### Abstract

Recent years have witnessed tremendous progress in our understanding of irritable bowel syndrome (IBS). It is evident that this is a truly global disease associated with significant symptoms and impairments in personal and social functioning for afflicted individuals. Advances in our understanding of gut flora-mucosal interactions, the enteric nervous system and the brain-gut axis have led to substantial progress in the pathogenesis of symptoms in IBS and have provided some hints towards the basic etiology of this disorder, in some subpopulations, at the very least. We look forward to a time when therapy will be addressed to pathophysiology and perhaps, even to primary etiology. In the meantime, a model based on a primary role for intestinal inflammation serves to integrate the various strands, which contribute to the presentation of IBS

### EPIDEMIOLOGY

In recent years, the true prevalence of IBS has been documented in many parts of the world. What is truly remarkable is how common IBS is, no matter where you look! It is absolutely clear, for example, that IBS is a common disorder, not only in North America and Western Europe but throughout Asia and Latin America and even in parts of Africa<sup>[1]</sup>. However, caution needs to be exerted in the interpretation of such studies. Typically,

community or hospital-based surveys of IBS prevalence have utilized some iteration of Rome or Manning criteria as their diagnostic instrument; whether these diagnostic tools, developed in the West, are equally valid in emerging nations, where confusion with symptoms related to chronic parasitic infestations, for example, may be an issue. Clearly, we have much to learn from the epidemiology and natural history of IBS or IBS-like symptoms in this context.

### DIAGNOSIS

Diagnostic confusion has also emerged as an issue in the West. Here, still the debate continues regarding potential overlap between IBS, IBD and celiac sprue<sup>[2]</sup>. Do reported instances of celiac sprue among patients with “typical” IBS, or the occurrence of IBS-type symptoms among IBD patients in apparent remission, reflect a true association between these disorders and, thereby, the effects of low grade inflammation on enteric nerve and muscle function, or does such apparent overlap simply serve to emphasize the non-specificity of many gastrointestinal symptoms? Explaining it simply, the gut has a limited symptomatic repertoire which may not allow us to differentiate between those complaints which are consequent upon continuing (but otherwise undetected) inflammation in IBD or in the non-compliant celiac and those which arise from a functional disorder, *per se*. Progress in this contentious area must await readily applicable measures of disease activity which are sufficiently sensitive and accurate to provide a true definition of remission.

In the meantime, how should the clinician interpret these dilemmas? It is evident, that the majority of celiacs now present later in life and usually with vague and non-specific gastrointestinal symptomatology; celiac disease must, therefore, be considered in all new IBS patients, especially in areas of high prevalence and regardless of the nature of presenting symptoms<sup>[3]</sup>.

### ASSOCIATED DISEASES

Over the years, IBS has been associated with a wide variety of intestinal and extra-intestinal symptoms and syndromes. Recent community surveys have confirmed how frequently IBS, functional dyspepsia (FD) and gastroesophageal reflux disease (and non-erosive reflux disease (NERD), in particular) overlap; a phenomenon that may complicate clinical trials as well as diagnostic and therapeutic strategies. My own belief is that we should be “lumpers” and not “splitters” here; I contend that efforts to separate IBS from FD and NERD are clinically unrealistic and

unhelpful. IBS has also been associated with a variety of psychological disorders; here, in contrast, the evidence for a true association is less firm, more recent analyses suggest that the occurrence of such symptomatology in IBS is largely the preserve of those who seek further referral alone and is not a feature of IBS in the community. Psychopathology should be viewed, therefore, not as a fundamental prerequisite for the development of IBS, but, rather, as a co-factor which, if present, will modify the individual's response to IBS symptomatology. IBS patients commonly complain of fatigue and tiredness; these appear to be real entities in IBS, yet have been scarcely acknowledged in the assessment of IBS activity or response to therapy. Urinary and gynecological symptoms are also common; the basis for these associations is less clear. Aware of the prominence of smooth muscle hyper-reactivity in both conditions, parallels have been drawn between IBS and asthma; whether these conditions are linked remains to be defined.

## **PATHOPHYSIOLOGY**

### ***Genetic factors***

While IBS patients commonly give a positive family history, the relative roles of "nature" and "nurture" in this intra-familial aggregation of functional disorders have received little attention. For example, in a recent community survey almost 20% of IBS sufferers reported abdominal symptoms in a first degree relative; a relative risk of 2.5<sup>[4]</sup>. Whether this association reflects reporting bias, shared environmental factors or a true genetic basis has been addressed in two recent twin studies which both identified a genetic component to IBS<sup>[5,6]</sup>. This is not the whole answer by any means; thus in the study by Levy and colleagues, while the concordance for IBS was twice as high in monozygotic than in dizygotic twins (15.2% *vs* 6.7%), a history of IBS in a parent was a more potent predictor of IBS in a twin than was the presence of IBS in the other twin<sup>[6]</sup>. These findings suggest a relatively minor role for genetic factors in the basic pathogenesis of IBS. Genetic factors may, however, influence disease expression and therapeutic response, as evidenced by recent studies of G-protein subunit, IL-10, CCK-1 receptor, alpha 2 adrenoceptor and serotonin transporter genotypes among IBS patients<sup>[7-11]</sup>. These are complex studies but may pave the way for real progress in our understanding of the true diversity of IBS<sup>[12]</sup>.

### ***Gastrointestinal motor dysfunction***

Dysmotility has long been considered a major factor in the pathophysiology of IBS, as indicated by the use, in the past, of such terms as the "spastic colon" to describe what is now referred to as IBS. Accordingly, it was suggested that gut spasm or other abnormal contractile activities led to the development of symptoms in IBS. There are, indeed, several reports of abnormal motor patterns in many parts of the gastrointestinal tract in IBS. The specificity of many of these abnormalities for IBS is, however, unclear<sup>[13]</sup>. In contrast, and of particular interest, are very recent observations on the handling of gas by the intestine in IBS<sup>[14,15]</sup>. Whereas gas infused into

the small intestine was rapidly evacuated through the gut in normal volunteers, a similar infusion resulted in gas retention, symptoms and an increase in abdominal girth in IBS patients<sup>[14]</sup>; all reversible by administration of a prokinetic agent<sup>[15]</sup>. Distension, often the most distressing "gas"-related symptom in IBS, has, until recently, been assumed to represent a disturbance of perception, as apparently objective tests of abdominal volume failed to detect any increase in IBS<sup>[16]</sup>. This assumption has now been questioned<sup>[17]</sup> and it may well come to pass that more detailed studies of changes in distension over time<sup>[18]</sup> may detect significant diurnal variations in girth in IBS. While the balance of evidence suggests that intestinal gas production is not abnormal in IBS, one can visualize how relatively local changes in the gas content could lead to symptoms, given the aforementioned intrinsic abnormality of gas transport<sup>[19]</sup> and the hypersensitivity to intraluminal gas that are known to occur in IBS<sup>[20]</sup>.

### ***Visceral hypersensitivity and hyperalgesia***

Recently, there has been considerable interest in these phenomena, not only in IBS, but also in functional disorders, in general<sup>[7]</sup>. The phenomenon of visceral hypersensitivity, to distention and other intra-luminal stimuli, appears to be common in patients with non-cardiac pain, FD and the irritable bowel, alike. Recently, it has been suggested that visceral hyperalgesia, the phenomenon whereby stimuli normally not experienced as painful become so, is highly specific for IBS<sup>[21]</sup>. Visceral hypersensitivity, visceral hyperalgesia and viscerosomatic referral (the phenomenon whereby stimuli are referred over wide areas) have, indeed, been confirmed, in IBS, in more recent studies, using a variety of methodologies and under controlled experimental conditions<sup>[22]</sup>. While visceral hyperalgesia has been postulated as being highly specific for IBS, it alone or in association with other manifestations of hypersensitivity cannot explain all of IBS; even the most celebrated enthusiasts for the sensory hypothesis concede that sensation is normal in some patients.

There are several possible anatomical locations for sensory abnormalities in IBS, ranging from sensory receptors on the gut wall, primary sensory afferent neurons, to the spinal cord and the brain itself. Research in this area in man is notoriously difficult; however, advances in functional brain imaging provided by such techniques as cerebral evoked potentials (CEP), positron emission tomography (PET), magnetoencephalography (MEG) and functional magnetic resonance imaging (fMRI), have provided insights into the brain's response to visceral stimuli. These and other studies have advanced the concept of an abnormal (or hypervigilant) central nervous system (CNS), in IBS, which records an exaggerated, inappropriate or aberrant perception of visceral events<sup>[23]</sup>. Other pieces of evidence support this concept. These include the conscious perception, by IBS patients, of intestinal motor events which are usually sub-conscious and evidence of abnormal psycho-neuro-hormonal responses, often implicating an abnormal hypothalamo-pituitary axis (HPA).

Motility and sensation may not be the most fundamental

causes of IBS; it is clear, however, that these phenomena play a significant role in symptom generation.

### **Infection, inflammation, immunity and IBS**

It may come as a real surprise to many to hear that infection and inflammation are now seen as potential factors in the etiology of IBS. With regard to infection, we are now beginning to see the real data to directly support the concept of post-infective or post-dysenteric IBS.

**Infection and IBS** First reported by McKendrick and Read<sup>[24]</sup>, the occurrence of IBS following bacteriologically-confirmed gastroenteritis has now been documented in several studies<sup>[25-30]</sup>. The risk of developing IBS following an episode of gastroenteritis is in the order of 4%-23%, with females, those with a more severe initial illness and pre-morbid psychopathology being most at risk<sup>[25,26,28,30]</sup>. One of these studies went on to establish a direct link between prior exposure to an infectious agent, persisting low-grade inflammation and IBS<sup>[28]</sup>. In this study, an increase in the number of chronic inflammatory cells in the rectal mucosa was seen only among those exposed patients who had developed IBS. Others have demonstrated a persisting increase in rectal mucosal enteroendocrine cells, T lymphocytes and gut permeability in patients with post-dysenteric IBS<sup>[29,30]</sup>. Post-infectious IBS may explain only a minority of cases of IBS but does represent a clear link between exposure to an environmental agent, inflammation and IBS, in predisposed individuals<sup>[31]</sup>.

**Inflammation and IBS** Direct and compelling evidence was first provided by Chadwick and colleagues for a role of inflammation in IBS, in general. They evaluated 77 IBS patients of whom 55% would be considered as diarrhea predominant; none had a confirmed infectious origin for their IBS<sup>[32]</sup>. All had colonic biopsies taken for conventional histology and immunohistology. Thirty-eight had normal histology, 31 demonstrated microscopic inflammation and 8 fulfilled the criteria for lymphocytic colitis. However, in the group with "normal" histology, immunohistology revealed increased intraepithelial lymphocytes as well as an increase in CD3+ and CD25+ cells in the lamina propria; all, therefore, showed evidence of immune activation. These features were even more evident in the microscopic inflammation group who, in addition, revealed increased neutrophils, mast cells and natural killer cells. All of these aforementioned immunopathological abnormalities were most evident in the lymphocytic colitis group who, alone, also demonstrated HLA-DR staining in crypts and increased CD8+ cells in the lamina propria. Interestingly, taking the group of IBS patients as a whole, CD3+ cell number was higher among those with diarrhea than among alternators or those with predominant constipation. In contrast, in the non-inflamed IBS group the presence of mast cells was a predictor of constipation. Surprisingly, given the aforementioned description of a direct relationship between symptoms and chronic inflammation among patients with post-infectious IBS, these authors did not find an association between either the nature of disease onset or disease duration and immunological findings. In an accompanying editorial, Collins suggested that the increased presence of CD25+ cells may have indicated "auto- or exogenous antigen challenge in these patients,

and that the CD25+ cells are preventing the progression to a more florid inflammatory response"<sup>[33]</sup>. That IBS patients may be predisposed to an, *albeit* contained, inflammatory response to luminal triggers is also supported by the finding, of Gonsalkorale and colleagues, of a reduced frequency of the high-producer phenotype for the anti-inflammatory cytokine interleukin-10 (IL-10) among IBS patients<sup>[9]</sup>. A direct linkage between immune activation and symptoms has been provided by the work of Barbara and colleagues who demonstrated, not only an increased prevalence of mast cell degranulation in the colon in IBS, but also a direct correlation between the proximity of mast cells to neuronal elements and pain severity<sup>[34]</sup>.

While the inflammatory hypothesis in IBS is in its infancy, there is already some evidence for the extension of the inflammatory process beyond the confines of the mucosal compartment. Tornblom and colleagues addressed this issue in ten patients with severe IBS by examining full-thickness jejunal biopsies obtained at laparoscopy<sup>[35]</sup>. In nine, they found low-grade infiltration of lymphocytes in the myenteric plexus; four of these had an associated increase in intraepithelial lymphocytes and six demonstrated evidence of neuronal degeneration. Nine patients had longitudinal muscle hypertrophy and seven had abnormalities in the number and size of interstitial cells of Cajal. Interestingly, three of their patients reported an acute onset of their IBS; in two, possibly precipitated by gastroenteritis. The finding of intraepithelial lymphocytosis is consistent with the reports of Chadwick and colleagues<sup>[32]</sup>, in the colon and of Wahnschaffe and colleagues, in the duodenum<sup>[36]</sup>. Most recently, in a group of 78 unselected IBS patients, we demonstrated, in peripheral blood mononuclear cells, an alteration in the ratio between the cytokines IL10 and IL12 which became skewed towards a Th1, pro-inflammatory profile<sup>[37]</sup>.

With regard to the pathophysiology of the mucosal inflammatory changes, Spiller proposed that these changes could represent a response to an initial bacterial infection among individuals who are rendered susceptible by a relative deficiency of anti-inflammatory cytokines<sup>[38]</sup>. Alternately, could this low-grade inflammation represent either an abnormal reaction to the normal flora or a contained response to qualitative or quantitative changes in the intrinsic flora? Whether IBS is accompanied by quantitative or qualitative changes in the bacterial flora of the small or large intestine remains a contentious issue; while some have described bacterial overgrowth in the small intestine<sup>[39,40]</sup> and qualitative alterations in the fecal flora<sup>[41,43]</sup> and increased bacterial fermentation<sup>[44]</sup>, in IBS, others have failed to replicate these findings<sup>[45]</sup>. The description of efficacy for certain probiotics, and *bifidobacterium*, in particular, in IBS<sup>[37]</sup> could also support a role of gut flora-mucosal interaction in IBS<sup>[46]</sup>. Bacterial overgrowth could also explain some of the proposed overlap between IBS and celiac sprue<sup>[47]</sup>.

## **MANAGEMENT**

Many IBS patients relate the onset of symptoms to intake of food and often incriminate specific food items. However, the role of food intolerance or food allergy in

IBS has remained undefined. While most would agree that there is scant evidence for classical food allergy in IBS, Whorwell and colleagues suggest that testing for food intolerance, utilizing IgG antibodies, can lead to a successful dietary modification regime<sup>[48]</sup>.

In recent years, much interest has been generated by serotonin and the potential role of serotonergic drugs in IBS<sup>[49]</sup>. Tegaserod, a 5HT<sub>4</sub> agonist, is effective in the therapy of female patients with constipation-predominant IBS and has demonstrated efficacy against some previously "resistant" symptoms, such as bloating<sup>[50,51]</sup>. Alosetron, a 5HT<sub>3</sub> agonist, is effective in females with diarrhea-predominant IBS, but its prescription is now limited due to reports on ischemic colitis<sup>[52]</sup>. Cilansetron, a 5HT<sub>3</sub> agonist, is effective in both males and females with diarrhea-predominant IBS<sup>[53]</sup>; here the specter of ischemic colitis has again become an issue with regulators, in the US. Indeed, ischemic colitis has become an issue for all of these agents, though it appears that many reports of association probably reflect diagnostic confusion *ab initio* between IBS and ischemic colitis rather than an effect of serotonergic agents, *per se*<sup>[54]</sup>.

Given the explosion that has occurred in our understanding of the enteric nervous system, and of the pathways that link it to the CNS, it should come as no surprise that many agonists and antagonists of other putative neurotransmitters and neuromodulators are under study in IBS and related disorders.

Given the potential role of infection and inflammation in at least some instances of IBS, efforts have been made to address this aspect of pathophysiology in IBS. In this regard, a probiotic, bifidobacterium infantis has proved to be a very successful agent in unselected IBS patients<sup>[37]</sup>. Clearly, this is an area of increasing interest.

## CONCLUSIONS

Our understanding of IBS has come a long way. This is a global disease associated with significant symptoms and impairments in personal and social functioning for afflicted individuals. Advances in our understanding of gut flora-mucosal interactions, the enteric nervous system and the brain-gut axis have led to substantial progress in the pathogenesis of symptoms in IBS and have provided some hints towards the basic etiology of this disorder, in some subpopulations, at the very least. We look forward to a time when therapy will be addressed to pathophysiology and, perhaps, even to primary etiology. In the meantime, as illustrated in Figure 1, I would suggest that a model based on a primary role for intestinal inflammation serves to integrate the various strands which contribute to the presentation of IBS.

**Figure 1** Interactions between the gut, the brain and the external and internal environments in IBS; the inflammation hypothesis (a personal view). Bacterial or viral infection, a disturbed flora or an abnormal response to a normal flora leads to mucosal inflammation which in turn can disrupt motility and augment visceral sensation. Centrally, perception is abnormal, thereby, contributing to symptom development. Central output can in turn influence motor events in the periphery. While not central to causation, psychological factors, either spontaneously or in response to environmental stressors, can influence motor and sensory events and immune activity in the gut.

### **Abstract**

Reports from countries with a high prevalence of *Helicobacter pylori* (*H pylori*) infection do not show a proportionately high prevalence of duodenal ulceration, suggesting the possibility that *H pylori* cannot be a primary cause of duodenal ulceration. It has been mooted that this discrepancy might be explained by variations in the prevalence of virulence factors in different populations. The aim of this paper is to determine whether the published literature gives support to this possibility. The relevant literature was reviewed and analyzed separately for countries with a high and low prevalence of *H pylori* infection and virulence factors. Although virulent strains of *H pylori* were significantly more often present in patients with duodenal ulcer than without the disease in countries with a low prevalence of *H pylori* infection in the population, there was no difference in the prevalence of virulence factors between duodenal ulcer, non-ulcer dyspepsia or normal subjects in many countries, where the prevalence of both *H pylori* infection and of virulence factors was high. In these countries, the presence of virulence factors was not predictive the clinical outcome. To explain the association between virulence factors and duodenal ulcer in countries where *H pylori* prevalence is low, only two papers were found that give little support to the usual model proposed, namely that organisms with the virulence factors are more likely than those without them to initiate a duodenal ulcer. We offer an alternative hypothesis that suggests virulence factors are more likely to interfere with the healing of a previously produced ulcer. The presence of virulence factors only correlates with the prevalence of duodenal ulcer in countries where the prevalence of *H pylori* is low. There is very little evidence that virulence factors initiate duodenal ulceration, but they may be related to failure of the ulcer to heal.

### **HELICOBACTER PYLORI VIRULENCE FACTORS AND DUODENAL ULCERATION**

Following Warren and Marshall's historic paper in 1984<sup>[1]</sup>, evidence for an association between duodenal ulceration and *Helicobacter pylori* (*H pylori*) infection has been strengthened. Earlier publications, however, were from developed countries, where the overall prevalence of *H pylori* infection was between 40% and 60%. The difficult problem that remained was why everyone with *H pylori* infection did not develop duodenal ulceration. This problem was increased by the reporting of the "African enigma" from the savannah regions of the West Coast of Africa<sup>[2,3]</sup>, where the prevalence of *H pylori* infection was much higher (> 90%), but the prevalence of duodenal ulceration was relatively low. This was followed by an increasing number of reports from other countries, where a high prevalence of *H pylori* infection did not correlate with a high prevalence of duodenal ulceration (Africa<sup>[4-8]</sup>, India<sup>[9-11]</sup>, China<sup>[12,13]</sup>, Japan<sup>[14,15]</sup>, Korea<sup>[16]</sup>, Peru<sup>[17]</sup>, Iran<sup>[18]</sup>, Vietnam<sup>[4]</sup>).

When it was later reported that some strains of *H pylori* were more virulent than others, this seemed a possible explanation of the paradox. In the more developed countries, the virulent factors, cagA (cytotoxin associated antigen) and vacA (vacuolating factor), were present in between 40% and 60% of *H pylori* strains, and it was suggested that these strains might prove to be the causal factors in duodenal ulceration and account for the discrepancies<sup>[19-24]</sup>.

There is no doubt about the association of these factors with duodenal ulceration in countries, where the overall prevalence of *H pylori* infection and virulence factors is relatively low, compared with countries where it is high. However, an increasing number of reports from countries, where *H pylori* infection is almost ubiquitous (70-90+%) and 77%-88% of the strains carry the viru-

lence factors *cagA* and *vacA*, have shown no relationship between these factors and clinical outcome (South Africa<sup>[6]</sup>, India<sup>[25,26]</sup>, China<sup>[27-31]</sup>, Japan<sup>[32-43]</sup>, Korea<sup>[44-47]</sup>, China Taiwan<sup>[48]</sup>, Thailand<sup>[49]</sup>, Sudan<sup>[50]</sup>, Turkey<sup>[51-53]</sup>, Nigeria<sup>[54,55]</sup>, Sri Lanka<sup>[56]</sup>, Bangladesh<sup>[57]</sup>, Serbia Montenegro<sup>[58]</sup>, Estonia<sup>[59]</sup>, Brazil<sup>[60]</sup>, Singapore<sup>[61,62]</sup>, Mexico<sup>[63]</sup>). A few similar reports have also come from countries with a low prevalence (Germany<sup>[45,64]</sup>, France<sup>[65,66]</sup>, Finland<sup>[67]</sup>, UK<sup>[68,69]</sup>, USA<sup>[42]</sup>).

Most *cagA* positive strains also carry the *vacA* gene. When present, the *cagA* gene secretes the toxic CagA protein, but not all *vacA* strains secrete a toxigenic protein. There are different allelic types of *vacA*, the types *vacAs1* and *vacAs1m1* are toxic and strongly associated with duodenal ulceration, mostly in countries with a relatively low prevalence of *H. pylori* infection. Once again, however, reports from countries with a high prevalence of these factors show no link between the presence of *vacAs1* [6,26,29,38,44,47-49,56,57,60,70] or *vacAs1m1* [25,26,29,41,44,52,55,59,65,70] and clinical outcome.

Other virulence markers have been reported: *iceA1* gene [induced by contact with gastric epithelium] and *babA2* gene (blood group antigen binding adhesin), which binds to Lewis B present on gastric epithelial cells, show an association with duodenal ulceration in countries, where the prevalence of *H. pylori* and these strains is low. However, reports from many countries with a high prevalence of *H. pylori* and these virulence markers again show that in these areas they are not predictive of the clinical outcome (*iceA1* [6,26,31,41,45,48,52,55,57,61,62,71-73], *babA2* [6,32,39,41,42,47,61]).

Thus, there remains the anomaly that, although duodenal ulceration is strongly associated with *H. pylori* infection and certain virulence factors in countries with a relatively low prevalence of both *H. pylori* infection and virulence factors, this association disappears in many countries<sup>[74]</sup> where these prevalences are high, and where *H. pylori* infection and virulence factors do not predict clinical outcome. This casts doubt upon whether *H. pylori* initiates duodenal ulcer. This doubt is strongly supported by the finding that most patients with a short history<sup>[75]</sup> or all with less than 6 month's history<sup>[76]</sup> of duodenal ulcer symptoms were uninfected with *H. pylori*.

Nonetheless the importance of *H. pylori* infection and virulence factors cannot be dismissed. There is no doubt that the eradication of *H. pylori* infection leads to healing of duodenal ulceration and the risk of recurrence is greatly reduced. There is also no doubt about the strong association of *H. pylori* and virulence factors with duodenal ulceration in countries where the overall prevalence of *H. pylori* infection is relatively low.

The tendency for *H. pylori* to be absent in the early case suggests that the organism is not the primary cause producing duodenal ulcer. The evidence that the chronic course of healing→recurrence→etc. of the typical chronic duodenal ulcer is converted in most cases into stable healing by eradicating *H. pylori* suggests that the organism, when present, interferes with the healing process.

There remains the question why the virulence factors are related to the presence of duodenal ulceration in the countries with a low prevalence of *H. pylori* infection. It is possible that colonization of nearby areas of antral epithelium or of gastric metaplasia in the duodenum by

*H. pylori* leads to the local release of toxins that produces the duodenal ulcer. However, this straightforward model has not been substantiated. The toxins concerned have been demonstrated and their toxic effects are determined mostly by their interaction with gastric epithelium<sup>[19]</sup> and there are only two papers reporting about the damage caused by toxins to duodenal mucosa. One paper<sup>[77]</sup> reports about the prevention of healing of mechanically abraded human duodenal epithelium *in vitro* by strains of wild *H. pylori*, particularly those carrying the *vacA* gene, and also by supernatant fluid containing the *vacA* cytotoxin. The other paper<sup>[78]</sup> reports about increased duodenal mucosal permeability, when exposed to *H. pylori* culture fluid in rats. It must be emphasized that neither paper reports about the *initiation* of ulceration.

As an alternative explanation, we advance the following more complicated model which we have partly suggested before<sup>[11,76]</sup>. *H. pylori* is killed by excess acid<sup>[79,80]</sup>. In countries, where the overall prevalence of *H. pylori* infection is low, duodenal ulcer patients initially may be free from *H. pylori* infection because of their high acid output. In the early stages of ulceration, many subjects, prior to seeking definitive treatment, control their symptoms with antacids, some including H<sub>2</sub> antagonists, which are available without prescription. This reduces the defense against infection with the organism in patients who have hitherto been resistant (since they start *H. pylori* negative). This partial reduction in resistance can be overcome by virulent, but not by non-virulent strains, so there is an association between the virulent strains and the chronic ulcer patients, most of whom have become *H. pylori*-positive for the organism by 6 months time<sup>[75,76]</sup>. The high baseline of infection with virulent strains, in the countries with a high prevalence, obscures this effect.

### Abstract

Many epidemiological reports indicate that *Helicobacter pylori* (*H. pylori*) infection plays an important role in gastric carcinogenesis. Several genetic and epigenetic alterations contribute to the initiation, promotion, and progression of the cancer cells in a multi-step manner. *H. pylori* is known to induce chronic inflammation in the gastric mucosa. Its products, including superoxides, participate in the DNA damage followed by initiation, and the inflammation-derived cytokines and growth factors contribute to the promotion of gastric carcinogenesis. By eradicating *H. pylori*, gastric inflammation can be cured; the therapy diminishes the levels not only of inflammatory cell infiltration, but also atrophy/intestinal metaplasia in part. A randomized controlled trial revealed that the eradication therapy diminished the gastric cancer prevalence in cases without pre-cancerous conditions. In addition, recent epidemiological studies from Japanese groups demonstrated that the development of gastric cancer, especially of the intestinal type, was decreased by successful eradication therapy, although these were designed in a non-randomized manner. However, it should be mentioned that endoscopic detection is the only way to evaluate the degree of gastric carcinogenesis. We have reported that the endoscopic and histological morphologies could be modified by eradication therapy and it might contribute to the prevalence of gastric cancer development. Considering the biological nature of cancer cell proliferation, it is considered that a sufficiently long-term follow-up would be essential to discuss the anticancer effect of eradication therapy.

### INTRODUCTION

*Helicobacter pylori* (*H. pylori*), a Gram-negative bacillus discovered in 1983, is the most popular pathogenic bacteria in the world. Approximately half of the population has *H. pylori* infection worldwide, and the prevalence is thought to be 80-90% in developing countries and 30-50% in developed countries<sup>[1]</sup>. Many studies clarified the implication of the bacteria as the cause of many gastroduodenal diseases, including histological chronic gastritis, peptic ulcer, and mucosal-associated lymphoid tissue (MALT) lymphoma<sup>[2,3]</sup>.

In particular, histological chronic atrophic gastritis is an important disease for gastric carcinogenesis. Two main causes for the promotion of atrophic gastritis are (1) *H. pylori* and (2) autoimmune factors such as antiparietal cell antibody. Although these two factors work synergistically in the promotion of atrophic gastritis<sup>[4,5]</sup>, autoimmune gastritis is a rare disease and most atrophic gastritis is thought to be induced by *H. pylori* infection in East-Asian countries such as in Japan, China, and Korea<sup>[6]</sup>. Therefore, it is likely that *H. pylori* is the most important factor for mucosal atrophy and we have confirmed this hypothesis in the Japanese population<sup>[7]</sup>.

Gastric cancer is the second most common cancer (next to lung cancer) in the world and the number of newly diagnosed cases was calculated as 750 000 persons per year<sup>[8]</sup>. As previously demonstrated by Correa *et al.*, atrophic gastritis and the following intestinal metaplasia are regarded as an essential status for intestinal type cancer development<sup>[9]</sup>. It has been widely accepted that there is a strong association between *H. pylori*-associated gastritis and gastric cancer. Nomura *et al.* and Parsonnet *et al.* first reported the relationship between *H. pylori* infection and gastric cancer in 1991<sup>[10,11]</sup>. In 1994, the International Center for Cancer Research officially recognized that *H. pylori* was a definite carcinogen for gastric cancer on the basis of several epidemiological reports<sup>[12]</sup>. Moreover, Huang *et al.* demonstrated the relationship between *H. pylori* seropositivity and gastric cancer by meta-

analysis<sup>[13]</sup>. The odds ratios for gastric cancer were calculated as 1.92 (1.32–2.78; 95%CI), 2.24 (1.15–4.4), and 1.81 (1.16–2.84) for all studies, cohort and case-control studies, respectively. In addition, many investigations showed the tight relationship between *H pylori* and not only intestinal type cancer, but also diffuse type cancer<sup>[13,14]</sup>. Even in gastric cancer at a younger age, we were able to detect a tight relationship between gastric cancer and *H pylori*<sup>[15]</sup>. In 2001, Uemura *et al.*<sup>[16]</sup> clearly demonstrated that gastric cancer developed only in patients with *H pylori* infection with a prospective study. They prospectively followed 1246 Japanese people for 7.8 years and found that gastric cancer had been detected in only 36 patients with *H pylori* infection. No gastric cancer was found in *H pylori*-negative patients in their study.

These findings strongly suggest the implication of *H pylori* in gastric carcinogenesis. Next, we should clarify the hypothesis as to whether we can control gastric carcinogenesis by the eradication of *H pylori*. In the present study, we have summarized the recent clinical evidence in this field and have attempted to answer this question.

### **Gastric inflammation induced by *Helicobacter pylori* infection and its carcinogenic effects**

Persistent infection of *H pylori* induces the characteristic inflammation in the gastric mucosa with the histological finding of mononuclear cell/neutrophil infiltration. In particular, the superoxides, such as nitric oxide, in the gastric mucosa play an important role in the initiation of the carcinogenesis as a mediator of carcinogenic nitrosamine formation, DNA damage and tissue injury. Studies have also revealed that *H pylori* infection in human beings is associated with the enhanced expression of iNOS by tissue neutrophils and mononuclear cells<sup>[17,18]</sup>. Previously, we have reported that the expression of inducible nitric oxide synthase and nitrotyrosine in chronic gastritis is a predictive marker for a high risk of gastric cancer development<sup>[19]</sup>. The iNOS-producing gastritis, which is supposed to be strongly associated with gastric cancer, showed a characteristic cytokine profile and serum gastrin pattern<sup>[20]</sup>.

Chronic inflammation results in the destruction of parietal cells of the oxyntic gland in the gastric corpus followed by the alteration of the pathophysiological status, including gastric acid secretion<sup>[21]</sup>. The pH of gastric juice is a major determinant of the nitrite and vitamin C concentrations in gastric juice. Previous studies reported a close linkage between low acid output and an increased concentration of nitrite and N-nitroso compounds in gastric juice<sup>[22]</sup>. Vitamin C was actively secreted into gastric juice and scavenges nitrite from the gastric juice and thereby acts to prevent the formation of nitrosamines. Vitamin C concentrations in gastric juice were found to be low in patients with hypochlorhydria status<sup>[23]</sup>. In addition, we have reported that gastric juice nitrite concentrations are higher and vitamin C concentrations are lower in patients with gastric cancer than those in atrophic gastritis, despite similar intra-gastric pH and *H pylori* status<sup>[24]</sup>.

Furthermore, inflammation-derived cytokines and growth factors are known to act as promotion/proliferation factors for gastric cancer cells. Especially,

hepatocyte growth factor has been reported to play a crucial role in epithelial/tumor cell proliferation, and its expression was promoted in *H pylori*-infected mucosa<sup>[25]</sup>. Churin *et al.* reported that *H pylori* activated c-Met (the receptor of HGF) in AGS cells, suggesting the important role of HGF in an autocrine manner<sup>[26]</sup>. In addition, the regulation of apoptotic signals is another important factor for the promotion/proliferation of cancer cells. *H pylori* was reported to be able to induce apoptosis of the gastric epithelial cells directly<sup>[27]</sup>. Nagasako *et al.*<sup>[28]</sup> have demonstrated that the Smad-5, which contributes to the apoptosis of gastric epithelial cells, is upregulated by *H pylori* infection.

Many recent advances have revealed the detailed molecular mechanisms of gastric inflammation induced by *H pylori*. The research on some virulent bacterial factors, VacA and CagA, were reported successively from Japanese groups. Fujikawa *et al.*<sup>[29]</sup> clarified that VacA binds to protein tyrosine phosphatase receptor type Z (Ptpz), which is a specific receptor on epithelial cells, and induces the intracellular pathway *via* G protein-coupled receptor kinase-interactor 1 (Git1) and pleiotrophin. On the other hand, the advantage of CagA is the most sensational in this field. Previously, Huang *et al.*<sup>[30]</sup> demonstrated the strong association between anti-CagA seropositivity and gastric carcinogenesis, suggesting the importance of CagA for gastric carcinogenesis. CagA protein produced in the bacterial cell is translocated into the host cell by a type IV secretory system<sup>[31]</sup>, followed by translocation to the membrane<sup>[32]</sup>, tyrosine phosphorylation of the EPIYA motif by *src*-family kinase and the activation of SHP-2 phosphatase, which is the important second messenger from CagA (Figure 1)<sup>[33]</sup>. Recent studies by Hatakeyama *et al.* clarified that the CagA protein showed diversity and was subclassified into two types, the Western type and East-Asian type, and the later type was reported to have a high affinity to SHP-2 and was regarded as a more harmful form<sup>[34]</sup>. It is possible to explain the international diversity of the prevalence of gastric cancer; in Western countries, the prevalence of gastric cancer is relatively low because Western type CagA (or Cag negative strain) is dominant. On the other hand in East-Asian countries, the more virulent strain (East-Asian type) is the major strain, and this is a reason for the higher prevalence of gastric cancer. However, it is still unclear why some Japanese/Chinese people do not show corpus atrophy, even if they carry the East-Asian type CagA. Mimuro *et al.*<sup>[35]</sup> suggested another signal pathway *via* growth factor receptor bound 2 (Grb2), which is independent of CagA phosphorylation. Intragastric diversity or other bacterial factors must be examined to solve this question, as well as the host factors and environmental factors including a high intake of salt<sup>[36]</sup>.

After successful *H pylori* eradication therapy, these harmful conditions are dramatically improved. There is no doubt that the eradication therapy can diminish the risk of the new development of gastric cancer or progression from the pre-malignant status. However, it should be emphasized that it takes a long time from when one cell transforms into a cancer cell to when we can detect the cancer tissue by endoscopic examination. Although the growth rate of gastric cancer cells differs

**Figure 1** Intracellular molecular pathway starting from *H. pylori* infection.

according to their biological or histological characteristics, Haruma *et al.*<sup>[37]</sup> reported that average doubling time of early gastric cancer is 16.6 mo in the polypoid type. From this fact, it is likely that when we detect the cancer lesion in the stomach by endoscopic examination, cancer cells must have already been present for many years, even if it is not detectable. Cancer cells have progressed through the multi-step process of genetic and epigenetic alteration of oncogenes<sup>[38]</sup>. These alterations must occur in the cancer cells in the initial stage, and it is unlikely that these could be always cancelled by eradication therapy alone.

### Reversibility of pre-malignant status; atrophic gastritis and intestinal metaplasia

Many reports have mentioned the improvement of neutrophil/lymphocyte infiltration after *H. pylori* eradication therapy. However, it is still controversial as to the improvement of glandular atrophy or intestinal metaplasia after the eradication therapy. Annibale *et al.* have concluded that eradication therapy does not improve mucosal atrophy<sup>[39]</sup>. Sung *et al.*<sup>[40]</sup> reported the results of a large-scale prospective randomized study and concluded that eradication therapy prevents the progression of atrophy, which was not reversible. However, some problems remain that the following period is relatively short in the former, and the basal grades of atrophy were mild in the latter study. On the other hand, Ohkusa *et al.*<sup>[41]</sup> and Haruma *et al.*<sup>[42]</sup> enrolled patients with atrophic gastritis and reported the reversibility of atrophy after *H. pylori* eradication therapy. Furthermore, we previously followed up 22 patients in whom *H. pylori* was eradicated for 5 years and confirmed that glandular atrophy is reversible both in the gastric corpus and in the antrum<sup>[43]</sup>. It should be noted that the reversibility of atrophy was found in the patients with moderate atrophy, and it took a long-time to confirm the reversibility. In cases with complete disappearance of the gland, such as cases with gastric adenoma, reconstruction of the gland may be unlikely. Recently, Sugiyama *et al.*<sup>[44]</sup> reported the regression of corpus atrophy after eradication. They emphasized the importance of the biopsy site, and demonstrated that the most suitable point is the lesser curvature of the gastric corpus.

Another major problem is the reversibility of the

intestinal metaplasia. Although some reports have refuted the improvement of intestinal metaplasia<sup>[39,45]</sup>, there has been a report suggesting the effect of eradication therapy in the improvement of intestinal metaplasia<sup>[41]</sup>. Correa *et al.*<sup>[46]</sup> reported that eradication therapy could regress not only the degree of atrophy, but also the intestinal metaplasia in a randomized controlled trial. Leung *et al.*<sup>[47]</sup> demonstrated that the eradication therapy could prevent the progression of intestinal metaplasia using a randomized controlled trial with a 5-year follow-up. However, to evaluate the status of intestinal metaplasia, biopsy specimens for point-diagnosis seem to be not suitable. Therefore, we performed dye-endoscopy using methylene blue solution, which allowed us to evaluate the degree of intestinal metaplasia as a "field". Our overall results suggested the reversibility of intestinal metaplasia by following up over long periods, even if all patients did not show a regression of the intestinal metaplasia<sup>[43]</sup>. At present, a large-scale prospective study (Japanese intervention trial of *H. pylori*) has been ongoing. In this study, the reversibility of atrophic gastritis was examined by endoscopic and histological examinations, and its final result will be published in 2006. Although the improvement of atrophic gastritis or intestinal metaplasia links to the regression of gastric carcinogenesis at the extremely early stage, a long-term (more than 10 years) follow-up study will be necessary to confirm the effect of eradication therapy on gastric carcinogenesis.

### Does eradication therapy truly diminish gastric cancer?

It is clinically important to clarify whether gastric carcinogenesis could be influenced by eradication therapy. Firstly, Uemura *et al.*<sup>[48]</sup> reported the reduced incidence of secondary developed gastric cancer by eradication therapy in patients with endoscopic resection of the primary gastric cancer. Because of the reason described above, their data did not suggest an anticarcinogenic effect of the eradication therapy, but instead an antiproliferative effect of cancer cell growth. Indeed, we have previously reported that the Ki-67 labeling index in cancer cells is lower in cancer lesions without *H. pylori* infection than in those with *H. pylori*<sup>[49]</sup>. Recently, Take *et al.*<sup>[50]</sup> reported that they followed up 1 120 peptic ulcer patients with eradication therapy prospectively (mean 3.4 years) and found that gastric cancer is more frequently detected in patients with failed eradication than those with successful eradication. They have also demonstrated that gastric cancer was never detected in duodenal ulcer patients, in whom atrophic gastritis should be absent. On the other hand, a Chinese group has demonstrated, with a randomized controlled trial, that there is a relative decrease in cancer incidence in patients with eradication therapy in the overall population, but this difference did not reach a level of significance<sup>[51]</sup>. Only in a subgroup without pre-cancerous lesions (without atrophy or intestinal metaplasia) they demonstrated the statistically reduced incidence of gastric cancer by eradication therapy. These results may be partially conflicting to each other and the reason for this is uncertain. However, we should pay attention to the difference in the clinical stage of gastric cancer detected and in the diagnostic ability of endoscopic examination

**Figure 2** Dye-endoscopic features of gastric adenocarcinoma at pre- (A) and post-eradication therapy (B). Tumors became flattened and indistinct after eradication therapy. Histological features of gastric neoplasm at post-eradication are demonstrated in panel (C). Patient was a 67-year-old male.

between both trials. Whereas, in the Japanese study, most gastric cancer lesions were detected in the early stage as an intramucosal cancer, lesions found in Chinese study were those in a more advanced stage. We could not conclude that these two studies were designed with the same method because the endpoints may be different.

Recently, Kamada *et al.*<sup>[52]</sup> also prospectively followed up 1 787 patients with eradication therapy (median 4.5 years) and demonstrated that gastric cancer could be detected in 20 patients (1.1%). Most cancer lesions were detected in the early stage as intramucosal cancer and its histology was intestinal type dominant (75%). We also prospectively examined 101 patients with atrophic gastritis prospectively for more than 60 mo (mean 63.2 months) and found gastric cancer incidence in 8 patients<sup>[53]</sup>. Most gastric cancers were detected in the early stage and their histologies were of the intestinal type, and this is in complete agreement with previous studies. In addition, gastric cancer is more frequently found in elderly patients than in younger patients ( $P < 0.05$ ). For the patients with atrophic gastritis, the age at the time of eradication therapy is an important factor for the occurrence of cancer after successful eradication. The long-term strict follow-ups after eradication seem to be necessary in elderly patients with atrophic gastritis.

#### **Does alteration of the tumor appearance after eradication therapy modulate the incidence of cancer discovery?**

As described above, the focus must be placed on the diagnostic ability of gastric cancer by endoscopic examination when we discuss the cancer discovery rate determined clinically. One of the difficulties of this field seems to be based on the methodology used to evaluate gastric carcinogenesis. Researchers can evaluate the degree of carcinogenesis only by the discovery rate of gastric cancer by endoscopic examination. Due emphasis must be placed on the differences in the diagnostic ability of each examination.

Moreover, endoscopic morphology might be influenced

directly by eradication therapy, thus affecting the discovery rate of gastric cancer. Previously, Gotoda *et al.*<sup>[51]</sup> reported the endoscopic regression of gastric adenoma after successful eradication therapy. If the eradication itself influences the tumor morphology, this may affect the tumor discovery rate. Then, we investigated the morphological changes in the gastric neoplasm after *H. pylori* eradication in Japanese patients. After a one-month follow-up, endoscopic re-evaluation revealed that one-third of the gastric tumor became indistinct and some tumors were difficult to discern with ordinary endoscopic observation<sup>[55]</sup>. All these altered lesions were of the superficial-elevated type, which is the characteristic appearance of intestinal type cancer, irrespective of the grade of histological appearance (adenoma or carcinoma) (Figure 2). The tumor appearance became flattened and the height of the lesions decreased, then the tumor became indistinct after eradication, even after a short time. In the depressed type cancer, that is typical for diffuse type gastric cancer, we could not find any morphological changes after eradication<sup>[55]</sup>. These results suggest that the morphology of the gastric neoplasm changes after eradication in the short-term, especially in the intestinal type gastric cancer, which were found characteristically in patients after eradication therapy. Even if the true incidence of cancer is not affected by eradication, the incidence of cancer discovery would be influenced by successful eradication therapy in cases of intestinal type cancer with elevated tumor features. Furthermore, we detected normal columnar epithelium over the neoplasm in some lesions (Figure 2). The appearance of normal foveolar epithelium must make it more difficult to detect gastric cancer by endoscopic observation. We could not explain the origin of this strange histological feature, but the most probable origin may be a regenerative change against the surface injury of the mucosal tumor tissue induced by the improved acid output after successful eradication. This must also contribute to the reduction in the rate of cancer discovery after successful eradication therapy and these overall alterations are quite rational for the explanation of the results reported by the Japanese researchers.

The mechanism of the antitumor promoting effect of *H. pylori* eradication therapy is still unknown. In the *in vitro* studies, *H. pylori* itself has been found to modify the expressions of several genes in gastric carcinoma cells<sup>[56]</sup>. Semino-Mora *et al.*<sup>[57]</sup> demonstrated the presence of *H. pylori*-derived toxic proteins and mRNAs in gastric tumor cells *in vivo*. However, their theory is still controversial, and, until now, it has been believed that *H. pylori* cannot exist in the gastric carcinoma cells. Thus, it is likely that *H. pylori* indirectly influences tumor cell growth by regulating the inflammatory reaction around the tumor tissue. Several cytokines have been induced by *H. pylori* infection and some of them may act as growth factors for tumor cells<sup>[25,58]</sup>. Suzuki *et al.*<sup>[59]</sup> reported the decreased level of HGF in the gastric mucosa after eradication, which was linked to the decreased cell turnover. These indicate the importance of gastric inflammation in the gastric mucosa rather than *H. pylori* itself on the luminal side. Gastrin is known to be an important gut-related hormone and a

growth factor for gastric cancer cells, and gastric tumor cells have been shown to contain its receptor<sup>[60]</sup>. However, it is unlikely that our new findings of the morphological changes were induced by a gastrin-related system<sup>[55]</sup>.

There are two ways in which gastric tumors may grow; one is invasive downward growth and the other is expansive growth in the upward (luminal) direction. The latter may include the reactive (non-neoplastic) factor, which may be regulated by the gastric inflammation induced by *H pylori* infection. Kamada *et al.*<sup>[52]</sup> analyzed the macroscopic features of gastric cancers discovered after eradication therapy and demonstrated that most lesions are of the depressed type. If the eradication therapy mainly influences the expansive growth, the true biological behavior of the gastric malignancies may not be improved by eradication therapy.

### **Clinical manifestations of *H pylori* eradication therapy and what are the problems in the next step?**

There is no doubt that eradication therapy diminishes the prevalence of cancer development. In the animal model with Mongolian gerbils, Shimizu *et al.*<sup>[61]</sup> demonstrated that *H pylori* eradication therapy diminishes the prevalence of gastric cancer incidence induced by *H pylori* infection and low-dose chemical carcinogen. Tatematsu *et al.*<sup>[62]</sup> also reported that *H pylori* eradication therapy regresses the heterotopic proliferative glands in the gastric mucosa of Mongolian gerbils, suggesting that the eradication reduces the promoting effect of the bacterium.

In human studies, we cannot discuss the anticarcinogenic effect of eradication therapy unless we follow up patients for a sufficiently long period (more than 10 years). As discussed above, it is very important that we distinguish the “development” of gastric cancer from the “discovery” of the tumor. In addition, it is clinically important to clarify whether eradication therapy can diminish the mortality rate for gastric cancer or not. It is very critical to know as to how we regress the biologically malignant gastric cancer, including diffuse-type cancer in younger patients. No reports have discussed this, and further study is necessary to answer this question.

Another problem to be solved is the “point of no return” of gastric carcinogenesis by eradication therapy. In the animal model, earlier eradication was demonstrated to be more effective for preventing the development of gastric cancer<sup>[63]</sup>. Since gastric cancer after eradication was frequently found in patients who received eradication in older age, we should consider that younger people should receive eradication therapy as early as possible. For the effective eradication for cancer prevention to be practical and economical, the selection of the population at higher risk should be clarified. It is especially necessary to identify the fundamental status of gastric inflammation in the development of diffuse type gastric cancer. Recent studies revealed that a high odds ratio for gastric cancer discovery was noticed in patients with nodular gastritis, which may be an important background for diffuse-type cancer<sup>[64,65]</sup>. This type of gastritis should be an important target for earlier eradication therapy to reduce cancer death. In addition, we should determine useful biomarkers for gastric inflammation, which would be beneficial for real clinical practice<sup>[66]</sup>.

## Abstract

Gastric cancer is one of the most frequent cancers in the world; almost two-thirds of gastric cancer cases and deaths occur in less developed regions. In China, based on two national mortality surveys conducted in 1970s and 1990s, there is an obvious clustering of geographical distribution of gastric cancer in the country, with the high mortality being mostly located in rural areas, especially in Gansu, Henan, Hebei, Shanxi and Shaanxi Provinces in the middle-western part of China. Despite a slight increase from the 1970s to early 1990s, remarkable declines in gastric cancer mortality were noticed in almost the entire population during the last decade in China. These declines were largely due to the dramatic improvements in the social-economic environment, lifestyle, nutrition, education and health care system after economic reforms started two decades ago. Nevertheless, gastric cancer will remain a significant cancer burden currently and be one of the key issues in cancer prevention and control strategy in China. It was predicted that, in 2005, 0.3 million deaths and 0.4 million new cases from gastric cancer would rank the third most common cancer. The essential package of the prevention and control strategy for gastric cancer in China would focus on controlling *Helicobacter pylori* (*H. pylori*) infection, improving educational levels, advocating healthy diet and anti-tobacco campaign, searching for cost-effective early detection, diagnosis and treatment programs including approaches for curable management and palliative care.

## GASTRIC CANCER IN THE WORLD

Gastric cancer is one of the most frequent cancers in the world, in both men and women. In the year 2002, the age standardized incidence rate was 22.0 per 100 000 in men, and 10.4 per 100 000 in women, and mortality rate was 16.3 per 100 000 in men, and 7.9 per 100 000 in women, according to the latest global estimation-GLOBOCAN 2002<sup>[1]</sup>. Despite a marked decrease, especially in mortality rate in many countries, the absolute number of gastric cancer cases and deaths is still a big burden of the local health program, since the world population and life expectancy are increasing. In 2002, it was estimated that there were 0.9 million new gastric cancer cases (0.60 million in men and 0.33 million in women) and 0.7 million deaths (0.45 million in men and 0.25 in women) from gastric cancer in the world. In men, gastric cancer ranks the third among the commonest cancers in incidence rate (after cancers of lung and prostate) and the second in mortality rate (after lung cancer), while in women, it is the fifth most common cancer in incidence and the fourth in mortality (after cancers of breast, cervix, lung and/or colon-rectum)<sup>[1]</sup>.

In terms of geographic distribution, almost two-thirds of gastric cancer cases and deaths occur in less developed regions. High rates apply to Japan, China, Korea, Central and South America, Eastern Europe, and parts of the Middle East, and low rates to North America, Australia and New Zealand, Northern Europe, and India<sup>[1,2]</sup>. Five-year relative survivals of around 20% or less are frequently reported. The incidence ratios of men to women generally range between 1.5 and 2.5, with higher ratios for intestinal than diffuse cancers and in high-risk populations<sup>[2]</sup>.

## NATIONAL GASTRIC CANCER MORTALITY PATTERN IN THE 1970s AND 1990s

In China, two national mortality surveys were conducted in 1973-1975 and 1990-1992, respectively, both organized by the National Office for Cancer Prevention and Control, the Ministry of Public Health, China. These two surveys showed the detail pattern and distribution of mortality rates for cancers in China at that time<sup>[3-7]</sup>. The first mortality survey was a nation-wide study. An atlas was published based on the survey results<sup>[4]</sup>, providing a visual geographic distribution of gastric cancer profile in early 1970s. A map of the gastric cancer mortality distribution for males is shown in (Figure 1) as an example. An obvious clustering of geographical distribution of gastric cancer appears in China, with the high mortality

Figure 1 Mortality rates of gastric cancer in men in China, 1973-1975<sup>[4]</sup>.

Table 2 Changes in the age-standardized mortality rates of gastric cancer between 1973 and 1975 and between 1990 and 1992 in China (rate per 100 000)

Area	Year 1973-1975			Year 1990-1992			Changes (%)		
	Men	Women	Total	Men	Women	Total	Men	Women	Total
Whole country	27.1	13.0	19.8	30.1	13.8	21.8	11.0	6.3	10.0
Urban	27.3	13.3	20.1	21.2	9.8	15.3	-22.2	-26.7	-23.8
Rural	26.7	12.6	19.4	33.7	15.4	24.4	26.4	22.1	25.8

being mostly located in the north (Liaodong Peninsula, Shandong Peninsula, Yangtze River Delta and middle-western provinces along Taihang Mountain and 'Hexi Zoulang').

The second mortality survey covered 10% of the whole population that proved as a representative sample to reflect national cancer profile<sup>[5-7]</sup>. The crude mortality rate of gastric cancer in China was 25.2 per 100 000 (32.8 per 100 000 in men and 17.0 per 100 000 in women), which accounted for 23.2% of the total cancer deaths in 1990-1992, making gastric cancer the first leading cause of cancer death<sup>[8]</sup>. The geographic variety in the distribution was similar to that in the first survey in the 1970s. Table 1 shows the first 20 areas with high mortality rates for the gastric cancer (rates adjusted by the 1982 national census population). Most of these high-risk areas are located in rural areas, especially in Gansu, Henan, Hebei, Shanxi and Shaanxi Provinces in the middle-western part of China.

By comparing the above two national mortality surveys, an increasing trend for the age-standardized mortality rates of gastric cancer was shown in the entire population in China during the two decades. Nevertheless, the increase only appeared in rural areas, while a decreasing trend was noticed in urban population<sup>[9,10]</sup> (Table 2). In terms of age-specific mortality rates, a decreasing trend was noticed among almost all age groups (except age group 70-79 years) in urban residents, while an increasing trend was seen among most of age groups (except age group 30-44 years) in rural areas<sup>[10]</sup>. Nevertheless, with almost two-thirds of the population reside in rural areas, gastric cancer was still the first most common cancer in the entire population in China during 1970s and early 1990s,

Table 1 The first 20 areas with high mortality rate for gastric cancer in China - according to the second national mortality survey in 1990-1992 (rate per 100 000)

Area	Rate	Area	Rate
Wuwei town, Gansu	117.78	Jiyuan town, Henan	66.59
Yangcheng county, Shanxi	104.01	Zhangye town, Gansu	64.43
Pingshun county, Shanxi	96.95	Jiexian county, Shaanxi	64.36
Changle county, Fujian	93.38	Tianchang county, Anhui	63.04
Shexian county, Hebei	85.64	Tianzhu Tibet Autho county, Gansu	59.18
Lujiang county, Anhui	84.46	Putian county, Fujian	58.83
Zanghuang county, Hebei	77.67	Linxian county, Henan	58.56
Neixiang county, Henan	77.45	Wudu county, Gansu	58.54
Yuanqu county, Shanxi	74.22	Tianjian Dist., Fuzhou city, Fujian	57.52
Linze county, Gansu	66.69	Xianju county, Zhejiang	53.99

although it dropped to the third in urban areas.

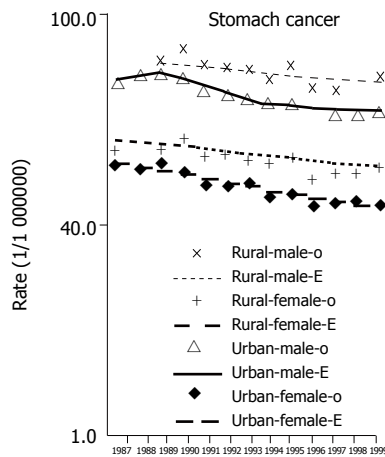

In addition to the above two national mortality surveys, there were a few publications on gastric cancer mortality trends at local levels, either in big cities such as Beijing, Shanghai, or in high-risk areas such as in Henan and Hebei Provinces<sup>[11-14]</sup>. Similarly, the mortality rates of gastric cancer remain high although there was a slight decreasing trend during different time periods among those areas. Therefore, gastric cancer is still the major common cancer and a big burden for local health resources and facilities.

## GASTRIC CANCER INCIDENCE AND MORTALITY PATTERNS AT THE NATIONAL LEVEL IN RECENT YEARS

Based on a routine mortality reporting system, covering 10% of the Chinese population, from the Ministry of Public Health which was submitted to the World Health Organization<sup>[15]</sup>, the gastric cancer mortality trends in China were analyzed from 1987 to 1999, using the joinpoint model. The trends were further combined with the ratio of incidence to mortality from data in seven cancer registries in China that were published in the 8<sup>th</sup> edition of Cancer Incidence in Five Continents<sup>[16]</sup>, to estimate and project the mortality and incidence for gastric cancer in 2000 and 2005 (by site, age, sex and area) at the national level, using the log-linear regression model with Poisson distribution assumption. These results have been serially published recently<sup>[17-19]</sup>.

According to the data from the Center of Health Information Statistics (CHIS) under the Ministry of Public Health, gastric cancer mortality rates were higher in rural than urban areas, and in men than in women. During 1987-1999, slight but significant declines in mortality were noticed in almost the entire subpopulation (except in urban men before 1991) and for most age groups (except age group 15-34) in rural areas (Figures 2 and 3). In 2000, 0.3 million deaths and 0.4 million new cases were estimated for gastric cancer, similar to what was projected in 2005, while the latter had a slight decrease in men but increase in women (Table 3). In 2005, in terms of incidence rates, gastric cancer would rank the third among the most common cancers in China (after cancers of lung

**Figure 2** Time trends for age-standardized mortality rates (both observed and expected by model) of gastric cancer during 1987-1999 in China, by areas (rural and urban) and sex (per 100 000)

and liver in men and after cancers of breast and lung in women)<sup>[19]</sup>.

## FACTORS INFLUENCING THE GASTRIC CANCER PATTERN IN CHINA

Despite a slight increase from 1970s to early 1990s, remarkable declines in gastric cancer mortality were shown during the last decade in China. These declines were largely due to the dramatic improvements in the social-economic environment, lifestyle, nutrition, education and health care system after economic reforms started two decades ago. These include better socio-economic circumstances, higher educational levels, better refrigeration, reduced consumption of salted, smoked, and chemically preserved foods, eating more fruit and vegetables and remarkably improved sanitary conditions of the house and living standards, supplement intake nutrients such as vitamin C, vitamin E, beta-carotene, selenium and decreased intake of nitrosamine, which was strongly suspected as a major

risk factor for gastric cancer<sup>[20-31]</sup>. *H. pylori* infection, which is defined by the World Health Organization as a definite gastric carcinogen, is linked to crowded living conditions, family size, sharing a bedroom, low socio-economic status, low educational level and poor sanitation, and infrequent hand washing before meals. The prevalence of *H. pylori* infection has reduced dramatically due to the improved socio-economic status and lifestyle changes during last decades, especially among urban areas. In addition, widespread prescription of antibiotics may be responsible for reducing *H. pylori* infection. Finally, some locally popular customs, such as drinking green tea, consuming tofu, and ginger have been suggested to have a possible protective effect on gastric cancer<sup>[32-35]</sup>.

However, huge demographic changes in China make the total number of incident cases and deaths from gastric cancer slightly declined in men between 2000 and 2005, while the number increased in women, despite the significant declining trends in rates among all age groups (Table 2)<sup>[17-19]</sup>.

## CONCLUSION

It is estimated that gastric cancer currently ranks the third among most common cancers, and will remain a significant cancer burden in China during the next decade. It will be, undoubtedly, one of the keys in cancer prevention and control strategy in China. The essential package would focus on controlling *H pylori* infection, improving educational levels, advocating healthy diet and anti-tobacco campaign, searching for cost-effective early detection, diagnosis and treatment programs including approaches for curable management and palliative care<sup>[36]</sup>.

of Bcl-2, release of  $\text{Ca}^{2+}$ , decreased the mitochondrial membrane potential and then led to the release of mitochondrial cytochrome C into the cytoplasm and caused the activation of caspase-3, and finally led to the occurrence of apoptosis.

**CONCLUSION:** Berberine induces p53 expression and leads to the decrease of the mitochondrial membrane potential, Cytochrome C release and activation of caspase-3 for the induction of apoptosis.

### Abstract

**AIM:** To investigate the relationship between the inhibited growth (cytotoxic activity) of berberine and apoptotic pathway with its molecular mechanism of action.

**METHODS:** The *in vitro* cytotoxic techniques were complemented by cell cycle analysis and determination of sub-G<sub>1</sub> for apoptosis in human gastric carcinoma SNU-5 cells. Percentage of viable cells, cell cycle, and sub-G<sub>1</sub> group (apoptosis) were examined and determined by the flow cytometric methods. The associated proteins for cell cycle arrest and apoptosis were examined by Western blotting.

**RESULTS:** For SNU-5 cell line, the IC (50) was found to be 48  $\mu\text{mol/L}$  of berberine. In SNU-5 cells treated with 25-200  $\mu\text{mol/L}$  berberine, G<sub>2</sub>/M cell cycle arrest was observed which was associated with a marked increment of the expression of p53, Wee1 and CDk1 proteins and decreased cyclin B. A concentration-dependent decrease of cells in G<sub>0</sub>/G<sub>1</sub> phase and an increase in G<sub>2</sub>/M phase were detected. In addition, apoptosis detected as sub-G<sub>0</sub> cell population in cell cycle measurement was proved in 25-200  $\mu\text{mol/L}$  berberine-treated cells by monitoring the apoptotic pathway. Apoptosis was identified by sub-G<sub>0</sub> cell population, and upregulation of Bax, downregulation

### INTRODUCTION

The growth of tumor cells not like normal cells is uncontrolled. It is a strategy to change biological properties of cancer cells that lead to apoptosis of killing cancer cells in order to reach chemotherapeutic function for anticancer drugs. Apoptosis is a physiological mode of cell death, which can be selectively triggered by cells in response to the stimuli<sup>[1]</sup>. Therefore, the induction of apoptosis is a key factor for anticancer drugs.

Berberine (5,6-dihydro-9,10-dimethoxybenzo[g]-1,3-benzodioxole[5,6-a]quinolizinium), a kind of alkaloid, was initially isolated from a Chinese herbal medicine and used as an antibiotic long ago; and it has effects against many bacterial species<sup>[2,3]</sup>. In the past years, berberine has subsequently been examined for anticancer activity following evidence of antineoplastic properties<sup>[3-5]</sup>. It has also been shown that berberine interacts with nucleic acids especially DNA<sup>[6]</sup> *in vitro*. Berberine exhibits the ability to induce apoptosis in human cancer cells<sup>[5,7]</sup> and promyelocytic leukemia HL-60 cells can form berberine complexes with DNA<sup>[8]</sup>.

Cell cycle studies showed that berberine induces rapid apoptosis in a subpopulation (S phase) of the cells<sup>[8]</sup>. It is

also reported that berberine has dose-dependent effects of berberine on G<sub>2</sub>/M phase and apoptosis in Balb/c 3T3 cells<sup>[9]</sup>. However, the effects of berberine on human gastric cells are still unclear. Therefore, the purpose of the present study was to find out the molecular mechanism of berberine underlying human gastric cancer cell line (SNU-5).

## MATERIALS AND METHODS

### Materials

Berberine, propidium iodide (PI), Tris-HCl, trypan blue, ribonuclease-A and Triton X-100 were obtained from Sigma Chemical Co. (St. Louis, MO, USA). Potassium phosphates, dimethyl sulfoxide (DMSO), and TE buffer were purchased from Merck Co. (Darmstadt, Germany). Iscove's modified Dulbecco's medium, glutamine, fetal bovine serum (FBS), and penicillin-streptomycin, trypsin-EDTA were obtained from Gibco BRL (Grand Island, NY, USA).

### Human gastric carcinoma cell line (SNU-5)

SNU-5 cell line (human gastric carcinoma; 33 years, female) was obtained from the Food Industry Research and Development Institute (Hsinchu, Taiwan). Cells were immediately placed into 75 cm<sup>2</sup> × 75 cm<sup>2</sup> × 75 cm<sup>2</sup> tissue culture flasks and grown at 37 °C under a humidified 50 mL/L CO<sub>2</sub> and 950 mL/L air in 800 mL/L Iscove's modified Dulbecco's medium supplemented with 200 mL/L FBS, 10 g/L penicillin-streptomycin (1 MU/L penicillin and 10 g/L streptomycin) and 10 g/L glutamine as described previously<sup>[10]</sup>.

### Measurement of cell viability after cells were co-treated with berberine determined by trypan blue exclusion and flow cytometry

SNU-5 cells were plated in 12-well plates at a density of 5 × 10<sup>5</sup> cells/well and grown for 24 h. Various concentrations of berberine were added to the cells for final concentrations of 0, 25, 50, 100, and 200 μmol/L, while only DMSO (solvent) was added for the control regivnen and grown for a different period of time at 37 °C, was added 50 mL/L CO<sub>2</sub> and 950 mL/L. The trypan blue exclusion and flow cytometry protocols were used as previously described for determining cell viability<sup>[7]</sup>.

### Flow cytometry analysis of DNA content for cell cycle and apoptosis analysis in SNU-5 cells co-treated with different concentrations of berberine

About 5 × 10<sup>5</sup> SNU-5 cells/well in 12-well plates were incubated with berberine (0, 25, 50, 100, and 200 μmol/L) for different time periods before the cells were harvested by centrifugation. The cells were fixed gently (drop by drop) in 700 mL/L ethanol (in PBS) in ice overnight at -20 °C and then re-suspended in PBS containing 40 g/L PI, 0.1 g/L RNase (Sigma) and 0/10 g/L Triton X-100. After 30 min at 37 °C in the dark, the cells were transferred to the tube, analyzed with flow cytometry (Becton-Dickinson, San Jose, CA, USA) equipped with an argon laser at 488 nm. Then cell cycle and apoptosis were determined and analyzed<sup>[7,10]</sup>.

### Inhibition of berberine-induced apoptosis by caspase inhibitor z-VAD-fmk in SNU-5 cells

In order to further examine whether caspase-3 activation was involved in apoptosis triggered by berberine, SNU-5 cells were pretreated with the cell permeable broad-spectrum caspase inhibitor z-VAD-fmk 3 h prior to the treatment with 100 μmol/L berberine. Apoptosis and caspase-3 activity were then determined as described above.

### Detection of reactive oxygen species (ROS) in SNU-5 cells co-treated with berberine by flow cytometry

The level of ROS in the SNU-5 cells was examined and quantitated by flow cytometry (Becton Dickinson FACS Calibur), using 2,7-dichlorodihydrofluorescein diacetate (DCFH-DA, Sigma). SNU-5 cells were treated with or without berberine (100 mmol/L) for 0, 0.5, 1, 1.5, 2, 4, 6, and 12 h to detect the changes of ROS. The cells were harvested and washed twice, re-suspended in 500 mL of 2,7-dichlorodihydrofluorescein diacetate (10 μmol/L) and incubated at 37 °C for 30 min and analyzed by flow cytometry as described previously<sup>[11]</sup>.

### Detection of Ca<sup>2+</sup> concentrations in SNU-5 cells co-treated with berberine by flow cytometry

The level of Ca<sup>2+</sup> in the SNU-5 cells was determined and quantitated by flow cytometry (Becton Dickinson FACS Calibur), using the Indo 1/AM (Calbiochem; La Jolla, CA, USA). Cells were treated with or without berberine (100 mmol/L) for 0, 0.5, 1, 1.5, 2, 4, 6, and 12 h to detect the changes of Ca<sup>2+</sup> concentrations. The cells were harvested and washed twice, and re-suspended in Indo 1/AM (3 mg/L) and incubated at 37 °C for 30 min and analyzed by flow cytometry as described previously<sup>[12]</sup>.

### Detection of mitochondrial membrane potential in SNU-5 cells co-treated with berberine by flow cytometry

The level of mitochondrial membrane potential in the SNU-5 cells was determined by flow cytometry (Becton Dickinson FACS Calibur), using DiOC<sub>6</sub> (4 mol/L) (Calbiochem, Inc., La Jolla, CA, USA). Cells were treated with or without various concentrations (0, 25, 50, 100, and 200 mmol/L) of berberine for 1, 2, 4, 6, 12, 24 h to detect the changes of mitochondrial membrane potential. The cells were harvested and washed twice, re-suspended in 500 mL of DiOC<sub>6</sub> (4 mol/L) and incubated at 37 °C for 30 min and analyzed by flow cytometry<sup>[11]</sup>.

### Detection of caspase-3 activity and apoptosis in SNU-5 cells co-treated with berberine by flow cytometry

The caspase-3 activity and apoptosis in the SNU-5 cells were determined by flow cytometry (Becton Dickinson FACS Calibur), using PhiPhiLux-G<sub>2</sub>D<sub>2</sub> (4 × 10<sup>-4</sup> mmol/L) (OncoImmunin, Inc., MD, USA). Cells were treated with or without various concentrations (0, 25, 50, 100, and 200 mmol/L) of berberine and co-treated with or without caspase-3 inhibitor (z-VAD-fmk) for 24 h to detect the changes of caspase-3 activity and apoptosis. The cells were harvested and washed twice, re-suspended in 50 mL PhiPhiLux-G<sub>2</sub>D<sub>2</sub> of (4 × 10<sup>-4</sup> mmol/L) and incubated at

**Figure 1** Percentage of viable SNU-5 cells treated with berberine with 24-h incubation. The SNU-5 cells ( $2 \times 10^5$  cells/well; 12-well plate) were plated in 80% Iscove's modified Dulbecco's medium+20% FBS with different concentrations of berberine for 24 h (Panel A) or 100  $\mu$ mol/L berberine for 6, 12, 24, 48, and 72 h (Panel B). Then the cells were collected by centrifugation and the viable cells were determined by trypan blue exclusion and flow cytometry as described in Materials and Methods. Each point is mean  $\pm$  SD of three experiments.

37 °C for 30 min and analyzed by flow cytometry as described previously<sup>[11]</sup>.

#### Effect of berberine on CDK1, Wee1, Cdc25, p53, JNK, Bcl-2, Bax, and cytochrome C of SNU-5 cells

The total protein was collected from SNU-5 cells treated with or without various concentrations of berberine for 48 h before CDK1, Wee1, Cdc25, p53, JNK, Bcl-2, Bax, and cytochrome C were measured by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and Western blot as described previously<sup>[12,13]</sup>.

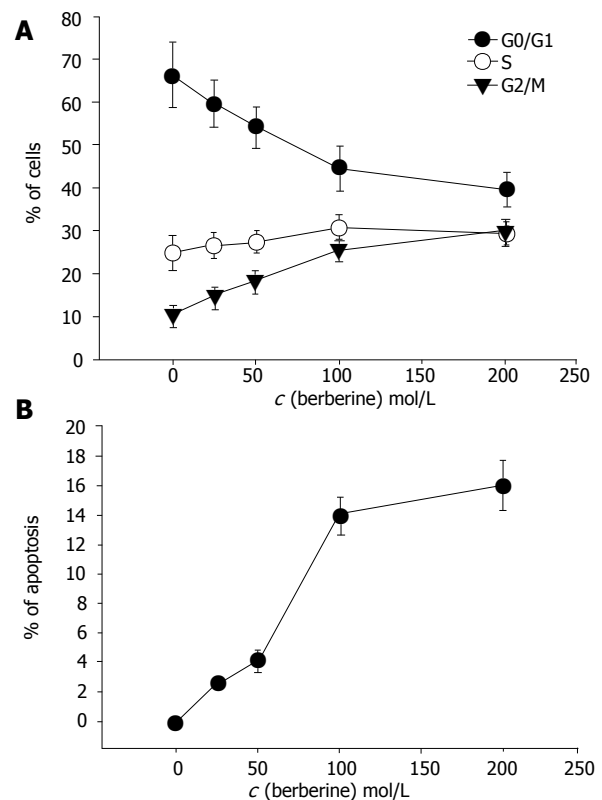

#### Statistical analysis

Student's *t*-test was used in statistical analysis between berberine-treated and control groups.  $P < 0.05$  was considered statistically significant.

## RESULTS

#### Effects of berberine on growth of SNU-5 cells

Percentage of cell growth was significantly different between the berberine-treated group and control group. The effects of berberine on SNU-5 cells were dose-dependent (Figure 1A). Increasing the time of incubation led to the decrease of percentage of cell growth (Figure 1B). Apparently the effects of berberine on SNU-5 cells also were time dependent.

**Figure 2** Flow cytometric analysis of the effects of berberine on SNU-5 cell cycle and sub-G<sub>1</sub> group. The SNU-5 cells were exposed to various concentrations of berberine for 48 h, and the cells were harvested and analyzed for cell cycle (Panel A: the percent of cells in phase) and sub-G<sub>1</sub> group (Panel B: the percent of cells in apoptosis) were analyzed by flow cytometry as described in Materials and methods. Data represents mean  $\pm$  SD of three experiments.

#### Cell cycle arrest and apoptosis induced by berberine in SNU-5 cells

First, we studied the cell cycle and occurrence of apoptosis induced by berberine. Cell cycle and apoptosis were detected by PI staining and annexin V method after 48 h of continuous exposure to berberine before analyzed by flow cytometry (Figures 2A and 2B). As shown in Figure 2, berberine induced G<sub>2</sub>/M arrest and apoptosis in a concentration- and time-dependent manner.

#### Effect of berberine on cyclin B, CDK1, Wee1, and CDC25C of SNU-5 cells

Berberine increased the expression of Wee1 and CDC25C (Figures 3A and 3B) but decreased the expression of cyclin B and CDK1 (Figures 3C and 3D) as detected by western blotting.

