I_{sc} , but it was significantly reduced by a protein kinase A inhibitor, H_{89} . RIA results showed that TMP (1 mmol/L) elicited a significant increase in cellular cAMP production, which was similar to that elicited by the adenylate cyclase activator, forskolin (10 μ mol/L). The TMP-elicited I_{sc} as well as forskolin- or IBMX-induced I_{sc} were abolished in

mice with homozygous mutation of the cystic fibrosis transmembrane conductance regulator (CFTR) presenting defective CFTR functions and secretions.

CONCLUSION: TMP may stimulate cAMP-dependent and CFTR-mediated Cl^- and HCO_3^- secretion. This may have implications in the future development of alternative treatment for constipation.

INTRODUCTION

Constipation presents a massive impact on health services, and the epidemiology investigation has demonstrated that the prevalence of constipation in many areas around the world is significantly high^[1,2]. Studies have shown that constipation results primarily from changes in gastrointestinal motility^[3]. In addition, alterations in regulating fluid and electrolyte transport across gut epithelia may represent another contributing factor in the pathophysiology of constipation^[4].

The mammalian colon is the final station of the gastrointestinal tract, where the organism has the last opportunity to modify the electrolyte contents in the feces with balanced absorptive and secretory activities. The epithelial layer covering the inner surface of colon is a typical electrolyte-transporting epithelium, which under physiological conditions absorbs water, sodium and chloride while secreting NaCl as well as potassium and bicarbonate through a number of ion channels, carriers, and pumps, located either on the luminal or on the basolateral membrane. Epithelial Na^+ channels populated in the apical membranes of the absorptive cells in the colon, which are amiloride-sensitive and well-known targets for mineralocorticoids, are responsible for Na^+ absorption^[5]. Cystic fibrosis transmembrane conductance regulator (CFTR), a cAMP-dependent Cl^- channel, is predominantly expressed in colonic

crypts^[6,7] and known to mediate both Cl^- ^[8,9] and HCO_3^- secretion^[10,11]. Disturbance of ion transport, like cholera toxin and cystic fibrosis (CF) may result in diarrhea^[12] or constipation^[13] with severe pathological consequences^[9].

The traditional therapeutic proposals, such as the employment of cathartic medications, stool softeners, lubricant grease, and enemas have some effects on constipation, but their side effects have restricted their use^[14].

In our previous study, we have observed that Bak Foong Pill, consisting of more than 20 herbal ingredients, a well known Chinese remedy widely used for treating gynecological disorders, exerts a stimulatory effect on anion secretion by the human colonic epithelia cell line T₈₄ primarily via the cAMP pathway with minor contribution from the Ca^{2+} pathway^[15]. This result highlights the potential for exploring an active component of Bak Foong Pills for treatment of constipation or other obstructive bowel syndromes in patients.

Tetramethylpyrazine (TMP, $\text{C}_8\text{H}_{12}\text{N}_2$, molecular weight 136.20), also known as ligustrazine, is the active compound extracted from one of the component herbs of Bak Foong Pill, *Ligustium Wollichii*. TMP is used in clinic to treat cardiovascular disorders because of its multitude of biological effects such as improving blood circulation and metabolism of cardiac muscle, increasing coronary flow, decreasing oxygen consumption, lowering blood pressure and inhibiting thrombosis^[16-18]. TMP may act as an inhibitor of phosphodiesterase (PDE) to increase intracellular cAMP thereby exerting its antiplatelet and vasodilatation effects^[19]. On the other hand, the effect of TMP on the release of calcium from internal stores has also been reported^[17]. Therefore, it is possible that TMP may be the active compound responsible for mediating the effect of Bak Foong Pills. The focus of this study was to investigate the effect of TMP on water and electrolyte transport properties of native mammalian colon with the hope of exploring new alternative treatment for constipation or obstructive bowel syndromes.

MATERIALS AND METHODS

Materials

TMP was purchased from the Fourth Pharmaceutical Factory of Beijing (Beijing, China). 3-Isobutyl-1-methylxanthine (IBMX), amiloride, DIDS, BAPTA-AM, POP and POPOP were obtained from Sigma Chemical Company (St. Louis, MO, USA). Calbiochem (San Diego, CA, USA) was the source for bumetanide, forskolin, TTX, H₈₉, and glibenclamide. Diphenylamine-2,2'-dicarboxylic acid (DPC) was purchased from Riedel de Haen Chemicals (Hannover, Germany). cAMP measurement kit was purchased from the Institute of Atomic Energy Science (Beijing, China). Stock solutions of all the chemicals were dissolved in DMSO. Final DMSO concentrations never exceeded 1 mL/L. Preliminary experiments indicated that the vehicle did not alter any baseline electrophysiological parameters.

Krebs-Henseleit (KH) solution contained (in mmol/L): 117, NaCl; 4.7, KCl; 1.2, MgCl_2 ; 1.2, KH_2PO_4 ; 24.8, NaHCO_3 ; 2.5, CaCl_2 ; 11.1, glucose. The solution was continuously bubbled with 95% O_2 and 50 mL/L CO_2 to

maintain the pH at 7.4. In Cl^- free solution, NaCl, KCl, and CaCl_2 were replaced by sodium gluconate, potassium gluconate, and calcium gluconate, respectively^[20]. When HCO_3^- free solution was used, NaHCO_3 was replaced by NaCl, and the solution was buffered with 10 mmol/L Hepes with a pH of 7.4 when gassed with 100% O_2 . In the Cl^- and HCO_3^- free solutions, NaCl and NaHCO_3 were replaced by sodium gluconate, KCl by potassium gluconate, and CaCl_2 by calcium gluconate. The solution was buffered with 10 mmol/L Hepes with a pH of 7.4 when gassed with 100% O_2 . In all solutions, the osmolarity was adjusted to 290 mOsm/L with D-mannitol if necessary.

Methods

Tissue preparation Adult male Sprague-Dawley rats (Laboratory Animal Services Center at The Chinese University of Hong Kong) ranging in age from 8 to 12 wk had free access to standard rodent laboratory food and water until the day of the experiments. The animals were killed by CO_2 asphyxiation in accordance with a protocol approved by Animal Research Ethics Committee of the Chinese University of Hong Kong. Segments of distal colon about 5 cm proximal to the anus were quickly removed, cut along the mesenteric border into a flat sheet and flushed with ice-cold KH solution. The tissues were pinned flat with the mucosal side down in a Sylgard-lined petri dish containing ice-cold oxygenated solution. The serosa, submucosa, and muscular layer were stripped away with fine forceps to obtain a mucosa preparation. Two to three of these stripped mucosal preparations were obtained from one animal. TTX was used to exclude possible involvement of neuronal circuitry.

CFTR mice CFTR mice, B6.129P2-*Cftr*^{*tm1Unc1*}, were purchased from Jackson's Laboratory (Bar Harbor, ME 04609, USA) and then bred in Laboratory Animal Services Center at The Chinese University of Hong Kong by mating heterozygous pairs genotyped by PCR amplification of genomic DNA isolated from the animals' tails, as described previously^[21]. Homozygous CFTR mutation (-/-) mice and their littermate wild-type CFTR (+/+) controls were utilized in the study. Preparation of mouse colonic mucosa was similar to that described for the rat. Mice were cared for in accordance with the Laboratory Animal Services Center of the Chinese University of Hong Kong guidelines.

Short circuit current measurement The short-circuit current (I_{sc}) was measured *in vitro* in Ussing chambers^[22]. Flat sheets of distal colon with intact mucosa were mounted between two halves of modified Ussing chambers, in which the total cross-sectional area was 0.45 cm². The mucosal and serosal surfaces of tissues were bathed with 10 mL of KH solution by recirculation from a reservoir maintained at 37 °C during the experiment. The solution was gassed with 95% O_2 and 50 mL/L CO_2 to maintain the pH at 7.4. An equilibration period of 30 min was given before the experiments. The tissues were continuously short-circuited, and the transepithelial potential difference (PD) was measured through Ag/AgCl reference electrodes (World Precision Instruments, Sarasota, Boca Raton, FL, USA) connected to a preamplifier that was connected in turn to a voltage clamp amplifier (DVC 1000; World Precision

Instruments). Voltage offset of two voltage electrodes and fluid resistance were adjusted and compensated prior to the onset of each measurement. At 0.5 intervals, a transepithelial PD of 0.1 mV (U) was applied to the tissue and the change in current (I) was measured. The tissue conductance (G_t) and the open-circuit PD could be calculated from these values according to Ohm's law ($G_t = I/U$ and $\text{PD} = I/G_t$). Drugs could be added directly to the apical or basolateral side of epithelium. Responses were continuously recorded on a chart recorder. The change in I_{SC} was calculated on the basis of the value before and after stimulation and normalized as current per unit area of epithelium ($\mu\text{A}/\text{cm}^2$), according to which, the total transmembrane charges ($\mu\text{C}/\text{cm}^2$) for 30 min could be calculated. The methodology for tissue preparation and measurement of electrical parameters across the mucosal sheets was described earlier^[23,24].

Measurement of cAMP Cytosolic cAMP concentrations were measured by radioimmunoassay analysis (RIA). After a 20-min period of equilibration in normal KH solution at 37 °C, the isolated mucosal sheet was treated with TMP, forskolin, TMP with IBMX, TMP with IBMX and forskolin. The mucosal sheet without treatment could act as control. The mucosal sheets were further incubated for 2 min and then rapidly frozen in liquid nitrogen and weighed 50.0 mg frozen tissue precisely. The tissues were homogenized in 2 mL of 1 N perchloric acid using a glass homogenizer. The homogenate was centrifuged at 1 000 r/min, 600 μL of the supernatant was extracted and neutralized with 300 μL of 20% KOH. The sediment was discarded after centrifugation. Six hundred microliters of the supernatant was extracted and evaporated in an electrothermal blast drier at 80 °C and the residue was dissolved in 200 μL TE buffer for further measurement. The amount of cAMP was determined by RIA with a ^3H -labeled cAMP kit (Institute of Atomic Energy Science). Procedures were performed according to the manufacturer's instructions.

Statistical analysis

Results were expressed as mean \pm SE. The number of experiments represented independent measurements on separate stripped mucosal preparation (two to three of these tissue preparations were obtained from one animal).

Comparisons between groups of data were made by either the Student's *t*-test (two-group comparison) or one-way ANOVA with Newman-Keuls post hoc test (three or more-group comparison). $P < 0.05$ was considered statistically significant. EC_{50} values were determined by nonlinear regression using GraphPad Prism software.

RESULTS

TMP-induced I_{SC} response in rat distal colon

Addition of TMP to either the apical or basolateral membrane could elicit I_{SC} responses with a greater response obtained with basolateral challenge. The present study only focused on the responses elicited by basolateral addition of TMP. As shown in Figure 1, the TMP response was concentration-dependent with an apparent EC_{50} of 0.994 mmol/L. At a concentration greater than 3 mmol/L, TMP induced a biphasic response with a fast transient peak followed by a sustained plateau.

To exclude possible involvement of enteric nervous system, 1 $\mu\text{mol/L}$ TTX was added to the basolateral side before the administration of TMP and no significant change in the TMP-evoked increase in I_{SC} was observed.

Ion basis of TMP-evoked I_{SC}

The increase in I_{SC} could be attributed to either enhanced movement of positive charges from the luminal to the serosal side (i.e., Na^+) or movement of negative charges into the lumen (i.e., Cl^- and/or HCO_3^-). Ion substitution experiments were conducted to determine the ionic basis for the increases in I_{SC} induced by TMP (Figure 2). When extracellular Cl^- or HCO_3^- was removed, the TMP-induced response measured by total charge transfer per unit area over a 30-min period was reduced by 58.4% ($n = 5$, $P < 0.01$) and 70.8% ($n = 4$, $P < 0.01$), respectively. When both Cl^- and HCO_3^- were replaced, 98.1% ($n = 6$, $P < 0.001$) of the response was abolished, indicating substantial contribution of Cl^- and HCO_3^- to the TMP-induced response (Figure 2A).

To test whether the TMP-induced I_{SC} responses were due to electrogenic Na^+ absorption, apical Na^+ was replaced but it did not reduce the TMP response ($n = 6$), excluding electrogenic Na^+ absorption across the colonic mucosa.

Figure 1 Effect of TMP on ion transport across rat colonic mucosa. **A:** Representative recordings of I_{SC} response to TMP (0.1, 1.0, 3.0, and 5.0 mmol/L) added to basolateral side. Arrowheads indicate the time of addition of TMP; **B:** Concentration-response curve of TMP with response indicated by the total

charge transfer per unit area over a 30-min period. Each data point was obtained from at least four individual experiments. Values are mean \pm SE of maximal increase in I_{SC} .

Figure 2 Ionic basis of TMP-induced I_{SC} . **A**: One millimole per liter of TMP-induced I_{SC} response (total charge transfer per unit area over 30-min period) obtained in various solutions was plotted with normal KH solution as the control; **B**: Summarized data showing the effect of 1 mmol/L of TMP-evoked

I_{SC} response in the apical presence of amiloride (0.1 mmol/L), apical Na⁺ removal, and basolateral Na⁺ removal from the bath solution. Values are mean±SE; ^b $P<0.001$, ^d $P<0.01$ vs control. NS, not significant.

However, removing Na⁺ from basolateral or bilateral bathing solution abolished TMP-induced I_{SC} response by 99.5% ($n = 4$, $P<0.001$, Figure 2B), suggesting that both Cl⁻ and HCO₃⁻ secretion might involve transport mechanisms that depend on basolateral Na⁺.

Effect of ion channel blockers

To investigate whether the TMP-induced I_{SC} response was mediated by activation of the apical anion channel, different anion channel blockers were used. As shown in Figure 3, the TMP-induced I_{SC} was completely inhibited by apical application of glibenclamide (1 mmol/L, $n = 9$), which has previously been shown to block CFTR^[25] or DPC (2 mmol/L, $n = 10$, data not shown). However, the TMP-induced I_{SC} response was not sensitive to apical addition of DIDS (100, 500 μmol/L, and 1 mmol/L, $n = 5$), known to block the Ca²⁺-activated Cl⁻ channel.

Amiloride, an inhibitor of the epithelial Na⁺ channel, was also used to assess the involvement of Na⁺ absorption. In our preparation of rat colonic mucosa, a small amount of amiloride-sensitive current was observed under basal conditions. However, we did not detect any decrement of TMP-induced I_{SC} response following apical amiloride (0.1 mmol/L) pretreatment ($n = 7$, Figure 2B).

Involvement of the second messengers

To address whether [Ca²⁺]_i was involved in mediating TMP-evoked anion secretion, BAPTA-AM (100 μmol/L), a membrane-permeable selective Ca²⁺ chelator, was

Figure 3 Effect of Cl⁻ channel blockers. Representative I_{SC} recording with arrows indicating the response to TMP (5 mmol/L, basolateral) and apical addition of channel blockers DIDS (100 mmol/L) and glibenclamide (1 mmol/L).

added bilaterally to the colonic mucosa for 45 min prior to the addition of TMP. The subsequent TMP-evoked I_{SC} was slightly reduced but not significant ($n = 6$, $P>0.05$, Figure 4).