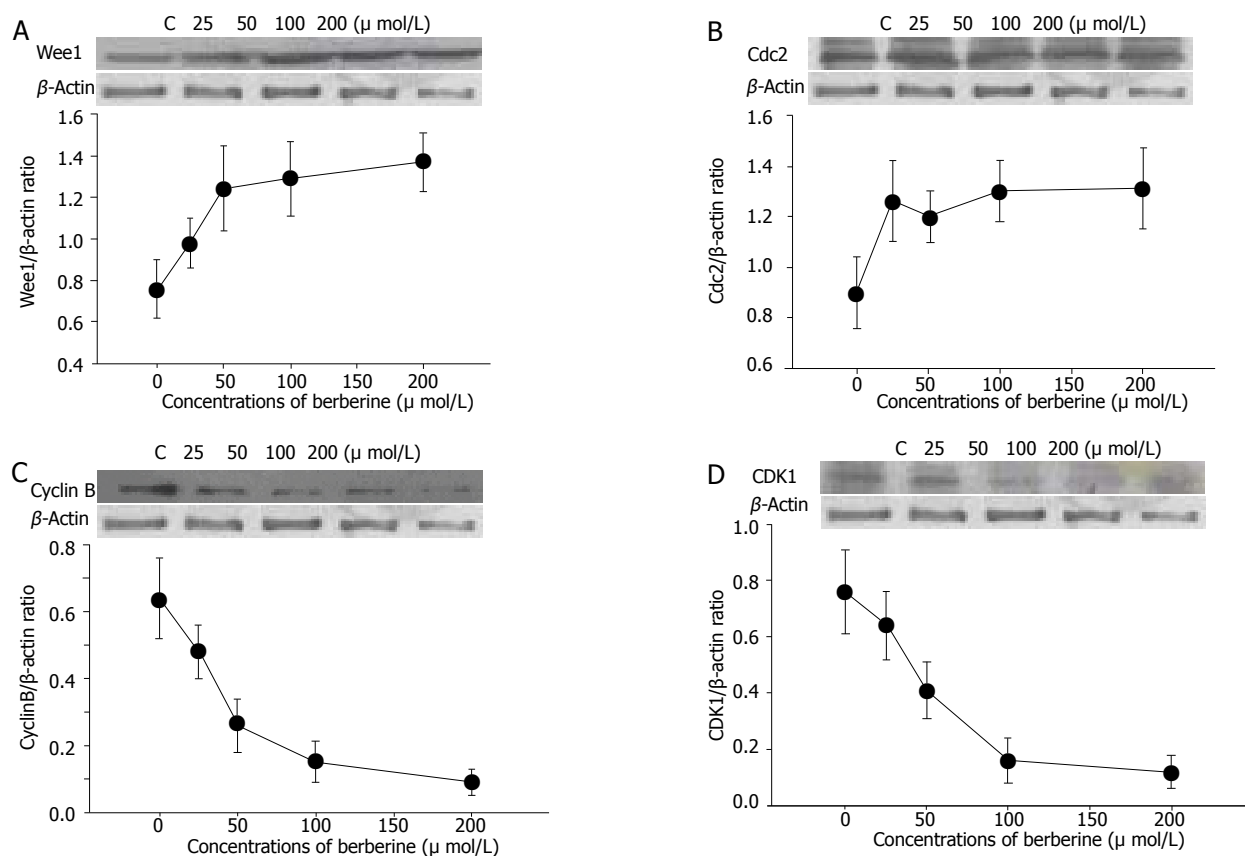

#### Effects of berberine on the production of reactive oxygen species (ROS) in SNU-5 cell line

Percentage of ROS was significantly different between the berberine-treated group and control group. The effects of berberine on taking up of DCFH-DA dye by SNU-5 cells were dose-dependent (Table 1) and time dependent (Figure 4A).

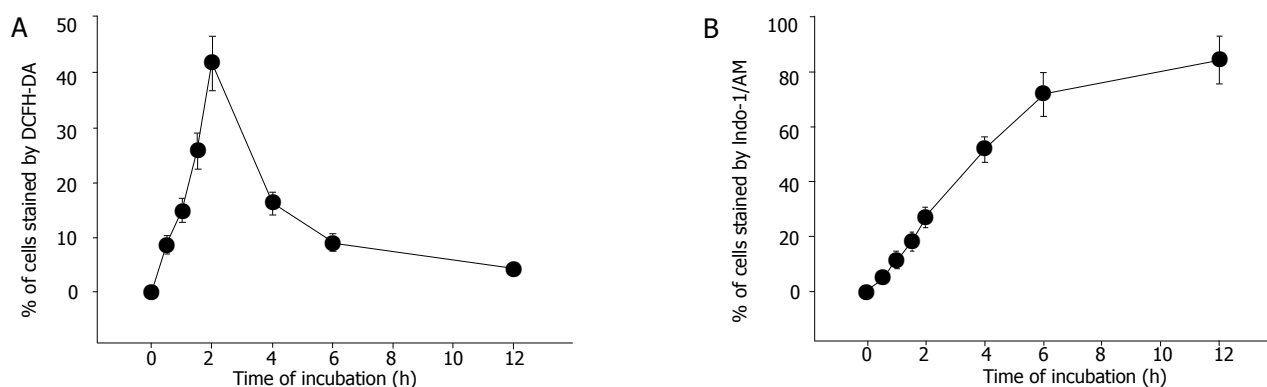

#### Effects of berberine on the production of Ca<sup>2+</sup> in SNU-5 cells

Percentage of Ca<sup>2+</sup> concentrations was significantly

**Figure 3** Changes of levels of CDK1 (A), cyclin B1 (B), Wee1 (C), and Cdc2 (D) in SNU-5 cells after exposure to berberine. SNU-5 cells ( $5 \times 10^5$  / L ) were treated with 0, 25, 50, 100, and, 200  $\mu\text{mol/L}$  berberine for 24 h, then cytosolic fraction and total protein were determined as described in Materials and Methods.

**Figure 4** Flow cytometric analysis of reactive oxygen species (A) and  $\text{Ca}^{2+}$  concentration (B) in human gastric carcinoma SNU-5 cells with 100  $\mu\text{mol/L}$  berberine for various time periods. The SNU-5 cells ( $5 \times 10^5$  cells/mL) were treated with 100  $\mu\text{mol/L}$  berberine for 0, 0.5, 1, 1.5, 2, 4, 6, and 12 h to detect the changes of ROS and  $\text{Ca}^{2+}$  concentration. The zero concentration was defined as control. The percentage of cells stained with DCFH-DA dye was determined by flow cytometry as described in the Materials and Methods section.

different between the berberine-treated group and control group. The effects of berberine on taking up of Indo-1/AM dye by SNU-5 cells were dose and time-dependent (Table 1, Figure 4B).

#### Effects of berberine on the mitochondrial membrane potential in SNU-5 cells

Percentage of mitochondrial membrane potential (MMP) was significantly different between the berberine-treated group and control group. Apparently the effects of berberine on the levels of MMP determined by the take

up of the DiOL6 dye in SNU-5 cells were dose and time-dependent (Table 1, Figure 5).

#### Inhibition of berberine-induced caspase-3 activity and apoptosis by z-VAD-fmk in SNU-5 cells

The results indicate the caspase inhibitor that berberine increased caspase-3 activity in a dose- and time-dependent manner (Figure 6A). The SNU-5 cells were pretreated with the cell permeable broad-spectrum caspase inhibitor (z-VAD-fmk) 3 h prior to the treatment with berberine. The z-VAD-fmk decreased the caspase-3 activity. After

**Table 1** Flow cytometric analysis of reactive oxygen species  $\text{Ca}^{2+}$  concentration and mitochondrial membrane potential in gastric carcinoma SNU-5 cells with treated various concentrations of berberine (mean  $\pm$  SD)

Berberine ( $\mu\text{mol/L}$ )	cells taking up DCFH-DA (%)	cells taking up Indo-1/AM (%)	cells taking up DiOC <sub>6</sub>
0	0.24 $\pm$ 0.06	1.69 $\pm$ 0.22	94.20 $\pm$ 9.29
25	10.47 $\pm$ 2.02 <sup>a</sup>	28.78 $\pm$ 2.49 <sup>a</sup>	74.14 $\pm$ 8.28 <sup>a</sup>
50	28.18 $\pm$ 3.14 <sup>a</sup>	42.47 $\pm$ 3.96 <sup>a</sup>	40.21 $\pm$ 5.08 <sup>a</sup>
100	62.28 $\pm$ 5.46 <sup>a</sup>	74.62 $\pm$ 6.48 <sup>a</sup>	17.40 $\pm$ 1.87 <sup>a</sup>
200	79.49 $\pm$ 7.08 <sup>a</sup>	91.38 $\pm$ 8.41 <sup>a</sup>	8.16 $\pm$ 1.04 <sup>a</sup>

The SNU-5 cells ( $5 \times 10^5$  cells/mL) were treated with 0, 25, 50, 100, and 200  $\mu\text{mol/L}$  of berberine. The zero concentration was defined as control. The percentage of cells taking up DCFH-DA dye, was determined by flow cytometry as described in the Materials and Methods. <sup>a</sup> $P < 0.05$ . *vs* control.

treated with berberine and z-VAD-fmk in SNU-5 cells, inhibition of berberine-mediated caspase-3 activation was accompanied with the marked attenuation of berberine-induced apoptotic cell death (Figure 6B).

#### Effect of berberine on p53, Bax, Bcl-2, and cytochrome C in SNU-5 cells

The results indicated that DADS increased the expression of p53 (Figure 3A), JNK phosphorylation (Figure 3B) and cytochrome C (Figure 3D) release but decreased the expression of Bcl-2 (Figure 3C) as detected by western blotting

## DISCUSSION

Berberine (25–200  $\mu\text{mol/L}$ ) was cytotoxic to SNU-5 cells in a dose- and time-dependent manner. The  $\text{IC}_{50}$  for SNU-5 cells was 48  $\mu\text{mol/L}$  (Figure 7). It is slightly different in HL-60 cells<sup>[8]</sup>. But the sensitivity of murine leukemia L1210 cells to the berberine is higher than that of HeLa cells<sup>[14]</sup>. Our results also showed that berberine induced ROS in a dose-dependent manner. It may be due to the cell death induced by ROS. Although it was demonstrated that berberine can decrease the intracellular ROS<sup>[5]</sup>, such variable effects are not uncommon. However, cells after treated with berberine for 48 and 72 h slightly increased their viability. They therefore may lead to the resistance to berberine due to the expression of multidrug-resistant transporters (mdr) because berberine can modulate expression of mdr1 gene product (pgp-170) that leads to reduced response to paclitaxel in digestive track cancer cells<sup>[15]</sup>.

Berberine arrests cells in S- and G<sub>2</sub>/M-phase of the cell cycle, but the former effect is transient. However, G<sub>2</sub>/M arrest is obvious. Apparently this effect is dose-dependent. Although it was reported that berberine could induce G<sub>0</sub>/G<sub>1</sub> cell cycle arrest in murine L1210 cells<sup>[14]</sup>, it was also reported that berberine can induce G<sub>2</sub>/M cell cycle arrest in Balb/c 3T3 cells<sup>[4,16]</sup>, suggesting that berberine induces cell cycle arrest depending on cell types. Therefore, the mechanism of berberine is not the same in all cell types. Western blot results from the present studies also demonstrated that berberine inhibits the levels of cyclin

**Figure 5** Flow cytometric analysis of mitochondrial membrane potential in human SNU-5 cells with 100  $\mu\text{mol/L}$  berberine for various time periods. The SNU-5 cells ( $5 \times 10^5$  cells/L) were treated with various concentrations of berberine. The zero concentration was defined as control. The percentage of cells stained with DiOC<sub>6</sub> dye, was determined by flow cytometry as described in the Materials and Methods.

B and CDK1 but increases the levels of Wee1 and Cdc2, which may be the factors for G<sub>2</sub>/M arrest in SNU-5 cells. It has been reported that increases of Cdc2 activity are in response to drug-induced G<sub>2</sub>/M arrest<sup>[16,17]</sup>. Formation of Cdc2-cyclin B complex is necessary for G<sub>2</sub>/M transition and cells to enter mitosis<sup>[16]</sup>. Our result demonstrated that berberine declined cyclin b levels in SNU-5 cells, and that G<sub>2</sub>/M arrest could be controlled by cyclin B rather than by Cdc2 activation. Cyclin-dependent kinases (Cdks) are the central regulators of cell division cycle. Inhibitors of Cdks ensure proper coordination of cell cycle events and regulate cell proliferation in tissues and organs. Wee1 homologs phosphorylate a conserved tyrosine to inhibit the mitotic cyclin-dependent kinase Cdk1<sup>[18]</sup>. It was also reported that the induction of Cdc2 phosphorylation due to the increase of Wee1 and Myt1 as well as the reduction of Cdc2 and cyclin B1, is involved in 1,25 [OH] 2VD3-induced G<sub>2</sub>/M arrest of keratinocytes<sup>[16,19]</sup>. It has been shown that multisite phosphorylation of either CDK, Cdc2, Wee1, or CDK-activating kinase is sufficient to generate dynamical behaviors including bistability and limited cycles<sup>[20,21]</sup>. Experimental depletion of Wee1 by a small interfering RNA directed to Wee1 mRNA could alleviate Vpr-induced G(2) arrest and allow normal progression from M into G phase<sup>[16]</sup>.

Cell cycle analysis revealed the presence of apoptotic cell death (sub-G<sub>1</sub> group) following treatment with berberine. We also did morphological examination which showed cell shrinkage, loss of cell-to-cell contact, membrane blebbing and chromatin condensation elicited by increasing berberine concentration and length of exposure. These results were also confirmed by fluorescence microscopy and flow cytometry. So far, many signals and stimuli have been reported to join the induction of apoptosis, therefore the survival of specific cells is under the control of a wide complex of signals. Especially the caspase activities have been demonstrated to be the regulators of apoptosis<sup>[22,23]</sup>. Most apoptosis models are involved in caspase activation and two main pathways: caspases-8 and -3 or activation of caspases-9 and -3 activation<sup>[24]</sup>. The caspases-9 and -3 are involved in the

**Figure 6** Flow cytometric analysis of the effects of berberine induced caspase-3 activity (A) and apoptosis (B). The SNU-5 cells were incubated with 100  $\mu\text{mol/L}$  berberine with or without z-VAD-fmk treatment for determination of caspase-3 activity and apoptosis.

**Figure 7** Changes of levels of p53(A), Bcl-2(B), Bax(C), and cytochrome C(D) in SNU-5 cells after exposure to berberine. SNU-5 cells ( $5 \times 10^6/\text{mL}$ ) were treated with 0, 25, 50, 100, and 200  $\mu\text{mol/L}$  berberine for 24 h, then cytosolic fraction and total protein were determined as described in Materials and Methods. The levels of p53, p21, Bcl-2, Bax, and cytochrome C were determined by Western blotting as described in Materials and Methods.

release of cytochrome C from mitochondria which causes the decrease of mitochondrial membrane potential. Our data demonstrated that berberine was able to induce the increase of  $\text{Ca}^{2+}$  and mitochondrial membrane potential loss and cytochrome C release in cytosolic fraction of SNU-5 cells, which correlates well with the activation of caspases-9 and -3. Our result also showed that berberine decreased the levels of Bcl-2 which control mitochondrial membrane potential and Bax was increased which promotes the cytochrome C release (Figure 8).

Berberine can decrease apoptosis induced by paclitaxel

in human cancer cell lines including gastric cancer cells<sup>[25,26]</sup>, whereas in the present study berberine induced cell cycle arrest and cell death (apoptosis) in SNU-5 cells in a dose- and time-dependent manner. Based on these findings, we suggest that berberine may contribute to the antineoplastic activity of gastric cancer cells. However, the molecular basis of such effects needs for further investigations. Although the exact binding sites or receptors of berberine on the SNU-5 cells are still unknown, the antineoplastic activity of berberine may provide a basis for further studies.

**Figure 8** Proposed model of berberine mechanism of action on G2/M arrest and apoptosis in SNU-5 cells. Berberine induced p53 expression that led to the decrease of cyclin B and CDK1 but increase of the expression of cdc25c and Wee1 for G2/M arrest. Berberine induced ROS,  $\text{Ca}^{2+}$  production and decreased MMP levels led to cytochrome C release and caspase-3 activity, causing apoptosis in SNU-5 cells.

## Abstract

**AIM:** Polo-like kinase 1 (PLK1) serine/threonine kinase plays a vital role in multiple phases of mitosis in gastric cancer cells. To investigate the effect of PLK1 depletion on mitosis and apoptosis of gastric cancer cells.

**METHODS:** PLK1 expression was blocked by small RNA interference (siRNA). The expression levels of PLK1, cdc2, cyclin B and caspase 3 were detected by Western blotting. Then, PLK1 depletion, cdc2 activity, cell proliferation, cell cycle phase distribution, mitotic spindle structure, and the rate of apoptosis of the PLK1 knockdown cells were observed.

**RESULTS:** PLK1 gene knockdown was associated with increased cyclin B expression, increased cdc2 activity (but not with the expression levels), accumulation of gastric cancer cells at G2/M, improper mitotic spindle formation, delayed chromosome separation and delayed or arrested cytokinesis. Moreover, PLK1 depletion in gastric cancer cells was associated with decreased proliferation, attenuated pro-caspase 3 levels and increased apoptosis.

**CONCLUSION:** Blockage of PLK1 expression may lead to decreased mitosis or even apoptosis in gastric cancer cells, indicating that PLK1 may be a valuable therapeutic target for gastric cancer.

## INTRODUCTION

The separation of chromosomes and the division of one cell into two daughter cells are the most dramatic events during the cell cycle. This process, known as mitosis, involves a series of structural changes in cells, including centrosome duplication, spindle formation and cytokinesis. The cdc2 - cyclinB protein complex, a mitosis promoting factor, is known to trigger and promote the completion of this complex process<sup>[1]</sup>, but the mechanism responsible for activating the cdc2 - cyclinB complex remained unknown until the conserved Polo-like kinase 1 (PLK1) was cloned by Golsteyn *et al.*<sup>[2]</sup>. PLK1 accumulates markedly during the G2/M phase in cells, where it phosphorylates and activates the cdc2 - cyclinB complex and other mitosis-involved substrates<sup>[3,4]</sup>. PLK1 is indispensable in some types of cell division including tumor cells<sup>[5]</sup>. Besides, PLK1 expression increases in multiple types of solid tumors such as non-small-cell lung cancer, head and neck cancer, esophageal cancer, colorectal cancer-associated glioma<sup>[6-10]</sup>. PLK1 is now considered as an oncogene, a potential target for cancer therapy. But to our knowledge, no previous work has examined the effect of PLK1 knockdown in gastric cancer cells. Here, we have used RNA interference technology to block the expression of PLK1 in gastric cancer cell line MKN45 and observed the changes in cell division phenotypes and cell viability.

## MATERIALS AND METHODS

### Cell culture

The gastric cancer cell line MKN45 was maintained in RPMI1640 medium containing 2 mmol/L glutamine and 100ml/L fetal bovine serum (Invitrogen, CA, USA) and incubated at 37°C in an atmosphere containing 50 mL/L of CO<sub>2</sub>.

### PLK1 siRNA

The Ambion software was used to design RNAi sequences targeting human PLK1 (accession no. NM 005030) and

the siRNA sequence with the highest putative efficacy (5'-CAACCAAAGTCGAATATGA 3') was synthesized by Shanghai GeneChem Co., Ltd. (PLK<sup>-</sup> group). Small RNA interference with randomized sequence (5'-TTCTCCGAACGTGTCACGT3') against no gene (scrambled siRNA group) and only liposome (liposome group) were transfected as internal control.

For the experiments, cells transfected with the DOTAP liposomal transfection reagent (Roche, Germany) were seeded at  $2 \times 10^5$  cells/well in six-well plates. After 24 h culture when cells were in the phase of log growth, 250  $\mu$ L Opti-MEM I was mixed with 7.5  $\mu$ L of 20  $\mu$ mol/L siRNA duplex, while another 250  $\mu$ L Opti-MEM I was separately incubated with 11.88  $\mu$ L of DOTAP liposome. The two mixtures were gently mixed and incubated for about 30 min at room temperature. For transfection, the entire mixture was added to each well in 1.5 mL of fresh medium containing 100 mL/L FBS without antibiotics. The final transfected concentration of siRNA was 75 nmol/L. Cells were collected for further assay at 24, 48, and 72 h after transfection.

#### **Western blotting**

Cells were lysed in AM1 lysis buffer (Active Motif, USA) and protein concentrations were measured with the BCA protein assay kit (Pierce, USA). Total protein (50  $\mu$ g) was resolved by 125 g/L SDS-PAGE and transferred onto PVDF membranes. After being blocked in TBST (20 mmol/L Tris, 137 mmol/L NaCl, 1 g/L Tween 20, pH 7.6) with 50 mL/L skim milk for 2 h at room temperature, membranes were incubated with PLK1, cyclinB, cdc2, procaspase 3, and  $\beta$ -actin primary antibodies (diluted 1:200; Santa Cruz Biotechnology, USA) for 2 h. Membranes were then washed thrice with TBST solution, followed by incubation for 1 h with HRP-linked secondary antibodies (1:1 000; Santa Cruz Biotechnology) at room temperature. Finally, membranes were visualized using the DAB reagent (Dako Corporation, Denmark).

#### **Kinase analysis**

Cdc2 kinase activity was measured using the cdc2-cyclinB kinase assay kit (MBL<sup>TM</sup> International, Japan) according to the manufacturer's instructions.

#### **Fluorescence-activated cell sorting analysis**

Cells were harvested by trypsin, washed with cold PBS and resuspended in 750 mL/L ethanol at 4°C for at least 8 h. The fixed cells were collected by brief centrifugation and resuspended in PBS containing 200  $\mu$ g/mL RNase and 15 mg/L propidium iodide. After incubation at room temperature for 30 min, samples were subjected to flow cytometry (FCM) for Fluorescence-activated cell sorting assay and cell cycle phase analysis.

#### **Immunofluorescence staining and confocal microscopy**

Cells were grown on coverslips, fixed with 40 g/L paraformaldehyde for 10 min and permeabilized with methanol for 2 min. After being washed thrice with 1 Triton X-100 in PBS, the coverslips were blocked with 20 mL/L FBS for 30 min, stained with 10 mg/L anti- $\alpha$ -

tubulin primary antibody for 2 h at room temperature and incubated with FITC-conjugated secondary antibody (Santa Cruz Biotechnology) for 30 min. Finally, the DNA was stained with TO-PRO-3 iodide (Molecular Probes, USA) and confocal microscopy was performed to obtain detailed images of the subcellular structures.

#### **MTT assay**

The MTT method was used to measure cell proliferation. Briefly,  $4 \times 10^3$  cells/well were cultured in 96-well plates. After 24 h, siRNA and liposome were added to transfect cells, and then at the designated time points (24, 48, 72, and 96 h after transfection), MTT (5 g/L) was added. Cells were incubated for 4 h and then the medium was removed and 100  $\mu$ L DMSO solution was added for 5 min. The absorbance of the reaction solution was measured at 570 nm and the data from the various time points were used to generate cell proliferation curves.

#### **Apoptosis detection**

Apoptosis was assessed with an Annexin V kit (BD Corporation, USA). In brief, cells were harvested, washed in PBS and labeled with Annexin V antibody and PI according to the manufacturer's protocol. Labeled cells were then subjected to FCM for the determination of apoptosis.

#### **Statistical analysis**

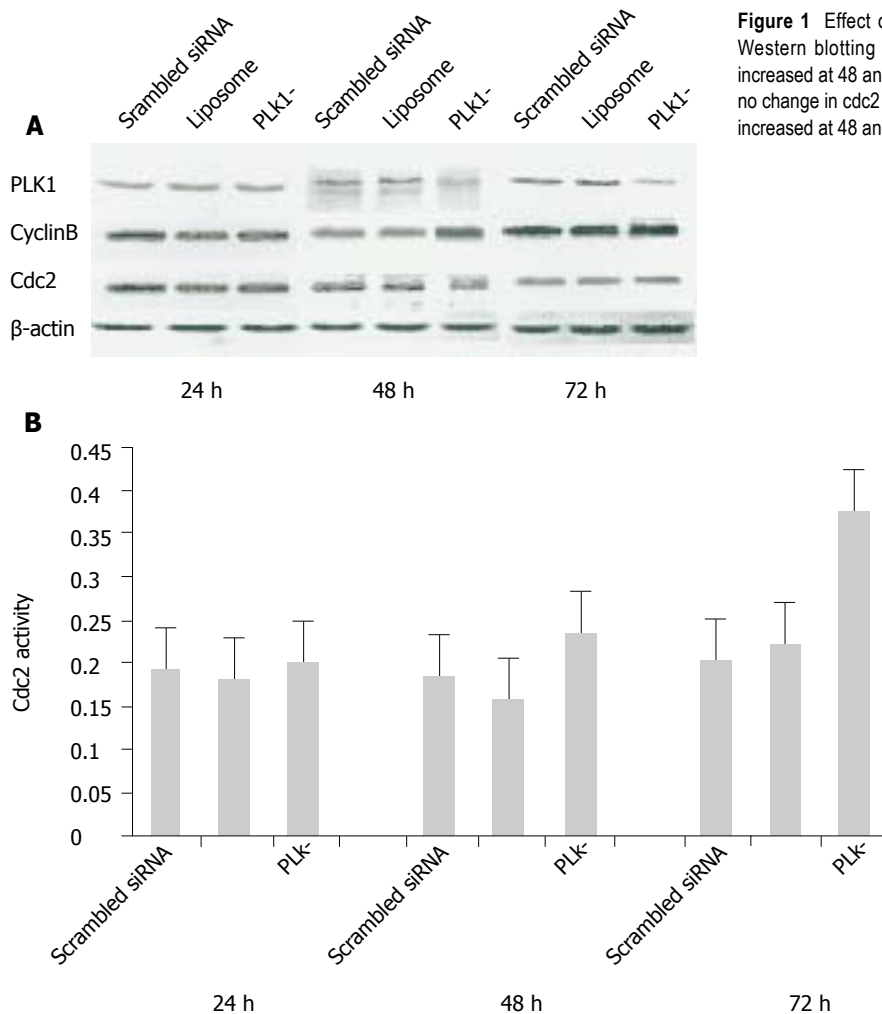

All experiments were repeated thrice. Data were analyzed with SPSS software version 11.0. Student's *t*-test was used to evaluate the difference in cell phase distribution between PLK<sup>-</sup> and scrambled siRNA groups. One-way analysis of variance (ANOVA) was used to test the effects of the three treatments on cdc2 activity and apoptosis rate. Two-way analysis of variance was performed to detect the random effects of the three treatments on cell proliferation (MTT assay), and Student-Newman-Keuls test was used to detect the difference between any two groups. The  $\chi^2$  test was employed to examine the difference in cell mitosis phenotypes under confocal microscope. Cell morphology was observed under inverted microscope between experimental and control groups.  $P < 0.05$  was considered statistically significant.

## **RESULTS**

#### **Increase in cyclinB expression and cdc2 activity following PLK1 knockdown by siRNA**

To determine the effect of siRNA on PLK1 depletion, we collected cell samples at 24, 48, and 72 h after transfection, extracted total cellular proteins and performed standard Western blotting of experimental cultures and scrambled siRNA-treated and liposome-only controls. PLK1 protein levels were reduced by 38.4% and 60.7% compared with the scrambled siRNA-treated control groups at 48 and 72 h, respectively, indicating that PLK1 gene expression was obviously blocked by the siRNAs (Figure 1A). We found that the cyclinB protein levels were 82.4% and 32.9% higher at 48 and 72 h, respectively in PLK1-depleted

**Figure 1** Effect of PLK1 depletion on members of the MPF complex. **A:** Western blotting showed that PLK1 levels decreased and cyclinB level increased at 48 and 72 h after RNAi targeting PLK, whereas there was almost no change in cdc2 level at 24, 48, and 72 h. **B:** Cdc2 activity was substantially increased at 48 and 72 h after PLK1 expression knockdown.

cells than in scrambled siRNA-treated cells (Figure 1A), while the mean activity of cdc2 kinase was increased in comparison to the controls (85.71% and 68% higher than scrambled siRNA-treated cells at 48 and 72 h, respectively,  $P < 0.05$ ), but there was no apparent difference at the protein level (Figures 1A and 1B).

#### Tumor cell accumulation in G<sub>2</sub>/M phase caused by PLK1 siRNA

Cell cycle phase distribution was measured by FCM at 24, 48, and 72 h after siRNA transfection. The mean percentage of cells with G<sub>2</sub> DNA content in the PLK<sup>-</sup> group was 40.15%, 36.58%, and 59.88%, while that in the scrambled siRNA control group was 14.59%, 10.11%, and 17.69% at 24, 48, and 72 h, respectively ( $P < 0.05$ , Figure 2A). Inverted microscopy was used to examine the morphological changes of tumor cells under five randomly chosen inverted microscopic fields. The percentage of rounded cells was higher in the experimental group than in the scrambled siRNA control group (41% *vs* 13%, 38.55% *vs* 13.21%, and 44.55% *vs* 18.2% at 24, 48, and 72 h, respectively) ( $P < 0.05$ , Figure 2B).

#### Decreased tumor cell proliferation caused by PLK1 siRNA

MTT assays were used to determine whether PLK1 gene depletion affected tumor cell proliferation. The resultant

proliferation curves indicated that the PLK1-depleted cells divided more slowly than cells in the two control groups ( $P < 0.05$ , Figure 3).

#### Spindle formation, chromosome separation and cytokinesis in gastric cancer cells delayed by PLK1 siRNA

Changes in the mitotic phenotypes of PLK1 knockdown and control cells were observed by immunofluorescence staining and confocal microscopy. The spindle structure lost its cohesiveness 48 h after siRNA transfection (Figure 4A). Images of the five different substages of mitosis could be acquired (Figure 4B). There were substantial differences in the amounts and percentages of cells between the experimental group and scrambled siRNA control group after 48 h ( $P < 0.05$ , Table 1) at the onset of mitosis. More PLK<sup>-</sup> cells (46% *vs* 20%) were at substage I (nuclear membrane breakdown and even chromosomal distribution in the cytoplasm) and fewer (1% *vs* 41%) were at substage II (chromosomal array along the equator plate) and III (2% *vs* 8%) (chromosomal segregation). Meanwhile, higher percentages of cells with dumbbell-shaped nuclei (33% *vs* 15%) and cytoplasmic bridges connecting two incompletely separated cells (8% *vs* 1%) were also shown in PLK<sup>-</sup> cells. These results collectively indicated that spindle formation, chromosome separation

**Table 1** Effect of PLK1-specific siRNA on MKN45 mitosis phenotype<sup>1</sup> (%)

	I	II	III	IV	V	Other types	Total
Scrambled siRNA	20	41	8	15	1	15	100
PLK <sup>-</sup>	46	1	2	33	8	10	100

<sup>1</sup>314 mitosis cells in control group and 233 mitosis cells in RNAi group were counted.

**Figure 2** Changes in tumor cell cycle after PLK1 depletion. **A:** Fluorescence-activated cell sorting (FACS) analysis revealed that PLK<sup>-</sup> MKN45 cells had an increased G<sub>2</sub> DNA content and were accumulated at G<sub>2</sub>/M phase. **B:** Cells treated with siRNA became rounder in shape.

**Figure 3** Effect of PLK1 depletion on cell proliferation.

and cytokinesis were delayed during mitosis in MKN45 cells transfected with PLK1-specific siRNA duplexes.

#### Increased apoptosis of MKN45 cells caused by PLK1 knockdown

To evaluate the role of PLK1 in tumor cell fate, PLK1-depleted cells were labeled with Annexin V antibody and subjected to FCM. The results showed that the mean apoptosis rate (including early and late apoptosis) at 48 and 72 h was higher in PLK1-depleted cells than in scrambled

siRNA cells (42.4% *vs* 21.4%, 53.8% *vs* 32.9%, *P* < 0.05, Figure 5A). Furthermore, Western blotting revealed that caspase 3 level was lower in PLK1-depleted cells (Figure 5B).

## DISCUSSION

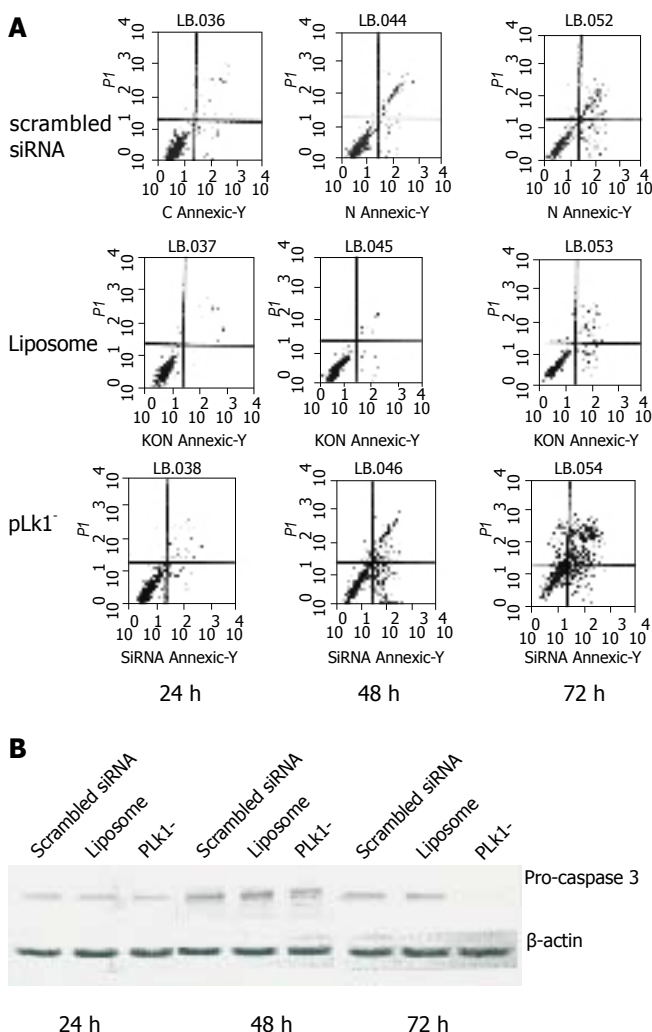

Gastric cancer is one of the most common malignancies in the world. Uncontrolled cellular proliferation is commonly associated with the poor prognosis of this disease. Human PLK1 plays a key role in some mitotic events<sup>[11,12]</sup>. Its expression is associated with tumor proliferation degree<sup>[13]</sup>. PLK1 depletion is associated with HeLa cell mitosis<sup>[5]</sup>. However, no previous work has examined the possible role of PLK1 in gastric cancer cell mitosis and cell fate. In this experiment, we have used siRNA technology to knockdown PLK1 gene expression and observed the changes in mitotic phenotypes of the gastric cancer cell line, MKN45.

The protein level of PLK1 was decreased by 38.4% and 60.7%, respectively at 48 and 72 h after the addition of the PLK1-specific siRNA, indicating that the interference is effective and this system is appropriate for the study of mitotic events under PLK1 knockdown conditions. A previous study has demonstrated that the direct motivation of driving cells from G<sub>2</sub> to M phase is caused by the cyclinB-cdc2 complex (also known as the mitosis promoting factor or MPF). PLK1 is responsible for phosphorylating and activating MPF at the G<sub>2</sub>/M checkpoint<sup>[3]</sup> and mediates the degradation of cyclinB by activating the anaphase-promoting complex at the end of mitosis<sup>[14,15]</sup>, indicating that PLK1 can initiate and maintain mitosis. In our PLK1 knockdown cells, the cyclinB level increased probably due to the failure of depleted PLK1

**Figure 4** Tumor cell mitosis decreases following PLK1 depletion. **A:** Control cells showed clear mitotic frameworks, whereas the spindles of the PLK<sup>-</sup> depleted cells were unclear and broken when the sister chromosomes were separated. **B:** The five examined substages of mitosis (I-V) in both control and PLK<sup>-</sup> depleted cells.

**Figure 5** PLK1 siRNA induces MKN45 apoptosis. **A:** Annexin V staining and FCM revealed a higher percentage of apoptotic PLK1-depleted cells at 48 and 72 h; **B:** Western blotting showed reduced pro-caspase 3 levels in PLK<sup>-</sup> cells at 48 and 72 h.

to activate APC. In addition, the activity (but not the

quantity) of cdc2 (a component of MPF) was increased by 85.7% and 68.0% at 48 and 72 h, respectively in PLK1 knockdown cells compared to scrambled siRNA controls. Previous reports indicate that PLK1 and its analogs seem to phosphorylate and activate cdc25<sup>[3,16]</sup>, which then dephosphorylates and activates the cdc2/cyclinB complex in different organisms<sup>[17,18]</sup>, suggesting that cdc2 may lose its activity under PLK1 knockdown conditions. Our observation of cdc2 activation seems to indicate that cdc2 is activated in a cdc25-independent manner.

Immunofluorescence and confocal microscopy revealed that the microtubule morphology was affected in PLK1-depleted cells, becoming broken and unclear. We were able to identify cells in both PLK1-depleted and control cultures corresponding to the five substages of mitosis: (I) nuclear membrane breakdown and even chromosomal distribution in cytoplasm; (II) chromosomal array along the equator plate; (III) chromosomal segregation; (IV) mitotic exit and nuclear membrane formation; (V) cytokinesis. These substages were observed at varying frequencies between the control and siRNA-treated cells. At the onset of mitosis, more siRNA-treated cells (46% *vs* 20%) were at substage I and fewer were at substage II (1% *vs* 41%) or III (2% *vs* 8%). Recent studies showed that PLK1 affects chromosomal separation by controlling the formation of mitotic spindle and phosphorylating cohesion to decrease the cohesion of sister chromosomes<sup>[19-21]</sup>. Our results revealed that in PLK1-depleted tumor cells, the mitotic spindle was disrupted (Figure 4A), which may be the reason why many PLK1-depleted cells are stalled in substage I and unable to progress to the subsequent stages requiring intact mitotic spindles.

In addition to its effect on chromosomal segregation, PLK1 is also closely associated with the exit from mitosis and subsequent cytokinesis. In the former, PLK1 appears to play a role in the activation of APC by destroying the APC inhibitor, Emi1<sup>[15,22]</sup>. In cytokinesis, PLK1 is associated with the phosphorylation and activation of motor-like protein (MKlp) 2<sup>[23]</sup> and nuclear distribution

gene C (NudC)<sup>[24,25]</sup>. In our study, 48 h after siRNA treatment,  $\alpha$ -tubulin immunofluorescence and DNA staining revealed a higher percentage of dumbbell-shaped cell nucleoli (33% *vs* 15%) and increased the number of cytoplasmic bridges connecting two incompletely separated cells (8% *vs* 1%), indicating that PLK1-depleted cells cannot successfully exit mitosis and reform two new nuclear membranes at anaphase but arrest mitosis during cytokinesis. In our study, immunohistochemistry and FCM experiments showed that the expression of PLK1-specific RNAi affected mitotic processes, causing tumor cells to accumulate at the mitotic phase and blocking them from completing cell division. In addition, our MTT assays indicated that PLK1-depleted cells decreased their proliferation.

We examined whether PLK1 depletion affected the fate of MKN45 cells. We used Annexin V staining to identify early and late apoptosis. Our results revealed that apoptosis increased significantly 48 and 72 h after the addition of the PLK1-specific siRNA. There was no obvious change at 24 h, indicating a delay before the apoptotic mechanism is triggered. Further examination revealed a sharp decrease in pro-caspase 3 levels. PLK1 can bind to and suppress the pro-apoptotic molecule p53 in HeLa cells<sup>[26]</sup>, while p53 is accumulated during PLK1-depletion-induced apoptosis<sup>[27]</sup>. Based on this, it may be interesting to clarify whether any other pathway is involved in PLK1 depletion-induced apoptosis.

In conclusion, PLK1 is vital to gastric cancer cell division. Gene or drug therapy aimed at depleting PLK1 level may have a potential value as a novel treatment for gastric cancer.

## Abstract

**AIM:** To detect the expression of CD44 correlated with the ability of micro-metastasis in peripheral blood and bone marrow of patients with gastric cancer and to deduce its clinical significance.

**METHODS:** Preoperative peripheral blood and bone marrow specimens from 46 patients with gastric cancer and 6 controls were studied by semi-quantitative RT-PCR amplification of CD44v6mRNA. Preoperative and postoperative peripheral blood specimens from 40 patients with gastric cancer and 14 controls were studied by quantitative RT-PCR amplification of CD44v6mRNA in the corresponding period.

**RESULTS:** Semi-quantitative RT-PCR amplification showed that CD44v6mRNA expression of peripheral blood and bone marrow was positive in 39 (84.8%) and 40 (86.9%) of 46 patients with gastric cancer, respectively. In peripheral blood, CD44v6mRNA expression was positive for diffuse type in 30 (93.8%) of 32 patients and for intestinal type in 9 (64.3%) of 14 patients. On the other hand, in bone marrow, CD44v6mRNA expression was positive for diffuse type in 31 (96.9%) of 32 patients and for intestinal type in 10 (71.4%) of 14 patients. There was a significant difference between the diffuse type and intestinal type. Quantitative RT-PCR amplification demonstrated that CD44v6mRNA was not expressed in the peripheral blood of controls and CD44v6mRNA expression was positive for preoperative peripheral blood in 40 patients with gastric cancer, the expression levels being from  $4.9 \times 10^8$  -  $3.2 \times 10^{11}$  copies/g RNA. The average expression level of CD44v6mRNA in peripheral blood was  $3.9 \times 10^{10}$

copies/g RNA. The expression levels of CD44v6mRNA in peripheral blood in gastric cancer patients after curative operation increased from  $5.5 \times 10^6$  -  $7.6 \times 10^9$  copies/g RNA and the average level was  $2.4 \times 10^8$  copies/g RNA (Figure 3B) ( $P=0.00496$ ). After curative operation, the expression level decreased markedly.

**CONCLUSION:** Semi-quantitative and quantitative RT-PCR amplification for CD44v6mRNA is a sensitive and specific method for the detection of micro-metastasis in peripheral blood and bone marrow, which might be used as an indicator of tumor burden and therapeutic effect.

Wang DR, Chen GY, Liu XL, Miao Y, Xia JG, Zhu LH, Tang D. micro-metastasis of CD44v6 in peripheral blood and bone marrow of patients with gastric cancer. *World J Gastroenterol* 2006; 12(1):36-42

<http://www.wjgnet.com/1007-9327/12/36.asp>

## INTRODUCTION

Micro-metastasis cannot be detected by a general clinical pathological method. Gastric cancer is one of the most frequent malignant tumors. Tumor invasion, metastasis, and relapse are correlated with the prognoses of gastric cancer. Tumors metastasize through lymph and blood circulation. Twenty percent of patients have micro-metastasis<sup>[1]</sup>. Tumor cell micro-metastasis in lymphocytes, peripheral blood, bone marrow, and abdominal cavity is the main reason of metastasis and relapse<sup>[2,3]</sup>. Discovering gastric cancer in time is not only important for predicting relapse and prognoses, but also important for making decisions concerning therapy. With the development of molecular biology technology, the method of inspecting micro-metastasis has become more reliable<sup>[4]</sup>. Semi-quantitative RT-PCR can reveal gastric cancer cells in peripheral blood and bone marrow<sup>[5,6]</sup>. CD44v6, a highly glycosylated cell surface protein, is involved in cell-cell and cell-matrix interactions and takes part in cell motility, tumor growth, and invasion<sup>[7]</sup>.

CD44 is an integral membrane glycoprotein with an apparent molecular mass ranging 85-250 ku. It is

**Table 1** Oligonucleotide primer and probe sequences used

Gene	Oligonucleotide	Location sequence	PCR product	bp
CD44v	Upper primer	5'-TCCAGGCAACTCCTAGTAGT-3'		740
	Lower primer	5'-CAGCTGTCCCTGTGTGCGAA-3'		
$\beta$ -Actin	Upper primer	5'-CTACAATGAGCTGCGTGTGGC-3'		206
	Lower primer	5'-CAGGTCCAGACGCA GGATGGC-3'

**Figure 1** Expression of CD44s (A) and CD44v (B) in gastric mucosa. T1, T5, T8, T9, T13: bone marrow from patients with gastric cancer; A2, A6, A10, A15: peripheral blood from patients with gastric cancer; N7, N12, N15, N16: Controls.

originally described as a lymphocyte homing receptor on circulating lymphocytes<sup>[8]</sup>. At least 20 variants (v) of CD44 have been reported<sup>[9,10]</sup> due to the alternative splicing of 10 exons (v<sub>1</sub>-v<sub>10</sub>) that encode the membrane proximal portion of the extracellular domain. It has been reported that the expression of variant 6 of CD44 is correlated with invasion and metastasis of certain types of human cancer<sup>[11]</sup>. The expression of CD44v6 and CD44v5 is correlated with tumor progression, metastasis, and prognosis of colorectal cancer, breast cancer, and gastric cancer.

In our study, we have also determined the expression of CD44v6mRNA using semi-quantitative RT-PCR in peripheral blood and bone marrow from 46 patients with gastric cancer. We have also determined the quantitative expression of CD44v6mRNA in peripheral blood specimens from 40 patients with gastric cancer and 14 controls using quantitative RT-PCR to display the role of CD44v6mRNA in clinical stage and prognosis of gastric cancer.

## MATERIALS AND METHODS

### Patients and serum samples

Eighty-six patients were randomly divided into gastric cancer group (52 male and 34 female patients with an average age of 58.6 years, ranging 32–81 years) and control group (14 male and 8 female patients with an average age of 53.8 years, ranging 40–65 years).

Serum samples were obtained from 86 patients with primary gastric cancer prior to surgery at the Department of Gastroenterology, the First Affiliated Hospital

of Yangzhou Medical University. The diagnosis was confirmed before surgery.

### Extraction of total RNA

Before surgery, serum samples were obtained from peripheral blood and bone marrow 1 d before surgery and 9 d after surgery. Single nucleated cells were separated and stored at -20 °C. Total RNA was extracted. After being centrifuged at 2 500 r/min for 10 min, 5 mL S-ACR was added and bathed on ice for 15 min, then the process was repeated and the samples were stored at -70 °C.

### cDNA synthesis, cDNA amplification, and semi-quantitative analysis

Primers sp1 and sp2 were from the cDNA sequence<sup>[12]</sup>. Primers p1, p2, and  $\beta$ -actin were from the cDNA sequence<sup>[13]</sup>. Primers were separately aimed at the standard and variant CD44s, CD44v6, and  $\beta$ -actin<sup>[14]</sup>. The three couples of primers were synthesized by Sagon Co., Canada and stored at -20 °C (sp1: 5'-GACACATATTGCTTCAATG CTTCAGC-3'; sp2: 5'-GATGCCAAGATGATCAGCCATTCTGGAAT-3'; P1: 5'-GACAGACACCTCAGTTTTTCTGGA-3'; P2: 5'-TTCCTTCGTGTGTGGGTAATGAGA-3'; forward  $\beta$ -actin: 5'-CTACAATGAGCTGCGTGTGGC-3'; backward  $\beta$ -actin: 5'-CAGGTCCAGACGCA GGATGGC-3'). After cDNA was synthesized and amplified, the product was analyzed and the density was scanned (semi-quantitative analysis). When the value of CD44v6mRNA/ $\beta$ -actin was less than 0.30 and more than 0.70, it was expressed as (-), (+), and (+).

### Real-time RT-PCR

The point characterized the reactions during cycling, when the PCR product was first detected. The product was accumulated after a fixed number of cycles. The higher the starting quantity of the target molecule, the earlier the significant increase in fluorescence was observed. The parameter C+ (threshold cycle) was defined as the fractional cycle number at which the fluorescence was generated. CD44v6 target message in unknown samples was quantified by measuring C+ and using a calibration curve to determine the starting target message. The precise amount of total RNA added into each reaction mix (based on absorbance) and its quality were difficult to assess. For each experimental sample, the amount of targets and endogenous reference were determined by the calibration curve. The target amount was then divided by the endogenous reference amount to obtain a normalized target value. The relative gene target expression was also normalized to healthy control serum sample. Each of the normalized target values was divided by the calibrator-normalized target value to generate the final relative expression.

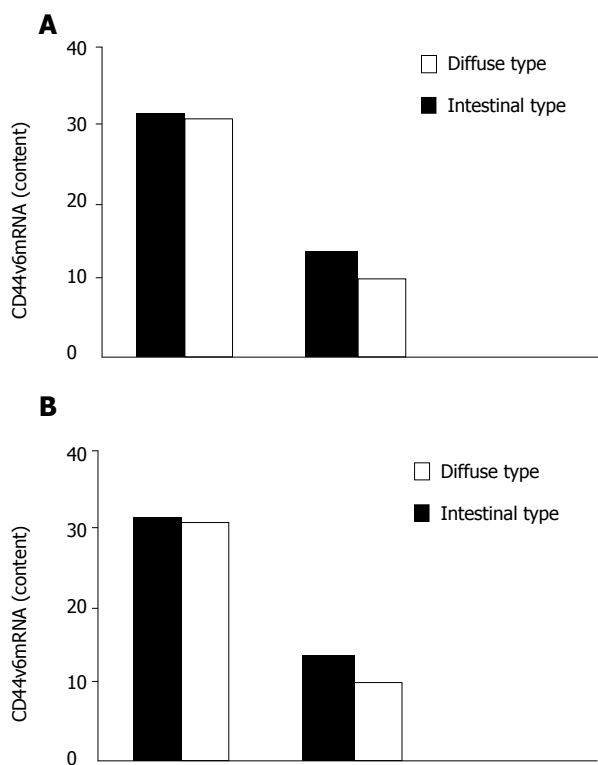

### Primers, probes, and PCR consumables

Primers and probes for the CD44v6 gene were chosen with the assistance of the computer programs Oligo 4.0 (National Bioscience) and Primer Express (Perkin-Elmer Applied Bio-systems). We conducted BLAST searches against dbEST and nr to confirm the total gene specificity

**Table 2** Relation between CD44v6mRNA expression in bone marrow and biologic behavior of gastric cancer

			CD44v6mRNA/ $\beta$ -actin				<i>P</i> value

	≤5 cm	22	3	3	4	12	

**Figure 2** CD44v6mRNA expression in bone marrow (A) and peripheral blood (B) from patients with gastric cancer.

of the nucleotide sequences chosen for the primers and probes, and the absence of DNA polymorphisms. The primer for CD44v6 was selected and compared to the sequences of the closely related CD44v6 gene. The sequences of the oligonucleotide are shown in (Table 1). The primers and probes were designated by the nucleotide position corresponding to the 5'-position, followed by the letter U for upper (sense strand) or L for lower (antisense strand). To avoid amplification of contaminating genome DNA, one of the two primers or the probe was placed at the junction between two exons or in different exons.

#### RNA extraction

Total RNA was extracted from serum specimens of gastric cancer by the acid-phenol quantum method<sup>[15]</sup>. The quality of RNA samples was determined by electrophoresis through denaturation of agarose gels and staining with

thallium bromide. The 18s and 28s RNA bands were visualized under ultraviolet light.

#### Calibration curve

Calibration curve was constructed with four fold serial dilutions of total RNA from healthy human serum. The diluted human total RNA was liquored and stored at -80 °C until use.

#### cDNA synthesis

Reverse transcription of RNA was performed in a final volume of 20  $\mu$ L containing 1 $\times$  RT-PCR buffer [500 mmol/L each dNTP, 3 mmol/L MgCl<sub>2</sub>, 75 mmol/L KCl, 50 mmol/L Tris-HCl, pH 8.3, 10  $\mu$ L of RNasin<sup>TM</sup> ribonuclease inhibitor (Promega), 10 mmol/L dithiothreitol, 50  $\mu$ L of superscript RNase H<sup>-</sup> reverse transcripts (Life Technologies), 1.5 mmol/L random hexanes and 1  $\mu$ g of total RNA (calibration curve points and patient samples)]. The samples were incubated at 20 °C for 10 min and at 42 °C for 30 min. Reverse transcripts were inactivated by heating at 99 °C for 5 min and cooling at 5 °C for 5 min.

#### PCR amplification

All PCR reactions were performed on an ABI PRISM 7700 Sequence Detection System. For each PCR, a master mixture was prepared on ice with 1 $\times$  TaqMan buffer; 5 mmol/L MgCl<sub>2</sub>; 200 mmol/L dATP, dCTP, and dGTP; 400 mmol/L dUTP; 300 mmol/L each primer; 150 mmol/L probe; 1.25  $\mu$ L of Ampli Taq gold DNA. Polymers and 10  $\mu$ L of each appropriately diluted reverse transcription sample were added to 40  $\mu$ L of the PCR master mixture. The thermal cycling conditions were: an initial demodulation step at 95 °C for 10 min and 50 cycles at 95 °C for 15 s, at 65 °C for 1 min. Experiments were performed in duplicate for each data point. Each PCR run included five points of the calibration curve (fourfold serially diluted human normal gastric cDNA), a non-template control, cDNA calibrator. All patient samples with a cv of the number of CD44v6mRNA copies > 10% were retested.

#### Statistical analysis

The association of factors was evaluated by the  $\chi^2$  test. The significance of difference among the means was

**Table 3** Relation between CD44v6mRNA expression in bone marrow and biologic behavior of gastric cancer

	Number of cases (n)	CD44v6mRNA/actin	P value			
			-	+	+	+

determined by the Student's t test and one-way analysis of variance. SPSS 11.0 for Windows 2000 was used.  $P < 0.05$  was considered statistically significant.

## RESULTS

### Semi-quantitative analysis

Proliferation of CD44s in peripheral blood and bone marrow from patients with gastric cancer and controls is shown in Figure 1A.

CD44v6mRNA expression in bone marrow and peripheral blood was positive in 40 (86.9%) and 39 (84.8%) of 46 patients with gastric cancer. The positive CD44v expression was slightly higher in bone marrow than in peripheral blood ( $P > 0.05$ ). The value of CD44v6mRNA expression was  $64.6\% \pm 21.66\%$  (Figure 1B).

In 46 patients with gastric cancer, diffuse type was found in 32 cases and intestinal type in 14 cases. Positive CD44v6mRNA expression in bone marrow was found in 31 (96.9%) of 32 diffuse type patients and 10 (71.4%) of 14 intestinal type patients (Figure 2A). On the other hand, positive CD44v6mRNA expression in peripheral blood was found in 30 (93.8%) of 32 diffuse type patients and 9 (64.3%) of 14 intestinal type patients (Figure 2B). There was a significant difference between the diffuse and intestinal types.

The relation between CD44v6mRNA expression and pathological type, lymph node metastasis, clinical pathology, and the size of tumor is presented in Tables 2 and 3.

### Calibration curve and dynamic range of real-time RT-PCR

The calibration curve was constructed from the total RNA extracted from healthy human gastric serum diluted fourfold in mouse total RNA. The primer chosen to analyze the CD44v6 gene did not amplify human genomic DNA or mouse cDNA. The dynamic range was at least three orders of magnitude in samples containing 50  $\mu$ g or 0.2 ng equivalent to total cDNA. A strong linear relation between Ct and log of the starting copy number was demonstrated ( $r^2 \geq 0.99$ ). The efficiency of the reaction (E) was 90%–100% calculated by the formula:  $E = 101/[m] - 1$ , where  $m$  is the slope of calibration curve.

To determine the cut-off value for altered CD44v6 gene expression at the RNA level in gastric cancer serum, the CD44v6 value (ratio of CD44v6mRNA to  $\beta$ -actin) was determined for four normal gastric serum RNAs. Because this value fluctuated between 0.5 and 1.7, values of 3 or more were considered as overexpression of the CD44v6 gene in tumor RNA samples.

### CD44v6mRNA status and clinical and pathological factors

We sought for links between CD44v6mRNA status and standard clinical, pathological and biological factors in gastric cancer. Significant association was found between the overexpression of CD44v6mRNA gene and standard histopathological grade ( $P < 0.05$ ) and negative progesterone receptor status ( $P < 0.001$ ). A trend toward a link between the overexpression of CD44v6 gene and

**Table 4** Quantitative expression of CD44v6mRNA in peripheral blood of patients with gastric cancer before and after surgery

40	M	37	D	+	T	III	980	69

estrogen receptor negativity was also observed ( $P=0.09$ ).

#### **CD44v6mRNA amplification (patients for CD44v6mRNA expression)**

As shown in Table 4, all the 20 peripheral blood samples of gastric cancer had the expression of CD44v6mRNA. The expression level ranged  $4.9 \times 10^8$  -  $3.2 \times 10^{11}$  copies/g RNA and the average levels of peripheral blood was  $3.9 \times 10^{10}$  copies/g RNA (Figure 3A). The expression level of gastric cancer was  $5.5 \times 10^6$  -  $7.6 \times 10^9$  copies/g RNA and the average level was  $2.4 \times 10^8$  copies/g RNA (Figure 3B) ( $P=0.00496$ ) after curative surgery.

## **DISCUSSION**

Gastric cancer is one of the most frequent malignant tumors. The survival rate of patients after radical surgery

of gastric cancer is 40% and patients always die because of metastasis and relapse<sup>[16]</sup>. Some patients have already existed micro-metastasis which is not detectable by general clinical pathology during the treatment. The detection of micro-metastasis is correlated with the prognosis of gastric cancer patients<sup>[17,18]</sup>. It was reported that micro-metastasis could be detected in lymph nodes of patients with intestinal cancer with negative pathology<sup>[19]</sup>. Micro-metastasis has been considered as an indicator of prognosis and the value of micro-metastasis is superior to the Duke's stage and tumor grade. Zhang *et al.*<sup>[20]</sup> demonstrated that tumor cells in metastatic lymph nodes of colorectal carcinoma possess cell proliferation activity and metastatic ability of tumor cells. Series slice examination has been used in inspecting tumor micro-metastasis since 1920s, but it is difficult to popularize<sup>[21]</sup>. RT-PCR is a sensitive and specific method which can find

a tumor cell from  $1 \times 10^6$  peripheral blood monocytes<sup>[22]</sup>. Positive CD44v6mRNA expression was found in 39 of 46 patients with gastric cancer and negative CD44v6mRNA expression in patients with remote metastasis. The latter may be caused by sampling error<sup>[23]</sup>.

In our research, the peripheral blood and bone marrow specimens from 46 patients with gastric cancer and 6 controls were compared. The positive CD44v6mRNA expression rate was 84.4% and 86.9%, respectively in patients with gastric cancer. The CD44v6mRNA expression rate of diffuse type cancers was higher than that of intestinal type cancers, suggesting that the expression of CD44v6mRNA is correlated with the malignant phenotype of gastric cancer and CD44v6mRNA can be used as an indicator of the degree of tumor invasion and lymph node metastasis<sup>[24]</sup>. The positive rate of CD44v6 is high in gastric cancer and may serve as a marker for diagnosing gastric cancer<sup>[25-27]</sup>.

The CD44v6mRNA expression rate in patients with lymph node or remote metastasis was higher than that in those without lymph node metastasis. The positive micro-metastasis rate of grades III-IV gastric cancer was significantly higher than that of grades I-II gastric cancer, suggesting that the expression of CD44v6mRNA can be used as an indicator of relapse and metastasis. CD44v6 expression is a significant risk factor for lymph node metastasis in patients with advanced carcinoma. Expression of CD44v6 plays an important role in tumor progression and may be a useful predictor of lymph node metastasis<sup>[28-32]</sup>.

The quantitative expression of CD44v6mRNA in 40 patients with gastric cancer before and after surgery showed that CD44v6mRNA was an indicator of tumor burden and therapeutic effect. The results showed that the expression level of CD44v6mRNA in peripheral blood of terminal gastric cancer patients (grades III-IV) was obviously higher than that in early gastric cancer patients (grades I-II). The expression level of CD44v6mRNA in gastric cancer patients with remote metastasis was obviously higher than that in those without metastasis. The expression level of CD44v6mRNA obviously decreased after curative surgery. The findings indicate that the expression level of CD44v6mRNA in peripheral blood is correlated with tumor burden.

Animal experiments indicate that 0.01% of tumor cells in circulation may lead to positive metastasis<sup>[31,33,34]</sup>. Gulmann *et al.*<sup>[35]</sup> showed that CD44v6 expression is a late phenomenon in the transformation of intestinal metaplasia to dysplasia/cancer. Gene expression of severe gastric mucosal dysplasia displays an obviously latent malignant tendency and gastric carcinoma with the expression of CD44v6 protein has a stronger ability to infiltrate and to metastasize via lymph nodes<sup>[36]</sup>. Serum level of sCD44v6 could be taken as the criterion for evaluating the development and prognosis of gastric cancer, as well as the therapeutic target for anti-metastasis<sup>[37]</sup>. Therefore, micro-metastasis should be routinely detected to afford evidence for establishing individual therapy scheme<sup>[38]</sup>. Quantitative RT-PCR can improve the diagnostic sensitivity and specificity. Semi-quantitative RT-PCR is restricted because it cannot generate accurate gene quantification<sup>[15]</sup>. In

our study, we have validated a RT-PCR method recently developed for the quantification of gene expression based on real-time analysis of PCR amplification and TaqMan methodology, which has several advantages over other RT-PCR-based quantitative assays such as competitive quantitative RT-PCR<sup>[39]</sup>.

Xin *et al.*<sup>[40,41]</sup> discovered that patients with positive CD44v6 have a lower 3- and 5-year survival rate ( $P = 0.0002$ ). Immunohistochemical detection of CD44v6 could now be used as an indicator of tumor progression in patients with gastric carcinoma. Tumor cells in the bone marrow indicate that patients have blood micro-metastasis<sup>[42]</sup>. The probability of relapse and remote metastasis is great for patients who have postoperative bone marrow micro-metastasis and dynamic observation of micro-metastasis in these patients can predict the therapeutic effect and establish individual therapy scheme. Yamaguchi *et al.*<sup>[43]</sup> found that CD44v6-positive cancers are more frequently associated with hematogenous metastasis. Therefore, blood is another metastatic route of gastric cancer. Detecting peripheral blood micro-metastasis of early gastric cancer patients is of great importance in predicting the prognosis and deciding the rational therapy of gastric cancer patients.

## Abstract

**AIM:** To evaluate the value of endoscopic ultrasonography (EUS) in the preoperative TNM staging of gastric cancer.

**METHODS:** Forty-one patients with gastric cancer (12 early stage and 29 advanced stage) proved by esophagogastroduodenoscopy and biopsies preoperatively evaluated with EUS according to TNM (1997) classification of International Union Contrele Cancer (UICC). Pentax EG-3630U/Hitachi EUB-525 echo endoscope with real-time ultrasound imaging linear scanning transducers (7.5 and 5.0 MHz) and Doppler information was used in the current study. EUS staging procedures for tumor depth of invasion (T stage) were performed according to the widely accepted five-layer structure of the gastric wall. All patients underwent surgery. Diagnostic accuracy of EUS for TNM staging of gastric cancer was determined by comparing preoperative EUS with subsequent postoperative histopathologic findings.

**RESULTS:** The overall diagnostic accuracy of EUS in preoperative determination of cancer depth of invasion was 68.3% (41/28) and 83.3% (12/10), 60% (20/12), 100% (5/5), 25% (4/1) for T1, T2, T3, and T4, respectively. The rates for overstaging and understaging were 24.4% (41/10), and 7.3% (41/3), respectively. EUS tended to overstage T criteria, and main reasons for overstaging were thickening of the gastric wall due to perifocal inflammatory change, and absence of serosal layer in certain areas of the stomach. The diagnostic accuracy of metastatic lymph node involvement or N staging of EUS was 100% (17/17) for N0 and 41.7% (24/10) for N+, respectively, and 66% (41/27) overall.

Misdiagnosing of the metastatic lymph nodes was related to the difficulty of distinguishing inflammatory lymph nodes from malignant lymph nodes, which imitate similar echo features. Predominant location and distribution of tumors in the stomach were in the antrum (20 patients), and the lesser curvature (17 patients), respectively. Three cases were found as surgically unresectable (T4 N+), and included as being correctly diagnosed by EUS.

**CONCLUSION:** EUS is a useful diagnostic method for preoperative staging of gastric cancer for T and N criteria. However, EUS evaluation of malignant lymph nodes is still unsatisfactory.

## INTRODUCTION

The incidence of gastric cancer is declining worldwide. However, it still remains the second most common cause of cancer-related death in the world<sup>[1,2]</sup>. Typically, gastric cancer is asymptomatic when cancer is at early stage of disease; therefore, majority of patients present in advanced stage, and the mortality rate of this disease is still very high. The diagnosis of gastric cancer is based on esophagogastroduodenoscopy with biopsy following double-contrast x-ray examination. Presently, endoscopic ultrasonography is the most reliable nonsurgical method obtainable for assessing the primary tumor with high diagnostic rate of staging gastric cancer and lymph node involvement. EUS is also becoming a promising diagnostic modality for the evaluation of gastrointestinal submucosal tumors and large gastric folds<sup>[3-7]</sup>.

The complete treatment of gastric cancer is surgery, only tumor resection with involved lymph nodes associated with satisfactory prognosis. Survival after surgery is highly dependent on the stage of gastric cancer or anatomical extent of disease at the time of operation. Therefore, the accurate preoperative staging of gastric cancer is the most significant prognostic factor that predicts surgical outcome

**Table 1 Relationship between EUS and anatomic layers of normal gastric wall**

EUS	Histology
1 <sup>st</sup> hypoechoic layer	Water interface and superficial mucosa
2 <sup>nd</sup> hypoechoic layer	Deeper mucosa
3 <sup>rd</sup> hyperechoic layer	Submucosa
4 <sup>th</sup> hypoechoic layer	Muscularis propria
5 <sup>th</sup> hyperechoic layer	Serosa and subserosal fat

Three cases of unresectable T4 N+ tumors were correctly diagnosed.

and 5 years of survival and is essential for well-informed decisions on stage depending patient management to plan appropriate treatment. Such precise stage depending management will limit the occurrence of unnecessary exploratory surgical interventions<sup>[8]</sup>.

The aim of the present study was to evaluate the usefulness of EUS in TNM staging of stomach cancer comparing with postoperative histopathological findings.

## MATERIALS AND METHODS

### Patients

Between April 2001 and April 2004, 41 patients (29 men and 12 women; age range, 28-80 years; mean age 57 years) with gastric cancer diagnosed by EGD and confirmed with biopsy specimen, underwent EUS examination prior to surgery for tumor depth of invasion and lymph node involvement at our Department of Endoscopy. Twelve of them were in early gastric cancer stage and 29 were in advanced stage. All patients underwent surgery.

### Apparatus and EUS examination procedures

The Pentax EG-3630U/Hitachi EUB-525 echo endoscope with real-time ultrasound imaging linear scanning transducers (7.5 and 5.0 MHz) and Doppler information was used in the present study. This echo endoscope also provides the instrument channel for performing fine-needle aspiration biopsy. On the tip of the endoscope, a balloon is placed which is filled by deaerated water for improved coupling of the ultrasound waves to the gastrointestinal wall by producing a fluid interface and displacing intraluminal air. Prior to each EUS, examination was performed by EGD with biopsy to confirm gastric cancer. After oropharyngeal local anesthesia, patients were examined in a left lateral position. The echo endoscope was advanced into the stomach, and the lesions were first examined endoscopically. Next the stomach was insufflated

**Table 4 Accuracy of EUS in preoperative determination of N stage in 41 patients with gastric cancer**

Histopathological N stage	n	EUS correct n/%	EUS incorrect n/%
PN0	17	N 17/100	-
PN+	24 (3)	N+ 10 (3)/41.7	N0 14/58.3 false negative
All cases	41 (3)	27 (3)/66	14/34

with 200-500 mL deaerated water and observed from the pylorus to the cardia by moving the tip of the endoscope for revealing cancer abnormalities and lymph nodes involvement. The findings were recorded at the computer database of our department and interpreted following a standard protocol with regard to tumor invasion according to the widely accepted five-layer structure of the gastric wall (Table 1).

The assessment of tumor invasion depth or T stage was defined as a hypoechoic structure alternating five-layer ultrasonographic structure of gastric wall. Tumors were staged according to TNM (1997) classification criteria of International Union contrele Cancer (UICC). T1 lesion was seen as a disruption of the first three layers (tumor invades the mucosa or submucosa). T2 lesion was seen as an invasion of the fourth layer (tumor invades the muscularis propria). T3 lesion was seen as a penetration through the fifth layer (tumor invasion of the serosa). T4 lesion was seen as an invasion of the adjacent organs and structures (Table 2). T1 stage showed EUS images of early gastric cancer, T2-T4 stages showed EUS images of advanced gastric cancer. Lymph nodes had round border and hypoechoic structures were considered as malignant. Stage N0 referred to no sign of metastasis. N+ referred to metastases in perigastric lymph nodes.

## RESULTS

Findings of the 41 patients at preoperative EUS were postoperatively compared with histopathological findings for T and N staging.

### Surgical findings

Tumors were located in the fundus and cardia region ( $n=4$ ), in the body ( $n=11$ ), in the body and antrum ( $n=2$ ), in the antrum ( $n=20$ ) of the stomach, diffusely located ( $n=2$ ) and residual stomach ( $n=2$ ). Distribution of tumors was in the anterior wall ( $n=5$ ), posterior wall ( $n=5$ ), greater curvature ( $n=5$ ), and the lesser curvature ( $n=17$ ) of the stomach and 9 were circumferential. Three cases

**Figure 1** Early and advanced gastric cancer cases. **A:** Endoscopic view of superficial depressed type of early gastric cancer; **B:** EUS image shows cancer invasion of 1<sup>st</sup> and 2<sup>nd</sup> (mucosal) layers of gastric wall, while 3<sup>rd</sup> (submucosal) layer is clear (T1 category). Histopathological findings of the surgically resected specimen corresponded with the EUS findings; **C:** Endoscopic view of advanced Borrmann II type of gastric cancer; **D:** EUS images show disruption of 1-4 layers of the gastric wall with hypoechoic cancer tissue, but 5<sup>th</sup> (serosal) layer is not involved (T2 category).

**Figure 2** A case of advanced gastric cancer. **A:** Endoscopic view of Borrmann III type of gastric cancer; **B:** EUS image demonstrates T3 cancer with malignant lymph node. Note the hypoechoic structure and sharp margin of the lymph node (1.0 cm x 0.6 cm).

were found as surgically unresectable (T4 N+).

#### Pathohistologic findings

**T staging:** The diagnostic accuracy of EUS was 83.3% in T1 staging, 60.0% in T2 staging, 100% in T3 staging, and 25% in T4 staging, respectively. Twenty-eight of forty-one cancers were staged correctly and the overall diagnostic accuracy of T stage was 68.3%. Ten cases were overstaged

(24.4%) and 3 cases were understaged (7.3%) (Table 3). Echoendoscopic features of early and advanced gastric cancer are presented in (Figures 1A-1D).

**N staging:** EUS correctly determined 27 of 41 patients with the overall accuracy of 66.0%. The accuracy of EUS in N0 staging was high, all 17 patients without malignant lymph node metastasis were diagnosed correctly. However, EUS findings of preoperative positive metastatic lymph nodes in 10 patients were not confirmed histopathologically, and the accuracy of EUS in N+ staging was 41.7% (Table 4). The endosonographic features of advanced gastric cancer with malignant lymph nodes are shown in Figure 2.

## DISCUSSION

The accurate staging of gastric cancer is the most important prognostic factor for patient management and EUS is the most reliable method in T and N staging of gastric cancer with high diagnostic rates. Such an accurate staging will apply the stage-depending correct management of the patients (radical surgery or palliative treatment) and will provide a great benefit avoiding unnecessary laparotomy on patients with unresectable disease. EUS is considered as the most accurate modality for T staging of gastric cancer in comparison with CT and intraoperative assessment<sup>[10,11]</sup>.

The accuracy of EUS for gastric cancer from different authors ranges 64.8% - 92% in T staging and 50% - 90% in N staging (Table 5). These studies demonstrated that EUS is the most accurate staging method for gastric cancer with a few incidences of overstaging and understaging. The excellent results of accuracy of both T and N staging are shown in a study by Botet *et al.*<sup>[12]</sup> to be 92% and 78%, respectively. The high accuracy of EUS in preoperative staging of gastric cancer is proved by our results. In the current study, EUS had a diagnostic accuracy of 68.3% for tumor invasion. EUS had 24.4% overstaging in T staging, 2 of the 12 T1 tumors overstaged as T2, 3 of the 20 T2 tumors overstaged as T3. The main reason of

<sup>1</sup>Year of article publication/duration of study not reported.

overstaging in T1 cancer is the thickening of gastric wall due to perifocal inflammatory reaction, which is difficult to distinguish from cancer tissue and imitates the presence of T2 cancer. Absence of serosal layer in certain regions of the stomach, the lesser curvature, the posterior wall of fundus and the anterior wall of antrum is the reason for overstaging T2 cancer. Cancers of these areas are classified histopathologically as T2 cancer, even carcinoma infiltrates through the whole gastric wall, because no serosal infiltration can be found.

EUS accuracy of metastatic lymph node involvement was 66% in the present study. Such slightly lower accuracy is related to the absence of standard differential echoendoscopic criteria for benign and malignant lymph nodes. Echoendoscopic features of metastatic lymph nodes from different authors include size > 10 mm, rounded structure, sharp demarcation of borders, and hypoechoic (dark) structure<sup>[25,26]</sup>. However, endoscopic ultrasonographic detection of metastatic lymph nodes is complicated, due to the difficulty of differentiation between malignant and inflammatory lymph nodes. Francois *et al.*<sup>[15]</sup> described that hypoechoic lymph nodes with well-defined margins and largest diameter/smallest diameter ratio less than 2 are considered to be malignant. Dittler and Siewert<sup>[14]</sup> noticed that, if EUS does not diagnose malignant lymph nodes in T1 or T2 stage, stage N0 can be assumed; if lymph nodes are visualized in stages T3 and T4, then they tend to be malignant. Results of certain studies<sup>[27]</sup> demonstrated that the EUS-guided fine-needle aspiration biopsy would be very useful to distinguish between benign and malignant lymph nodes.

Other reasons for inaccuracy of evaluation of tumor lymph nodes are related to the limited depth of transducer, and unsatisfactory visualization of distant lymph node by EUS. EUS cannot permit the assessment of tissue beyond the depth of about 5–6 cm.

The presence of ascites in gastric cancer patients is a poor prognostic sign and implies the presence of peritoneal metastasis. EUS-guided fine-needle aspiration biopsy also has been successfully used to detect malignant ascites<sup>[28–30]</sup>. EUS detection of distant metastatic lymph nodes and distant metastasis or M staging of gastric cancer

is insufficient due to limited penetration depth of this method as mentioned above. Therefore, combined use of EUS and CT, which is superior to EUS for gaining information about distant metastasis, should be effective for the management of gastric cancer patients for appropriate treatment options.

In conclusion, EUS is a useful diagnostic method for accurate preoperative staging for T and N criteria for gastric cancer. The accurate preoperative staging is extremely essential for proper stage-depending patient management, which improves the 5-year survival rate of this dismal prognostic disease. However, EUS evaluation of malignant lymph nodes is still unsatisfactory. Therefore, great effort should be taken to study differential criteria of malignant lymph nodes from benign lymph nodes.

positive rate for HBsAg was significantly lower in the extremely elderly group and the proportion of patients negative for HBsAg and HCVAb obviously increased in the extremely elderly group ( $P < 0.001$ ). There were no significant differences in the following parameters: diameter and number of tumors, Child-Pugh grading, tumor staging, presence of portal thrombosis or ascites, and positive rate for HCVAb. Extremely elderly patients did not often receive surgical treatment ( $P < 0.001$ ) and they were more likely to receive conservative treatment ( $P < 0.01$ ). There were no significant differences in survival curves based on the Kaplan-Meier methods in comparison with the overall patients between the two groups. However, the survival curves were significantly worse in the extremely elderly patients with stage I/II, stage I/II and Child-Pugh grade A cirrhosis in comparison with the non-elderly group. The causes of death did not differ among the patients, and most cases died of liver-related diseases even in the extremely elderly patients.

**CONCLUSION:** In the patients with good liver functions and good performance status, aggressive treatment for HCC might improve the survival rate, even in extremely elderly patients.

## Abstract

**AIM:** To identify the clinical and prognostic features of patients with hepatocellular carcinoma (HCC) aged 80 years or more.

**METHODS:** A total of 1310 patients with HCC were included in this study. Ninety-one patients aged 80 years or more at the time of diagnosis of HCC were defined as the extremely elderly group. Two hundred and thirty-four patients aged  $\geq 50$  years but less than 60 years were regarded as the non-elderly group.

**RESULTS:** The sex ratio (male to female) was significantly lower in the extremely elderly group (0.90:1) than in the non-elderly group (3.9:1,  $P < 0.001$ ). The

## INTRODUCTION

With the arrival of the aging society, an increasing number of elderly patients with cancer is predicted in the future. Hepatocellular carcinoma (HCC) is one of the

**Table 1** Age distribution of the 1 310 patients with hepatocellular carcinoma

Age (yr)	Number of HCC patients
<30	3

60-70	485
70-80	452
80<	91
Total	1 310

most common cancers and the age distribution of HCC patients has steadily increased because of the improved management of chronic liver diseases<sup>[1-5]</sup>. As a result, we sometimes encounter patients with HCC aged 80 years or more. However, the clinical characteristics and the long-term prognosis of these patients still remain obscure because they often have concomitant diseases and therefore long-term follow-up for such patients remains difficult. In recent studies, “the elderly” have usually been defined as to be at the ages of 60, 65, or 70 years and above<sup>[1-4]</sup>. The average life expectancy of Japanese males is 78.36 years, while that of females is 85.33 years<sup>[6]</sup>. With the increase in the average lifetime, the age at which a person is considered elderly is rising. Clarifying the optimal treatment strategy for extremely elderly patients with HCC has thus become an urgent necessity. However, to our knowledge, there have been so far few reports evaluating extremely elderly patients with HCC aged 80 years or more<sup>[5]</sup>. Hence, in this study, we aimed to clarify the age-specific clinical characteristics of HCC, and to evaluate the survival and characteristics of extremely elderly patients. We, therefore, undertook a retrospective study of 91 extremely elderly patients with HCC aged 80 years or more in comparison to the non-elderly patients from 1 310 consecutive HCC patients.

## MATERIALS AND METHODS

A total of 1 310 consecutive patients were enrolled in this study. The patients were newly diagnosed with HCC and observed from January 1992 to December 2003 at the Department of Medicine and Molecular Science, Gunma University Graduate School of Medicine and nine affiliated hospitals, namely, Maebashi Red Cross Hospital, Isesaki Municipal Hospital, Kiryu Kousei General Hospital, Tone Chuo Hospital, National Nishigunma Hospital, Saiseikai Maebashi Hospital, Public Tomioka General Hospital, Fuji Heavy Industries Ltd, Health Insurance Society General Ota Hospital, and Shimada Memorial Hospital. A diagnosis of HCC was confirmed histopathologically or clinicopathologically from biopsy specimens or combined examinations of ultrasonography, computed tomography, and selective angiography. For each patient, the following data were recorded: age, sex, hepatitis B surface antigen (HBsAg), hepatitis C virus antibody (HCVAb), biochemical analysis (total bilirubin, albumin, prothrombin time, platelet count, and ICG R15), serum alpha-fetoprotein (AFP), protein induced by vitamin K absence

or antagonist II (PIVKA-II), diameter and number of tumors, Child-Pugh grading, tumor staging, presence of portal thrombosis or ascites, initial therapy, and survival. The AFP level was divided into two categories: 20 µg/L or less, and more than 20 µg/L. PIVKA-II level was also divided into two categories: < 40 and ≥ 40 AU/L. The diameter of the largest tumor was measured in its greatest dimension if the patient had two or more tumors. The number of HCCs was divided into two groups: solitary and non-solitary tumors. Portal thrombosis was defined as a protrusion of the tumor into the first and/or second branch, or into the main trunk of the portal vein. The presence of concomitant disease with a strong impact on the prognosis (e.g., malignant neoplasm, cardiovascular disease, and cerebrovascular disease) was recorded. The types of initial treatment for HCC were categorized into five categories: (1) transcatheter arterial embolization (TAE) or transcatheter arterial infusion (TAI); (2) percutaneous injection or ablation [percutaneous ethanol injection (PEI), microwave ablation (MA), or radiofrequency ablation (RFA)]; (3) surgical resection, including liver transplantation; (4) systemic or reservoir chemotherapy; and (5) supportive care. According to their age at the initial diagnosis, the patients were categorized into two groups: an extremely elderly group consisting of 91 HCC patients aged ≥ 80 years and a non-elderly group comprising 234 HCC patients aged ≥ 50 years but < 60 years.

## Statistical analysis

Differences in the proportions were evaluated by Fisher's exact probability test. Differences in the means were evaluated by the Student's *t*-test. The survival curves according to the Kaplan-Meier method were compared using the log-rank test. Using Cox's proportional hazard model, a multivariate analysis was performed to evaluate the prognostic factors. *P* < 0.05 was considered statistically significant.

## RESULTS

### Characteristics of extremely elderly and non-elderly groups

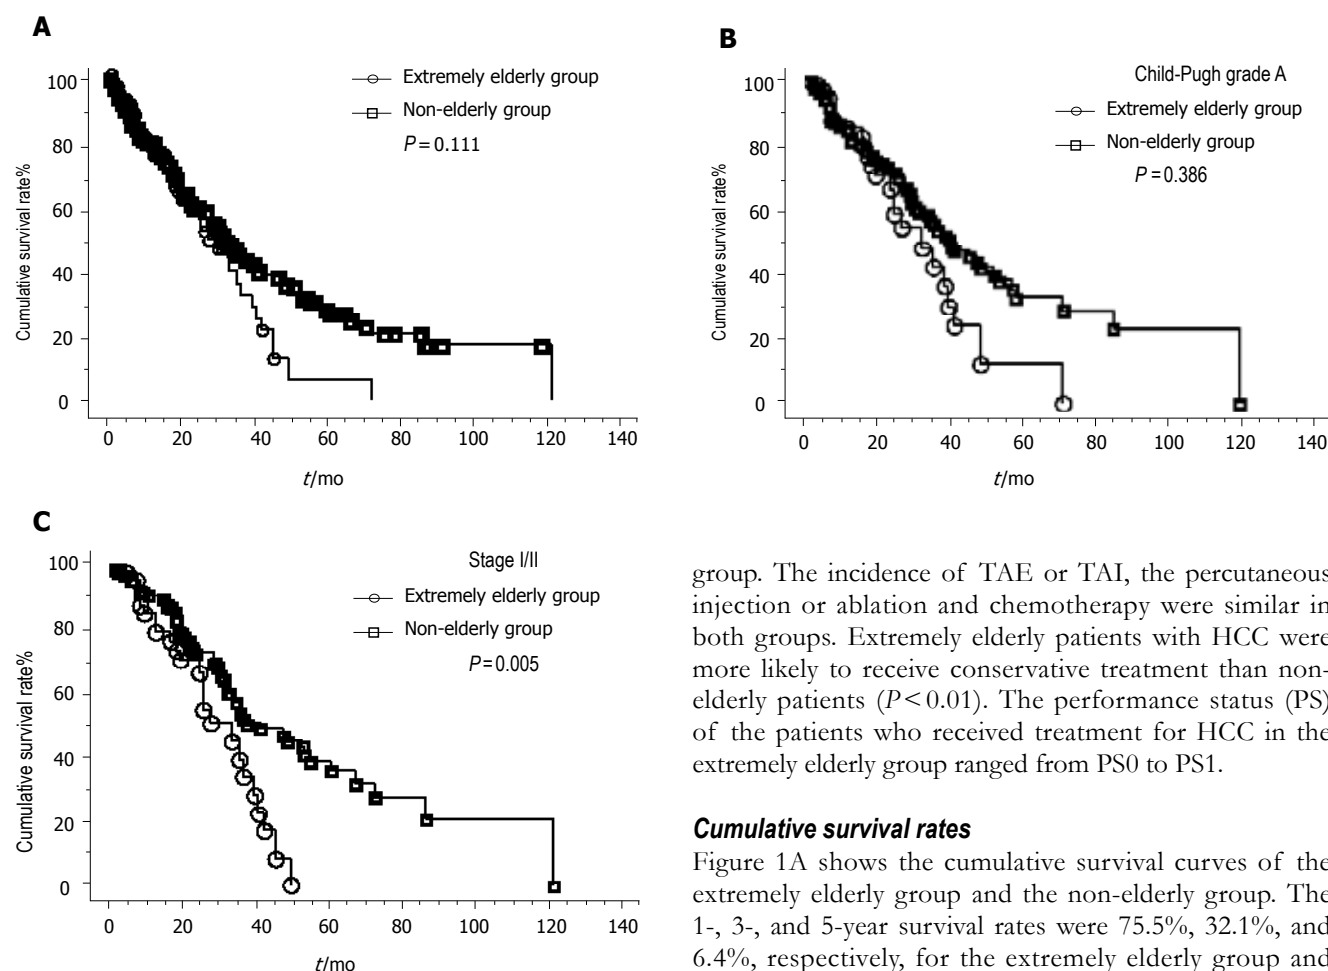

The age distribution of 1 310 patients with HCC is shown in Table 1. The mean age of the 1 310 patients with HCC was 66.7 ± 9.3 years (range, 20-94 years; median, 68 years). There were 91 patients who were older than 80 years, and 234 patients aged ≥ 50 years but less than 60 years. The characteristics of the extremely elderly group and the non-elderly group are summarized in Table 2. The sex ratio, with a comparable male to female ratio was 0.90:1 in the extremely elderly group and 3.9:1 in the non-elderly group, showing that women were more prevalent in the extremely elderly group (*P* < 0.001). The positive rate for HBsAg was significantly lower in the extremely elderly group (*P* < 0.001). The proportion of the patients negative for HBsAg and HCVAb markedly increased in the extremely elderly group (*P* < 0.001). The prothrombin time and platelet count were significantly higher in the extremely elderly group (*P* < 0.001 and *P* < 0.01, respectively), while ICG R15 was significantly lower in the extremely elderly group (*P* < 0.001) than in the non-elderly group.

uk; unknown

**Figure 1** Survival curves of extremely elderly group and non-elderly group. **A:** All patients; **B:** Child-Pugh grade A patients; **C:** stage I/II patients.

There were no statistical differences in the prevalence of HCVAb, total bilirubin, albumin, AFP, PIVKAI, diameter and number of tumors, Child-Pugh grading, tumor stage, and presence of portal thrombosis or ascites. Table 3 shows the type of initial treatment. None of the patients underwent a surgical resection in the extremely elderly

group. The incidence of TAE or TAI, the percutaneous injection or ablation and chemotherapy were similar in both groups. Extremely elderly patients with HCC were more likely to receive conservative treatment than non-elderly patients ( $P < 0.01$ ). The performance status (PS) of the patients who received treatment for HCC in the extremely elderly group ranged from PS0 to PS1.

### Cumulative survival rates

Figure 1A shows the cumulative survival curves of the extremely elderly group and the non-elderly group. The 1-, 3-, and 5-year survival rates were 75.5%, 32.1%, and 6.4%, respectively, for the extremely elderly group and 79.3%, 43.8%, and 26.5%, respectively, for the non-elderly group. The difference in the survival rates between the two groups was not statistically significant ( $P = 0.114$ ). Figure 1B shows the cumulative survival curves of the patients with Child-Pugh grade A in the two groups. Although the survival tended to be worse in the extremely elderly patients, it did not reach statistical significance ( $P = 0.111$ ). There were also no significant differences in survival curves regarding the Child-Pugh grade B/C patients ( $P = 0.386$ ). Due to the small number of patients with stage I tumors in the extremely elderly group, we compared

**Table 3** Types of initial treatment for patients with hepatocellular carcinoma.

Treatment	Extremely elderly (80 yr or more)	Non-elderly (50-60 yr old)	P-value
TAE or TAI	59	128	NS
PEI or RFA or MA	18	62	NS
Surgery (liver trans- plantation)	0	28 (3)	$P < 0.001$
Chemotherapy	2	7	NS
Supportive care	12	9	$P < 0.01$

TAE, Transcatheter arterial embolization; TAI, Intranscatheter arterial infusion; PEI, percutaneous ethanol injection; MA, Microwave ablation; RFA, Radiofrequency ablation; NS, not significant.

**Table 4** Causes of death in extremely elderly patients with HCC

Cause of death	Extremely elderly (80 yr or more)	Non-elderly (50-60 yr old)	P-value
HCC	27	77	NS
Hepatic failure	17	25	
Gastrointestinal- Bleeding	4	6	
Others	7	9	
Unknown	0	6	

the patients with stage I/II tumors between both groups. Figure 1C shows the cumulative survival curves of the stage I/II patients in both groups. The survival curves were significantly worse in the extremely elderly patients with stage I tumors in the extremely elderly group, we compared the patients with stage I/II tumors between both groups. Figure 1C shows the cumulative survival curves of the stage I/II patients for both groups. The survival curves were significantly worse in the extremely elderly patients with stage I/II tumors ( $P = 0.005$ ). However, there were no significant differences in survival curves regarding stage III/IV ( $P = 0.479$ ) or stage IV ( $P = 0.794$ ) disease. In stage I/II and Child-Pugh grade A patients, the survival curves were significantly worse in the extremely elderly patients ( $P = 0.005$ ). Survivals adjusted for the etiology of liver disease were also calculated. No significant differences were observed in the survival curves regarding HCV-related disease between the extremely elderly and non-elderly groups ( $P = 0.142$ ). There were also no significant differences in the survival curves of the patients negative for HBsAg and HCVAb between the two groups ( $P = 0.447$ ). Due to the small number of patients positive for HBsAg in the extremely elderly group, we could not compare those patients between both groups.

To evaluate the prognostic factors for the extremely elderly HCC patients and non-elderly patients, we performed a multivariate analysis using Cox's proportional hazard model, which showed that the Child-Pugh grading ( $P < 0.05$ ), tumor staging ( $P < 0.01$ ), albumin ( $P < 0.01$ ), and platelet count ( $P < 0.05$ ) were prognostic factors for extremely elderly patients with HCC. The Child-Pugh grading ( $P < 0.05$ ), tumor staging ( $P < 0.05$ ), and diameter of tumors ( $P < 0.01$ ) were found to be prognostic factors for the non-elderly patients with HCC. The age, sex, HBsAg, HCVAb, total bilirubin, prothrombin time,

number of tumors, and presence of portal thrombosis or ascites were not found to be prognostic factors, based on Cox's proportional hazard model. In the overall patients with HCC, the Child-Pugh grading ( $P < 0.05$ ), tumor staging ( $P < 0.05$ ) and diameter of tumors ( $P < 0.01$ ) were found to be prognostic factors. The age was not found to be associated with the prognosis of the overall patients with HCC.

### Cause of death of extremely elderly patients with HCC

Of the 91 patients aged  $\geq 80$  years, 55 (60.4%) patients died during the observation period table 4. The causes of death among the 55 patients were HCC-related or hepatic failure in 44 patients (80.0%), gastrointestinal bleeding, including the rupture of esophageal varices in 4 patients (7.3%), and other diseases not related to HCC or liver cirrhosis in 7 patients (12.7%), such as pneumonia, renal failure and brain bleeding. In the non-elderly group, 123 (52.6%) patients died during the observation period. The causes of death among the 123 patients were HCC-related or hepatic failure in 102 patients (82.9%), gastrointestinal bleeding, including rupture of esophageal varices in six patients (5.0%), and other diseases not related to HCC or liver cirrhosis in nine (7.3%) and no records in six patients (5.0%).

### Concomitant diseases of the patients with HCC

Of the 91 patients, 71 (78.0%) patients had concomitant diseases with liver disease in the extremely elderly group. As shown in Table 5, a variety of concomitant diseases were observed in the extremely elderly patients. "Others" in malignant neoplasms included: one ureteral carcinoma, one skin cancer, and one malignant lymphoma. "Other diseases" included: three benign prostatic hypertrophy, one idiopathic thrombocytopenia, one lichen planus, one ovarian cyst, one adrenal adenoma, and six others. On the other hand, 89 of 234 patients (38.0%) had concomitant diseases with liver disease in the non-elderly group. The ratio of patients having concomitant diseases was significantly higher in the extremely elderly group ( $P < 0.001$ ).

## DISCUSSION

Although the survival of the patients with an early stage and a good liver function was better in the non-elderly group, we could not find any significant difference in overall survival curves or causes of death between the extremely elderly and non-elderly groups with HCC. Even though the extremely elderly patients had various concomitant diseases, most of the patients demonstrating HCC died from HCC-related causes. As a result, HCC was a life-limiting factor even though the patients were extremely elder. In Japan, based on data from 2003<sup>[6]</sup>, the average life expectancies at birth are 78.36 years for males and 85.33 years for females. In addition, an 80-year-old male has an average life expectancy of 8.26 years, while a female aged 80 years can expect to live another 11.04 years<sup>[6]</sup>. The 5-year survival rate in the extremely elderly group with HCC was only 6.4% in this study. We, therefore, have to treat HCC even though such patients are over 80 years of age and have concomitant diseases.

**Table 5 Concomitant diseases in extremely elderly patients with hepatocellular carcinoma.**

Dohmen *et al.*<sup>[5]</sup> analyzed 36 patients aged  $\geq 80$  years and concluded that the survival rates are not significantly different from the non-elderly group, and that the advanced stage of HCC, not an advanced age, has the greatest influence on the survival rate in extremely elderly patients<sup>[5]</sup>. Hoshida *et al.*<sup>[8]</sup> evaluated 135 patients with chronic liver disease aged  $\geq 80$  years and found that most patients (63.5%) would die of diseases other than liver diseases, such as pneumonia, especially in the non-cirrhosis group. It is reasonable that the extremely elderly patients without HCC die of diseases other than liver diseases. However, in their study, 18 patients with HCC at the start of observations had a poor prognosis.

Although there was no difference in the Child-Pugh grading, the extremely elderly group had good liver function as indicated by the prothrombin time or ICGR15 level. We speculated that patients with a poor liver function might die of liver failure and will not be able to live until 80 years of age when complicated with HCC. Otherwise, not only the liver function, but also other genetic or environmental factors may contribute to the development of HCC in extremely elderly patients. In this study, extremely elderly patients with HCC had a relatively good PS. The 10 hospitals included in this study

are core hospitals for each area. The patients with a poor PS or poor liver function might have been excluded by the primary physician for aggressive treatment of HCC and thus might not have been introduced to these 10 hospitals.

Females were more prevalent in the extremely elderly group ( $P < 0.001$ ). The proportion of females in the general population is known to gradually increase with increasing age<sup>[6]</sup>. Males are usually dominant in non-elderly patients with HCC and their prognosis of HCC is quite poor. We speculated that males with HCC might die of liver-related diseases before 80 years of age. However, we could not determine the reason why the female ratio significantly increased in the extremely elderly group of HCC. Previous studies reported that HBV-associated HCC is common in younger patients in Japan<sup>[11-13]</sup>. Our results were compatible with our expectation because only 3.3% of the HBV-associated HCC was identified in the extremely elderly group in contrast to 15.3% in the non-elderly group ( $P < 0.001$ ). The ratio of non B and non C hepatitis patients significantly increased in the extremely elderly group. Other factors except for hepatitis virus infection such as alcohol or genetic disturbance may thus contribute to the development of HCC in the extremely elderly group.

Regarding the initial treatment, Collier *et al.*<sup>[10]</sup> reported in 1994 that elderly patients ( $\geq 65$  years) with HCC are more likely to receive conservative treatment than younger patients ( $< 65$  years), despite a similar disease stage. Conversely, Poon *et al.*<sup>[3]</sup> concluded that a hepatic resection and TAE for HCC in elderly patients ( $\geq 70$  years) are well tolerated and show an improved survival rate. Percutaneous localized therapies or TAE were similarly performed in both the extremely elderly and non-elderly groups in this study and there were no obvious differences regarding adverse effects. However, no surgical resections were performed in the extremely elderly group. The oldest patient receiving a surgical resection as the initial treatment among these 1 310 patients was 77 years. The extremely elderly patients with HCC were more likely to receive conservative treatment than the non-elderly patients. Non-invasive treatments may have been selected due to the patient age or quality of life. Indeed, post-operative complications, such as pneumonia, show an incremental risk with age<sup>[14]</sup>. The elderly patients are more liable to succumb to post-operative organ failure and complications, especially infections<sup>[14]</sup>. The PS and physiological age are therefore considered to be more important than the chronological age in elderly patients with HCC.

In conclusion, there is no statistical difference in the overall survival rate between the extremely elderly and non-elderly groups after the diagnosis of HCC. HCC is considered to be a life-limiting factor even in extremely elderly patients. Therefore, in patients with good liver functions and good PS, aggressive treatment of HCC might improve the survival rate, even in extremely elderly patients.

### Abstract

**AIM:** To assess subcellular localization of KL-6 mucin and its clinicopathological significance in colorectal carcinoma as well as metastatic lymph node and liver tissues.

**METHODS:** Colorectal carcinoma tissues as well as metastatic lymph node and liver tissues were collected from 82 patients who underwent colectomy or hepatectomy. Tissues were subjected to immunohistochemical analysis using KL-6 antibody.

**RESULTS:** Of the 82 colorectal carcinoma patients, 6 showed no staining, 29 showed positive staining only in the apical membrane, and 47 showed positive staining in the circumferential membrane and/or cytoplasm. Positive staining was not observed in non-cancerous colorectal epithelial cells surrounding the tumor tissues. The five-year survival rate was significantly lower in cases showing positive staining in the circumferential membrane and/or cytoplasm (63.0%) than those showing positive staining only in the apical membrane (85.7%) and those showing no staining (100%). Statistical analysis between clinicopathological factors and subcellular localization of KL-6 mucin showed that KL-6 localization in the circumferential membrane and/or

### INTRODUCTION

MUC1, a transmembrane glycoprotein<sup>[1, 2]</sup>, has been detected in various cancer cell lines and secretory epithelial cells lining the respiratory, reproductive, and gastrointestinal tracts<sup>[3-6]</sup>. It has been suggested that MUC1 may influence cell-to-cell adhesion, diminish the immune response, and be involved in intracellular signaling<sup>[7, 8]</sup>. In carcinoma cells, it has been reported that high levels of MUC1 expression correlate with the invasive characteristic of tumors<sup>[9-13]</sup>. Our latest study has also shown that aberrant expression of MUC1, which was detected by KL-6 antibody, is associated with cancer progression in the carcinoma of the ampulla of Vater<sup>[14]</sup>.

In normal epithelium, MUC1 is predominantly present on the apical surface of the epithelial cells<sup>[15, 16]</sup>. Recently, it has been reported that, in breast carcinoma, MUC1 is expressed not only on the apical surface but also on

circumferential and basal membranes and in the cytoplasm of the carcinoma cells<sup>[15,16]</sup>. Furthermore, this aberrant localization of MUC1 has been reported to be associated with worse prognosis for the patient<sup>[17]</sup>. These findings suggest that subcellular observation of MUC1 expression in carcinoma cells is likely important for understanding the function of MUC1 and improving the prediction of prognosis. However, little is known about the clinical significance of subcellular localization of KL-6 mucin in other carcinomas.

In this study, we focused on subcellular localization of MUC1 in colorectal carcinoma as well as in the metastatic lymph nodes and liver tissue. MUC1 expression was immunohistochemically detected using KL-6 antibody, which recognizes the sialylated oligosaccharide moiety of MUC1 as a part of an epitope<sup>[18]</sup>. In colorectal carcinoma tissues, it has been suggested that the expression of KL-6 mucin is associated with tumor aggressiveness<sup>[10,19]</sup>. However, the subcellular localization and physiological function of KL-6 mucin in colorectal carcinoma have remained unknown. In this paper, we report that aberrant subcellular expression of KL-6 mucin in the circumferential membrane and/or cytoplasm is associated with lymph node and liver metastases and worse prognosis in colorectal carcinoma.

## MATERIALS AND METHODS

### Patients

Colorectal carcinoma tissues were collected from 82 consecutive patients (55 males and 27 females;  $64.5 \pm 11.4$  years, mean  $\pm$  SD) with a single primary colorectal adenocarcinoma who underwent surgical resection at the Department of Surgery, Graduate School of Medicine, the University of Tokyo, between January 1991 and December 1992. For all cases with lymph node and liver metastasis, whole specimens of resected lymph nodes and metastatic liver tissues were collected from 36 and 7 patients, respectively, in the study group. All specimens were classified according to Japanese Classification of Colorectal Carcinoma by the Japanese Society for Cancer of the Colon and Rectum<sup>[20]</sup>, including the status of lymph node and liver metastasis at the time of surgical intervention and the depth of invasion (m, invasion of mucosa; sm, invasion of submucosa; mp, invasion of muscularis propria; ss, invasion of subserosa or subadventitia; se, invasion of serosa or adventitia; and si, invasion of adjacent structures).

### Immunohistochemical staining

The immunohistochemical staining approach matched that of previous studies<sup>[14]</sup>. Briefly, 4  $\mu$ m-thick sections were cut from archival formalin-fixed paraffin-embedded tissue blocks, deparaffinized, and dehydrated using a graded series of ethanol solutions. Endogenous peroxidase activity was halted through administration of 3 mL/L hydrogen peroxide/methanol for 30 min. The slides were rinsed with phosphate-buffered saline and then blocked with normal goat serum for 30 min at room temperature. The sections were then incubated with a KL-6 monoclonal antibody solution (1:200 dilution; Eisai, Tokyo, Japan)

for 60 min at room temperature. After the sections were incubated with biotinylated secondary antibody for 60 min, bound biotinylated antibody was then tested by the biotin-streptavidin-peroxidase complex method following the manufacturer's instructions (Histofine SAB-PO kit; Nichirei, Tokyo, Japan). 3,3'-Diaminobenzidine was used as the chromogen, and hematoxylin was used as a counterstain. The negative control sections were treated by omitting the primary antibody to monitor background staining.

### Evaluation of immunohistochemically stained carcinomas

Overall staining was evaluated in carcinoma cells observed in 10 random microscopic fields, or in the entire area if the tissue sample comprised less than 10 fields. Subcellular staining patterns were recorded by judging the apical membrane, circumferential membrane, and cytoplasm as described elsewhere<sup>[17]</sup>. Three investigators (Q.G., W.T., and N.K.) separately judged the staining characteristics, and the discrepancies were resolved through mutual observation and discussion of the microscopic fields.

### Statistical analysis

The  $\chi^2$ -test was used to evaluate the relationship between staining pattern and clinicopathological parameters. Survival curves were calculated using the Kaplan-Meier method and compared with the results of the log-rank test. Two patients (one in the no-staining group, another in the apical membrane staining group) were excluded from the data analysis for survival because the cause of death for these patients was not colorectal cancer.  $P < 0.05$  was considered statistically significant. Statview 5.0J (Abacus Concepts, Berkeley, CA, USA) statistical software was used for data analyses.

## RESULTS

### Subcellular localization of KL-6 mucin

Among the 82 cases of colorectal carcinoma, 76 cases showed positive staining of KL-6 mucin. As shown in Figure 1, there was a considerable heterogeneity in the subcellular localization of KL-6 mucin. Staining was observed in either the apical or circumferential membrane (Figures 1A and 1B). Some cases showed positive staining in the cytoplasm in addition to the membranous region (Figures 1C and 1D). The number of cases showing the respective subcellular staining patterns are summarized in Table 1. It is notable that cytoplasmic staining tended to be accompanied by positive staining in the circumferential membrane (37/45, 82%) rather than in the apical membrane (8/45, 18%). Positive staining was not observed in non-cancerous colorectal epithelial cells in any case of this study (data not shown).

### Relationship between survival and subcellular localization of KL-6 mucin

The five-year survival rate was 85.7% for cases showing positive staining only in the apical membrane ( $n = 28$ ), 61.5% for cases showing positive staining in the circumferential membrane ( $n = 39$ ), and 64.4% for cases showing positive staining in cytoplasm ( $n = 45$ ) (data

**Figure 1** Immunohistochemical staining of colorectal adenocarcinoma tissues using KL-6 antibody ( $\times 200$ ). **A:** Positive staining in the apical membrane; **B:** positive staining in the circumferential membrane; **C:** positive staining in the apical membrane and cytoplasm; **D:** positive staining in the circumferential membrane and cytoplasm.

**Figure 2** Kaplan-Meier curves for overall survival rates of patients with colorectal adenocarcinoma. Patients with KL-6 expression in the circumferential membrane and/or cytoplasm (solid line, group C,  $n = 46$ ), in the apical membrane (dashed line, group A,  $n = 29$ ) and without KL-6 staining (dotted line, group N,  $n = 5$ ) were followed up for more than 70 mo. Two of 82 patients were excluded from the data analysis as described in Materials and Methods.

not shown). There were significant differences between the cases showing positive staining only in the apical membrane and the cases showing positive staining in the circumferential membrane ( $P = 0.021$ ), and between the cases showing positive staining only in the apical membrane and the cases showing positive staining in cytoplasm ( $P = 0.033$ ). On the other hand, the five-year survival rate was 100% for the cases showing no staining ( $n = 5$ ). These results suggested that a subcellular KL-6 expression profile was associated with survival, and that cases showing positive staining in the circumferential membrane and/or cytoplasm showed worse prognosis.

As described above, cytoplasmic staining tended to be accompanied with positive staining of the circumferential membrane. Therefore, we classified the cases into the following three groups according to their subcellular staining profile: group N, negative ( $n = 6$ ); group A,

**Table 1** Summary of subcellular staining of KL-6 mucin in colorectal adenocarcinoma

Group <sup>1</sup>	KL-6 mucin staining			<i>n</i>
	Apical membrane	Circumferential membrane	Cytoplasm	
N	Negative	Negative	Negative	6
A	Positive	Negative	Negative	29
C	Positive	Negative	Positive	8
C	Negative	Positive	Negative	2
C	Negative	Positive	Positive	37

<sup>1</sup>Patient groups N, A, and C were categorized according to the subcellular expression profile of KL-6 mucin (see text).

positive only in the apical membrane ( $n = 29$ ); and group C, positive in the circumferential membrane and/or cytoplasm ( $n = 47$ ) (Table 1). As shown in Figure 2, the five-year survival rate was significantly lower in group C (63.8%) than that in group A (85.7%;  $P = 0.029$ ). On the other hand, group N showed the highest five-year survival rate (100%).

### Relationship between clinicopathological factors and subcellular localization of KL-6 mucin

The relationship between clinicopathological factors and subcellular KL-6 mucin staining of the colorectal adenocarcinomas is summarized in Table 2. Positive staining in the circumferential membrane and/or cytoplasm was significantly associated with the presence of venous invasion, lymphatic invasion, and lymph node metastasis. This subcellular staining characteristic was also associated with the progression of the depth of invasion and histological stage (Table 2). Notably, all cases having lymph node ( $n = 36$ ) or liver metastasis ( $n = 7$ ) showed positive staining in the circumferential membrane and/or cytoplasm. This suggested that aberrant subcellular expression of KL-6 mucin in the circumferential

membrane and/or cytoplasm might participate in the metastasis of tumor.

### Expression of KL-6 mucin in metastatic lesions

We next examined the expression of KL-6 mucin in lymph node and liver metastatic lesions (Figure 3). For all the 36 cases with lymph node metastasis and all seven cases with liver metastasis, positive staining was observed in metastatic lesions as well as in the primary colorectal carcinoma tissues.

## DISCUSSION

MUC1 is abundantly expressed at the surface of epithelial cells in many tissues<sup>[3-6]</sup>. MUC1 expression is also observed in carcinomas that arise in several parts of the body, such as the colon, breast, lung, pancreas, papillary thyroid, and gallbladder<sup>[9-13]</sup>. The deduced amino acid sequence of MUC1 mucin reveals four distinct domains: the

NH<sub>2</sub>-terminal domain consisting of a hydrophobic signal sequence; a highly *O*-glycosylated tandem-repeat domain; a transmembrane domain; and a cytoplasmic domain<sup>[1,2,6]</sup>. Previous studies on MUC1 expression in colorectal carcinoma have primarily focused on the tandem-repeat domain, and suggested that tumor cells expressing high levels of MUC1 may have increased invasive and metastatic potential<sup>[10]</sup>. However, little is known about the detailed clinicopathological relationship among expression profile of MUC1, metastatic potentiality, and the prognosis for colorectal adenocarcinoma. On the other hand, although the processing of the full length MUC1 core proteins is similar in both normal and tumor cells, they have a remarkable diversity in oligosaccharide moieties<sup>[21,22]</sup>. Therefore, we targeted KL-6 mucin, a type of MUC1 bearing sialylated oligosaccharide recognized by KL-6 antibody<sup>[18]</sup>. Since sialylation of tumor cell glycoconjugates is thought to contribute to tumor progression and metastasis<sup>[23-26]</sup>, targeting KL-6 mucin bearing sialylated oligosaccharide seems to be a reasonable strategy.

In our preliminary study, KL-6 mucin was observed in carcinoma cells but not in the surrounding normal cells. However, classification of KL-6 staining evaluated by overall expression level did not show significant relationships between the expression level of KL-6 mucin, metastasis, and patient's prognosis (data not shown). Recently, some reports on breast carcinoma have suggested a significant relationship between metastasis and subcellular location of MUC1 rather than its overall expression level, which led us to focus on the subcellular location of KL-6 mucin in colorectal carcinoma.

In the present study, the circumferential and/or cytoplasmic expression of KL-6 mucin was significantly correlated with lymph node metastasis in colorectal adenocarcinomas (Table 2). In addition, this aberrant localization of KL-6 mucin was likely to participate also in liver metastasis, since all cases having liver metastasis (*n* = 7) showed positive staining in the circumferential membrane and/or cytoplasm (Table 2). It is known that normal epithelial cells release a tailless, soluble form of MUC1 which targets exclusively the apical membrane in tissues<sup>[21]</sup>. However, in carcinoma cells with aberrant overexpression of MUC1, this apical polarization is lost, resulting in aberrant localization of MUC1 over the entire cell membrane and in the cytoplasm<sup>[15,16]</sup>. It has been proposed that MUC1 mediates anti-adhesion activity by interfering with cell-to-cell and/or cell-to-extracellular matrix interactions, thereby facilitating detachment of tumor cells from the primary growth<sup>[6, 27-29]</sup>. This is likely true of KL-6 mucin in colorectal adenocarcinoma, since a high frequency of metastasis was observed in cases showing any aberrant localization of KL-6 mucin (Table 2). This aberrant subcellular expression of KL-6 mucin might facilitate detachment of tumor cells from the primary growth, resulting in an increased ability of the tumor cells to metastasize.

It is notable that all the cases tested showed positive staining in metastatic lesions as well as the primary colorectal carcinoma tissues. Interestingly, in some cases presenting lymph node or liver metastasis, aberrant subcellular localization of KL-6 was observed in only

**Figure 3** Immunohistochemical staining of metastatic lymph node and liver tissues using KL-6 antibody (x200). **A:** Positive KL-6 expression in a metastatic lymph node; **B:** positive KL-6 expression in metastatic liver tissues.

a few tumor cells (less than 5%) in the primary lesions (data not shown). This suggests that the significant factor is the subcellular location rather than the level of KL-6 expression, and is coincident with a report that breast carcinomas with the cytoplasmic staining pattern, even in a minor focus, are associated with a higher incidence of lymph node metastasis<sup>[17]</sup>. However, a considerable number of cases showing positive membranous and/or cytoplasmic staining did not present with metastases. Further investigation is needed to understand the role of KL-6 expression in metastatic events of colorectal adenocarcinoma.

Some studies have reported that, in breast carcinoma, patients expressing MUC1 in the non-apical membranes show worse prognosis than those expressing MUC1 in the apical membrane<sup>[17,30]</sup>. Our observation also showed that there was a significant relationship between subcellular location of KL-6 and prognosis in colorectal adenocarcinoma (Figure 2;  $P = 0.029$ ). The five-year survival rates for the cases with apical membrane staining and those with circumferential and/or cytoplasmic staining of KL-6 mucin were 85.7% and 63.0%, respectively (Figure 2). Moreover, our data also showed that cases without KL-6 staining had a better prognosis than those with the apical staining of KL-6 mucin. These data suggest that the expression characteristics of KL-6 mucin would be useful for the prediction of a patient's prognosis in colorectal adenocarcinoma.

In conclusion, subcellular localization of KL-6 mucin plays a crucial role in determining disease outcome and expression of KL-6 mucin in the circumferential

membrane and/or cytoplasm is an important indicator for lymph node and liver metastases as well as the prognosis of patients with colorectal adenocarcinoma.

## Abstract

**AIM:** To examine whether antithrombin (AT) could prevent hepatic ischemia/reperfusion (I/R)-induced hepatic metastasis by inhibiting tumor necrosis factor (TNF)- $\alpha$ -induced expression of E-selectin in rats.

**METHODS:** Hepatic I/R was induced in rats and mice by clamping the left branches of the portal vein and the hepatic artery. Cancer cells were injected intrasplenically. The number of metastatic nodules was counted on day 7 after I/R. TNF- $\alpha$  and E-selectin mRNA in hepatic tissue, serum fibrinogen degradation products and hepatic tissue levels of 6-keto-PGF<sub>1 $\alpha$</sub> , a stable metabolite of PGI<sub>2</sub>, were measured.

**RESULTS:** AT inhibited increases in hepatic metastasis of tumor cells and hepatic tissue mRNA levels of TNF- $\alpha$  and E-selectin in animals subjected to hepatic I/R. Argatroban, a thrombin inhibitor, did not suppress any of these changes. Both AT and argatroban inhibited I/R-induced coagulation abnormalities. I/R-induced increases of hepatic tissue levels of 6-keto-PGF<sub>1 $\alpha$</sub>  were significantly enhanced by AT. Pretreatment with indomethacin completely reversed the effects of AT. Administration of OP-2507, a stable PGI<sub>2</sub> analog, showed effects similar to those of AT in this model. Hepatic metastasis in congenital AT-deficient mice subjected to hepatic I/R was significantly increased compared to that observed in wild-type mice. Administration of AT significantly reduced the number of hepatic metastases in congenital AT-deficient mice.

**CONCLUSION:** AT might reduce I/R-induced hepatic metastasis of colon cancer cells by inhibiting TNF- $\alpha$ -

induced expression of E-selectin through an increase in the endothelial production of PGI<sub>2</sub>. These findings also raise the possibility that AT might prevent hepatic metastasis of tumor cells if administered during the resection of liver tumors.

## INTRODUCTION

Hepatic ischemia/reperfusion (I/R) is sometimes induced by temporary clamping of the portal triad during resection of a liver tumor and a portal vein for advanced pancreatic head cancer<sup>[1, 2]</sup>. Hepatic I/R may promote hematogenous liver metastases of cancer cells that detach during the surgical procedure<sup>[3]</sup>. Endothelial leukocyte adhesion molecules such as E-selectin and intercellular adhesion molecule-1 have been demonstrated to be critically involved in the adhesion of tumor cells to endothelial cells, thereby promoting the metastasis of tumor cells<sup>[4-8]</sup>. Expression of these adhesion molecules in endothelial cells is markedly enhanced by pro-inflammatory cytokines such as tumor necrosis factor (TNF)- $\alpha$ , which plays a critical role in the development of I/R-induced liver injury<sup>[9, 10]</sup>.

Antithrombin (AT), a physiological serine protease inhibitor, plays a critical role in the regulation of the coagulation cascade<sup>[11]</sup>. In addition to such regulatory role in the coagulation system, AT exerts an anti-inflammatory activity by increasing the endothelial production of prostacyclin (PGI<sub>2</sub>), which is capable of inhibiting TNF- $\alpha$  production by monocytes<sup>[12-14]</sup>. According to this anti-inflammatory property, AT reduces I/R-induced liver injury by inhibiting TNF- $\alpha$  production in rats<sup>[15, 16]</sup>. These observations suggest that AT might reduce I/R-induced hepatic metastasis of cancer cells

by decreasing the expression of leukocyte adhesion molecules such as E-selectin through an increase in the endothelial production of PGI<sub>2</sub>. In the present study, we have examined whether AT could reduce the metastasis of cancer cells injected intrasplenically in rats and congenital AT-deficient mice subjected to hepatic I/R.

## MATERIALS AND METHODS

### Reagents

AT and argatroban ((2R,4R)-4-methyl- $\{N^2-[(3\text{-methyl-1,2,3,4-tetrahydro-8-quinolyl})\text{ sulfonyl}]\text{-L-arginyl}\}$ -2-piperidinecarboxylic acid monohydrate) were obtained from the Mitsubishi-Welpharma Co., Ltd. (Osaka, Japan). OP-2507 (15 *cis*-(4-*n*-propylcyclohexyl)-16,17,18,19,20-pentano-9-deoxy-6,9- $\alpha$ -nitrolo-prostaglandin F<sub>1</sub> methyl ester), a prostacyclin analog, was obtained from the Ono Pharmaceutical Co., Ltd. (Osaka, Japan). Indomethacin (IM), xylazine and RPMI 1640 were purchased from Sigma (St. Louis, MO, USA). Penicillin G, streptomycin, and fetal bovine serum (FBS) were obtained from Invitrogen (Gaithersburg, MD, USA). Ketamine hydrochloride was purchased from Parke-Davis (Morris Plains, NJ, USA). All other reagents were of analytical grade.

### Animals

Pathogen-free male Fisher 344 (F344) rats, weighing 180–210 g, and C57BL/6 mice, weighing 18–22 g, were obtained from Clea Japan (Tsukuba, Japan). Congenital AT-deficient mice (AT<sup>+/-</sup>) were kindly provided by Dr. Kojima, Nagoya University. Plasma levels of AT in AT<sup>+/-</sup> mice were about 50% of that in wild type<sup>[17]</sup>. Care and handling of the animals were in accordance with the National Institute of Health guidelines and the animals were fed standard animal chow and water. All the animal experiments were carried out in a humane manner after receiving permission from the Animal Experiment Committee of the university and in accordance with the Regulation of Animal Experiment and Japanese Governmental Law.

### Cell lines

RCN-H4 cells, derived from hepatic metastasis of a F344 rat colon adenocarcinoma cell line, were provided by RIKEN Cell Bank (Tsukuba, Japan)<sup>[18, 19]</sup>. RCN-H4 cells were maintained in RPMI 1640 supplemented with 100 mL/L heat inactivated FBS, 100 kU/L penicillin G and 100 mg/L streptomycin in a humidified 950mL/L air-50 mL/L CO<sub>2</sub> at 37 °C. B16-F10 melanoma cells, which are syngeneic to C57BL/6 mice, were gifted from Cell Resource Center of Tohoku University (Sendai, Japan). B16-F10 cells were maintained in the same medium that was used for RCN-H4 cell culture.

### Rat hepatic metastasis model

Under anesthesia with diethyl ether, F344 rats underwent laparotomy. Warm ischemia of the median and left hepatic lobes was induced by clamping the left branches of the portal vein and the hepatic artery. The right lobe was perfused to prevent intestinal congestion. During the period of hepatic ischemia, the rat's abdomen was

covered with a plastic wrap to prevent dehydration. AT (500 U/kg) and OP-2507 (3 µg/kg) were dissolved in double distilled water, and administered intravenously 20 min after ischemia. Argatroban (1 mg/kg) and IM (5 mg/kg) were administered subcutaneously 30 min prior to ischemia. After 30 min of ischemia, the clamp was removed and the right lobe and caudate lobe were resected to prevent shunting to them after reperfusion with 4-0 silk. After resection of the right and caudate lobes, RCN-H4 cells (2×10<sup>6</sup> cells/rat) were intrasplenically administrated using a 30-gauge needle and the wound was closed with 3-0 silk. Sham-operated animals underwent the same operation but without clamping. During the surgical operation, the rat's body temperature was kept between 35.5 °C and 36.5 °C by using a heating pad. The rates of breathing and heart beating were stable during the operation. None of the animals died until the 7<sup>th</sup> day after the operation.

### Mouse hepatic metastasis model

The same surgical procedure as for F344 rats was performed for every mouse except for the anesthesia method (ketamine, 75 mg/kg body weight plus xylazine, 25 mg/kg body weight) and ischemia time (60 min). After resection of the right and the caudate lobes, B16-F10 cells (2×10<sup>5</sup> cells/mouse) were intrasplenically administrated. AT (500 U/kg) was administered 10 min before reperfusion. None of the animals died until the 7<sup>th</sup> day after the operation.

### Calculation of hepatic metastatic nodules

Animals were killed on the 7<sup>th</sup> day after the operation. The liver was removed, fixed with 10% buffered formalin for a few days, and cut into slices, each about 4 mm thick serially. These slices were stained with hematoxylin-eosin. The number of metastatic nodules was counted under a dissecting microscope (Olympus, Tokyo, Japan) at a magnification of ×100. The liver slice area was calculated with IP Lab software (Solution Systems Co., Ltd.) on a Macintosh computer. The number of metastatic nodules was normalized by the slice area (nodule number/cm<sup>2</sup>).

### Measurement of serum concentration of fibrin and fibrinogen degradation products

Ninety minutes after reperfusion, blood samples were collected in tubes containing 0.1 volume of 38g/L sodium citrate. Blood was centrifuged at 2 000 r/min for 10 min. Serum levels of fibrinogen degradation products (FDP (E)) were measured by a latex agglutination assay, as previously described<sup>[20]</sup>.

### Assay for 6-keto-PGF<sub>1α</sub> in liver

Levels of 6-keto-PGF<sub>1α</sub>, a stable metabolite of PGI<sub>2</sub>, in liver tissue were measured as described previously<sup>[15, 21]</sup>. In brief, tissue samples were weighed and homogenized in 0.1 mol/L phosphate buffer (pH 7.4) containing 0.5 g/L sodium azide. The homogenate was centrifuged (2 000 r/min, at 4 °C for 10 min) and the supernatant was stored at -80 °C until measurement. The concentration of 6-keto-PGF<sub>1α</sub> was determined with a specific enzyme immunoassay kit (Amersham, Buckinghamshire, UK). The results were expressed as nanograms of 6-keto-PGF<sub>1α</sub> per

**Figure 1** Effects of antithrombin (AT) and various agents on the number of hepatic metastatic nodules in rats after ischemia/reperfusion (I/R). <sup>b</sup> $P < 0.01$  vs sham; <sup>c</sup> $P < 0.05$ , <sup>d</sup> $P < 0.01$  vs I/R+saline.

gram tissue.

### RNA extraction and cDNA synthesis

Total RNA was isolated after homogenization of the tissue samples in TRIzol reagent according to the manufacturer's instructions. RNA was reverse transcribed into cDNA in a 20- $\mu$ L reaction volume containing 2  $\mu$ L RNA (1  $\mu$ g) in RNase-free water, 2  $\mu$ L of 10 $\times$  RT buffer, 4.4  $\mu$ L of 25 mmol/L MgCl<sub>2</sub>, 4  $\mu$ L deoxy NTPs mixture, 1  $\mu$ L random hexamers, 0.4  $\mu$ L RNase inhibitor, and 0.5  $\mu$ L multiscribe reverse transcriptase (50 MU/L). Reverse transcription was performed at 25 °C for 10 min, at 37 °C for 60 min, and at 95 °C for 5 min, followed by quick chilling on ice and storage at 4 °C until subsequent amplification.

### Real-time quantitative reverse transcription-polymerase chain reaction (RT-PCR)

Real-time quantitative RT-PCR analysis was performed in triplicate using the ABI PRISM 7700 Sequence Detection System instrument and software (Applied Biosystems, Foster City, CA, USA). The primers and probes for the TaqMan system were designed using Primer Express software (Applied Biosystems) and synthesized using PE ABI (Weiterstadt, Germany). The 5'-end nucleotide of the probe was labeled with a reporter dye (FAM). The sequences of the PCR primer sets and probes used for each gene were purchased from TaqMan Gene Expression Assays (Applied Biosystems). The reaction conditions and PCR cycles were set according to the manufacturer's directions.

### Statistical analysis

All data were expressed as mean  $\pm$  SD. The results were compared using an analysis of variance (ANOVA) followed by Scheffe's test. An associated probability of  $P < 0.05$  was considered to be statistically significant.

## RESULTS

### Effects of AT and argatroban on I/R-induced increase of hepatic metastasis in rats

**Figure 2** Changes in hepatic tumor necrosis factor (TNF)- $\alpha$  mRNA levels (A) and effects of antithrombin (AT) and various agents on TNF- $\alpha$  mRNA levels (B) in rats subjected to hepatic ischemia/reperfusion (I/R). <sup>b</sup> $P < 0.01$  vs pre-ischemia. <sup>d</sup> $P < 0.01$  vs sham and I/R+saline.

When intrasplenically injected, colon cancer cells formed a significant number of metastatic nodules in the liver of rats subjected to hepatic I/R on d 7 after the injection of cancer cells. The number of metastatic nodules in animals subjected to hepatic I/R was 13.6-fold than that observed in sham-operated animals (Figure 1). AT significantly inhibited the increase in the number of metastatic nodules in animals subjected to hepatic I/R (Figure 1). In contrast, argatroban, a synthetic selective inhibitor for thrombin, had no effect on this increase (Figure 1).

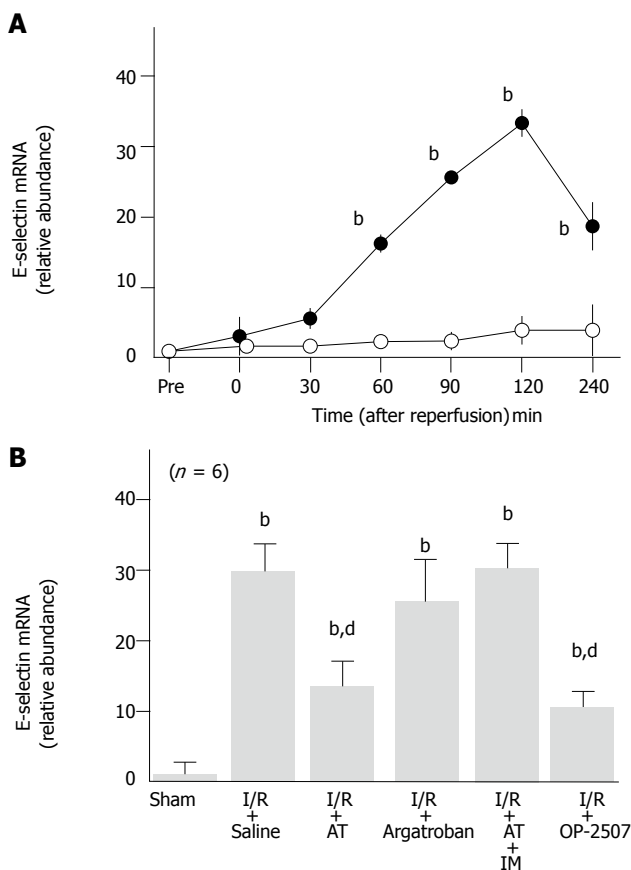

### Effects of AT and argatroban on hepatic I/R-induced increase of TNF- $\alpha$ mRNA in hepatic tissue

Hepatic tissue levels of TNF- $\alpha$  mRNA did not significantly increase in sham-operated animals, while these significantly increased 30 min after hepatic I/R and decreased thereafter to pre-ischemia levels (Figure 2A). AT significantly inhibited the I/R-induced increases in the hepatic tissue TNF- $\alpha$  mRNA levels, whereas argatroban did not inhibit these increases (Figure 2B).

### Effects of AT and argatroban on hepatic I/R-induced increase of E-selectin mRNA in hepatic tissue

Although hepatic tissue levels of E-selectin mRNA did not increase in sham-operated animals, these levels began

**Figure 3** Changes in hepatic E-selectin mRNA levels (A) and effects of antithrombin (AT) and various agents on E-selectin mRNA levels (B) in rats subjected to hepatic ischemia/reperfusion (I/R). <sup>b</sup>*P*<0.01 vs pre-ischemia. <sup>d</sup>*P*<0.01 vs sham and I/R+saline.

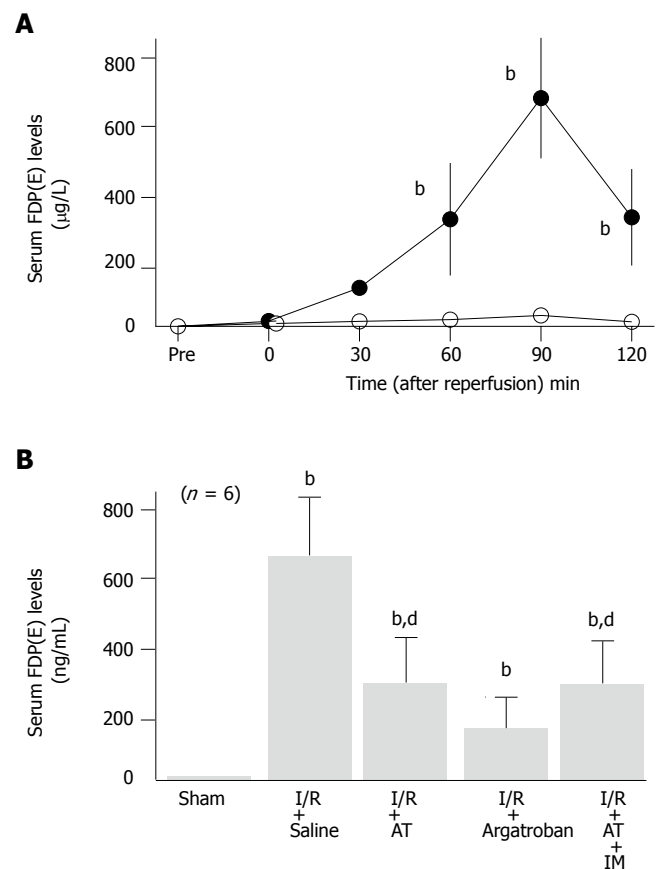

to increase 60 min after reperfusion, peaking at 120 min after reperfusion in animals subjected to hepatic I/R (Figure 3A). AT significantly inhibited the I/R-induced increases of E-selectin mRNA levels observed in hepatic tissue 120 min after reperfusion, whereas argatroban did not inhibit these increases (Figure 3B).

#### Effects of AT and argatroban on I/R-induced increase of serum FDP(E)

Serum levels of FDP(E) significantly increased after reperfusion, peaking 90 min after reperfusion in animals subjected to hepatic I/R, while these levels did not increase in sham-operated animals (Figure 4A). Both AT and argatroban inhibited the hepatic I/R-induced increases of serum FDP(E) observed 90 min after reperfusion (Figure 4B).

#### Effect of AT on hepatic tissue levels of 6-keto-PGF<sub>1α</sub>

To examine whether AT reduced the hepatic I/R-induced increase in the number of metastatic nodules by promoting the endothelial release of PGI<sub>2</sub>, we have analyzed the effect of AT on the hepatic tissue levels of 6-keto-PGF<sub>1α</sub> after reperfusion. Hepatic tissue levels of 6-keto-PGF<sub>1α</sub> increased after reperfusion, peaking 90 min after reperfusion (Figure 5A). These levels were significantly higher in the I/R group than in sham-operated animals (Figure 5B). Administration of AT significantly enhanced

**Figure 4** Changes in serum concentrations of fragment E of fibrin and fibrinogen degradation products (FDP(E)) (A) and effects of antithrombin (AT), argatroban and AT+indomethacin (IM) on serum concentrations of FDP(E) (B) in rats after hepatic ischemia/reperfusion (I/R). <sup>b</sup>*P*<0.01 vs pre-ischemia. <sup>d</sup>*P*<0.01 vs sham and I/R+saline.

the I/R-induced increases in hepatic levels of 6-keto-PGF<sub>1α</sub> 90 min after reperfusion, whereas argatroban did not (Figure 5B).

#### Effect of IM on anti-metastatic effect of AT observed in our experimental model

The anti-metastatic effect of AT was not observed in animals pretreated with IM which is known to inhibit cyclooxygenases (Figure 1). AT did not inhibit hepatic I/R-induced increases of TNF-α and E-selectin mRNA in hepatic tissue from animals pretreated with IM (Figures 2B and 3B). Hepatic I/R-induced increases in serum levels of FDP(E) were inhibited by AT in animals pretreated with IM (Figure 4B). Pretreatment of animals with IM significantly inhibited increases in hepatic tissue levels of 6-keto-PGF<sub>1α</sub> in animals given AT 90 min after reperfusion (Figure 5B).

#### Effect of OP-2507 on hepatic I/R-induced increase in the number of metastatic nodules and hepatic tissue levels of TNF-α and E-selectin mRNA

To determine whether PGI<sub>2</sub> inhibited I/R-induced increase in the number of hepatic metastases, we have examined the effect of OP-2507 on the I/R-induced increase in the number of hepatic metastatic nodules. As shown in Figure 1, the increase in the number of metastatic nodules in

**Figure 5** Changes in hepatic 6-keto-PGF<sub>1α</sub> levels (A) and effects of antithrombin (AT) and AT plus indomethacin (IM) on hepatic 6-keto-PGF<sub>1α</sub> levels (B) in rats subjected to hepatic ischemia/reperfusion (I/R). <sup>a</sup>*P*<0.05, <sup>b</sup>*P*<0.01 vs pre-ischemia. <sup>c</sup>*P*<0.01 vs sham. <sup>d</sup>*P*<0.01 vs I/R+saline and I/R+AT.

animals subjected to hepatic I/R was significantly inhibited by OP-2507. OP-2507 inhibited the I/R-induced increases in hepatic tissue levels of TNF-α and E-selectin mRNA observed 30 and 120 min after reperfusion, respectively (Figure 2B and 3B).

### Hepatic I/R-induced metastasis of B16-F10 cells in congenital AT-deficient mice

To know whether endogenous AT also inhibited hepatic metastasis of B16-F10 cells injected intrasplenically, we have compared the number of hepatic metastatic nodules observed after I/R in congenital AT-deficient mice (AT<sup>+/-</sup>) with that observed in wild-type C57BL/6J mice. The hepatic I/R-induced increase in the number of hepatic metastatic nodules observed 7 d after reperfusion was significantly higher in congenital AT<sup>+/-</sup> mice than in wild type mice (Figure 6). AT decreased the number of hepatic metastatic nodules in AT<sup>+/-</sup> mice subjected to hepatic I/R (Figure 6).

## DISCUSSION

In the present study, AT reduced the hepatic I/R-induced increase of hepatic metastasis in rats to which colon cancer cells were intrasplenically injected. TNF-α is a pro-inflammatory cytokine that increases the expression

**Figure 6** The number of hepatic metastatic nodules in congenital antithrombin (AT)-deficient mice. <sup>b</sup>*P*<0.01 vs AT<sup>+/+</sup>. <sup>d</sup>*P*<0.01 vs AT<sup>+/-</sup>.

of leukocyte adhesion molecules such as E-selectin, thereby contributing to the lodgment of cancer cells on the sinusoidal surface, leading to metastatic nodule formation<sup>[22]</sup>. AT inhibited hepatic I/R-induced increases in hepatic tissue levels of TNF-α and E-selectin mRNA, suggesting that AT might inhibit the hepatic I/R-induced increase of colon cancer cells metastases in our rat model by inhibiting TNF-α production. TNF-α plays a critical role in microthrombus formation in hepatic I/R<sup>[23]</sup>. Since thrombin increases the expression of E-selectin by activating protease-activated receptor-1 on endothelial cells<sup>[24]</sup>, AT might inhibit the hepatic metastasis of colon cancer cells by inhibiting thrombin activity. However, this possibility seemed less likely, since argatroban, a selective inhibitor of thrombin that inhibited hepatic I/R-induced increases of serum FDP (E) to the same extent as AT, did not inhibit the development of hepatic metastases in the present study. We have previously reported that AT inhibits hepatic I/R-induced increases in hepatic tissue levels of TNF-α by promoting the I/R-induced increase in endothelial production of PGI<sub>2</sub><sup>[16]</sup>. Consistent with this report is the present observation demonstrating that AT enhanced the hepatic I/R-induced increases in hepatic tissue levels of 6-keto-PGF<sub>1α</sub>. Pretreatment with IM reversed the effects of AT, including the inhibition of metastasis and increases in hepatic tissue levels of both TNF-α and E-selectin mRNA, suggesting that AT might inhibit hepatic I/R-induced increase in the metastasis of colon cancer cells by increasing endothelial production of PGI<sub>2</sub>. Furthermore, OP-2507, a stable derivative of PGI<sub>2</sub>, showed effects similar to those of AT, supporting the hypothesis described above.

Hepatic metastasis of intrasplenically injected cancer cells was significantly increased in heterozygous congenital AT-deficient mice whose plasma AT level is about half that of wild type mice<sup>[17]</sup> and replacement of AT in congenital AT-deficient mice reversed this increase in hepatic metastasis in the present study. These observations suggest that endogenous AT as well as AT given intravenously might be critically involved in the inhibition of hepatic I/R-induced increase of hepatic metastases in our experimental model.

Although the findings of the present study strongly

suggest that AT might inhibit the metastasis of colon cancer cells via the promotion of endothelial production of PGI<sub>2</sub>, it is possible that a direct inhibition of tumor cell growth by AT also contribute to the inhibition of hepatic I/R-induced increase of colon cancer cell metastases. Our preliminary experiments using the monotetrazolium assay demonstrated that AT (5 kU/L) significantly inhibits the growth of RCN-H4 cells after incubation for 48 h<sup>[25]</sup>. Therefore, although IM pretreatment abrogated the anti-metastatic effect of AT in the present study, a direct effect of AT on cancer cell growth might contribute, at least in part, to the anti-metastatic effect of AT. This possibility should be further examined in future experiments.

AT concentrates are currently available for the treatment of disseminated intravascular coagulation and thrombosis in the clinical setting<sup>[26-28]</sup>. The findings of the present study raise the possibility that AT concentrates can effectively prevent hepatic metastasis of cancer cells during hepatectomy. These possibilities should be further examined in the clinical setting in the near future.

## ACKNOWLEDGMENT

### Abstract

**AIM:** To evaluate the attitude of primary care physicians in the diagnosis and treatment of *Helicobacter pylori* (*H. pylori*) infection.

**METHODS:** Primary care physicians in the Seoul metropolitan area answered self-administered questionnaire from January to March 2003.

**RESULTS:** One hundred and eight doctors responded to the questionnaire. The most frequent reasons for testing *H. pylori* infection were gastric and duodenal ulcers (93.5% and 88.9%, respectively). For patients with *H. pylori* positive dyspepsia, 28.7% of doctors always tried to eradicate the worm and 34.4% treated selectively. A large proportion (28.7%) of primary care physicians treated *H. pylori* on a patient's request basis. Only 9.3% of primary care physicians always conducted follow-up testing after treating *H. pylori* infection. When *H. pylori* was not cleared by the first treatment, 40.7% of doctors reused the same regimen, 16.7% changed to another triple regimen and 25% to a quadruple regimen.

**CONCLUSION:** It has been well documented that the issuance of guidelines alone has little impact on practice. Communication between primary care physicians and gastroenterologists in the form of continuous medical education is required.

**Key words:** *Helicobacter pylori*; Guidelines; Primary care

### INTRODUCTION

It is now accepted that infection of the gastric mucosa with *Helicobacter pylori* (*H. pylori*) causes chronic gastritis. More than 90% of peptic ulcer patients are infected with *H. pylori* and it has been shown that successful treatment prevents ulcer relapse<sup>[1-3]</sup>. National and international guidelines have been published on the management of *H. pylori*, and it is tacitly assumed that these guidelines are adhered to in clinical practice<sup>[4-7]</sup>. But, there seems to be a discrepancy between current testing and treatment guidelines and clinical practice<sup>[8,9]</sup>. In particular, the approaches used in primary practice may differ markedly from those used in referral hospitals<sup>[10-13]</sup>. Patients commonly visit both primary care physicians and gastroenterologists because of upper gastrointestinal symptoms. Variable *H. pylori* detection methods, including serologic assays and the urea breath test, are currently used. Although most physicians do not believe that *H. pylori* causes non-ulcer dyspepsia, the majority often prescribe antibiotics for *H. pylori* eradication. The extent to which research findings regarding *H. pylori* have modified physicians' practice in general has not been well studied. We conducted the present study to determine whether current guidelines regarding *H. pylori* infection have influenced diagnostic and therapeutic primary care practice.

### MATERIALS AND METHODS

From January to March 2003, we conducted an observational, transverse study by using a self-administered questionnaire. Primary care physicians in the metropolitan area of Seoul were randomly selected from the membership database of the Seoul Medical Association. Questionnaires were distributed by post, and non-respondents were sent reminders and then contacted by telephone. One hundred and thirty-five doctors participated in the study.

**Table 1** Korean guidelines for *H. pylori* treatment (Korean *H. pylori* Study Group, 1998)

Indication for <i>H. pylori</i> eradication	Peptic ulcer Regardless of the stage of ulcer Low-grade MALT associated lymphoma Stage IE1 After endoscopic mucosal resection (EMR) of early gastric cancer (EGC)
Recommended first line therapy	PPI-based triple therapy for 1-2 wk - PPI (omeprazole 20 mg or lansoprazole 30 mg or pantoprazole 40 mg) b.i.d. - Amoxicillin (not ampicillin) 1 000 mg b.i.d. - Clarithromycin (or metronidazole) 500 mg b.i.d.
Follow-up after eradication therapy	Urea breath test: test of choice, if available Or both biopsy urease test and histology At least 4 wk after completion of therapy Serology: not useful to confirm the eradication
Recommended second-line therapy	Quadruple therapy for 1 wk (PPI+conventional bismuth-based triple therapy) - PPI (omeprazole 20 mg or lansoprazole 30 mg or pantoprazole 40 mg) b.i.d. - Denol 120 mg b.i.d. - Metronidazole 400-500 mg t.i.d. - Tetracycline 500 mg q.i.d.

**Figure 1** When do you test for *H. pylori*?**Figure 2** Which test do you prefer?

## RESULTS

One hundred and eight doctors (80%) responded to the survey. We itemized below the physicians' responses to the questions given in the questionnaire.

### When do you test for *H. pylori*?

Primary care physicians widely used the *H. pylori* test in cases of gastric ulcer and duodenal ulcer (88.9% and 93.5%, respectively, Figure 1). But they conducted tests for *H. pylori* only in 26.9% and 13% of patients, after surgery

for early gastric cancer or Maltoma (Figure 1). Frequently physicians tested for *H. pylori* in cases of gastritis and due to a patient's request (25.0% and 58.3%, respectively, Figure 1).

### Which test do you prefer?

More than half of the primary care physicians stated that they used the rapid urease test and biopsy, (55.6% and 54.6%, respectively, Figure 2), and a minority used the urea breath test and serology (8.3% and 22.2%, respectively, Figure 2).

### How do you eradicate *H. pylori* infection?

An 88% of physicians responded that they prescribed a proton pump inhibitor (PPI)-based triple regimen according to Korean guidelines (Table 1, Figure 3), and only small numbers were found to prescribed dual and quadruple regimens (2.8% and 2.8%, respectively, Figure 3).

### How long do you treat *H. pylori* infection?

The majority of physicians responded that they prescribe medication for 7, 14 d (90.7%), according to Korean guidelines (Figure 4). A small number responded that they prescribed for less than 7, 21 or 28 d, accounting for 4.6%, 1.9%, 2.8%, respectively (Figure 4).

### Do you perform follow-up testing after treating *H. pylori* infection?

Only 9.3% replied that they always conducted follow-up testing after treating *H. pylori* infection (Figure 5). The majority of primary care physicians stated that they selectively apply follow-up tests (Figure 5).

### What kind of method do you prefer as follow-up test?

The majority percent of physicians stated that they used the rapid urease test or biopsy, accounting for 35.2% and 25.9%, respectively (Figure 6), while a minority favored urea breath testing or serology, accounting for 21.3% and 6.5%, respectively (Figure 6).

### Treatment plan after failure to eradicate *H. pylori*

Surprisingly, a large proportion (40.7%) of primary care physicians prescribed the original regimen after failure to eradicate *H. pylori* (Figure 7). Only 25.0% physicians

Figure 3 How do you eradicate *H. pylori* infection?

Figure 4 How long do you treat *H. pylori* infection?

Figure 5 Do you perform follow-up testing after treating *H. pylori* infection?

Figure 6 What kind of method do you prefer as follow-up test?

prescribed regimens complying with Korean guidelines (Figure 7).

#### Do you treat *H. pylori* infection in dyspepsia patients without peptic ulcer?

Physicians (31.5%) responded that they always eradicate *H. pylori* (Figure 8), while 10.2% treated *H. pylori* on patient's request without testing (Figure 8).

#### Do you medicate for *H. pylori* eradication by patient's request?

A large number (28.7%) of physicians responded positively (Figure 9).

## DISCUSSION

The prevalence of *H. pylori* among Korean adults is 60%-80%<sup>[14]</sup>, and gastric cancer remains the most common malignancy in Korea<sup>[15]</sup>. Most Korean primary care physicians are interested in *H. pylori*, and more frequently prescribe medication for the treatment of *H. pylori* than gastroenterologist. The indications for *H. pylori* eradication in Korea (Korean *H. pylori* Study Group, 1998) are peptic ulcer, low-grade MALT-associated lymphoma, and post-endoscopic mucosal resection of early gastric cancer (Table 1). The recommended first-line therapy in Korea is the PPI-based triple therapy for 1 to

2 weeks. PPI would be the omeprazole, lansoprazole, or pantoprazole (Table 1). The treatment of choice in terms of antibiotics is the amoxicillin+clarithromycin (Table 1). The recommended second-line therapy according to the Korean guidelines is quadruple therapy for a week (Table 1), based on PPI, Denol, metronidazole, and tetracycline (Table 1). The issued Korean guidelines are similar to those issued by the Asia Pacific Consensus Conference on the management of *H. pylori* infection<sup>[6]</sup>. The survey conducted for the present study involved mailing a questionnaire to primary physicians in Seoul, Korea. The questions primarily addressed physician decisions concerning the evaluation and treatment of *H. pylori* infection in patients with gastroenterologic disease. Alternative treatment regimens were also examined. The survey results indicate that primary care physicians widely adopt *H. pylori* testing in cases of gastric ulcer and duodenal ulcer according to Korean guidelines. However, physicians only conduct *H. pylori* testing in 26.9% and 13.0% of postoperative early gastric cancer and Maltoma patients. In addition, they frequently test for *H. pylori* in cases of gastritis and due to a patient's request, accounting for 25.0% and 58.3%, respectively, but many do not perform follow-up testing after *H. pylori* treatment. Only 9.3% of primary care physicians always conduct follow-up testing after *H. pylori* treatment. The majority of primary care physicians prefer the rapid urease test

Figure 7 Treatment plan after failure to eradicate *H. pylori*.

Figure 8 Do you treat *H. pylori* infection in dyspepsia patients without peptic ulcer?

Figure 9 Do you medicate for *H. pylori* eradication by patient's request?

or biopsy, accounting for 35.2%, 25.9%, respectively, as follow-up tests, because generally in Korea primary care physicians have an endoscopic unit, but not urea breath test equipment; 6.5% physicians use a serology-based follow-up test. Only 25.0% prescribe a quadruple regimen as second line therapy, contrary to the Korean guidelines and a large number (40.7%) of physicians prescribe the same regimen after failing to eradicate *H. pylori*. In addition, they frequently treat *H. pylori* in cases of non-ulcer

dyspepsia and patient's request. This finding is at odds with the current guideline and primary care practice for the diagnosis and treatment of *H. pylori* infection in Korea. Moreover, the finding of the present study compare well with data published in other countries<sup>[10-13]</sup>. Thus, the issuance of guidelines has little impact on practice. Our findings suggest that communication programs, such as continuous medical education, between primary care physicians and gastroenterologists are needed. Moreover, schemes designed to ensure guideline implementation should be preceded by a detailed analysis of likely primary care physician response.

### Abstract

**AIM:** To further elucidate the pathogenesis and mechanisms of the high risk of gallstone formation in Crohn's disease.

**METHODS:** Gallbladder bile was obtained from patients with Crohn's disease who were admitted for elective surgery (17 with ileal/ileocolonic disease and 7 with Crohn's colitis). Fourteen gallstone patients served as controls. Duodenal bile was obtained from ten healthy subjects before and after the treatment with ursodeoxycholic acid. Bile was analyzed for biliary lipids, bile acids, bilirubin, crystals, and crystal detection time (CDT). Cholesterol saturation index was calculated.

**RESULTS:** The biliary concentration of bilirubin was about 50% higher in patients with Crohn's disease than in patients with cholesterol gallstones. Ten of the patients with Crohn's disease involving ileum and three of those with Crohn's colitis had cholesterol saturated bile. Four patients with ileal disease and one of those with colonic disease displayed cholesterol crystals in their bile. About 1/3 of the patients with Crohn's disease had a short CDT. Treatment of healthy subjects with ursodeoxycholic acid did not increase the concentration of bilirubin in duodenal bile. Several patients with Crohn's disease, with or without ileal resection/disease had gallbladder bile supersaturated with cholesterol and short CDT and contained cholesterol crystals. The biliary concentration of bilirubin was also increased in patients with Crohn's colitis probably not due to bile acid malabsorption.

**CONCLUSION:** Several factors may be of importance for the high risk of developing gallstones of both cholesterol and pigment types in patients with Crohn's disease.