To test whether TMP exploited the cAMP pathway, the additive effect of forskolin (10 μmol/L, $n = 7$) or IBMX (100 μmol/L, $n = 6$) was examined. As shown in Figure 5A, no further increase in I_{SC} by TMP was observed when the I_{SC} was first elicited by the adenylate cyclase (AC) activator, forskolin, or PDE inhibitor, IBMX. Similarly, little or reduced forskolin or IBMX-induced I_{SC} response was observed if the I_{SC} was first activated by TMP (data not shown), indicating significant overlapping of the TMP signaling pathway with the cAMP-dependent one. This possibility was further tested by examining the effect of the protein kinase A (PKA) inhibitor, H₈₉. The I_{SC} response to TMP could be blocked by 91.7% upon bilateral pretreatment with 5 μmol/L H₈₉ ($n = 7$, Figure 5B).

It is also possible that TMP may alter arachidonic acid metabolism affecting production of prostaglandins (PG), which are also known to be a mediator of other secretagogues of intestinal secretion^[26]. Therefore, the effect of PG synthesis inhibitor, indomethacin, on TMP-induced I_{SC} increase was also determined. In the presence of basolateral indomethacin (10 μmol/L), the TMP-induced I_{SC} response reduced but substantial response remained with concentration-dependent characteristics (Figure 6). The indomethacin-insensitive TMP response could be inhibited by H₈₉ (data not shown), consistent with the involvement of the cAMP pathway.

Figure 4 Effect of BAPTA-AM on TMP-evoked I_{SC} . Values are mean±SE; NS, not significant.

Figure 6 Concentration-response curve for TMP-induced transmembrane charges (30 min) in the presence of indomethacin (10 $\mu\text{mol/L}$). Each data point was obtained from at least four individual experiments. Values are mean \pm SE of maximal increase in charge.

Intracellular cAMP measurement

RIA was performed to study the effect of TMP on colonic epithelial intracellular cAMP levels and the results are shown in Figure 7. The intracellular cAMP content could be stimulated from a basal level of 20.0 ± 5.8 nmol/L ($n = 9$) to 45.8 ± 5.0 nmol/L ($n = 6$, $P < 0.005$) in response to AC activator forskolin (10 $\mu\text{mol/L}$), or to 48.8 ± 9.9 nmol/L ($n = 10$, $P < 0.05$) in response to TMP (1 mmol/L).

Effect of TMP on CF mouse colonic mucosa

Since CFTR is a cAMP-dependent Cl^- channel, the involvement of the cAMP-dependent pathway as shown above suggests that the secretory response elicited by TMP may be mediated by CFTR. To test this hypothesis, mutant CF mice with homozygous mutation of CFTR (-/-) were

Figure 7 Effect of TMP on intracellular cAMP level. Each column represents mean \pm SE; ^a $P < 0.05$, ^b $P < 0.01$ vs control (KHS).

used and the effect of TMP on colonic mucosa was compared to that obtained from the wild type, CFTR (+/+). TMP (5 mmol/L) added to the basolateral side of the wild type colonic mucosa produced a sustained increase in I_{sc} response ($n = 3$, Figure 8A), which mimicked the forskolin-induced I_{sc} response ($n = 3$, Figure 8B). The same concentration of TMP was used to challenge colonic mucosa from CF mice and no TMP response was observed ($n = 5$, Figure 8C), neither with addition of forskolin (10 $\mu\text{mol/L}$, $n = 3$) or IBMX (100 $\mu\text{mol/L}$, $n = 3$), indicating that both TMP-induced Cl^- and HCO_3^- secretion was mediated by CFTR.

DISCUSSION

The present study has demonstrated a stimulatory effect of TMP on colonic anion secretion but not Na^+ absorption. The TMP-induced increase in I_{sc} is not considered to be mediated by electrogenic Na^+ absorption because it was not inhibited by apical addition of amiloride, the epithelial sodium channel blocker, or by Na^+ removal from apical side. Previous studies have also shown that isolated rat distal colon is largely devoid of electrogenic Na^+ transport^[27]. However, replacement of extracellular Cl^- and HCO_3^- ions, or addition of Cl^- channel blockers, greatly attenuated the TMP-induced I_{sc} , suggesting that TMP has a primary effect on the anion secretion by the colon of rodents. It is interesting to note that both Cl^- and HCO_3^- secretions seem to be Na^+ -dependent since Na^+ removal from basolateral solution almost completely abolished the TMP-induced I_{sc} , suggesting involvement of basolateral

Na^+ -dependent transporting mechanisms, i.e., both Na^+ - HCO_3^- cotransporter^[28] and Na^+ - K^+ - 2Cl^- cotransporter^[29] are implicated in secondary active Cl^- and HCO_3^- secretion in many epithelia including the intestine.

The results of the present study suggest that CFTR is the likely candidate pathway for apical Cl^- and HCO_3^- exit since the TMP-evoked anion secretion was completely inhibited by glibenclamide and DPC, which are known to block CFTR^[25,30], but not by DIDS which has no effect on the activity and conductance of CFTR^[31]. The strong evidence indicating the involvement of CFTR came from the studies on CF mice with CFTR homozygous mutation. The complete abolition of the TMP-induced response in CFTR mutated colonic mucosa suggests that both TMP-stimulated Cl^- and HCO_3^- secretions are mediated by CFTR, which is consistent with an important role of CFTR in HCO_3^- as well as Cl^- secretion in many epithelial tissues^[32]. It is interesting to note that removing Cl^- or HCO_3^- alone from the bathing solution resulted in 58.4% and 70.8% attenuation in TMP-induced I_{SC} , respectively. The summated inhibition is more than 100%, suggesting interaction between the two ions, possibly during their transport by CFTR. The phenomena that the presence of one ion interferes with the transport of another ion have been previously reported to be associated with CFTR^[33]. In native guinea pig pancreatic duct cells, CFTR is between 3-5 times more selective for Cl^- over HCO_3^- ; however, extracellular HCO_3^- significantly inhibits CFTR current carried by Cl^- . The interaction between Cl^- and HCO_3^- secretion may also have physiological bearing in the colon, the details of which, especially the role of CFTR, remain to be elucidated.

The involvement of CFTR also suggests that the effect of TMP is mediated primarily by the cAMP-dependent pathway since CFTR is a cAMP-activated Cl^- channel^[34] and mainly responsible for cAMP-dependent anion secretion^[35]. The amount of cAMP available to activate PKA to phosphorylate CFTR is determined by the balance between cAMP production by AC and cAMP hydrolysis by PDE^[36]. cAMP can be stimulated either by activation of AC or inhibition of PDE. The observation that TMP failed to further increase the I_{SC} , or lack of additive effect after a maximal stimulation with forskolin (AC activator) or IBMX (PDE inhibitor) suggests that the signaling pathway mediating the effect of TMP may overlap with the cAMP pathway. These indicate that TMP, forskolin and IBMX share a common intracellular pathway (i.e., a rise in $[\text{cAMP}]_i$). This notion is further supported by the inhibition of the TMP responses by H_{89} , an inhibitor of PKA, which is the primary target for intracellular cAMP. The present results obtained from RIA studies demonstrate an enhancement of intracellular cAMP by TMP in the rat colon.

While there is no question about the involvement of cAMP in mediating the TMP effect, how TMP activates intracellular cAMP remains to be elucidated. Previous studies reported that the antiplatelet activity of TMP is due to the enhancement of intracellular cAMP by acting as a PDE inhibitor^[19]. Although we do not have any substantial evidence to support this, the asymmetrical I_{SC} response to apical and basolateral challenge of TMP suggests differential distribution of the component(s) of the signaling pathway

involved. In this regard, it is interesting to note that PDE subtypes are differently localized in the apical and basolateral membrane domains of T_{84} colonic epithelial cells^[8]. Therefore, the more potent effect of TMP observed when applied to the basolateral membrane can be explained by the presence of greater amount of a certain PDE subtype in the basolateral domain of the colonic mucosa, if TMP is indeed acting as a PDE inhibitor. Further studies along this line are necessary in order to understand the detail mechanism of cAMP activation by TMP.

It should be mentioned that while the TMP effect does not appear to involve the enteric nervous system, portion of the TMP effect could be blocked by indomethacin, an inhibitor of PG synthesis, indicating the involvement of PG which is well known for its function as the mediator of other secretagogues and acts by stimulating AC in the intestinal epithelium^[37]. The present studies also demonstrate that both the indomethacin-sensitive and indomethacin-insensitive TMP response could be blocked by H_{89} indicating the involvement of cAMP in both cases. Therefore, TMP may indirectly activate cAMP via PG, apart from its possible direct action as a PDE inhibitor.

Although previous studies demonstrating effects of TMP on cardiac vascular function^[17] have suggested its action on the Ca^{2+} pathway, the present results suggest that TMP acts primarily on the cAMP but not on the Ca^{2+} pathway, at least for the concentration range used in the present study. However, it should be noted that the treatment with BAPTA-AM in the present study did appear to reduce the TMP response although the effect was not significant. Therefore, TMP might have a minor action on the Ca^{2+} -dependent pathway, which may also be TMP concentration dependent. We have preliminary data indicating increased Ca^{2+} involvement with increased TMP concentrations. Further studies using direct Ca^{2+} measurement may be required to clarify this.

The effect of TMP on colonic anion secretion by a primary action on the cAMP pathway is consistent with our previous studies with Bak Foong Pills, indicating that TMP may be an active compound responsible for mediating the stimulatory effect of Bak Foong Pills on colonic anion secretion previously observed^[15]. Since Cl^- secretion is the main driving force for fluid secretion across the colon^[9], and HCO_3^- secretion at the luminal surface is considered to have a decisive influence on a constant pH microclimate sustenance^[38], the ability of TMP to enhance the secretion of these anions secretion may have implications in future development of alternative treatment for constipation. Most importantly, as an active compound of many popular traditional Chinese medicines, TMP has been in clinical use with trivial side effects and few clinically relevant drug interactions reported. Taken together, TMP may have therapeutic potential for treatment of constipation caused by disturbance of electrolyte and fluid transport in the GI tract.

Abstract

AIM: To establish a simplified method for generating peptide-major histocompatibility complex (MHC) class I tetramers.

METHODS: cDNAs encoding the extracellular domain of human lymphocyte antigen (HLA)-A*0201 heavy chain (A2) and β_2 -microglobulin (β_2m) from total RNA extracted from leukocytes of HLA-A2⁺ donors were cloned into separate expression vectors by reverse transcription-polymerase chain reaction. The recombinant A2 and β_2m proteins were expressed in *Escherichia coli* strain BL21(DE3) and recovered from the inclusion body fraction. Soluble A2 proteins loaded with specific antigen peptides were refolded by dilution from the heavy chain in the presence of light chain β_2m and HLA-A2-restricted peptide antigens. The refolded A2 monomers were biotinylated with a commercial biotinylation enzyme (BirA) and purified by low pressure anion exchange chromatography on a Q-Sepharose (fast flow) column. The tetramers were then formed by mixing A2 monomers with streptavidin-PE in a molar ratio of 4:1. Flow cytometry was used to confirm the expected tetramer staining of CD8⁺ T cells.

RESULTS: Recombinant genes for HLA-A*0201 heavy chain (A2) fused to a BirA substrate peptide (A2-BSP) and mature β_2m from HLA-A2⁺ donor leukocytes were successfully cloned and highly expressed in *E. coli*. Two soluble monomeric A2-peptide complexes were reconstituted from A2-BSP in the presence of β_2m and peptides loaded with either human cytomegalovirus pp65₄₉₅₋₅₀₃ peptide (NLVPMVATV, NLV; designated as A2-NLV) or influenza virus matrix

protein Mp58-66 peptide (GILGFVFTL, GIL; designated as A2-GIL). Refolded A2-NLV or A2-GIL monomers were biotinylated and highly purified by single step anion exchange column chromatography. The tetramers were then formed by mixing the biotinylated A2-NLV or A2-GIL monomers with streptavidin-PE, leading to more than 80% multiplication as revealed by SDS-PAGE under non-reducing, unboiled conditions. Flow cytometry revealed that these tetramers could specifically bind to CD8⁺ T cells from a HLA-A2⁺ donor, but failed to bind to those from a HLA-A2⁻ donor.

CONCLUSION: The procedure is simple and efficient for generating peptide-MHC tetramers.

INTRODUCTION

Cytotoxic T lymphocytes (CTLs), or CD8⁺ T cells, play a critical role in the clearance of viral infections and the eradication of tumors^[1]. A better understanding of cellular immunity against viruses and/or tumor cells requires careful analysis of the responding CD8⁺ T cells, particularly in terms of their numbers and effector functions^[2]. Because specific CD8⁺ T cells are often vastly outnumbered by irrelevant T cells, quantification of antigen-specific T cells often requires *in vitro* culture and re-stimulation, which may introduce bias in the results^[2]. The standard method for deriving specific CTL frequency information is limiting dilution analysis (LDA)^[2]. However, accumulating evidence indicates that this technique may significantly underestimate the number of specific CTLs, because it does not detect cells that lack proliferative potential^[2,3]. This limitation has been overcome by the introduction of peptide-major histocompatibility complex (MHC) class I tetrameric complex technology^[3-6], which initiates a profound revolution in the field of cellular immunology^[7-10]. Peptide-MHC tetramer-based assays have enabled direct flow cytometric quantification^[3-6], phenoty-

ping^[3,8-11] and even functional analysis^[8,11] of antigen-specific CD8⁺ T cells. Thus, peptide-MHC tetramer technology is a powerful tool for evaluating the fundamental aspects of T-cell immunity.

Though tetramer technology for direct quantification of the frequency and/or function of antigen-specific CTLs has been generally accepted, wide application of tetramer strategies is limited by the complex procedures necessary for tetramer production^[3]. Moreover, the expression level of recombinant human MHC class I heavy chain in *Escherichia coli* is usually minimal due to the low translation frequency of human proteins in *E. coli*^[12]. To address these problems, we sought to develop a simplified and efficient method for production of peptide-MHC class I tetramers. We constructed prokaryotic expression vectors for recombinant human lymphocyte antigen (HLA)-A2 heavy chain and β_2m -microglobulin (β_2m) proteins, in which nucleotide residues in the translation initiation region (TIR) were substituted to the preferred codons for *E. coli*^[13] and decreased the G/C content in this region^[14]. The recombinant A2 and β_2m proteins were overexpressed in *E. coli* in the form of inclusion bodies, thus facilitating their high purity isolation by simple washing and centrifugation. Further simple procedures allowed us to establish an efficient, streamlined procedure for the preparation of HLA-A2 tetramers. This improved procedure should facilitate the general application of tetramer technology in both basic research and clinical applications.