**Key words:** Bile acid; Biliary lipid composition; Bilirubin; Crohn's disease; Gallstone disease

Lapidus A, Åkerlund JE, Einarsson C. Gallbladder bile composition in patients with Crohn's disease. *World J Gastroenterol* 2006; 12(1): 70-74

<http://www.wjgnet.com/1007-9327/12/70.asp>

### INTRODUCTION

The prevalence of gallstone disease in patients with Crohn's disease is about two-fold higher than that in general population<sup>[1-8]</sup>. This is true not only for patients with ileal disease/resection but also for patients with Crohn's colitis. No large studies of gallstone composition are available in patients with Crohn's disease but in two small series, while both pigment stones and cholesterol-rich stones have been reported<sup>[9,10]</sup>. The pathogenesis of gallstones in patients with Crohn's disease still remains to be elucidated.

One hypothesis for the increased prevalence of gallstone disease in patients with Crohn's disease is that the bile acid malabsorption in patients with diseased or resected ileum may lead to cholesterol supersaturated bile. In fact, supersaturated bile has been reported in some<sup>[11-14]</sup> but not all studies of patients with ileal disease or resection<sup>[8-10,15-19]</sup>.

Another hypothesis for gallstone formation in patients with Crohn's disease is that patients with ileal disease or resection develop pigment stones as a consequence of increased spillage of malabsorbed bile acids into the colon where they solubilize unconjugated bilirubin and promote its absorption and thereby increase the rate of bilirubin secretion into the bile. In support of this hypothesis, an increased concentration of bilirubin in gallbladder bile or duodenal bile of patients with chronic ileitis or previous ileectomy has been reported<sup>[10,14,17,18]</sup>. Brink *et al.*<sup>[20]</sup> demonstrated that bile acid malabsorption after ileectomy of rats induces enterohepatic circulation of bilirubin and doubles the secretion rate of bilirubin into the bile. The same research group has also shown that adding ursodeoxycholic acid to the diet of mice and rats can increase the cecal bile acid levels and bilirubin secretion rates into the bile probably by inducing enterohepatic cycling of bilirubin<sup>[21]</sup>.

The aims of the present study were to determine the biliary lipid composition, occurrence of cholesterol crystals, crystallization time, and bilirubin concentration in gallbladder bile of patients with ileal Crohn's disease

**Table 1** Characteristics of patients with Crohn's disease and controls with gallstone disease

Patient group	n	Sex (M/F)	Mean age (range) (yr)	Previous surgery	Present surgery	Medical treatment
Crohn's disease						
Ileitis or ileocolitis	17	8/9	38 (23-70)	Ileal or ileocolonic resection (n = 12)	Colonic or ileocolonic resection (n = 15) Cholecystectomy (n = 2)	Steroids (n = 11) Azathioprine (n = 4) Nitromidazole (n = 6) 5-ASA (n = 2)
Colitis	7	5/2	42 (28-57)	Partial colonic resection (n = 3)	Partial colonic resection or colectomy (n = 7)	Steroids (n = 5) Azathioprine (n = 1) Nitromidazole (n = 3)
Gallstone disease	14	1/13	47 (27-57)		Cholecystectomy (n = 14)	

with or without the involvement of colon and especially patients with Crohn's colitis in comparison to patients with cholesterol gallstone disease undergoing cholecystectomy served as control group and to study the influence of treatment with ursodeoxycholic acid on the duodenal concentration of bilirubin in human subjects.

## MATERIALS AND METHODS

### Patients and healthy subjects

Twenty-four patients with Crohn's disease admitted for elective surgery were included in the study. Clinical details are given in (Table 1). One patient had slightly elevated serum alkaline phosphatase level and three had slightly elevated transaminase and/or gamma glutamyl transpeptidase (GGT)-level. All other patients had normal laboratory tests of liver function including serum bilirubin. Seventeen patients had ileal or ileocolonic disease and 7 patients had Crohn's disease confined solely to the colon. Two patients with gallstones were cholecystectomized, one of them simultaneously underwent colectomy. All other patients were admitted for ileal, ileocolonic or colonic resection due to the failure of pharmacological treatment.

Fourteen consecutive patients with cholesterol gallstones admitted for cholecystectomy served as controls (Table 1).

In another experiment, 10 healthy subjects (6 men and 4 women, mean age 44 years) were studied before and after the treatment with ursodeoxycholic acid.

Informed consent was obtained from all the participants. The ethical aspect of the study was approved by the Ethical Committee of Karolinska Hospital Huddinge.

### Experimental procedures

After the abdomen was opened, bile from the gallbladder was obtained by needle aspiration. The bile was collected in sterile tubes surrounded by foil and sent to the laboratory for analysis.

The healthy subjects were treated with ursodeoxycholic acid (Ursofalk® in 250 mg capsules, obtained from Dr Falk Pharma, Freiburg, Germany) at a daily dose of 15 mg/kg for 3 wk. Before and after the treatment, the bile was collected with an oroduodenal tube in the morning after an overnight fast. Gallbladder contraction was stimulated by an intravenous injection of cholecystokinin and 5-10 mL of the concentrated bile was obtained through the tube. The bile was collected in a test tube surrounded by a foil and was sent to the laboratory for analysis. Serum samples

were also collected for analysis of bilirubin.

### Biliary bilirubin concentration

An aliquot of the bile was immediately diluted with saline and the bilirubin concentration was determined by a similar procedure as for serum bilirubin as described previously<sup>[18]</sup>. The biliary concentration was expressed as mmol/L in gallbladder bile and as micromoles of bilirubin per millimole bile acid in duodenal bile.

### Biliary lipids and bile acid composition

A portion of the gallbladder bile was immediately extracted with 20 volumes of chloroform-methanol 2:1 (vol/vol) and analyzed for cholesterol and phospholipids. Cholesterol was determined by an enzymatic method<sup>[22]</sup> and phospholipids by the method of Rouser *et al.*<sup>[23]</sup> The total bile acid concentration in one aliquot of the bile sample was determined using 3- $\alpha$ -hydroxy steroid dehydrogenase assay<sup>[24]</sup>. The relative concentration of cholesterol bile acids and phospholipids was expressed as molar percentage of the total biliary lipids. The cholesterol saturation was calculated according to Carey<sup>[25]</sup>. Bile acid composition was determined using gas-liquid chromatography<sup>[26]</sup>.

### Analysis of cholesterol crystals and crystallization time (CDT)

Gallbladder bile samples were examined for typical rhomboid monohydrate cholesterol crystals by polarizing light microscopy on pre-heated slides. CDT was determined by the method of Holan *et al.*<sup>[27]</sup> with minor modifications<sup>[28]</sup>. After centrifugation of about 6 mL bile at 100 000 g for 2 h, 3 mL from the middle phase was transferred into a sterile glass vial and sealed with a cap equipped with permeable silicon membrane. The vial was stored in darkness in an incubator at 37 °C. About 3  $\mu$ L from the top, middle and bottom portions was aspirated each day, mixed and placed on a pre-heated slide and viewed thoroughly by polarizing light microscopy. CDT was defined as the number of days until the appearance of typical rhomboid monohydrate cholesterol crystals.

### Statistical analysis

Data were given as mean  $\pm$  SE. Comparisons of the data between patients and healthy subjects were calculated using Mann-Whitney's rank sum test and Wilcoxon's sum of rank test.  $P < 0.05$  was considered statistically significant.

**Table 2 Biliary lipid composition and cholesterol saturation (mean  $\pm$  SE)**

	Crohn's disease ileitis or ileocolitis (n = 17)	Crohn's disease colitis (n = 7)	Crohn's disease all patients (n = 24)	Gallstone disease (n = 14)

Bilirubin (mmol/L)	4.6 $\pm$ 0.7 <sup>a</sup>	5.9 $\pm$ 1.6	5.0 $\pm$ 0.7	2.6 $\pm$ 0.2

\* Significantly different from corresponding value of patients with gallstone disease. <sup>a</sup>P < 0.05 vs patients with gallstone disease.

## RESULTS

### Gall bladder bile composition

Data on biliary lipid composition are given in (Table 2). The cholesterol saturation of bile was significantly lower in patients with Crohn's disease confined to the colon than in patients with the gallstone. In contrast, 10 out of 17 patients with Crohn's disease involving the ileum had cholesterol-saturated bile. Nevertheless, all patients with CD as a group tended to have lower cholesterol saturation compared to patients with gallstone ( $P = 0.055$ ).

Bile acid composition is shown in (Table 3). Cholic acid, chenodeoxycholic acid and deoxycholic acid were the dominant bile acids both in patients with Crohn's disease and in patients with gallstone. The patients with Crohn's disease had significantly lower proportions of deoxycholic acid and lithocholic acid than the patients with gallstone. The proportions of cholic acid and chenodeoxycholic acid were concomitantly increased.

The biliary bilirubin concentration was about 50% higher in patients with Crohn's disease than in patients with gallstone (Table 4). No difference was obtained between patients with Crohn's disease confined to the colon and those with ileal involvement. The bilirubin concentration tended to be higher in patients with Crohn's disease

confined to the colon in patients with ileal involvement but the difference did not reach statistical significance.

### Cholesterol crystals and CDT

Cholesterol crystals were present in four gallbladder samples of the 17 patients with Crohn's disease involving the ileum. One of the patients with cholesterol crystals also had gallstones and was cholecystectomized. The gallbladder bile was saturated with cholesterol. Only one of the patients with Crohn's colitis displayed cholesterol crystals. Also this patient had gallstones in saturated bile and was cholecystectomized. Most of the patients (9 out of 14) with cholesterol gallstones displayed cholesterol crystals.

CDT was measured only in patients with Crohn's disease. Six out of sixteen patients with ileal involvement had a short CDT (mean 4 d, range 1-7 d). Two of six patients with Crohn's colitis also had a short CDT (4 and 5 d, respectively).

### Treatment with ursodeoxycholic acid

The results are summarized in (Table 5). Ursodeoxycholic acid accounted for (0.5  $\pm$  0.5)% of the total biliary bile acids before the treatment. Treatment with ursodeoxycholic acid increased the bile acid to (54.8  $\pm$  3.8)%. Cholic acid, chenodeoxycholic acid, and deoxycholic acid were concomitantly decreased. Treatment with ursodeoxycholic acid decreased the cholesterol saturation from (101  $\pm$  10)% to (52  $\pm$  5)%. The biliary bilirubin concentration expressed as mmol/mol bile acid did not change after the treatment with ursodeoxycholic acid. The serum concentration of bilirubin also did not change after the treatment with ursodeoxycholic acid.

## DISCUSSION

Several studies have shown that patients with ileal Crohn's

s disease and/or previous ileal resection have elevated bilirubin levels in the bile<sup>[10,14,17,18]</sup>. Animal experiments showed that ileectomy-induced bile acid malabsorption increases bilirubin secretion into the bile<sup>[20]</sup>, suggesting that the increased bilirubin levels in patients with ileal disease and/or resection may be due to induced enterohepatic cycling of bilirubin because of bile acid malabsorption. Orally given ursodeoxycholic acid can compete with ileal absorption of endogenous bile acids and cause bile acid malabsorption in rodents as well as in human subjects<sup>[29–31]</sup>. Meéndez-Saánchez *et al*<sup>[21]</sup> also showed that oral administration of ursodeoxycholic acid to rodents induces biliary secretion of bilirubin and increases cecal bile acid levels as well as bilirubin concentrations. In the present study however, oral administration of ursodeoxycholic acid to healthy subjects did not increase the bilirubin concentration in bile, which makes it unlikely that bile acid malabsorption increases bilirubin secretion into the bile in human beings. This is further confirmed by our finding in the present study that patients with Crohn's colitis but without the involvement of the distal ileum and apparent bile acid malabsorption also had elevated bilirubin levels in the bile. In fact, bilirubin concentrations tended to be higher in patients with Crohn's disease confined to the colon than in those with ileal involvement. In contrast to our results, Brink *et al*<sup>[10]</sup> and Pereira *et al*<sup>[14]</sup> have shown that bilirubin level is normal in the gallbladder bile of patients with Crohn's colitis.

If the increased bilirubin concentration in the bile of patients with Crohn's disease is not due to an enhanced enterohepatic circulation of bilirubin because of bile acid malabsorption, what could then be the explanation? Theoretically increased bilirubin content can be explained by an increased formation and excretion into the bile and/or a decreased metabolism of bilirubin in the intestine with subsequent absorption and enterohepatic circulation of bilirubin. An increased formation of bilirubin may originate from hemolysis. However, none of the patients in the present study had hemolysis or hyperbilirubinemia. Therefore, the most likely explanation for the increased biliary content of bilirubin in the patients is an increased

intestinal absorption. Normally, bilirubin is deconjugated and degraded to urobilinogen and other products in the colon<sup>[32]</sup>. In Crohn's disease, an altered colonic bacterial flora may enhance the deconjugation with a subsequently increased absorption of unconjugated bilirubin from the intestine and an increased excretion of bilirubin into the bile<sup>[33]</sup>.

Two patients with Crohn's disease, one with the disease involving the ileum and the other one with Crohn's colitis were cholecystectomized. The gallbladder bile in both of them was supersaturated with cholesterol and contained cholesterol crystals, indicating that the stones are cholesterol type. Another three patients with ileal involvement but without Crohn's colitis displayed cholesterol crystals in the gallbladder bile. About 1/3 of the patients with Crohn's disease with but without the ileal disease had a short CDT. Half of these patients had unsaturated gallbladder bile. This finding is in agreement with a recent report by Keulemans *et al*<sup>[19]</sup> who showed that patients with Crohn's disease have an increased tendency to form cholesterol crystals. They have also found that the crystallization behavior is the same in patients with ileal disease as in those with the disease confined to the colon and is caused by increased cholesterol crystallization promoting activity.

Several of the patients with ileal disease but without gallstones displayed cholesterol saturated gallbladder bile (Table 5). However, the mean value of the cholesterol saturation in this group of patients was the same as that obtained in the healthy subjects, which is in agreement with our previous finding that patients with ileal resection due to Crohn's disease have a normal saturation of the bile<sup>[16,18]</sup>.

In conclusion, patients with Crohn's disease involving the ileum and those with Crohn's colitis have elevated concentration of bilirubin in the gallbladder bile. Oral administration of ursodeoxycholic acid to healthy subjects does not increase the biliary concentration of bilirubin. These results speak against the previously described hypothesis that the increased concentration of bilirubin in the bile samples from patients with Crohn's ileitis

or previous ileal resection is due to malabsorption of bile acids that spill into the colon where they solubilize unconjugated bilirubin and increase its absorption and enterohepatic circulation. In some patients with ileal disease/resection, the gallbladder bile is supersaturated with cholesterol and contains cholesterol crystals. About 1/3 of the patients with Crohn's disease with but without the ileal involvement have a short CDT probably because of increased cholesterol crystallization promoting activity in the gallbladder bile. Thus, several factors including cholesterol supersaturated bile, short CDT and increased bilirubin concentration, may be of importance for the high risk of developing gallstones of both cholesterol and pigment types in Crohn's disease.

## Abstract

**AIM:** To further assess of the incidence and localization of Crohn's disease (CD) in a well-defined population during the 1990s and to evaluate the prevalence of CD on the 1<sup>st</sup> of January 2002.

**METHODS:** In a retrospective population based study, all 16-90 years old citizens of Stockholm County diagnosed as having CD according to Lennard Jones' criteria between 1990 and 2001 were included. Case identification was made by using computerized inpatient and outpatient registers. Moreover private gastroenterologists were asked for possible cases. The extent of the disease and the frequency of anorectal fistulae were determined as were the ages at diagnosis. Further, the prevalence of CD on the 1<sup>st</sup> of January 2002 was assessed.

**RESULTS:** All the 1 389 patients, 689 men and 700 women, fulfilled the criteria for CD. The mean incidence rate for the whole period was 8.3 per 10<sup>5</sup> (95%CI 7.9-8.8). There was no difference between the genders. The mean annual incidence of the whole study period for colorectal disease and ileocecal disease, was 4.4 (95%CI 4.0-4.7) and 2.4 (95%CI 2.1-2.6) per 10<sup>5</sup>, respectively. Perianal disease occurred in 13.7% (95%CI 11.9-15.7 %) of the patients. The prevalence of CD was 213 per 100 000 inhabitants.

**CONCLUSION:** The incidence of CD has markedly increased during the last decade in Stockholm County and 0.2% of the population suffers from CD. The increase is attributed to a further increase of colorectal disease, while the incidence of ileocecal disease has remained stable.

## INTRODUCTION

Crohn's disease (CD) is one of the major inflammatory bowel diseases (IBD) that challenges many gastroenterologists in their everyday work. Although CD has been recognized for over 70 years<sup>[1]</sup>, its etiology still remains unclear. An explanatory factor for the unsolved etiology may be the heterogeneous appearance of the disease.

Although descriptive epidemiological studies can hardly prove the etiology of the disease, they are very important in the pursuit of risk factors that can be further assessed in etiological epidemiological studies. Furthermore, they are useful for planning the health care system, development of new pharmaceuticals and therapeutic endeavors.

The former increasing incidence of CD in countries located in the north<sup>[2-5]</sup> seems to have leveled off during the eighties. Nevertheless, the incidence continued to increase in Scotland and Iceland during the eighties and early nineties<sup>[6,7]</sup>. An increasing incidence of CD has also been assessed in former low-incidence countries in southern Europe, Asia, and Japan<sup>[8-10]</sup>. Although numerous epidemiological studies of CD have been performed since the 1960s, there are only few population-based studies that have explored the incidence of CD during the last decade<sup>[11-14]</sup>.

When Burrill B Crohn and his colleagues first described CD in 1932<sup>[1]</sup>, the most common site of the disease was the ileocecal area. It was not until 1960 that CD localized to the colon and/or rectum was regarded as an entity of its own<sup>[15]</sup>, unrelated to ulcerative colitis (UC). Pure colorectal disease has become more common over the years. In a previous survey of patients diagnosed with CD in Stockholm between 1955 and 1989, the proportion of colorectal disease doubled from 14% to 32% during the study period<sup>[16]</sup>. This phenomenon has been reported from other areas as well<sup>[6,7,17]</sup>.

As the mortality due to CD is low<sup>[18]</sup>, an increasing

number of patients will suffer from CD. There are scarce current prevalence rates available<sup>[13,19,20]</sup>.

The primary aim of this study was to further assess the incidence and localization of CD in a well-defined population during the 1990s and to evaluate the prevalence of CD on the 1<sup>st</sup> of January 2002.

## MATERIALS AND METHODS

### *Study area and population*

Stockholm County covers an area of 6 519 km<sup>2</sup> with both urban and rural parts. The population increased from 1.64 to 1.84 million inhabitants between 1990 and 2001<sup>[21]</sup>. The number of individuals aged 16-90 years increased from 1.33 to 1.47 million during the same period and attributed to approximately 80% of the total population. The distribution between the genders was constant during the study period with a share of 49% men. The proportion of aliens was 9.4% in 2001.

There were 9 major hospitals and further 13 established gastroenterologists in private practice taking care of patients with IBD during the study period. The number of lower GI endoscopies (i.e. sigmoidoscopies and colonoscopies) performed in Stockholm County increased from 4 787 to 19 778 per year between 1993 and 2001<sup>[22]</sup>.

### *Case identification*

In Stockholm County, there has been a computerized central registration of all diagnoses for inpatients since 1969. Since 1993, diagnoses have also been successively registered for outpatients and all patients attending the outpatient clinic at the hospitals. The general practitioners have got their diagnoses registered since 1996. Diagnoses were registered according to the International Statistical Classification of Disease (ICD-9 1987-1996, ICD-10 1997 and onwards).

A survey of possible cases was made from the records registered as CD (ICD code 555 and K.50) in the inpatient register between 1990 and 2002 and the outpatient register between 1993 and 2002.

Gastroenterologists in private practice were asked about possible cases and their colonoscopy and histology reports were assessed. All records (paper, microfilmed, and electronic) were retrospectively scrutinized. Patients with an established probable or definite diagnosis of CD according to Lennard Jones' criteria<sup>[23]</sup> were included in the study. Included patients should be citizens of Stockholm County and were diagnosed as having CD between 1<sup>st</sup> January 1990 and 31<sup>st</sup> December 2001. Patients younger than 16 years at diagnosis were not included in the study.

### *Definitions*

The diagnosis of CD and extent of the disease at diagnosis were based on radiological and/or endoscopic reports including macroscopic and microscopic findings as previously described in detail<sup>[16]</sup>.

Date of diagnosis was defined as the first examination revealing signs of CD. If the diagnosis was changed from UC to CD, the first diagnosis date of IBD was considered. Date of presentation of symptoms which are consistent with IBD was approximated to months with a certainty

expressed as either the first or the 15<sup>th</sup> day of the month. In cases, where only the year could be estimated, the date of onset was set as the 1<sup>st</sup> of July.

The type of diagnostic examination(s) performed at the time for diagnosis was noted. The localization of CD was determined based on these diagnostic examinations and classified into five groups: oro-jejunal disease, small bowel disease (inflammation of the small bowel excluding the distal 30 cm of the terminal ileum), ileocecal disease (inflammation including the distal 30 cm of the ileum with or without isolated involvement of the cecum), ileocolonic disease (continuous or discontinuous inflammation of the ileum and colon) and colorectal disease (inflammation in the colon only and/or rectum). The group of oro-jejunal disease consisted of patients with solely oro-jejunal disease and patients with mainly oro-jejunal disease but also inflammation in a more distal part of the intestine.

The extent of colorectal disease was further classified into three groups. For assessment of the disease extent, the colon was schematically divided into four areas consisting of the ascending, transverse, descending, and sigmoid respectively. Colonic disease could either be segmental disease with the involvement of one, two or three of the four schematic areas, left-sided disease extending proximally from the rectum but not beyond the splenic flexure, or total colonic disease with inflammation in all the four areas. Patients with segmental or total colonic disease could have either rectal involvement or rectal sparing. Anorectal fistulae included fistulas and abscesses in the rectum, anal canal or perianal area that appeared before the diagnosis of CD, at the time of diagnosis or at any time during the follow-up period.

If data concerning the parameters mentioned above were uncertain to assess, the data were labeled as unreliable and excluded from actual analysis.

### *Data management and statistical methods*

The cases of CD as well as the population were grouped into 15-year age specific groups: 16-30 years, 31-45 years, 46-60, 61-75, and 75-90. Information about the population in Stockholm County was obtained from the National Central Statistical Register<sup>[21]</sup>.

Incidence rates were calculated for 2-year periods and expressed as annual incidence rates. For each 2-year period, the age specific incidence was calculated by dividing the number of cases by the number of person years in each age group. The population was not adjusted (i.e. subtracted) for previous incidence cases. Calculations were made separately for men and women. The annual incidence was adjusted for sex and age by using the population in Stockholm County in 1995 as a standard population. Incidence rates were expressed as cases per 10<sup>5</sup> inhabitants with a 95% confidence interval (CI) based on the assumption that the number of cases follows a Poisson distribution. A Poisson model (Breslow) was used to study the relationship between sex, calendar year, age and the risk of CD. The hazard function of individuals aged 16-88 years was assumed to be  $\exp[\beta_0 + \beta_1 \cdot \text{minimum}(\text{age}, 45) + \beta_2 \cdot \text{maximum}(0, \text{minimum}(\text{age} - 45, 70 - 45)) + \beta_3 \cdot \text{maximum}(0, \text{age} - 70) + \beta_4 \cdot \text{minimum}(\text{calendar year} - 1990, 6) + \beta_5 \cdot \text{maximum}(0, \text{calendar year} -$

1996) +  $\beta_6 \cdot \text{sex}$ ]. The coefficients  $\beta_1$ ,  $\beta_2$ ,  $\beta_3$ ,  $\beta_4$ ,  $\beta_5$ , and  $\beta_6$  reflected the trends of the risk,  $\beta_1 = \beta_2 = \beta_3 = \beta_4 = \beta_5 = \beta_6 = 0$  corresponded to no change of risk<sup>[24]</sup>.

Time between the onset of symptoms and diagnosis was calculated as the median.

The extent of disease at diagnosis was assessed as incidence rates as well as proportions, i.e. percentages of the total number of cases. Comparison between men and women with respect to the localization of disease was performed by  $\chi^2$  test. The Kruskal-Wallis test was applied for comparison of age at onset and calendar time at onset between localization of disease. If a significant importance of localization was obtained, each localization was compared to all the others by use of Fisher's permutation test.

The probability of anorectal fistulae and rectal involvement, depending on age, sex, and localization of the disease, was estimated by the use of logistic regression. The two-tailed tests were used.

The Ethics Committee at Huddinge University Hospital approved the study.

## RESULTS

Basic data are shown in Table 1.

Altogether 1 389 patients fulfilled the inclusion criteria. A total of 569 patients (41%) had a definite diagnosis of CD and 820 patients (59%) had a possible diagnosis of CD according to Lennard Jones' criteria.

Information regarding the onset of symptoms, methods of diagnosis, occurrence of anorectal fistulae and rectal involvement was not available in 26, 9, 96, and 31 patients respectively. Twenty-eight percent of the patients were prescribed azathioprine or equivalent immunosuppressive medicine at any time during the follow-up.

### Time between onset of symptoms and diagnosis

The median time between the onset of symptoms and

NA, not assessed.

diagnosis was 6.5 mo (range 0–376 mo) for the whole study period. Patients with small bowel disease and ileocecal disease had a longer median time to diagnosis (12.8 and 10.9 mo, respectively) than patients with ileocolonic and colorectal disease (6.1 and 5.9 mo, respectively) ( $P < 0.005$ ).

### Diagnostic procedures

The diagnostic procedures performed between the first-time visit and the diagnosis of CD are shown in Table 2.

If a colonoscopy/ileocolonoscopy was performed, the examination was considered as the “main examination”. Otherwise, the examination that provided most information for diagnosing and evaluation of the extent of disease was labeled as “main examination”. The total number of procedures reflected how many patients underwent each specific examination.

Altogether 70.2% of the patients underwent an endoscopic examination of the colon and the terminal ileum was inspected in 29.2% of these patients. An enteroclysis was performed in 43% of all patients. Six percent of the patients were diagnosed by surgery. The remaining patients underwent only flexible/rigid sigmoidoscopy or miscellaneous examinations.

### Incidence

The mean annual incidence rate for the entire study period was 8.3% (95%CI 7.9%–8.8%) per 100 000 inhabitants. The mean annual incidence rate was 7.7% (95%CI 7.1–8.3%) and 8.9% (95%CI 8.3–9.6%), respectively, during the first and second half of the study period (Figure 1).

The mean increase in incidence per year was estimated to be 7.6% (95%CI 4.3–11.1%) between 1990 and 1996 with the highest increase (21.0%) between 1990 and 1992 (95%CI 5.4–38.8%) and (14.1%) between 1994 and 1996 (95%CI 1.8–27.8%). The maximum incidence rate was found in 1996–1997 with an annual mean of 10.3% (95%CI 9.1–11.5%) per 100 000 inhabitants. After 1996, the annual incidence decreased with a mean of 4.6% per year (95%CI 1.0–8.0%).

No statistical difference in incidence rates was found between men and women [8.6% (95%CI 7.9–9.2%) *vs* 8.1% (95%CI 7.5–8.7%) ] for the entire study period.

### Age at diagnosis

The highest age specific incidence was found among those aged 16–30 years at diagnosis with a mean incidence rate

**Figure 1** Annual incidence rate (mean per two-year periods  $\times 10^{-5}$ ) of Crohn's disease in Stockholm County (1990-2001).

**Figure 3** Incidence of Crohn's disease in Stockholm County by the extent of disease at diagnosis per  $10^5$  inhabitants (1990-2000).

of  $12.3 \text{ per } 10^5$  (95%CI 10.1-14.6) for the entire study period. A maximum incidence rate was observed during 1996-1997 with  $17.1 \text{ per } 10^5$ .

The relationship between age and the risk of CD by using a Poisson model, with the calendar year fixed to 1995, allowed the curve to bend at the arbitrary ages 30, 45, 60, and 75 years (Figure 2). With increasing age, the incidence decreased on an average of 1.7% per year between 16 and 30 years ( $P < 0.05$ ) and 3.9% per year between 30 and 45 years ( $P < 0.001$ ). Thereafter, the incidence increased again on a yearly average of 2.2% ( $P < 0.05$ ) resulting in a second peak at the age of 60 years. In the elderly, the incidence rate decreased with an average of 1.2% and 3.9% per year between 60 and 75 years and over 75 years, respectively. Although the crude number of cases was lower in the older age groups, the bimodal peak in incidence was attributed to fewer person-years of follow-up in the older age groups compared with the younger age groups.

The proportion of patients older than 60 years at diagnosis was 17.7% and the proportion of all patients older than 75 years at diagnosis was 4.2%.

#### Extent of disease at diagnosis

The incidence of CD by the extent of disease at diagnosis is shown in Figure 3.

**Figure 2** Relationship between age and the incidence of Crohn's disease in Stockholm County (1990-2001), determined by using a poisson model, with the calendar year fixed to 1995, allowing the curve to bend at the arbitrary ages 30, 45, 60, and 75 yr.

**Figure 4** Localization of Crohn's disease in Stockholm County (1990-2001).

The mean annual incidence in the whole study period for colorectal and ileocecal disease was 4.4% (95%CI 4.0-4.7%) and 2.4% (95%CI 2.1-2.6%), respectively. Corresponding figures for ileocolonic disease, small bowel disease and oro-jejunal disease were 1.1% (95%CI 1.0-1.3%), 0.3% (95%CI 0.2-0.4%) and 0.2% (95%CI 0.1-0.2%), respectively. The only significant change over time was a decreasing incidence of small bowel disease throughout the study period ( $P < 0.05$ ).

The overall proportion of colorectal and ileocecal disease was 52.3% (95%CI 49.7-55.0%) and 28.3% (95%CI 26.0-30.7%), respectively (Figure 4).

Age influenced the localization of CD at diagnosis. By comparing each disease localization to the others, patients with colorectal ( $P < 0.005$ ) and small bowel disease ( $P < 0.005$ ) were found to be older at diagnosis. In contrary, patients with ileocolonic ( $P < 0.001$ ) and proximal disease ( $P = 0.055$ ) were younger.

In pure colorectal disease, 36.3% of the patients had total colonic involvement, 40.2% had segmental disease and 23.5% had distal colorectal disease. Rectal

**Figure 5** Percentage of patients with Crohn's disease ( $n = 1293$ ) having perianal fistulae/abscesses in Stockholm County during 1990-2001 by age specific groups ( $P < 0.05$ ).

inflammation at diagnosis was found in 67.8% of the patients with colorectal disease.

Distal colorectal disease was associated with a higher age at diagnosis ( $P < 0.005$ ) and inversely total colonic disease was associated with a lower age at diagnosis compared to the rest of the patients ( $P < 0.001$ ). Age did not influence the risk of segmental colorectal disease.

Gender had no influence on either disease localization or extent of colorectal disease at diagnosis.

### Anorectal fistulae

Anorectal fistulae occurred before or after the diagnosis of CD in 13.7% (95%CI 11.9-15.7%) of the patients whose data were assessable ( $n = 1\,293$ ). Gender as well as age had a significant impact on the occurrence of fistulae. Men were more likely to develop this kind of perianal disease than women (15.8% *vs* 11.6%,  $P < 0.05$ ). The impact of age on anorectal fistulae is shown in Figure 5. The disease localization did not influence the frequency of fistulae.

### Prevalence

Calculations were based on all adult patients ( $> 16$  years) with CD living in Stockholm County on the 1<sup>st</sup> of January 2002. Of the 1 389 patients diagnosed between 1990 and 2001, 71 patients were dead and 76 patients had moved out from the area. From the earlier cohort of 1 936 patients diagnosed during 1955-1989<sup>[16]</sup>, 368 patients were dead and 239 patients had moved out. Twelve patients diagnosed in Stockholm before 1955 were still living in the area.

The present case identification survey revealed 327 patients diagnosed outside the Stockholm County, 128 patients diagnosed as UC before 1990 and later got the diagnosis changed from UC to CD and 97 patients diagnosed as CD during 1955-1989 but not included in the previous study<sup>[16]</sup> for unknown reasons. The prevalence was calculated by dividing the total number of patients with CD (3 135) by the adult population ( $> 16$  years) in Stockholm County (1 469 048). Accordingly, the prevalence of CD among the adults in Stockholm County on the 1<sup>st</sup> of January 2002 was estimated to be 213 per 100 000 inhabitants.

## DISCUSSION

Including a former published study<sup>[16]</sup>, the development of CD has now been documented for 45 years in Stockholm County. Thereby, one of the largest population based cohort of patients with CD in the world has been collected.

There are pros and cons regarding study designs. A prospective study may be considered more faultless but is unfeasible in a large study area with many hospitals and gastroenterologists. Shortcoming of a retrospective study can be lack of uniform diagnostic criteria or incomplete data collection. Patients in Stockholm are handled by a limited number of gastroenterologists and the diagnosis is therefore uniform. However, endoscopy has been escalating during the last years. A potential aim to retrospectively assess smoking habits in this study was abandoned due to the lack of reliable data, else sufficient data regarding different parameters were available. The pro of the present retrospective study is a long follow-up period when case ascertainment can be accomplished in the meantime.

The number of patients having a definite diagnosis of CD according to Lennard Jones' criteria<sup>[23]</sup> in this study was lower (41%) than that in our previous study of CD in Stockholm (73%)<sup>[16]</sup>. One explanation could be that fewer patients underwent surgery. Specimens for histopathological examination were less available and thereby granulomas and submucosal signs of CD might be undetected. Some uncertainty may arise about the "probable" cases of CD according to Lennard Jones' criteria. Case ascertainment was assured by scrutinizing the records retrospectively. By following the clinical course of CD, the diagnosis was further ascertained and all included cases were bonafide cases of CD.

Long-term incidence data are scarce in the literature from the late 1990s and onwards<sup>[12-14,25-27]</sup>. The incidence of CD among the adults in the present study was 70% higher than that in Stockholm during 1985-1989, with the highest incidence rate in 1996-1997. The registry of outpatients begun in 1993 and theoretically, the lower incidence found in 1990-1993 may represent an incomplete case ascertainment. Similarly, the drop-off in incidence during the last 4 years of the study could represent decreased ascertainment. However, all patients with CD in Stockholm are regularly followed up and should be identified sooner or later. Diagnoses are registered continuously and a marked delay of identification is unlikely, thus the case ascertainment is reliable.

A 55% increase of the incidence rate was also seen in Denmark where the incidence rate reached a maximum with approximately 10 per 10<sup>5</sup> in 1998-2002<sup>[12]</sup>. In Northern France, the incidence of CD increased 23% during a similar time period<sup>[14]</sup>. Still, the overall incidence rate is lower in France than in Stockholm. The highest incidence rates have previously been reported from North Eastern Scotland<sup>[7]</sup> and Manitoba in Canada<sup>[19]</sup> and now also from Sweden. This may illustrate a north-south gradient of CD that still exists although less pronounced than believed earlier<sup>[10]</sup>. The proportion of immigrants in Stockholm has not changed during the last decade and

should therefore not affect the results<sup>[21]</sup>.

CD is in general believed to affect women more frequently than men<sup>[14,17,28]</sup> although several studies have not found any difference<sup>[4,10]</sup>. This study confirmed earlier observations from Stockholm that gender does not influence the risk for CD<sup>[16]</sup>.

CD mostly occurs in young adults, but can present itself at any time in life<sup>[29]</sup>. The age specific distribution in this study is consistent with some former studies with the highest incidence found among young adults and thereafter decreasing incidence rates with increasing age and a second peak in the elderly<sup>[7,16,17,30]</sup>. Nevertheless, the overall incidence among the elderly was substantially higher in this study compared with other studies<sup>[31,32]</sup>.

Pure colorectal disease and small bowel disease are associated with a high age in contrast to our previous study where only small bowel disease was related to a high age at diagnosis. It has been suggested that smoking CD patients are more likely to develop small bowel disease than non-smoking patients<sup>[33]</sup>. Smoking habits were not evaluated in this retrospective study. However, one can speculate whether smoking was more tolerable in the society previously with an ensuing larger group of smokers among the older population. This assumption is strengthened by the fact that this entity of CD was the only one that decreased throughout the study period. Colorectal CD may be misclassified as ischemic colitis as well as diverticulosis. Both conditions are common in this age group. CD patients with concomitant diverticular disease are more likely to have granulomas but the misclassification should be limited by finding granulomas in other parts of the intestine<sup>[31]</sup>. Focal inflammation is one of the criteria of CD and distinguishes colorectal CD from UC.

This study focused on CD in adults since a study of children with IBD in northern Stockholm has been recently performed<sup>[27]</sup>. That study showed an increasing incidence of pediatric CD during the latter 1990s with an incidence of 8.4 per 10<sup>5</sup> in 1999-2001, thus identical rates were found in adults in the present study.

Anorectal fistulae, strongly associated with CD, have been reported in almost 40% of the patients, preferably in those with colorectal involvement<sup>[34]</sup>. Though patients with colorectal disease accounted for a huge proportion, the frequency of anorectal fistulae was low in the present study and on the whole, no relation was found between the frequency of fistulae and the disease localization. Inclusion of patients with mild colorectal disease might cause a dilution effect and a false low frequency of fistulae. A short follow-up period may be an alternative explanation and moreover, a general increased use of azathioprine may theoretically have prevented the development of fistulae.

The increasing incidence of CD is found in patients with solely colorectal disease. This entity of CD was first described in 1960 but an increasing proportion of colorectal CD was not reported before the late eighties<sup>[15]</sup>.

The increase of colorectal disease can be attributed to a factual increase, a switch from UC to CD or more accurate diagnostic procedures. Unfortunately, there are no contemporary data regarding the development of UC in Stockholm County. However, Jacobsen *et al*<sup>[12]</sup> have shown a concomitant substantial increase of both UC and CD

in North Jutland in Denmark between 1988 and 2002, which supports a factual increase of CD and contradicts a diagnostic shift from UC to CD. In contrast, the incidence of UC decreased by 17% in Northern France during a comparable time period<sup>[14]</sup>. If hypothetically, the decreasing incidence of UC should represent a corresponding increase of CD, still there would be a 50% increase of CD not due to a reclassification from UC to CD in Stockholm during the 1990s. The diagnosis of CD is partly based on histopathology and may vary between different pathologists<sup>[35]</sup>. In this study one single pathologist did most of the histopathological examinations.

The number of lower GI endoscopies performed in the area has increased fourfold<sup>[22]</sup>. This escalating access to medical service may have led to an examination of more patients with only mild symptoms. Patients with minor colonic inflammation that might have been overlooked with previously used barium enemas could therefore have attributed to the increased incidence of CD.

The median time between presentation of symptoms and diagnosis is rather similar to that found in 1955-1989<sup>[16]</sup>. The shortest time is found in patients with disease in the colon, while patients with small bowel disease have a longer period of symptoms before the diagnosis. This fact may illustrate the advantage of endoscopic technique in the diagnosis of IBD. Recently, the capsule endoscopy has been introduced in Sweden and is used to a limited extent<sup>[36]</sup>. With a more widespread use of this new technique, disease in the ileum may be more frequently detected<sup>[37]</sup>. Consequently an increased number of patients with small bowel CD will be diagnosed and thereby the incidence of CD will probably further increase in the future.

In conclusion, this follow-up study of CD in Stockholm County shows that the incidence increases by 80% from the 1980s to the 1990s. As much as 0.2% of the adult population in Stockholm County suffers from CD. The disease appears at any age and there is no predominance regarding gender. Colorectal CD is the most common localization and the frequency of anorectal fistulae is less evident than that in the past.

Baldi F, Cappiello R, Cavoli C, Gherzi S, Torresan F, Roda E. Proton pump inhibitor treatment of patients with gastroesophageal reflux-related chronic cough: A comparison between two different daily doses of lansoprazole. *World J Gastroenterol* 2006; 12(1): 82-88

<http://www.wjgnet.com/1007-9327/12/82.asp>

## Abstract

**AIM:** To compare two different daily doses of lansoprazole given for 12 weeks and to assess the role of gastrointestinal (GI) investigations as criteria for selecting patients.

**METHODS:** Out of 45 patients referred for unexplained chronic persistent cough, 36 had at least one of the GI investigations (endoscopy, 24-h esophageal pH-metry and a 4-week trial of proton pump inhibitor (PPI) therapy) positive and were randomly assigned to receive either 30 mg lansoprazole o.d. or 30 mg lansoprazole b.i.d. for 12 weeks. Symptoms were evaluated at baseline (visit 1) after the PPI test (visit 2) and after the 12-week lansoprazole treatment period (visit 3).

**RESULTS:** Thirty-five patients completed the study protocol. Twenty-one patients (60.0%) reported complete relief from their cough with no difference between the two treatment groups (58.8% and 61.1% had no cough in 30 mg lansoprazole and 60 mg lansoprazole groups, respectively). More than 80% of the patients who had complete relief from their cough at the end of the treatment showed a positive response to the PPI test.

**CONCLUSION:** Twelve weeks of lansoprazole treatment even at a standard daily dose, is effective in patients with chronic persistent cough. A positive response to an initial PPI test seems to be the best criterion for selecting patients who respond to therapy.

**Key words:** Gastroesophageal reflux; Cough; Proton pump inhibitors; Lansoprazole

## INTRODUCTION

There is increasing evidence that many otolaryngologic or pulmonary conditions, ranging from very mild symptoms such as hoarseness to very severe diseases such as cancer, may be caused by gastroesophageal reflux (GER)<sup>[1]</sup>. In particular, GER seems to account for a relevant proportion of patients with asthma, cough, and laryngitis. Chronic persistent cough is a very common and disabling complaint for which patients seek medical care. It has been shown that in non-smoking patients with a normal chest X-ray and not taking angiotensin-converting enzyme (ACE) inhibitors the four most common causes of cough are post-nasal drip syndrome (PNDS), asthma, GER and chronic bronchitis<sup>[2]</sup>. These four conditions may account for as many as 90% of the cases of chronic cough. Moreover, GER by itself has been found to be responsible for 10%-40% of them even in the absence of reflux symptoms<sup>[3]</sup>. For these reasons, antisecretory drugs have been proposed for the treatment of patients with chronic cough possibly due to GER. Most studies on this topic have been performed with proton pump inhibitors (PPIs) at higher daily doses and for generally longer periods than those usually employed for typical GER disease. These studies have shown better results in terms of symptom resolution and improvement of laryngeal signs for PPIs *vs* placebo, but the success rate has been relatively low and quite variable, ranging from 35% to 60%<sup>[4-6]</sup>. This variability in response may be due to the differences either in selection criteria or in treatment regimens. Since the poorest outcomes<sup>[4]</sup> have been obtained in the study in which PPIs were given at the highest daily dose and for the longest period, patient selection may be the critical factor.

Thus, published studies suggest that antireflux treatment of patients with GER-related respiratory symptoms, particularly chronic cough, must be carried

out with profound and prolonged acid inhibition in order to achieve satisfactory results in about two-thirds of the cases. However, the optimal treatment regimen and the criteria for patient selection need to be better defined.

The aim of our study was to evaluate the relative efficacy of two different daily doses of lansoprazole given for 12 weeks to patients with chronic persistent cough that could be reasonably ascribed to GER, and to assess the role of gastrointestinal (GI) investigations (endoscopy, 24-h esophageal pH-metry and a 4-week trial of empiric PPI treatment) as criteria for selecting patients with chronic cough who could benefit from antireflux treatment.

## MATERIALS AND METHODS

### Patients

The study protocol was approved by the Ethics Committee of the S. Orsola-Malpighi Hospital, Bologna, Italy and all participants gave their written informed consent. A pretrial analysis determined that 15 patients were required in each treatment to demonstrate equivalence between 30 and 60 mg/d lansoprazole treatment groups in terms of cough severity and frequency with 80% power at an alpha level of 0.05.

Patients aged 18-70 years with unexplained chronic persistent cough (i.e. for at least 3 days per week for a minimum of 3 months) were enrolled in the study over a period of 1 year (from June 2002 to June 2003). All patients were consecutively referred by otolaryngologists and pulmonologists after the exclusion of oropharyngeal or respiratory diseases potentially responsible for the cough (particularly asthma and PNDS) by means of a diagnostic evaluation which included medical history, physical examination, methacholine challenge test, chest X-ray and fiber-optic laryngoscopy. Patients were excluded if they were pregnant or breastfeeding; had systemic diseases, cardiac and pulmonary disorders, viral and bacterial or fungal infections, neoplasia or Zollinger–Ellison syndrome; or received previous treatment with drugs that interfered with their gastric acid secretion (H<sub>2</sub>-antagonists, PPIs) and chronic treatment with NSAIDs, phenytoin, warfarin, tricyclic antidepressants, reserpine, beta-agonists, anticholinergics, antihistamines, inhaled steroids, or ACE inhibitors. Patients with chronic alcohol or drug abuse were also excluded, as were smokers.

After an initial clinical evaluation aimed at assessing the presence of associated typical reflux symptoms (heartburn and regurgitation) and the severity of cough, all patients underwent a diagnostic work-up which included upper GI endoscopy, 24 h esophageal pH-metry and a trial of empiric PPI therapy (PPI test, 30 mg lansoprazole b.i.d. for 4 weeks). The investigations were always performed in the same sequence, i.e. in the order of endoscopy, pH-metry and the PPI test.

A patient was considered eligible for 12 wk of lansoprazole treatment if at least one of the GI investigations was positive.

### Symptom assessment

The severity of cough was evaluated according to a visual analog scale (VAS) graded from 0 to 10 and to a four-level

scoring system, regarding the previous week, calculated as follows:

- *Overall frequency*: 0 = absent, 1 = occasional (<3 d/wk), 2 = often (3-6 d/wk), 3 = every day
- *Daily frequency*: 0 = absent, 1 = 1 episode, 2 = 2-3 episodes, 3 = >3 episodes
- *Severity*: 0 = absent, 1 = mild (not interfering with daily activities), 2 = moderate (sometimes interfering with daily activities), 3 = severe (regularly interfering with daily activities and/or sleep).

Symptoms were evaluated at baseline (visit 1), after a 4-wk PPI trial (visit 2) and a 12-week lansoprazole treatment period (visit 3).

### Upper GI endoscopy

All patients underwent upper GI endoscopy performed by the same gastroenterologist. The presence of esophagitis was noted and graded according to the Savary-Miller classification: grade I = single erosive or exudative lesion, oval or linear, on only one longitudinal fold; grade II = non-circular multiple erosions or exudative lesions on more than one longitudinal fold with or without confluence; grade III = circular erosive or exudative lesions; grade IV = chronic lesions, ulcers, strictures, or short esophagus, isolated or associated with grade I-III lesions; grade V = Barrett's epithelium, isolated or associated with grade I-III lesions<sup>[7]</sup>. Grades I-IV were considered diagnostic of erosive esophagitis and endoscopy was considered positive for the purpose of this study.

### Twenty-four h esophageal pH-metry

After an overnight fast, two glass electrodes previously calibrated with buffer solutions at pH 7.0 and 1.0, were assembled with the sensors 15 cm apart and introduced into the stomach by the nasopharyngeal route. The distal electrode was positioned 5 cm above the lower esophageal sphincter (LES) so that the proximal one was located distal to the upper esophageal sphincter (UES). The location of the LES was determined by a combination of pH step-up technique, manometry (always performed in patients with hiatus hernia; 8 cases) and visualization under fluoroscopy if needed. The probe was connected to a digital portable recording unit (pH-day, Menfis, Italy) with a sampling frequency of one signal every second. Patients were asked to maintain their usual lifestyle and diet. They were provided with a diary card to record timing of meals, duration of nocturnal rest, time of cough occurrence and type of symptoms. Moreover, they were instructed to push an event marker button on the recording unit at the time of occurrence of their major complaint (cough). The pH-metry was stopped after 23-24 h. After being extracted, the electrodes were calibrated again with buffer solutions at pH 7.0 and 1.0. GER was evaluated as acid exposure fraction time (percent of time with pH <4). For the purpose of this study, pH-metry was considered positive if the percentage of total time with pH <4 was >4.73%<sup>[8]</sup> at the distal recording site or >1.00% at the proximal site (these values exceeded the 95<sup>th</sup> percentile of those previously obtained in normal subjects in our laboratory). In patients with normal values at both

recording sites, we calculated the symptom index (SI), i.e., the number of cough episodes associated with acid reflux (that was simultaneous with or occurring within 5 min before or after the reflux episode) divided by the total number of cough episodes multiplied by 100, together with the symptom sensitivity index (SSI), i.e., the number of cough episodes associated with acid reflux, divided by the total number of reflux episodes multiplied by 100. We considered the investigation positive, if the SI was >50% with a SSI >20%<sup>[9]</sup>.

### PPI test

After endoscopy and 24-h pH-metry, all patients received a 4-week open-label course of 30 mg lansoprazole administered before breakfast and dinner. Before PPI trial (visit 1) was started and at the end of the treatment course (visit 2) the patients were interviewed regarding their main symptom, i.e., cough, and asked to rate symptom severity during the previous week on a VAS graded 0-10<sup>[10]</sup>. The test was considered positive, if the post-treatment value was 0 or if the difference between the pre- and post-treatment values was ≥5.

### Intervention

Patients with a positive finding in at least one of the three assessments (endoscopy, pH-metry and symptom relief during a 4-week PPI trial) were randomized to either 30 mg lansoprazole oral capsules in the morning and identical placebo capsules in the evening or 30 mg lansoprazole in the morning and 30 mg lansoprazole in the evening before meals for 12 wk. Active drug and placebo were both supplied by Takeda Italia Pharmaceuticals (Rome, Italy). Both patients and investigators were blinded to the treatment status. Patients were interviewed and VAS was assessed at the end of treatment, and pill counting was performed to check for compliance with treatment.

Symptomatic response was defined as complete (VAS and score values = 0), partial (VAS value ≥ 1 but ≤ 50% of the baseline value and score value <5) or absent.

### Statistical analysis

Data were analyzed by the Student's *t* test for independent data of continuous variables, by the Mann-Whitney's non-parametric test for discrete variables and by the  $\chi^2$  test for nominal variables reported as contingency tables<sup>[11]</sup>. The Wilcoxon's rank-sum test or the Friedman test was

**Table 2** Analysis of concordance between 24 h pH-metry and PPI test

	24 h pH-metry		Total
	Positive	Negative	
PPI test positive	12	11	23
PPI test negative	14	8	22
Total	26	19	

Youden's index = -0.1174 K (measure of reliability) = -0.115 (no reliability).

used for the comparison of symptom scores. A two-sided significance level of 0.05 was chosen.

Equivalence between the two treatment regimens was determined using the Schuirman one-sided test procedure. Mean VAS values recorded at visit 3 (after 12 wk of double-blind therapy) in the reference group (60 mg/day lansoprazole) were transformed to 100, and then the same transformation equation was applied to the mean VAS values at visit 3 in the 30 mg/d lansoprazole group. Equivalence was demonstrated if the 90% confidence intervals (CIs) for the difference between the transformed mean VAS values in each group were within the standard deviation (± 20).

## RESULTS

### Patient selection

Forty-five patients (7 men, mean age 54.5 ± 11.1 years, age range 29-70 years) referred for unexplained chronic persistent cough underwent the GI investigations aimed at the detection of GER disease (Table 1). Most of the patients were middle-aged females and 25 (55.5%) also reported typical reflux symptoms (heartburn and/or regurgitation occurring at least once per week). Thirty-six (80%) patients were positive for at least one test. Only a few patients (*n* = 7, 15.5%) had endoscopy-proven esophagitis, while about 50% had pathological GER and a positive PPI test. Twenty-four patients (53.3%) were found to have pathological reflux, 12 at both recording sites, 10 at the distal site only and just 2 at the proximal site only. Two out of 21 patients with negative pH-metry were found to have a positive SI and considered as positive for pH-metry. Twenty-three patients had a positive PPI test, five of them reported complete disappearance of cough, while the remaining 18 had a reduction in cough symptoms of 76.8% ± 10.1%. There was no association between an abnormal result of any of the aforementioned tests and the presence or absence of associated GER symptoms. There was a lack of concordance between the results of pH-metry and those of the PPI test (Table 2). In fact, 12 patients were positive for both tests and 8 were negative for both tests (44.4%), while in the other 25 cases the tests provided opposite results.

Of the 36 patients who satisfied the criteria for admission to the 12-week lansoprazole treatment, 12 had positive PPI test and pH-metry, 11 had a positive PPI test only and 13 had positive pH-metry only. Esophagitis was not the only pathological finding in any of the patients. One of the patients did not continue the study due to

unwillingness, while the remaining 35 completed the study protocol (17 on 30 mg/d lansoprazole and 18 on 60 mg/d lansoprazole) and were considered for our efficacy analysis. There was no statistically significant difference between the two treatment groups with regard to age, gender, presence of esophagitis, or 24-h pH-metry and PPI trial outcome (Table 3).

### Effect of treatment

Patients' symptoms as assessed with both the subjective (VAS) and the objective (score) system, improved significantly at the end of the 12-wk treatment period *vs* baseline in both treatment groups, with no statistically significant difference either between the two groups or between the values at visits 2 and 3 (Table 4). The 90% CIs of the difference in the transformed mean VAS scores at 12 wk were within the standard deviation, thereby demonstrating equivalence of the two regimens.

At the end of the 12-wk treatment period 21 patients (60.0%) reported complete relief of their cough with no difference between the two treatment groups (10/17 and 11/18 had no cough in the 30 mg/d lansoprazole and 60 mg/d lansoprazole groups, respectively, Figure 1). In patients selected for the 12-wk course of lansoprazole a PPI was actually taken for 16 wk (including the 4-wk PPI test). At the end of the PPI test, 10 (28.6%) of the 35 patients who continued to complete 12 wk of therapy showed complete relief of their cough. During the following course of PPI the percentage of symptom-free patients increased up to about 60% at the end of the 3-mo period, independently of the daily dose of the drug.

**Figure 1** Percentage of patients showing symptomatic response at the end of 12-wk treatment with 30 mg/d (n = 17) or 60 mg/d (n = 18) lansoprazole.

### Patient characteristics and outcome of treatment

In order to determine the factors that may have influenced the treatment outcome, we compared the characteristics of patients who achieved complete relief of their symptoms with those who showed only partial relief or no symptomatic response (Table 5). As shown in the table, the positivity of the PPI test was significantly different between the two groups. In fact, more than 80% of patients who had complete relief of their cough at the end of treatment had a positive response to the PPI trial in comparison to only 28.6% of those who did not satisfactorily respond. None of the other factors, including the daily lansoprazole dose, was significantly correlated with the positive outcome of the treatment. Moreover, the rate of complete symptom relief at the end of the 12-wk course in patients classified as PPI test-positive was 81.8% in comparison to only 23.1% in those with a negative test (Figure 2).

## DISCUSSION

The correlation between respiratory or otolaryngologic symptoms and GER is usually ascertained in patients with unexplained chronic cough by the exclusion of other common causes such as asthma and PNDS, and the finding of pathognomonic signs such as posterior laryngitis, also called "reflux laryngitis", as well as the demonstration of pathological reflux<sup>[4-6]</sup>.

In our study, the pathogenetic role of reflux was suspected after the exclusion of common otolaryngologic or pneumological causes and after a careful work-up aimed at the detection of GER disease. The presence of posterior laryngitis was not included in our criteria because the sensitivity of this finding is generally thought to be low, while its specificity is ill-defined<sup>[12]</sup>. About 50% of our patients complained of typical reflux symptoms, such as heartburn and regurgitation, but this finding seemed to be of little relevance, since it was not correlated with the presence of esophagitis, pathological reflux or specifically, a positive response to the PPI trial (Table 1).

As expected, only a few patients had endoscopically proven esophagitis. This is in agreement with the previous observations in patients with so-called extra-esophageal manifestations of GER disease, showing that

**Table 5** Comparison between patients with symptomatic response and non-responders

	Responders [ <i>n</i> = 21 (%)]	Non-responders [ <i>n</i> = 14 (%)]
GER symptoms	14 (66.7)	5 (35.7)
Treatment with 60 mg/d lansoprazole	11 (52.4)	7 (50.0)
Erosive esophagitis	5 (23.8)	2 (14.3)
pH-metry positive	10 (47.6)	13 (92.8)
PPI test positive	18 (85.7)	4 (28.6) <sup>b</sup>

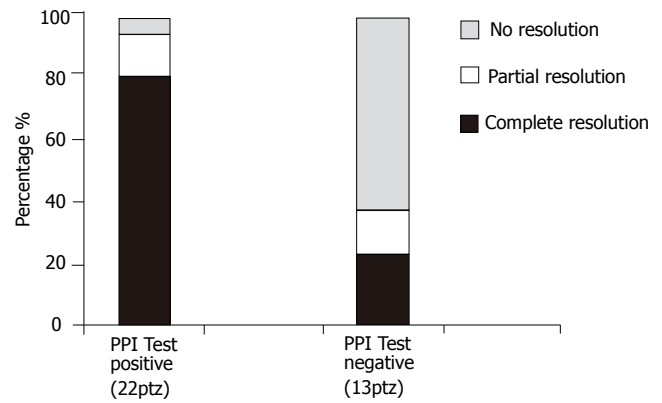

Responders = patients with VAS and score values of 0; non-responders = patients with VAS and score values  $\geq 1$ ; <sup>b</sup>*P* < 0.01 *vs* responders.

endoscopic evidence of esophagitis is found in 25%-40% of patients with asthma<sup>[13-14]</sup> and in only 10%-25% of patients with otolaryngologic disorders<sup>[6,15]</sup>. Therefore, upper GI endoscopy has a very low sensitivity in patients with atypical GER symptoms and, in the absence of other clinical indications, should not be included in the diagnostic work-up of these patients.

Ambulatory 24-h esophageal pH-metry is considered the gold standard for GER detection, with a high sensitivity in patients with typical symptoms<sup>[16]</sup>. Studies performed in patients with extra-esophageal symptoms showed that diagnostic sensitivity ranges 50%-80% in patients with asthma<sup>[17,18]</sup> and otolaryngologic manifestations, such as laryngitis or cough<sup>[4,6,19]</sup>. Moreover, the use of a double esophageal probe has been proposed in the latter patient group<sup>[19]</sup>. However, the usefulness of proximal pH-metry has been questioned since its sensitivity and reproducibility are too low<sup>[14,20]</sup>. Our results have confirmed the findings of others, showing that the diagnostic gain provided by dual-channel pH-metry is very low<sup>[4]</sup>.

Since the presence of "physiological" reflux does not necessarily imply the absence of a casual link between reflux and symptoms, the diagnostic sensitivity of 24-h pH-metry may be improved by including the evaluation of a symptom/reflux correlation (SI), especially in patients with atypical symptoms, such as non-cardiac chest pain<sup>[21]</sup>. On the other hand, the SI has two major potential limitations: (1) it is feasible only in patients with symptoms during the recording period and this is not always the case (in our patient group 77.7% reported cough episodes during pH-metry), and (2) its value may be questioned if patients have only few symptomatic episodes during the recording period. For this reason, as suggested by previous studies<sup>[22]</sup>, we considered a correlation between a given symptom and a reflux event to be present for SI values > 50% together with a SSI > 20%. We performed this evaluation as part of the analysis of our 24 h pH-metry tracings and found that 17 of the 21 patients with negative pH-metry reported cough during the recording period, with 2 of them showing a positive SI, thus increasing the diagnostic value of this investigation.

An empirical trial with PPIs (the so called "omeprazole or PPI test") has been recently proposed for the diagnosis of GER disease in patients with various clinical presentations, especially those with atypical or extra-esophageal symptoms. The diagnostic sensitivity

**Figure 2** Percentage of patients showing symptomatic response at the end of 12-wk treatment with 30 or 60 mg/d lansoprazole (*n* = 35), subdivided according to the outcome of PPI test. *P* < 0.05 *vs* negative PPI test.

of this test is generally validated *vs* 24-h pH-metry as a gold standard. The variability of results reported thus far depends on the differences in treatment schedules (daily doses, duration) and the outcomes chosen (cut-off point for symptom improvement, VAS, questionnaires, *etc.*). Doses used in clinical studies range 40-80 mg of omeprazole or 60 mg of lansoprazole daily from 1 to 14 d in patients with symptoms suggestive of GER disease or non-cardiac chest pain<sup>[23-29]</sup> and from 7 to 90 d in patients with extra-esophageal manifestations<sup>[4,30,31]</sup>. In patients with laryngeal symptoms, in which a longer duration and a high daily dosage are considered necessary for obtaining a significant symptom improvement, the test is in general fairly sensitive, with values ranging 62.5%-81%<sup>[4,30,31]</sup>. Thus, our PPI test consisted of 4-week administration of 60 mg/d lansoprazole. According to a similar study<sup>[28]</sup> we used a VAS graded 0-10 to assess as objectively as possible the severity of symptoms perceived by our patients and we considered the PPI test positive if symptoms disappeared (grade 0) or were reduced by at least 50% in comparison to the pre-administration value. In our study the test was positive in 63.9% of patients with a sensitivity similar to that previously reported.

In our study there was a lack of concordance between the results of the 24 h esophageal pH-metry and those of the PPI test (Table 2). In fact there was agreement in only 20 patients (44.4%). It was reported that there is a significant direct correlation between pH-metry and response to the omeprazole test in patients with typical reflux symptoms (65.8% of patients with concordant results, *P* = 0.04)<sup>[23]</sup>. In contrast, a study<sup>[4]</sup> performed in patients with chronic cough showed concordance between the two tests in only half the cases (52.2%). This lack of concordance is not surprising and may depend on the intrinsic limitations of both pH-metry (*i.e.* absence of symptoms during the recording period in patients with "physiological" reflux) and the PPI test (inadequacy of treatment dose or duration). It may also depend on the simultaneous and independent existence of two conditions, GER and cough, not causally linked.

For all these reasons in our study, we proposed that at least one of the GI investigations (endoscopy, pH-metry,

PPI test) had to be positive in order to select the cough patients in whom a 12-wk lansoprazole course could be reasonably proposed as a treatment choice.

The efficacy of PPI treatment in patients with extra-esophageal manifestations has been previously established<sup>[4,6]</sup>. Our study showed that both lansoprazole regimens significantly reduced symptom scores in comparison to baseline values (Table 4). There was a further reduction of the values recorded at visit 3 in comparison to those at visit 2, but the difference was not statistically significant. Moreover, it is interesting to note that there was a good concordance between the subjective (VAS) and objective (score) analysis, suggesting that they can be used interchangeably for symptom assessment. The success rate was also evaluated on an individual basis in terms of symptom resolution (Figure 1) which was graded on three levels according to the complete, partial or poor improvement of the symptoms. At the end of the 12-week treatment course about 60% of the patients reported complete relief of their cough (58.8% and 61.1% had no cough in the 30 mg/d lansoprazole and 60 mg/d lansoprazole groups, respectively). We did not find significant differences between the two treatment regimens but our study was only powered to show equivalence rather than efficacy. Studies performed in patients with chronic cough treated with PPIs have reported a complete relief of the symptom in a percentage of patients ranging 26%-43%<sup>[4,5]</sup> but the comparison among the studies is difficult because of different patient selection criteria and treatment regimens. A study that used the same drug and treatment duration as the present study<sup>[6]</sup> has reported a complete resolution of symptoms in 50% of patients with idiopathic laryngitis, which is very similar to our results.

In our study, the patients selected for the 12-wk course of PPI after the test period actually took lansoprazole for 16 weeks, and some of these patients experienced symptom relief at the end of the first 4 weeks, 10 of them showing complete resolution of their cough. This suggests that 1-month PPI administration at a double daily dose may be an effective therapy in about one-third of these cases. The percentage of symptom-free patients increased up to about 60% at the end of the 12-wk period, independently of the daily dose of the drug.

The analysis of factors that could have influenced the outcome (Table 5) clearly showed that the positivity of the PPI test was significantly different between complete and incomplete responders to PPI treatment. None of the other factors, particularly the presence of GER symptoms, seemed to be associated with the positive outcome of treatment. This is in agreement with previous studies in patients with cough<sup>[4,6]</sup> and laryngitis<sup>[6]</sup>. Indeed, the response to an initial treatment with a PPI has been suggested as the best method for identifying patients with GER-related chronic cough<sup>[4]</sup>. Our results show that PPI test may predict response to a longer course of PPI treatment in patients with atypical reflux symptoms. The rate of complete symptom relief at the end of the 12-week course in our patients classified as PPI test-positive was 81.8% (the highest, to our knowledge, among those reported in similar studies) in comparison to only 23.1% of those with a negative test (Figure 2).

In conclusion, a 12-wk course of lansoprazole is effective in relieving symptoms of patients with unexplained chronic persistent cough. A positive response to an initial 4-wk administration of PPI at a double daily dose seems to be an effective criterion for selecting patients who obtain the best results from the PPI treatment.

## Abstract

**AIM:** To study whether early postoperative enteral nutrition reduces the incidence of complications and/or improves nutritional status following duodenohepaticoduodenectomy (DHP).

**METHODS:** We studied 39 patients who underwent DHP for a peri-ampullary mass. Twenty-three patients received total parental nutrition and then started to have an oral intake of nutrition between postoperative day (POD) 7 and 14 [late postoperative enteral nutrition (LPEN) group]. Sixteen patients started to have enteral feeding through a jejunosomy catheter the day after the operation [early postoperative enteral nutrition (EPEN) group]. The incidence of complications and laboratory data at the early postoperative stage were studied in comparison between LPEN and EPEN groups.

**RESULTS:** Serum levels of albumin and total protein in the EPEN group were significantly higher than those in the LPEN group. The loss of body mass index was significantly suppressed in the EPEN group as compared to the LPEN group. The lymphocyte count decreased immediately after the operation was restored significantly faster in the EPEN group than in the LPEN group. The EPEN group showed significantly fewer incidences of postoperative pancreatic fistulas, as well as a significantly shorter length of hospitalization than the LPEN group. There were no significant differences in the incidences of other postoperative complications between the two groups, such as delayed gastric emptying, surgical site infection, cholangitis, and small bowel obstruction.

**CONCLUSION:** EPEN is a safe and beneficial

## INTRODUCTION

Postoperative nutritional support was shown to reduce the incidence of complications and/or to shorten the hospitalization period<sup>[1,2]</sup>. Recently, early postoperative enteral nutrition (EPEN) has been proposed as the novel method for nutritional support after surgery, especially after gastric and colorectal resection<sup>[3-9]</sup>. Several studies suggested that EPEN possibly improves also the postoperative outcome of patients after duodenohepaticoduodenectomy (DHP)<sup>[10-13]</sup>, which is one of the most invasive operations in the upper abdominal surgery with a high incidence of postoperative complications<sup>[14-19]</sup>. Whereas, EPEN has been introduced with complications such as troubles of jejunal feeding tube and delayed gastric emptying<sup>[10-13,20,21]</sup>. Taken together, the overall benefit of EPEN after DHP remains controversial.

The purpose of the present study was to evaluate the influence of EPEN on the incidence of postoperative complications. Moreover, by analyzing a variety of clinical parameters including laboratory data, body mass index (BMI), and the duration of hospitalization, we attempted to determine which method of postoperative nutritional support, enteral or non-enteral, was more advantageous in the total management of patients who had undergone DHP.

## MATERIALS AND METHODS

### Materials

We investigated a total of 39 patients who had undergone

Table 1 Patient profiles

	LPEN group (n = 23)	EPEN group (n = 16)	P value
Demographics			
Age (range)	67.2 yrs (42-82)	68.0 yrs (54-81)	0.8137
Gender: male	65.2%	56.3%	0.8168
Underlying disease (%)			0.6206
Cholangiocarcinoma	9 (39.1)	2 (12.5)	
Pancreatic carcinoma	6 (26.1)	8 (50.0)	
IPMN	4 (17.4)	3 (18.8)	
CPV	3 (13.1)	1 (6.2)	
Others	1 (4.3)	2 (12.5)	

IPMN: Intraductal papillary mucinous neoplasm; CPV: Carcinoma of the papilla of Vater; Other diseases: Gastrointestinal stromal tumor, primary sclerosing cholangitis, and pancreatic metastasis of renal cell carcinoma

DHP for a peri-ampullary mass from 2000 to 2005 at Kochi Medical School, including 24 men and 15 women (mean age of 67.5 years; 43-82 years). Among these 39 patients, there were 14 cases of pancreatic invasive ductal carcinoma, 11 of cholangiocarcinoma, 7 of intraductal papillary mucinous neoplasms, 4 of carcinoma of the papilla of Vater, 1 of gastrointestinal stromal tumor, 1 of primary sclerosing cholangitis, and 1 of metastatic renal cell carcinoma (Table 1). All patients underwent a complete perioperative physical examination and laboratory investigations. Moreover, a variety of relevant parameters regarding the operative procedure and anesthesia were recorded in all cases.

### Operative procedure

In all patients, the reconstructive technique was used to anastomose the pancreas first, followed by the hepatic duct and the duodenum with a Braun anastomosis. The pancreatic-enteric anastomosis was performed as a pancreaticojejunostomy in an end-to-side fashion. In patients of the EPEN group, a feeding jejunostomy catheter was placed at the end of surgery and before closing the wound through the anterior wall of the stomach using a modified Witzel technique. Furthermore, in all cases of pylorus-preserving pancreaticoduodenectomy (PpPD), the gastrotomy tube was inserted from the afferent loop of the jejunum into the stomach for the purpose to prevent delayed gastric emptying.

### Postoperative nutrition

We determined the amount of calories required for postoperative nutrition according to the Harris-Benedict equation<sup>[22]</sup>. Some patients received total parenteral nutrition and then started to have oral intake of nutrition usually between POD 7 and 14, as determined late postoperative enteral nutrition (LPEN) group. The second group of patients started to have EPEN through a catheter-feeding jejunostomy on POD1 (within 24 h after surgery), as determined EPEN group. Enteral feeding was started at a rate of 20 mL/h and gradually increased by 10 mL/h a day up to the final rate (70 mL/h).

### Laboratory and clinical investigations

The operation time, blood loss volume, and amount

Table 2 Operative characteristics

Group	Characteristics	LPEN group (n = 23)	EPEN (n = 16)	P value
Operative procedure (%)				0.0371
PpPD		12 (52.2)	14 (87.5)	
PD		11 (47.8)	2 (12.5)	
Demographics (range)				
Operative time (min)		516 (360-765)	509 (370-605)	0.5417
Blood loss volume (mL)		1 014 (400-1 650)	908 (400-1 600)	0.0593
Transfused patients (%)		17 (73.9)	8 (53.3)	0.3384
RC-MAP (U)		1.9 (0-10)	1.1 (0-6)	0.0599
FFP (U)		9.2 (0-40)	5.3 (0-10)	0.1220
IOR (%)		2 (8.7)	7 (43.8)	0.0190

PD: Pancreaticoduodenectomy; PpPD: Pylorus-preserving pancreaticoduodenectomy; RC-MAP: Red cells in mannitol-adenine-phosphate solution; FFP: Fresh frozen plasma; IOR: intra-operative radiotherapy.

of blood transfusion during and after the surgery were carefully recorded. Samples for laboratory investigations were taken on POD 1, 4, 6, and 14. The laboratory parameters included serum levels of total protein, albumin, total bilirubin, cholinesterase, alanine transaminase, aspartate transaminase, lactate dehydrogenase, alkaline phosphatase, gamma-glutamyl transpeptidase, amylase, urea nitrogen, and creatinine. The BMI was measured before surgery and on POD 6 and 14. Postoperative complications, including surgical site infection, leakage from anastomosis, pancreatic fistula, cholangitis, small bowel obstruction and delayed gastric emptying, were carefully monitored every day. The duration of hospitalization was defined as the time from the day of the surgery to the day of discharge. The progress of all patients, following their discharge from hospital, was monitored by our hospital.

### Pancreatic fistula

We determined the occurrence of pancreatic fistula based on the following criteria: the concentrations of amylase and lipase in the drainage fluid being three times higher than that in the serum on consecutive PODs, and the drainage volume being more than 10 mL/d. Amylase and/or lipase concentrations in the serum and drainage fluid were checked on POD 1, 3, 4, 5, and 7, and twice a week thereafter<sup>[23-25]</sup>.

### Statistical analysis

We tested for statistical significance using the  $\chi^2$  test, the Fisher's exact test and the *t* test. *P* < 0.05 was considered statistically significant. Where appropriate, values were expressed as mean  $\pm$  SD.

## RESULTS

We retrospectively reviewed 39 patients who had undergone DHP between 2000 and 2004 at Kochi Medical School, and subdivided them into two groups, 23 patients in the LPEN group and 16 patients in the EPEN group (Table 1). Hospital mortality was 2.6%. There were no significant differences between the two groups in age,

**Table 3** Postoperative outcome of patients with pancreatic surgery

Characteristics	LPEN group (n = 23)	EPEN group (n = 16)	P value
BMI			
Baseline	21.75 ± 3.16	22.58 ± 2.60	0.8044
POD 6	20.43 ± 2.67	2.40 ± 2.59	0.0305
POD 14	20.14 ± 2.50	22.38 ± 2.55	0.0111
Postoperative complications (%)			
Anastomotic leakage	0 (0.0)	0 (0.0)	NS
Surgical site infection	2 (8.7)	2 (12.5)	0.8797
Pancreatic fistula	9 (39.1)	1 (6.3)	0.0279
Ventral hernia	0 (0.0)	1 (6.3)	0.4103
Cholangitis	6 (26.1)	5 (31.3)	0.9926
Small bowel obstruction	1 (4.3)	1 (6.3)	0.6362
Delayed gastric emptying	1 (4.3)	2 (12.5)	0.5571
Length of hospitalization (days)	44.3 ± 19.0	31.7 ± 8.8	0.0011

NS: not significant

**Figure 1** Peripheral lymphocyte coun. \* $P < 0.05$  vs LPEN.

gender, and the incidence of underlying diseases.

PpPD was carried out in 26 cases and PD in 13 cases. The frequencies of PpPD and intra-operative radiotherapy (IOR) were significantly higher in the EPEN group than in the LPEN group, because we started IOR for all patients with pancreatic carcinoma in 2002 ( $P < 0.05$ ). There were no significant differences between the two groups in other parameters (Table 2) including operation time, blood loss volume, and the proportion of patients who received blood transfusion including red blood cells in mannitol-adenine-phosphate solution (RC-MAP) and fresh frozen plasma (FFP).

The baseline preoperative values of all laboratory parameters were comparable between the two groups. In the postoperative course, however, several parameters showed a significant difference. The lymphocyte count decreased immediately after the operation (at POD 1) in both groups (Figure 1), which was more obviously seen in the EPEN group compared to the LPEN group ( $P < 0.05$ ), probably due to the higher incidence of IOR (Table 2). However, during POD 1 and 4, lymphocyte count in the LPEN group continuously decreased, but increased in the EPEN group. There was no significant difference between the two groups in lymphocyte count at POD 4 and

**Figure 2** Serum albumin level. \* $P < 0.05$  vs LPEN.

thereafter. The serum levels of albumin (Figure 2) and the total protein (data not shown) decreased immediately after the operation in both groups. However, albumin levels at POD 4, 6, and 14 (Figure 2) and total protein levels at POD 6 and 14 (data not shown) in the EPEN group were significantly higher than those in the LPEN group. These findings in the restoration of nutritional parameters were consistent with the alteration in BMI. Loss of BMI was significantly suppressed in the EPEN group as compared to the LPEN group (Table 3).

None of the cases had a complication of anastomotic leakage. The EPEN group had a significantly lower incidence of pancreatic fistula than the LPEN group ( $P < 0.05$ ). There was no significant difference between the two groups in the incidence of other postoperative complications, including surgical site infection, ventral hernia, cholangitis, small bowel obstruction, and delayed gastric emptying (Table 3). Finally, the EPEN group also required a significantly shorter length of hospital stay than the LPEN group ( $P < 0.01$ ).

## DISCUSSION

In the present study, we employed 39 patients who underwent DHP and subdivided them into two groups according to the procedures of the postoperative nutritional support: the EPEN and LPEN groups. There was no significant difference in baseline profiles between the two groups except for the following two parameters, which should be considered in the analysis of the results. First, the number of patients with PD was greater in the LPEN group than in the EPEN group. EPEN after DHP was introduced in our department in 2002, in order to assess its utility. Until then, almost all patients who underwent PD for a peri-ampullary mass were postoperatively administered with total parenteral nutrition. However, we believed that there were no significant differences in the surgical procedure because two surgeons performed the pancreatic surgery in this study period. Second, the number of patients with IOR was much greater in the EPEN group than the LPEN group. The difference was caused by the fact that we started IOR for all patients with pancreatic carcinoma in 2002<sup>[26-28]</sup>.

Although the serum levels of albumin and total protein

dropped remarkably in all the patients after the operation, they recovered quickly in the EPEN group, and were significantly higher than those in the LPEN group at the early postoperative stage. Consistent with these findings, loss of BMI was significantly suppressed in the EPEN group as compared to the LPEN group. These findings indicate that EPEN modulates a metabolic response, favoring the synthesis of proteins. We believe that nutritional improvement observed in the EPEN group was not influenced by a large proportion of patients with PpPD (87.5%), since PpPD has been reported to provide a long-term nutritional support for operated patients but has not any benefit for nutritional status in early postoperative stage<sup>[29]</sup>.

Furthermore, the lymphocyte count fell immediately after surgery in the EPEN group probably due to the IOR, resulting in the significantly lower level as compared to the LPEN group ( $P < 0.05$ ). However, the lymphocyte count in the EPEN group increased thereafter, and reached at the similar level observed in the LPEN group at POD 14. These findings suggest that the administration of EPEN not only improves the nutritional status but also improves whole-body protein kinetics.

There was no significant difference between two groups in the incidence of infectious complications, such as surgical site infection and cholangitis, and also noninfectious complications, such as ventral hernia and small bowel obstruction. Although the EPEN group contained a significantly greater number of patients with PpPD than the LPEN group, there were no significant differences in the occurrence of delayed gastric emptying between the two groups. The incidence of delayed gastric emptying has been reported in 7-36% of patients with DHP<sup>[18,30-34]</sup>. Usually, the delayed gastric emptying is more frequently seen in patients with PpPD than in patients with PD, and is typically associated with prolonged hospitalization. In our study, tube gastrostomy was created in all patients who underwent PpPD, and thus patients with delayed gastric emptying had no vomiting.

Pancreatic fistula is considered as a major postoperative complication of DHP and has been reported in 5-24% of patients with DHP<sup>[23,35-38]</sup>. In our study, surprisingly, the incidence of pancreatic fistula was significantly lower in the EPEN group (6.3%) than in the LPEN group (39.1%). There have been some concerns that EPEN could increase the possibility of pancreatic fistulae because of its stimulatory effect on exocrine pancreatic secretion. Our data show that EPEN has no bad influence upon the occurrence of pancreatic fistula but rather works to prevent it.

In conclusion, EPEN is a safe and beneficial procedure for patients who have undergone DHP. EPEN improves early postoperative outcomes, including nutritional status and whole-body protein kinetics. Furthermore, EPEN contributes to a significantly lower incidence of pancreatic fistula, resulting in a shorter duration of hospitalization compared to the LPEN group. Based on these findings, EPEN can provide regular postoperative nutritional support following DHP.

### Abstract

**AIM:** To determine the expression of L1 in pancreatic neuroendocrine tumor and to correlate it with WHO classification of this tumor.

**METHODS:** We retrospectively analyzed L1 expression in 63 cases of pancreatic neuroendocrine tumor by immunohistochemistry on paraffin sections of primary tumors or metastases. Staining was performed by peroxidase technique with monoclonal antibody UJ127.11 against human L1. All tumors were classified according to WHO classification as well-differentiated neuroendocrine tumors and carcinomas or poorly-differentiated neuroendocrine carcinomas.

**RESULTS:** L1 was detected in 5 (7.9%) of 63 pancreatic neuroendocrine tumors. Four (44.4%) of 9 poorly-differentiated carcinomas expressed L1. In contrast, only 1 (1.9%) of 54 well-differentiated tumors or carcinomas was positive for L1. No expression was found in Langerhans islet cells of normal pancreatic tissue. Cross table analysis showed a significant association between L1 expression and classification of neuroendocrine tumors of the pancreas ( $P < 0.01$ ).

**CONCLUSION:** L1 is specifically expressed in poorly-differentiated pancreatic neuroendocrine carcinomas that are known to have the worst prognosis. L1 might be a marker for risk prediction of patients diagnosed with

### INTRODUCTION

Neuroendocrine tumors of the gastroenteropancreatic axis are rare and characterized by significant phenotypic differences. They can present themselves as benign or highly malignant and their clinical behavior is very heterogeneous. They are considered to originate from cells of the disseminated neuroendocrine cell system<sup>[1]</sup>. Most endocrine tumors of the pancreas are well-differentiated neuroendocrine tumors or carcinomas. Frequently, they appear to be malignant with the exception of insulinoma<sup>[2]</sup>. Fifty percent to sixty percent of these tumors are functionally active and secrete insulin, gastrin, vasoactive intestinal polypeptide (VIP), glucagon or other rare hormones and consequently cause characteristic syndromes. The most important criteria of malignancy include a tumor size of more than 2 cm, angioinvasion and proliferative activity of more than 2% of the tumor cells apart from metastases to the regional lymph nodes and the liver or invasion of adjacent organs<sup>[3,4]</sup>. Neuroendocrine tumors of the pancreas are classified according to the WHO classification into well-differentiated tumors and carcinomas or poorly-differentiated carcinomas<sup>[4,5]</sup>. Poorly-differentiated neuroendocrine carcinomas of the pancreas are highly malignant with a bad prognosis<sup>[3]</sup>.

Neoplastic cells frequently re-express adhesion molecules involved in cell migration during tissue morphogenesis and fetal development<sup>[6]</sup>. The L1 cell adhesion molecule (CD171) is a 200-220 ku type I glycoprotein of the immunoglobulin superfamily and plays a role in development of the nervous system by regulating cell interactions, includ-

ing neuronal migration<sup>[7,8]</sup>. L1 also mediates neuron-neuron adhesion, neurite outgrowth on Schwann cells, neurite fasciculation and myelination<sup>[7]</sup>. L1 undergoes homophilic L1-L1 binding and heterophilic interactions with several ligands such as integrins<sup>[9,10]</sup>. L1 is expressed also in hematopoietic and certain epithelial cells as well as in a variety of tumors, such as of neuroblastomas, melanomas, small cell lung cancer and breast carcinomas<sup>[11-15]</sup>. Metalloproteinase (ADAM10) also triggers cell migration and cleaves L1 from the tumor cell surface<sup>[8,12,16-18]</sup>. Recently, it was reported that expression of L1 has a prognostic significance in ovarian and uterine carcinomas and is associated with metastasis of melanomas<sup>[19,20]</sup>. Furthermore, L1 is expressed in neuroendocrine tumors of the skin<sup>[21]</sup>. Up-regulation of L1 expression has also been observed in malignant pleural mesotheliomas and malignant peripheral nerve sheath tumors by microarray expression profiling<sup>[22,23]</sup>.

The aim of this study was to determine the expression of L1 in neuroendocrine tumors of the pancreas and its relation to tumor stage of this heterogeneous cancer type. We detected the expression of L1 in 4 (44.4%) of 9 poorly differentiated pancreatic neuroendocrine carcinomas. However, only 1 (1.9%) of 54 well-differentiated tumors or carcinomas was positive for L1. Cross table analysis showed a significant correlation between L1 expression and poorly-differentiated neuroendocrine carcinomas. Our data indicate that L1 is a specific marker for malignant phenotype of pancreatic neuroendocrine carcinomas.

## MATERIALS AND METHODS

### Study design and patients

The study was approved by the Ethics Committee of the Chamber of Physicians in Hamburg, Germany. Written informed consent was obtained from all patients for use of the resected samples. For this study, 63 patients with pancreatic neuroendocrine tumors were chosen retrospectively. We selected patients on the basis of availability of tissues and did not stratify them due to rare occurrence and different treatment strategies. Forty-seven primary tumors of the pancreas and 38 metastases (21 from liver, 16 from lymph nodes and 1 from spleen) were available. All tumors were categorized into 3 groups according to WHO classification of 2 000 into well-differentiated tumors (grade 1a) and carcinomas (grade 1b) or poorly-differentiated neuroendocrine carcinomas (grade 2)<sup>[4]</sup>. Briefly, this classification was based on tumor size, angioinvasion, proliferating activity, histological differentiation and hormonal activity. All data including sex, histology, depth of tumor invasion, lymph node metastasis, tumor type and disease stage were obtained from the clinical and pathological records.

### Immunohistochemical staining and evaluation of expression

Immunohistochemical staining was performed for 5- $\mu$ m thick sections of formalin-fixed and paraffin-embedded tissues placed on pre-coated slides with 3-triethoxysilylpropylamin (Merck, Darmstadt, Germany). After deparaffinization with Rotihistole (Merck) and rehydration in ethanol and TBS (0.05mol/L, pH 7.6) containing 10 g/L Tween 20 (Sigma, Deisenhofen, Germany), tissue sections

were pre-treated for 30 min in 10 g/L ammonium chloride (NH<sub>4</sub>Cl) in TBS, for 15 min in 0.05 mol/L glycine/TBS and then boiled with ChemMate<sup>®</sup> target retrieval solution (Dako, Hamburg, Germany) in a microwave oven according to the manufacturer's instructions. Staining was performed with the peroxidase method (HRP-AEC System, Cell and Tissue Staining Kit; R&D Systems, Minneapolis, MN, USA). The primary antibody, a murine anti-human L1 monoclonal antibody (IgG<sub>1</sub>, clone UJ127) (NeoMarkers, Fremont, CA, USA) binding to the extracellular domain of this molecule, was diluted at 1:50 in antibody diluent (Dako) and slides were incubated overnight in a humidity chamber at 4°C<sup>[24]</sup>. For each sample one slide, a control section was incubated with irrelevant murine monoclonal IgG<sub>1</sub> (MOPC21; Sigma) as a negative control to determine the unspecific binding. All washing steps were done with TBS containing 10 g/L Tween 20. Counterstaining was performed with Haemalaun Mayer (Merck) for 30 s followed by Mayer's haematoxylin solution (Merck) for 7 min. At last, slides were covered with coverslips with aqueous mounting medium (Aquatex<sup>®</sup>; Merck). Specimens were considered immunopositive for L1 when >20% of the tumor cells had clear evidence of immunostaining. Peripheral nerves present in almost all sections served as internal positive controls. Langerhans islet cells were negative for L1 in normal pancreatic tissue. Immunohistochemical analysis and scoring of the sections were performed by two independent investigators and one pathologist in a blinded fashion. Two sections were scored differently and in these cases the opinion of the pathologist was decisive.

### Statistical analysis

We used SPSS for Windows (SPSS Inc., Chicago, IL USA) for statistical analysis. The immunostaining results of L1 and WHO classification of neuroendocrine tumors of the pancreas were calculated using a cross table and statistical analysis was performed with *F*-test. *P*<0.05 was considered statistically significant.

## RESULTS

### Characteristics of the patients

Sixty-three patients suffering from pancreatic neuroendocrine tumor were included in the study. Characteristics of the patients are listed in Table 1. Briefly, the median age of the study population was 57 years, 32 (50.8%) patients were male and 31 (49.2%) female. According to WHO classification for neuroendocrine tumors of the gastroenteropancreatic axis, 50 (79.4%) were classified as well-differentiated neuroendocrine tumors (grade 1a), 4 (6.3%) as well-differentiated carcinomas (grade 1b) and 9 (14.3%) as poorly-differentiated neuroendocrine carcinomas (grade 2), being the most malignant phenotype. Eleven (17.5%) tumors showed hormone production and 6 (9.5%) of 63 patients suffered from endocrine neoplasia (MEN) type I.

### Immunohistochemical analysis of L1 in pancreatic neuroendocrine tumors

L1 expression was determined by immunohistochemical analysis in samples from 63 pancreatic neuroendocrine tu-

**Table 1 Characteristics of the patients and levels of L1 expression *n*(%)**

Variable	Patients	L1-positive tumors
Total	63	5 (7.9)
Male	32 (50.8)	4 (12.5)
Female	31 (49.2)	1 (3.2)
<i>WHO classification of neuroendocrine pancreatic tumour</i>		
Well-differentiated neuroendocrine tumour (grade 1a)	50 (79.4)	1 (2.0)
Well-differentiated neuroendocrine carcinoma (grade 1b)	4 (6.3)	0

Total	58	5	63

$P < 0.01$  by Fisher's test (two-sided)

mor patients. Forty-seven primary tumors of the pancreas and 38 metastases (21 from liver, 16 from lymph nodes and 1 from spleen) were available and immunostained. In 18 patients, both primary tumor and metastases (12 from lymph nodes, 3 from liver, 2 from both lymph nodes and liver, 1 from liver and spleen) were investigated. In 16 patients, only metastases were available (14 from liver, 1 from lymph nodes, 1 from both lymph nodes and liver). No differences in terms of positivity or negativity of L1 expression were detected between primary tumor and metastases in any patient. Figure 1 shows the representative negative and positive staining patterns for L1 of pancreatic neuroendocrine tumors. Staining was not detected in normal pancreatic islet cells.

Five (7.9%) of 63 cases were L1-positive (Table 1). were stained. The remaining 58 (92.1%) patients were negative for L1. According to the WHO classification, 4 (44.4%) of 9 poorly-differentiated neuroendocrine carcinomas (grade 2) were L1-positive. Only 1 (1.9%) of 54 well-differentiated neuroendocrine tumor samples (grade 1a) was L1-positive. None of the 4 well-differentiated neuroendocrine carcinomas (grade 1b) was positive for L1. Although only 9 poorly-differentiated pancreatic neuroendocrine carcinomas (grade 2) were available, these results showed that L1 was specifically expressed in poorly dif-

ferentiated tumors. Forty-four point four percent of these most highly malignant tumors were positive for L1 compared to 1.9% in the group of well-differentiated neuroendocrine tumors or carcinomas (grade 1a and 1b).

### **Correlation between L1 expression and WHO classification of tumor**

A significant correlation between L1 expression and well-differentiated neuroendocrine tumor (grade 1a) and (grade 1b) or poorly-differentiated neuroendocrine carcinoma (grade 2) was found by Fisher's exact test ( $P < 0.01$ , Table 2).

## **DISCUSSION**

Pancreatic neuroendocrine tumors or carcinomas are rare and clinically very heterogeneous. Neuroendocrine-specific molecules are positive markers of endocrine differentiation in tumor cells<sup>[1]</sup>. Little is known about the molecular differences between benign and malignant phenotypes of neuroendocrine tumors of the pancreas. Cell adhesion molecules, such as L1, have been repeatedly implicated in tumor progression and metastasis. In this study, we determined L1 expression in 7.9% of 63 cases of pancreatic neuroendocrine tumor. Since L1 is not expressed in normal Langerhans islet cells, which are believed to be the precursor cells of pancreatic neuroendocrine tumors, an up-regulation of L1 expression in tumor cells may be associated with tumorigenesis in this tumor type.

We used immunohistochemical analysis for detection of L1 in tumor cells. Because the optimal cutpoint approach has some limitations in statistical evaluation of prognostic factors, we chose a cutpoint of 20% L1-positive tumor cells in the analysed cell population, achieving an easy discrimination of immunostained tumor tissue as proposed by Altman and colleagues<sup>[25]</sup>.

In our study, there were 9 patients with poorly-differentiated neuroendocrine carcinoma according to WHO classification (grade 2). Out of these, 4(44.4%) had positive L1 expression. L1 In contrast, only 1 (1.9%) of 54 well-differentiated tumors and carcinomas (grade 1a and 1b) was positive for L1. Statistical analysis showed a significant correlation between L1 expression and poor differentiation of pancreatic neuroendocrine tumors (grade 2), suggesting that L1 is a marker for poorly differentiated and highly malignant pancreatic neuroendocrine carcinomas. Although the number of L1-positive tumors in our study was too low for a final conclusion, the number of L1-negative tumors supports our notion that L1 is a marker for malignancy of this tumor entity.

These observations are in agreement with previous studies correlating expression of L1 in different tumors of neuroectodermal origin, such as melanomas or uterine and ovarian carcinomas, with malignancy and poor prognosis<sup>[15,19-21,26]</sup>. Our results prove that expression of L1 can also be found in another neuroendocrine tumor, namely the neuroendocrine tumor of the pancreas.

Further studies are needed to determine the potential prognostic value of L1 expression in patients suffering from pancreatic neuroendocrine carcinomas. Our data also indicate that downregulation of L1 expression by antisense technologies may be used as a therapeutic method.

**Figure 1** L1 expression in pancreatic neuroendocrine tumours or carcinomas. Immunohistochemical staining was performed by peroxidase method using monoclonal antibody UJ.127 against L1. Poorly-differentiated L1-positive pancreatic neuroendocrine carcinomas (grade 2; A and B) were shown in comparison to well-differentiated L1-negative tumours (grade 1a; C and D). Peripheral nerves (arrows) stained in (C, D) served as internal positive controls (Magnification  $\times 200$  (A and C) and  $\times 400$  (B and C)).

### Abstract

**AIM:** To investigate the clinicopathological risk factors for immediate post-operative fatal recurrence of hepatocellular carcinoma (HCC), which may have practical implication and contribute to establishing high risk patients for pre- or post-operative preventive measures against HCC recurrence.

**METHODS:** From June 1994 to May 2004, 269 patients who received curative resection for HCC were reviewed. Of these patients, those who demonstrated diffuse intra-hepatic or multiple systemic recurrent lesions within 6 mo after surgery were investigated (fatal recurrence group). The remaining patients were designated as the control group, and the two groups were compared for clinicopathologic risk factors.

**RESULTS:** Among the 269 patients reviewed, 30 patients were enrolled in the fatal recurrence group. Among the latter, 20 patients showed diffuse intra-hepatic recurrence type and 10 showed multiple systemic recurrence type. Multivariate analysis between the fatal recurrence group and control group showed that pre-operative serum alpha-fetoprotein (AFP) level was greater than 1 000 µg/L ( $P=0.02$ ; odds ratio=2.98), tumor size greater than 6.5 cm ( $P=0.03$ ; OR=2.98), and presence of microvascular invasion ( $P=0.01$ ; OR=4.89) were the risk factors in the fatal recurrence group. The 48.1% of the patients who had all the three risk factors and the 22% of those who had two risk factors experienced fatal recurrence within 6 mo after surgery.

**CONCLUSION:** Three distinct risk factors for immediate post-operative fatal recurrence of HCC after curative resection are pre-operative serum AFP level > 1 000 µg/L,

### INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the common causes of cancer death among Koreans, and it is also one of the frequently occurring cancers worldwide. Surgical resection of the liver has been one of the mainstays in the curative treatment of this cancer. Recent advances in anatomical knowledge of liver, surgical skills and instruments, intra- and post-operative management techniques have led to a marked reduction in post-operative mortality rates. However, recurrence after curative partial hepatectomy for HCC occurs in approximately 70% of patients<sup>[1-3]</sup>, and even after careful selection of relatively early disease patients for liver transplantation (OLT) according to the Milan selection criteria. It has been reported that the recurrence rate is about 20%<sup>[4]</sup>. This finding is considered to be the most significant risk factor for the survival of the patient.

The pattern of recurrence after curative surgery for HCC is variable. Among these diverse patterns of recurrence, diffuse intra-hepatic recurrence and multiple systemic recurrences are thought to be fatal not only because there is no effective treatment strategy, but also these recurrence patterns inevitably mean a short remaining survival time. Moreover, the development of such fatal recurrences soon after surgical resection may indicate the presence of multiple intra-hepatic micro-metastases or systemic dissemination and colonization of HCC cells at the time of surgery. But present clinical technology does not allow pre-operative determination of micro-metastatic lesions, and therefore the available

approach at present is the determination of risk factors for immediate post-operative fatal recurrence.

Numerous studies have investigated the recurrence of HCC after partial hepatectomy and have reported a number of risk factors for recurrence. But the application of such risk factors in the practical field for surgeons is difficult, which may be due to the fact that the limitation of application of these risk factors is confusing, and sometimes too broad in perspective. In this study, we attempted to elucidate the risk factors involved in the recurrence of HCC soon after partial hepatectomy, which entail more practical implications for the liver surgeon.

## MATERIALS AND METHODS

### Patients

From June 1994 to May 2004 for a period of 10 years, the medical records of 322 HCC patients who received partial hepatectomy at the Department of Surgery, Ajou University Hospital were reviewed. These patients were divided into the fatal recurrence group and the control group. The inclusion criteria of the fatal recurrence group were the patients who had diffuse intra-hepatic recurrence or multiple systemic recurrence within 6 mo after curative surgical resection of HCC. The rest were designated as the control group, and risk factors for the fatal recurrence group were analyzed.

Among the total 322 patients, the following were excluded from this study: patients who died within 6 mo after surgery due to reasons other than recurrence; patients who were lost to follow-up within 6 mo after surgery; patients whose histopathologic examination showed fibrolamellar or combined cholangiohepatocellular carcinoma pathologies; and patients who received non-curative resection.

### Methods

The criteria for curative liver resection followed by the authors were the General Rules for the Study of Primary Liver Cancer Guidelines set up by the Korean Liver Cancer Study Group<sup>[5]</sup>. In these guidelines, the definition of curative surgery for HCC is classified as A1, A2, and B: "A1 = tumor size < 2 cm and no residual tumor after resection, without vascular or ductal invasion; A2 - tumor size 2 - 5 cm and no residual tumor after resection, without vascular or ductal invasion; and B = no residual tumor after resection, but not included in A1 or A2". Those who were regarded as non-curative resection were the patients with gross evidence of residual tumor, tumor invasion into the 1<sup>st</sup> order branch of the portal vein or main portal vein, tumor invasion of the left, right, middle, and inferior right or short hepatic vein and tumor invasion into 2<sup>nd</sup> or 1<sup>st</sup> order branches of the intra-hepatic bile duct or common hepatic duct.

Pre-operative radiological evaluation included abdominal ultrasonography, abdominal computerized tomography (CT) scans and hepatic angiography. Magnetic resonance imaging (MRI) and/or positron emission tomography (PET) scan were also conducted when deemed necessary by the physician in charge. To evaluate the residual liver function, all patients received the dye

retention test using indocyanine green (ICG) in addition to the general chemistry tests. Also, to accurately assess the degree of curative surgery, all patients underwent intra-operative ultrasonography evaluation.

Post-operative follow-up consisted of monthly serum alpha-fetoprotein (AFP) level examination, and abdominal ultrasonography and plain chest films at every 3 mo. Abdominal CT was performed every 6 mo. The follow-up continued until the patient died of disease. If the serum AFP level did not decrease to normal level or abnormally increased or if one or more suspicious recurrent lesions were detected on ultrasonography during the post-operative follow-up, the results were then further confirmed by abdominal CT and/or chest CT and/or PET scan and hepatic angiography.

Diffuse intra-hepatic recurrence was defined as five or more recurrent lesions in the remnant liver as demonstrated by hepatic angiography<sup>[6]</sup>, and multiple systemic recurrence was defined as two or more systemic recurrent lesions without evidence of intra-hepatic recurrence, as shown by imaging studies.

Twenty-four variables were compared between the fatal recurrence group and control group. The patient factors were: age, sex, presence of symptoms, hepatitis B antigen status, hepatitis C antibody status, Child's classification, pre-operative serum AST and ALT levels, pre-operative ICG R-15 and serum AFP levels, the grade of hepatitis, and stage of cirrhosis in non-tumor liver tissues. The tumor factors that were investigated were: size of tumor, single or multiple lesions, tumor growth patterns, presence of tumor capsule and invasion of tumor capsule, gross evidence of vascular or bile duct tumor involvement, formation of intra-tumor septum, tumor invasion of the Glisson's capsule, presence of microvascular invasion and the Edmond-Steiner grade of tumor cells. Successful anatomic resection and tumor margins of more than 1 cm were defined as surgical factors. The anatomical resection was defined as complete segmental resection of the Couinaud's segment system. The pathological review was performed by an experienced pathologist (Kim) in the Department of Pathology in our institute.

### Statistical analysis

Univariate statistical analysis was performed using  $\chi^2$  test and Student's *t*-test, and multivariate analysis was carried out using logistic regression analysis.

## RESULTS

Among the 322 patients, 53 patients were excluded from this study: 7 patients who died within 6 mo after surgery due to reasons other than recurrence (3 of 7 patients were post-operative in-hospital mortality); 3 patients who were lost to follow-up within 6 mo after surgery; 10 patients whose histopathologic examination showed fibrolamellar or combined cholangiohepatocellular carcinoma pathologies; and 33 patients who were regarded as non-curative resection.

Among the 269 patients who were included in this study, the mean follow-up period was  $32.2 \pm 25.6$  mo (range, 4 - 107 mo). Of the 269 patients, 42 (15.6%) experienced

**Table 1** Univariate analysis of host factors for immediate post-operative diffuse intra-hepatic recurrence or multiple distant recurrence after curative resection for HCC

Host factor	Patients (%) or (mean $\pm$ SD)		P
	Fatal recurrence group	Control group	
Sex, male (%)	76	74	NS
Mean age(yr)	49.2 $\pm$ 9.9	52.1 $\pm$ 10.4	NS

**Table 3** Multivariate analysis of significant risk factors for immediate postoperative diffuse intrahepatic recurrence or multiple distant recurrence after curative resection of HCC

Risk factors	Odds ratio	Standard error	P
Microvascular invasion	4.89	0.62	0.01
AFP $\geq$ 1 000 ng/mL	2.98	0.46	0.02
Tumor size $\geq$ 6.5 cm	2.98	0.50	0.03

tumor recurrence within 6 mo after curative resection. Among these 42 patients, 20 (47%) patients demonstrated diffuse intra-hepatic recurrence and 10 (24%) patients showed multiple systemic recurrence without evidence of intra-hepatic recurrence. Thus, the fatal recurrence group included 30 patients (11.2%, 30/269).

The mean disease-free survival time until recurrence

of HCC of the patients in the fatal recurrence group was 3.9 $\pm$ 1.7 mo, and the mean survival time after recurrence was 6.7 $\pm$ 6.1 mo. The remaining 12 patients who were not in the fatal recurrence group but had tumor recurrence or recurrences within 6 mo after resection had the mean disease-free survival time until recurrence at 3.4 $\pm$ 1.8 months after surgery; however, the mean survival time after recurrence was 25.4 $\pm$ 29 mo, and this was significantly longer when compared to the fatal recurrence group ( $P<0.05$ ).

Of the 269 patients, 41 (15%) patients died within 1 year of surgery. Among these 41 patients, 35 (13%, 35/269) patients died of recurrence.

The fatal recurrence group consisted of 23 males and 7 females with the mean age of 49.2 $\pm$ 9.9 years. In the 239 control group patients, there were 178 males and 61 females with the mean age of 52.1 $\pm$ 10.4 years, showing no significant difference of gender and age between the two groups.

Univariate analysis of patient factors between the two groups showed that there were significant differences with regard to the presence of pre-operative tumor-related symptoms ( $P=0.042$ ) and serum AFP levels ( $P=0.00$ ) (Table 1). The tumor-related symptoms included right upper quadrant pain, radiating shoulder pain, weight loss, and palpable abdominal mass. Univariate analysis showed that significant tumor and surgical risk factors between the two groups were tumor size, infiltrative growth pattern, multiple tumors, gross vascular or ductal invasion, microvascular invasion, Glisson's capsule invasion, and less than 1 cm resection margin (Table 2).

Multivariate analysis showed that there were three major risk factors for early post-operative fatal recurrence: microvascular invasion ( $P=0.01$ , OR = 4.89); tumor size  $>6.5$  cm ( $P=0.03$ , OR = 2.98); and pre-operative serum AFP levels  $>1$  000  $\mu$ g/L ( $P=0.02$ , OR = 2.98) (Table 3).

Among the 269 patients, 27 patients had all the three risk factors, and of them 13 (48.1%) patients experienced actually fatal recurrence within 6 mo after curative surgery. There were 50 patients who had two risk factors, among them 11 (22%) patients experienced fatal recurrence. In addition, 71 patients were found to have only one risk

Table 4 Predictive values of risk factors for fatal recurrence after curative resection of HCC

	<i>n</i>	Number of fatal recurrence <sup>1</sup>	PPV (%)	NPV (%)	Test efficiency (%)	<i>P</i> <sup>2</sup>
All three risk factors present	27	13	48.1	92.9	88.5	0.023

factor, among whom 5 (7%) patients experienced fatal recurrence within 6 mo after surgery. Table 4 illustrates the statistical difference of positive predictive value between the different numbers of risk factors.

## DISCUSSION

It has been known that risk factors which affect the pattern and timing of recurrence are different. In general, tumor factors have been considered as significant risk factors in early recurrence, while liver function factors have been reported more significant in late recurrent disease<sup>[7-9]</sup>. Recurrence of HCC is the major risk factor for the survival of the patient after surgery. Previous studies have showed that early death within 1 year of surgery due to recurrence of the disease was approximately 10%<sup>[7]</sup>, which was in consistent with our study.

Curative treatment modalities for HCC are composed by surgical resection, liver transplantation, and percutaneous ablation<sup>[10]</sup>. Among these modalities, surgical resection has been traditionally known to be the most effective mode of therapy for HCC<sup>[11,12]</sup>, but some serious problems, such as post-operative liver failure due to underlying cirrhosis and post-operative recurrence, still remain. To overcome these problems, alternative curative methods, such as local ablation therapy and liver transplantation, are being widely employed<sup>[4,13]</sup>.

Local cauterization therapies for HCC include injection of chemical agents, such as alcohol, and the use of heat energy, such as radiofrequency or microwave techniques. These are applicable for early HCC patients even with poor hepatic functional reserve who are not suitable for surgery. Among these alternatives, radiofrequency ablation is considered to be more efficacious compared to alcohol injection methods in terms of cellular necrosis at the tumor margins or destruction of intra-tumoral septum. But, complete response rates have been reported to be very low for tumors that are more than 5 cm in diameter, and the tumor may not be easily accessible due to its difficult location in the liver in some instances<sup>[14,15]</sup>.

Liver transplantation has been shown to result in a favorable outcome in selected HCC patients with uncompensated or compensated liver function<sup>[4,16]</sup>. But,

in patients with advanced HCC, high rate of recurrence after OLT is a major problem of this mode of treatment. Possibly, accompanying immunosuppression may contribute to accelerating recurrence after OLT. Also, even if liver transplantation is indicated, the lack of donors and high cost of the procedure limits the wide employment of this modality.

According to a series reported by Llovet *et al*<sup>[10]</sup>, surgical resection can be a more effective modality, rather than OLT or local ablative treatment, especially in early stage HCC with good hepatic functional reserve. However, because of the limitations of the aforementioned local therapy and liver transplantation, it is a common practice to perform partial hepatectomy with curative intention in patients even with intermediate or advanced HCC, if surgery can completely remove the tumor and as long as the functional liver reserve allows the procedure in hopes of long-term survival<sup>[11]</sup>. Recent advances in pre-operative liver function reserve assessment, surgical techniques and intra- and post-operative management have contributed to lowering the post-operative mortality rate after partial hepatectomy to below 5%. Subsequently, it is thought that hepatectomy has become safer than before and therefore, the indications for resection have been accordingly broadened. Therefore, in the practical field, it is thought that the efficacy of treatment is higher in advanced HCC than local ablation therapy or OLT.

When recurrent HCC appears immediately after partial hepatectomy for HCC, it is thought that metastases of occult cancer cells that were not detected either grossly or by imaging techniques were already present at the time of surgery. If it is possible to detect these occult micro-metastases in the pre-operative evaluation stage, then surgical resection of main tumor may be contraindicated. And it has been shown in previous studies that the liver regeneration process after partial hepatectomy may enhance the growth of occult metastases which rapidly develops into overt metastasis<sup>[17-19]</sup>. Therefore, the effort to predict these micro-metastasis and systemic dissemination of cancer cells should not be indolent.

In this study, using multivariate analysis, we were able to observe that the characteristic risk factors in the fatal recurrence group were tumor size > 6.5 cm, serum AFP

levels  $> 1\,000\ \mu\text{g/L}$  and microvascular invasion. It has been well documented that large tumors are a risk factor for recurrence after surgery, and that larger the tumor size is the earlier the recurrences is after curative resection. One of the reasons for this has been postulated as the frequent presence of micro-metastases of tumor cells beyond the resection margins at the time of surgery. Lai *et al.*<sup>[20]</sup> reported that intra-hepatic micro-satellite lesions are found at a greater distance from the primary tumors  $> 4$  cm in size. In addition, intra-hepatic micro-satellites at greater distances from the primary tumor are observed frequently in HCC with multiple tumors, presence of vascular invasion, and microvascular invasion, thus making low-actual curability by partial hepatectomy. The mechanism for such intra-hepatic microscopic metastasis is due to vascular invasion, which is considered to be a risk factor for early post-operative recurrence. This has been confirmed by reports that have identified microvascular invasion or gross portal vein invasion as significant risk factors for recurrence after liver transplantation or partial hepatectomy for HCC<sup>[9,21-23]</sup>. In previous studies, vascular invasion by the tumor has been regarded as microscopic intra-hepatic metastasis<sup>[6,24]</sup>.

The rate of recurrence is high after OLT for HCC that is above the Milan criteria. The only mechanism of the recurrence after OLT is due to vascular invasion of HCC cells that leads to extensive systemic dissemination and circulation of the cancer cells at the time of transplantation. This has been suggested as the mechanism responsible for early post-operative intra-hepatic recurrence or distant metastasis after partial hepatectomy<sup>[25]</sup>.

Previous studies have demonstrated that there is no significant difference in post-transplantation recurrence between the patients with solitary lesion of up to 6.5 cm in size and the patients with lesions of less than 5 cm (Milan criteria)<sup>[16]</sup>. Interestingly, although the presence of HCC lesions of more than 5 cm is traditionally considered as advanced disease, our results could not show the tumor size  $> 5$  cm to be a significant risk factor of the fatal recurrence group in the multivariate analysis. The statistical difference appeared when the lesion size of 6.5 cm was compared, indicating it as a significant risk factor. This result was in agreement with the previous data by Yao *et al.*<sup>[16]</sup> who reported that the upper limit of HCC lesion size for transplantation was 6.5 cm, since the greater sized lesions led to significantly high rates of recurrence. These observations not only imply that when the size of tumor is greater than 6.5 cm, there is a greater possibility of systemic dissemination, but also that tumor greater than 6.5 cm may require strict control with adjuvant therapy against early post-operative recurrence as a consequence of circulating cancer cells or micro-metastatic lesion after partial hepatectomy for HCC.

Systemic adjuvant chemotherapy is the mainstay treatment modality for controlling systemic dissemination of cancer cells after surgical resection of HCC. Although many studies have failed to show clear benefits of adjuvant systemic chemotherapy for HCC in randomized control trials, Yamamoto *et al.*<sup>[26]</sup> Suggested that post-operative adjuvant oral 5-fluorouracil may be beneficial for stage II

HCC patients with relatively favorable liver function and there are randomized control trials of immunotherapy and interferon therapy with positive results for the prevention of recurrence after resection of HCC<sup>[27,28]</sup>. Needless to say, further more in-depth studies are required to clarify efficacy of adjuvant therapy, because advanced HCC may be potentially curable surgically, tumor recurrence from systemic dissemination of cancer cells is a frequent outcome of the disease. Therefore, in order to enhance surgical curability theoretically, it is essential to initially remove all gross disease while implementing pre- or post-operative chemotherapy or immunotherapy to control disseminated cancer cells or micro-metastasis.

Previous data have shown that high pre-operative AFP level is a significant risk factor for early post-operative recurrence<sup>[29-31]</sup>. In this study, we also observed the similar result that serum AFP level  $> 1\,000\ \mu\text{g/L}$  is one of the significant risk factors. Also, the pre-operative serum AFP level is thought to be closely correlated with vascular invasion of tumor and dissemination of HCC cells<sup>[25]</sup>, and thus it may provide valuable prognostic information for the pre-operative evaluation.

In conclusion, the high risk patients who have two or three risk factors mentioned in this study (serum AFP  $> 1\,000\ \mu\text{g/L}$ , microvascular invasion, tumor size  $> 6.5\text{cm}$ ) should be the candidates of various adjuvant clinical trials against early post-operative fatal recurrence. Furthermore, our results may provide a control for comparing effectiveness of adjuvant clinical trial against early post-operative fatal recurrence after curative resection of high risk HCC patients.

### Abstract

**AIM:** To determine the proteolytic activity and expression of gelatinase B in serum of gastric cancer patients and their correlation with the stage of the tumor.

**METHODS:** Sera from 23 patients who underwent surgery for primary gastric cancer as the experimental group and from 11 as the control group were used to determine the proteolytic activity and its inhibition by EDTA and 1,10-phenanthroline. Gelatinase B activity was detected by SDS polyacrylamide gel electrophoresis (SDS-PAGE) and SDS-PAGE zymography.

**RESULTS:** Proteolytic enzyme activity was increased in gastric cancer patients when compared to the control group ( $P < 0.05$ ). The proteinases were determined to be metalloproteinases upon inhibition test with specific metalloproteinase inhibitors 1,10-phenanthroline ( $P < 0.05$ ) and EDTA ( $P < 0.01$ ). SDS-PAGE and SDS-PAGE zymography revealed gelatinase B (proMMP-9) activity and its molecular mass of 92 ku.

**CONCLUSION:** Proteinase activity is overexpressed in serum of gastric cancer patients. Gelatinase B in serum plays an important role in the progression of gastric cancer. ProMMP-9 can be used as a marker for invasiveness of gastric cancer.

### INTRODUCTION

Proteolysis occurs in normal tissue but is limited in duration. A general aspect of malignant neoplasms may be an unbalance of proteolysis, which favors invasion<sup>[1]</sup>.

Tumor progression is a step-wise process. Multiple alterations in normal cells can lead to a localized tumor that can finally invade the surrounding tissues and metastasize. Tumor cell invasion involves attachment of tumor cells to the underlying basement membrane, local proteolysis and migration of tumor cells through the proteolytically modified region<sup>[2]</sup>. Local proteolysis is facilitated by proteinases outside the tumor cells, perhaps bound to the cell surface and/or secreted from the tumor cells. Recent data suggest that proteinases inside the tumor cells also participate in local proteolysis by digesting phagocytic extracellular matrix. In order to metastasize, cells must be able to move into the vasculature (intravasation), survive in the circulation, move out of the vasculature (extravasation), invade the surrounding tissues and grow. All these steps involve interactions among tumor cells, stromal cells, invading lymphocytic cells, endothelial cells, and extracellular matrix. Proteinases expressed in these cells are believed to participate in many of these steps<sup>[3-7]</sup>.

Matrix metalloproteinases (MMPs) are extracellular enzymes capable of degrading many extracellular matrix proteins. They are classified into five groups according to their structure and substrate specificity: collagenases, gelatinases, stromelysins, matrilysins and membrane-type MMPs. There is considerable evidence that MMPs play a major role in diverse physiologic processes and pathologic processes, including aspects of embryonic development, tissue morphogenesis, wound repair, inflammatory diseases and cancer. Overexpression and activation of MMPs have been linked with a variety of diseases<sup>[8-10]</sup>.

In the matrix metalloproteinase of MMP family, including a 72 ku enzyme resembling matrix metalloproteinase-2 (MMP-2) known as gelatinase A and

a 92 ku enzyme resembling matrix metalloproteinase-9 (MMP-9) known as gelatinase B, have been demonstrated to be closely associated with several tumor systems and to invasive potential of tumor cells<sup>[11-13]</sup>. Type IV collagenase can degrade not only interstitial matrix but also the basement membrane. Malignant ascites<sup>[14]</sup> is the direct and prominent manifestation of advanced malignant diseases associated with invasion and metastasis of peritoneal cavity by tumor cells. In the present study, we detected the gelatinase B activity in the sera from patients with gastric cancer by gelatin zymography in order to provide the scientific basis for clinical diagnosis of gastric cancer.

## MATERIALS AND METHODS

### Reagents

N<sup>ε</sup>-benzoyl-arginine p-nitroanilide hydrochloride (BAPNA), EDTA and 1,10-phenanthroline were purchased from Sigma-Aldrich Chemie GmbH (Steinheim, Germany). The chemicals used for electrophoresis were from Merck (Darmstadt, Germany). Gelatin was purchased from Difco (Detroit, MN, USA). The mini gel electrophoresis equipment SE260 was from Hoefer Scientific Instruments (San Francisco, CA, USA).

### Clinical specimens

In this study, we used 23 patients with gastric cancer as the experimental group and 11 patients as the control group. All patients with gastric cancer underwent surgery in the Institute for Digestive Diseases, Clinical Center of Serbia, from June 2002 to January 2004 and received neither chemotherapy nor radiation therapy before surgery. Of these patients, 15 (65%) were men and 8 (35%) were women with a mean age of 58 years (range: 38-75 years).

We had preoperative pathological diagnoses for all patients. Eleven patients underwent abdominal exploration or feeding jejunostomy because of liver metastases, peritoneal dissemination or malignant ascites. Twelve patients underwent radical surgery. In these patients, pathological examinations including depth of the tumor invasion, vascular invasion, lymphatic permeation, and lymph node metastasis were made according to the general rules of gastric cancer outlined by the Japanese Research Society for Gastric Cancer. In the control group, all the 11 patients were diagnosed to have groin hernia.

According to the TNM Classification System of the UICC, there were 2 stage 1, 3 stage 2, 5 stage 3, and 2 stage 4 tumors. According to their histological differentiation, there were 3 well, 4 moderately, and 5 poorly differentiated tumors. The clinicopathological features were found by reviewing all HE stained tissue sections.

### Proteolytic activity

Proteolytic activity was determined using the method described by Ebeling *et al*<sup>[15]</sup>.

### Metalloproteinase inhibition test

The effect of EDTA and 1,10-phenanthroline (in concentration of 5 mmol/L) on proteolytic activity of the serum was examined. The serum was incubated at 37 °C for 30 min and the remaining proteolytic activity was

determined under standard conditions.

### SDS-PAGE

SDS-PAGE was performed with 75 g/L polyacrylamide gel<sup>[16]</sup> under no reduction conditions using a solution mixture of protein markers containing ovalbumin (45 ku), bovine serum albumin (BSA, 67 ku), β-galactosidase (116 ku) and myosin (200 ku). Serum was diluted in 200 g/L sucrose to prepare the samples. The samples were analyzed by SDS-PAGE to determine the molecular mass.

### SDS-PAGE zymography

Samples were analyzed by SDS-PAGE zymography according to the method of Kleiner and Stetler-Stevenson<sup>[17]</sup> to determine the molecular mass and relative abundance of the gelatinases present. Samples were incubated for 40 min at 37 °C and electrophoreses were performed without reduction of 75 g/L polyacrylamide gels copolymerized with 0.01 g/L gelatin at 4 °C at a constant current of 15 mA. When the tracking dye at the front reached the bottom of the gel, the gel was removed and shaken gently for 45 min in 0.25 g/L Triton x-100 to remove SDS. Then the gel slabs were transferred to a bath (without Triton x-100) and washed for 20 min to remove Triton x-100. The above procedure was repeated twice at 4 °C. Then the gels were incubated and shaken for 60 h in 0.1 mol/L glycine, 50 mmol/L Tris-HCl, 5 mmol/L CaCl<sub>2</sub>, 1 μmol/L ZnCl<sub>2</sub>, 0.5 mol/L NaCl, pH 8.3, at 37 °C. Regions of proteolytic activity were visualized as clear zones against a blue background after 3-h staining with Coomassie brilliant blue.

### MMP inhibition test on zymography

In order to verify that the clear zones resembling matrix metalloproteinase, 5 mmol/L EDTA was added into the samples before incubation to inhibit MMP activities on gelatin zymography.

### Statistical analysis

Mann-Whitney test and Wilcoxon signed rank test were used for statistical analysis.  $P < 0.05$  was considered statistically significant.

## RESULTS

### Proteolytic activity

Proteolytic activity was increased ( $P < 0.05$ ) in gastric cancer patients compared to the control group (Tables 1 and 2). On the other hand, there was no significant correlation in proteolytic activity among the patients after radical or palliative surgery.

### Metalloproteinase inhibition test

EDTA and 1,10-phenanthroline inhibited proteolytic activity on BAPNA superstrate in the sera of patients with gastric cancer. 1,10-phenanthroline ( $P < 0.05$ ) showed less inhibition on proteolytic activity than EDTA ( $P < 0.01$ ) (Table 1).

### Detection of gelatinase B in serum

The samples of gastric cancer patients were shown on

**Table 1** Proteolytic activity and inhibition of metalloproteinase activity in serum of patients with gastric cancer

<sup>1</sup>Radical surgery.

SDS-PAGE Coomassie brilliant blue staining bands at the mass position of 92 ku. The protein molecular mass of 92 ku was detected in 82% of patients with gastric cancer. Molecular mass of 92 ku indicated MMP-9 protein (Figure 1). In the control group, MMP-9 protein was not detected.

The gelatinase B activity was detected by SDS-PAGE zymography as the clear bands against the blue background (Figure 1) in the sera of gastric cancer patients. There were no clear bands in the control group. The clear bands detected by gelatin zymography were characterized by the activity of gelatinases A (72 ku) and B (92 ku). The reaction was positive for band migrating at approximately 220 and 92 ku and for bands at 200 and 116 ku in some samples. The 220-ku band was strongly positive for gelatinase B, suggestive of homodimer. The 200- and 116-ku bands were interpreted as proMMP-9/TIMP-1 complexes.

#### Metalloproteinase inhibition test by zymography

Gelatinase B activity in the serum of gastric cancer patients was inhibited by EDTA.

## DISCUSSION

Proteolytic activity in the sera of patients with gastric cancer was higher than that in the control group, indicating that proteolysis can be degraded by ECM<sup>[18-20]</sup>. For the occurrence of metastasis, tumor cells must repeatedly cross over the basement membrane barrier, a process for which

**Table 2** Proteolytic activity and inhibition of metalloproteinase activity in serum of control group

**Figure 1** Results of SDS-PAGE and SDS-PAGE zymography. 1: Serum of gastric cancer patients with EDTA inhibitor; 2: serum of control group; 3: molecular mass determination; 4: Protein marker mixture.

proteolysis of ECM components is required<sup>[21,22]</sup>. Some of the proteins associated with invasion and metastases of tumors are produced by tumor cells. Then, the proteins (whole or fragments) may accumulate in blood or urine of patients.

According to the inhibition test with EDTA and 1,10-phenanthroline, proteinases are found to be metalloproteinases and the inhibition is an additional biochemical parameter for correlation of proteolytic activity and gastric cancer. Increased levels of metalloproteinase have been implicated in the invasive potential of tumors<sup>[23-26]</sup>. These results suggest that overexpression of metalloproteinases in the serum plays an important role in the progression of gastric cancer.

Overexpression of type IV collagenase has been demonstrated in a variety of cancers including colorectal cancer<sup>[27]</sup>, gastric cancer<sup>[28]</sup>, and breast cancer. There is evidence that type IV collagenase activity or concentration is increased in the plasma of patients with advanced carcinoma<sup>[29-33]</sup>. It was reported that type IV collagenase activity is increased in urine<sup>[34]</sup> and ascites<sup>[14]</sup> of cancer patients.

In the present study, we initially measured the gelatinase B activities in the serum of gastric cancer patients. The

results demonstrated that proteolytically active proMMP-9 was significantly associated with cancer. Proteolytic activity was shown in tumor patients. On the basis of molecular size and inhibition by EDTA, the bands were respectively interpreted as proMMP-9 (92 ku) and its putative dimmer 220 ku and proMMP-9/TIMP-1 complexes (200 and 116 ku). The activated form of gelatinase B (83 ku) was not detected in the serum of cancer patients. Gelatinase A activity was not detected in the serum of gastric cancer patients. The gelatinases, particularly gelatinase A, seem to be important in the initial stage of tumor invasion<sup>[12]</sup> as they degrade the components of the basement membrane, while other MMPs contribute to the later stages of tumor invasion<sup>[35]</sup>. In some reports<sup>[36]</sup>, gelatinase B in gastric carcinoma is positively correlated with the existence of vessel permeation, lymph node metastasis or the depth of tumor invasion.

In conclusion, gelatinase B protein may serve as a marker for invasiveness and metastasis of gastric cancer<sup>[37-39]</sup>. ProMMP-9 can be used for the detection of primary or recurrent cancer and for the estimation of tumor extent.

## ACKNOWLEDGMENT

Prof Ivanka Karadžić from the Institute of Chemistry, School of Medicine, University of Belgrade for her suggestions and friendly support.

### Abstract

**AIM:** To determine the plasma carnitine ester profile in adult patients with ulcerative colitis (UC) and compared with healthy control subjects.

**METHOD:** Using ESI triple quadrupole tandem mass spectrometry, the carnitine ester profile was measured in 44 patients with UC and 44 age- and sex-matched healthy controls.

**RESULTS:** There was no significant difference in the fasting free carnitine level between the patients with UC and the healthy controls. The fasting propionyl- ( $0.331 \pm 0.019$  vs  $0.392 \pm 0.017$   $\mu\text{mol/L}$ ), butyryl- ( $0.219 \pm 0.014$  vs  $0.265 \pm 0.012$ ), and isovalerylcarnitine ( $0.111 \pm 0.008$  vs  $0.134 \pm 0.008$ ) levels were decreased in the UC patients. By contrast, the level of octanoyl- ( $0.147 \pm 0.009$  vs  $0.114 \pm 0.008$ ), decanoyl- ( $0.180 \pm 0.012$  vs  $0.137 \pm 0.008$ ), myristoyl- ( $0.048 \pm 0.003$  vs  $0.039 \pm 0.003$ ), palmitoyl- ( $0.128 \pm 0.006$  vs  $0.109 \pm 0.004$ ), palmitoleyl- ( $0.042 \pm 0.003$  vs  $0.031 \pm 0.002$ ) and oleylcarnitine ( $0.183 \pm 0.007$  vs  $0.163 \pm 0.007$ ;  $P < 0.05$  in all comparisons) were increased in the patients with UC.

**CONCLUSION:** Our data suggest selective involvement of the carnitine esters in UC patients, probably due to their altered metabolism.

### INTRODUCTION

Ulcerative colitis (UC) is a disorder of the idiopathic and chronic inflammation of the colonic mucosa. The etiology and the pathogenesis of the disease are yet unknown; a classic study on isolated colonic epithelial cells demonstrated decreased utilization of n-butyrate. Since the major energy sources of the epithelial cells of the distal colon are the short-chain fatty acids (SCFAs), these cells are able to metabolize other fuels, such as glucose and glutamine, only at a much lower rate<sup>[1]</sup>. SCFAs are generated from carbohydrates by bacterial degradation and they are readily absorbed by the colon and represent energy fuels for the colonocytes and other tissues, such as the skeletal muscle<sup>[2,3]</sup>. Patients with distal UC may have increased or moderately decreased stool SCFA concentrations, reflecting their altered absorption<sup>[4,5]</sup>. UC can, therefore, be regarded essentially as an SCFA oxidation failure-associated disease, where the energy deficiency is a primary event in the development of the disease<sup>[1]</sup>.

L-carnitine plays an essential role in the energy metabolism, since it enables the transport of activated long-chain fatty acids (LCFA) as carnitine esters across the inner mitochondrial membrane. Moreover, it is able to form esters with several medium- and SCFAs of both endogenous and exogenous origins<sup>[6,7]</sup>. The impact of altered SCFA metabolism in UC prompted us to study the circulating carnitine ester profile in the UC patients.

### MATERIALS AND METHODS

#### Patients

We examined 44 patients with UC (25 males, 19 females,

**Table 1** Some major clinical and laboratory parameters in patients with ulcerative colitis and control subjects (mean  $\pm$  SE)

Parameters	UC patients, <i>n</i> = 44	Controls, <i>n</i> = 44
Females/males	19/25	24/20
CRP (mg/L)	12.2 $\pm$ 4.5	2.6 $\pm$ 0.5
Albumin (g/L)	44.6 $\pm$ 0.7	50.2 $\pm$ 0.8
Iron ( $\mu$ mol/L)	16.1 $\pm$ 1.2	23.7 $\pm$ 1.6
Hb (g/dL)	131.3 $\pm$ 2.5	159 $\pm$ 1.2
MCV (L)	86.2 $\pm$ 1.2	94.8 $\pm$ 2.5
WBC (G/L)	7.6 $\pm$ 0.4	9.2 $\pm$ 0.6
BMI (kg/m <sup>2</sup> )	24.6 $\pm$ 0.6	24.1 $\pm$ 0.5
PLT (G/L)	298.5 $\pm$ 13.5	228.3 $\pm$ 10.4
Both ileum and colon localization	5/44 (11.4%)	
Rectosigmoid		
localization only	8/44 (18.2%)	
Colon localization	31/44 (70.4%)	

mean age: 39.7 years, range: 17-65 years), and 44 carefully selected clinically healthy age-, sex-, weight-, and height-matched control subjects (20 males, 24 females, mean age: 37.0 years, range: 23-60 years). The control subjects did not receive any drug medication, while the UC patients were treated with either sulfasalazine or 5-aminosalicylic acid. We assumed that these drugs do not have any influence on the carnitine status since there were no such data available in the literature.

Diagnosis of the disease relied upon the history of the patients, clinical symptoms, negative stool examination for bacteria and parasites, and histologic results of rectal and/or colonic biopsy. Exclusion criteria in both groups were as follows: secondary causes of colonic disease, systemic diseases, any malformations, evidence of intestinal bacterial infection, history or evidence of any inherited metabolic disease, hepatic or renal disease, and pregnancy. (Table 1) shows the clinical parameters of the UC patients.

The clinical and laboratory data were the results of measurements performed from sample aliquots of blood collected after an overnight fasting precisely between 08:00 a.m. and 08:30 a.m., both in the UC patients and in the healthy control subjects. This strict post-alimental time scheduling was introduced to prevent the diet or fasting time-induced dynamic changes of carnitine esters in the circulation<sup>[8]</sup>.

Informed consent was obtained from each participant of the study and the study design was approved by the Departmental Ethics Committee.

## Methods

Plasma albumin, iron, and C-reactive protein levels were determined by routine methods. The hemoglobin (Hb), mean corpuscular volume (MCV), white blood cells (WBC) and platelet (PLT) were measured by automated analysis (sysmex XE 2100, Japan). The body mass index (BMI) was calculated as body weight/height<sup>2</sup> (in kg/m<sup>2</sup>).

Acylcarnitines were measured after derivatization as butyl esters using isotope dilution mass spectrometry method in a Micromass Quattro Ultima ESI triple-quadrupole mass spectrometer. The procedure was principally the method described previously<sup>[9]</sup>. Essentially,

10  $\mu$ L of plasma was spotted and dried onto a filter paper and prepared by extraction with 200  $\mu$ L of methanol containing internal deuterium-labeled standards (0.76  $\mu$ mol/L [<sup>2</sup>H<sub>3</sub>] -free carnitine, 0.04  $\mu$ mol/L [<sup>2</sup>H<sub>3</sub>] -propionylcarnitine, 0.04  $\mu$ mol/L [<sup>2</sup>H<sub>3</sub>] -octanoylcarnitine and 0.08  $\mu$ mol/L [<sup>2</sup>H<sub>3</sub>] -palmitoylcarnitine). After 20 min of agitation, the supernatant was evaporated to dryness under nitrogen at 40 °C and then 100  $\mu$ L of 3 mol/L butanolic HCl was added. The solution was incubated at 65 °C for 15 min and evaporated to dryness again under nitrogen at 40 °C and re-dissolved in 100  $\mu$ L of the mobile phase (acetonitrile:water 80:20). A total of 10  $\mu$ L of sample aliquots were introduced to the ESI cone by using Waters 2795 HPLC system. The free carnitine and all acylcarnitines were determined by ESI-MS/MS analysis using positive precursor ion scan of *m/z* 85; scan range was 200-550 *m/z*. The capillary voltage was 2.50 kV, while the cone voltage was 55 V, and the collision energy was 25 eV. The flow rate was 100  $\mu$ L/min and the total analysis time was 4 min per sample. Each sample was measured in triplicates starting with the injection step, and the results were the means of the three determinations.

## Statistical analysis

Student's *t* test for unpaired samples was used for the statistical analysis. The values were expressed as mean  $\pm$  SE, in three decimals for the carnitine esters with respect to the low levels in the case of the long-chain carnitine esters. *P* < 0.05 was considered statistically significant.

## RESULTS

The plasma circulating carnitine ester profiles are shown in Table 2. The plasma level of free carnitine and acetyl carnitine did not differ between the UC patients and the controls. By contrast, significant decreases were observed in fasting propionyl-, butyryl-, and isovaleryl carnitine ester levels in UC patients as compared with the controls. The level of total short-chain carnitine esters was markedly lower in the patients with UC (9.855  $\pm$  0.094  $\mu$ mol/L) than in the healthy controls (11.003  $\pm$  0.100  $\mu$ mol/L, *P* < 0.01).

The levels of octanoyl-, and decanoylcarnitine were decreased in the healthy subjects. The levels of total medium-chain acylcarnitines were obviously higher in the UC patients (0.629  $\pm$  0.007  $\mu$ mol/L) than in the control subjects (0.548  $\pm$  0.007  $\mu$ mol/L, *P* < 0.01).

In the long-chain acylcarnitine group, the plasma levels of myristoyl-, palmitoyl-, palmitoleyl- and oleoylcarnitine were significantly decreased in the healthy group. The levels of total long-chain carnitine esters were markedly higher in the patients with UC (0.596  $\pm$  0.005  $\mu$ mol/L) than in the controls (0.515  $\pm$  0.009  $\mu$ mol/L, *P* < 0.01).

In addition, the level of total carnitine esters was significantly decreased in the UC patients (11.080  $\pm$  0.035  $\mu$ mol/L) as compared with the healthy controls (12.066  $\pm$  0.037  $\mu$ mol/L, *P* < 0.01).

## DISCUSSION

Carnitine [ $\beta$ -hydroxy- $\gamma$ -(trimethylamino) butyric acid]

**Table 2 Plasma carnitine ester profiles in ulcerative colitis patients and controls ( $\mu\text{mol/L}$ , mean  $\pm$  SE)**

	UC patients, <i>n</i> = 44	Controls, <i>n</i> = 44

<sup>a</sup>*P* < 0.05 vs controls.

is known as a carrier for transporting activated LCFA into the mitochondrial matrix for  $\beta$ -oxidation. With this function the L-carnitine plays an essential role in the energy metabolism<sup>[6]</sup>. Moreover, the carnitine molecule is able to form esters with several medium- and short-chain fatty acids of both endogenous and exogenous origins<sup>[6,7]</sup>. The circulating carnitine ester spectrum can reflect affected cellular metabolism of the short-, medium-, and long-chain fatty acids. Therefore, the monitoring of the carnitine ester composition is a widespread tool for the diagnosis of several inborn errors of metabolism. Besides the complete metabolic blockage caused by the inherited lack of enzyme activities, influences on carnitine ester spectra may be the consequence of only partially affected flux of metabolites via the carnitine acyltransferases.

In the present study, significant decrease was found in the fasting plasma levels of propionyl-, butyryl-, and isovalerylcarnitine esters, leading to the decrease of SCFA carnitine esters. Although the pathogenesis of UC is still unknown, a widely accepted hypothesis focuses on the pivotal role of the diminished availability of SCFAs for the enteral cells. Normally, SCFAs are rapidly absorbed from the colon and have many properties, as they represent an energy source for colonocytes and if they are exported to other tissues. Moreover, they affect lipid metabolism, colonic mucosal blood flow, motility, and mucus secretion<sup>[2]</sup>. In the normal case, the major energy source of the epithelial cells of the distal colon derives from the metabolism of the SCFAs<sup>[10]</sup>, which is impaired in UC<sup>[1]</sup>. In addition to the SCFA metabolism, the influenced coenzyme A esterification has been reported to be associated with UC<sup>[11]</sup>. In the cells, the fatty acyl

moieties are transferred from coenzyme A to the beta hydroxyl group of the carnitine via the short-, medium, and long-chain carnitine acyltransferases<sup>[6]</sup>. These events separately or in combination, can explain the decrease of the circulating SCFA carnitine esters.

The circulating plasma carnitine profile is determined by the balance of the release and uptake mechanisms. Carnitine releases into the circulation by the liver primarily as acylcarnitine<sup>[12]</sup>. While in the hepatic vein, the ester proportion is relatively high, approximately half of the total carnitine is esterified. The actual ester pattern detected in the peripheral blood is a result of the uptake/release action of the peripheral tissues; and in a peripheral venous blood, much less (approximately 1/3-1/4 of the total carnitine) is esterified. Whereas, the decrease of the SCFA carnitine esters found in the UC patients could be explained as discussed earlier. Based on the current knowledge, it is much more difficult due to the limited nature of the data, to explain the opposite change of the medium- or long-chain carnitine esters. Only a few studies are available reporting alterations of fatty acid metabolism. However, the data are inconsistent, but suggest the involvement of LCFA metabolism in UC<sup>[13-15]</sup>. Further studies are required to clarify these issues.

After the positive results on topical SCFA treatment in UC<sup>[16]</sup>, Gasbarrini *et al*<sup>[3]</sup> studied propionyl-L-carnitine administration as rectal irrigation and found that improved clinical picture and histological status of the bowel are improved. In the light of the current findings, the likely decreased tissue reserves could be corrected by administration of the drug and the positive outcome could be a consequence of the successful replacement therapy. Whether the already known beneficial therapeutic effects of special LCFA containing or supplemented with diets<sup>[14,15,17-20]</sup> are due to at least in part, a similar replacement phenomenon, also remains to be elucidated.

### Abstract

**AIM:** To investigate the effect of percutaneous endoscopic gastrostomy (PEG) on gastroesophageal reflux (GER) in mechanically-ventilated patients.

**METHODS:** In a prospective, randomized, controlled study 36 patients with recurrent or persistent ventilator-associated pneumonia (VAP) and GER > 6% were divided into PEG group ( $n = 16$ ) or non-PEG group ( $n = 20$ ). Another 11 ventilated patients without reflux (GER < 3%) served as control group. Esophageal pH-metry was performed by the "pull through" method at baseline, 2 and 7 d after PEG. Patients were strictly followed up for semi-recumbent position and control of gastric nutrient residue.

**RESULTS:** A significant decrease of median (range) reflux was observed in PEG group from 7.8 (6.2 - 15.6) at baseline to 2.7 (0 - 10.4) on d 7 post-gastrostomy ( $P < 0.01$ ), while the reflux increased from 9 (6.2 - 22) to 10.8 (6.3 - 36.6) ( $P < 0.01$ ) in non-PEG group. A significant correlation between GER (%) and the stay of nasogastric tube was detected ( $r = 0.56$ ,  $P < 0.01$ ).

**CONCLUSION:** Gastrostomy when combined with semi-recumbent position and absence of nutrient gastric residue reduces the gastroesophageal reflux in ventilated patients.

### INTRODUCTION

Life threatening nosocomial pneumonia secondary to aspiration of gastric contents is frequent in intubated mechanically-ventilated patients<sup>[1,2]</sup>. A number of causes have been implicated in the development of ventilator-associated pneumonia (VAP) during mechanical ventilation, namely the oropharyngeal colonization<sup>[2]</sup>, body position<sup>[3]</sup>, nasogastric tube (NGT)<sup>[4]</sup>, and its size<sup>[5]</sup>. Supine position and the length of patient's permanence in this position are other potential risk factors for aspiration<sup>[3]</sup>. Though the semi-recumbent position reduces the risk of pulmonary aspiration, gastroesophageal reflux (GER) is still possible<sup>[6,7]</sup>. However, GER occurs with a significantly higher incidence in semi-recumbent mechanically-ventilated patients with NGT than without (74% vs 35%)<sup>[8]</sup>. According to other studies<sup>[9,10]</sup>, large-bore tubes do not cause more reflux than small-bore ones.

If the duration of nasogastric intubation correlates with the degree of GER, NGT removal after gastrostomy should normally decrease both GER and aspiration pneumonia rates. Percutaneous endoscopic gastrostomy (PEG), however, is considered neither as a non-pharmacological measure for the prevention of VAP, nor as an adjunctive measure to its treatment because it elicits an increase in GER, aspiration, and incidence of pneumonia, at least in the early post-gastrostomy period<sup>[8,11]</sup>. Nevertheless, in these studies the body position was not specified and the gastric content was not controlled after gastrostomy.

The aim of the present study was to investigate if long-standing presence of NGT for feeding is associated with increased incidence of GER and if PEG combined with semi-recumbent position and avoidance of gastric nutrient retention lead to decreased incidence of GER in mechanically-ventilated patients.

**Figure 1** Correlation between duration of NGT and mechanical ventilation standing period to the GER rate measured in 70 patients.

## MATERIALS AND METHODS

### Pilot study

Simultaneous measurement of gastric and esophageal pH was performed during a 24-h period<sup>[12]</sup> in 23 adult intensive care patients, who were mechanically-ventilated and had a NGT in place for a duration of 3-90 d. Exclusion criteria from the study included unstable hemodynamic state, administration of morphine, atropine, theophylline, barbiturates, and cisapride, and a past history of GER or hiatal hernia. GER was expressed as percentage of the time when the esophageal pH was less than 4 in a given 24-h period of time GER (%). Values of GER less than 3% were considered as normal. In these 23 patients, there was a positive correlation of the duration of nasogastric intubation in mechanically-ventilated patients to the degree of GER (%) ( $r = 0.78$ ,  $P < 0.01$ ). GER mainly occurred after a 10-d period of NGT and mechanical ventilation. Based on these results, only patients who were on mechanical ventilation with NGT for more than 10 d were enrolled in the main study.

### Main study and patient selection

The institutional review board approved the study protocol and informed consent was obtained from patient

**Figure 2** Variation of the median GER (%) together with 10%, 25%, 75%, and 90% from pH-metries originated from the sensor located at 20 cm proximally to the lower esophageal sphincter. The symbol in the 48-h period is lacking in patients of non-PEG-group since no pH-metry was performed in that period in this group of patients.

s kin in each case. Over a 28-mo period, 39 consecutive mechanically-ventilated patients with NGT in place, suffering from persistent or recurrent VAP and presenting a GER above 6% constituted the study population. The diagnosis of persistent or recurrent VAP was established according to the criteria previously described<sup>[13,14]</sup>. The exclusion criteria mentioned in the pilot study were maintained. Nineteen patients were randomly allocated to receive PEG, but three among them were excluded because of hiatal hernia (2 cases) and intestinal bloating (1 case). Finally, 16 patients received PEG (PEG group) and 20 did not (non-PEG group). In the non-PEG group patients the eventual presence of hiatal hernia was possibly missed, since no endoscopy was performed for PEG placement. Twelve patients in the PEG group and 15 patients in the non-PEG group presented persistent pneumonia. The rest of the patients in both groups had recurrent pneumonia. Eleven mechanically-ventilated patients with acute respiratory failure and NGT for more than 15 d and GER lower than 3% were used as controls. Patients enrolled in the study had comparable severity scores of VAP or acute respiratory failure, radiographic scores and ventilation parameters (data not shown). The characteristics of patients are presented in (Table 1).

Gastrostomy was performed using the pull through (Ponsky) technique<sup>[15]</sup> after feeding was stopped for 24 h. Patients of all groups were on continuous drip NGT or PEG-feeding at 60 mL/h with a polymeric diet of energy content of 1 000 kcal/L. Thereafter, they were placed in a semi-recumbent position (30°) and the volume of the gastric nutrient residue was measured with a syringe at 8-h intervals. If the nutrient volume exceeded 200 mL, feeding was withheld and restarted when the volume decreased. These two measures were followed for the subsequent 20-d period during which conventional treatment for pneumonia was applied.

All pH-metries were performed on a 24 h basis. Baseline pH-metries and those performed on d 7 in non-PEG patients were carried out as follows: with the patient in semi-recumbent position a single crystal antimony multi use electrode was used which disposes three sensors

located at the tip, 15 and 30 cm, respectively connected to a portable recorder (Digitrapper Mk III, Synectics Medical AB, Stockholm, Sweden). The electrode had a diameter of 2.1 mm at the level of the sensors and was attached via an adhesive material to a new 14 bore NGT so that the distal pH-meter sensor corresponded at 10 cm proximally to the tip of the NGT. In this way, reflux associated with the presence of NGT could be detected. An *in vitro* calibration of the whole system was carried out with buffer solutions of pH 1 and pH 7 before each pH-metry.

After ordinary NGT removal, the new NGT with the sensor probe attached was introduced via the nose into the stomach until acid pH was recorded with the distal and middle sensors as previously described<sup>[12]</sup>. The electrode was then slowly withdrawn until the middle sensor channel detected a sudden pH change from acid ( $< 4$ ) to above 5. The electrode was then withdrawn for further 5 cm. In this way, the distal sensor was located into the stomach and the middle and proximal sensors were located at 5 and 20 cm above the lower esophageal sphincter, respectively. The correct positioning of the electrode was verified at the end of pH-metry and before its withdrawal by a chest x-ray. The recording device measured pH values every 4 s and stored the mean of 20 values every 80 s.

Patients received sucralfate, 2 g twice daily via NGT at least 72 h before the study for gastric mucosa protection. Antacids, H-2 blocking agents or omeprazole that could interfere with pH neutralization were not used and for the same reason feeding was stopped 6 h before and during the period of pH-metry. Patients were not sedated nor paralyzed.

In PEG group patients, two additional pH-metries were carried out: the first at an early (48 h) post-PEG period and the second at a late (7 d) post-PEG period. The first pH-metry investigated the described increased incidence of reflux and/or aspiration at that period<sup>[8]</sup>. The second pH-metry also performed in the non-PEG group of patients was carried out in order to estimate and evaluate the effectiveness of PEG on reflux. These additional pH-metries were performed in the same manner with the following modifications: a two-sensor probe was used and positioned in such a way that the distal and proximal sensors were located at 5 and 20 cm over the lower esophageal sphincter, respectively. With the two-sensor probe the lower esophageal sphincter was free from the presence of any catheter. Patients were fed through PEG and the degree of reflux was assessed in the absence of NGT.

PEG was arbitrarily considered effective if within a 7-d post PEG period the GER (%) decreased by more than 60% compared to the pre-PEG value? PEG and non-PEG patients were followed up for 20 d for pneumonia healing and all patients for weaning from mechanical ventilation and intensive care discharge.

### Statistical analysis

To evaluate the differences in GER (%) between the three study periods (pre-PEG *vs* early and late post-PEG) in each group, Wilcoxon's signed-rank test was used. To assess the changes in the number of days of mechanical ventilation and NGT standing, pneumonia occurrence

before PEG, weaning after PEG, days from PEG to discharge between the two groups, Wilcoxon's rank sum test was performed. Spearman's *r* was used to detect if there was any correlation between the standing-period of NGT and GER (%). Statistical significance was defined as a *P* value of 0.05 or less.

## RESULTS

The correlation between GER (%) and duration of NGT permanence in the 23 patients from the pilot study along with the values obtained from the first pH-metry in the 47 patients of the main study is shown in Figure 1. After 20 d of NGT *in situ*, 38 out of 50 patients (76%) presented a reflux rate of above 6% while all the 14 patients with NGT *in situ* for less than 15 d had a reflux rate of less than 6%.

The pH-metry from the lower esophageal sensor consistently recorded 15 - 20% higher GER than that from the upper sensor. However, since the importance of reflux detection in the upper part of esophagus is greater in relation to aspiration, only data from the upper sensor were presented. The median (range) GER (%) in the PEG group was 7.8 (6.2 - 15.6) at baseline. Forty-eight hours post-PEG, though there was no significant change in the median value [8.7 (0.1 - 19)], an increase in GER (%) was observed in 5 out of 16 patients. On d 7, post-PEG, GER (%) decreased to 2.7 (0 - 10.4) ( $P < 0.01$ ). In contrast, in the non-PEG group, GER (%) increased from 9 (6.2 - 22) at baseline to 10.8 (6.3 - 36.6) on d 7 ( $P < 0.01$ ) (Figure 2).