MATERIALS AND METHODS

Materials

E. coli strain DH5 α was stored in our laboratory. *E. coli* strain BL21(DE3) and plasmid pET-3c were purchased from Novagen (Madison, WI, USA). *Nde*I, *Bam*HI, T4 DNA ligase and high fidelity DeepVent Taq polymerase were purchased from New England Biolabs (Beverly, MA, USA). The TRIzol reagent and ThermoScript reverse transcription-polymerase chain reaction (RT-PCR) system were obtained from Invitrogen (Carlsbad, CA, USA). Q-Sepharose (fast flow) was obtained from Amersham (Uppsala, Sweden). Mouse anti-human monoclonal antibodies CD3-FITC, CD8-CyChrome and HLA-A2-FITC were purchased from PharMingen (San Diego, CA, USA). Streptavidin R-phycoerythrin (PE) conjugate (streptavidin-PE) was purchased from Molecular Probes (Eugene, OR, USA). Protein molecular mass markers were obtained from Sigma (St. Louis, MO, USA). The biotinylation enzyme, BirA, was purchased from Avidity (www.avidity.com). The NLVPMVATV (NLV) peptide derived from pp65 (pp65₄₉₅₋₅₀₃) of HCMV^[11], and the GILGFVFTL (GIL) peptide derived from the matrix protein (Mp₅₈₋₆₆) of the influenza A virus^[15], were synthesized by BioAsia (Shanghai, China) and purified to >98%. All other chemicals were from Sigma and were analytically pure.

Cloning of HLA-A*0201 heavy chain and β_2m cDNAs

Heparinized human peripheral blood was collected from three HLA-A2 positive (identified by anti-human HLA-A2-FITC staining and flow cytometric analysis) donors by venipuncture. Total RNA was extracted from freshly isolated

PBMCs using the TRIzol reagent. cDNAs were synthesized from the isolated RNA using the ThermoScript RT-PCR system according to the recommended procedure. PCR amplification of the resultant cDNA was performed in a total volume of 50 μ L containing high fidelity DeepVent Taq polymerase. For amplification of β_2m , PCR was performed with an initial denaturation for 2 min at 94 °C, followed by 35 cycles of 94 °C for 30 s, 55 °C for 30 s and 72 °C for 1 min, and a final extension for 10 min at 72 °C. The primers (5'-ATA TCC ATA TGT CTC GCT CCG TGG CCT TAG-3' and 5'-AAC TAG GGA TCC TTA CAT GTC TCG ATC CCA C-3') were designed to amplify the entire coding sequence of human β_2m cDNA. For amplification of the mature HLA-A*0201 heavy chain, PCR was performed as above except that the extension time at 72 °C was 1.5 min and the primers (5'-TAT ACA TAT GGG CTC TCA CTC CAT GAG GTA TTT C-3' and 5'-AAC CAG GGA TCC TAC ACT TTA CAA GCT GTG AGA G-3') were designed to amplify the entire coding sequence of mature A2. The resultant PCR products were cloned into the *Nde*I-*Bam*HI sites of the pET-3c vector. Randomly selected clones were *Nde*I/*Bam*HI digested and screened for the presence of a correctly sized insert. Several independent clones were submitted for DNA sequencing of the HLA-A*0201 heavy chain cDNA using the dye-labeled deoxy-terminator protocol on a 377 automated DNA sequencer (Applied Biosystems). The cloned β_2m cDNA was also confirmed by DNA sequencing analysis.

Construction of expression vector for mature β_2m

To create a β_2m expression construction with optimized codon usage and G/C content, the DNA fragment for mature β_2m was PCR amplified from the cloned β_2m cDNA using specific primers (5'-AT ATC CAT ATG ATT CAA CGT ACT CCA AAA ATT CAA GTT TAC TCA CGT CAT CC-3' and 5'-CGA CTG GAT CCT TAC ATG TCT CGA TCC CAC TTA AC-3'). The underlined codons were optimized for expression in *E. coli*^[13] by synonymous substitutions from ATC, CAG, AAG, CAG to ATT, CAA, AAA and CAA, respectively. These alterations also reduced the G/C content in the TIR. The resulting PCR product was inserted into the *Nde*I-*Bam*HI sites of the pET-3c vector, and a positive clone with a correct sized insert was confirmed by DNA sequencing. This recombinant plasmid was designated as pET- β_2m .

Construction of expression vector for extracellular domain of HLA-A2 heavy chain fused with BirA substrate peptide (BSP)

To construct an expression vector in which the HLA-A2 heavy chain was fused with BSP, the DNA fragment encoding a Gly-Ser linker and a BSP (LHHILDAQKMWVWNR) was fused to the 3' end of the cDNA encoding the extracellular domain of the HLA-A2 heavy chain (1-275) by PCR amplification from cloned HLA-A2 heavy chain cDNA with specific primers (5'-ATA CAT ATG GGT TCT CAT TCT ATG CGT TAT TTT TTT ACA TCT GTT TCC CGG CCC GGC CGC-3' and the 3' primer 5'-GCG CGG ATC CTT AAC GAT GAT TCC ACA CCA TTT TCT GTG CAT CCA GAA TAT GAT GCA GAG AGC CCG GCT CCC ATC TCA GGG T-3'). The underlined codons were

optimized for expression in *E. coli*^[13], and reduced the G/C content without any changes in amino acid sequence. These codons were changed from GGC, CAC, TCC, AGG, TTC, TTC, TCC and GTG, respectively. The resultant PCR product was *NdeI/BamHI* digested and subcloned into plasmid pET-3c. Clones with correct sized inserts were verified by direct sequencing, and the recombinant plasmid was designated as pET-A2-BSP.

Expression and isolation of recombinant A2-BSP and β_2m proteins

BL21(DE3) competent cells were transformed with either pET- β_2m or pET-A2-BSP, single colonies were used to inoculate 100 mL of LB medium, and cultures were incubated at 37 °C overnight until cells reached the stationary phase. Each stationary culture was diluted 10-fold with fresh LB medium (to 1 L) and incubated at 37 °C for a further 2 h, 0.4 mmol/L isopropyl β -D-thiogalactopyranoside (IPTG) was added, and cells were incubated for an additional 4 h. Cells were collected by centrifugation, and insoluble protein aggregates (inclusion bodies) were purified essentially as described^[16]. In brief, each cell pellet was re-suspended in 50 mmol/L Tris-HCl buffer (pH 8.0) containing 1 mmol/L EDTA, 0.1 mmol/L phenylmethylsulfonyl fluoride (PMSF) and 10 mmol/L dithiothreitol (DTT), and then sonicated on ice. The insoluble pellet was collected by centrifugation and washed with washing buffer (50 mmol/L Tris-HCl pH 8.0, 100 mmol/L NaCl, 1 mmol/L EDTA, 1 mmol/L DTT and 5 g/L Triton X-100), followed by three more rounds of sonication, centrifugation and collection. The pellet was washed three more times with washing buffer without Triton X-100 and the isolated inclusion body pellet was dissolved in 20 mmol/L 2-(N-morpholino)ethanesulfonic acid (pH 6.0, containing 8 mol/L urea, 10 mmol/L EDTA, and 0.1 mmol/L DTT). The insoluble material was pelleted by centrifugation and removed. The protein concentration of the remaining solution was determined by measuring $A_{280\text{ nm}}$ and $A_{260\text{ nm}}$, and calculated according to the empirical formula ($1.45 \times A_{280\text{ nm}} - 0.74 \times A_{260\text{ nm}} = \text{protein concentration in mg/mL}$). The protein solution was immediately frozen at -70 °C.

Refolding of monomeric HLA-A2

The HLA-A2 monomers were refolded essentially as described by Garboczi and Wiley^[17], with slight modifications. Briefly, 2 mg of peptide (NLV or GIL peptide) dissolved in DMSO was added in drops to 200 mL of pre-chilled refolding buffer (100 mmol/L Tris-HCl pH 8.0, containing 400 mmol/L L-arginine, 2 mmol/L EDTA, 5 mmol/L reduced glutathione, 0.5 mmol/L oxidized glutathione and 0.2 mmol/L PMSF). Then, 6 mg A2-BSP in 1 mL injection buffer containing 3 mol/L guanidine-HCl pH 4.2, 10 mmol/L sodium acetate and 10 mmol/L EDTA was forcefully injected to the stirring reaction through a 26-gauge needle as close to the stir bar as possible. Five micrograms of β_2m was injected similarly, and the refolding mixture was incubated at 10 °C for 3 d. At the end of the incubation, 200 mL of the refolding mixture was concentrated to 5 mL with an ultrafiltration apparatus (Amicon, Millipore, Bedford, MA, USA) containing a 10 ku molecular mass cut-off membrane,

and dialyzed against 10 mmol/L Tris-HCl buffer (pH 8.0, containing 0.2 mmol/L PMSF). The refolded monomeric HLA-A2 was centrifuged to eliminate precipitates, and then biotinylated.

Biotinylation and purification of monomeric HLA-A2

The refolded HLA-A2 was enzymatically biotinylated by incubation with BirA according to the procedure provided by the supplier (Avidity Co.). The biotinylated HLA-A2 was dialyzed against 10 mmol/L Tris-HCl buffer (pH 8.0, containing 0.2 mmol/L PMSF) and loaded onto an anion-exchanger Q-Sepharose column (2 cm×8 cm) equilibrated with the same buffer. The column was eluted with a 0-300 mmol/L NaCl linear gradient, and 1.5 mL fraction was collected. Fractions exhibiting both HLA-A2 heavy chain and β_2m bands upon SDS-PAGE analysis were pooled and concentrated to 300 μ L. The buffer of the biotinylated HLA-A2 was changed to 0.01 mol/L phosphate-buffered saline (PBS, pH 7.4) containing 0.2 mmol/L PMSF and 2 mmol/L EDTA through ultrafiltration.

Tetramerization of soluble HLA-A2 monomers

HLA-A2 tetramers were formed by mixing the biotinylated proteins with streptavidin-PE at a molar ratio of 4:1. Tetramers were analyzed by SDS-PAGE of samples prepared without boiling, in a loading buffer that contained no reducing reagent^[10].

Tetramer staining and flow cytometry

Peripheral blood mononuclear cells (PBMCs) were separated from 3 mL whole blood of two volunteers (over 40 years) by centrifugation over a Ficoll-Hypaque density gradient (Lymphoprep; NYCOMED, Norway). For staining, 1×10^6 cells suspended in 50 μ L PBS containing 20 mL/L fetal calf serum and 1 g/L sodium azide were incubated on ice for 1 h with 10 μ L of CD3-FITC, 10 μ L of CD8-CyChrome and 1 μ g of HLA-A2 tetramer. After being washed, the cells were fixed in 300 μ L of 10 g/L paraformaldehyde and detected on a FACSCalibur flow cytometer (Becton Dickinson, San Jose, CA, USA). For each sample, 50 000 events were collected and analyzed with the CELLQuest software (Becton Dickinson). The results were expressed as the percentages of tetramer-binding cells in the total T cell population.

RESULTS

Cloning of cDNA for HLA-A*0201 heavy chain and β_2m

The cDNA encoding the mature HLA-A2 heavy chain was RT-PCR amplified from total RNA of three HLA-A2 positive donors (identified as such by flow cytometry after anti-HLA-A2-FITC staining). The DNA fragments with the expected length (1 100 bp) were inserted into pET-3c, and eight independently transformed DH5a clones were identified to have the correct insert (Figure 1). DNA sequencing of these clones showed that six clones from donors 1 and 2 contained the cDNA for HLA-A*0201 heavy chain (designated pET-A2), while those from donor 3 contained the cDNA for HLA-A*0207 heavy chain. The cDNA sequence for HLA-A*0201 was submitted to GenBank (accession number AY191309).

Figure 1 Identification of clones with correct sized inserts, using *NdeI/BamHI* double digestion. Lanes 1 and 4-8: pET-A2 clones from donors 1 and 2; lanes 2 and 14: pET-3c; lanes 3 and 11: 200-bp DNA ladder; lanes 9 and 10: pET-A2 clones from donor 3; lanes 12 and 13: pET-A2-BSP.

Similarly, the cDNA encoding β_2m was cloned from the total RNA of one donor and inserted into pET-3c (data not shown). The sequence was verified by DNA sequencing and found to be identical to the published one (submitted to GenBank, accession number AY187687).

Construction of expression vectors for recombinant A2-BSP and β_2m proteins

According to Altman's strategy^[3], the DNA fragment encoding a Gly-Ser linker and a BSP (LHHILDAQKMWVWNR) was fused to the 3' end of the DNA fragment encoding the extracellular domain of HLA-A*0201 heavy chain (residues from 1 to 275) by PCR amplification of plasmid pET-A2. In order to increase the expression level in *E. coli*, our primers introduced synonymous substitutions at the 5' region, intended to reduce the G/C content of the TIR and to optimize codons for the bias usage of *E. coli*^[13,14]. The amplified DNA fragment (900 bp) was inserted into pET-3c. Two clones with the correct insert were confirmed by DNA sequencing, and the generated expression vector was designated as pET-A2-BSP (Figure 1).

The expression vector for mature β_2m was similarly constructed by PCR amplification using cloned β_2m cDNA as template. The codons at the 5' region were optimized for better expression of β_2m in *E. coli*. The sequence of the insert was verified by DNA sequencing, and the vector was designated as pET- β_2m .

Refolding and biotinylation of monomeric HLA-A2

The expression vectors pET-A2-BSP and pET- β_2m were transformed into *E. coli* BL21(DE3). The cells showed leaky expression of the two proteins, and the expression levels increased dramatically after induction with IPTG (Figure 2). The molecular mass of the recombinant β_2m was approximately 12 ku, which was consistent with that of native human β_2m , while the engineered A2 heavy chain-BSP fusion protein (A2-BSP) had the expected molecular mass of 33 ku. The expression levels of these two recombinant proteins accounted for more than 20% of the total cellular proteins (Figure 2). The yields were approximately 32 and 50 mg/L for A2-BSP and β_2m , respectively. Western blotting showed that the recombinant β_2m could react with antibodies against human native β_2m (data not shown). HLA-A2 heavy chain expression was not analyzed by Western blotting, because

Figure 2 SDS-PAGE (150 g/L) analyses of recombinant A2-BSP and β_2m proteins expressed in *E. coli* strain BL21(DE3). Lane 1: BL21 (pET- β_2m) before IPTG induction; lane 2: BL21 (pET- β_2m)+IPTG; lane 3: supernatant of BL21 (pET- β_2m) lysate; lane 4: washed inclusion body of β_2m ; lane 5: MW marker; lane 6: BL21 (pET-3c)+IPTG; lane 7: BL21 (pET-A2-BSP) before IPTG induction; lane 8: BL21 (pET-A2-BSP)+IPTG; lane 9: supernatant of BL21 (pET-A2-BSP) lysate; lane 10: washed inclusion body of A2-BSP. HC: heavy chain.