In the following 20-d period, the weaned, discharged, and died patients were respectively 11 and 4 ( $P = 0.006$ ), 10 and 2 ( $P < 0.01$ ), and 3 and 5 in PEG and non-PEG groups. The respective values for patients in the control group were 8, 8, and 1. The outcome of the PEG-group was similar to that of the control group.

## DISCUSSION

This study showed that the degree of GER correlated with the duration of NGT *in situ*. Removal of NGT and feeding through PEG with the patients in semi-recumbent position along with the volume control of the nutrient gastric residue resulted in a decrease or even elimination of the reflux in almost two-thirds of the patients. Additionally, PEG seemed to exert a favorable effect on pneumonia healing rate, weaning period, and patient discharge from ICU.

There are several reasons for frequent GER occurrence in the critically ill patients. Drugs depressing the function of lower esophageal sphincter and/or delaying gastric emptying, such as morphine, atropine, theophylline, and barbiturates, are frequently administered in the critically ill patients<sup>[16]</sup>. The presence of NGT is an important cause of reflux, since it may induce lower esophageal sphincter relaxation<sup>[17]</sup>. In patients undergoing elective laparotomy and nasogastric intubation, a significant increase in the mean number of reflux episodes has been observed during the perioperative period in contrast to those without NGT (137 *vs* 8,  $P < 0.01$ )<sup>[18]</sup>. The mean lower esophageal sphincter pressures are also lower in the same patients, and reflux occurs within 24 h after NGT insertion at the

induction of anesthesia. Similarly, in patients undergoing cardiac surgery with simultaneous esophageal and tracheal pH-metry, reflux is seen more frequently in those with a NGT in place than in those without ( $P < 0.001$ )<sup>[19]</sup>.

The above observations lead to the notion that NGT removal after PEG should theoretically eliminate or decrease the incidence of GER. However, data in the literature paradoxically support the opposite. There is evidence that PEG or percutaneous endoscopic jejunostomy provides no benefit in terms of reflux and/or incidence of aspiration pneumonia<sup>[8,11,19-23]</sup>. In a study of 64 patients, 9 developed aspiration pneumonia within 3 d of the procedure and four died<sup>[8]</sup>. Aspiration occurred in 11% of 79 patients with either neurologic disorders or cancer, whose PEG or percutaneous endoscopic jejunostomy was performed<sup>[11]</sup>. In another study comprising 20 malnourished patients, aspiration was the most common adverse event following percutaneous endoscopic jejunostomy, accounting for 50% of deaths<sup>[20]</sup>. Similarly, GER seems to be a frequent disorder following PEG in children<sup>[21-23]</sup>. Yet, in 58 neurologically disabled patients who had clinical evidence of aspiration pneumonia, 17 demonstrated pneumonia after gastrostomy<sup>[24]</sup>. As a result of the negative outcomes, the use of PEG has declined during recent years. However, in all these studies the body position following PEG was not reported and the volume of gastric nutrient residue was not controlled.

The positive results found in our PEG group compared to those reported in the literature have to be attributed to the volume control of the nutrient gastric residue and the semi-recumbent position during the whole 20-observation period. The semi-recumbent position has been previously shown to reduce aspiration of gastric contents<sup>[6]</sup>. Gastric distension is also an important cause of lower esophageal sphincter transient relaxation, thus permitting GER<sup>[25]</sup>. It seems that owing to gravity, semi-recumbency, and avoidance of gastric retention prevent reflux of gastric juice into the esophagus.

The results of the present study describe the pathophysiological sequence of PEG-induced lower esophageal sphincter restoration. In 11/16 patients in the PEG group, the reflux rate did not decrease during the first 48 post-PEG hours. Moreover, in 5 of them GER (%) increased in this period. These results indicate that "PEG was arbitrarily considered effective if within a 7-day post PEG period the GER (%) decreased by more than 60% compared to the pre-PEG value". Thus, a period of at least 7 d seems to be required after NGT removal before lower esophageal sphincter returns to its normal function. The same findings also provide an explanation for the high incidence of aspiration pneumonia encountered during the early post-PEG period<sup>[7,8,17,18]</sup>.

The role of GER in the pathogenesis of VAP is still controversial<sup>[26-28]</sup>. All patients in the present study suffering from persistent or recurrent pneumonia were severely ill and failed to respond to the usual therapeutic measures. However, reflux was eliminated in 10 out of 16 patients undergoing PEG who weaned from the respirator and discharged from ICU within the 20-d period of observation. In contrast, among the 20 non-PEG patients reflux increased through time and only 4 and 2 patients

were weaned and discharged, respectively. The curative rate of PEG-group was similar to that of control group with the GER being lower than 3%. Among the 11 patients with GER < 3% only one presented VAP. Therefore, it is concluded that GER is implicated in the pathogenesis of VAP and the elimination of reflux results in a more favorable outcome, possibly because the repetitive instillation of infective materials to the trachea that occurs during reflux, is halted.

In conclusion, NGT presence seems to promote reflux of gastric contents, resulting in aspiration and/or pneumonia. The NGT replacement by PEG combined with semi-recumbent position and control of gastric residue can decrease GER in the majority of patients. However, there is persistence of GER and aspiration in some patients, which may be due to the functional alteration of the lower esophageal sphincter rather than ineffectiveness of PEG *per se*. Gastrostomy combined with semi-recumbency and control of gastric residue should be taken into consideration for the effective management and prevention of VAP.

## Abstract

**AIM:** To compare the efficacy of self-expandable metallic stents (EMS) in the treatment of distal and proximal stricture of malignant biliary tumors.

**METHODS:** From March 1995 to June 2004, 61 patients (40 males, 21 females) with malignant biliary obstruction who received self-expandable metallic stent implantation were reviewed retrospectively. The stents were inserted by an endoscopic or percutaneous transhepatic method. We tried to place two stents in the biliary system in T or Y configuration in cases of hilar tumors with bilateral hepatic duct obstruction. The end points of the study were stent occlusion or patient death.

**RESULTS:** The mean time of stent patency was  $421 \pm 67$  d in the group of proximal stricture (group I) and  $168 \pm 18$  d in the group of distal stricture (group II). The difference was significant in borderline between the two groups ( $P = 0.0567$ ). The mean survival time was  $574 \pm 76$  d in group I and  $182 \pm 25$  d in group II. There was a significant difference between the two groups ( $P = 0.0005$ ).

**CONCLUSION:** EMS implantation is a feasible, palliative method for unresectable malignant biliary obstruction. The clinical efficacy of EMS in patients with proximal hilar tumors is better than that in patients with distal tumors.

## INTRODUCTION

Biliary stent placement is the treatment of choice for malignant biliary obstruction caused by unresectable neoplasms<sup>[1,2]</sup>. Although self-expandable metallic stents (EMS) are much more expensive than plastic stents, EMS is claimed to be superior to plastic stents in long-term stent patency<sup>[3]</sup>. At first, when EMS is uncovered, the tumor often invades the stent via meshes of the metallic stent, resulting in stent obstruction<sup>[1]</sup>. To overcome the problem of tumor ingrowth in uncovered metallic stents, covered EMS have been developed in the 1990s<sup>[1,4,5]</sup>. However, complications of covered EMS, such as cholecystitis and pancreatitis, should be noted<sup>[1,5]</sup>.

Uncovered EMS are introduced into Taiwan in the 1990s to overcome the weak points of plastic stents<sup>[2]</sup>. In our hospital, we have begun to use uncovered EMS for the treatment of unresectable malignant biliary obstruction since 1995 and covered EMS in selective cases since 2002.

Lee *et al*<sup>[6]</sup> found that the clinical efficacy of EMS in patients with hilar tumor is superior in those with common bile duct obstruction. Rieber and Brambs<sup>[7]</sup> demonstrated that worse results are seen in patients with pancreatic tumors and with lymph nodes metastases of the colon and gastric cancers. We have found similar trends in our practice. Therefore, we performed this study to compare the efficacy of EMS in the treatment of distal and proximal stricture of malignant biliary tumors.

## MATERIALS AND METHODS

From March 1995 to June 2004, 61 patients (40 males, 21 females) with malignant biliary obstruction who received EMS implantation were reviewed retrospectively. Neoplasms were unresectable and the diagnosis was based on pathological examination or clinical and imaging findings.

The patients received endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC) initially. Plastic stent drainage, nasobiliary drainage or PTC was set up when the neoplasms were confirmed to be unresectable, the patients were assigned to insertion of EMS if they agreed. Wallstent (Schneider, Switzerland) and Ultraflex diamond stent (Microvasive; Boston Scientific Corporation, MA, USA) were used in our patients. EMS were inserted either by therapeutic duodenoscopy (TJF 200, Olympus, Tokyo, Japan) or by the percutaneous transhepatic approach. We tried to place two stents in

**Figure 1** Kaplan-Meier graph showing cumulative stent patency. The difference was borderline significant between the two groups.

**Figure 2** Kaplan-Meier graph showing survival of the patients. There was a significant difference observed between the proximal tumor and distal tumor.

the biliary system in T or Y configuration in cases of hilar tumors with bilateral hepatic duct obstruction. Covered EMS were inserted only in patients with distal stricture.

The lesions were defined as distal stricture if the tumors were located at or below the orifice of the cystic duct. The lesions were defined as proximal stricture if the tumors were located above the orifice of the cystic duct.

Stent occlusion was defined as recurrence of jaundice or cholangitis with evidence of stent stenosis requiring biliary intervention after successful insertion of EMS. The stent patency period was calculated as the time between stent placement and its occlusion or patient death. Cumulative stent patency and patient survival were evaluated by the Kaplan-Meier technique. The end points of the study were stent occlusion or patient death.

## RESULTS

### Patient enrollment and characteristics

Sixty-one patients were enrolled in this study. The patients were divided into two groups according to their obstruction level.

Group I (21 patients) was consisted of proximal stricture patients. The obstruction level was above the orifice of the cystic duct. The group included 19 patients with hilar cholangiocarcinoma and two patients with hepatocellular carcinoma. Twelve patients with hilar cholangiocarcinoma received two stents (in T or Y configuration) for drainage of bilateral hepatic ducts.

Group II (40 patients) was consisted of distal stricture patients. The obstruction level was at or below the orifice of the cystic duct. The group included 9 patients with cholangiocarcinoma, 17 patients with pancreatic cancers, 3 patients with ampulla of Vater cancers, 2 patients with gall bladder cancers, and 9 patients with lymph node metastases of colon cancer (2/9), gastric cancer (3/9), lung cancer (1/9), nasopharyngeal cancer (1/9), hepatocellular cancer (1/9) and laryngeal cancer (1/9).

Eight patients in group I (8/21) and 24 patients (24/40) in group II died at the time of evaluation. Covered EMS were inserted in seven patients with distal stricture and the

other 53 patients received uncovered stents.

If stent stenosis was noted during follow-up, either a second EMS (six patients), or a plastic stent through an original EMS (three patients) or PTCD (one patient) or nasobiliary drainage (three patients) was set up. However, some patients chose conservative treatment after stent occlusion.

### Stent patency and survival

The mean time of stent patency was  $421 \pm 67$  d in group I and  $168 \pm 18$  d in group II. The difference was significant in borderline between the two groups ( $P=0.0567$ ). The mean survival time was  $574 \pm 76$  d in group I and  $182 \pm 25$  d in group II. There was a significant difference between the two groups ( $P=0.0005$ ). Cumulative stent patency and patient survival according to the Kaplan-Meier life table are shown in Figures 1 and 2.

### Early complications

Early complications were defined as "complications occurring within 30 d after EMS placement". Nine cases had early complications. Seven of them belonged to distal stricture and two belonged to proximal stricture. The clinical features of early complications are listed in Table 1.

### Late complications

Late complications were defined as "complications occurring after 30 d of EMS placement". A patient with hilar cholangiocarcinoma suffered from common bile duct stones 175 d after stent placement. Endoscopic sphincterotomy was performed and the stones were extracted. Gallbladder empyema was in two patients. One of them received covered EMS due to cholangiocarcinoma near the orifice of the cystic duct and symptoms occurred 66 d after stent placement. The other patient received uncovered EMS due to hilar cholangiocarcinoma and symptoms occurred 37 d after stent placement. Percutaneous transhepatic gallbladder drainage (PTGBD) relieved their symptoms. Three patients with pancreatic cancers suffered from gastric outlet obstruction (on days 80, 93 and 270 respectively) due to tumor invasion into the duodenum. Bypass surgery relieved their outlet

Table 1 Early complications after insertion of metallic stents

Case	Complications	Type of stent	Timing of complication	Management	Result
1	Acute pancreatitis	Covered stent	Immediately	Conservative	Recovered
2	Acute pancreatitis	Covered stent	Immediately	Conservative	Recovered
3	Acute pancreatitis with pseudocyst	Uncoverd stent	Immediately	Percutaneous catheter drainage	Recovered
4	Inadequate expansion of stent	Uncoverd stent	3 d	Balloon dilatation	Good
5	Inadequate expansion of stent	Uncoverd stent	3 d	Balloon dilatation	Good
6	Acute cholangitis without Stent stenosis	Uncoverd stent	22 d	Antibiotics	Recovered
7	Peritonitis	Uncoverd stent	30 d	Antibiotics	Recovered
8	Stent occlusion	Uncoverd stent	22 d	PTCD	Good
9	Subcapsular liver abscess	Uncoverd stent	1 d	Percutaneous catheter drainage	Recovered

Case 1-7: distal stricture.

Case 8-9: proximal stricture.

obstructions.

### Complications of covered EMS

It seemed that more complications occurred in patients who received covered EMS. However, we could not arrive at any final conclusion due to the limited number of cases in our series. Acute pancreatitis occurred immediately after stent placement in two cases (2/8). Fortunately, they recovered uneventfully after conservative treatment. Stent migration (1/8) was found in a patient with an ampulla of Vater tumor 85 d after stent placement. He received conservative treatment only because of tumor infiltration in the entire second portion of the duodenum and the patient expired soon after. One patient developed gallbladder empyema (1/8) 66 d after stent placement. Her symptoms were relieved after PTGBD.

## DISCUSSION

Endoscopic or percutaneous transhepatic stentplacement in the biliary tree has become a main stream in the treatment of inoperable malignant obstructive jaundice<sup>[1]</sup>. The major drawback of plastic stents is early stent clogging and migration in spite of various modifications in the design<sup>[2,3]</sup>. The use of EMS apparently improves the weak points of plastic stents. Although EMS is much more expensive than plastic stents, it is a cost-effective strategy<sup>[3,8]</sup>. EMS improves patient compliance due to prolonged stent patency and less complications<sup>[3]</sup>.

According to Lee *et al.*<sup>[6]</sup>, patients with hilar obstruction have better clinical efficacy than those with common bile duct obstruction. In our study, we demonstrated similar results. Stent patency and patient survival were better in our patients with proximal stricture than in those with distal stricture. Twelve of 21 patients with proximal stricture received bilateral biliary drainage in our series. If one of the two stents were occluded, jaundice would rarely develop. However, stent occlusion would cause immediate jaundice in distal strictures.

Our study demonstrated that most of early

complications were related to the effect of stents or manipulation procedures. Acute pancreatitis(3/9) might be due to occlusion of the pancreatic duct by covered stents or secondary to the ERCP procedure. Liver abscess (1/9) might be due to the contamination of the procedure. The inadequate expansion of EMS (2/9) might be due to poor function of the metallic wires.

Most late complications were related to tumor progression. The first case with gallbladder empyema in our study might be due to the dual effects of covered stents and tumor progression. The second case with gallbladder empyema might be due to tumor progression with cystic duct occlusion. The gastric outlet obstruction in patients with pancreatic cancers was, surely due to tumor extension. Almost all stenoses of the stent and/or cholangitis are caused by tumor growth with occluded ducts, but cholangitis unrelated to stent occlusion can be noted<sup>[11]</sup>.

Although the patency of EMS is longer, there are many drawbacks after their placement, such as tumor ingrowth or overgrowth, mucosa hyperplasia induced by chronic inflammatory reaction to the stent meshes, biliary sludge and food impaction in transpapillary stents<sup>[9]</sup>. Covered stents are significantly superior to uncovered stents by preventing tumor ingrowth<sup>[1,4,5]</sup>. However covered stents are risky for occlusion of branch ducts (such as side branches of bile ducts, cystic ducts or pancreatic ducts), stent migration and sludge formation. Only eight of our patients with distal stricture received covered stents, and complications occurred in four of eight. Complications included acute pancreatitis (2/8), gallbladder empyema (1/8) and stent migration (1/8). A higher rate of migration is another possible disadvantage of covered stents<sup>[10]</sup>. Due to the limited number of covered stents in our series, further studies are needed to determine the frequency of side effects in covered stents.

Because of the high cost of EMS, selection of patients and types of stents are important. Life expectancy shorter than 6 mo<sup>[8]</sup> or tumors with liver metastases<sup>[12]</sup> are not cost-effective for EMS placement. Although many

types of EMS are now available, which type can best improve the cost-effectiveness and quality of life remains unknown<sup>[13-16]</sup>.

In conclusion, EMS implantation is a feasible, palliative method for unresectable malignant biliary obstruction. The clinical efficacy of EMS in patients with proximal hilar tumors is superior to that in patients with distal tumors. Covered EMS is risky in regard to the complications due to pancreatitis although stent patency may be longer.

### Abstract

**AIM:** To evaluate the diagnostic accuracy, sensitivity, specificity of contrast-enhanced computed tomographic colonography in detecting local recurrence of colorectal cancer.

**METHODS:** From January 2000 to December 2004, 434 patients after potentially curative resection for invasive colorectal cancer were followed up for a period ranging from 20 to 55 mo. Eighty of the four hundred and thirty-four patients showing strong clinical evidence for recurring colorectal cancer during the last follow-up were enrolled in this study. Each patient underwent contrast-enhanced computed tomographic colonography and colonoscopy on the same day. Any lesions, biopsies, identified during the colonoscopic examination, immediate complications and the duration of the procedure were recorded. The results of contrast-enhanced computed tomographic colonography were evaluated by comparing to those of colonoscopy, surgical finding, and clinical follow-up.

**RESULTS:** Contrast-enhanced computed tomographic colonography had a sensitivity of 100%, a specificity of 83% and an overall accuracy of 94% in detecting local recurrent colorectal cancer.

**CONCLUSION:** Conventional colonoscopy and contrast-enhanced tomographic colonography can complement each other in detecting local recurrence of colorectal cancer.

### INTRODUCTION

Colorectal cancer has the third highest incidence of all cancers worldwide. Approximately 70% of colorectal cancer patients can undergo potentially curative surgical resection. Unfortunately, colorectal cancer recurs in 30% of these patients. With the advent of more aggressive surgical resection for recurrent colorectal cancer<sup>[1]</sup>, early detection of recurrent cancers while they are still limited to a local site is important to improve the patient's survival. If radical resection of locally recurrent colorectal cancer is performed before distant metastatic or unresectable disease develops, one-third to one-half of patients can increase their survival time. However, potentially curative surgery is followed by a period of uncertainty as to whether the operation has successfully cured the cancer. Treatment failure is usually apparent during the first 3 years after surgery. The precise post-operative surveillance procedures<sup>[2]</sup> are based on clinical assessment, CEA, colonoscopy, ultrasound and computerized tomography depending on the site of primary tumor. The role of follow-up in the early diagnosis of recurrent colorectal cancer in patients having undergone resection has been investigated extensively. A large array of screening tests is available for detecting recurrent colorectal cancer, but each test has its particular limitations. Computed tomographic colonography is a new method to exploit recent developments in image acquisition which applies algorithms of virtual-reality systems to build three-dimensional models of the inner surface of the colon tube thereby simulating the conventional colonoscopic view<sup>[3-5]</sup>. The colon wall and pericolonic structures can also be detected at the same time. Computed tomographic colonography has a high accuracy in detecting colonic neoplasia<sup>[6-8]</sup>. Like computed tomography, contrast-

enhanced computed tomography is performed after a patient receives an air enema, and uses a narrow collimation and reconstruction interval to detect colonic lesions. Contrast-enhanced computed tomographic colonography theoretically has the ability to detect local cancer recurrence by examining both the colonic mucosa and the pericolic tissue. The use of IV contrast material in contrast-enhanced computed tomographic colonography facilitates a thorough examination of metastatic disease in solid organs. Contrast-enhanced computed tomographic colonography can display both mucosa and extramucosal local recurrence, metachronous polyps and cancers, hepatic and peritoneal metastasis<sup>[9]</sup>. This study aimed to assess the diagnostic accuracy, sensitivity, and specificity of contrast-enhanced computed tomographic colonography in detecting local recurrence of colorectal cancer following curative resection.

## MATERIALS AND METHODS

### Patients

From January 2000 to December 2004, 434 patients who underwent potentially curative resection for invasive colorectal cancer (181 stage B, 253 stage C) were followed up for a period ranging from 20 to 55 mo. Eighty of the four hundred and thirty-four patients showed strong clinical evidence for recurring colorectal cancer at the last follow-up. Patients with an end or diverting colostomy or those who had contraindications for IV contrast dye were excluded.

### Methods

Eighty patients who were sent for conventional colonoscopy and agreed to receive contrast-enhanced computed tomographic colonography were enrolled in this study. Written informed consent forms for both conventional colonoscopy and contrast-enhanced computed tomographic colonography were obtained from each patient. The average age of the patients was 64 years (range, 28-82 years). The ratio of male to female was 43:37. The clinical manifestations of local recurrence included bloody stools, increased serum CEA level ( $\geq 50$  ng/mL), abdominal mass and colonic obstruction. Previous resection for invasive colorectal cancer included stages B and C of rectal cancer and colon cancer. Each patient underwent contrast-enhanced computed tomographic colonography and colonoscopy. The endoscopist was not informed of the radiological results on the same day. The average time between previous resection and contrast-enhanced computed tomographic colonography was 32 mo (range, 20-55 mo). Twenty-four hours before contrast-enhanced computed tomographic colonography, each patient received a standard bowel preparation<sup>[10,11]</sup> consisting of 4 L of polyethylene glycol solution and 25 mg bisacodyl tablets. Prior to computed tomographic scanning, patients were placed in a left lateral decubitus position on the computed tomographic table for the introduction of a rectal enema tube. After insertion of the rectal tube, the colon was inflated with room air to patient tolerance. To reduce bowel peristalsis and colon spasms, 20 mg of buscopan was administered intravenously immediately before air

insufflation. Patient's tolerance with regard to the volume of insufflated air was measured (range, 1 500-2 000 cm<sup>3</sup>). Adequate colonic distention was checked with a computed tomographic scout. If inadequate distention developed at any colon segment, idiosyncratic positioning or additional air insufflation was performed to improve colonic distention in the collapsed regions. Contrast-enhanced computed tomographic colonography was performed employing 150 mL of Isovue-300 (Bracco Diagnostics, Princeton, NJ, USA) IV contrast medium injected at a rate of 3-5 mL/s. Images were acquired 70 s after the injection.

Computed tomographic examinations were conducted with Sightspeed Plus and Sightspeed QX/i computed tomographic scanners (General Electric Medical Systems). The patient was first examined in the supine position, and then in the prone position. Images were acquired with a 5-mm beam collimation (table speed of 10 mm/s, and reconstruction slice overlap of 2.5 mm, 230-260 mA, 120 kV). A gastrointestinal radiologist with experience in computed tomographic colonography analyzed the volumetric computed tomographic datasets using a Sun Advantage Windows (General Electric Medical Systems)<sup>[12,13]</sup> and the General Electric Navigator program that reformats the axial two-dimensional multiplanar and three-dimensional endoluminal images<sup>[14,15]</sup> and allowed for comparison of supine and prone datasets. Local recurrence was rated as either present, absent or indeterminate. Local recurrence was recorded as present when the characteristic appearance of an enhancing, primary extracolonic mass on intraluminal masses at or near the surgical anastomosis with or without adjacent adenopathy was identified by the contrast-enhanced computed tomography. Predominantly intraluminal abnormalities at the anastomosis were considered indeterminate for local recurrence. The liver, peritoneum, retroperitoneum, lung bases, and lymph nodes were also evaluated for the presence of metastatic disease. The colonoscopic examination was performed 2 h after contrast-enhanced computed tomographic colonography. The incidence of lesions, immediate complications, and the overall duration of the colonoscopic examination were recorded. Examination reports being indeterminate for local recurrence on contrast-enhanced computed tomographic colonography but negative colonoscopic examinations were counted as false positive examinations in statistical analysis. The sensitivity, specificity, and accuracy of contrast-enhanced computed tomographic colonography for post-operative detection of local recurrence and metastatic colorectal cancer were estimated.

## RESULTS

All the 80 patients completed the contrast-enhanced computed tomographic colonography successfully. No patients had pain or complications during the procedures. Table 1 presents the findings of the contrast-enhanced computed tomographic colonography. Examination results were as follows. Local recurrence was found in 51 patients. Seventy-five of the eighty patients had adequate colonic inflation throughout the entire colon. Two of the five remaining patients had inadequate transverse colon distention and three had inadequate sigmoid colon distention though additional

**Figure 1** Virtual double contrast of the colon in a patient with local recurrence at previous anastomotic site.

air was insufflated and the positions of the patient were changed. In contrast-enhanced computed tomographic colonography, all the five patients showing thickened segmental colon wall and external luminal tumor mass compression (Figure 1) were classified as present local recurrence. The colonoscopic findings in these corresponding segmental regions showed only lumen stenosis, but no mass or mucosal lesions were found in the lumen in all the five patients. All the five patients received laparotomy for local recurrence based on a clinical presentation of three abdominal palpable masses and two colon obstructions. Surgical findings showed external colon lumen recurrent masses at previous anastomotic sites in all the five patients. Two of the five patients also had peritoneal metastasis. They all received resection of the local recurrent tumor and the colon segment with or without colostomy diversion.

Of the 51 patients with local recurrence, colonoscopic findings showed a tumor or a stricture with friable mucosa at the anastomosis, prompting a biopsy for recurrent adenocarcinoma. All the 51 patients with positive findings on both contrast-enhanced computed tomographic colonography and colonoscopy received laparotomy for local recurrence. Surgical findings showed local recurrence in all 51 patients, 35 of the 51 patients underwent segmental resection of the recurrent colorectal cancer with anastomosis, the remaining 16 patients underwent segmental resection of the colorectal cancer with colostomy diversion. All the 51 patients with local recurrence with or without liver metastasis or peritoneal metastasis received adjuvant chemotherapy after surgery.

The colonoscopic findings in the five patients which were classified as indeterminate by contrast-enhanced computed tomographic colonography revealed mucosa swelling, erythema in two patients and multiple ulcers at anastomotic site in three patients.

All the five patients underwent both contrast-enhanced computed tomographic colonography and colonoscopy 6 months later. No local recurrence or distant metastases were found, and their anastomotic sites were normal.

The colonoscopic finding in one patient, whose contrast-enhanced computed tomographic colonography

**Table 1** Performance-based contrast-enhanced computed tomographic colonography findings in 80 patients

	Patients (n)
Local recurrence	
Present	51
Indeterminate	5
Not present	24
Metachronous cancer	1
Distant metastasis	
Liver	8
Peritoneal	5

showed no local recurrence but a metachronous mass at the ascending colon, revealed a tumor at the ascending colon. The patient with metachronous cancer underwent right hemicolectomy with anastomosis. No distant metastasis or local recurrence was found in this case. The remaining 23 patients whose contrast-enhanced computed tomographic colonography did not show local recurrence were negative for colonoscopy. All the 23 patients were routinely followed up. There was no true false-negative local recurrent cancer on contrast-enhanced computed tomographic colonography. However, the five patients classified as indeterminate for local recurrence in contrast-enhanced computed tomographic colonography reports were false positive. Contrast-enhanced computed tomographic colonography had a sensitivity of 100%, a specificity of 83%, and an overall accuracy of 94% in detecting local recurrent colorectal cancer.

## DISCUSSION

In patients who have undergone potentially curative colonic resections for invasive colorectal cancer, hematogenous metastases and local recurrence are the most important factors influencing prognosis. After surgery, however, there is a period of uncertainty as to whether the operation has cured the cancer or not. Treatment failure will usually be apparent during the first 2-3 years after surgery. Precise post-operative surveillance procedures, including clinical assessment, colonoscopy, abdominal computed tomography, are employed to detect recurrence of colorectal cancer. Although colonoscopy can detect intraluminal local recurrence, some local recurrences are not intraluminal and are endoscopically obscure. Abdominal computed tomography can detect hepatic and peritoneal metastases, but it is not reliable for detecting local recurrence except in those patients with a previous abdominoperineal resection. Unlike these two tests, contrast-enhanced computed tomographic colonography directly displays the anastomosis, luminal surface, colon wall and pericolonic tissues. It has, therefore, a potential to detect mucosal, intramural and extracolonic local recurrences. In our study, the overall accuracy was 94%, which is similar to that in the study by Fletcher *et al* [16]. At the same time, it is also advantageous over the colonoscopy for detecting extracolonic local recurrence and peritoneal metastasis. In this study, 46 of the 51 local recurrences developed from the extraluminal soft tissue and local lymph nodes, nearly previous anastomotic area. At the same time, 40 of the 51 cases were rectal can-

cer and 47 of stage C at their original primary cancer. It may be the reasons that were related to high local recurrent rate of our samples. As shown in our study, 5 of the 51 patients (10%) who had local recurrence detected by contrast-enhanced computed tomographic colonography had no intraluminal recurrence by colonoscopic examination.

However, all the five patients received laparotomy for local recurrence of abdominal mass and intestinal obstruction. External colon lumen local recurrence with or without peritoneal metastasis was found during surgery. Contrast-enhanced computed tomographic colonography may also show the structure of the colon when colonoscopy is incomplete<sup>[17]</sup>. Although contrast-enhanced computed tomographic colonography has a high sensitivity (100%) for local recurrent colorectal cancer, its specificity is only 83% as shown in our study. This may be due to the inability of contrast-enhanced computed tomographic colonography to distinguish local recurrence from inflammation when enhancing soft tissue is present. Our results showed that five patients, classified as indeterminate by contrast-enhanced computed tomographic colonography, had colonoscopic findings of mucosa swelling, erythema or multiple ulcers. No local recurrence was identified in any of these five patients during the subsequent follow-up. These indeterminate conditions were then considered as false positive examinations. Another significant difference in this technique in comparison to colonoscopy is that a biopsy cannot be taken during contrast-enhanced computed tomographic colonography. However, it is recognized that contrast-enhanced computed tomographic colonography is more accurate in detecting extraluminal recurrent tumor than conventional colonoscopy.

In conclusion, contrast-enhanced computed tomographic colonography has several advantages over alternative tests in detecting local recurrent colorectal cancer. It can be a very helpful adjuvant method to colonoscopy in detecting extraluminal local recurrence, peritoneal carcinomatosis and distant metastasis. With regard to the threat of colorectal cancer and the early detection of local recurrence and distant metastasis in patients who have undergone potentially curative colonic resections for invasive colorectal cancers, conventional colonoscopy and contrast-enhanced tomographic colonography can complement each other.

## INTRODUCTION

The incidence rate of chronic hepatitis B (CHB) is high in China. The status of virus replication and the process of hepatic fibrosis are regarded as important. At present, TGF- $\beta$ 1 is known not only as a cytokine which adjusts proliferation, development, conversion, and differentiation of cells, but also as an important transmitter of hepatic fibrosis. It plays an important role in the formation of cirrhosis<sup>[1-3]</sup>. The synthesis and degradation of extracellular matrix (ECM) are adjusted by it<sup>[4,5]</sup>. This study was to observe the influence of HBcAg on the expression of TGF- $\beta$ 1 in liver tissue of low-grade CHB patients.

## MATERIALS AND METHODS

### Reagents

Mouse anti-human TGF- $\beta$ 1 antibody was purchased from Fuzhou Maxim Biotechnology Co., Ltd (Lot No.: 30212238L). The PV-9000 kit was provided by Beijing Zhongshan Golden Bridge Biotechnology Co., Ltd. Rabbit anti-human HBcAg was purchased from Fuzhou Maxim Biotechnology Co., Ltd.

### Clinical data

A total of 93 low-grade CHB patients (68 males and 25 females, mean age 33.3 years, ranging from 17 to 56 years) were analyzed. HBcAg was expressed as plasma type in the liver tissue of 50 cases and no HBcAg was expressed in 43 cases. The diagnosis of all cases was coincident with the program of prevention and cure for viral hepatitis<sup>[6]</sup>.

### Liver biopsy

The liver biopsy was taken from 93 cases under B ultrasound guidance. The liver tissue longer than 1.0 cm and without break was fixed by formaldehyde solution and embedded in paraffin. Six serial sections (4  $\mu$ m thick) were prepared for HE, Masson, Gordon Sweet, HBsAg, HBcAg, and TGF- $\beta$ 1.

## Abstract

**AIM:** To study the influence of HBcAg on the expression of transforming growth factor-beta 1 (TGF- $\beta$ 1) in liver tissue of low-grade chronic hepatitis B (CHB) patients.

**METHODS:** The expression of TGF- $\beta$ 1 and HBcAg in liver samples from 93 low-grade CHB patients was detected by immunohistochemistry and valuated by semi-quantitative scoring.

**RESULTS:** In the 93 low-grade CHB patients, HBcAg was expressed in cell plasma but not in the liver tissue. There was no significant difference between the two groups.

**CONCLUSION:** The expression of TGF- $\beta$ 1 is not related with HBcAg expressed as plasma type in the tissues of low-grade CHB patients.

Liu YG, Lu JH, Wang XX, Yang JL, Lang ZW, Meng X, Zhang LJ, Sun L, Zhang SJ, Li JQ, Song CZ. Influence of HBcAg in liver cell plasma on expression of transforming growth factor-beta 1 in liver tissue of low-grade chronic hepatitis B patients. *World J Gastroenterol*

**Table 1 Influence of HBcAg in liver cell plasma on the expression of TGF- $\beta$ 1 in liver tissue of low-grade CHB patients**

Groups	Expression of TGF- $\beta$ 1 protein by semi-quantitative scoring(Score)					Total
	0	1	2	3	4	
HBcAg expression in cell plasma	2	2	19	23	4	50
No HBcAg expression in liver tissue	4	2	13	20	4	43

### Immunohistochemistry

TGF- $\beta$ 1 antigen was repaired by microwave in pH 6.0 citrate solutions. The next procedure was performed according to the instructions of PV-9000 kit. TGF- $\beta$ 1 was observed randomly at least in five portal areas under 200 light microscope and the expression of TGF- $\beta$ 1 was evaluated with semi-quantitative scoring method: score 0: no stain or no cell was hyperchromatic or the positive cells were less than 1% of total liver tissues; score 1-4: the areas of positive cells in hepatic lobules, hepatic sinusoid, portal areas, and fibrous plate were 1%-9%, 10%-15%, 16%-20% and more than 20% of total liver tissues, respectively<sup>[7]</sup>.

### Statistical analysis

Statistical analyses were carried out with the rank test.

## RESULTS

### TGF- $\beta$ 1 expression

The positive cells of TGF- $\beta$ 1 were mainly distributed over the focal necrosis and the active fibrosis areas. They were mainly expressed in the interstitial cells of hepatic sinusoid and the inflammatory cells of portal areas. Some bile duct cells and plasma hepatocytes were also expressed.

### HBcAg expression

In the 93 low-grade CHB patients, HBcAg was expressed in cell plasma but not in the liver tissue. There was no significant difference between the two groups ( $H = 0.004$ ,  $P > 0.05$ , Table 1).

## DISCUSSION

TGF- $\beta$ 1 is a cluster of active polypeptides with closely correlative structures and similar functions. Five isomers (TGF- $\beta$ 1-5) have been found though TGF- $\beta$ 1 is the main content of TGF- $\beta$  in human liver and has important functions. It mainly comes from the Kupffer cells (KCs) though hepatic stellate cells (HSCs) can autocrine TGF- $\beta$ 1. TGF- $\beta$ 1 can transfer anti-signals of cell cycle with Smad molecules and inhibit gene transcription of cell cycle correlative proteins<sup>[8]</sup>. It can inhibit the expression of cyclin related to P70<sup>s6k</sup> through P70<sup>s6k</sup> (serine/threonine kinase)<sup>[9]</sup>. The upregulation of connective tissue growth factor (CTGF) expression is related to TGF- $\beta$ 1<sup>[10]</sup> and it may be the core of activation in HSCs. TGF- $\beta$ 1 can inhibit the proliferation of quiescent HSCs but cannot inhibit the activated HSCs<sup>[11]</sup>. In CHB, its serum level is increased<sup>[12-15]</sup>

and its expression in the liver is reinforced<sup>[16-18]</sup>. TGF- $\beta$ 1 is one of the network cytokines related to hepatic fibrosis and can accelerate the synthesis of ECM and inhibit the degradation of ECM<sup>[19]</sup>. Following the expression of TGF- $\beta$ 1, the proliferating cell nuclear antigen (PCNA) decreases in the liver<sup>[20]</sup>. TGF- $\beta$ 1 can inhibit regeneration of hepatocytes<sup>[21]</sup> and accelerate apoptosis of hepatocytes<sup>[22-24]</sup>, but not HCC cells<sup>[25]</sup>. Powell *et al*<sup>[26]</sup> showed that the risk of developing cirrhosis is higher in hyper-expression than in hypo-expression of TGF- $\beta$ 1.

Some scholars have found that the expression of TGF- $\beta$ 1 in the liver tissues is not related with HBcAg and HBV DNA in the serum of CHB patients<sup>[27,28]</sup>. In our study, TGF- $\beta$ 1 in the liver tissue of low-grade CHB patients did not influence the status of inflammation and fibrosis with the comparability improved. We found that the expression of TGF- $\beta$ 1 evaluated by semi-quantitative scoring was not related with HBcAg expression in liver cell plasma of low-grade chronic hepatitis B. We suppose that the expression of some cytokines is not related with hepatitis B virus possibly due to the role of virus replication and body immune response.

## Abstract

**AIM:** To verify the safety and efficacy of plasma shock wave lithotripsy (PSWL) in fragmenting impacted stones in the bile duct system.

**METHODS:** From September 1988 to April 2005, 67 patients (26 men and 41 women) with impacted stones underwent various biliary operations with tube (or T-tube) drainage. Remnant and impacted stones in the bile duct system found by cholangiography after the operation were fragmented by PSWL and choledochofiberscopy. A total of 201 impacted stones were fragmented by PSWL setting the voltage at 2.5-3.5 kV, and the energy output at 2-3 J for each pulse of PSWL. Then the fragmented stones were extracted by choledochofiberscopy. The safety and efficacy of PSWL were observed during and after the procedure.

**RESULTS:** One hundred and ninety-nine of 201 impacted stones (99.0%) in the bile duct system were successfully fragmented using PSWL and extracted by choledochofiberscopy. The stone clearance rate for patients was 97% (65/67). Ten patients felt mild pain in the right upper quadrant of the abdomen, and could tolerate it well. Eleven patients had a small amount of bleeding from the mucosa of the bile duct. The bleeding was transient and stopped spontaneously within 2 min of normal saline irrigation. There were no significant complications during and after the procedure.

**CONCLUSION:** PSWL is a safe and effective method for fragmenting impacted stones in the bile duct system.

**Key words:** Impacted stone; Plasma shock wave lithotripsy; Choledochofiberscopy

## INTRODUCTION

Primary bile duct stones, especially intrahepatic ones, are common findings in Asian patients and challenging problems encountered in biliary surgery<sup>[1,2]</sup>. Retained and recurrent stones represent the two main problems in the surgical treatment of stones. With the application of intra- and postoperative choledochofiberscopy, the incidence of retained stones after surgery has been markedly reduced. Though many postoperative remnant stones can be extracted via choledochofiberscopy, it remains difficult to extract impacted stones or very large stones<sup>[3]</sup>. Impacted stones preclude insertion of the Dormia basket and cannot be captured with conventional techniques via choledochofiberscopy. Since large stones cannot pass through the T-tube fistula, it is both time consuming and frustrating to remove such stones. In order to solve this problem, we combined plasma shock wave lithotripsy (PSWL) with choledochofiberscopy. Both *in vitro* and *in vivo* studies have been conducted since the 1980s to test the safety and efficacy of this technique and the combination is widely used in clinical practice<sup>[4]</sup>.

## MATERIALS AND METHODS

### Patients

From September 1988 to April 2005, 67 patients (26 men and 41 women) with impacted stones or very large stones in the bile duct system underwent PSWL in combination with choledochofiberscopy in our hospital. The mean age of the patients involved was  $53 \pm 3$  years (range, 26-83 years). Of the 67 patients, 3 had a diagnosis of acute cholecystitis with cholelithiasis and previously underwent cholecystostomy with tube drainage, 36 patients had choledocholithiasis and underwent choledocholithotomy and common bile duct exploration with T-tube drainage, and 28 patients had a diagnosis of hepatolithiasis with or without stones in the extra-hepatic bile duct and received common bile duct exploration, intrahepatic bile duct stone removal via the common bile duct with the use of stone

**Table 1** Sites of impacted or huge remnant stones

Sites	Impacted stones, <i>n</i> (%)
Distal end of common bile duct	22 (10.9)
Common bile duct	14 (7.0)
Cyst duct	3 (1.5)
Hilus of hepatic duct	10 (5.0)
Left hepatic duct	24 (11.9)
Left internal hepatic duct	71 (35.3)
Left external hepatic duct	8 (4.0)
Right hepatic duct	14 (7.0)
Right anterior hepatic duct	3 (1.5)
Right posterior hepatic duct	32 (15.9)
Total	201 (100)

forceps and partial hepatectomy as well as T-tube drainage when necessary. No cholangiocarcinoma was encountered in these patients. In our study, 39 patients were transferred from other hospitals. About eight attempts or so were made to extract choledochofiberscopic stones. Twenty-eight patients were admitted to our hospital at the beginning of their treatment.

### Methods

All the patients underwent PSWL combined with choledochofiberscopic stone extraction without any anesthesia or sedation. The drainage tube was removed from the gallbladder or from the common bile duct, and a flexible choledochofiberscope (model CHF-T20), 6 mm in diameter with a 2.6-mm working channel (Olympus, Tokyo, Japan), was inserted through the drainage fistula into the gallbladder or the bile duct system. Once the impacted or large remnant stones were found, the PSWL probe (co-designed by the Institute of Physics at the Chinese Academy of Sciences and the Department of Surgery at the Third Hospital of Peking University) was inserted into the sites of the stones through the working channel of a choledochofiberscope. The tip of the PSWL probe (length, 100 cm; diameter 2 mm, flexibility similar to that of the catheter of Dormia basket) was targeted at the impacted stones and kept approximately 5 mm away. On the basis of the build-in PSWL circuit, the voltage switch was set at 2.5–3.5 kV and the energy output at 2–3 J for each pulse of PSWL. The number of PSWL pulses sufficient to break down a stone varied in each case. The treatment was continued until the impacted stones were fragmented sufficiently by PSWL to permit extraction with the Dormia basket (Olympus, SCOP Medicine, Tokyo, Japan) or passage into the duodenum via the sphincter of Oddi with normal saline perfusion. The bile ducts were irrigated during the procedure with normal saline and gentamycin, 4 U per 500 mL of normal saline, through the working channel of a choledochofiberscope<sup>[5]</sup>.

## RESULTS

In the 67 patients, 201 impacted or very large remnant stones were found in the bile ducts. The locations of stones are shown in Table 1. The gross appearance of the stones (39/201, 19.4%) found in the extrahepatic bile duct was consistent with that of the cholesterol stones. The

stones found in the intrahepatic bile duct (162/201, 80.6%) resembled the pigment stones. We measured the size of impacted stones by direct visualization on cholangiogram. No difference in stone size was found between cholesterol and pigment stone groups. The size ranged from 5 to 50 mm in diameter, with 16 stones smaller than 10 mm, 167 stones between 10 and 20 mm, 16 between 21 and 30 mm, and 2 larger than 30 mm in diameter, respectively.

In our study, 199 of the 201 stones in the extra- and intrahepatic bile ducts of 67 patients were fragmented successfully by PSWL, and then extracted under a choledochofiberscope. Each PSWL procedure took several minutes to half an hour. The success rate of fragmentation with PSWL was 99.0% (199/201). Twenty-one stones required fewer than 10 pulses of PSWL sparks for fragmentation, 65 stones 11–50 pulses, 78 stones 51–100 pulses and 37 stones more than 100 pulses. The maximum number of PSWL sparks required was 700 pulses and the minimum was only two. The average number of pulses used was  $52 \pm 151$ .

Of the 201 stones, two were not fragmented by PSWL, one remained unfragmented though four procedures of PSWL totaling 1 063 pulses were carried out. A repeat operation was necessary for this failed PSWL. A huge impacted hard stone, 50 mm in diameter, was found in the left internal hepatic duct, which was not amenable to extraction with stone forceps. The left hepatic duct was opened and the large pigment stone was eventually extracted via a bile duct incision. Another impacted stone in the neck of the gallbladder was not fragmented by PSWL because the patient refused to fragment it by PSWL. Cholecystectomy was performed for this patient at last and the tightly impacted cholesterol stone was extracted from an incision at the neck of the gallbladder.

In 65 of the 67 patients, the fragmented stones were extracted successfully using a Dormia basket which was inserted into the bile duct through the working channel of a choledochofiberscope. The stone clearance rate was 97% (65/67). In 35 patients, only one choledochofiberscope procedure was needed to achieve clearance of remnant stones, whereas 22 patients required 2 to 5 procedures, 7 patients 6 to 10 procedures and 1 patient 18 procedures. The average number of procedures was  $2 \pm 41$ . A total of 171 procedures were performed.

In the process of fragmenting stones with PSWL via choledochofiberscopy, all the patients felt vibration. Ten patients felt mild pain in the right upper quadrant of the abdomen and could tolerate it well. Eleven patients had a small amount of bleeding from the mucosa of the extra- and intrahepatic bile ducts. It was thought that the bleeding was induced by the pulse of PSWL sparks. The bleeding was transient and stopped spontaneously within 2 min of normal saline irrigation. No other serious PSWL-related complications occurred during and after the procedure.

## DISCUSSION

Impacted stone is one of the challenging problems in biliary surgery. Before the advent of PSWL, impacted stones or very large stones were removed using biopsy forceps through the working channel of a choled-

ochofiberscope. The procedure is time-consuming and often frustrating. To solve this problem, we designed the PSWL in 1980s and have conducted a series of experiments both *in vitro* and *in vivo* to test its safety and efficacy before its application in clinical practice. Fresh cholesterol and pigment stones can be fragmented effectively both *in vitro* and *in vivo* by PSWL<sup>[4]</sup>.

Plasma shock wave lithotripsy uses magnetic pressure ( $F = B^2/8\pi$ ) exerted on plasma. The plasma shock wave is derived from the magnetic pressure. The total magnetic energy is constant. Since magnetic field  $B$  can be increased by decreasing the area in which  $B$  exists, a stronger wave can be achieved with low energy. PSWL has three advantages. First, there is no impulse to luminal wall when PSWL is used to break down gallstones within the lumen. Second, when PSWL is combined with choledochofiberscopy, there is no heat injury and no vapor to obscure the visual field of a choledochofiberscope due to its low energy. Third, PSWL has its selection when it acts on an elastic buffer. Fragmentation of gallstones is achieved by impulsion of PSWL. When impulsion acts on elastomer, the fragmentation is selective. Therefore, PSWL can effectively break down nonelastic stones, while leaving the elastic soft tissue intact<sup>[5]</sup>.

In our study, 38 impacted or large cholesterol stones and 161 pigment stones were fragmented successfully by PSWL in the extra- and intra-hepatic bile ducts. The success rate of fragmentation was 99.0% (199/201), and the success rate of stone clearance was 97% (65/67).

Only two stones were not fragmented by PSWL. One impacted stone in the intrahepatic bile duct could not be fragmented by multiple procedures of PSWL with a total of 1 063 pulses of PSWL sparks delivered. Re-operation was performed for the involved patient, and the stone was too hard and too large (diameter, 50 mm) to be fragmented and extracted with stone forceps. The intrahepatic bile duct was opened and the stone was removed manually. Another cholesterol stone at the neck of the gallbladder was not fragmented by two procedures of PSWL with 84 pulses of PSWL sparks delivered. Cholecystectomy was performed for this patient, and a large hard cholesterol stone (diameter, 30 mm) at the neck of the gallbladder was removed.

In the present study, we successfully fragmented 199 impacted stones in extra- and intrahepatic bile ducts using PSWL when the conventional methods failed to remove them. The voltage switch was set at 2.5 - 3.5 kV, and the energy output was controlled within the range of 2 - 3 J at each pulse of PSWL. It may be very difficult to put a choledochofiberscope at the site of an impacted stone due to branches, strictures and angles of intrahepatic bile ducts. Therefore, it is unavoidable to spark directly on the impacted stone and the wall of bile duct in performing lithotripsy. In our study, 11 sites of intrahepatic bile ducts were sparked directly using the PSWL probe. Minor bleeding from the inflammatory mucosa of the bile duct occurred, and the bleeding stopped spontaneously within 2 min. No serious complications were found during and after the treatment, indicating that PSWL is a very safe method for breaking down stones *in vivo*.

The PSWL probe is flexible and can be easily placed at

the site of impacted stones to fragment the stones through the working channel of a choledochofiberscope. The position of the probe tip can be adjusted by pulling it back and forth through the working channel. The best position is 5 mm away from the stone. At this position, the PSWL probe can release energy most effectively.

Electrohydraulic shock wave lithotripsy (ESWL) and PSWL have their similarities and differences. Using discharge in fluid to induce high-amplitude hydraulic pressure waves of varying wavelengths, ESWL can fragment stones extracorporeally or intracorporeally. The extracorporeal lithotripter uses the ellipsoid reflector to reflect the shock wave into the intracorporeal site to break down the stones. The ellipsoid reflector has two focus points. One is extracorporeal, where the shock wave is emitted by discharge. The other is intracorporeal, where stones are located. Stone fragmentation and clearance rates of 76%<sup>[6]</sup> and 92%<sup>[7]</sup> have been achieved. Our study showed that PSWL was more effective than ESWL.

It was reported that the overall complication rate for ESWL is 13.2% - 22%<sup>[7,8]</sup>. Bleeding and perforation are the main problems. Perhaps the power of ESWL is strong enough not only to fragment stones, but also to damage the bile duct wall. Harrison *et al*<sup>[9]</sup> reported that to avoid grave complications, the ESWL probe should not directly contact the bile duct wall. However, PSWL may safely break down the stones without damaging the bile duct wall when the PSWL probe is in contact with the bile duct wall, suggesting that the safety of PSWL is superior to that of ESWL.

Laser has been used to fragment stones in common bile duct<sup>[10]</sup> and intrahepatic bile duct<sup>[11,12]</sup>. Orii *et al*<sup>[11]</sup> reported that yttrium-aluminum laser has enough power to crush pigment stones, but its efficacy on cholesterol stones is not satisfactory. Prat *et al*<sup>[13]</sup> reported that bile duct stones can be fragmented by laser lithotripsy. The overall success rate for stone clearance is 87.5% and the complication rate is 18.8%. Harris *et al*<sup>[14]</sup> reported that the success rate for fragmentation of stones by laser lithotripsy is 96%, whereas the complication rate is 28%. The complications may be due to the impact of laser fiber tip on the bile duct wall<sup>[13]</sup>. Therefore, care must be taken to advance the laser filament to the end of the scope, with the scope straight outside the patient. The relatively rigid, sharp filament may perforate the side wall of the working channel if it is advanced with force through a bent scope. Firing the laser, while the tip of the filament is inside the working channel can also damage the lining of the channel<sup>[14]</sup>. These shortcomings limit the efficacy of laser lithotripsy. Hochberger *et al*<sup>[10]</sup> have strongly suggested that laser can be used in the gallbladder and common bile duct, but not in intrahepatic duct. In terms of safety, PSWL is also superior to laser. The use of mechanical lithotripsy is limited to the treatment of stones in the common bile duct and in the gallbladder. It cannot be used to treat intrahepatic bile duct stones<sup>[13]</sup>. Ultrasound lithotripsy is limited to break down stones in the gallbladder because it cannot reach the bile duct<sup>[16]</sup>.

In conclusion, PSWL is a very safe and effective method for *in vivo* fragmentation of impacted stones or large remnant stones. The PSWL combined with

choledochofiberscopy, can fragment and clear most stones when a choledochofiberscope is inserted into the bile duct system.

## Abstract

**AIM:** To evaluate the diagnostic angiography and therapy for acute massive hemorrhage in gastrointestinal tract.

**METHODS:** Twenty-five cases of acute hemorrhage in gastrointestinal tract admitted between April 2002 and September 2004 were reviewed and analyzed by angiography and embolotherapy.

**RESULTS:** Fifteen patients were men and ten patients were women. The Seldinger technique and method of coaxial duct were used to get access to the bleeding region. PVA particles, gelfoam, and coils were used for embolism. All bleeding sites could be confirmed and were successfully embolized. Hemostasis was achieved in all the patients without bleeding again. The cure rate was 100%.

**CONCLUSION:** Interventional therapy can not only ascertain the bleeding site, but also stop the bleeding. The method is simple and the effect is certain.

## INTRODUCTION

Great achievements have been made in interventional therapy in China since 1980s. The method of diagnosis and therapy for hemorrhage in gastrointestinal tract have made great progress<sup>[1]</sup>. Transcatheter catheter embolization is widely used in the treatment of acute massive hemorrhage in gastrointestinal tract. Selective angiography can confirm the bleeding site in gastrointestinal tract. We carried out selective or superselective embolotherapy to achieve quick hemostasis. Selective angiography is the most effective measure to detect hemorrhage<sup>[2]</sup>.

## MATERIALS AND METHODS

### Patients

Twenty-five patients with hemorrhage in the gastrointestinal tract admitted between April 2002 and September 2004 were treated with interventional therapy. Fifteen patients were men and ten patients were women. There were 10 cases of gastric hemorrhage, 1 case of duodenal hemorrhage, 9 cases of small intestinal hemorrhage, 3 cases of colonic hemorrhage, and 2 cases of liver disruption. The major clinical manifestation was substantive bloody stools. Some cases had hematemesis. Hemorrhagic shock occurred in five cases. All patients received treatment but hemorrhage could not be controlled. The diastolic blood pressure was lower than 40 mmHg in four patients.

### Equipment and materials

Angiostar Plus-type DSA machine was purchased from Siemens Company. Catheter 4F and RADISITE® SP catheter 3 F were purchased from Cook Company. The contrast medium ultravist® 370 was obtained from Schering Company. PVA particles and coils were bought from Cook Company. All patients received celiac arteriography as well as superior and inferior mesenteric arteriography to identify the bleeding artery.

### Methods

The patients underwent celiac arteriography as well as superior and inferior mesenteric arteriography. Eight patients received superselective catheterization to get access to the corresponding site of feeding artery and then embolotherapy was carried out with the corresponding materials.

## RESULTS

A total of 25 patients underwent angiography for

**Figure 1** A 25-year-old patient with acute life-threatening gastrointestinal bleeding. **A:** Extravasation was made from a ramification of gastrointestinal artery. **B:** Superselective angiography of the bleeding artery as an aneurysm sign of a ramification belonging to gastrointestinal artery. **C:** Control angiography after embolization with 500-710 µm PVA particles and coils demonstrating complete hemostasis.

**Figure 2** A 51-year-old patient with acute gastrointestinal bleeding. **A:** Contrast medium extravasation from a ramification of gastrointestinal artery. **B:** Complete hemostasis after embolization with 500-710 µm PVA particles and coils.

acute gastrointestinal bleeding. There were 15 men (60%) and 10 women (40%) (mean age 54 years, range 34-74 years). Among the 25 patients, 3 were accompanied with hematemesis, 3 had shock, 15 had bleeding from mesenteric superior artery confirmed by angiography, 2 had hemorrhage from intestinum rectum, 6 had gastric hemorrhage, and 2 had liver arteriorrhesis. Eighteen cases underwent embolism with PVA particles or PVA particles plus gelfoam and seven cases underwent coil embolism. Angiographic embolization was successful in 25 patients with gastrointestinal bleeding, and the success rate was 100%. There were no intestinal parva necrosis and other severe complications in this group (Figure 1 and 2).

## DISCUSSION

Acute massive hemorrhage in gastrointestinal tract is one of the most acute abdomen<sup>[3]</sup>. The mortality of emergency surgery is about 10%<sup>[4]</sup>. It is difficult to identify the bleeding site and cause of hemorrhage. The treatment of hemorrhage in gastrointestinal tract includes non-operative treatment, exploratory laparotomy and interventional embolotherapy<sup>[5,6]</sup>.

Though endoscopy has been used universally, it still has some limitations in diagnosis<sup>[7,8]</sup>. Antishock and hemostasis

can decrease hemorrhage but cannot achieve permanent hemostasis.

Intervention embolotherapy for gastrointestinal hemorrhage is a convenient and efficient microinvasive therapy<sup>[9]</sup>. When acute hemorrhage in gastrointestinal tract occurs, hemorrhage is often massive<sup>[10,11]</sup>. According to the leakage location of the contrast medium, we performed superselective catheterization for feeding artery embolism, which achieved hemostasis immediately, suggesting that it is a practical and effective method for old and weak patients and those who cannot tolerate operation. Embolotherapy for lower digestive tract hemorrhage is a choice of treatment<sup>[12]</sup>. We proved that it could prevent intestinal tract ischemia.

Examination of DSA has the most important clinical value and can prevent other tissue overlapping and dynamically observe the status of artery ramification, capillaries and refluxing veins, particularly for intestinal parva as well as ascending, transverse, and descending colon. The major cause of hemorrhage is tumor and vascular malformation. Our study proved DSA could show tumor blood vessel malformation and precise image for further embolotherapy and exauresis.

Gelfoam is safer and PVA particles may be better for vascular malformation because they can achieve permanent embolism. With regard to the magnitude of PVA particles and coils, we prefer to use larger particles instead of the smaller ones.

When gastrointestinal tract hemorrhage occurs, the body constitution of patients is possibly weak and the patients usually have hemorrhagic shock<sup>[13]</sup>. Angiography can find out the source of hemorrhage and is an important treatment modality<sup>[14,15]</sup>.

In conclusion, angiography with embolization can successfully control acute massive gastrointestinal bleeding. Embolotherapy can stop acute bleeding and prolong the life of patients.

### Abstract

**AIM:** To investigate the therapeutic effects of resveratrol (RESV) as a free radical scavenger on experimental severe acute pancreatitis (SAP).

**METHODS:** Seventy-two male Sprague-Dawley rats were divided randomly into sham operation group, SAP group, and resveratrol-treated group. Pancreatitis was induced by intraductal administration of 0.1 mL/kg 4% sodium taurocholate. RESV was given intravenously at a dose of 20 mg/kg body weight. All animals were killed at 3, 6, 12 h after induction of the model. Serum amylase, pancreatic superoxide dismutase (SOD), malondialdehyde (MDA), and myeloperoxidase (MPO) were determined. Pathologic changes of the pancreas were observed under optical microscope.

**RESULTS:** The serum amylase, pancreatic MPO and the score of pathologic damage increased after the induction of pancreatitis, early (3, 6 h) SAP samples were characterized by decreased pancreatic SOD and increased pancreatic MDA. Resveratrol exhibited a protective effect against lipid peroxidation in cell membrane caused by oxygen free radicals in the early stage of SAP. This attenuation of the redox state impairment reduced cellular oxidative damage, as reflected by lower serum amylase, less severe pancreatic lesions, normal pancreatic MDA levels, as well as diminished neutrophil infiltration in pancreas.

**CONCLUSION:** RESV may exert its therapeutic effect on SAP by lowering pancreatic oxidative free radicals and reducing pancreatic tissue infiltration of neutrophils.

### INTRODUCTION

Resveratrol (3,5,4'-trihydroxystilbene) is a naturally occurring phytoalexin present in grapes, fruits, and a variety of medicinal plants<sup>[1]</sup>. It is the major active component of Rhubarb and Giant Knotweed Rhizome, etc., in traditional Chinese medicine. In *in vitro*, *ex vivo*, and *in vivo* experiments, RESV displays diverse pharmacological effects including modulation of lipoprotein metabolism and cardiovascular protection<sup>[2]</sup>, anti-inflammation<sup>[3]</sup>, platelet antiaggregatory activity<sup>[2]</sup>, antimicrobial activity<sup>[4]</sup>, antiallergic activity<sup>[5]</sup>, anticancer properties<sup>[6,7]</sup>, and most notably, antioxidant properties<sup>[8]</sup>. In the present study, the sodium taurocholate-induced model of SAP was used to investigate the effects of RESV on SOD, MDA, MPO, serum amylase, and pancreatic pathological change to assess the role of oxidative stress in SAP and the therapeutic effects of RESV on SAP.

### MATERIALS AND METHODS

#### Materials

RESV was obtained from Huike Botanical Development Co, stocked solution of RESV was made in Tween-80 at the concentration of 10 mg/mL and kept frozen. Sodium taurocholate was purchased from Sigma Chemical Co. SOD, MDA, and MPO assay reagents were from Nanjing Jiangcheng Bioengineering Institute.

#### Animals

Male Sprague-Dawley rats weighing 250-300 g, purchased from Laboratory Animal Center attached to Medical College of Xi'an Jiaotong University, were used. All animals were housed in a macroion cage at 22-24 °C in a 12/12-h light/dark cycle. The animals were given a standard rat chow and fasted overnight with free access to water before the experiment. Care was provided in accordance with the "Guide for the care and use of laboratory animals" (NIH publication No. 85-23, revised in 1996). The study was approved by the Subcommittee on Experimental Animal Care of our institution.

**Table 1** Pancreatic histopathologic scoring in rats (mean  $\pm$  SE)

	<i>n</i>	Sham operation	SAP	RESV-treated
3 h	8	0.283 $\pm$ 0.112	9.236 $\pm$ 0.624 <sup>b</sup>	5.283 $\pm$ 0.646 <sup>d</sup>
6 h	8	0.219 $\pm$ 0.171	11.357 $\pm$ 0.535 <sup>b</sup>	5.598 $\pm$ 0.417 <sup>d</sup>
12 h	8	0.112 $\pm$ 0.051	13.559 $\pm$ 0.636 <sup>b</sup>	6.003 $\pm$ 0.717 <sup>d</sup>

<sup>b</sup> $P < 0.01$  vs Sham operation; <sup>d</sup> $P < 0.01$  vs SAP group.

**Figure 1** Comparison of serum amylase in rats.

### Induction of severe acute pancreatitis

The rats were anesthetized by an intraperitoneal injection of pentobarbital (30 mg/kg, Sigma). Through a midline incision, the duodenum and the pancreatic bile duct were identified, and the duodenal wall was punctured with a 24-gauge Teflon catheter. The catheter was advanced into the common pancreatic bile duct. A microvascular clamp was placed on the duct at the hilum of the liver, a microtube clamp was placed around the catheter and the wall of the duct close to the duodenum to prevent reflux. Four percent sodium taurocholate (1 mL/kg body weight, Sigma T-0750) was injected into the pancreatic bile duct for 60 s. The clamp remained in place throughout the intraductal infusion to prevent misdirected flow into the biliary system.

### Experimental design

Seventy-two rats were randomly divided into sham operation group: laparotomy followed by tipping of the pancreas without any infusion, SAP group: receiving infusion of 40 g/L sodium taurocholate into the pancreatic bile duct, RESV-treated group: perfused with RESV at a dose of 20 mg/kg body weight through vena dorsalis penis 10 min after the induction of SAP. After 3, 6, and 12 h, eight rats from each group were killed and blood was taken from the left ventricle of the heart. The samples were centrifuged (3 000 r/min, 10 min, 4°C) and serum was derivatized and immediately stored at -70 °C for amylase determination. The pancreas was removed; the head of pancreas was fixed in 40 g/L paraformaldehyde for histologic analysis. Caudal pancreatic tissue was powdered using a mortar and pestle on dry ice and immediately stored

at -70 °C for determining pancreatic SOD, MDA, and MPO.

### Histopathologic analysis

Tissue samples of the pancreas were fixed in 40 g/L paraformaldehyde and embedded with paraffin. Five-micrometer thick sections were stained with hematoxylin/eosin and examined and graded as previously described<sup>[9]</sup>. The total surface of the slides was scored by one blinded pathologist for four different variables (edema, acinar necrosis, hemorrhage and fat necrosis, inflammation and perivascular infiltrate) to determine the severity of pancreatic injury.

### Detection of serum amylase and measurement of pancreatic SOD, MDA, and MPO

Amylase activity in serum was determined using an automatic biochemistry analyzer (Hitachi 7170). Pancreas was homogenized in physiological saline or 5 g/L HTAB using ultrasonication. The SOD content was measured using the xanthine oxidase technique based on the spectrophotometric monitoring of SOD-mediated reduction of DTNB at 550 nm. The concentration of MDA was quantified by thiobarbituric acid reaction and MPO contents were determined as described by Bhatia *et al*<sup>[10]</sup>.

### Statistical analysis

Results were expressed as mean  $\pm$  SE. Statistical analysis was done using the SPSS10.0 software package. One-way analysis of variance was used to establish whether the difference among the three groups was statistically significant.  $P < 0.05$  was considered statistically significant.

## RESULTS

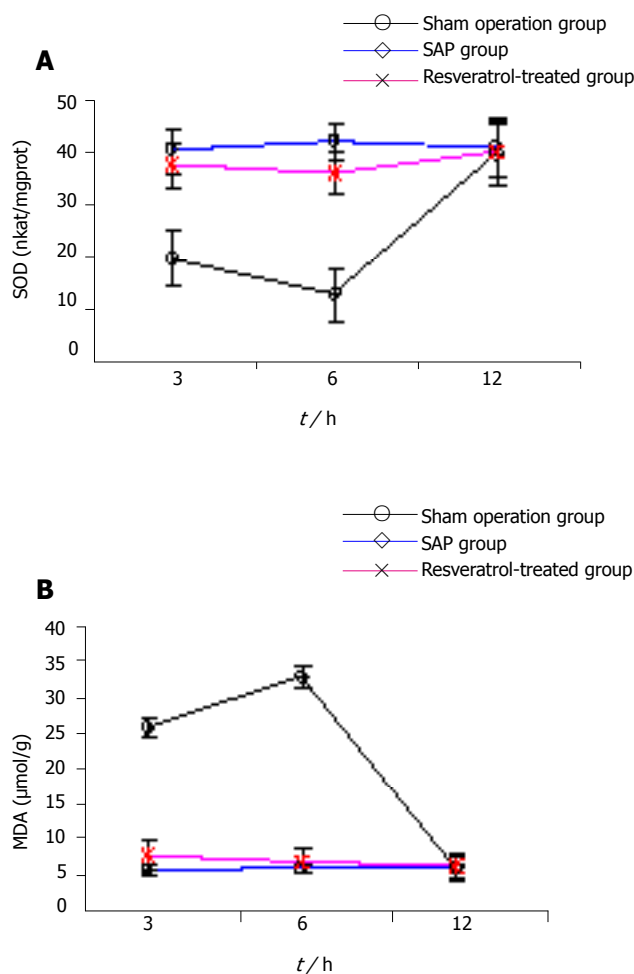

### Histopathology

There was no or a small amount of clear ascitic fluid in sham operation group. More than 8 mL turbid hemorrhagic ascites could be seen in all rats of SAP group. No obvious change or slight edema could be seen in sham operation group. Pancreas in SAP group displayed disparate edema with punctiform or lamellar hemorrhage and necrosis. Saponified spots could be seen at pancreas, epiploon, mesentery, peritoneum, and perinephric fat. Pancreatic tissue was normal in sham operation group. In SAP group, pancreatic tissue displayed interstitial edema, widened lobula interspace, inflammatory cell infiltration, hemorrhage and necrosis. Microthromb could be found inside the small vessels around focal necrosis of the pancreas. In contrast, in RESV-treated group, the ascitic fluid diminished significantly and turbidity was lower than that in SAP group. Saponified spots, pancreatic edema, necrosis, inflammatory cell infiltration decreased significantly in RESV-treated group (Table 1).

### Serum amylase

Compared to sham operation group, the serum amylase in SAP group increased at all time points ( $P < 0.01$ ), decreased significantly in RESV-treated group when compared to SAP group at the corresponding time points ( $P < 0.01$ , Figure 1).

**Figure 2** Comparison of pancreatic SOD(A) and MDA(B) at different time points.

**Figure 3** Comparison of pancreatic MPO at different time points.

### SOD and MDA in pancreatic tissue

Compared to sham operation group, pancreatic SOD descended and MDA increased in SAP group at 3 and 6 h ( $P < 0.01$ ), but there was no difference between the two groups at 12 h in SOD and MDA. In contrast, pancreatic SOD increased and MDA descended in RESV-treated group at 3 and 6 h when compared to SAP group ( $P <$

0.01), but there was no difference in SOD and MDA at 12 h between two groups (Figures 2A and 2B).

### MPO in pancreatic tissue

Compared to sham operation group, the pancreatic MPO in SAP group increased at all time points ( $P < 0.01$ ), but decreased significantly in RESV-treated group when compared to SAP group at the corresponding time points ( $P < 0.01$ , Figure 3).

## DISCUSSION

The pathogenesis and therapeutics of SAP are constantly emphasized in general surgery. Sanfey *et al.*<sup>[11]</sup> have suggested a possible involvement of oxygen free radicals (OFRs) in acute pancreatitis. In 1995, Kishimoto *et al.*<sup>[12]</sup> detected pancreatic OFRs in acute pancreatitis using the technique of chemiluminescence probe and high sensitive photon counting and found that OFRs emerge 2-3 h after the induction of acute pancreatitis, demonstrating that there exists peroxidation in acute pancreatitis. OFRs can attack polyunsaturated fatty acid's aldehyde group inside the biomembrane, initiating lipid peroxidation and accordingly forming lipid peroxidation products, as such MDA, which result in the loss of membrane stability and release of acinar cell enzyme precursors, and activate phospholipase A1 which can decompose lecithinum inside cellular membrane, further causing tissue damage. SOD is an internal antioxidant. OFRs *in vivo* are augmented when acute pancreatitis develops, which results in the consumption of antioxidant, SOD activity decrease. Therefore, it is difficult to prevent damage to the pancreas and other organs by lipid peroxidation. Detection of pancreatic SOD and MDA can reflect the peroxidation of pancreatic acinar cells and indirectly reflect the damage due to OFRs.

A number of antioxidant therapies can improve pancreatitis induced by the administration of cerulein<sup>[13]</sup> and infusion of taurocholate<sup>[14]</sup>. Lasztity *et al.*<sup>[15]</sup> found that when enteral formula enriched with n-3 polyunsaturated fatty acids is used in the treatment of acute pancreatitis, the erythrocyte SOD activity is elevated significantly. Leonard *et al.*<sup>[8]</sup> showed that RESV can scavenge OFRs as measured by spin trapping competitions using sodium formate as a second free radical scavenger, and is effective in inhibiting lipid peroxidation of cellular membranes. In the present study, when compared to sham operation group, 3 h after the induction of SAP, pancreatic SOD decreased significantly, reaching perigee at 6 h, and returned to the level of sham operation group at 12 h. In contrast, 3 h after the induction of SAP, pancreatic MDA increased significantly, reaching to apogee at 6 h, and returned to the level of sham operation group at 12 h. Simultaneously, the serum amylase and pancreatic histopathologic score increased gradually. The results indicated that overproduction of OFRs occurs in early SAP and is a significant factor for aggravating pathogenetic condition. This is coincident with the research by Reinheckel *et al.*<sup>[16]</sup>. When compared to SAP group, pancreatic SOD in RESV-treated group increased significantly at 3 and 6

h ( $P < 0.01$ ), whereas pancreatic MDA in RESV-treated group decreased significantly at 3 and 6 h ( $P < 0.01$ ). On the other hand, compared to SAP group, both serum amylase and pancreatic histopathologic score in RESV-treated group decreased at all three time points ( $P < 0.01$ ) indicating that RESV can depress earlier OFR production and lipid peroxidation of cellular membrane, diminish enzyme precursor release and necrosis of acinar cells, thus ameliorating pancreatic pathological lesions.

Neutrophils are the other major cellular source of OFRs during acute pancreatitis<sup>[17,18]</sup>, and can directly release several inflammatory cytokines, evoking systemic inflammatory reactive syndrome (SIRS). since OFRs can exert a chemoattractant effect, thereby promoting accumulation of leukocytes in the inflamed gland<sup>[17]</sup>. Decreased acinar OFR production after RESV treatment may contribute to the reduced neutrophil infiltration, further ameliorating SIRS in SAP. In our study neutrophil sequestration within the pancreas was estimated by measuring tissue MPO activity. When compared to SAP group, the pancreatic MPO decreased at all the time points in RESV-treated group ( $P < 0.01$ ). Moreover, studies showed that RESV can suppress the activation of NF- $\kappa$ B. Thus, RESV treatment might lead to the suppression of NF- $\kappa$ B activation and the subsequent prevention of several inflammatory mediator genes from being actively expressed<sup>[19-21]</sup>. This mechanism may also help to reduce the sequestration of neutrophils in the pancreas and the associated OFR generation, thus effectively attenuating pancreatic damage.

In conclusion, overproduction of OFRs takes place in early SAP, and is a significant factor for aggravating pathogenetic condition. RESV can ameliorate pathological lesions in the pancreas by lowering pancreatic OFRs and reducing pancreatic tissue infiltration of neutrophils. It may have certain therapeutical effects on acute pancreatitis.

### Abstract

**AIM:** To describe the risk profile of patients in hospital with hepatitis C virus (HCV) infection in Poland.

**METHOD:** Using a structured questionnaire, all patients with confirmed HCV infection were interviewed about the risk factors.

**RESULTS:** Among the 250 patients studied, transfusion before 1993 was the primary risk factor in 26%, intravenous drug use setting in 9% and occupational exposure in health-care in 9%. Women were more likely to have a history of occupational exposure or transfusion before 1993 and less likely to undergo minor surgery. Known nosocomial risk factors (transfusion before 1993, dialysis) were responsible for 27% of infections, probable nosocomial factors (transfusions after 1992, minor surgery) for 14% and further 9% were occupationally acquired infections.

**CONCLUSION:** A careful history investigation can identify a known or probable risk factor for HCV acquisition in 59% of patients with HCV infection. Preventive activities in Poland should focus on infection control measures in health-care setting.