Figure 3 Analyses of refolded A2-GIL (A) and A2-NLV (B) monomers after purification and biotinylation with SDS-PAGE (150 g/L). In (A) lane 1: protein MW marker; lane 2: solubilized β_2m ; lane 3: solubilized A2-BSP; lane 4: refolded A2-GIL monomer; lane 5: biotinylated A2-GIL monomer; lane 6: peak I (β_2m) (Figure 4); lane 7: peak II (purified A2-GIL). In (B) lane 1: protein MW marker; lane 2: refolded A2-NLV monomer; lane 3: biotinylated A2-NLV monomer; lane 4: peak I (β_2m); lane 5: peak II (purified A2-NLV). HC: heavy chain.

no suitable antibody was available. Both A2-BSP and β_2m were largely expressed in the insoluble fraction (inclusion bodies), which facilitated purification through simple washing and centrifugation (Figure 3, lanes 2 and 3).

Monomeric HLA-A2 was refolded by dilution of A2-BSP and β_2m with refolding buffer in the presence of HLA-A*0201-restricted antigenic peptides. Two peptides were used to reconstitute the HLA-A2 complex. One was the immunodominant NLVPMVATV (NLV) peptide, which was derived from pp65 (pp65₄₉₅₋₅₀₃) of HCMV^[11] and used to

reconstitute the HLA-A2-NLV (hereafter referred to as A2-NLV) complex. The other was the predominant CTL epitope GILGFVFTL (GIL) peptide derived from the matrix protein (Mp₅₈₋₆₆) of influenza A virus^[15], which was used to reconstitute the HLA-A2-GIL (referred to as A2-GIL) complex. The yield of refolding was about 10-15%. The refolded A2-NLV and A2-GIL complexes appeared as two bands (A2-BSP and β_2m) on SDS-PAGE (Figure 3). After biotinylation, each complex was purified by single Q-Sepharose column chromatography. Typically, three peaks eluted from the column, as shown by monitoring of absorbance at 280 nm (Figure 4). Soluble β_2m eluted as the first peak. The second peak comprised the desired soluble HLA-A2 complex (A2-NLV or A2-GIL) consisting of a heavy chain and β_2m (Figure 3), which was of 95% purity as analyzed with the PhotoCapt Ver11.01 software (Vilber Lourmat, France). The fractions in this peak were pooled and concentrated by ultrafiltration. The third peak contained non-protein materials with a much higher absorbance at 260 nm than at 280 nm. Refolding without peptide (negative control) yielded no stable HLA-A2 complex.

Figure 4 A typical elution profile of biotinylated HLA-A2 monomer from Q-Sepharose (fast flow) column (2 cm x 8 cm).

Formation of HLA-A2 tetramers

HLA-A2 tetramers were formed by mixing the biotinylated A2-NLV or A2-GIL monomers with streptavidin-PE at a 4:1 molar ratio. SDS-PAGE analysis of the HLA-A2 tetramers could be used to estimate the extent of tetramer formation, because the complex formed between streptavidin and biotin was stable in the absence of boiling treatment and DTT^[10]. As shown in Figure 5, the single main band observed in the lanes of monomeric A2-NLV or A2-GIL corresponded to the 33 ku heavy chain, as β_2m quickly migrated to the bottom of the gel. Software analysis (PhotoCapt Ver11.01) showed that the amount of heavy chain in the A2-NLV tetramer lane was about 10-20% of that in the lane containing monomeric HLA-A2, indicating that about 80% of the A2-NLV monomer formed multimers with streptavidin-PE. The A2-GIL tetramer showed a similar extent of multimer formation.

Staining of CTLs with HLA-A2 tetramers

Finally, the A2-NLV and A2-GIL tetramers were tested by flow cytometry for their abilities to identify HCMV- or influenza-specific CD8⁺ T cells in freshly isolated PBMCs

from HLA-A2 positive and negative donors. PBMCs were analyzed by three-color flow cytometry after A2-NLV and A2-GIL tetramer staining. Background staining was performed with streptavidin-PE instead of the tetramers.

Figure 5 SDS-PAGE (75 g/L) analyses of A2-NLV and A2-GIL tetramers under non-reducing conditions without boiling. Lane 1: protein MW marker; lane 2: empty; lane 3: A2-NLV monomer (5 µg); lane 4: A2-NLV tetramer (5 µg A2-NLV monomer + 8 µg streptavidin-PE); lanes 5 and 8: streptavidin-PE (8 µg); lane 6: A2-GIL monomer (5 µg); lane 7: A2-GIL tetramer (5 µg A2-GIL monomer + 8 µg streptavidin-PE). HC: heavy chain.

Subpopulations of CD8⁺ T cells specific for either pp65₄₉₅₋₅₀₃ or Mp₅₈₋₆₆ epitopes were found in HLA-A2 positive donors by A2-NLV or A2-GIL tetramer staining. Of the total T cells, 0.19% were stained by the A2-NLV tetramer, while 0.17% bound to the A2-GIL tetramer (Figure 6). However, only 0.07% and 0.12% of T cells from the HLA-A2 negative donor were nonspecifically stained by the A2-NLV or A2-GIL tetramers, respectively, which was comparable to the control staining with streptavidin-PE (0.06%). This result suggests that these tetramers are quite specific for MHC-restricted T cells.

DISCUSSION

As the current method of limiting dilution assay (LDA) tends to underestimate CTL frequency^[2,3], other methods have been sought for the quantification of antigen-specific CD8⁺ T cells in immune responses. T cell antigen receptors (TCR) expressed on CD8⁺ T cells can recognize peptide-MHC complexes, the specific ligands on the antigen-presenting cells (APCs). Therefore, direct staining of CD8⁺ T cells with their soluble cognate ligands should be an ideal approach. However, the strategy initially failed because soluble monomeric peptide-MHC complexes have low affinities for the T-cell receptor (TCR)^[1-3]. This obstacle has been overcome by Altman *et al.*^[3]. Tetramer reagents have been shown to bind specifically to cognate T cells in numerous systems, allowing fast and direct quantification of antigen-specific T cells by flow cytometry^[3,4,8,9,18-20]. Thus, tetramer-based assays have become a powerful new technology for detecting antigen-specific T cells^[4,8,21]. However, the general application of this strategy is limited by the complex, labor intensive protocols required for preparing specific peptide-MHC tetramers.

It is difficult to prepare a large amount of MHC class I heavy chain, because the translation efficiency in *E. coli* is very

low. However, optimization of codons in the TIR has been shown to increase translation efficiency^[14]. Sato *et al.*^[12], found that the expression of wild type HLA-A*2402 heavy chain in *E. coli* is undetectable, whereas a synonymous mutant in which the TIR mammalian usage codons are replaced by those of *E. coli*, can be expressed at high levels. Lakey *et al.*^[22], showed that the production of recombinant mycobacterial proteins increases 54-fold following selective replacement of low-usage *E. coli* codons in mycobacterial proteins with high-usage *E. coli* codons. In addition, the high G/C content in the TIR can block the expression of human proteins in *E. coli*^[14]. The previous paper did not include a detailed description of the expression vector or *E. coli* system, instead of referring readers to the system used by Garboczi^[17], in which no codon or G/C content changes were described. In the present study, recombinant proteins were expressed largely in the form of inclusion bodies, which greatly facilitated isolation and purification of the refolded peptide-MHC complexes, thus simplifying the tetramer preparation procedure. In addition to the difficulty in obtaining a large amount of MHC heavy chain, the practical application of tetramers is also limited by the complexity of the necessary

preparation procedures. In this study, we reconstituted the monomeric HLA-A2 complexes based on the dilution strategy described by Garboczi^[17]. After biotinylation, the HLA-A2 monomer could be highly purified by single step ion-exchange chromatography. It should be noted that the purification in the present study was carried out in a low pressure chromatography system requiring no HPLC facilities, whereas the previous protocol included three purification steps with high performance column chromatography^[3].

The results of this study indicate that the generated reagents can be used for the detection of antigen-specific T cells. Our novel procedure for generating tetramers should be applicable for preparing other HLA-A2 tetramers or for generating tetramers of other human MHC class I alleles.

Tetramer technology is primarily used to determine the frequency of antigen-specific T cells^[3-5], and has been extensively used in evaluating the dynamics of cytomegalovirus (CMV)-specific CTL responses in humans^[5-7,9,11]. It is generally believed that adults over 40 years in developing countries are almost 100% CMV positive^[9], and that the pp65₄₉₅₋₅₀₃ NLV peptide (NLVPMVATV) is the predominant CMV epitope presented by HLA-A2 molecules^[11,23]. Quantification

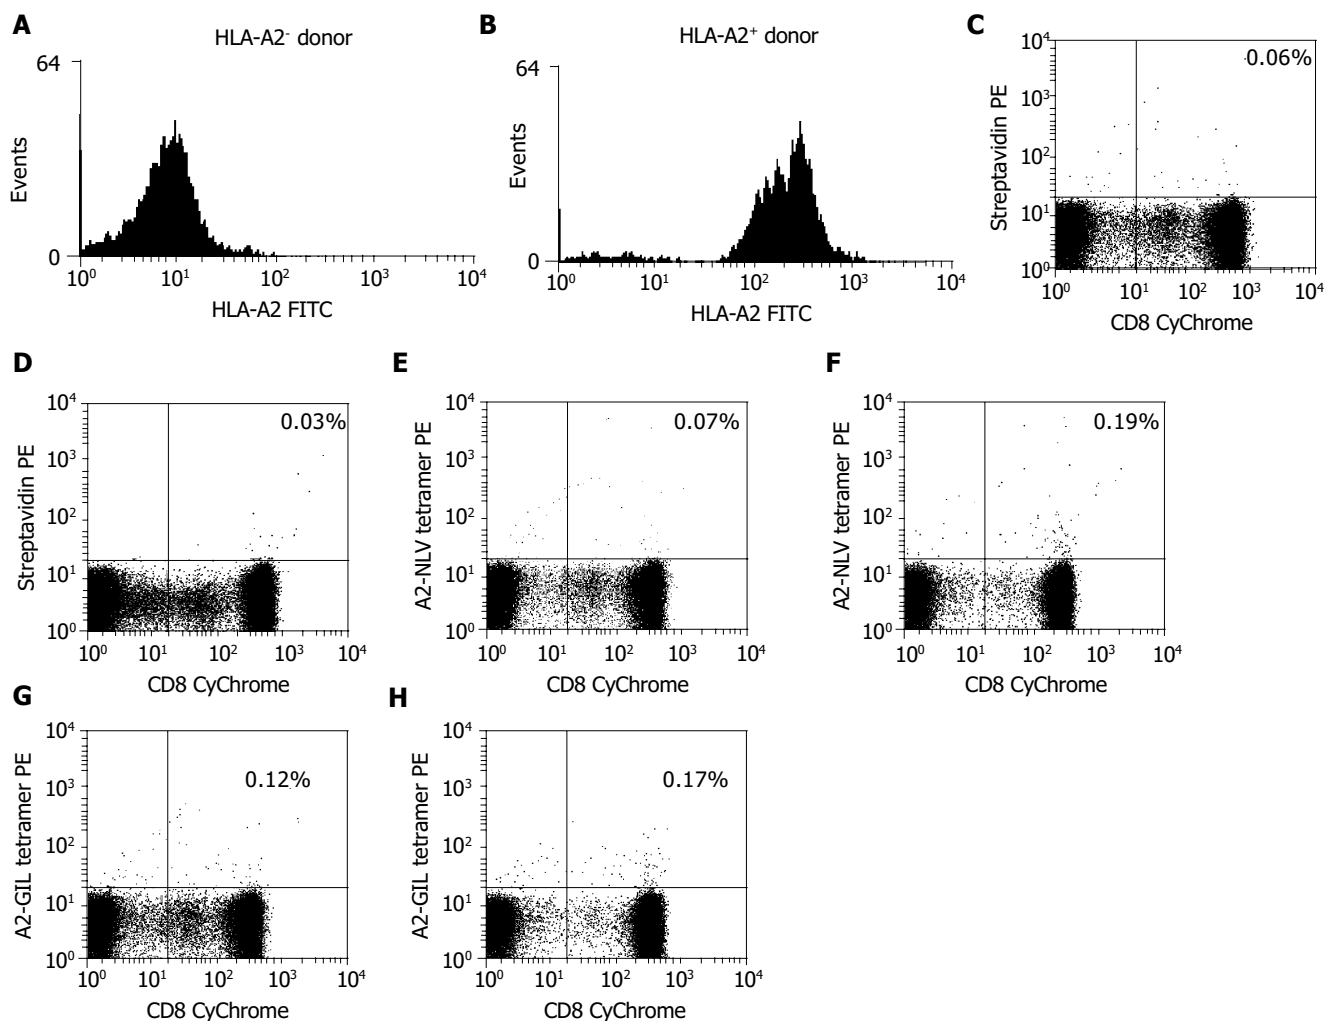

Figure 6 Flow cytometry of antigen-specific CD8⁺ T cells stained with A2-NLV tetramer (panels E and F) and A2-GIL tetramer (panels G and H) from both HLA-

A2 positive (B) and negative (A) donors. Background staining was performed with streptavidin-PE instead of the tetramers (C and D).

of specific T cells in the peripheral blood of healthy CMV carriers using an A2-NLV tetramer demonstrated that the percentage of NLV-specific CTLs in CMV carriers is about 0.02-6.19% within the CD8⁺ T cell population^[24]. In our study, tetramer staining showed that there were 0.19% NLV-specific CTLs among total T cells from the peripheral blood of a randomly selected HLA-A2-positive volunteer over 40 years, confirming again that NLV dominates the HLA-A2-restricted cellular immune response against CMV^[23]. There is substantial evidence that quantification of NLV-specific CTLs by tetramers is of clinical significance^[5-7,9,11,24,25]. Despite antiviral therapy, CMV remains an important cause of morbidity and mortality after allogeneic stem cell transplantation (SCT)^[26]. Through direct quantification of CMV-specific CD8⁺ T cells using A2-NLV tetramers, several studies demonstrated that recovery of CMV-specific CD8⁺ T cells after SCT is critical for protection against CMV disease^[6,7,25]. Accordingly, enumeration of HLA-restricted, CMV-specific CD8⁺ T cells by tetramer technology in grafts, and monitoring of these cells after SCT may constitute a rapid and sensitive tool for identifying SCT recipients at risk for developing CMV disease. Hence, tetramer technology is of value both in the development of novel transplant protocols and in clinical management of individual cases^[5-7,9,25].

It is also possible to combine tetramer staining with other flow cytometry-based assays to gain more phenotypic or even functional information on antigen-specific CTLs^[3,8,10,12]. For example, tetramer staining can be combined with intracellular detection of cytokines (e.g. interferon- γ), chemokines (e.g. macrophage inflammatory protein 1 α), and cytotoxins (e.g. perforin/granzymes) following *in vitro* antigen/mitogen stimulation to assess the functional status of tetramer-positive T cells^[27,28]. Moreover, tetramers can be used in the isolation of antigen-specific cells for characterization and even expansion of immunotherapeutic use^[11,25,29]. Conjugation of a specific tetramer with antibodies against a tumor-associated antigen has been used to redirect CMV-specific CTLs to kill tumor cells by binding to the surface of tumor cells and sensitizing them to lysis by tetramer-specific CTLs, suggesting the potential therapeutic application of tetramers^[30]. Thus, tetramer technology has opened new routes for further study of T-cell responses and tumor immunotherapy.