### INTRODUCTION

Hepatitis C virus (HCV) is the most common chronic blood-borne infection in developed countries and the major cause of chronic liver disease, cirrhosis and hepatocellular cancer. Since no effective vaccine against HCV infection is available, reducing the spread of the disease relies on primary prevention activities that can cut the transmission routes and reduce or eliminate the risk of acquiring infection. Since its discovery in 1989, much has been learnt about the ways in which HCV is transmitted. Well-known and common modes of transmission involve transfusions received before the routine screening of blood donors was implemented (in Poland since July 1992), intravenous drug use (IVDU), hemodialysis, and occupational exposure to the infected blood in health-care facilities<sup>[1-3]</sup>. Sexual transmission of HCV has also been demonstrated, but it is known to occur with less frequency compared to hepatitis B or HIV. Other risk factors are considered, but their role has not been established convincingly. Some case-control studies linked HCV infection to surgical or dental procedures, endoscopies, tattooing, body piercing, acupuncture, household contact with an anti-HCV person, and intranasal cocaine use. The results of the studies are, however, conflicting and some expert groups have found no associations between those exposures and HCV infections. In fact, there may be geographical differences in predominance of certain routes of transmission over others. Although the data on HCV epidemiology in Eastern Europe are scarce, the available literature and experts' opinions indicate that surgical and parenteral procedures (independent from blood transfusions) account for 40%-71% of HCV infections<sup>[4]</sup>.

The precise data on HCV prevalence in the general population in Poland is lacking since no population-based study was carried out. According to WHO estimates about 1.4% of general Polish population may be infected with HCV, which means about 560 000 persons in the whole country<sup>[5]</sup>. At the same time, statistics of the National Institute of Hygiene in Warsaw registered about 13 000 infections in the years 1997-2003 (compulsory registration of HCV started in 1997)<sup>[6]</sup>. It is clear that most people with HCV infection in Poland are unaware of their status, even if we assume under-reporting by medical and laboratory services.

In Poland, in contrast to USA or UK, where drug use prevails, many HCV cases are presumed to be nosocomial infections. Previous studies based on the samples of patients hospitalized for acute or chronic hepatitis C linked as many as 59%-71% of HCV infections to medical procedures<sup>[7]</sup>. Our recent case-controlled study aiming at identifying medical procedures associated with exposure to HCV found that transfusions (OR = 3.7, 95%CI = 2.2-6.3), minor surgery (OR = 3.2, 95%CI = 1.5-6.7) and dental care (OR = 2.3, 95%CI = 1.4-4.0) were independently associated with HCV infection<sup>[8]</sup>. In Poland, hepatitis B virus (HBV) infection, which spreads in a similar way to HCV, is also frequently a medically linked disease<sup>[9]</sup>.

Identifying risk factors is important in order to plan preventive activities and is also necessary to target screening for people with higher pre-screening probability of the disease.

We undertook this study in order to describe the risk profile in a population of patients seeking care in a tertiary care level hospital in a defined region of Poland.

## MATERIALS AND METHODS

### Patients

The study took place in the Department of Infectious Diseases, Medical University of Białystok (north-eastern Poland) between June 1, 1998 and December 31, 2004. All consecutive adult patients with acute or chronic hepatitis C admitted to the department were invited to participate. This department is the biggest hepatologic center in Podlaskie Region (1 200 000 inhabitants, north-eastern Poland), where the majority of patients with chronic viral hepatitis from the whole region are referred for evaluation and antiviral treatment.

The diagnosis of hepatitis C was based on the presence of anti-HCV antibodies (ELISA, third generation test, IMx MEIA, Abbott, Chicago, USA) and was confirmed by means of HCV-RNA testing (qualitative nested RT-PCR). The standard procedures with a suspected case of chronic hepatitis C include initial testing for anti-HCV and determination of ALT levels, and repeating the tests for anti-HCV and ALT levels after 6 mo. If anti-HCV is repeatedly positive and ALT levels remain elevated above the normal range, patients are tested for HCV-RNA, and liver biopsy is performed. Since confirmatory tests using immunoblotting were not available, only the patients who were positive for anti-HCV and HCV-RNA were included in the present study.

### Methods

All patients were interviewed extensively by one of the two doctors with the use of a structured questionnaire. The questionnaire covered demographic data (age, sex, education, job, place of living) and information about the possible risk factors. The risky exposures considered in our study were as follows: (1) known risk factors, such as IVUD, transfusions of blood or blood products before 1993, employment as a health-care worker with exposure to blood or other fluids, hemodialysis, and sexual contact with an anti-HCV positive person; (2) probable risk factors, such as household (non-sexual) contact with an

**Table 1** Prevalence of all known and probable risk factors among 250 chronic hepatitis C patients (n, %)

Risk factors	All n = 250 (100%) n (%)	F n = 92 (36.8%) n (%)	M n = 158 (63.2%) n (%)
Known risk factors			
IVDU	22 (8.8)	4 (4.4)	18 (11.4)
Transfusion <1993	67 (26.8)	31 (33.7)	36 (22.8)
Hemodialysis	5 (2.0)	3 (3.3)	2 (1.3)
Occupational exposure - health-care	34 (13.6)	21 (22.8) <sup>1</sup>	13 (8.2) <sup>1</sup>
Sexual exposure to HCV	2 (0.8)	0 (0.0)	2 (1.3)
Probable risk factors			
Transfusions after 1992	17 (6.8)	6 (6.5)	11 (7.0)
Minor surgery	36 (14.4)	5 (5.4) <sup>2</sup>	31 (19.6) <sup>2</sup>

anti-HCV positive person, transfusion after 1992, and minor surgery; and (3) other potential risk factors for HCV infection, such as surgeries, endoscopies, tattoos, previous hospitalizations, and acupuncture. In further analysis, the patients with more than one risk factor were classified as having only the risk factor according to the hierarchy. The hierarchy of risk factors used in our study was based on the data from medical literature as well as on the results of our previous study indicating the link between history of minor surgery, transfusion after 1992 and increased risk for HCV infection in Poland. We did not include dental care (which had also been associated with HCV infection) into probable risk factors because of the low specificity of that exposure with nearly 90% of the study group providing history of dental treatment. For comparisons between groups, the patients were stratified by age (<45 or ≥ 45 years) and by gender.

### Statistical analysis

The statistical calculations were performed with the use of statistical package, Statistica Pl. Fisher's exact test was used for the analysis of differences in risk factors between groups (males vs females, younger vs older and younger vs older patients of the same sex). A P value < 0.05 was considered statistically significant.

## RESULTS

A total of 420 anti-HCV positive individuals were evaluated during the study period and 250 were eligible for the study. In the remaining 170 cases, the results of HCV-RNA testing were either negative or unavailable. Among the study group, there were 92 females (36.8%) and 158 males (63.2%). Patients' age ranged from 18 to 70 years with the mean age of 39.7 (± 2.8) years. Females were found to be obviously older compared to males (mean age, 43.4 vs 38.4 years, P < 0.05). Majority of the patients came from urban setting (219 patients, 87.6%) and had secondary (120, 48.0%) or elementary (80, 32.0%) education.

Table 1 presents the overall prevalence of the considered

known and probable risk factors. In the studied hepatitis C group, there were no cases of household (non-sexual) exposures to HCV and that factor is not presented in the table. The most prevalent reason was transfusion before 1993 in 67 (26.8%) cases, followed by minor surgeries in 36 (14.4%) cases, occupational exposure in 34 (13.6%) cases during health-care and IVDU in 22 (8.8%) cases. Table 2 displays hierarchical distribution of primary risk factors for HCV infection (each case is represented only once). Overall known risk factors could be identified in nearly 45% of patients and probable in further 14%. About 41.0% had no known or probable risk factors according to the criteria established in our study. Three factors, such as history of transfusion before 1993, occupational exposure and minor surgery, were significantly associated with gender. The first two factors occurred more frequently in females while minor surgery was more common among

males. There was a clear tendency towards more frequent occurrence of IVDU among males, but the difference did not reach statistical significance.

Overall females were more probable than males to have known risk factors (53.3% vs 39.9%, *P* < 0.05). The prevalence of drug use in the younger group (21/152, 13.8%) was significantly higher than that in the older group (1/98, 1.0%, *P* < 0.05). IVDU in our study was almost limited to males under the age of 45 with 82% (18/22) of patients.

In our study, females ≥45 years were the group with the highest frequency (49%) of unidentified (without known or probable risk factors) source of HCV infection, but the difference was not statistically significant.

Table 3 depicts the overall prevalence of other potential exposures to HCV among 103 patients without known or probable risk factors. Only one person denied all of the considered risk factors.

Known nosocomial risk factors (hemodialysis, transfusion before 1993) were responsible for 27% of all infections, while probable nosocomial risk factors (transfusion after 1992, minor surgery) were responsible for 14% of infections. Further 9% were occupationally acquired infections in health-care workers. Altogether at least 50% of all HCV infections in our study were associated with a health-care sector.

## DISCUSSION

Hepatitis C infection affects approximately 560 000 people in Poland. Difficulties in identifying risky exposures result from the fact that most cases are clinically silent and remain undiagnosed for many years. In addition, some potential risk factors (e.g., dental care, hospitalizations) are very common and their non-specific nature hinders

establishing their role in HCV transmission and makes targeting prevention measures difficult.

The demographic characteristics of our sample were comparable to the data collected by National Institute of Hygiene in Warsaw for all 2 255 new hepatitis C cases registered in Poland in 2003 (incidence 5.90/100 000 inhabitants)<sup>[6]</sup>. In our group, males constituted 63% of cases and males under the age of 45 made up nearly 44% of all HCV infections. The national statistics for 2003 indicate that 57% of HCV infections occurred in males, and younger males between 20 and 24 years of age had the highest incidence of infection (10.8/100 000 inhabitants). Similarly, as in our findings, majority of the registered new cases came from urban setting (80.0%). Currently, there are no national reports on the distribution of risk factors among registered HCV cases in Poland.

In our study, known risk factors could be identified in nearly 45% of HCV infections. As expected, transfusions before 1993 represented the most prevalent known exposure. Transfusion before 1993 could be documented in more than 60% of HCV infected females under the age of 45. In a majority of cases, the infection was the iatrogenic effect of postpartum iron-deficiency anemia treatment. Blood transfusion was frequently used to raise the hemoglobin levels and to allow earlier discharge from hospital.

Primary prevention activities have been already undertaken and current procedures have virtually eliminated the risk of HCV infection from blood transfusion. The knowledge of history of transfusion is important for secondary prevention, which means target screening for HCV infection. Testing should be routinely offered to the persons with the history of transfusions before 1993, accompanied by appropriate counseling and medical management.

IVDU was responsible for 9% of infections and was almost exclusively limited to males under the age of 45. At the same time, younger males made the group with high frequency of no known or probable risk factors. It may be speculated that, at least in some of those cases, incidental drug use could be responsible. Many of American blood donors found to be positive for HCV infection revealed the history of drug use, despite initial denial of such exposure<sup>[10]</sup>. In our study, the rate of HCV infections resulting from drug use among males <45 years of age (17%) was still much lower than that reported in similar groups in the United States (59%-60%)<sup>[11,12]</sup>. This finding confirms the primary role of nosocomial HCV spread in Poland and may reflect lower numbers of drug users in Poland compared to USA or other Western European countries. Estimates of the prevalence of problem drug use (defined as injecting drug use or long duration, regular use of opiates, cocaine and/or amphetamines) range in European Union countries between 2 and 10 cases per 1 000 of the population aged between 15 and 64 years, and Poland remains in the low range<sup>[13]</sup>. As in many Central and Eastern European countries, the major problem regarding drug use in Poland concerns heroin. Opiate users represent the biggest proportion of persons admitted to residential treatment due to drug addiction.

Shared usage of contaminated needles and syringes results in high prevalence of HCV antibodies. Among 100 parenteral drug users in Warsaw, 76% were found to be seropositive for anti-HCV<sup>[14]</sup>. Another possible explanation for relatively low percentage of intravenous drug users in our study might be failing secondary prevention of HCV infection among drug-dependant population in Poland. In this respect, it is possible that drug users are under-represented in the hospital samples because of the hindered access to screening procedures, health-care services and long-term antiviral treatment.

Occupational infections constituted nearly 10% of primary risk factors in our study and occurred mostly in women in both age groups. Nurses are the predominant occupational group injured by needles and other sharp-edged instruments, because they are the largest segment of the workforce in health-care, and also because they may have a higher rate of injury. This group sustains about 50% of all needle-stick injuries. The accidents typically happen when workers are recapping needles, transferring body fluids from one container to another, or when they do not dispose the used needles properly<sup>[15,16]</sup>. In 2001, hepatitis C constituted the major cause of all occupational blood-borne infections in health-care workers in Poland<sup>[17]</sup>.

In this study, known nosocomial and probable nosocomial risk factors were responsible for 27% and 14% of all infections, respectively. Fortunately, the major nosocomial risk factor, transfusion of contaminated blood, has been virtually eliminated. After the introduction of screening of all blood donations for HCV-RNA, the calculated risk of HCV infection resulting from the transfusion of blood during window period is about 1/1 000 000 blood units<sup>[18]</sup>.

In 102 out of 103 HCV-infected individuals without known or probable risk factors, other potential exposures could be found and most of those were medically linked.

Our study confirms that hospital setting remains as an important source of infection. This seems to be a common feature in Eastern European countries. Nosocomial transmission of HCV is possible if infection-control techniques or disinfection procedures are inadequate and contaminated equipment is shared among the patients. Diagnostic or treatment procedures (surgical or parenteral procedures without blood transfusions) in hospitals were indicated as the source of infection in approximately 59%-65% cases in Poland, 59% in Latvia and 46% in Hungary<sup>[4]</sup>.

Our study had certain limitations as follows: the patients with IVDU or hemodialysis were under-represented in the sample; the percentage of patients with probable risk factors was related to our definition of those factors; and we did not include certain medical procedures or events into that category because previous case-control study did not confirm their relation to HCV infection and because some of them could not be the cause but the result of HCV infection (endoscopies, hospitalizations). In our previous study, we found an increased risk associated with minor surgery<sup>[8]</sup>. Including that exposure into probable risk factors category could overestimate the percentage of patients in our study with known or probable risk factors. The possible overestimation was almost limited to men.

In our experience, a careful history can elicit a risk factor in nearly 60% of hepatitis C infections. The study reveals that overall of at least 50% of HCV infections are associated with health-care sector (transfusions, occupational exposure, other nosocomial exposures). Among the remaining 40% of patients without known or probable risk factors, almost all individuals provided a history of contact with health-care sector preceding diagnosis of hepatitis C. There is a clear tendency towards association of risk factors with age and gender. IVDU occurs mainly in younger males, whereas transfusion before 1993 was more common in younger females. Females are more probable to acquire the infection performing occupational activities in health-care. The two groups with the highest rates of risk factors were women > 44 years and men < 45 years. We speculate that hospitalization and surgery are responsible for some of those infections in older females and IVDU in the younger males.

We conclude that preventive activities against HCV spread in Poland should focus on infection control measures in health-care setting.

## INTRODUCTION

Adenomatous polyp of the colon is quite a common disease, but its presentation as intussusception is very rare. The diagnosis of the underlying lesion in adult intussusception is often difficult, and it is commonly established only after surgical exploration. However, a modern imaging technique, CT, can be helpful in the precise preoperative identification of the etiology of the intussusception<sup>[1,2]</sup>. Although surgical resection is generally indicated in most adult intussusceptions, it is still controversial whether or not the sigmoidorectal intussusception should be reduced before resection. We present here a rare case of large villotubular adenoma of the sigmoid colon as a cause of sigmoidorectal intussusception, and it was treated by laparoscopic anterior resection after a manual reduction using our own technique.

## CASE REPORT

A 56-year-old male was referred by his general practitioner to our Coloproctology Clinic for further evaluation and management of an intraluminal rectal mass with intermittent rectal bleeding for one day. The sodium phosphate enema (Fleet® Enema; CB Fleet Co, Lynchburg, VA, USA) was used for bowel preparation for sigmoidoscopy in the local clinic. The local practitioner finished the sigmoidoscopy without any complications and gave a presumptive diagnosis of rectal mass with partial downward displacement of involved bowel. The rectal mass was detected at 15 cm from anal verge upon flexible sigmoidoscopy (Figure 1A), and the local practitioner did not explore the entire colon beyond the lesion. Several hours after his admission, he suddenly had lower abdominal cramping pain with rectal bleeding during bowel preparation using polyethylene glycol electrolyte solution. A digital rectal examination palpated a protuberant mass-like lesion with a smooth surface. An emergency colonoscopy revealed a sausage-like protrusion at the rectum about 3 cm proximal to the anal verge (Figure 1B),

## Abstract

We present herein a case report of sigmoidorectal intussusception as an unusual case of sigmoid adenomatous polyp. The patient was a 56-year-old man who suffered from rectal bleeding for one day. He initially visited his general practitioner and was diagnosed as having an intraluminal mass of 15 cm from the anal verge. Several hours after admission to our coloproctology clinic, he suddenly presented with lower abdominal cramping pain with rectal bleeding during his bowel preparation using polyethylene glycol electrolyte solution. An emergency colonoscopy revealed that the invaginated colon with polypoid mass was protruded to the lower rectum. Gastrograffin enema showed that the invaginated bowel segment was 3 cm from the anal verge. CT scan showed the typical finding of intussusception. We performed laparoscopic anterior resection and anastomosis after the sponge-on-the-stick-assisted manual reduction. The permanent pathologic finding showed villotubular adenoma of the sigmoid colon.

Park KJ, Choi HJ, Kim SH, Han SY, Hong SH, Cho JH, Kim HH. Sigmoidorectal intussusception of adenoma of sigmoid colon treated by laparoscopic anterior resection

**Figure 1** Endoscopic findings. **A:** Flexible sigmoidoscopy at a local clinic showing the mass lesion 15 cm from the anal verge, and the partial downward displacement of involved bowel (arrow); **B:** Colonoscopy at our clinic showing the invaginated bowel with a round mass lesion about 3 cm from the anal verge.

and our initial endoscopic diagnosis was nongangrenous sigmoidorectal intussusception that was caused by a polyp. A CT scan of the pelvis was performed to obtain a detailed delineation of the lesion. The CT showed a round target-shaped mass lesion consistent with intussusception, and the leading lesion was thought to be a benign mass with a low likelihood of malignancy (Figure 2). Our clinical impression was sigmoidorectal intussusception secondary to benign adenomatous polyp of the sigmoid colon. For the next step, we tried a contrast study using gastrograffin for the reduction as well as for the diagnostic imaging of the intussusception. This also showed an invaginated bowel segment at the lower rectum about 3 cm proximal to the anal verge (Figure 3), and a hydrostatic pressure was given via the rectum for reduction, but it was in vain.

After the general anesthesia, he was placed supine in the modified lithotomy position using Dan Allen stirrups. After the insertion of the umbilical port for the establishment of pneumoperitoneum, surgery was begun in the Trendelenburg position. On laparoscopic exploration, the neck or commencement of the intussusception was located at the rectosigmoid junction, but the distal end was not identified in the peritoneal cavity. The rectal wall of the involved segment was mildly edematous, but it was otherwise healthy on gross examination. No other intra-abdominal pathologic findings were detected. For the manual reduction of the intussusception, we tried to push up the distal end of invaginated segment with a lubricated sponge-on-the-stick from the anus while monitoring by a laparoscope. This maneuver made it

**Figure 2** Contrast enhanced CT scan of pelvis showing a homogeneously well enhancing mass at the intussuscepted bowel tip.

**Figure 3** Gastrograffin study showing a large smooth-invaginated mass intussuscepting into the rectum.

possible to laparoscopically visualize the distal end of the intussusception in the pelvic cavity. We then pulled the intussuscepted segment out proximally using a laparoscopic bowel grasper, but this trial failed. We next tried manual reduction again by grasping the upper ring fold of the intussusception steadily by the index and middle fingers of the surgeon through a suprapubic vertical midline incision 4 cm in length while simultaneously pushing the lowest segment up using a lubricated sponge-on-the-stick via the anus; in this fashion we were successful in reducing the intussuscepted segment. The leading point of the intussusception was located in the mid-sigmoid colon. We performed laparoscopic anterior resection on an oncologic basis because the pathology of the mass had not been confirmed as being benign. After the resection of the segment, the specimen was extracted via the previous suprapubic vertical midline incision. The bowel continuity was safely restored using a standard double-stapling technique between the descending colon and midrectum. The final pathologic diagnosis was villotubular adenoma of the sigmoid colon measuring 2.5 cm × 2 cm in size (Figure 4). The patient was discharged from the hospital 8 d after the operation without any complications.

## DISCUSSION

Intussusception is a quite different entity in adults from

**Figure 4** Hematoxylin and eosin staining of the lesions. **A:** The polypoid mass of the colon showing branching papillary projections composed of proliferated glands and thin fibrous stalks ( $\times 10$ ); **B:** The proliferated glands of the polyp (left) lined by single or pseudostratified hyperchromatic columnar cells as compared with normal colonic mucosa (right), but without any malignant changes ( $\times 40$ ).

that found in children. An organic etiology is found in 70%-90% of adult intussusceptions, and primary or secondary malignant neoplasia are documented in about 20%-50% of adult intussusceptions<sup>[3-5]</sup>. In particular, intussusception occurring in large bowel is more likely to have a malignant etiology<sup>[4]</sup>. Large polypoid adenomas and lipomas are the most common benign leading points found in adult colocolic intussusception<sup>[5,6]</sup>. Most reported cases of sigmoido-recto-anal intussusception in the literature are caused by adenoma or carcinoma<sup>[7-10]</sup>, as compared to our case where the lowest intussuscepted segment was located in the lower rectum without protrusion through the anus.

In pathogenesis of intussusception, peristalsis and ingested food push the lesion with the adjacent bowel, which telescopes into the relaxed intestinal segment distal to it<sup>[3]</sup>. We initially planned to perform colonoscopy after bowel preparation using the polyethylene glycol electrolyte solution, not only to inspect the entire colon but to make a more specific diagnosis of the intussusception. But based on the findings that the patient suddenly complained of lower abdominal pain during bowel preparation and that the intussusceptum was detected 3 cm apart from anal verge at our clinic contrary to the sigmoidoscopic finding that the mass was reported to be 15 cm proximal to the anal verge at previous clinic, this bowel preparation might be, at least, an accelerating factor of intussusception by increased peristalsis. On the ground of clinical course in our case, whole gut irrigation as a bowel preparation should be used with caution because it may accelerate

intussusception.

Early diagnosis and appropriate treatment are essential for intussusception because the mesentery of the involved segment is trapped between the overlapping layers of the bowel and its vascularity may be compromised. Unfortunately, a precise preoperative diagnosis is established in only less than half of the cases<sup>[3,5,11]</sup>. Two factors may be responsible for the low accuracy of the preoperative diagnosis in adult intussusception. One reason is the rare incidence of the intussusception itself and the other reason is the vague or nonspecific symptomatology. This condition is often misdiagnosed as a large polyp<sup>[9,12]</sup> or rectal prolapse<sup>[7,8]</sup> because of the wide variety of nonspecific symptoms that include abdominal pain, nausea and/or vomiting. It is noteworthy that, in most reports, the experience of the adult intussusception at each institution is limited to one or two cases per year<sup>[3-6,11]</sup>. Accordingly, the surgeon must keep in mind the possibility of intussusception even though the clinical signs of the patient may be very subtle.

Radiologic investigations may be helpful to distinguish intussusception from other common causes of intestinal obstruction, and for precisely identifying the etiologies of the intussusception preoperatively<sup>[13]</sup>. The characteristic finding of intussusception on a contrast study is a cup-shaped filling defect that is often accompanied with an additional filling defect representing the leading tumor<sup>[3]</sup>. Hydrostatic reduction under radiologic control, as employed in children, is less effective in adults and risk of perforation during the procedure is not negligible<sup>[10]</sup>. Generally, CT scan is acknowledged to be the most useful radiologic method that may provide additional preoperative information including the possible extension and/or dissemination of a malignant tumor<sup>[2,5,11,14]</sup>. The most common CT finding is a thickened segment of bowel with an eccentrically placed crescent-like fatty area; this represents the intussusception and the intussuscepted mesentery. This appears either as a round target mass or as a long sausage-shaped mass<sup>[14]</sup>.

The appropriate management of adult intussusception is not always clear cut. Most authors agree that operative management of adult intussusception is almost always indicated because of high likelihood of neoplasm as a leading point, particularly if this occurs in the colon. There is controversy about the reduction before resection in cases of sigmoidorectal intussusception, even though most surgeons agree that primary surgical resection without a prior attempt at reduction is the treatment of choice in colocolic adult intussusception<sup>[3,5,13]</sup>. Several aspects to consider for reduction prior to resection are the reduction of externally viable bowel despite mucosal necrosis, intraluminal or transperitoneal seeding, venous embolization of malignant cells, and spillage of succus through inadvertent perforation<sup>[5]</sup>. For patients with sigmoidorectal intussusception, however, the decision regarding the operative procedure may be changed according to tumor involvement of the lower rectum. If the lower rectum is involved, an abdominoperineal resection is indicated. However, without evidence of distal disease, an initial reduction may permit a sphincter-saving procedure instead of the abdominoperineal resection as

advocated by Matsuda *et al*<sup>[15]</sup>. In this sense, we would like to emphasize the significance of an attempt at manual reduction of the sigmoidorectal intussusception prior to resection, especially for those cases caused by benign lesion whereby an unnecessary abdominoperineal resection can be avoided. Because most colonic intussusceptions do not lead to complete obstruction, adequate preoperative bowel preparation is generally possible and this allows for a primary anastomosis<sup>[4]</sup>.

There are good reasons for laparoscopic anterior resection in this case. The first reason is that the wide resection of intussuscepted colon and its mesentery dictates the most important technical consideration, because two-thirds of colocolic intussusceptions are associated with a malignant lesion<sup>[4]</sup>. Although preoperative findings were compatible to benign lesion, definite histopathologic diagnosis could not be made in an emergency situation. Moreover, the size of the sessile polyp was large enough (2 cm×2.5 cm on pathologic measurement) for surgeons to consider the possibility of a malignant polyp. In these emergency circumstances, choice of surgical procedure should be judged assuming a possibility of malignancy. The second is the danger in the reduction of externally viable bowel with mucosal necrosis. The third is that intra-abdominal exploration is possible to exclude dissemination in benign-appearing but malignancy-undeniable polyp in an emergency situation. Validities of laparoscopic oncologic colon surgery has been already established in the randomized multicenter trial<sup>[16]</sup>.

In summary, the sigmoidorectal intussusception caused by sigmoid villotubular adenoma can be reduced by the push-up reduction technique, and safely treated by laparoscopic anterior resection. Our own technique using the sponge-on-the-stick is very useful in the situation that an abdominoperineal resection is, at first, deemed to be inevitable because the intussuscepted segment is very close to the anus. Therefore, this prior reduction technique followed by a resection can be considered for the sigmoidorectal intussusception to avoid inadvertent abdominoperineal resection. In conclusion, our principle of prior reduction technique followed by a laparoscopic resection may be of use in the management of benign sigmoidorectal intussusception involving lower rectum to avoid permanent stoma. Besides, it may also be applicable

to instances of proven malignant intussusception involving the rectum provided that the lesion is confirmed to be localized without intra-abdominal dissemination or metastasis on the laparoscopic exploration before reduction and bowel resection.

## Abstract

A 39-year-old male patient complaining of bilateral hand joint arthralgia was evaluated and found to have chronic hepatitis C and systemic sarcoidosis involving lung, skin, liver, and spleen. Hepatic and cutaneous sarcoidoses were confirmed by the presence of numerous noncaseating granulomas on histological examination. Pulmonary and splenic involvements were diagnosed by imaging studies.

Fifteen months later, the sarcoidotic lesions in lung, liver, and spleen were resolved by radiological studies and a liver biopsy showed no granuloma but moderate to severe inflammatory activity. Systemic sarcoidosis is a rare comorbidity of chronic hepatitis C which may spontaneously resolve.

<http://www.wjgnet.com/1007-9327/12/150.asp>

## INTRODUCTION

Sarcoidosis is a granulomatous disorder of unknown etiology, and is characterized by widespread noncaseating granulomas in many organs. Most commonly sarcoidosis affects the lungs, followed by mediastinal, hilar lymph nodes, and skin. Hepatic involvement of systemic

sarcoidosis is frequently demonstrated<sup>[1]</sup>. In fact, sarcoidosis is the most common cause of hepatic granulomas in the West, and infectious disorders resulting from HCV or HIV infections are possible comorbidities of hepatic sarcoidosis. Most reported cases of HCV associated-sarcoidosis are not the consequence of HCV infection *per se*, but are the results of interferon antiviral therapy<sup>[2,3]</sup>. However, cases of HCV associated-sarcoidosis without interferon therapy have also been recently reported and the possibility of HCV infection *per se* inducing sarcoidosis by activating host immune systems has been suggested<sup>[3,4]</sup>.

Active sarcoidosis and active viral hepatitis are somewhat incompatible because sarcoidosis is a reflection of activated host cellular immunity to an unknown stimulant, while an augmented cellular immunity is one of the main mechanisms by which HCV replication is suppressed by antiviral agents. Thus, changes in the activities of viral hepatitis *vs* sarcoidosis are worth observing when they simultaneously affect a patient.

We experienced a case of systemic sarcoidosis in a patient with chronic hepatitis C who did not receive interferon therapy, and observed the spontaneous resolution of sarcoidotic lesions with more aggravated hepatitis activities during the natural course of this rare comorbidity.

## CASE REPORT

A 39-year-old male patient was admitted because of bilateral hand joint arthralgia, who developed suddenly and impaired hand grip. His serum rheumatoid factor titer (102.7 kU/L) was elevated but other associated clinical features were not compatible with a diagnosis of rheumatoid arthritis. Moreover, his joint symptom improved in 2 d without specific medication.

The patient had suffered from diabetes and chronic hepatitis C for 20 years and received treatment with oral hypoglycemic agents and subcutaneous insulin injections. He was told that his hepatitis activities were mild and need not receive antiviral therapy for chronic hepatitis C. He was in a relatively good condition until 4 mo prior to admission, when he developed fatigue, myalgia, and a mild dry cough. He visited other hospitals for these symptoms and was found to have small pulmonary nodules, which were attributed to past tuberculous infection. His respiratory symptoms improved over the intervening 4 mo, but fatigue and weakness persisted.

A physical examination disclosed no remarkable findings except for three oval brownish papular skin rashes

**Figure 1** Multiple low-attenuating nodular lesions in the liver and an enlarged spleen (A) and their disappearance after 15 mo (B) on CT images.

**Figure 3** Scattered reticulonodular opacities and multiple fine parenchymal nodules in the case of sarcoidosis (A) and their absence after 15 mo (B).

on the periumbilical and lower back areas. Chest X-ray revealed tiny nodules scattered throughout the lung fields and maxillary sinus haziness was found on skull X-ray. Complete blood cell counts with differential counts were all within the normal ranges. Serological markers for HBV infection (HBsAg and anti-HBs) were negative but anti HCV antibody was positive. A sensitive polymerase chain reaction (PCR) detected serum HCV RNA and identified the genotype of the HCV as 1b. Blood chemistry tests revealed 23 IU/L aspartate aminotransferase (AST), 29 IU/L alanine aminotransferase (ALT), 237 U/L alkaline phosphatase, 8.3 g/dL total protein, 3.8 g/dL albumin, 0.8 mg/dL total bilirubin, 9.4 mg/dL total calcium, 3.0 mg/dL phosphorus, 7.6% hemoglobin A1C, 201 mg/dL fasting blood sugar, 90% (11.6 s, INR 1.05) prothrombin time, 3.3 ng/mL alpha-fetoprotein, 17.3 mg/dL BUN, 0.9 mg/dL creatinine, 1.34 mg/dL free T4 (normal: 0.9-1.8 mg/dL), and 2.84 mIU/L TSH (normal: 0.3-6.5 mIU/L). Cryoglobulin was negative and serum angiotensin converting enzyme concentration was in the upper normal range, 51.8 U/L (normal: 8-52 U/L).

Abdominal ultrasonography showed multiple ill-defined low echoic nodular lesions in the liver and an enlarged spleen implying the presence of liver cirrhosis and hepatocellular carcinoma, but no evidence of enhancement was identified among the numerous low-attenuation nodules scattered throughout the liver and spleen on his

**Figure 2** Broad areas of granulomatous inflammation (A) and their disappearance (B) with portal and periportal inflammation, and porto-portal fibrous septa accompanying piecemeal necrosis in hepatic lobules after 15 mo (HE  $\times 200$ ).

abdominal CT scan (Figure 1A). Upper gastrointestinal endoscopic findings were normal and there was no clinical evidence of portal hypertension. A liver biopsy was performed as a basal evaluation of the chronic HCV infection and as a diagnostic procedure for the multiple hepatic nodules, which revealed numerous granulomas with multinucleated giant cells and occasional asteroid bodies in addition to the features of chronic hepatitis such as a mild inflammatory reaction and moderate fibrosis (Figure 2A). Special stains for tuberculosis and fungus, using acid fast bacillus (AFB) and periodic acid Schiff (PAS) were negative, and Mycobacterium tuberculosis nucleic acid was not detected by PCR in the liver tissue.

A high-resolution chest CT scan showed multiple fine nodules distributed in peribronchial areas, especially in the upper and middle lobes, without lymph node enlargement, which was compatible with type III pulmonary sarcoidosis (Figure 3A). Lung tissues obtained by transbronchial lung biopsy revealed a patchy distribution of mild interstitial and perivascular fibrosis, without distinctive granulomas or significant inflammatory cell infiltrations, and stains for AFB and PAS and PCR was negative for Mycobacterium tuberculosis nucleic acids. An analysis of cell types obtained by bronchoalveolar lavage showed that 42% were lymphocytes that consisted of CD4+ cells (63%) and CD8+ cells (37%), a CD4/CD8 ratio of 1.7. Cytologic analysis of bronchial washing fluid for malignant cells was negative and his pulmonary function test was normal.

Granulomatous inflammation with asteroid bodies and multinucleated giant cells were also found in skin biopsy specimens of the periumbilical lesions. Echocardiographic

and ophthalmologic evaluations and a thyroid function test, performed to determine the presence of indolent organ involvement, were all within the normal ranges. With a diagnosis of systemic sarcoidosis involving lung, liver, skin, spleen, and mild chronic hepatitis C, no specific therapies for either sarcoidosis or chronic hepatitis C were adopted, because there was no definitive evidence for significant organ dysfunction and disease progression.

Radiologic and biochemical examinations after 2 months showed no significant changes. After then, he went abroad and was not followed up for a year. Fifteen months later, the hepatosplenic and pulmonary sarcoidotic lesions were remarkably improved on radiologic examination (Figures 1B and 3B) and a liver biopsy showed no remnant granulomas, but moderate to severe inflammatory activities in the lobular and periportal areas, and grade 3 septal fibrosis (Figure 2B). Blood chemistry showed a markedly elevated serum transaminase level (AST 392 IU/mL, ALT 608 IU/mL) with a high serum viral load (serum HCV RNA  $2.6 \times 10^5$  IU/mL).

## DISCUSSION

Liver involvement in sarcoidosis is reported in 40%-70% of patients, but significant hepatic dysfunction is rare<sup>[5]</sup>. The histologic features of hepatic sarcoidosis are variable. Granulomas are identified in all the patients and cholestasis presenting as ductal or periductal inflammation and ductopenia are evident in more than 50% of patients. Necroinflammatory changes and vascular changes are found in 41% and 29%, respectively, and hepatic fibrosis is also found in about 20% of patients<sup>[6]</sup>. Asteroid bodies are found in about 10% of hepatic sarcoidosis cases<sup>[1]</sup>. The hepatic histologic findings in the present case are compatible with those of hepatic sarcoidosis, although chronic HCV infection may also have contributed. Hypodense nodular lesions in the liver and spleen as seen in the CT scans of this patient have been reported to be a characteristic feature of hepatosplenic sarcoidosis<sup>[7]</sup>. Splenic sarcoidosis appears as a nonspecific splenomegaly with retroperitoneal lymphadenopathies in most cases of abdominal sarcoidosis, and approximately 15% of cases present as multiple focal low-attenuating nodules<sup>[8,9]</sup>. The constitutional symptoms, arthritis, paranasal sinusitis, pulmonary nodules, and noncaseating granulomas in the liver and skin tissues of this patient, are all consistent with the characteristic features of systemic sarcoidosis.

Reported comorbidities of sarcoidosis include infectious diseases, neoplastic disorders, and immunologic-inflammatory diseases such as lupus erythematosus, myasthenia, and primary biliary cirrhosis. HCV infection is reported to be the most commonly associated infectious disease of sarcoidosis, however most cases are associated with interferon antiviral therapy<sup>[2,3]</sup>. Treatment-associated cases of sarcoidosis have been reported in many disorders such as chronic hepatitis C, chronic myelogenous leukemia, renal cell carcinoma and lymphoma, in which the beneficial effect of interferon therapy has been established. Importantly, in cases of chronic hepatitis C, interferon can both induce sarcoidosis<sup>[10]</sup> and reactivate sarcoidosis<sup>[11]</sup>, and

interferon-based combination antiviral regimens cannot eliminate the occurrence of sarcoidosis<sup>[12]</sup>.

Interferon not only has direct antiviral activity but also has potent immune stimulating activities especially on T helper (Th1) immune response<sup>[10,13]</sup>, which is also involved in the pathogenesis of sarcoidosis<sup>[14,15]</sup>. Granulomas in sarcoidosis have an abundance of CD4+ T lymphocytes and mononuclear phagocytes, which are thought to be a result of cytokine stimulation and immunologic dysregulation<sup>[16]</sup>. Moreover, ribavirin, an antiviral agent which augments the anti-HCV effect of interferon in chronic hepatitis C, also enhances Th1 cytokine response, while inhibiting Th2 cytokine response<sup>[17,18]</sup>. Thus it appears that treatment-associated sarcoidosis in chronic hepatitis C is mediated by an augmentation of Th1 immune response.

Cases of sarcoidosis and chronic hepatitis C with no history of interferon therapy are rarely reported. Bonnet *et al*<sup>[4]</sup> reported two cases of pulmonary sarcoidosis associated with untreated chronic hepatitis C, one presented with respiratory and cutaneous symptoms that responded to corticosteroid therapy, the other manifested as cervical lymph adenopathies with pulmonary symptoms and responded poorly to corticosteroids. However, sarcoidosis hepatic involvement was absent in both cases, liver biopsies showed features of chronic hepatitis but no granulomas. Our case is unique in that treatment-unrelated hepatic sarcoidosis and its spontaneous resolution were proven histologically in this chronic hepatitis C patient.

Interferon-based antiviral therapy is the standard treatment for chronic hepatitis C, but careful evaluations are required before starting the treatment because many adverse events can be induced by interferon. Flu like symptoms, cytopenia, depression, hyperglycemia, and thyroid dysfunctions are commonly encountered during interferon therapy. Interstitial lung disease, cardiomyopathy, and retinopathy rarely develop. Thus severe depression, autoimmune disorders, and uncontrolled diabetes contraindicate interferon therapy<sup>[19]</sup>. In addition to these disorders, sarcoidosis must also be considered, not only during interferon therapy but also before antiviral therapy, since sarcoidosis may preclude interferon administration.

The clinical course of pulmonary sarcoidosis is variable with a spontaneous remission rate of 40% over a 6-mo observation period before steroid therapy<sup>[20]</sup>. In addition, the clinical course of treatment-associated sarcoidosis in chronic viral hepatitis is also variable. The discontinuation of interferon with or without corticosteroid therapy usually improves sarcoidotic lesions<sup>[11]</sup>, but the remission of pulmonary sarcoidosis has also been reported though interferon therapy is continued<sup>[21]</sup>. However, the natural course of treatment-unrelated sarcoidosis in chronic hepatitis C has not been previously reported.

Although corticosteroid therapy can suppress the active inflammatory reaction of sarcoidosis, its effect on clinical outcome has not been fully established. Moreover, it often provokes serious adverse events, such as hepatic functional deterioration and enhanced viral replication<sup>[22]</sup>. In a few cases of hepatic sarcoidosis, corticosteroid therapy could normalize liver enzymes but could not achieve histologic improvements<sup>[23-25]</sup>. Due to the potential provocation of viral replication and uncertain efficacy in a

clinically stable condition, the patient was simply observed without corticosteroid therapy

In view of the fact that sarcoidosis is a manifestation of an augmented (Th1) immune response to an unidentified stimulant and that interferon-induced immune activation is an important mechanism of viral replication suppression in chronic hepatitis C, hepatitis activities may be suppressed when chronic hepatitis C is combined with active sarcoidosis. In fact, the present case provides clinical evidence that supports this postulation, because serum ALT levels and histologic hepatitis activities were mild when the patient initially presented with active systemic sarcoidosis; whereas 15 mo later when the sarcoidotic lesions resolved, hepatitis activities were aggravated with a higher serum ALT level and a high serum HCV RNA titer. In conclusion, it is prudent to keep in mind that systemic sarcoidosis is a rare comorbidity of chronic hepatitis C which may spontaneously resolve.

## Abstract

Acute abdominal pain with signs and symptoms of peritonitis due to sudden extravasation of chyle into the peritoneal cavity is a rare condition that is often mistaken for other disease processes. The diagnosis is rarely suspected preoperatively. We report a case of spontaneous chylous peritonitis that presented with typical symptoms of acute appendicitis such as intermittent fever and epigastric pain radiating to the lower right abdominal quadrant before admission.

## INTRODUCTION

Chylous ascites is the accumulation of a milky or creamy peritoneal fluid rich in triglycerides due to the presence of lymph. It is a rare clinical condition that results from the disruption of the abdominal lymphatic system. Multiple causes have been described including abdominal malignancy, cirrhosis, inflammation, congenital and postoperative or traumatic causes, and miscellaneous disorders. Management is based on identifying and treating the underlying cause. A sudden outpouring of chyle into the peritoneal cavity may produce acute chylous peritonitis. Patients with such defect usually present with

the features of acute abdomen. Very few cases of acute chylous peritonitis have been described in the literature. We have discussed the clinical features and management of acute chylous peritonitis, and its rarity and presentation compared to common surgical emergencies, such as acute appendicitis.

## CASE REPORT

A 22-year-old male presented with intermittent fever and abdominal pain for two days before admission. He first presented at a clinic, where acute appendicitis was suspected. He was referred by the clinic to our hospital for further management. The symptoms of abdominal distension and pain were continuous and aggravated by any movement. The patient did not have any history of previous trauma or similar pain, and there was nothing relevant in his past medical history. He did not smoke cigarettes or consume alcohol, and denied any recent long distance or overseas travel. On examination, his temperature was 38.2 °C, pulse rate was 80/min, and blood pressure was 116/70 mmHg. The systemic examination was unremarkable. The abdomen was soft and ovoid in shape, and there was tenderness over the periumbilical and right lower quadrant regions. Bowel sounds were audible. Blood analysis gave the following values: total leukocyte count,  $11.6 \times 10^9/\mu\text{L}$ ; Hb, 143 g/L; platelet count,  $31.4 \times 10^9/\mu\text{L}$ ; neutrophils, 64.3%; lymphocytes, 22.7%; Na, 141 mmol/L; K, 3.9 mmol/L; urea, 3.9 mmol/L; creatinine, 70.7  $\mu\text{mol/L}$ ; glucose, 5.3 mmol/L; AST, 367 nkat/L; and ALT, 133 nkat/L.

The chest X-ray was normal, but the abdominal X-ray showed nonspecific gas-filled loops of the large intestine. Computed tomography of the abdomen with contrast showed lobulated fluid accumulation over the retroperitoneal space extending from the level of the renal hilum into the right side pelvis and right inguinal area (Figure 1). Suspecting a ruptured appendix, we performed an exploratory laparotomy. When entering the peritoneum, we noted a large amount of milky fluid in the peritoneal cavity. Chylous ascites was first considered because of the obvious lymphatic leakage from the thoracic duct after we opened the retroperitoneum (Figure 2). We performed suture ligation of the lymphatic leakage and drainage of the retroperitoneal lymphocele. Postoperative drainage was < 100 mL in the first week. The patient commenced a low-fat diet, and was recovering well after a 6-month follow-up.

## DISCUSSION

Ascites is the presence of excess fluid in the peritoneal

**Figure 1** Accumulation of lobulated fluid over the retroperitoneal space and at the para-cecum region shown by computed tomography with contrast to the abdomen.

**Figure 2** Obvious lymphatic leakage from the thoracic duct after the retroperitoneum was opened.

cavity and is a common clinical finding with a wide range of causes, which can require varied treatment. Acute chylous peritonitis is defined as an acute abdomen with all the signs of acute peritoneal irritation resulting from free chyle in the peritoneal cavity, without any underlying disease. Acute chylous peritonitis can also involve extravasation of milky or creamy peritoneal fluid that is rich in triglycerides with small amounts of cholesterol and phospholipids, caused by the presence of thoracic or intestinal lymph in the abdominal cavity. Chylous ascites occurs in one in 20 000 patients admitted to the hospital<sup>[1]</sup>.

The lymphatic system is an accessory route through which fluids and protein flow from the interstitial spaces to the vascular system. Almost all tissues of the body have lymphatic channels composed of one-way valves that drain the excess fluid from the interstitial spaces of tissue. These channels play a pivotal role in clearing the interstitium of debris and bacteria, which are carried to lymph nodes where they are opsonized and phagocytized. Gastrointestinal tract lymphatics also transport absorbed water and lipids to the circulatory system<sup>[2]</sup>. In the gut, long chain triglycerides are converted into monoglycerides, free fatty acids, and absorbable chylomicrons, which explain

the high content of triglycerides and the milky, cloudy appearance of lymph. In our case, the triglyceride concentration in the ascites fluid was 5.48 mmol/L, much higher than the blood triglyceride concentration of 102 mg/dL. The basal flow rate of lymphatic fluid through the thoracic duct averages about 1.0 mL/kg per an hour, with a total volume of 1 500–1 700 mL/d. These volumes increase markedly with the ingestion of fats, and fluid rates as high as 200 mL/h have been reported<sup>[3]</sup>.

Chylous ascites may result from many pathological conditions, including congenital defects of the lymphatic system; nonspecific bacterial, parasitic, and tuberculous peritoneal infections; liver cirrhosis; malignant neoplasm; and blunt abdominal trauma. These etiologies may be categorized into distinct mechanism-based groups<sup>[4]</sup>. The most common etiological factors are abdominal malignancy and congenital lymphatic abnormalities in adults and children, respectively<sup>[5]</sup>. We have presented an unusual case of spontaneous chylous ascites-related peritonitis mimicking acute appendicitis in a young adult. Abdominal surgery is another common cause that is most frequently associated with the resection of an abdominal aortic aneurysm or retroperitoneal lymph node dissection<sup>[6]</sup>. Various vascular surgical procedures such as aorta-to-femoral artery bypass may cause chylous complications<sup>[7]</sup>. It has been suggested that overloading of the lymphatic channels with chyle after a heavy fatty meal may cause extravasation of chyle intraperitoneally and retroperitoneally<sup>[8]</sup>.

Abdominal distension is the most common symptom in patients with chylous ascites. Other clinical features include abdominal pain, anorexia, weight loss, edema, weakness, nausea, dyspnea, weight gain, lymphadenopathy, early satiety, fever, and night sweats. The clinical presentation of acute abdomen is less common. Free chyle is relatively nonirritating to the serosal surface, but pain may result from the stretching of the retroperitoneum and the mesenteric serosa<sup>[8]</sup>. The pain is severe and a physical examination may lead to the misdiagnosis of appendicitis, cholecystitis, mesenteric arterial embolism, or a perforated viscus. The unusual case we present here is spontaneous chylous ascites-related peritonitis mimicking acute appendicitis in a young adult. Just like a similar case reported by Lamblim *et al*<sup>[9]</sup> the diagnosis was established by the celiotomy.

The diagnosis of chylous ascites is confirmed by analyzing the ascites fluid, which is only possible if such a diagnosis is suspected preoperatively. The chief characteristics of chylous effusions include a milky appearance, separation into a creamy layer on standing, lacking an odor, alkaline chemical properties, specific gravity greater than 1.012, bacteriostatic properties, 3% total protein, staining of fat globules with Sudan red stain, fat content of 0.4%–4%, and total solids > 4%<sup>[10]</sup>. The triglyceride level is an important diagnostic tool, and concentration in the chylous ascites is typically two to eight times that of plasma<sup>[11]</sup>. True chylous ascites must be distinguished from “chyliform” and “pseudochylous” effusions, in which the turbid appearance is due to cellular degeneration from bacterial peritonitis or neoplasm.

However, the triglyceride concentration is low in these effusions. Other diagnostic tests such as computed tomography, lymphangiography, lymphoscintigraphy, and laparotomy have the highest yield of diagnostic information<sup>[4]</sup>.

The optimal management of true chylous peritonitis depends upon the underlying etiology. In patients with symptoms of an acute abdominal process, immediate exploration should be performed. Laparotomy usually allows a definitive diagnosis and provides an opportunity to address the underlying cause. The source of chylous extravasation can be corrected by ligation of the leaking lymphatics or removal of the offending lesion, the cause of many congenital and all traumatic cases. The goals of nonsurgical therapy for chylous ascites include maintaining or improving nutrition, and decreasing the rate of chyle formation. Dietary intervention involves a diet that is rich in protein, and low in fat and medium-chain triglycerides to decrease lymph flow in the major lymphatic tracts and to facilitate the closure of chylous fistulas<sup>[12]</sup>. Total parenteral nutrition can be used to achieve complete bowel rest and might allow resolution of the chylous ascites. Somatostatin improves chylous ascites by inhibiting lymph fluid excretion through specific receptors found in the normal intestinal wall of lymphatic vessels<sup>[13]</sup>. In patients with a large amount of ascites, a total paracentesis to relieve discomfort and dyspnea can be performed and repeated as needed. However, one should note the risk of infection and fat emboli. If the patients are poor surgical candidates and refractory to nonsurgical treatment, peritoneovenous shunting may be an option, although these shunts carry a high rate of complications<sup>[14]</sup>.

In conclusion, we have described a rare case of acute chylous peritonitis that mimicked acute appendicitis, but could not identify the cause. This case suggests that diagnostic laparoscopy may play an important role in the initial management of this condition<sup>[15]</sup>.

### TO THE EDITOR

Percutaneous local therapies, such as percutaneous ethanol injection (PEI), microwave coagulation and radiofrequency ablation (RFA), are frequently used worldwide for the treatment of hepatocellular carcinoma (HCC) because of their high effectiveness. Although these treatment modalities can induce effectively coagulated tumor necrosis in the liver, they may cause adverse effects on extrahepatic abdominal organs. There are, however, no published reports on the influence of percutaneous local therapies on the gastric myenteric activity. Therefore, it is unclear whether or not gastric function is affected by percutaneous local therapies. In this study, to make clear the effect of PEI and RFA on the gastric function, we continuously recorded the gastric myoelectric activity by electrogastrography (EGG) and estimated the effect of percutaneous local therapies for HCC on gastric function.

Five patients with HCC (3 males and 2 females; age

ranging from 66 to 81 years) were enrolled in the present study. Written informed consent was obtained from each patient. We have developed several novel percutaneous local therapies for HCC. The first is the combination of PEI and RFA (PEI-RFA). In this treatment modality, RFA is performed immediately after PEI. The second is percutaneous ethanol-lipiodol injection (PELI). In this modality, mixture of pure ethanol and lipiodol, a lipid-based contrast medium, at a ratio of 10:1, is injected percutaneously into HCC. The last is the combination of PELI and RFA (PELI-RFA). Usefulness of these new treatment modalities has been reported elsewhere<sup>[1-7]</sup>. In the present study, two patients with HCC underwent PELI and three underwent PELI-RFA.

We recorded EGG before and 3 d after therapy, and the results were compared. EGG was recorded with a portable electrogastrographic recorder (NIPRO; Tokyo, Japan). Five electrodes were affixed to the abdomen as shown in Figure 1, and EGG was recorded for 30 min during a fasting period and again during a postprandial period. We evaluated the percentages of bradycardia (<2.4 c/min), normogastria (2.4 - 3.6 c/min), and tachycardia (>3.6 c/min), as well as the dominant frequency (DF) and the postprandial-to-fasting power ratio (PR). We also examined clinical abdominal symptoms, using the questionnaire reported by Svedlund *et al.* (Gastrointestinal Symptom Rating Scale, GSRS)<sup>[8]</sup> which was translated into Japanese. The translated form was provided by Astra Zeneca (Tokyo, Japan). Measured values were expressed as mean  $\pm$  SE. Comparisons before and after therapy were performed by the paired Student's *t* test, and *P* < 0.05 was accepted as a significant difference.

The results are summarized in Table 1. Because the similar EGG patterns were obtained from all the channels, the data of channel 1 are shown in Table 1. After percutaneous local therapies for HCC, the percentages of bradycardia in the fasting period were significantly increased, while the percentages of normogastria in the same period were significantly decreased. The PR of normogastria and bradycardia was significantly decreased after therapy. Conversely, no significant differences were found in the calculated GSRS scores obtained from the questionnaire before and after therapy. This study is the first report to estimate the effect of percutaneous local therapies for HCC on the gastric myenteric activity. The present results indicate that percutaneous therapies for HCC may impair gastric function even when clinical symptoms are not apparent.

The first EGG measurement in humans was performed by Alvarez<sup>[9]</sup>. This method can be used to noninvasively assess the electrical activity generated by gastric smooth

**Table 1 Comparisons between before and after therapy (mean  $\pm$  SE)**

	Before	After
Bradygastria (%)	54.0 $\pm$ 7.4	77.4 $\pm$ 5.6 <sup>a</sup>

<sup>a</sup> $p < 0.05$  vs before therapy

**Figure 1** The positions of electrodes for EGG recording. X, xiphoid process; N, navel; RMCL, right mid-clavicular line; LMCL, left mid-clavicular line; C, central terminal electrode placed on the patient's ventral midline about halfway between the umbilicus and the xiphoid process; A, channel 1 placed on an intersecting point between RMCL and a vertical bisectrix of the line XC; B, channel 2 placed on intersecting point between LMCL and a vertical bisectrix of the line XC; D, channel 3 placed on intersecting point between RMCL and a vertical bisectrix of the line NC; E, channel 4 placed on intersecting point between LMCL and a vertical bisectrix of the line NC.

muscles. EGG is believed to reflect the electrical control activity and gastric motility regulated by pacemakers. In humans, these EGG waves originated from the pacemaker area along the major curvature of the stomach and propagated aborally with increasing velocity, at intervals of approximately 20 s<sup>[10]</sup>. EGG has been shown to provide useful information for clinical diagnoses<sup>[10]</sup>. EGG abnormalities have been observed in disorders of gastric emptying, nausea and vomiting<sup>[10]</sup>.

Percutaneous local therapies is of great significance in the treatment of HCC and metastatic liver tumors. PELI, PEI-RFA and PELI-RFA are new therapeutic methods for HCC, which we have developed. We have confirmed the usefulness of these novel percutaneous local therapies in the treatment of HCC<sup>[1-7]</sup>. It has been shown that transcatheter arterial chemoembolization affected the gastric myenteric activity and that overproduction of endogenous prostaglandin was related to dysrhythmia of the gastric myenteric activity<sup>[11]</sup>. In this pilot study,

we demonstrated that the gastric myenteric activity was affected by percutaneous local therapies for HCC, although abdominal symptoms were not apparent and GSRS scores obtained from the questionnaire did not change significantly after therapy. It is a significant clinical matter that delayed gastric transit may occur after percutaneous therapy for HCC. Because it has been reported that patients with HCC tend to have gastrointestinal dysfunction<sup>[12]</sup>, we have to pay attention to gastric dysfunction after percutaneous local therapies for HCC even when there are no clinical symptoms. The mechanisms underlying the effect of percutaneous local therapies for HCC on extrahepatic abdominal organs need further exploration.

## ACKNOWLEDGMENTS

# Acknowledgments to Reviewers of World Journal of Gastroenterology

Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of *World Journal of Gastroenterology*. The editors and authors of the articles submitted to the journal are grateful to the following reviewers for evaluating the articles (including those were published and those were rejected in this issue) during the last editing period of time.

### Kyoichi Adachi, MD

Department of Gastroenterology and Hepatology, Shimane University, School of Medicine Shimane, 89-1 Enya-cho, Izumo-shi Shimane 693-8501, Japan

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (WJG, *World J gastroenterology* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7<sup>th</sup>, 14<sup>th</sup>, 21<sup>st</sup> and 28<sup>th</sup> of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

**Published by**  
The WJG Press

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297mm×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations.

#### Online submission

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to [wjg@wjgnet.com](mailto:wjg@wjgnet.com) for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

#### Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4(297 mm×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or \*.rtf format to:

### Editorial Office

#### World Journal of Gastroenterology

Editorial Department: Apartment 1066, Yishou Garden,  
58 North Langxinzhuang Road,  
PO Box 2345, Beijing 100023, China  
E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)  
<http://www.wjgnet.com>

### MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

#### Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished,

disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

#### Abstract

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

#### Key words

Please list 3-10 key words that could reflect content of the study.

#### Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

#### Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126×76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

#### Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

#### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P*<0.05, <sup>b</sup>*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P*<0.05 and <sup>d</sup>*P*<0.01 are used. Third series of *P* values can be expressed as <sup>e</sup>*P*<0.05 and <sup>f</sup>*P*<0.01. Other notes in tables or under illustrations should be expressed as <sup>1</sup>*F*, <sup>2</sup>*F*, <sup>3</sup>*F*; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

#### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

### PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

### Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>)

### Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

### Format

Standard journal article (list all authors and include the PubMed ID [PMID] where applicable)

- 1 **Das KM**, Farag SA. Current medical therapy of inflammatory bowel disease. *World J Gastroenterol* 2000; 6: 483-489 [PMID: 11819634]
- 2 **Pan BR**, Hodgson HJF, Kalsi J. Hyperglobulinemia in chronic liver disease: Relationships between *in vitro* immunoglobulin synthesis, short lived suppressor cell activity and serum immunoglobulin levels. *Clin Exp Immunol* 1984; 55: 546-551 [PMID: 6231144]
- 3 **Lin GZ**, Wang XZ, Wang P, Lin J, Yang FD. Immunologic effect of Jianpi Yishen decoction in treatment of Pixu-diarrhoea. *Shijie Huaren Xiaobao Zazhi* 1999; 7: 285-287

Books and other monographs (list all authors)

- 4 **Sherlock S**, Dooley J. Diseases of the liver and biliary system. 9th ed. Oxford: Blackwell Sci Pub, 1993: 258-296

Chapter in a book (list all authors)

- 5 **Lam SK**. Academic investigator's perspectives of medical treatment for peptic ulcer. In: Swabb EA, Azabo S. Ulcer disease: investigation and basis for therapy. Marcel Dekker, 1991: 431-450

Electronic journal (list all authors)

- 6 **Morse SS**. Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1):24 screens. Available from: URL: <http://www.cdc.gov/ncidod/EID/eid.htm>

### Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

### Statistical data

Present as mean  $\pm$  SD and mean  $\pm$  SE.

### Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as *r* (in italics), degree of freedom as  $\gamma$  (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

### Units

Use SI units. For example: body mass, *m* (*B*) = 78 kg; blood pressure, *p*(*B*) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose)  $6.4 \pm 2.1$  mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5  $\mu$ g/L; CO<sub>2</sub> volume fraction, 50 mL/L CO<sub>2</sub> not 5% CO<sub>2</sub>; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

### Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

### Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindIII*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *Helicobacter pylori*, *H pylori*, *E coli*, etc.

## SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

### Language evaluation

The language of a manuscript will be graded before sending for revision.

- (1) Grade A: priority publishing;
  - (2) Grade B: minor language polishing;
  - (3) Grade C: a great deal of language polishing;
  - (4) Grade D: rejected.
- The revised articles should be in grade B or grade A.

### Copyright assignment form

It is the policy of *WJG* to acquire copyright in all contributions. Papers accepted for publication become the copyright of *WJG* and authors will be asked to sign a transfer of copyright form. All authors must read and agree to the conditions outlined in the Copyright Assignment Form (which can be downloaded from <http://www.wjgnet.com/wjg/help/9.doc>).

### Final check list for authors

The format is at: <http://www.wjgnet.com/wjg/help/13.doc>

### Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: <http://www.wjgnet.com/wjg/help/10.doc>

### Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

### Publication fee

Authors of accepted articles must pay publication fee.

## World Journal of Gastroenterology standard of quantities and units

Number	Nonstandard	Standard	Notice
1	4 days	4 d	In figures, tables and numerical narration
2	4 days	four days	In text narration
3	day	d	After Arabic numerals
4	Four d	Four days	At the beginning of a sentence
5	2 hours	2 h	After Arabic numerals
6	2 hs	2 h	After Arabic numerals
7	hr, hrs,	h	After Arabic numerals
8	10 seconds	10 s	After Arabic numerals
9	10 year	10 years	In text narration
10	Ten yr	Ten years	At the beginning of a sentence
11	0,1,2 years	0,1,2 yr	In figures and tables
12	0,1,2 year	0,1,2 yr	In figures and tables
13	4 weeks	4 wk	
14	Four wk	Four weeks	At the beginning of a sentence
15	2 months	2 mo	In figures and tables
16	Two mo	Two months	At the beginning of a sentence
17	10 minutes	10 min	
18	Ten min	Ten minutes	At the beginning of a sentence
19	50% (V/V)	500 mL/L	
20	50% (m/V)	500 g/L	
21	1 M	1 mol/L	
22	10 μM	10 μmol/L	
23	1N HCl	1 mol/L HCl	
24	1N H <sub>2</sub> SO <sub>4</sub>	0.5 mol/L H <sub>2</sub> SO <sub>4</sub>	
25	4rd edition	4 <sup>th</sup> edition	
26	15 year experience	15- year experience	
27	18.5 kDa	18.5 ku, 18 500u or M:18 500	
28	25 g.kg <sup>-1</sup> /d <sup>-1</sup>	25 g/(kg·d) or 25 g/kg per day	
29	6900	6 900	
30	1000 rpm	1 000 r/min	
31	sec	s	After Arabic numerals
32	1 pg L <sup>-1</sup>	1 pg/L	
33	10 kilograms	10 kg	
34	13 000 rpm	13 000 g	High speed; g should be in italic and suitable conversion.
35	1000 g	1 000 r/min	Low speed. g cannot be used.
36	Gene bank	GenBank	International classified genetic materials collection bank
37	Ten L	Ten liters	At the beginning of a sentence
38	Ten mL	Ten milliliters	At the beginning of a sentence
39	umol	μmol	
40	30 sec	30 s	
41	1 g/dl	10 g/L	10-fold conversion
42	OD <sub>260</sub>	A <sub>260</sub>	"OD" has been abandoned.
43	One g/L	One microgram per liter	At the beginning of a sentence
44	A260 nm <sup>b</sup> P<0.05	A <sub>260</sub> nm <sup>a</sup> P<0.05	A should be in italic. In Table, no note is needed if there is no significance instatistics: <sup>a</sup> P<0.05, <sup>b</sup> P<0.01 (no note if P>0.05). If ther is a second set of P value in the same table, <sup>c</sup> P<0.05 and <sup>d</sup> P<0.01 are used for a third set: <sup>a</sup> P<0.05, <sup>b</sup> P<0.01.
45	<sup>*</sup> F=9.87, <sup>§</sup> F=25.9, <sup>#</sup> F=67.4	<sup>1</sup> F=9.87, <sup>2</sup> F=25.9, <sup>3</sup> F=67.4	Notices in or under a table
46	KM	km	kilometer
47	CM	cm	centimeter
48	MM	mm	millimeter
49	Kg, KG	kg	kilogram
50	Gm, gr	g	gram
51	nt	N	newton
52	l	L	liter
53	db	dB	decibel
54	rpm	r/min	rotation per minute
55	bq	Bq	becquerel, a unit symbol
56	amp	A	ampere
57	coul	C	coulomb
58	HZ	Hz	
59	w	W	watt
60	KPa	kPa	kilo-pascal
61	p	Pa	pascal
62	ev	EV	volt (electronic unit)
63	Jonle	J	joule
64	J/mm <sup>3</sup>	kJ/mol	kilojoule per mole
65	10×10×10cm <sup>3</sup>	10 cm×10 cm×10 cm	
66	N·km	KN·m	moment
67	x±s	mean±SD	In figures, tables or text narration
68	Mean±SEM	mean±SE	In figures, tables or text narration
69	im	im	intramuscular injection
70	iv	iv	intravenous injection
71	Wang et al	Wang <i>et al.</i>	
72	EcoRI	EcoRI	<i>Eco</i> in italic and RI in positive. Restriction endonuclease has its prescript form of writing.
73	Ecoli	<i>E.coli</i>	Bacteria and other biologic terms have their specific expression.
74	Hp	<i>H pylori</i>	
75	Iga	<i>Iga</i>	writing form of genes
76	igA	IgA	writing form of proteins
77	~70 kDa	~70 ku

## Brief Introduction of Editorial Board

2004-2006

Published by The WJG Press, PO Box 2345, Beijing 100023, China  
Fax: +86-10-85381893 E-mail: wjg@wjgnet.com <http://www.wjgnet.com>

The *World Journal of Gastroenterology* Editorial Board consists of 685 members, representing a team of worldwide experts in gastroenterology and hepatology. They are from 52 countries including: Albania (1), Argentina (1), Australia (16), Austria (7), Belarus (1), Belgium (11), Brazil (1), Bulgaria (1), Canada (10), China (58), Croatia (2), Czech(1), Denmark (5), Egypt (3), Finland (1), France (27), Germany (71), Greece (1), Hungary(1), Iceland (1), India (6), Iran (2), Ireland (2), Israel (5), Italy (51), Japan (137), Lebanon(2), Lithuania (1), Macedonia(1), Malaysia (3), Mexico (2), Monaco (1), Netherlands (15), New Zealand (1), Nigeria(1), Norway(2), Pakistan(1), Poland (6), Portugal (1), Russia (3), Singapore (3), Slovakia (1), South Africa (1), South Korea (9), Spain (27), Sweden (6), Switzerland (8), Turkey (7), United Arab Emirates(1), United Kingdom (37), United States (121), Yugoslavia (1).