In summary, we have established a simplified and efficient procedure for generating peptide-MHC tetramers, a highly specific and very useful reagent with a number of important applications in cellular immune response studies. The present method may provide an alternative method for the preparation of MHC class I tetramers, and promote the use of this exciting technology.

patients with fistula (48.6%) than those without it (26.2%) ($P = 0.0388$, $OR = 2.67$).

CONCLUSION: The results suggest that *CTLA4* located at 2q33 is a determinant of UC and responsible for fistula formation in CD in the Japanese.

Abstract

AIM: To examine an association between the cytotoxic T-lymphocyte antigen 4 (*CTLA4*) gene that plays a role in downregulation of T-cell activation and inflammatory bowel disease consisting of ulcerative colitis (UC) and Crohn's disease (CD) in the Japanese.

METHODS: We studied 108 patients with UC, 79 patients with CD, and 200 sex-matched healthy controls, with respect to three single nucleotide polymorphisms (SNPs) in *CTLA4*, such as C-318T in the promoter region, A+49G in exon 1 and G+6230A in the 3' untranslated region (3'-UTR) by a PCR-restriction fragment length polymorphism method, and to an (AT)_n repeat polymorphism in 3'-UTR by fragment analysis with fluorescence-labeling on denaturing sequence gels. Frequency of alleles and genotypes and their distribution were compared statistically between patients and controls and among subgroups of patients, using χ^2 and Fisher exact tests.

RESULTS: The frequency of "A/A" genotype at the G+6230A SNP site was statistically lower in UC patients than in controls (3.7% vs 11.0%, $P = 0.047$, odds ratio (OR) = 0.311). Moreover, the frequency of "G/G" genotype at the A+49G SNP site was significantly higher in CD

INTRODUCTION

Chronic inflammatory bowel disease (IBD) is a multifactorial disorder characterized by non-specific inflammation of the gastrointestinal tract, resulting in intestinal malabsorption and immune defense abnormalities, especially an exaggerated T-cell response^[1,2]. Ulcerative colitis (UC) and Crohn's disease (CD) are common major forms of IBD. Although the etiology of IBD remains unknown, both environmental and genetic factors may contribute to the occurrence of this disorder^[3,4]. Genome-wide linkage analyses and candidate gene-based association studies have shown possible IBD-susceptibility loci at 16q12 (IBD1), 12p13 (IBD2), 6p21 (IBD3), 14q11 (IBD4), 5q31-q33 (IBD5), 19p13 (IBD6), 1p36 (IBD7), and 16p (IBD8)^[5-7]. The caspase activating recruitment domain 15/nucleotide oligomerization domain 2 gene (*CARD15/NOD2*) located at 16q12 is one of them, and its mutations were associated with CD in the Caucasians, but not in the Japanese^[8-11]. This may be due to different genetic background between the races.

As a candidate gene susceptible to IBD, we focused on the cytotoxic T-lymphocyte antigen 4 (*CTLA4*) gene located at 2q33, because CTLA4 is a T-cell receptor that binds to B7-1 (CD80) and B7-2 (CD86) during antigenic stimulation of T cells, and plays a role in downregulation of T-cell activation against another competitive receptor, CD28, which operates on upregulation of T-cell activation^[12-14]. Since *CTLA4*-deficient mice developed a lethal lymphoproliferative

disease characterized by massive T-lymphocytic infiltration in all tissues^[15,16], diminution of downregulation of T-cell activation through CTLA4 may result in an exaggerated T-cell response and subsequent continuous inflammation in the gastrointestinal mucosae, probably leading to the development of IBD. Three single nucleotide polymorphisms (SNPs) in the human *CTLA4*, i.e., a C-318T SNP in the promoter region^[17], an A+49G SNP in exon 1^[12], and a G+6230A SNP in the 3' untranslated region (3'-UTR)^[18], and an (AT)_n repeat polymorphism in 3'-UTR^[19] have been reported. Current studies showed an association of *CTLA4* polymorphic alleles with inhibitory function of CTLA4 at the mRNA and protein levels in peripheral blood mononuclear cells^[20,21], and also with various autoimmune diseases, such as Graves' disease^[18,22], rheumatoid arthritis^[23], multiple sclerosis^[24], type I diabetes mellitus^[18,25], Hashimoto's disease^[18,26], and others^[27-29], of which pathoetiology is probably similar to IBD. However, there was no association of two *CTLA4* SNPs, C-318T and A+49G, with IBD in both the Dutch and Chinese populations^[30].

In this study, we examined on whether three *CTLA4* SNPs, C-318T, A+49G, and G+6230A, and an (AT)_n repeat polymorphism in 3'-UTR are associated with IBD in the Japanese.

MATERIALS AND METHODS

Subjects

The subjects studied comprised 108 patients with UC, 79 patients with CD, and 200 gender-matched unrelated healthy volunteers as controls (Table 1). All participants were Japanese who were randomly recruited from eight general health clinics in the Nagasaki district, Japan. The study protocol was approved by the Committee for the Ethical Issue on Human Genome and Gene Analysis in Nagasaki University, and written informed consent was obtained from each participant. Diagnosis of IBD was made according to endoscopic, radiological, histological, and clinical criteria provided by both the Council for International Organizations of Medical Sciences in WHO and the International Organization for the Study of Inflammatory Bowel Disease^[31-33]. Patients with indeterminate colitis, multiple sclerosis, systemic lupus erythematosus, or other recognized autoimmune diseases were excluded from the subjects studied.

Table 1 Clinical characteristics of study subjects

Characteristics	Patients with		Controls
	UC	CD	
Number of subjects	108	79	200
Age range (yr)	14-83	17-75	20-60
Age (mean±SD)	44.0±16.9 ^b	34.5±12.7	32.5±11.1
Male/female (%)	57 (52.8)/51 (47.2)	47 (59.5)/32 (40.5)	125 (62.5)/75 (37.5)

^bP<0.01 vs controls.

Patients with UC were classified into three subgroups according to age at onset (<40 or ≥40 years), localization and extension of disease (pancolitis, left-sided colitis, or proctitis), and presence or absence of colectomy as an

indicator of severity. Likewise, patients with CD were divided into subgroups according to age at onset (<40 or ≥40 years), localization and extension of lesions (ileum, ileocolon, or colon), presence or absence of fistula, and performance of operation such as partial resection of intestine, and stricture plasty.

Determination of three SNPs and (AT)_n repeat polymorphism

Genomic DNA was extracted from whole blood of each subject using the DNA Extractor WB-rapid Kit (Wako, Osaka, Japan) according to the manufacturer's protocol. Presence or absence of polymorphic alleles at three SNP sites in the human *CTLA4*, a C/T SNP at nt -318 (C-318T) in the promoter region^[17], an A/G SNP at nt +49 in exon 1 (A-49G)^[12], and a G/A SNP at nt +6 230 (G+6230A) in 3'-UTR^[18], were determined with the PCR-restriction fragment length polymorphism methods. Polymorphic region was amplified by PCR with a GeneAmp PCR System 9700 thermal cycler (Applied Biosystems, Foster City, CA, USA) using 150 µg of genomic DNA in a 25-µL reaction solution containing 10 mmol/L Tris-HCl (pH 8.3), 50 mmol/L KCl, 1.5 mmol/L MgCl₂, 0.2 mmol/L each dNTPs, 15 pmol of forward primer: 5'-AATGAATTGGACTGGATGG-3' and reverse primer: 5'-TTACGAGAAAGGAAGCCGTG-3' for C-318T SNP^[17]; forward primer: 5'-CTGAACACCGCTC-CCATAAA-3' and reverse primer: 5'-CCTCCTCCATCTT-CATGCTC-3' for A+49G SNP; or forward primer: 5'-TGATTCATTCAGTATCTGGTGGAG-3' and reverse primer: 5'-AGGGGAGGTGAAGAACCCTGT-3' for G+6230A SNP, and 1 U Taq DNA polymerase. The amplification protocol comprised initial denaturation at 94 °C for 5 min, 35 cycles of denaturation at 94 °C for 30 s, annealing at 60 °C (C-318T), at 65 °C (A+49G), and at 62 °C (G+6230A) for 30 s, and extension at 72 °C for 30 s, and final extension at 72 °C for 5 min. The PCR products were digested with *Mse*I (New England BioLabs Inc., Beverly, MA, USA), *Bln*I (New England BioLabs Inc.), and *Tai*I (MBI Fermentas Inc., Hanover, MD, USA), to detect C-318T, A+49G, and G+6230A, respectively. All these products were subjected to electrophoresis on a 6% polyacrylamide gels and visualized with UV transilluminator (Alpha Innotech Co., San Leandro, CA, USA).

A (AT)_n repeat polymorphism in 3'-UTR of *CTLA4*^[19] was investigated by fragment analysis with fluorescence-labeling on denaturing sequence gels. Polymorphic region was amplified by PCR using 150 µg of genomic DNA in a 25-µL reaction solution containing 10 mmol/L Tris-HCl (pH 8.3), 50 mmol/L KCl, 1.5 mmol/L MgCl₂, 0.2 mmol/L each dNTPs, 15 pmol of forward primer labeled with 6-carboxyfluorescein dye (Applied Biosystems): 5'-GCCAG-TGATGCTAAAGGTTG-3' and reverse primer: 5'-AACATACGTGGCTCTATGCA-3', and 1 U Taq DNA polymerase. The amplification protocol comprised initial denaturation at 94 °C for 5 min, 35 cycles of denaturation at 94 °C for 30 s, annealing at 64 °C for 30 s, and extension at 72 °C for 30 s, and final extension at 72 °C for 5 min. The PCR products were analyzed on a 6% denaturing sequence gel with an internal size marker, GeneScan 500XL ROX (Applied Biosystems), by ABI Prism 377 genetic analyzer and ABI Prism 3100 genetic analyzer (Applied Biosystems).

Statistical analysis

Gender and age values between UC or CD patients and controls were evaluated by χ^2 -test and unpaired Student's *t*-test, respectively. Allele frequencies were estimated by the gene-counting method, and χ^2 -test was used to identify significant departures from the Hardy–Weinberg equilibrium. SNP and genotype frequencies and their distributions were compared between UC or CD patients and controls, between individuals with and without a genotype, and among subgroups of UC or CD patients, using χ^2 and Fisher exact tests. Odds ratio (OR) with 95% confidence interval was calculated by multiple logistic regression analysis using the JMP program package (version 5, SAS Institute Inc., Cary, NC, USA) and the StatView program package (version 5, SAS Institute Inc.). A *P* value of 0.05 or less was considered statistically significant.

RESULTS

Frequencies and distributions of CTLA4 polymorphic alleles

We identified frequencies and distributions of alleles at the

three SNP sites and seven alleles of the (AT)_{*n*} repeat polymorphism of *CTLA4* among the subjects examined (Table 2). Distributions of *CTLA4* polymorphic alleles in our study population well corresponded to the Hardy–Weinberg equilibrium (Table 2). The results imply that the population we studied has a homogeneous genetic background. The alleles, “C” at nt -384, “A” at nt +49, “G” at nt +6 230, and “(AT)₇” in 3'-UTR, are wild types, while other alleles are variants. Since the frequencies of two alleles, (AT)₂₀ and (AT)₂₂, were very low (<2%), they were not considered for subsequent multiple logistic regression analysis. There were no significant differences in frequency of any alleles between IBD and controls.

Frequencies and distributions of CTLA4 genotypes

Of a total of 108 UC patients, 4 (3.7%) had “A/A” genotype at the G+6230A SNP site, the incidence being significantly lower than that (22/200, 11.0%) in the controls (*P* = 0.047, OR = 0.311) (Tables 3 and 4). There were no significant

DISCUSSION

We have shown that “A/A” genotype at the G+6230A SNP site of *CTLA4* is associated with insusceptibility to UC. This suggests that individuals with “A/A” genotype at nt +6 230 may have some resistance to UC, or reversely, those with “G/G” or “G/A” genotypes are susceptible to UC. Moreover, “G/G” genotype at the A+49G SNP site was more frequently observed in CD patients with fistula than those without it. These findings suggest that *CTLA4* is one of genetic factors for the predisposition to the onset and/or development of UC and CD. However, since the number of UC patients with “A/A” genotype at the G+6230A SNP site in our study population is small (Table 5), it remains to be confirmed whether the association is reproducible in larger Japanese samples as well as in other populations. Although a previous study in the Dutch and Chinese populations did not find an association between *CTLA4* and IBD, it never dealt with the G+6230A SNP site^[30]. Therefore, the present study is the first report on an association of *CTLA4* polymorphisms with IBD.

CTLA4 consists of four exons that encode leader peptide, ligand-binding domain, transmembrane domain, and cytoplasmic tail, respectively. In humans, there are two isoforms of *CTLA4*, which are a full-length isoform (*f*/*CTLA4* transcript) and a soluble isoform (*s*/*CTLA4* transcript) which lacks exon 3 by alternative splicing. Especially, *s*/*CTLA4* is secreted and circulating in human sera^[34,35]. It binds CD80/86 molecules and subsequently inhibits T-cell proliferation *in vitro*^[35]. Expression of the human *CTLA4* mRNA isoforms by alternative splicing correlates genotype, G+6230A SNP^[18]. The ratio of *s*/*CTLA4* to *f*/*CTLA4* at mRNA level in unstimulated T cells was 50% lower in individuals with “G/G” genotype at nt +6 230 than in those with “A/A” genotype^[18]. Although expression of *CTLA4* isoforms at protein level and activities of T-cell signal pathway were not examined, individuals with “G/G” genotype at nt +6 230 may reduce the production of *s*/*CTLA4* transcript, and subsequently diminish the inhibition of T-cell activation, probably leading to an increase in T-cell proliferation and chronic inflammation in epithelial cells of the colon. Moreover, the A+6230G SNP was associated with the susceptibility to autoimmune diseases, i.e., Grave’s disease, autoimmune hypothyroidism, and type 1 diabetes mellitus^[18]. As well as these autoimmune diseases, autoantibodies against

colonic epithelial cells, such as anticolon antibodies, antitropomyosin antibodies, and antineutrophil cytoplasmic antibodies, are frequently found in sera of patients with UC^[36-38]. Thus, it is plausible that UC is also an autoimmune disease and some genetic factors are common between UC and autoimmune diseases.

Fistula formation in CD patients is one of the indicators of severity. Our results indicated that CD patients with “G/G” genotype at nt +49 more frequently had fistula. Since intracellular distribution of CTLA4 in individuals with “G/G” genotype at nt +49 was qualitatively different from that with “A/A”, and downregulation of T-cell activation in individuals with “G/G” genotype was reduced^[39], CD patients with “G/G” genotype may show progressive and severe clinical course. It remains to be investigated why the A+49G SNP is associated with fistula formation in Japanese CD patients.

In conclusion, our study showed that *CTLA4* is one of the determinants of UC and responsible for fistula formation in CD in the Japanese.

ACKNOWLEDGMENTS

We are grateful to physicians, patients, and volunteers for participating in this study. We thank Miss Naoko Sakemi and Dr. Hiroshi Soda for their support.

Abstract

AIM: The balance between oxidants and antioxidants can play an important role in the initiation and development of liver diseases. Recently, we have described a new automated method for the determination of total antioxidant capacity (TAC) in human serum and plasma.

METHODS: We measured TAC and corrected TAC (CTAC -abstraction of interactions due to endogenous uric acid, bilirubin and albumin) in 52 patients with chronic liver diseases (41 patients with primary biliary cirrhosis (PBC), 10 patients with chronic hepatitis C and 13 patients with viral HCV cirrhosis) as well as in 10 healthy controls. In 23 PBC patients measurement were also done 6 mo after treatment with ursodeoxycholic acid (UDCA). The TAC assay was based on a modification of the crocin bleaching assay. The results were correlated with routine laboratory measurements and the histological stage of PBC.

RESULTS: There were no significant differences in TAC between the various groups. However, CTAC was considerably increased in the PBC group compared to controls and cirrhotics. Analysis of these patients according to disease stages showed that this increase was an early phenomenon observed only in stages I and II compared to controls, cirrhotics and patients with chronic hepatitis C). After 6 mo of treatment with UDCA, levels of CTAC decreased to those similar to that of controls.

CONCLUSION: Patients in the early stages of PBC present with high levels of corrected total antioxidant capacity

INTRODUCTION

Evidence of enhanced production of free radicals or significant decrease of antioxidant defense have been reported in all types of liver damage. A large number of studies have focused on the pathogenetic significance of oxidative stress in liver injury as well as on therapeutic interventions with antioxidant and metabolic scavengers^[1-4]. Primary biliary cirrhosis (PBC) is a chronic granulomatous cholestatic disorder characterized by a possible immunological attack on bile ducts leading to fibrosis, cirrhosis, liver failure, and death. Several studies suggest that oxidant stress plays a key role in the progression of this disease^[5-7].

Circulation of oxidative molecules has been incriminated in lipoprotein oxidation and the generation of increased arterial deposits, ultimately leading to atherosclerosis^[8-11]. However marked hypercholesterolemia, typical of severe longstanding cholestasis in PBC patients, is not associated with an excess risk of cardiovascular disease^[12]. Since the antioxidant status in PBC has been reported to be compromised, with several important components of the antioxidant defense mechanism being significantly decreased^[5] there is a disagreement between these data.

Recently, we have introduced a new automated method for the estimation of the plasma total antioxidant capacity^[13]. In the present study we assayed and evaluated the levels of antioxidant capacity in patients with chronic liver diseases, by this method. In addition, we have also corrected these results per a number of analytes, directly affecting redox potential, thus introducing the concept of "corrected antioxidant capacity". Our results indicate that, although the total

antioxidant capacity of patients with chronic liver diseases do not differ significantly from normal subjects, the corrected antioxidant capacity is increased in PBC patients, indicating that a counterbalancing mechanism might be present.

MATERIALS AND METHODS

Patient population

The study included 41 Greek patients with PBC (35 women and 6 men, median age 62 years, range 31-85 years) followed up at the Department of Gastroenterology of the University Hospital of Heraklion, Crete. Thirty-seven of them were positive for antimitochondrial antibody (AMA)-M2 testing by immunofluorescence and by ELISA. All patients had typical biochemical pattern. Liver histology consistent with PBC was available in 38 patients. Three patients with clinical evidence of portal hypertension (esophageal varices) and positive AMA-M2 were not submitted to liver biopsy. At the time of diagnosis 25 patients (median age 58 years, range 31-71) were in histological stage I or II and 16 patients (median age 67 years, range 54-85) were in histological stage III or IV, according to Ludwig *et al.*, criteria^[14]. Laboratory data and clinical details at the time of diagnosis and prior to initiation of UDCA therapy are shown in Table 1. All patients were negative for markers of hepatitis B and C.

UDCA at a dose of 15 mg/(kg • d) was administered to all patients. Serum levels of TAC were measured in all patients prior to initiation of UDCA therapy. In 23 patients (14 in stages I-II and 9 in stages III-IV) TAC was also measured after 6 mo of UDCA therapy. No patients were withdrawn from treatment during this 6-mo period.

A group of 13 patients (8 men and 5 women, median age 53 years, range 41-64 years) with biopsy-proven postviral HCV liver cirrhosis was also enrolled. Another group of 10 patients (5 men and 5 women, median age 36 years, range 22-49 years), with biopsy-proven chronic hepatitis C was also included in the study as disease controls. No patient used alcohol. Finally, 10 healthy volunteers, matched to the PBC population for age and sex, served as a reference group.

In another group of 10 cirrhotic PBC patients and in all 13 control cirrhotics TAC levels estimations were also made in blood taken from the hepatic vein during catheterization for the measurement of wedged hepatic pressure done for assessment of portal hypertension. The group of PBC patients catheterized had been receiving UDCA treatment for at least 1 year.

Blood was collected from all patients and controls and was immediately centrifuged at 4 °C. All serum samples were stored at -70 °C until assayed. The study was approved by the local hospital Ethics committee, and written informed consent was obtained from all patients.

Determination of TAC

Plasma total antioxidant capacity (TAC) was measured on an Olympus AU-600 analyzer using the TAC kit (Medikon SA, Gerakas, Greece) as described previously^[13]. Briefly, antioxidants in the sample inhibit the bleaching of crocin from ABAP [2,2-azobis-(2-amidinopropane) dihydrochloride] to a degree that is proportional to their concentration. The assay was performed at 37 °C in the following steps: 2 µL

of sample, calibrator or control were mixed with 250 µL of crocin reagent (R1) and incubated for 160 s. Subsequently, 250 µL of ABAP (R2) were added and the decrease in absorbance at 450 nm was measured 26 s later. Values of TAC were expressed as mmol/L.

Routine clinical chemistry

Plasma uric acid, albumin, total bilirubin, alkaline phosphatase, aminotransferases, and γ-glutamyl transpeptidase were determined on an Olympus AU-600 analyzer using Olympus reagents provided by Medicon Hellas (Gerakas, Greece).

Statistical analysis

Statistical analysis of data was performed by the use of the SyStat v 10.0 program (SPSS Inc, Chicago, IL, USA), and the Origin v 5.0 program (MicroCal, Northampton, MA, USA). Paired and unpaired *t*-test were used where applicable. A *P* value less than 0.05 was considered statistically significant.

RESULTS

Total and corrected plasma antioxidant capacity in chronic liver diseases (Table 1)

Figure 1 presents levels of TAC in the several groups tested. It appears that TAC values are slightly elevated in PBC patients, but this was not of statistical significance. No statistically significant differences between any of the groups could be identified. Since all patients did not have decompensated disease, our results show that the total antioxidant capacity is unaltered in non-hospitalized patients.

Table 1 TAC and CTAC in patients and controls

Group	TAC (mmol/L)	CTAC (mmol/L)
Control	1.493±0.059	0.797±0.057
Cirrhotics	1.532±0.095	0.723±0.069
PBC	1.664±0.062	1.012±0.068
PBC I-II	1.691±0.080	1.096±0.077
PBC III-IV	1.593±0.086	0.789±0.117
CAH	1.477±0.080	0.875±0.072

Figure 1 Total plasma antioxidant capacity in chronic liver diseases. Slightly elevated TAC levels were found in PBC patients.

As TAC is a complex measurement, that is affected by a number of serum constituents, including bilirubin, we also calculated the corrected TAC. Corrected TAC (CTAC) is depicted in Figure 2. As stated in our previous work¹³, this

calculated parameter represents the fraction of circulating antioxidants, after elimination of interference by endogenous metabolites. Our previous work has shown that uric acid and bilirubin, and in a lesser degree albumin, are the major endogenous substances linearly interfering with coefficients of 0.11, 0.11, and 0.01 mmol/L of TAC per mg/dL respectively. We have therefore assayed these analytes and subtracted their interferences from the obtained values of TAC to estimate possible modifications of the antioxidant activity, without those interferences. Increased levels of CTAC in patients with PBC compared to controls ($P<0.05$) and cirrhotics ($P<0.01$) were found (Figure 2). Further analysis shows that this increase is mainly attributed to early PBC patients (stages I and II $P<0.01$, compared to controls, cirrhotics and patients with chronic hepatitis C), while late PBC patients (stages III and IV) had CTAC levels similar to controls.

Figure 2 Corrected plasma antioxidant capacity in chronic liver diseases. Increased levels of CTAC were found in PBC patients. Only early PBC patients (stages I and II) had high CTAC levels. ^a $P<0.05$, ^b $P<0.01$ vs controls.

UDCA treatment reduces TAC and CTAC values to control levels (Table 2)

In 23 patients that received 6 mo of UDCA therapy a reduction of both TAC and CTAC was noticed as shown in Figure 3. Reduction was significant in the early stages of PBC. In late stages, a reduction of CTAC was also noted but this was at the limit of statistical significance.

Table 2 TAC and CTAC in PBC patients before and after UDCA treatment

Group		Before UDCA	After UDCA	Significance
PBC Total	TAC	1.697±0.077	1.289±0.093	<0.001
	CTAC	1.068±0.071	0.601±0.093	<0.001
PBC I-II	TAC	1.762±0.082	1.243±0.124	<0.001
	CTAC	1.169±0.076	0.660±0.115	<0.001
PBC III-IV	TAC	1.527±0.184	1.410±0.049	NS
	CTAC	0.789±0.153	0.448±0.091	NS

CTAC values are higher in peripheral blood samples compared to hepatic vein samples (Table 3)

Hepatic vein samples, taken during catheterization for estimation of portal hypertension had lower values of both TAC and CTAC as shown in Figure 4 compared to peripheral

vein samples. This was significant only for the cirrhotic patients. In the treated PBC patients a similar trend was observed but it did not reach statistical significance.

Table 3 TAC and CTAC in serum samples collected from hepatic and peripheral vein in cirrhotic and PBC patients

Group		Hepatic	Peripheral	Significance
Cirrhotics	TAC	1.357±0.052	1.532±0.095	<0.05
	CTAC	0.563±0.031	0.757±0.073	<0.05
PBC	TAC	1.494±0.074	1.587±0.071	NS
	CTAC	0.821±0.032	0.913±0.042	NS

Figure 3 UDCA treatment reduces TAC and CTAC values. A significant reduction of CTAC was observed in the early stages of PBC. In late stages, a reduction of CTAC was also noted but this was at the limit of statistical significance. ^b $P<0.001$ vs TAC.

Figure 4 CTAC values are higher in peripheral blood samples compared to hepatic vein samples. Hepatic vein samples had lower values of both TAC and CTAC compared to peripheral vein samples. This was significant only for the cirrhotic patients. In the treated PBC patients a similar trend was observed but it did not reach statistical significance. ^a $P<0.05$ vs others.

DISCUSSION

Production of reactive species, including free radicals, is an integral part of human metabolism. Because of the high potential to damage vital biological systems, reactive species have now been incriminated in aging and in more than 100 disease states^[15,16]. A complex system of neutralizing antioxidants exists in plasma and intra- and extracellular fluids, but an imbalance (oxidant stress) between free radical production and use can cause damage to DNA, lipids, proteins, and other biomolecules^[5]. Nevertheless, most markers of oxidative

damage have not been fully validated^[17]. Endogenous antioxidant defenses (superoxide dismutases, H₂O₂-removing enzymes, metal binding proteins) are inadequate to prevent damage completely, so diet-derived antioxidants are important in maintaining health^[16,18,19]. The sum of endogenous plus food-derived antioxidants represents the total antioxidant capacity of extracellular fluid. The overall antioxidant capacity may give more relevant biological information compared to that obtained by the measurement of individual parameters, as it considers the cumulative effect of all antioxidants present in plasma and body fluids^[20].

A great variety of methods have been proposed for the assay of total antioxidant activity or capacity of serum or plasma^[20,21]. Many researchers have stressed the distinction between antioxidant *activity* and antioxidant *capacity*: *Antioxidant activity* corresponds to the rate constant of a single antioxidant against a given free radical; *antioxidant capacity*, on the other hand, is the number of moles of a given free radical scavenged by a test solution, independently of the capacity of any one antioxidant present in the mixture. In the case of plasma being a heterogeneous solution of diverse antioxidants the antioxidant status is better reflected by antioxidant capacity rather than activity. This capacity is a combination of all redox chain antioxidants, including several analytes such as thiol bearing proteins, and uric acid. An increase of antioxidant capacity of plasma indicates absorption of antioxidants and improved *in vivo* antioxidant status^[22], or the result of the activation of an adaptation mechanism to oxidative stress. It should be noted that, due to the participation of diverse metabolites to the antioxidant capacity of human plasma, its increase may not be necessarily a desirable condition. Indeed, in some cases, such as renal failure (uric acid), icteric status (bilirubin), hepatic damage (hypoalbuminemia) the variation of several metabolites modify plasma antioxidant capacity in a deleterious direction, a situation returning to normal values after correction of the underlying disease^[23]. Recently, we have introduced a new automated method for the assay of the plasma antioxidant activity, based on crocin bleaching. This method (the TAC assay) gives an estimation of the integrated plasma antioxidant capacity. Furthermore, we also determine the interference of a number of endogenous analytes, such as uric acid, and bilirubin, which have been found to produce a major interference of TAC, while albumin results in a smaller interference^[13].

In the present work, we have simultaneously assayed TAC and the concentrations of these analytes in patients with chronic liver diseases. As reported in the results no differences between TAC levels of the study groups were noted but patients in early stages of PBC had higher levels of CTAC. Other researchers have reported low total antioxidant capacity in PBC patients. Aboutwerat *et al.*, reported that oxidant stress, as reflected in a spectrum of lipid peroxidation and antioxidant markers, is a significant feature of early-stage PBC. They also reported that the total antioxidant capacity in whole serum (measured with an enhanced chemiluminescent technique) was significantly reduced in PBC patients but was normal in protein-free serum, suggesting that protein-bound components make an important contribution^[5]. Floreani *et al.*, measured a number

of antioxidant substances in both primary biliary cirrhosis and primary sclerosing cholangitis patients and reported significantly lower levels of retinol, alpha-tocopherol, total carotenoids, lutein, zeaxanthin, lycopene, alpha- and beta-carotene in these patients compared to healthy controls^[24]. Discrepancies among these studies and our results could be attributed to different factors:

1. The different methods of assay of TAC, measuring a number of discrete molecules. The TAC assay, used in the present study is an integrator of the totality of antioxidants circulating at a given time point in the blood.

2. The distinction of activity and capacity discussed previously. Indeed, through chain oxidative-reduction reactions, a number of antioxidants measured at a given time point may not act as antioxidants *per se*^[25].

Calculation of the corrected TAC (in which the interference of a number of endogenous metabolites has been subtracted) appears to provide a better estimate of the real antioxidant activity of the organism. However, the interpretation of the changes in plasma or serum antioxidant capacity depends upon not only the method used in detecting these changes, but also the conditions under which the plasma or serum antioxidant capacity is determined, because the determined antioxidant capacity reflects changes in a dynamic system. Furthermore an increased antioxidant capacity in plasma or serum is not necessarily a desirable condition if it is due to an adaptive response to increased oxidative stress at an early stage^[21]. Our finding of increased CTAC in the early stages of PBC may reflect such an early response.

Ursodeoxycholic acid has been reported of having a marginal therapeutic effect for primary biliary cirrhosis^[26]. Ursodeoxycholic acid treatment reduces intracellular hydrophobic bile acid levels and thereby may have a cytoprotective effect on cell membranes^[27]. It has also been reported that UDCA reduced the deoxycholic acid-associated loss of the mitochondrial membrane potential and decreased the production of reactive oxygen species^[28-30]. Our finding of TAC and CTAC reduction after UDCA treatment especially in the early stages of PBC maybe an indication that UDCA contributes to the normalization of the oxidative status in PBC patients.

Finally this is the first report that presents evidence of increased total antioxidant capacity originating from the periphery compared to the hepatic veins in patients with viral cirrhosis. Although the group of PBC patients used in this study had received UDCA treatment a similar trend can be noticed. Whether this is a feature of cirrhosis or a universal phenomenon cannot be concluded from our data. Although similar measurements cannot be performed in normal subjects, it would be interesting to further validate this result with studies on a bigger PBC population.

In conclusion, CTAC is considerably increased in the serum of PBC patients of stages I and II, but not in patients with viral cirrhosis or chronic hepatitis C. This increased antioxidant capacity in serum maybe due to an adaptive response to increased oxidative stress. Treatment with UDCA decreased the levels of CTAC to values similar to those of controls indicating a possible normalizing effect of UDCA on the oxidative status in PBC patients. Further study is needed for the finding of higher levels of CTAC in blood

samples drawn from peripheral veins compared to samples from hepatic veins in cirrhotic patients.

Abstract

AIM: Persistent cholestasis is a rare complication of severe trauma or infections. Little is known about the possible pathomechanisms and the clinical course.

METHODS: Secondary sclerosing cholangitis was diagnosed in five patients with persistent jaundice after severe trauma (one burn injury, three accidents, one power current injury). Medical charts were retrospectively reviewed with regard to possible trigger mechanisms for cholestasis, and the clinical course was recorded.

RESULTS: Diagnosis of secondary sclerosing cholangitis was based in all patients on the primary sclerosing cholangitis (PSC)-like destruction of the intrahepatic bile ducts at cholangiography after exclusion of PSC. In four patients, arterial hypotension with subsequent ischemia may have caused the bile duct damage, whereas in the case of power current injury direct thermal damage was assumed to be the trigger mechanism. The course of secondary liver fibrosis was rapidly progressive and proceeded to liver cirrhosis in all four patients with a follow-up >2 years. Therapeutic possibilities were limited.

CONCLUSION: Posttraumatic sclerosing cholangitis is a rare but rapidly progressive disease, probably caused by ischemia of the intrahepatic bile ducts via the peribiliary capillary plexus due to arterial hypotension. Gastroenterologists should be aware of this disease in patients with persistent

INTRODUCTION

For a long time it is known that after severe trauma marked cholestasis can occur^[1-3]. Different reasons were held responsible for this including hepatic hypoxia, inflammation, and mass transfusions^[1,4]. Unfortunately, cholangiographic studies to detect changes of the bile ducts to exclude obstructive jaundice were not done, primarily as most of these studies were performed in the pre-ERCP era.

On the other side, gastroenterologists are occasionally confronted with patients with a history of persistent cholestasis who have survived life-threatening events with long-term stays in intensive care units. In the diagnostic work-up ERC in some of these patients shows a PSC-like picture with strictures and dilatations of the intrahepatic bile ducts.

Except one recent report by Engler *et al.*^[5], these patients are characterized badly in the literature. Therefore, we report on five patients with secondary sclerosing cholangitis after life-threatening injuries in order to demonstrate the clinical course, evaluate measures for diagnosis, and discuss possible trigger mechanisms for posttraumatic sclerosing cholangitis.

MATERIALS AND METHODS

All five patients (one woman and four men; age 18-71 years) presented with acute or persistent cholestasis. Three of them were seen as outpatients between January 2001 and June 2003, 4 to 22 mo after occurrence of cholestasis (Table 1). Patient 5 was seen as consultant during the initial stay of the patient on the intensive care unit of a burn clinic after

occurrence of jaundice, patient 1 is a former case of one of the hospitals that has already been published and who was re-evaluated^[6].

Time between the occurrence of cholestasis and definitive diagnosis ranged between 2 and 27 mo.

All patients experienced life-threatening injuries and needed long-term treatment on intensive care units (ICU) (from 23 to 88 d, Table 1). Mechanical ventilation was necessary in all patients (from 13 to 62 d). Temporary acute renal failure occurred in patients 3 and 4 (maximum creatinine 3.6 mg/dL [-1.0] on d 5 and 1.6 mg/dL on d 4, respectively). In all patients several surgeries had to be performed (without abdominal surgery), in three of them pleural drainages were necessary.

The charts of these patients at their initial hospital stay were intensely reviewed, especially concerning periods of hypotension, therapy with vasopressors and RBC units, septic fever, antibiotics, mechanical ventilation, and liver function tests to find triggers for subsequent bile duct damage. Pre-injury liver function tests were documented if available. Diagnostic work-up included ERC, liver biopsy, imaging studies of the liver and vessels of the liver hilus (ultrasound, doppler ultrasound, CT, and/or MRI), and the exclusion of other liver diseases (e.g. viral hepatitis, hereditary, and autoimmune liver diseases). Liver biopsies (also from hospitals outside) were re-evaluated by one pathologist. The further course was observed and recorded.

For the purpose of the study an increase in liver function tests more than twice above the upper limit of normal was defined abnormal.

RESULTS

Before the trauma no patient had known liver disease. No comorbidities were present with the exception of patient 3 (arterial hypertension, cardiac arrhythmias). No patient reported about alcohol abuse. On hospital admission patient 5 (power current injury) had increased values of ALT (alanine aminotransferase) and AST (aspartate aminotransferase) due to direct thermal cell damage. In all other patients liver function tests were normal on admission. No other liver diseases or thrombosis of hepatic artery and veins were found.

Early course

In all patients as the first sign of bile duct damage a permanent increase of GGT (gamma glutamyl transferase) twice above the upper limit of normal was first documented between d 4 and 11 (Table 2). Alkaline phosphatase (AP) and bilirubin rose during the next 2 weeks in all but patient 1 in whom bilirubin increased after four weeks and patient 2 whose bilirubin levels according to a milder course of cholestasis reached twice the upper limit of normal only once. Aminotransferases always increased secondary to signs of cholestasis (Table 2). As an example the early course (first month) of AST, ALT, GGT, AP, and bilirubin in patient 3 is shown in Figure 1A.

Possible reasons for bile duct damage

Details of different parameters during intensive care of the patients are shown in Table 2.

Table 1 Summary of patients' characteristics

	Patient 1	Patient 2	Patient 3	Patient 4	Patient 5
Sex	Female	Male	Male	Male	Male
Age (yr)	56	41	56	71	18
Initial event	Room fire	Motorbike accident	Tractor accident	Fall from a raised hide	Power current accident and fall
Injuries	Burn injury: 34 % of body surface (hands, head, neck, back)	Polytrauma with avulsions (left subclavian artery, forearm, anterior tibial artery) and fractures (left humeral shaft, pelvis, both lower legs)	Polytrauma with serial rib fracture, hemothorax, pleural effusion, fracture of right joint ankle	Polytrauma with burst fractures of lumbar spine, paraplegia, rib fractures, pneumothorax	Burn injury (36 % of body surface), multiple rib fractures, hemothorax, fractures of the thoracic vertebrae 5 to 9
Intensive care (d)	58	23	34	26	88
Time from occurrence of cholestasis until diagnosis (mo)	4	27	4	13	2
Treatment start with UDCA	mo 4	mo 22	mo 4	mo 13	mo 1
Follow-up(mo)	55 (death)	48	41	33	12
Complications	Liver cirrhosis (Child-Pugh C), variceal bleeding, death due to liver insufficiency	Small intrahepatic gallstones after 6 mo (endoscopically extracted), liver cirrhosis (Child-Pugh A)	unbearable pruritus during first year, liver cirrhosis (Child-Pugh A)	liver cirrhosis (Child-Pugh B), recurrent stomal bleeding	-

UDCA: urso deoxycholic acid.

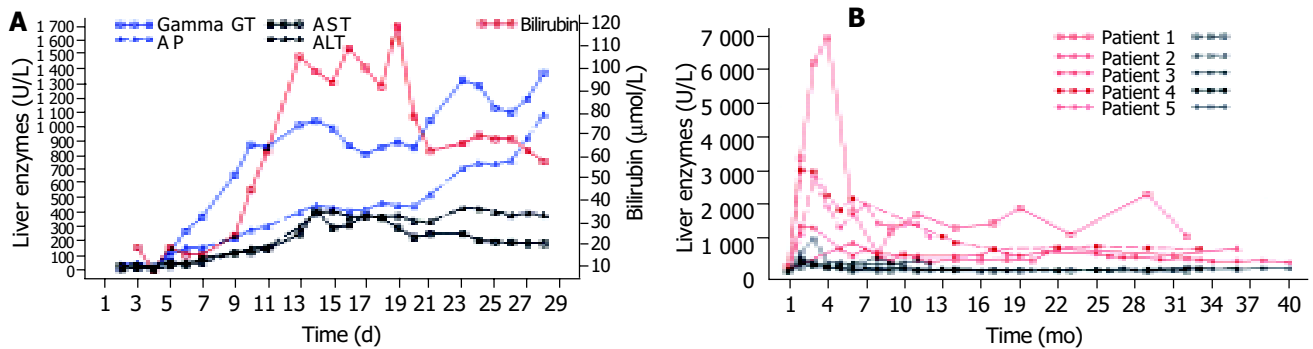

Figure 1 A: Liver function tests of patient 3 in the first month showing the strong increase of cholestasis followed by a milder rise of aminotransferases; **B:** Long-time course of AP (red) and ALT (black) of all patients showing the initial strong

increase of AP with a subsequent slow decrease and only a mild initial rise of ALT with nearly normal values in the long term.

Severe arterial hypotension with a systolic blood pressure of ≤ 70 mmHg as a possible cause of bile duct ischemia occurred in four patients. Only patient 5 experienced no hemodynamic instability throughout the whole course. In contrast to all other patients aminotransferases were already increased at clinic admission and nearly normalized during the following days. According to the pattern of his burns current flow through the body was diagnosed. Therefore, a direct thermal damage of the intrahepatic bile ducts can be suspected.

Two patients (patients 2 and 3) suffered of sudden strong blood loss requiring mass transfusions in patient 2 (30 RBC units, 11 fresh frozen plasma units, and four platelet concentrates during the first four hours after hospital admission), whereas a moderate decrease of the hemoglobin occurred in the other patients. After ICU admission all patients received parenteral nutrition via central venous lines, and additional enteral feeding via a nasogastric tube was

started in all cases between d 2 and 5.

Imaging findings

Imaging findings are shown in Table 3.

Ultrasound Ultrasound was repeatedly performed in all patients. Depending on the time since occurrence of cholestasis different findings were recorded (Table 3).

In the early phase (first 2 mo) the liver was described as normal or enlarged with homogeneous or hyperechoic parenchyma, bile ducts were normal in all patients, gallbladder sludge was seen in four patients. Later on liver parenchyma got more and more inhomogeneous and signs of liver cirrhosis (nodularity/irregularity of liver surface, inhomogeneous parenchyma, splenomegaly) occurred. Intrahepatic bile ducts showed segmental dilatation in two patients after 12 to 24 mo, whereas the common bile duct remained normal in all patients.

Table 2 Patients' data and important findings during the early course at the intensive care unit

	Patient 1	Patient 2	Patient 3	Patient 4	Patient 5
Time of increase of liver function tests $> 2 \times$ ULN (d)					
GGT ¹	10 ¹	6	5	4	11
AP	18	18	9	12	15
Bilirubin	36	6 ²	10	8	13
AST	18	52	9	12	16
ALT	18	23	9	7	19
Mechanical ventilation (d)	36;	13;	25;	16;	62;
	PEEPmax. 6 mmHg; FiO ₂ not documented	PEEPmax. 10 mmHg; FiO ₂ max. 0.6	PEEPmax. 8 mmHg; FiO ₂ max. 0.6	PEEPmax. 15 mmHg; FiO ₂ max. 0.7	PEEPmax. 20 mmHg; FiO ₂ max. 0.6
Severe hypotension (systolic blood pressure < 70 mm Hg) ³	d 1 (2 h)	d 1 (45 min)	d 2 (30 min) and d 3 (60 min)	d 1 (30 min)	None
Vasopressor therapy	Dobutamine d 1-8 dopamine d 1-18 norepinephrine d 1-7	None	Norepinephrine d 3-5 and d 9-17	Norepinephrine d 2-4	None
Minimum hemoglobin ³	7.3 g/dL (d 3)	2.4 g/dL (d 1)	7.2 g/dL (d 3)	8.6 g/dL (d 1)	7.9 g/dL (d 4)
Transfusions (RBC units) ³	30	34	10	10	24
Fever (> 38.0 °C)	d 7-16	d 6-13	d 2-25	d 5-17	d 2-20
Antibiotics ³	Cefotaxim, imipenem, sulbactam, mezlocillin	None	Piperacillin/sulbactam	None	Piperacillin/tazobactam, ciprofloxacin, meropenem, levofloxacin, fluconazol

ALT: alanine aminotransferase; AP: alkaline phosphatase; AST: aspartate aminotransferase; FiO₂max.: maximum fraction of inspired oxygen; GGT: gamma glutamyl transferase; PEEPmax.: maximum positive end-expiratory pressure; ULN: upper limit of normal ¹No control of liver function tests between d 4 and 10; ²A bilirubin value $2 \times$ ULN was noted only once at d 6; ³Until increase of GGT $\geq 2 \times$ ULN.

Table 3 Diagnostic findings in posttraumatic sclerosing cholangitis during the course of the disease (ultrasound, MRT/MRCP, ERCP, and liver histology)

	Patient 1	Patient 2	Patient 3	Patient 4	Patient 5
1 - 2 mo					
Ultrasound	L normal, BD normal, GB sludge	L normal, BD normal, GB sludge	L normal, BD normal, GB sludge	L normal, BD normal, GB sludge	L enlarged, hyperechoic, BD normal, GB contracted, splenomegaly
ERC	Stenoses and loss of IHBD, CBD normal, GB normal	-	IHBD irregular, CBD normal, GB normal	-	-
MRT/MRCP	-	-	-	L normal, BD normal, GB normal	-
4 - 6 mo					
Ultrasound	L cirrhosis, BD normal, GB stones	L inhomogeneous, BD normal	L inhomogeneous with hyperechoic areas alongside the IHBD, BD normal, GB normal,	-	L enlarged, BD normal, BD normal, splenomegaly
ERC	-	-	IHBD: multifocal short strictures and dilatations, CBD normal, GB normal (Figure 2)	-	IHBD irregular, beaded appearance, CBD normal, GB normal
Liver histology	Substantial cholestasis; inflammation of the portal tracts, liver lobules, and sporadically the bile ducts; feathery degeneration of hepatocytes; fibrosis around bile ducts; regenerative bile duct proliferations	Portal tract inflammation, occasionally lymphocytes in bile duct epithelium; several necrotic foci with foamy macrophages in the liver acini; bridging fibrosis; regenerative bile duct proliferations	Canalicular bile thrombi; edematously swollen portal tracts; inflammatory infiltrates, esp. around bile ducts; occasionally feathery degeneration of hepatocytes; minimal fibrosis	-	-
12 - 24 mo					
Ultrasound	L inhomogeneous cirrhosis BD normal, GB stones and sludge, splenomegaly, distinct ascites	L enlarged, inhomogeneous, hyperechoic areas segment 7/8, IHBD slightly dilated, CBD normal, GB stones, splenomegaly	L cirrhosis, BD normal, GB normal, splenomegaly	L cirrhosis, IHBD slightly dilated, CBD normal, GB normal, splenomegaly	-
ERC	stenoses and loss of IHBD, CBD normal, GB normal	IHBD: loss and stenoses of right-sided bile ducts, a long, stretched running left bile duct (suitable to liver hypertrophy), CBD normal, GB stones	-	IHBD: multifocal high-grade strictures and dilatations on the left side, bile ducts on the right side not presentable, CBD normal	-
MRT/MRCP	-	L atrophy of right liver, hypertrophy of left liver; reduced signal intensity of segments 2 and 3 and partly 7 and 8; IHBD segmentally dilated, CBD pseudoobstruction, GB stones, splenomegaly	L macronodular cirrhosis, CBD pseudoobstruction, splenomegaly	-	-
Liver histology	No cholestasis; complete liver cirrhosis	-	Occasionally canalicular cholestasis; mild portal inflammation (predominantly lymphocytes); some regenerative bile duct proliferations; mild fibrosis; (sampling error ?)	Substantial cholestasis (bile thrombi in dilated canaliculi); occasionally lymphocytes in the epithelium of bile ducts; numerous regenerative bile duct proliferations in the periphery of portal tracts; cirrhosis (Figure 4)	

BD: bile ducts; CBD: common bile duct; GB: gallbladder; IHBD: intrahepatic bile ducts; L: liver.

Computed tomography CT scans performed in patient 1 18 mo and in patient 3 10 d and 4 mo after the onset of cholestasis confirmed sonographic findings.

MRT/MRCP MRT/MRCP in patient 3 in the early phase showed normal abdominal findings. In two patients MRT/MRCP was performed after 2 years. In patient 2 MRT/MRCP disclosed atrophy of the right liver, hypertrophy of the left liver, a reduced signal intensity in segments 2 and 3 and partly 7 and 8, and peripheral segmental dilatation of intrahepatic bile ducts rather unusual findings (Figure 2). In patient 3 signs of liver cirrhosis with large nodules and inhomogeneous liver parenchyma were present.

ERC Diagnostic ERC was performed in all patients. Together with the history it led to diagnosis in all patients. Already three weeks after first signs of cholestasis slight changes of the intrahepatic bile ducts were noticed (patient 3). After four to six months multifocal strictures and dilatations of the intrahepatic bile ducts (comparable to lesions in primary sclerosing cholangitis) occurred (Figure 3), that were also present after 12-24 mo. The common bile duct and the cystic duct were normal in all patients at all times.

Liver histology

Liver biopsy was performed in four patients (in no one in the acute phase), at least once in three patients and three times in one patient (patient 3) (Table 3). After 4-6 mo

portal inflammation (predominantly lymphocytes) with involvement of the bile ducts, necrosis of periportal hepatocytes, fibrosis of different degree, and depending on the biochemical extent of cholestasis bile thrombi were present. After 12-24 mo complete liver cirrhosis was diagnosed in patients 1 and 4, whereas in patient 3 only mild fibrosis was diagnosed, possibly due to a sampling error (clinically cirrhosis). Inflammation of the portal tracts with involvement of bile ducts was still present. Regenerative bile duct proliferations were a prominent feature. As an example liver histology of patient 4 is shown in Figure 4.

Follow-up, treatment, and complications

The patients were followed between 12 and 55 mo after trauma (Table 1).

The long-time courses of AP and ALT of all patients are shown in Figure 1B.

All patients were treated with ursodeoxycholic acid after different periods of time (Table 1).

Liver cirrhosis was diagnosed clinically and/or histologically in all four patients with a follow-up of >2 years. It occurred already at mo 5 in patient 4. In this case it was diagnosed macroscopically during colostomy which was performed due to fecal incontinence following paraplegia. Decompensation of liver cirrhosis with large amounts of ascites occurred in patient 1 already after 18 mo. This patient died after 55 mo due to hepatic insufficiency.

Figure 2 MRT of patient 2 (T1-weighted after contrast medium) showing an area centrally in the liver with reduced signal intensity, a dilatation of the bile duct in segment 6, and splenomegaly.

Figure 3 ERCP of patient 3 showing a normal cystic and common bile duct, but multifocal short strictures and dilatations of the intrahepatic bile ducts (4 mo after occurrence of cholestasis).

Figure 4 Liver histology of patient 4 (13 mo after occurrence of cholestasis). **A:** Portal inflammation, severe cholestasis with bile thrombi, HE (20x); **B:** Lymphocytic infiltration of a small bile duct (arrow). Periodic acid Schiff's reaction

after treatment with diastase (100x); **C:** Immunostaining for cytokeratin 7. Regenerative bile duct proliferations show a strong expression of cytokeratin 7 (25x).

Liver transplantation was planned for patient 3 after 4 mo, but due to improvement of liver function tests and clinical symptoms transplantation was cancelled. Patient 5 is designated for liver transplantation.

DISCUSSION

Cholestasis is common in long-term ICU patients. However, in most cases it is mild and resolves within weeks after clinical improvement of the patient.

Secondary sclerosing cholangitis after trauma ("posttraumatic SC") is a rare and probably underdiagnosed complication of severe trauma with to our knowledge only two publications in the literature^[5,6]. Our patients shared the following findings, thus leading to the diagnosis: (1) a severe, life-threatening trauma; (2) slowly increasing signs of cholestasis with a secondary moderate rise of aminotransferases; (3) the typical PSC-like appearance of the intrahepatic bile ducts with multifocal strictures and dilatations; and (4) the exclusion of other liver diseases. All patients except patient 5 had normal liver function tests at hospital admission. After a few days a slow, but constant increase of signs of cholestasis was noted with a subsequent rise of aminotransferases that never exceeded 15 times of ULN. This differs from "shock liver" where an acute elevation of the aminotransferases to at least 20 times ULN is required for diagnosis^[7]. According to our results ERC is of essential importance for the diagnosis. Probably earlier than MRC, ERC best shows the PSC-like bile duct changes (multifocal strictures and dilatations, beaded appearance) that occur only intrahepatically in posttraumatic SC. The possibility to aspirate bile for microbiological examination is another advantage of ERC compared to all non-invasive imaging procedures as to our experience and some case reports in the literature in some intensive care patients with severe, long-lasting infections requiring mechanical ventilation jaundice may be caused by secondary bacterial or fungal cholangitis without preexisting biliary obstruction^[8,9]. The value of ultrasound, CT, and MRT in the early course is to exclude obvious biliary obstruction, later they may help to diagnose secondary development of liver cirrhosis.

Posttraumatic SC seems to be rapidly progressive. Liver cirrhosis was diagnosed clinically or by liver biopsy in all patients with a follow-up of more than 2 years, in one patient already after 5 mo, in the others after 18-24 mo. After decompensation of liver cirrhosis at mo 18 and esophageal variceal bleeding at mo 22, one patient died after 55 mo due to hepatic insufficiency. This rapidly progressive course compares well with the experience of Engler *et al.*^[5]. In their series all four patients with a follow-up of more than 2 years developed liver cirrhosis, three of them during the second year.

All patients were treated with UDCA after 1-22 mo. As this was an uncontrolled retrospective study clear conclusions concerning the therapeutic value of UDCA are not possible, but the efficacy seems to be rather limited. In patients with posttraumatic SC and end-stage liver disease liver transplantation may be the only therapeutic option. In contrast to Engler *et al.* we are not convinced that endoscopic interventions for treatment of strictures (dilatation or

stenting) are beneficial as bile duct strictures were multifocal and localized intrahepatically in all of our patients. This is comparable to PSC where only patients with a dominant extrahepatic stricture appear to have some potential benefit from endoscopic treatment^[10]. Even in the patients of Engler *et al.*^[5], endoscopic therapy (with the additional risk of secondary bacterial cholangitis) did not stop disease progression. However, for diagnostic reasons early ERC appears necessary.

Interestingly, bilirubin levels of all patients decreased without intervention after 2-6 mo. Proliferation of bile ducts in the portal tracts with metaplasia of hepatocytes may have improved bile flow. This phenomenon was also described in drug-induced prolonged cholestasis with ductopenia^[11]. However, posttraumatic SC progresses in spite of decreasing bilirubin levels.

What are the possible mechanisms for posttraumatic sclerosing cholangitis? As shown in Table 2 we examined several factors that are discussed in the literature, which could have contributed to bile duct damage^[5,6,12]. In our opinion the dominant cause is arterial hypotension with subsequent ischemia of the intrahepatic bile ducts which occurred in four of the five patients in the early course after the accident (in patient 5 according to the pattern of burns current flow through the body was diagnosed suggesting a direct thermal damage of the intrahepatic bile ducts). It can be assumed that through temporary hypoperfusion, possibly aggravated by vasopressor therapy, an ischemic damage of the intrahepatic bile duct epithelium occurred which led to secondary scarring of the bile ducts and subsequent cholestasis. In contrast to shock liver the initial damage is not characterized by rapidly increasing aminotransferases as the liver via the portal vein - seems to be perfused sufficiently. After the acute ischemic phase, parallel to bile duct changes, increasing signs of cholestasis occur. Later, aminotransferases raise secondary to bile duct obstruction as in other obstructive bile duct diseases. Possibly due to the non-reversible scarring of the bile ducts with persistence of cholestasis and comparable to experimental bile duct ligation liver fibrosis and cirrhosis develop rather quickly^[13].

In all of our patients only the intrahepatic bile ducts were affected. The reason may be the blood supply of the bile ducts^[14-16]. Whereas the extrahepatic biliary system seems to be well supplied, mainly by two parallel to the common bile duct running arteries which are fed by branches of eight arteries on the average (retroduodenal artery, gastroduodenal artery, left and right hepatic artery, *etc.*), the intrahepatic ducts are supplied by a nonaxial network of small arteries deriving only from the right and left hepatic artery. They form a plexus of arterioles, venules, and capillaries within the peribiliary adventitia with a second plexus within the biliary wall primarily composed of capillaries ("peribiliary capillary plexus"). This structure, possibly especially the blood supply via the left and right hepatic artery as functional end arteries, may cause the vulnerability of the intrahepatic bile ducts to ischemic events. Except in the periphery of the liver portal-venous blood plays no role in the supply of the bile ducts.

Other factors like systemic inflammation or transfusions

may contribute to progressing cholestasis in some patients, but may be of minor importance.

In conclusion, after severe, life-threatening injuries a small number of patients develop jaundice that is caused by multiple intrahepatic bile duct strictures. The main trigger may be ischemia and subsequent damage of the bile ducts due to transient arterial hypotension. Slowly progressive cholestasis after severe injury in patients without prior liver disease is the hallmark of posttraumatic sclerosing cholangitis. The diagnosis is confirmed by ERC. The major characteristics of posttraumatic SC are summarized in Table 4. The course of this form of secondary sclerosing cholangitis appears to be rather progressive without promising therapeutic options (except probably liver transplantation). Gastroenterologists should be aware of this disease in patients with cholestasis after severe trauma.

Table 4 Characteristics of posttraumatic sclerosing cholangitis

1	No former liver disease
2	Severe life-threatening injury with temporary severe arterial hypotension
3	Slowly increasing signs of cholestasis
4	Secondary moderate rise of aminotransferases
5	PSC-like appearance of intrahepatic bile ducts (multifocal strictures and dilatations)
6	Exclusion of other liver diseases (esp. hepatic artery thrombosis)

Abstract

AIM: Complete resection of the bile duct carcinoma is sometimes difficult by subepithelial spread in the duct wall or direct invasion of adjacent blood vessels. Nonresected extrahepatic bile duct carcinoma has a dismal prognosis, with a life expectancy of about 6 mo to 1 year. To improve the treatment results of locally advanced bile duct carcinoma, we have been conducting a clinical trial using regional hyperthermia in combination with chemoradiation therapy.

METHODS: Eight patients complaining of obstructive jaundice with advanced extrahepatic bile duct underwent thermo-chemo-radiotherapy (TCRT). All tumors were located in the upper bile duct and involved hepatic bifurcation, and obstructed the bile duct completely. Radiofrequency capacitive hyperthermia was administered simultaneously with chemotherapeutic agents once weekly immediately following radiotherapy at 2 Gy. We administered heat to the patient for 40 min after the tumor temperature had risen to 42 °C. The chemotherapeutic agents employed were cis-platinum (CDDP, 50 mg/m²) in combination with 5-fluorouracil (5-FU, 800 mg/m²) or methotrexate (MTX, 30 mg/m²) in combination with 5-FU (800 mg/m²). Number of heat treatments ranged from 2 to 8 sessions. The bile duct at autopsy was histologically examined in three patients treated with TCRT.

RESULTS: In respect to resolution of the bile duct, there were three complete regression (CR), two partial regression (PR), and three no change (NC). Mean survival was 13.2±10.8 mo (mean±SD). Four patients survived for more than 20 mo. Percutaneous transhepatic biliary drainage (PTBD) tube could be removed in placement of self-expandable metallic stent into the patency-restored bile duct after TCRT. No major side effects occurred. At

autopsy, marked hyalinization or fibrosis with necrosis replaced extensively bile duct tumor and wall, in which suppressed cohesiveness of carcinoma cells and degenerative cells were sparsely observed.

CONCLUSION: Although the number of cases is rather small, TCRT in the treatment of locally advanced bile duct carcinoma is promising in raising local control and thus, long-term survival.