### HONORARY EDITORS-IN-CHIEF

**Ke-Ji Chen, Professor**, Xiyuan Hospital, Chinese Traditional Medicine University, Beijing 100091, China

**Li-Fang Chou, Professor**, Department of Public Finance, National Chengchi University, Chih-Nan Rd., Sec. 2, Zhi-Nan Road, Taipei 11623, Taiwan, China

**Dai-Ming Fan, Professor**, Director of Department of Gastroenterology, Xijing Hospital, Fourth Military Medical University, Xi'an 710032, Shaanxi Province, China

**Zhi-Qiang Huang, Professor**, Abdominal Surgery Institute of General Hospital of PLA, Fuxing Road, Beijing 100853, China

**Shinn-Jang Hwang, Professor**, Department of Family Medicine, Taipei Veterans General Hospital, VGH, 201, Shih-Pai Road, Section 2, 11217, Taiwan, China

**Min-Liang Kuo, PhD**, Laboratory of Molecular and Cellular

Toxicology, Institute of Toxicology, College of Medicine, National Taiwan University, No. 1, Section 1, Jen-Ai Road, Taipei, Taiwan, China

**Nicholas F LaRusso, MD**, Center for Basic Research in Digestive Diseases, Division of Gastroenterology and Hepatology, Mayo Clinic College of Medicine, 200 First Street, SW, Rochester, MN 55905, United States

**Jie-Shou Li, Professor**, Academician of Chinese Academy of Engineering, Department of General Surgery, General Hospital of Nanjing Command Area, 305 East Zhongshan Road, Nanjing 210002, Jiangsu Province, China

**Geng-Tao Liu, Professor**, Department of Pharmacology, Institute of Materia Medica, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing 100050, China

**Lein-Ray Mo, MD**, Department of Internal Medicine, Tainan Municipal Hospital, 670, Chung-Te Rd., Tainan 701, Taiwan, China

**Fa-Zu Qiu, MD**, Hepatic Surgery Center of Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan 430030, Hubei Province, China

**Eamonn M Quigley, Professor**, Department of Medicine National University of Ireland, Cork, Cork University Hospital Clinical Sciences Building Wilton, Cork, Ireland

**David S Rampton, Professor**, Centre for Gastroenterology, Institute of Cell and Molecular Science, Queen Mary School of Medicine and Dentistry, London E1 2AD, United Kingdom

**Rudi Schmid, MD**, 211 Woodland Road, Kentfield, California 94904, United States

**Nicholas J Talley, MD, PhD**, Professor of Medicine, Division of Gastroenterology and Hepatology, Mayo Clinic College of Medicine, 200 First Street S.W., PL-6-56, Rochester, MN 55905, United States

**Guido NJ Tytgat, Professor, Academic Medical Centre, University of Amsterdam, Meibergdreef 9, 1105 AZ Amsterdam, The Netherlands**

**Jaw-Ching Wu, MD, Ph.D, Director and Professor, Institute of Clinical Medicine, National Yang-Ming University, Department of Medical Research and Education, Taipei Veterans General Hospital, Taipei, Taiwan, China**

**Meng-Chao Wu, Professor, Academician of Chinese Academy of Sciences Vice, President of Chinese Medical Association, President of Hospital of Hepato-Biliary Surgery, Second Military Medical University, 225 Changhai Road, Shanghai 200438, China**

**Ming-Shiang Wu, Dr, Associate Professor, Internal Medicine, National Taiwan University Hospital, No 7, Chung-Shan S. Rd., Taipei 100, Taiwan, China**

**Jia-Yu Xu, Professor, Shanghai Second Medical University, Rui Jin Hospital, 197 Rui Jin Er Road, Shanghai 200025, China**

**Hui Zhuang, Professor, Department of Microbiology, Peking University Health Science Center, 38 Xueuyuan Road, Haidian District, Beijing 100083, China**

#### PRESIDENT AND EDITOR-IN-CHIEF

**Lian-Sheng Ma, Professor, President and Editor-in-Chief, *World Journal of Gastroenterology*, The WJG Press, Apartment 1066 Yishou Garden, 58 North Langxinzhuang Road, PO Box 2345, Beijing 100023, China**

#### EDITOR-IN-CHIEF

**Bo-Rong Pan, Professor, Outpatient Department of Oncology, The Fourth Military Medical University, 175 Changle West Road, Xi'an 710032, Shaanxi Province, China**

#### ASSOCIATE EDITORS-IN-CHIEF

**Gianfranco D Alpini, Professor, Internao Medicine and Medical Physiology, Scoh Whot Hospital, 702 SW H.K. dod genloop MRB rm316B, Temple 76504, United States**

**Bruno Annibale, Professor, Digestive and Liver Disease Unit, University "La Sapienza" II School of Medicine, Via di Grottarossa 1035, Roma 00189, Italy**

**Jordi Bruix, MD, BCLC Group, Liver Unit, Hospital Clinic, University of Barcelona. Villarroel 170. 08036 Barcelona, Spain.**

**Roger William Chapman, MD, Department of Hepatology, Oxford University, Medical School, Oxford Radcliffe Hospital, Oxford ox3 9DV, United Kingdom**

**Alexander L Gerbes, Professor, Medizinische Klinik II, Munich, Germany, Marchioninstr 15, Munich D-81377, Germany**

**Shou-Dong Lee, Professor, Department of Medicine, Taipei Veterans General Hospital, 201 Shih-Pai Road, Sec. 2. Taipei 112, Taiwan, China**

**Walter Edwin Longo, Professor, Department of Surgery, Yale University School of Medicine, 205 Cedar Street, New Haven 06510, United States**

**You-Yong Lu, Professor, Beijing Molecular Oncology Laboratory, Peking University School of Oncology and Beijing Institute for Cancer Research, #1, Da-Hong-Luo-Chang Street, Western District, Beijing 100034, China**

**Masao Omata, MD, Department of Gastroenterology, Graduate School of Medicine, University of Tokyo, Tokyo 113-8655, Japan**

**Harry HX Xia, PhD, MD, Department of Medicine, Queen Mary Hospital, The University of Hong Kong, Pokfulam Road, Hong Kong, China**

#### MEMBERS OF THE EDITORIAL BOARD

##### Albania

**Bashkim Resuli, MD, Department of Internal Medicine and University Service of Gastrohepatology, University Hospital Center "Mother Theresa", Medical Faculty of Tirana, Tirana, Albania**

##### Argentina

**Julio Horacio Carri, Professor, Internal Medicine-Gastroenterology,**

**Universidad Nacional de Córdoba, Av.Estrada 160-P 5-Department D, Córdoba 5000, Argentina**

##### Australia

**Minoti Vivek Apte, Associate Professor, Pancreatic Research Group, South Western Sydney Clinical School, The University of New South Wales. Liverpool, NSW 2170, Australia**

**Filip Braet, Associate Professor, Australian Key Centre for Microscopy and Microanalysis, Madsen Building (F09), The University of Sydney, Sydney NSW 2006, Australia**

**Andrew D Clouston, Associate Professor, Histopath Laboratories, Suite 4, Level 9, Strathfield Plaza, Strathfield, Sydney, 2135, Australia**

**Darrell Hewry Gordon Crawford, Associate Professor, Department of Gastroenterology and Hepatology, Princess Alexandra Hospital, IPSWICH RD, Woolloongabba, Bris Bane 4102, Australia**

**Michael Anthony Fink, MBBS FRACS, Department of Surgery, The University of Melbourne, Austin Hospital, Melbourne, Victoria 3084, Australia**

**Robert John Lovat Fraser, Associate Professor, Investigations and Procedures Unit, Repatriation General Hospital, Daw Park, Australia**

**Yik-Hong Ho, Professor, Department of Surgery, School of Medicine, James Cook University, Townsville 4811, Australia**

**Gerald Johannes Holtmann, Professor, Department of Gastroenterology and Hepatology, Royal Adelaide Hospital, North Terrace, Adelaide 5000, Australia**

**Michael Horowitz, Professor, Department of Medicine, University of Adelaide and Director, Endocrine and Metabolic Unit, Royal Adelaide Hospital, Level 6, Eleanor Harrauld Bullding, North Terrace, Adelaide 5000, Australia**

**Phillip S Oates, Dr, Department of Physiology, School of Biomedical and Chemical Sciences, The University of Western Australia, Perth, WA, Australia**

**Stephen M Riordan, Associate Professor, Gastrointestinal and Liver Unit, The Prince of Wales Hospital, Barker Str, Randwick 2031, Australia and University of New South Wales, Sydney, Australia**

**Ian C Roberts-Thomson, Professor, Department of Gastroenterology and Hepatology, The Queen Elizabeth Hospital, 28 Woodville Road, Woodville South 5011, Australia**

**Nathan Subramaniam, Dr, Membrane Transport Laboratory, The Queensland Institute of Medical Research 300 Herston Road, Herston, Brisbane, QLD 4006, Australia**

**Herbert Tilg, Professor, Division of Gastroenterology and Hepatology, Department of Medicine, University Hospital Innsbruck, Anichstrasse 35, Innsbruck 6020, Austria**

**Martin John Veysey, MD, Teaching and Research Unit, Gosford Hospital, PO Box 361., Gosford NSW 2250, Australia**

**Daniel Lindsay Worthley, Dr, Department of Gastroenterology and Hepatology, Flinders Medical Centre, Room 3D230, Bedford Park, SA 5042, Australia**

##### Austria

**Alfred Gangl, Professor, Department of Medicine 4, Medical University of Vienna, Allgemeines Krankenhaus, Waehringer Guertel 18-20, Vienna A-1090, Austria**

**Kurt Lenz, Professor, Department of Internal Medicine, Konventhospital Barmherzige Brueder, A-4020 Linz, Austria. kurt.**

**Markus Peck-Radosavljevic, Professor, Department of Internal Medicine IV, Division of Gastroenterology and Hepatology, University of Vienna, Waehringer Guertel 18-20, A-1090 Vienna, Austria**

**Rudolf E Stauber, Professor, Department of Internal Medicine, Medical University Graz, Division of Gastroenterology and Hepatology, Auenbruggerplatz 15, A-8036 Graz, Austria**

**Michael Trauner, Professor, Medical University Graz, Auenbruggerplatz 15, Graz A-8036, Austria**

**Harald Vogelsang, Professor,** Gastroenterology, AKH- KIM IV, Wahringergasse 18-20, Vienna A-1090, Austria

**Guenter Weiss, Professor,** Department of General Internal Medicine, Clin. Immunol. and Infect. Diseases, Medical University, Anichstr. 35, A-6020 Innsbruck, Austria

#### Belarus

**Yury Kharitonovich Marakhouski, Professor,** Department of Gastroenterology and Nutrition, Byelorussian Medical Academy Postgraduate Education, Brovkiy str 3, Minsk 220013, Belarus

#### Belgium

**Rudi Beyaert, Professor,** Department of Molecular Biomedical Research, Flanders Interuniversity Institute for Biotechnology and Ghent University Technologiepark 927,B-9052 Gent, Belgium

**Bart Rik De Geest, Dr,** Center for Molecular and Vascular Biology, Katholieke Universiteit Leuven, Campus Gasthuisberg, Herestraat 49, Leuven 3000, Belgium

**Inge Irma Depoortere, PhD,** Centre for Gastroenterological Research, Gasthuisberg OandN, bus 701, Leuven 3000, Belgium

**Olivier Detry, Dr,** Department of Abdominal Surgery and Transplantation, University of Liège, CHU Sart Tilman B35, B-4000 Liège, Belgium

**Karel Geboes, Professor,** Laboratory of Histo- and Cytochemistry; University Hospital K.U.Leuven, Capucienenvoer 33, 3000 Leuven, Belgium

**Thierry Gustot, Dr,** Division of Gastroenterology, Erasme University Hospital, Free University of Brussels, 808 Lennik St, 1070 Brussels, Belgium

**Yves J Horsmans, Professor,** Department of Gastroenterology, Cliniques Universitaires Saint-Luc, Avenue Hippocrate, 10, Brussels 1200, Belgium

**Geert G Leroux-Roels, Professor,** Center for Vaccinology, Ghent University, De Pintelaan 185, Ghent 9000, Belgium

**Louis Libbrecht, MD, PhD,** Department of Pathology, University and University Hospitals of Leuven, Minderbroedersstraat 12, Leuven 3000, Belgium

**Yvan Vandenplas, Professor,** Department of Pediatrics, AZ-VUB, Laarbeeklaan 101, Brussels 1090, Belgium

**Eddie Wisse, Professor,** Irisweg 16, Keerbergen 3140, Belgium

#### Brazil

**Heitor Rosa, Professor,** Department of Gastroenterology and Hepatology, Federal University School of Medicine, Rua 126 n.21, Goiania - GO 74093-080, Brazil

#### Bulgaria

**Zahariy Krastev, Professor,** Department of Gastroneterology, Universiti Hospital "St. Ivan Rilski", #15, blvd "Acad. Ivan Geshov", Sofia 1431, Bulgaria

#### Canada

**Matthew Bjerknes, PhD,** Department of Medicine, Medical Science Building, University of Toronto, 1 King's College Circle, Toronto, Ontario, M5S-1A8, Canada

**Michael F Byrne, MD,** Clinical Associate Professor, Division of Gastroenterology Vancouver General Hospital, 100-2647 Willow Street Vancouver BC V5Z 3P1, Canada

**Wang-Xue Chen, Dr,** Institute for Biological Sciences, National Research Council Canada, 100 Sussex Drive, Room 3100, Ottawa, Ontario K1A 0R6, Canada

**Hugh James Freeman, Professor,** Department of Medicine, University of British Columbia, UBC Hospital 2211 Wesbrook Mall, Vancouver, BC V6T 1W5, Canada

**Chantal Guillemette, Professor,** Canada Research Chair in Pharmacogenomics, Laboratory of Pharmacogenomics, CHUL Research Center, T3-48, 2705 Boul. Laurier, Québec, Canada, G1V 4G2, Canada

**Samuel S Lee, Professor,** Department of Medicine, University of Calgary, Health Science Centre, Rm 1721, 3330 Hospital Dr NW, Calgary, AB, T2N 4N1, Canada

**Gerald Y Minuk, Dr,** Section of Hepatology, University of Manitoba, Room 803E-715 McDermot Avenue, Winnipeg, Manitoba R3E 3P4, Canada

**Morris Sherman, Dr,** Department of Medicine, University Health Network, Toronto M5G 2C4, Canada

**Alan BR Thomson, MD,** Division of Gastroenterology, University of Alberta, 205 College Plaza, 8215 - 112 Street, Edmonton, Alberta T6G 2C8, Canada

**Eric M Yoshida, MD,** Department of Medicine, University of British Columbia, 100-2647 Willow Street, Vancouver V5Z 3P1, Canada

#### China

**Henry LY Chan, MD, Associate Professor,** Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong, China

**Xiao-Ping Chen, Professor,** Institute of Hepato-Pancreato-Biliary Surgery, Tongji Hospital, 1095# Jie-fang Da-dao, Wuhan 430030, Hubei Province, China

**Jun Cheng, Professor,** Dean Assistant, Beijing Earth Altar Hospital Dean 13 Earth Altar Park, Anwai Avenue, East District, Beijing 100011, China

**Chi-Hin Cho, Chair and Professor,** Department of Pharmacology, The University of Hong Kong, 21 Sassoon Road, Hong Kong, China

**Zong-Jie Cui, PhD, Professor,** Institute of Cell Biology, Beijing Normal University, 19 XinJieKouWaiDaJie, Beijing 100875, China

**Da-Jun Deng, Professor,** Department of Cancer Etiology, Peking University School of Oncology, 1 Da-Hong-Luo-Chang Street, Western District, Beijing 100034, China

**Er-Dan Dong, Professor,** Department of Life Science, Division of Basic Research in Clinic Medicine, National Natural Science Foundation of China, 83 Shuangqing Road, Haidian District, Beijing 100085, China

**Sheung-Tat Fan, Professor,** Department of Surgery and Center for the Study of Liver Disease, The University of Hong Kong, Queen Mary Hospital, 102 Pokfulam Road, Hong Kong, China

**Xue-Gong Fan, Professor,** Department of Infectious Diseases, Xiangya Hospital, Central South University, Changsha 410008, China

**Jin Gu, Professor,** Peking University School of Oncology, Beijing Cancer Hospital, Beijing 100036, China

**De-Wu Han, Professor,** Institute of Hepatology, Shanxi Medical University, 86 Xinjian South Road, Taiyuan 030001, China

**Ming-Liang He, Associate Professor,** Faculty of Medicine, The Center for Emerging Infectious Diseases, The Chinese University of Hong Kong, Hong Kong, China

**Fu-Lian Hu, Professor,** Department of Gastroenterology, Peking University First Hospital, 8 Xishiku St, Xicheng District, Beijing 100034, China

**Wayne HC Hu, MD,** Department of Medicine, University of Hong Kong, 302, New Clinical Building, Queen Mary Hospital, Pokfulam Road, Hong Kong, China

**Guang-Cun Huang, PhD,** Department of Pathology, Shanghai Medical College, Fudan University, 138 Yixueyuan Road, Shanghai 200032, China

**Xiao-Long Ji, Professor,** Institute of Nanomedicine, Chinese Armed Police General Hospital, 69 Yongding Road, Beijing 100039, China

**Ching Lung Lai, Professor,** Department of Medicine, The University of Hong Kong, Queen Mary Hospital, Hong Kong, China

**Kam Chuen Lai, MD,** Department of Medicine, The University of Hong Kong, Queen Mary Hospital, Hong Kong, China

**Yuk Tong Lee, MD,** Department of Medicine and Therapeutics,

Prince of Wales Hospital, Shatin, New Territories, Hong Kong, China

**Suet Yi Leung, Dr**, Department of Pathology, The University of Hong Kong, Hong Kong, China

**Wai-Keung Leung, MD**, Department of Medicine and Therapeutics, Prince of Wales Hospital, The Chinese University of Hong Kong, Shatin, Hong Kong, China

**Zhi-Hua Liu, Professor**, Cancer Institute, Chinese Academy of Medical Sciences, 17 Panjiayuan Nanli, Beijing 100021, China

**Ai-Ping Lu, Professor**, China Academy of Traditional Chinese Medicine, Dongzhimen Nei, 18 Beixincang, Beijing 100700, China

**Jing-Yun Ma, Professor**, Managing Director, *World Journal of Gastroenterology*, PO Box 2345, Beijing 100023, China

**Lun-Xiu Qin, Professor**, Liver Cancer Institute and Zhongshan Hospital, Fudan University, 180 Feng Lin Road, Shanghai 200032, China

**Yu-Gang Song, Professor**, Department of Training, The First Military Medicine University, The First Military Medicine University, Guangzhou 510515, China

**Qin Su, Professor**, Department of Pathology, Cancer Hospital and Cancer Institute, Chinese Academy of Medical Sciences and Peking Medical College, PO Box 2258, Beijing 100021, China

**Yuan Wang, Professor**, Institute of Biochemistry and Cell Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai 200031, China

**Benjamin Chun-Yu Wong, Professor**, Department of Medicine, University of Hong Kong, Queen Mary Hospital, Hong Kong, China

**Wai-Man Wong, MD**, Department of Medicine, University of Hong Kong, St Paul's Hospital, 2 Eastern Hospital Road, Causeway Bay, Hong Kong, China

**Hong Xiao, Professor**, Managing Director, Acta Pharmacologica Sinica, 294 Taiyuan Road, Shanghai 200031, China

**Dong-Liang Yang, Professor**, Department of Infectious Diseases, Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, 1095 Jiefang Avenue, Wuhan 430030, Hubei Province, China

**Yuan Yuan, Professor**, Cancer Institute of China Medical University, 155 North Nanjing Street, Heping District, Shenyang 110001, Liaoning Province, China

**Man-Fung Yuen, Associate Professor**, Department of Medicine, The University of Hong Kong, Queen Mary Hospital, Hong Kong, China

**Jian-Zhong Zhang, Professor**, Department of Pathology and Laboratory Medicine, Beijing 306 Hospital, 9 North Anxiang Road, PO Box 9720, Beijing 100101, China

**Xin-Xin Zhang, Professor**, Department of Infectious Disease, Rui Jin Hospital, 197, Rui Jin Er Road, Shanghai 200025, China

**Zhi-Rong Zhang, Professor**, West China School of Pharmacy, Sichuan University, 17 South Renmin Road, Chengdu 610041, Sichuan Province, China

**Shu Zheng, Professor**, Scientific Director of Cancer Institute, Zhejiang University, Secondary Affiliated Hospital, Zhejiang University, 88# Jiefang Road, Hangzhou 310009, Zhejiang Province, China

#### Croatia

**Tamara Cacev, MSc**, Division of Molecular Medicine, Rudjer Boskovic Institute, Bijenicka c. 54, Zagreb 10000, Croatia

**Marko Duvnjak, MD**, Department of Gastroenterology and Hepatology, Sestre milosrdnice University Hospital, Vinogradska cesta 29, 10 000 Zagreb, Croatia

#### Czech

**Milan Jirsa, Dr**, Laboratory of Experimental Medicine - building Z1, Institute for Clinical and Experimental Medicine, Videnska 1958/9, Praha 4, 140 00, Czech

#### Denmark

**Peter Bytzer, Associate Professor**, Department of Medical Gastroenterology, Institution University of Copenhagen, Glostrup University Hospital, NMD Ringvej, Copenhagen DK-2600, Denmark

**Hans Gregersen, Professor**, The Research Administration, Aalborg Hospital, Hobrovej 42 A, Aalborg 9000, Denmark

**Jens H Henriksen, Professor**, Department of Clinical Physiology, Hvidovre Hospital, University of Copenhagen, Kettegaard Allé 30, Hvidovre DK-2650, Denmark

**Fin Stolze Larsen, Associate Professor**, Hepatology A-2121, Rigshospitalet University Hospital of Copenhagen, Blegdamsvej 9, Copenhagen 2100, Denmark

**Søren Møller, Chief Physician**, Department of Clinical Physiology 239, Hvidovre Hospital, Kettegaard alle 30, DK-2650 Hvidovre, Denmark

#### Egypt

**Abdel-Rahman El-Zayadi, Professor**, Department of Hepatology and Gastroenterology, Ain Shams University and Cairo Liver Center, 5, El-Gergawy St. Dokki, Giza 12311, Egypt

**Sanaa Moharram Kamal, Professor**, Department of Gastroenterology and Liver Disease, Ain Shams Faculty of Medicine, 22, Al Ahram St, Roxy, Heliopolis, Cairo, Egypt

**Ayman Yosry, Professor**, Gastrointestinal Endoscopy and Liver Unit, Cairo University, Cairo, Egypt

#### Finland

**Pentti Sipponen, Professor**, Head of the Division, Huslab, Helsinki University Central Hospital, Division of Pathology Pathology, Jorvi Hospita, Huslab, Helsinki University Central Hospital, Espoo 02740, Finland

#### France

**Corlu Anne, PhD**, Inserm U522, Hôpital Pontchaillou, rue Henri Le guilloux, Rennes 35033, France

**Denis Ardid, PhD**, INSERM/UdA E 9904, Laboratoire de Pharmacologie Medicale, Faculte de Medecine, 63001 Clermont-Ferrand Cedex 1, France

**Charles Paul Balabaud, Professor**, Service d'hepatologie, Hospital Saint André, 1 Rue Jean Burguet, Bordeaux 33075, France. charles

**Jacques Belghiti, Professor**, Department of HepatoPancreatoBiliary Surgery Beaujon hospital, 100 Bd Gal Leclerc, Clichy 92110, France

**Pierre Brissot, Professor**, Liver Disease Unit And Inserm U-522, University Hospital Pontchaillou, 2, Rue Henri Le Guilloux, Rennes 35033, France

**Patrice Philippe Cacoub, Professor**, Department of Internal Medicine Hopital La Pitié Salpêtrière 41 Boulevard de l'hôpital 75013 Paris, France

**Franck Carbonnel, Professor**, Department of Gastroenterology, Chu de Besancon, Boulevard Fleming, Besancon 25000, France

**Laurent Castera, Dr**, Laurent Castera, MD, Service d'Hépatogastroentérologie, Hôpital Haut Lévêque, Avenue Magellan, 33604 Pessac, France

**Bruno Clément, Professor**, Inserm U-620, University of Rennes I, Faculty of Medicine, 2 ave. L. Bernard, Rennes 35043, France

**Jacques Cosnes, Professor**, Department of Gastroenterology, Hospital St. Antoine, Hospital St. Antoine, 184 rue du Faubourg St-Antoine, PARIS 75012, France

**Thomas Decaens, Dr**, Service d'hépatologie et de Gastroentérologie, Unité de transplantation hépatique, Hôpital Henri Mondor, 51 av du Marechal de Lattre de Tassigny 94010 Créteil Cedex, France

**Francoise Lunel Fabiani, Professor**, Laboratoire De Bacteriologie Virologie Et Hygiene, 4 Rue Larrey, Angers 49933, France

**Gérard Feldmann, Professor**, Inserm U481, Faculté de Médecine Xavier Bichat 16 rue Henri Huchard, PARIS 75018, France

**Jean Fioramonti, MD**, Department of Neurogastroenterology and

**Manuel Romero-Gómez, MD, Professor**, Hepatology Unit, Hospital Universitario de Valme, Ctra de Cádiz s/n, Sevilla 41014, Spain

#### Sweden

**Curt Einarsson, Professor**, Department of Medicine, Karolinska Institute, Karolinska University Hospital Huddinge, Department of Gastroenterology and Hepatology, K 63, Huddinge SE-141 86, Sweden

**Xupeng Ge, MD, PhD**, Division of Transplantation Surgery, CLINTEC, Karolinska Institute, Karolinska University Hospital-Huddinge, Stockholm 14186, Sweden

**Hanns-Ulrich Marschall, Associate Professor**, Karolinska Institutet, Department of Medicine, Division of Gastroenterology and Hepatology, Karolinska University Hospital Huddinge, Stockholm S-14188, Sweden

**Lars Christer Olbe, MD**, Gastrosurgical Research, Sahlgrenska University Hospital, Sahlgrenska University Hospital, AstraZeneca RandD, Mölndal 431 83, Sweden

**Xiao-Feng Sun, Professor**, Department of Oncology, Biomedicine and Surgery, Department of Oncology, Biomedicine and Surgery, Linköping University, Linköping 581 85, Sweden

**Ervin Tóth, Endoscopy Unit**, Department of Medicine, Malmö University Hospital, Lund University, Entrance 44, Malmö S-205 02, Sweden

#### Switzerland

**Christoph Beglinger, Professor**, University Hospital, Division of Gastroenterology, University of Basel, Petersgraben 4, Basel CH-4031, Switzerland

**Pierre A Clavien, MD**, Department of Visceral and Transplantation Surgery, University Hospital Zurich, 100 Ramistrasse, Zurich 8091, Switzerland

**Jean-Francois Dufour, Professor**, Department of Clinical Pharmacology Inselspital, University of Berne 35 Murtenstrasse 3010 Berne, Switzerland

**Franco Fortunato**, Department of Visceral and Transplantation Surgery, University Hospital Zurich, Sternwartstrasse 14, Zürich CH-8091, Switzerland

**Jean Louis Frossard, Dr**, Division of Gastroenterology, Geneva University Hospital, Rue Micheli du Crest, 1211 Geneva 14, Switzerland

**Gerd A Kullak-Ublick, Professor**, Laboratory of Molecular Gastroenterology and Hepatology, Department of Internal Medicine, University Hospital Zurich, Zurich CH-8091, Switzerland

**Bruno Stieger, Professor**, Department of Medicine, Division of Clinical Pharmacology and Toxicology, University Hospital, Zurich 8091, Switzerland

**Arthur Zimmermann, Professor**, Director, Institute of Pathology of the University, Berne, Switzerland, Murtenstrasse 31, 3010 Berne, Switzerland

#### Turkey

**Yusuf Bayraktar, Professor**, Department of Gastroenterology, School of Medicine, Hacettepe University, Ankara 06100, Turkey

**Figen Gurakan, Professor**, Department of Pediatric Gastroenterology, Hacettepe University Medical Faculty, Ankara 06100, Turkey

**Aydin Karabacakoglu, Dr**, Assistant Professor, Department of Radiology, Meram Medical Faculty, Selcuk University, Konya 42080, Turkey

**Serdar Karakose, Dr**, Professor, Department of Radiology, Meram Medical Faculty, Selcuk University, Konya 42080, Turkey

**Hizir Kurtel, Professor**, Department of Pharmacology, Marmara University, School of Medicine, Istanbul 34668, Turkey

**Osman Cavit Ozdogan, Associate Professor**, Department of Gastroenterology, Liver Unit, Marmara University School of Medicine, Istanbul 34662, Turkey

**Cihan Yurdaydin, MD**, Department of Gastroenterology, Hepatology Institute, University of Ankara Medical School, Cebeci Tip Fakultesi Hastanesi, Dikimevi, Ankara 06100, Turkey

#### United Arab Emirates

**Sherif M Karam, Dr**, Department of Anatomy, Faculty of Medicine and Health Sciences, United Arab Emirates University, POBox17666, Al-Ain, United Arab Emirates

#### United Kingdom

**Anthony Thomas Roger Axon, Professor**, Department of Gastroenterology, Infirmary At Leeds, Room 190a, Clarendon Wing the General Infirmary At Leeds great George Stree, Leeds Ls1 3ex, United Kingdom

**Mairi Brittan, Dr**, Centre for Diabetes and Metabolic Medicine, Institute of Cell and Molecular Science, Queen Mary's School of Medicine and Dentistry, London E1 2AT, United Kingdom

**Andrew Kenneth Burroughs, Dr**, Professor, Liver Transplantation and Hepatobiliary Medicine Unit, Royal Free Hospital, Pond Street NW3 2QJ, London, United Kingdom

**Paul Jonathan Ciclitira, Professor**, The Rayne Institute (GKT), St Thomas' hospital, London NW32QG, United Kingdom

**Amar Paul Dhillon, Professor**, Department of Histopathology, Royal Free Hospital, Pond Street, London NW3 2QG, United Kingdom

**Elizabeth Furrie, PhD**, Department of Immunology, Ninewells hospital and Medical School, Dundee DD1 9SY, United Kingdom

**Daniel Richard Gaya, Dr**, Gastrointestinal Unit, Molecular Medicine Centre, School of Molecular and Clinical Medicine, University of Edinburgh, Western General Hospital, Crewe Road, Edinburgh EH4 2XU, United Kingdom

**Subrata Ghosh, Professor**, Department of Gastroenterology, Imperial College London, Hammersmith Hospital, 9 Lady Aylesford Avenue, Stanmore, Middlesex, London HA7 4FG, United Kingdom

**William Greenhalf, PhD**, Division of Surgery and Oncology, University of Liverpool, UCD Building, 5th Floor, Royal Liverpool University Hospital, Daulby Street, Liverpool, L69 3GA, United Kingdom

**Peter Clive Hayes, Professor**, Liver Unit, Royal Infirmary, Si Little France Crescent, EH16 4SA, United Kingdom

**Gwo-Tzer Ho, MBChB**, Gastrointestinal Unit, Western General Hospital, Edinburgh, EH4 2XU, United Kingdom

**Anthony R Hobson, Dr**, Section of Gastrointestinal Sciences, University of Manchester, Eccles Old Road, Hope Hospital, Clinical

Sciences Building, Salford M6 8HD, United Kingdom

**David Paul Hurlstone, Dr**, Department of Endoscopy, B Floor, Royal Hallamshire Hospital, Glossop Road, Sheffield, Room BD69, South Yorkshire S10 2TN, United Kingdom

**Brian T Johnston, MD**, Department of Gastroenterology, Royal Victoria Hospital, Grosvenor Road, Belfast BT12 6BA, United Kingdom

**David EJ Jones, Professor**, Liver Research Group, University of Newcastle, SCMS, 4th Floor William Leech Building, Medical School, Framlington Place, Newcastle-upon-Tyne NE2 4HH, United Kingdom

**Michael A Kamm, Professor**, Department of Gastroenterology, St Mark's Hospital, St Mark's Hospital, Watford Road, Harrow HA1 3UJ, United Kingdom

**Patricia F Lalor, Dr**, Liver Research Laboratory, Room 537 Institute of Biomedical Research, Division of Medical Science, University of Birmingham, Birmingham B15 2TT, United Kingdom

**Hong-Xiang Liu, PhD**, Department of Pathology, Division of Molecular Histopathology, University of Cambridge, Box 231, Level 3, Lab Block, Addenbrooke's Hospital, Hills Road, Cambridge CB2 2QQ, United Kingdom

**Dermot Patrick McGovern, Dr** The Wellcome Trust Centre for Human genetics IBD, Roosevelt Drive Headington, Oxford OX3 7BN, United Kingdom

**Giorgina Mieli-Vergani, Professor**, Institute of Liver Studies, King's College Hospital, Denmark Hill, London, SE5 9RS, United Kingdom

**Nikolai V Naoumov, Professor**, Department of Medicine, Institute of Hepatology University College London, 69-75 Chenies Mews, London WC1E 6HX, United Kingdom

**John P Neoptolemos, Professor**, Division of Surgery and Oncology, University of Liverpool, Royal Liverpool University Hospital, Daulby Street, Liverpool, L69 3GA, United Kingdom

**James Neuberger, Professor**, Liver Unit, Queen Elizabeth Hospital, Birmingham B15 2TH, United Kingdom

**Mark S Pearce, Dr**, Paediatric and Lifecourse Epidemiology Research Group School of Clinical Medical Sciences, University of Newcastle, Sir James Spence Institute, Royal Victoria Infirmary, Newcastle upon Tyne, NE1 4LP, United Kingdom

**Marco Senzolo, Dr**, Liver Transplantation and Hepatobiliary Unit, Royal Free Hospital, London, United Kingdom

**Robert Sutton, Professor**, Division of Surgery and Oncology, School of Clinical Science, University of Liverpool, Royal Liverpool University Hospital, Daulby Street, Liverpool L69 3GA, United Kingdom

**Simon D Taylor-Robinson, MD**, Department of Medicine A, Imperial College London, Hammersmith Hospital, Du Cane Road, London W12 0HS, United Kingdom

**Ulrich Thalheimer, Dr**, Liver Transplantation and Hepatobiliary Medicine Unit, Royal Free Hospital, Pond Street, NW3 2QG London, United Kingdom

**Nick Paul Thompson, MD**, Department of Medicine, Freeman Hospital, Newcastle Upon Tyne, NE7 7DN, United Kingdom

**David Tosh, PhD**, Centre For Regenerative Medicine, Department of Biology and Biochemistry, University of Bath, Claverton Down, Bath BA2 7AY, United Kingdom

**Frank Ivor Tovey, OBE, ChM, FRCS**, Honorary Research Fellow, Department of Surgery, University College London, London, United Kingdom

**Diego Vergani, Professor**, Institute of Liver Studies, King's College Hospital, London SE5 9RS, United Kingdom

**Peter James Whorwell, Professor**, Academic Department of Medicine, Education and Research Centre, Wythenshawe Hospital, Southmoor Road, Manchester, M23 9LT, United Kingdom

**Karen Leslie Wright, Dr**, Department of Pharmacy and Pharmacology, University of Bath, Claverton Down, Bath BA2 7AY, United Kingdom

**Min Zhao, Professor**, School of Medical Sciences, University of Aberdeen, Foresterhill AB252ZD, United Kingdom

#### United States

**Christian Cormac Abnet, PhD, MPH**, Investigator, Nutritional Epidemiology Branch Division of Cancer Epidemiology and Genetics, 6120 Executive Blvd, EPS/320, MSC 7232 Rockville, MD 20852, United States

**Gary A Abrams, Associate Professor**, Department of Medicine, University of Alabama at Birmingham, 1530 3rd Ave South, Birmingham 35294, United States

### Abstract

Gastric cancer is the second most frequent cancer in the world, accounting for a large proportion of all cancer cases in Asia, Latin America, and some countries in Europe. *Helicobacter pylori* (*H. pylori*) is regarded as playing a specific role in the development of atrophic gastritis, which represents the most recognized pathway in multistep intestinal-type gastric carcinogenesis. Recent studies suggest that a combination of host genetic factors, bacterial virulence factors, and environmental and lifestyle factors determine the severity of gastric damage and the eventual clinical outcome of *H. pylori* infection. The seminal discovery of *H. pylori* as the leading cause of gastric cancer should lead to effective eradication strategies. Prevention of gastric cancer requires better screening strategies to identify candidates for eradication.

### INTRODUCTION

*Helicobacter pylori* (*H. pylori*) is a Gram-negative, microaerophilic bacterium which expresses an abundant amount of urease. Infection with this bacterium is a worldwide phenomenon. Prevalence increases with age, but differs quite dramatically among populations<sup>[1-4]</sup>. In the USA, prevalence is less than 20% at 20 years old and approximately 50% at 50 years<sup>[2]</sup>. In Japan, it is less than

20% under 20 years, increasing to a plateau of 70-80% at 40 years<sup>[3]</sup>, while in Korea, it is 50% at 5 years and 90% at 20 years<sup>[4]</sup>.

The epidemiological data suggest that *H. pylori* gastritis is associated with gastric carcinogenesis<sup>[5,6]</sup>. *H. pylori* colonizes the gastric mucosa and elicits both inflammatory and immune lifelong responses, including the release of various bacterial and host-dependent cytotoxic substances<sup>[7]</sup>. Pathological and clinical studies have convincingly proved the etiological role of *H. pylori* in the development of chronic gastritis<sup>[8]</sup> and peptic ulcer<sup>[9]</sup>. Moreover, *H. pylori* infection has been recognized as a risk factor for both the diffuse and intestinal types of gastric cancer<sup>[10]</sup>, and the bacterium itself is classified as a class I carcinogen by the World Health Organization and International Agency for Research on Cancer Consensus Group<sup>[11]</sup>.

*H. pylori* strains carrying the cytotoxin-associated gene A (*cagA*) gene are strongly associated with an increased risk of gastric adenocarcinoma<sup>[12]</sup>. Recent studies suggest that the severity of gastric damage and eventual clinical outcome of *H. pylori* infection are determined by a combination of host genetic and bacterial virulence factors<sup>[13-17]</sup>. *cagA* is divided into two major subtypes, the East Asian and Western types<sup>[18]</sup>. The grade of gastric atrophy (and therefore gastric cancer risk) is higher in patients with East Asian *cagA*-positive strains than in those with *cagA*-negative or Western *cagA*-positive strains. Of interest is that atrophy grade varies even among patients with East Asian *cagA*-positive strains<sup>[19]</sup>, and that most *H. pylori*-infected subjects in fact develop no significant disease, remaining asymptomatic throughout their lives. The reasons for this are not explained by bacterial virulence factors alone; rather, genetic factors of the host should also be considered to play a role in *H. pylori*-induced outcomes.

Here, we discuss recent developments in gene-environment interaction and the importance of *H. pylori* eradication in the prevention of gastric cancer.

### Association between *H. pylori* and gastric cancer

*H. pylori* has been associated with the location of gastric cancers, specifically those of the body and antrum. No association is seen with the location of cardiac tumors<sup>[20]</sup>. *H. pylori* gastritis is characterized by severe, acute and chronic inflammation which would last for decades if not treated<sup>[21]</sup>. Such persistent inflammation likely has serious biological implications. For example, activated neutrophils generate reactive oxygen and nitrogen species, which are mutagenic and carcinogenic<sup>[22,23]</sup>. Atrophic

**Figure 1** Deregulation of SHP-2 tyrosine phosphatase by the *H. pylori* virulence factor CagA. CagA is delivered into gastric epithelial cells by the bacterial type IV secretion system. CagA deregulates the SHP2 oncoprotein. CagA is noted for its variation, particularly at the SHP2-binding site.

gastritis, intestinal metaplasia and dysplasia are known to be precancerous. Uemura *et al* reported that gastric cancer developed in 36 (2.9%) of 1246 infected and none of 280 uninfected patients<sup>[24]</sup>. Among their patients with *H. pylori* infection, those with severe gastric atrophy, corpus-predominant gastritis and intestinal metaplasia were at a significantly higher risk for gastric cancer. Direct associations between *H. pylori* infection and gastric cancer have been examined for many regions and ethnic groups<sup>[25]</sup>. In their retrospective analysis of a nested case-control study, Wang *et al* reported that the risk of death from gastric cancer in the *H. pylori* -positive cohort was 1.985 times to the -negative control cohort (95% CI, 1.0026-3.9301), and that the OR of *H. pylori* infection for gastric cancer was 4.467 (95% CI, 1.161-17.190)<sup>[26]</sup>. The high incidence of infection in patients with gastric cancer has been confirmed for both the intestinal and diffuse types, and is particularly strong in the former<sup>[27]</sup>. However, while *H. pylori* appears to play a role in the initial step as a causative agent for chronic gastritis, the development of gastric cancer is multi-factorial.

Khanna *et al* in India reported a lower prevalence of *H. pylori* infection in gastric cancer patients than in the healthy controls, without significance, and suggested that *H. pylori* may not be responsible for gastric cancer<sup>[28]</sup>. On the other hand, Enroth *et al* showed that relative risk estimates for the association between *H. pylori* and gastric cancer risk are to some extent determined by the diagnostic method used to detect *H. pylori* infection<sup>[29]</sup>. The loss of serological markers of *H. pylori* infection following the onset of severe atrophy and intestinal metaplasia is a well-known phenomenon, not least in Japan<sup>[30]</sup>.

While some studies have reported no association with gastric cancer, the summary statistic derived from a meta-analysis indicated no doubt as to the existence of an association<sup>[25]</sup>.

### Role of *cagA*-positive *H. pylori* in the pathogenesis of gastric cancer

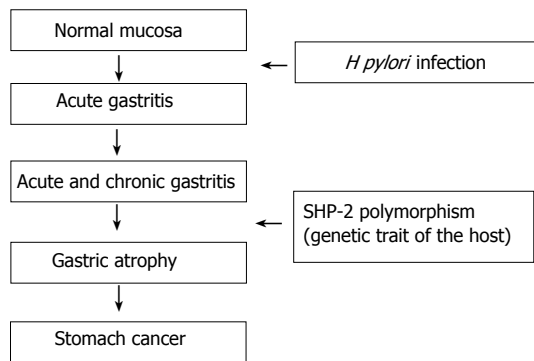

Recent studies have suggested that patients infected with *cagA*-positive strains of *H. pylori* are at a significantly higher risk for gastric cancer than those carrying *cagA*-negative strains<sup>[31-36]</sup>. *CagA* protein, encoded by the *cagA* gene, is one of the most studied virulence factors of *H. pylori* and is a highly immunogenic protein. The *cagA* gene is one of several genes of a pathogenicity island (PAI) called the *cag* PAI. The *cag* PAI contains 31 genes, 6 of which are thought to be encoded by a putative type IV secretion system. Although *H. pylori* *cagA*-positive isolates from the USA and Japan induce similar IL-8 and apoptosis levels<sup>[37]</sup>, the grade of gastric atrophy (and gastric cancer risk) is higher in patients with the East Asian *cagA*-positive strains than in those with *cagA*-negative or Western *cagA*-positive strains<sup>[18]</sup>. In Asian populations, however, almost all infected subjects harbor *cagA*-positive strains, raising legitimate questions about the relevance of this virulence factor as a risk determinant in such populations.

Held *et al* reported that although patients with antibodies to *CagA* at greatest risk of gastric cancer, risk is still significantly higher in those with *cagA*-negative *H. pylori* infections than in uninfected persons<sup>[38]</sup>. Anti-*CagA* responses correlate with neutrophil infiltration, a low anti-*H. pylori* IgG titer or combined with *H. pylori* seronegativity was closely associated with non-cardia gastric cancer, independently of ethnicity<sup>[40]</sup>. A meta-analysis of the relationship between *CagA* seropositivity and gastric cancer showed that infection with *cagA*-positive *H. pylori* increased the risk for gastric cancer over that with *H. pylori* infection alone<sup>[41]</sup>. Because antibodies to *CagA* remain positive for longer than IgG antibodies to *H. pylori*<sup>[42,43]</sup>, the risk for gastric cancer based on *H. pylori* IgG antibody might be underestimated<sup>[35,44]</sup>.

*CagA* is delivered into epithelial cells by the *cag* type IV secretion system, then phosphorylated on tyrosine residues and wired to the eukaryotic signal transduction pathway, which plays a major role in *H. pylori* -host cell interactions and pathogenesis (Figure 1)<sup>[45-48]</sup>. In the injected gastric epithelial cell, *CagA* induces cellular spreading and elongation, termed the hummingbird phenotype, and this is thought to play a crucial role in the pathogenesis of *cagA*-positive *H. pylori* infection. This *CagA*-dependent morphological transformation of gastric epithelial cells requires src homology 2 domain-containing protein tyrosine phosphatase-2 (SHP-2)<sup>[49]</sup>. SHP-2 plays a key role in the intracellular signaling elicited by a number of growth factors, hormones and cytokines<sup>[50,51]</sup>. East Asian-type *CagA* exhibits stronger SHP-2-binding activity than Western-type *CagA*<sup>[19]</sup>. *CagA*-SHP-2 signaling may induce apoptosis and elevate the epithelial cell turnover associated with *cagA*-positive *H. pylori* infection<sup>[26-32]</sup>. Extra cycles of DNA replication would increase the chance of genetic mutation leading to abnormal proliferation.

We have reported the association of a frequent single nucleotide polymorphism (SNP, JST057927, G-to-A) in the *PTPN11* gene that encodes SHP-2 with gastric atrophy and gastric cancer<sup>[52]</sup>. We found that this polymorphism increased the risk of gastric atrophy and gastric cancer among *H. pylori* -seropositive Japanese subjects. Carriage of the G allele of *PTPN11* increased the risk of atrophy

**Figure 2** Multistep model for the progression of gastric cancer.

whereas the *A/A* genotype was protective against it. The SHP-2-binding activity of *CagA* influences the its virulence in the induction of gastric atrophy, the precursor lesion of gastric cancer. *PTPN11 G/A* polymorphism may constitute a genetic trait of the host predisposing to atrophy among those infected (Figure 2). *CagA*-SHP-2 complex formation may induce abnormal proliferation and movement of gastric epithelial cells, cellular changes that may eventually lead to gastric atrophy and gastric carcinoma. Against this, however, several groups have reported that SHP-2 is not involved in *CagA* action<sup>[53,54]</sup>. The resolution of this controversy is awaited.

#### **Effect of pro-and anti-inflammatory cytokine gene polymorphism on *H pylori*-induced gastric cancer**

High mucosal levels of cytokines in *H pylori*-infected patients have been reported, including IL-8, IL-6, IL-1B, TNF- $\alpha$ , MIP 1 $\alpha$  and IL-2<sup>[55-62]</sup>. Host cytokine gene polymorphisms *IL-1B*, *IL-1RN*, *TNF- $\alpha$*  and *IL-10* are suggested to be part of the genetic background predisposing patients to noncardia gastric cancer in response to *H pylori*<sup>[13,15,17,63]</sup>. *IL-1B* and *TNF- $\alpha$*  are functional polymorphisms that affect the production of IL- $\beta$  and TNF- $\alpha$ , which inhibit gastric acid secretion<sup>[64,65]</sup>. The *IL-1B* gene encoding IL-1 $\beta$  is highly polymorphic, and several diallelic polymorphisms have been reported, two in the promoter region at positions -511 and -31, representing C-T and T-C transitions, respectively. Several studies have shown that these two polymorphisms are in near-total linkage disequilibrium<sup>[13,66]</sup>. They have been shown to significantly affect gastric mucosal IL-1 $\beta$  production in response to *H pylori* infection<sup>[67,68]</sup>, and it is this higher production of IL-1 $\beta$  which most likely mediates their effect on gastric acid secretion. Zambon *et al* have reported that among host genetic factors contributing to *H pylori* disease outcome, *IFN- $\gamma$  AA* favors *cagA*-positive *H pylori* infection, *TNF- $\alpha$  TT* favors duodenal ulcer, while *IL-10 TT* favors intestinal metaplasia and noncardia gastric cancer<sup>[69]</sup>. In Japan and Korea, however, these associations appear less clear<sup>[70,71]</sup>.

#### ***H pylori*-induced gastric cancer and environmental and lifestyle factors**

A joint World Health Organization/Food and Agriculture Organization Expert Consultation concluded that salt and salt-preserved food probably increase the risk of gastric

cancer<sup>[72]</sup>. Substantial evidence from ecological, case-control and cohort studies suggest that cancer risk may also increase with a high intake of some traditional salt-preserved foods and salt *per se*, and that this risk could be decreased with a high intake of fruits and vegetable<sup>[73,74]</sup>. Other established non-dietary factors include cigarette smoking<sup>[75]</sup>. Tsugane *et al* have documented that the consumption of salted food (pickled vegetables and miso soup) appears to increase the risk of *H pylori* infection<sup>[76]</sup>. Salted food intake has been shown to act synergistically to promote the development of gastric cancer in Mongolian gerbils treated with N-methyl-N-nitrosourea (MNU)<sup>[77]</sup>, and a synergistic enhancing effect between salted food intake and *H pylori* infection has also been reported in a case-control study in Korea<sup>[78]</sup>. Motani *et al*<sup>[79]</sup> reported that smoking and a high intake of miso soup were associated with noncardia cancer regardless of *H pylori* infection, and also a strong association between *cagA*-positive *H pylori* and noncardia cancer. Although *H pylori* infection is clearly an important risk factor for gastric cancer, smoking cessation and dietary modification may be practical strategies for the prevention of non-cardia gastric cancer among both *H pylori*-positive and -negative subjects.

Conclusive proof for a preventive effect of *H pylori* eradication on gastric carcinogenesis will never be available, because doing so would require the inclusion of individuals in a placebo trial in which the end point is gastric cancer; for not only practical but also ethical and economic reasons, no such study will ever be performed. The alternative is randomized controlled studies that are designed to examine the regression of preneoplastic conditions, such as intestinal metaplasia and gastric atrophy, as surrogate end points of eradication treatment success. One such study is a prospective, randomized, placebo-controlled, population-based primary prevention study of 1630 healthy carriers of *H pylori* infection from Fujian Province, China, recruited in July 1994 and followed up until January 2002<sup>[80]</sup>. A total of 988 participants did not have precancerous lesions (gastric atrophy, intestinal metaplasia, or gastric dysplasia) on study entry. Patients were randomly assigned to receive *H pylori* eradication treatment by a 2-wk course of omeprazole 20 mg, a combination product of amoxicillin and clavulanate potassium, 750 mg, and metronidazole 400 mg, all twice daily ( $n = 817$ ); or placebo ( $n = 813$ ). Among the 18 new cases of gastric cancer that developed, no overall reduction was observed in participants who received *H pylori* eradication treatment ( $n = 7$ ) compared with those who did not ( $n = 11$ ). In a subgroup of patients with no precancerous lesions on entry, no patient developed gastric cancer during a follow-up of 7.5 years after *H pylori* eradication treatment compared with those who received placebo (0 *vs* 6;  $P = 0.02$ ). Although the incidence of gastric cancer development at the population level was similar between participants receiving *H pylori* eradication treatment and those receiving placebo over 7.5 years in a high-risk region of China, eradication of *H pylori* significantly decreased the development of gastric cancer in the subgroup of *H pylori* carriers without precancerous lesions.

A second study was conducted in Hong Kong<sup>[81]</sup>.

The authors randomized 435 subjects into placebo and eradication groups, the latter of whom received a one-week course of anti-*H pylori* therapy of OAC (omeprazole 20 mg, amoxicillin 1g, and clarithromycin 500 mg twice a day). Clearance of *H pylori* infection at 5 years was confirmed by histology in 164 (74.5%) who had received the eradication therapy versus only 20 (9.3%) subjects in the placebo group. Ten subjects developed invasive gastric cancer during the 5-year follow-up period, four in the eradication and six in the placebo group. Overall progression of gastric intestinal metaplasia (IM), defined as a surrogate marker of cancer, was seen in 52.9% of subjects. Eradication of *H pylori* was significantly associated with a decrease in the risk of IM progression. Patients assigned to receive OAC had a significantly lower risk of progression compared with those who received placebo (OR for progression 0.63; 95% CI, 0.43-0.93). When those in the OAC group with eradication were compared with those in the placebo group with persistent infection, the OR of histological progression was further reduced to 0.48 (95% CI, 0.32-0.74). Although this intervention study failed to demonstrate an effect on gastric cancer risk, eradication of *H pylori* was protective against the progression of a premalignant gastric lesion, namely IM.

Another study was reported from Mexico<sup>[82]</sup>. A total of 316 *CagA*-positive subjects were randomized into placebo ( $n=155$ ) and eradication groups ( $n=161$ ), who received 20 mg of omeprazole, 1 g of amoxicillin and 500 mg of clarythromycin, all twice a day for 1 week. Endoscopy was performed at baseline and at 6 weeks and 1 year, with seven biopsies from each endoscopy reviewed by two pathologists. Cure rates in the eradication group were 79.2% and 75.7% at 6 weeks and 1 year, respectively, compared with respective placebo rates of 2.9% and 1.9% ( $P<0.001$ ). Outcome measures were both a consensus "worst biopsy" diagnosis and a weighted index score that incorporated the degree of severity of preneoplasia, with changes in these outcomes compared over time. No significant change in the worst biopsy diagnosis was observed between groups (improvement/worsening: placebo, 19.4%/10.5%; treatment, 22.5%/8.3%;  $P=0.74$ ). The change in index score was favorably greater in the treatment than in the placebo subjects (intention-to-treat analysis,  $P=0.03$ ). These studies of intermediate biomarkers provide circumstantial evidence that *H pylori* eradication diminishes the risk of gastric cancer.

Following partial gastrectomy, the mucosa of the residual stomach usually undergoes severe changes, such as gastric atrophy, intestinal metaplasia and dysplasia<sup>[83,84]</sup>. The 1996 Maastricht Consensus Report strongly recommended eradication in infected patients who had undergone gastrectomy for early gastric cancer<sup>[85]</sup>. Definite proof of the merit of eradication awaits the completion of a large randomized trial using cancer as the outcome. Nevertheless, the evidence now available supports a conclusion for eradication.

Effective *H pylori* eradication along with a natural decrease in infection due to improved living conditions have resulted in declining gastric cancer rates in Western countries, although this still remains a significant cause of morbidity and mortality in other parts of the world. While

the genes in *cag* PAI are the most strongly virulence-related among those reported to date, other genes have also been reported as candidates that determine outcome in *H pylori*-infected persons<sup>[86,87]</sup>. Studies that identify further bacterial as well as host genetic factors that place the patient at greatest risk of disease progression may enhance our approach to better screening strategies, and will improve the control of *H pylori* infection in affected subjects.

## Abstract

Lactose malabsorption is a very common condition characterized by intestinal lactase deficiency. Primary lactose malabsorption is an inherited deficit present in the majority of the world's population, while secondary hypolactasia can be the consequence of an intestinal disease. The presence of malabsorbed lactose in the colonic lumen causes gastrointestinal symptoms. The condition is known as lactose intolerance. In patients with lactase nonpersistence, treatment should be considered exclusively if intolerance symptoms are present. In the absence of guidelines, the common therapeutic approach tends to exclude milk and dairy products from the diet. However, this strategy may have serious nutritional disadvantages. Several studies have been carried out to find alternative approaches, such as exogenous  $\beta$ -galactosidase, yogurt and probiotics for their bacterial lactase activity, pharmacological and non pharmacological strategies that can prolong contact time between enzyme and substrate delaying gastrointestinal transit time, and chronic lactose ingestion to enhance colonic adaptation. In this review the usefulness of these approaches is discussed and a therapeutic management with a flow chart is proposed.

## INTRODUCTION

Lactose malabsorption is a very common condition

characterized by lactase deficiency, an enzyme occurring in the brush border membrane of the intestinal mucosa that hydrolyzes lactose to its components galactose and glucose<sup>[1]</sup>. High concentrations of this enzyme are physiologically present in neonates. Post weaning, a genetically programmed and irreversible reduction of its activity occurs in the majority of the world's population<sup>[2]</sup> which results in primary lactose malabsorption. Secondary hypolactasia can be the consequence of any condition that damages the small intestinal mucosa brush border or significantly increases the gastrointestinal transit time. Thus, secondary hypolactasia is transient and reversible<sup>[3]</sup>.

The presence of malabsorbed lactose in the colonic lumen does not necessarily result in gastrointestinal symptoms. Only when lactose malabsorption is associated with clinical manifestations as bloating, flatulence, abdominal pain and diarrhea, "lactose intolerance" occurs<sup>[4]</sup>.

Diagnosis of lactose intolerance is often made on a clinical basis and in response to an empirical trial of dietary lactose avoidance. A number of methods are available to diagnose lactose malabsorption<sup>[4-8]</sup>. The lactose breath hydrogen test is nowadays considered a very simple and useful test in subjects with suspected lactose malabsorption. Undigested lactose is fermented by the colonic microflora with production of hydrogen detectable in pulmonary excretion<sup>[6]</sup>. Direct lactase enzyme activity performed on small intestinal tissue biopsy samples may be utilized, but it is an invasive procedure and its reliability can be low because disaccharidase activity in a small biopsy specimen does not necessarily reflect the jejunal activity as a whole<sup>[4]</sup>. Recent evidence suggests that a genetic test of the -13910 C/T polymorphism can be used as the first stage screening test for adult-type hypolactasia<sup>[9,10]</sup>.

## THERAPEUTIC STRATEGIES

In patients with lactase nonpersistence, treatment is considered exclusively in the presence of intolerance symptoms<sup>[11]</sup>. In the absence of guidelines, the common therapeutic approach tends to exclude milk and dairy products from the diet. However, this strategy may have serious nutritional disadvantages, chiefly for reduced intake of substances such as calcium, phosphorus and vitamins, and may be associated with decreased bone mineral density<sup>[12,13]</sup>. To overcome these limits, several studies have been carried out to find alternative approaches, such as exogenous  $\beta$ -galactosidase, yogurt and probiotics for their bacterial lactase activity, pharmacological and non

pharmacological strategies that can prolong contact time between enzyme and substrate delaying gastrointestinal transit time, and chronic lactose ingestion to enhance colonic adaptation.

### Exogenous $\beta$ -galactosidase

Enzyme-replacement therapy with microbial exogenous lactase (obtained from yeasts or fungi) represents a possible strategy for primary lactase deficiency. Enzymes can be added in a liquid form to milk before its consumption or administered in a solid form (capsules or tablets) together with milk and dairy products. Several studies were conducted adding the soluble enzyme to milk some hours before its consumption, thus obtaining a "preincubated milk" [9, 14-17]. This strategy is effective in reducing both  $H_2$  breath excretion and subjective manifestations of discomfort after milk ingestion. However, these trials were carried out on relatively small series populations. They were not placebo-controlled, and results were not comparable since there was a lack of homogeneity in patient subsets. Furthermore, preincubated milk was not considered practical because of the necessity to add the enzyme some hours before its consumption. The low-lactose milk is a preincubated milk in which the lactose is already pre-hydrolyzed; this product is commercially available but not distributed everywhere (i.e. restaurant, cafeterias, etc). To obviate these problems, several studies have been carried out to show the effectiveness of replacement therapy even when lactase is administered at mealtime [18-22].

In a recent double-blind, placebo-controlled crossover study in 30 intolerant subjects with lactose malabsorption, we showed that both "preincubated milk" and milk treated at mealtime are similarly able to significantly reduce  $H_2$  excretion and symptom score, suggesting that enzymes can be used at mealtime because of its better practicality [23].

While the efficacy of liquid exogenous lactase in reducing both  $H_2$  excretion and symptoms is widely emphasized, results about the exact rate of efficacy are somehow discordant. Several factors may justify these discrepancies. The different enzyme origin can play a role. It is well-known that, at the same dose, enzymes obtained from different microorganisms have different efficacy in hydrolyzing lactose. In fact, comparative studies have already shown the higher efficacy of lactase derived from *K. lactis* than that of the enzyme obtained from *A. niger* [5, 19]. The contribution of residual intestinal mucosal lactase activity should also be considered to explain the variation in intolerance symptoms experienced by lactose malabsorbers. The results of non crossover studies without considering intra-individual variables can be biased, if the residual intestinal mucosal enzyme activity is ignored. Moreover, the different dosage of the enzyme could be another influencing factor. In fact, it is known that a close relationship exists between the amount of lactose to be hydrolyzed and the enzyme units required [5, 21]. Moreover, the stomach pH and bile salt concentrations could influence the efficacy of exogenous lactase.

Solid lactase preparations, in capsules and tablets, are commercially available alternatives for enzyme-replacement therapy. Several studies have investigated and confirmed their efficacy [25-26]. However, comparative studies have

shown that these preparations are more expensive and significantly less effective than prehydrolyzed milk probably due to the enzyme gastric inactivation [11, 17]. Their use can be suggested for solid dairy products.

Therapy compliance with  $\beta$ -galactosidase is assured by good palatability [16, 21, 23] though there are some reported taste alterations [27]. The safety of lactase preparations has recently been confirmed [28]. In conclusion, the addition of exogenous lactase, especially at mealtime, seems to be effective, practical and with no side effects.

### Yogurt and probiotics

It is well-known that fermented milk products improve lactose digestion and symptoms of intolerance in lactose maldigesters [17, 29, 30]. Onwulata *et al* [17] demonstrated that commercially available plain yogurt is as effective in reducing  $H_2$  and symptoms as prehydrolyzed milk. The use of fermented milk is based on the presence of endogenous lactase activity of yogurt microorganisms. Yogurt is made of milk incubated mainly with two species of lactic acid bacteria, *L. bulgaricus* and *S. thermophilus* [29, 31]. These microorganisms participate in lactose hydrolysis both during fermentation processes and after lactose ingestion [32-34]. It has been calculated that fermentation decreases lactose content by approximately 25-50% [33-34]. At the same time, this process results in an acid taste and just for this tartness several subjects dislike yogurt. To overcome this limit, the addition of high concentrations of viable *L. acidophilus* to cold milk has been proposed as an alternative to yogurt, obtaining an unfermented milk (sweet acidophilus milk). However, in a comparative crossover study carried out in eleven lactose malabsorbers, Payne *et al* [5] first demonstrated that sweet acidophilus milk does not reduce  $H_2$  excretion and symptoms significantly as milk treated with a commercial lactase preparation. Further studies have confirmed the inadequate effectiveness of sweet acidophilus milk [17, 33, 35]. To explain these findings, it has been proposed that bacterial lactase in sweet acidophilus milk is insufficient to show a measurable effect or is not easily available in the intestinal lumen, becoming accessible only if disruption of the cell membrane occurs [30, 33]. In fact, the cell membrane structures of lactic acid bacteria play a key role in the availability of  $\beta$ -galactosidase [17, 36]. Lin *et al* [37] compared *L. bulgaricus* and *L. acidophilus*, two thermophilic bacteria with similar  $\beta$ -galactosidase activity, bile sensitivity and active transport system for lactose, while differing in the resistance of the cell wall membrane structures, as shown by sonication time for maximum  $\beta$ -galactosidase activity measurements. By measuring  $H_2$  excretion and clinical score, they found that *L. bulgaricus* is a better choice for manufacturing non fermented milk products, because the cell wall membrane structures of *L. bulgaricus* are less tough than those of *L. acidophilus*, with a consequent better ability to release the enzyme.

To effectively release  $\beta$ -galactosidase, bacteria need an intact cell wall as mechanical protection of the enzyme during gastric passage and against the action of bile [38]. It was demonstrated that gastric acid degrades bacterial lactase activity in 20-60 min [39]. However, the association of *L. acidophilus* BG2F04 with omeprazole does not result in reduced hydrogen production and gastrointestinal symp-

toms are not improved after lactose ingestion with respect to lactobacilli without it <sup>[40]</sup>. These results could have been due to the selected lactic bacteria. In fact, it is well-known that lactobacilli behave differently depending on the species <sup>[41, 42]</sup>. As recently demonstrated, administration of the multiprobiotic product VSL3 cannot reduce H<sub>2</sub> excretion and clinical score <sup>[43]</sup>. Further investigations are necessary to clarify the probiotics role in lactose intolerance therapy, also considering their well-known beneficial effects on intestinal functions, gas metabolism and motility <sup>[38]</sup>.

The bacterial  $\beta$ -galactosidase activity of yogurt is considered to be the main factor responsible for improving lactose digestion; its greater osmolality and energy density can also play a role <sup>[38]</sup>. Yogurt delays gastric emptying and intestinal transit causing slower delivery of lactose to the intestine, thus optimizing the action of residual  $\beta$ -galactosidase in the small bowel and decreasing the osmotic load of lactose <sup>[3, 38]</sup>.

### Strategies influencing gastrointestinal transit

Leichter *et al* <sup>[44]</sup> showed that full-fat milk (high energy milk) increase lactose tolerance compared to skimmed milk and aqueous lactose solution. It has been reported that fat improves carbohydrate absorption slowing down gastric emptying and intestinal transit time with a consequent prolongation of contact time between enzyme and substrate <sup>[45-47]</sup>. Other studies have not confirmed these results <sup>[48, 49]</sup>. In particular, Vesa *et al* <sup>[49]</sup> have proved that the ingestion of high energy milk delays more significantly gastric emptying than half-skimmed milk but it does not result in a significant improvement in lactose tolerance. To improve lactose digestion by delaying gastric emptying, co-ingestion of food together with dairy products has also been proposed, and it has been demonstrated that lactose is better tolerated when taken with other foods <sup>[19, 50]</sup>.

Pharmacological approaches that can modify gastric emptying and intestinal transit have also been considered. A double-blind randomized cross-over placebo-controlled study <sup>[51]</sup> evaluated the effect of propantheline and metoclopramide on lactose digestion, and found that propantheline-induced prolongation of gastric emptying improves lactose tolerance as measured by reduced symptoms and H<sub>2</sub> breath concentration compared to placebo or metoclopramide. Loperamide has been proposed for its activity on oral-cecal transit time. Szilagy *et al* <sup>[52]</sup> demonstrated that loperamide improves H<sub>2</sub> excretion and symptoms when administered together with milk. Later on, the authors concluded that the use of loperamide is not advisable because of its side-effects and high cost <sup>[53]</sup>.

### Adaptation

Lactase is a non inducible enzyme <sup>[1]</sup>, but it was also reported that continuous lactose consumption decreases hydrogen excretion and the severity of gastrointestinal symptoms <sup>[54-58]</sup>. Decreased hydrogen excretion is not necessarily the consequence of increased lactose digestion but can depend on adaptive phenomena. This "adaptation" is associated with changes in gut microflora as well as in some colonic functions and features. The increased microbial  $\beta$ -galactosidase activity is one of the hypothesized mechanisms. Hertzler *et al* <sup>[59]</sup> showed that fecal  $\beta$ -galactosidase activity is increased after daily milk feeding for 10 d. However, the lower H<sub>2</sub> production

**Figure 1** Proposal of therapeutic management in lactose intolerant patients with lactase deficit

is not related to higher levels of lactase in the existing flora. It has been suggested that changes in the intestinal microflora could decrease hydrogen production and/or increase intestinal gas consumption <sup>[60]</sup>. Hill *et al* <sup>[61]</sup> have proved that malabsorbed lactose enhances the fermentation ability of bifidobacteria and other lactic acid bacteria which can metabolize lactose without hydrogen production. Perman *et al* <sup>[62]</sup> hypothesized that the reduction of colonic pH due to the fermentation of malabsorbed lactose affects bacterial metabolism and inhibits hydrogen production. The placebo effect has been suggested as an additional factor to explain the adaptation in response to continuous lactose ingestion. In a controlled double-blind study, Briet *et al* <sup>[59]</sup> have demonstrated increased fecal  $\beta$ -galactosidase, reduced H<sub>2</sub> excretion and improved symptoms after lactose ingestion for 13 d. However, in the control group with sucrose, no sign of metabolic adaptation could be found except for a reduced clinical score, suggesting a placebo effect.

### PROPOSAL OF THERAPEUTIC MANAGEMENT

We suggest a flow chart for the therapeutic management of lactose malabsorption considering data gathered from literature and our personal experience (Figure 1). We underline that not all subjects with lactase deficit have to be treated, but just symptomatic ones, since there are no known adverse effects of lactose maldigestion other than acute gastrointestinal symptoms <sup>[11]</sup>. Furthermore, most lactose-intolerant people can ingest 12 g/d of lactose (equivalent to one cup of milk), without experiencing adverse symptoms <sup>[63-64]</sup>.

It is necessary to distinguish between primary and secondary lactase deficit. In the secondary form a temporary lactose-free diet is necessary only until a complete recovery of the causative pathological condition is obtained. Lactose breath test can be advised to verify the recovered enzymatic activity. In primary hypolactasia, a different therapeutic strategy should be considered because of the irreversibility of the condition. Initially, a temporary avoidance of milk and dairy products from the diet should be indicated to obtain symptom remission. Subsequently, we suggest a gradual re-introduction of dairy products considering the individual threshold dose, to assure an ad-

equate intake of essential nutritional substances. In order to raise the threshold dose, some non-pharmacological and pharmacological strategies should be considered. Changes in dietary habits, as the ingestion of milk together with other foods such as brioches, cookies and cake, and the consumption of fermented and matured dairy products can assure an adequate milk intake while preventing the onset of intolerance symptoms. Chronic consumption of milk seems to be useful to favorite the adaptation. Considering the dose-dependent lactose absorption, we suggest the distribution of the daily milk amount in small meals. If these strategies fail to reduce lactose intolerance, some pharmacological therapies are available. The addition of exogenous lactase in a liquid form to milk at mealtime has been demonstrated effective and practical. Pre-hydrolyzed milk preparations (i.e. on sale low-lactose content milk) could also be advisable.  $\beta$ -galactosidase tablets or capsules are suitable only for consumption of solid dairy products. Based on the literature data no other pharmacological strategies can be suggested. A pharmacological support of calcium and vitamins is required independently of the chosen therapeutic approach if the daily intake of dairy products is not assured.

### Methylation

Tamura G. Alterations of tumor suppressor and tumor-related genes in the development and progression of gastric cancer. *World J Gastroenterol* 2006; 12(2):192-198

<http://www.wjgnet.com/1007-9327/12/192.asp>

### Abstract

The development and progression of gastric cancer involves a number of genetic and epigenetic alterations of tumor suppressor and tumor-related genes. The majority of differentiated carcinomas arise from intestinal metaplastic mucosa and exhibit structurally altered tumor suppressor genes, typified by *p53*, which is inactivated via the classic two-hit mechanism, i.e. loss of heterozygosity (LOH) and mutation of the remaining allele. LOH at certain chromosomal loci accumulates during tumor progression. Approximately 20% of differentiated carcinomas show evidence of mutator pathway tumorigenesis due to *hMLH1* inactivation via hypermethylation of promoter CpG islands, and exhibit high-frequency microsatellite instability. In contrast, undifferentiated carcinomas rarely exhibit structurally altered tumor suppressor genes. For instance, while methylation of *E-cadherin* is often observed in undifferentiated carcinomas, mutation of this gene is generally associated with the progression from differentiated to undifferentiated carcinomas. Hypermethylation of tumor suppressor and tumor-related genes, including *APC*, *CHFR*, *DAP-kinase*, *DCC*, *E-cadherin*, *GSTP1*, *hMLH1*, *p16*, *PTEN*, *RASSF1A*, *RUNX3*, and *TSLC1*, can be detected in both differentiated and undifferentiated carcinomas at varying frequencies. However, the significance of the hypermethylation varies according to the analyzed genomic region, and hypermethylation of these genes can also be present in non-neoplastic gastric epithelia. Promoter demethylation of specific genes, such as *MAGE* and *synuclein  $\gamma$* , can occur during the progressive stages of both histological types, and is associated with patient prognosis. Thus, while the molecular pathways of gastric carcinogenesis are dependent on histological background, specific genetic alterations can still be used for risk assessment, diagnosis, and prognosis.

### INTRODUCTION

Ever since the initial report of frequent mutation of the *p53* tumor suppressor gene in primary gastric cancers<sup>[1]</sup>, a growing number of genetic and epigenetic alterations in tumor suppressor and tumor-related genes have been determined to be involved in gastric carcinogenesis. In addition to *p53* mutations, *epithelial (E)-cadherin* mutations are also frequent and appear to be important in gastric carcinogenesis<sup>[2,3]</sup>, such that germline mutations of *p53* and *E-cadherin* have both been associated with hereditary gastric cancer<sup>[4,5]</sup>. These genes are frequently inactivated by the combination of mutation and loss of heterozygosity (LOH)<sup>[1,3]</sup>, although *E-cadherin* can also be inactivated by promoter hypermethylation<sup>[6]</sup>. LOH at other chromosomal loci can accumulate during gastric cancer progression<sup>[7]</sup>. In contrast, mutations of the DNA mismatch repair genes *hMSH2* and *hMLH1* are rare, despite the finding of high-frequency microsatellite instability (MSI) in gastric cancers<sup>[8-10]</sup>. Recently, hypermethylation of the *hMLH1* promoter CpG island was found to be responsible for the development of the majority of gastric cancers exhibiting MSI<sup>[11]</sup>. Thus, inactivation of *hMLH1* via promoter methylation leads to MSI, and subsequently to mutations in simple repetitive sequences contained within a number of target genes associated with cell proliferation, apoptosis, or mismatch repair, e.g., *transforming growth factor- $\beta$  type II receptor (TGF- $\beta$  RII)*, *bcl-2-associated X (BAX)*, *hMSH3*, and *E2F-4*<sup>[12]</sup>. In addition to *hMLH1*, promoter hypermethylation of tumor suppressor and tumor-related genes such as *APC*, *CHFR*, *COX2*, *DAP-kinase*, *DCC*, *E-cadherin*, *GSTP1*, *HRK*, *LOX*, *MGMT*, *p14*, *p15*, *p16*, *PTEN*, *RASSF1A*, *RUNX3*, *14-3-3 sigma*, *THBS1*, *TIMP-3*, and *TSLC1* has also been described in gastric cancer<sup>[6,11,13-36]</sup>. Hypermethylation can occur in both neoplastic and non-neoplastic gastric epithelia, and therefore is regarded as an early event in gastric carcinogenesis. Another epigenetic alteration, hypomethylation, also appears to be involved in gastric carcinogenesis. Global DNA hypomethylation is thought

**Key words:** Gastric cancer; *p53*; *E-cadherin*; *hMLH1*;

to occur during the early stages of tumor development in gastric and other tissues, similar to promoter hypermethylation described above<sup>[37-40]</sup>. However, demethylation of individual genes, such as *MAGE* and *synuclein-γ*, probably occurs during the progressive stages of gastric carcinogenesis, after global DNA hypomethylation<sup>[41,42]</sup>.

From a histopathologic point of view, gastric cancers are classified as either differentiated carcinomas, which form tubular or papillary structures (roughly corresponding to the intestinal type), or undifferentiated carcinomas in which such structures are inconspicuous (roughly corresponding to the diffuse type)<sup>[43,44]</sup>. It was thought that differentiated carcinomas, with a predominantly intestinal cellular phenotype, originated from gastric epithelial cells that had undergone intestinal metaplasia, while undifferentiated carcinomas rose from native gastric epithelial cells<sup>[43-45]</sup>. However, recent advances in mucin histochemistry and immunohistochemistry indicate that some differentiated carcinomas have a predominantly (and, on occasion, exclusively) gastric cellular phenotype and appear to be derived from foveolar epithelial cells<sup>[46,47]</sup>. It also appears that gastric cancers can undergo changes in cellular phenotype over time, from gastric to intestinal<sup>[48]</sup>. Thus, differentiated carcinomas may develop from native gastric mucosa or intestinal metaplastic mucosa. Therefore, although it has been proposed that different genetic pathways exist for differentiated and undifferentiated histological types<sup>[49]</sup>, the tumor types must share some common genetic alterations as a significant proportion of differentiated carcinomas progress to become undifferentiated carcinomas<sup>[50]</sup>. Indeed, recent studies have indicated that tumor cell phenotype is a marker of particular genetic aberrations<sup>[46,47]</sup>.

In this article, genetic and epigenetic alterations involved in the development and progression of gastric cancer are reviewed in relation to tumor histogenesis.

## GENETIC AND EPIGENETIC ALTERATIONS IN GASTRIC CANCER

### *p53*

The *p53* gene product functions as a cellular gatekeeper and plays important roles in cell growth and division. It assists DNA repair by effecting G<sub>1</sub> arrest in the presence of DNA damage, induces DNA repair genes, and initiates apoptosis if DNA strand breaks fail to repair<sup>[51]</sup>. Mutation of *p53* is one of the most prevalent genetic alterations in human cancer, including gastric carcinoma. The gene is usually inactivated through the classic two-hit mechanism, i.e. LOH and mutation of the remaining allele, rather than by DNA methylation<sup>[52]</sup>. The frequency of *p53* mutations in early and advanced differentiated gastric carcinomas is consistent at around 40% each, similar to that observed for advanced undifferentiated carcinomas<sup>[53,54]</sup>. However, *p53* mutations are rare in early undifferentiated carcinomas<sup>[17,55]</sup>. Thus, *p53* gene mutation is thought to be an early event, critical in the development of differentiated carcinomas, and the frequent detection of *p53* mutations in advanced undifferentiated carcinomas is postulated to be due to the frequent conversion of differentiated cancers to an

undifferentiated phenotype as the tumors progress<sup>[50]</sup>.

### *hMLH1*

Epigenetic methylation-associated inactivation of the *hMLH1* mismatch repair gene is a potent trigger of MSI, especially high-frequency MSI (MSI-H)<sup>[56]</sup>. Since the first report of *hMLH1* inactivation associated with DNA methylation in colorectal cancer<sup>[56]</sup>, similar epigenetic alterations have been described in gastric cancer<sup>[11,13,16]</sup>. DNA methylation of *hMLH1* promoter region CpG island is tightly associated with the loss of hMLH1 expression in gastric cancers exhibiting MSI<sup>[11,13,16]</sup>. About 20% of early differentiated carcinomas exhibit MSI-H<sup>[47]</sup>, while early undifferentiated carcinomas show no evidence of MSI (as described below)<sup>[17]</sup>. *hMLH1* methylation is frequently observed in gastric cancers from elderly patients<sup>[51]</sup> and has also been described in non-neoplastic gastric epithelia surrounding gastric cancers with MSI<sup>[16,57]</sup>. Thus, this field defect may increase the risk of subsequent neoplasia as MSI-H has also been observed in patients with multiple gastric cancers<sup>[58]</sup>.

### *E-cadherin*

*E-cadherin* is a member of a family of transmembrane glycoproteins involved in calcium-dependent cell-to-cell adhesion and appears to play a role in organogenesis and morphogenesis<sup>[59]</sup>. Germline *E-cadherin* mutations have been reported in familial diffuse-type of gastric cancers<sup>[5]</sup>. *E-cadherin* is frequently inactivated via the classic two-hit mechanism in sporadic forms of undifferentiated-scattered (diffuse) type gastric carcinomas, but not in differentiated or undifferentiated adherent type gastric carcinomas<sup>[2,3]</sup>. While nearly half of the undifferentiated-scattered (diffuse) type gastric carcinomas contain *E-cadherin* mutations<sup>[2,3]</sup>, such mutations are rare in early undifferentiated carcinomas<sup>[3,60]</sup>, and are only detected in the undifferentiated component of mixed differentiated/undifferentiated carcinomas<sup>[61]</sup>. This suggests that *E-cadherin* mutations are involved in the de-differentiation of such tumors. In contrast, *E-cadherin* methylation, which is associated with decreased *E-cadherin* expression, is observed in >50% of early stage undifferentiated carcinomas<sup>[6,17]</sup>, and is also observed in surrounding non-cancerous gastric epithelia<sup>[14,31]</sup>. Thus, the epigenetic inactivation of *E-cadherin* via promoter methylation may play a major role in the development of purely undifferentiated carcinomas of the stomach, while mutation of the gene may lead to the de-differentiation of differentiated gastric tumors.

### Other tumor suppressor genes

*APC* gene mutation is a critical genetic event in both the familial and sporadic forms of colorectal tumorigenesis<sup>[62,63]</sup>. *APC* mutations are rare in extracolonic cancers, including gastric carcinomas, with less than 10% of both differentiated and undifferentiated gastric carcinomas containing such mutations<sup>[17,46,54,64]</sup>. While *APC* promoter methylation has also been reported in colorectal and other human neoplasms<sup>[65]</sup>, *APC* methylation (promoter 1A) does not appear to be oncogenic in gastric cancer<sup>[18]</sup>. Mutation and promoter methylation of *DCC*,

*p16*, and *PTEN* genes have also been investigated in gastric cancer<sup>[14,23,24,66]</sup>. Although few mutations in these genes have been found, the promoter regions of *DCC* and *p16*, but not *PTEN*, exhibit frequent methylation, suggesting that epigenetic inactivation of *DCC* and *p16* may be involved in gastric carcinogenesis<sup>[14,23]</sup>. *DAP-kinase* promoter methylation is more frequent in undifferentiated than in differentiated type tumors<sup>[21,30,32]</sup>. While *RASSF1A* gene mutations are uncommon, silencing of the gene by promoter methylation is frequent in carcinomas, including gastric carcinomas<sup>[19,67]</sup>. *RUNX3*, one of the three mammalian runt-related genes, was recently identified as a tumor suppressor gene that frequently shows loss of expression due to hemizygous deletion and hypermethylation in gastric cancer<sup>[27]</sup>. *RUNX3* methylation is mostly cancer-specific, and is observed in about half of all gastric cancer cases<sup>[32]</sup>. *TSLC1* has been shown to be inactivated by biallelic methylation in a proportion of primary gastric cancers<sup>[25]</sup>. *CHFR* hypermethylation is found to occur concurrently with *hMLH1* hypermethylation and is more frequent in patients over 70 years of age<sup>[68]</sup>.

Thus, many tumor suppressor and tumor-related genes are methylated in neoplastic and non-neoplastic gastric epithelia, although the significance of hypermethylation is dependent on the analyzed genomic region<sup>[69]</sup>. In non-neoplastic gastric epithelia, hypermethylation tends to initially occur in the 5'- and 3'-flanking regions of CpG islands and then spreads toward the transcription start site, whereupon protein expression is shut down. This ultimately results in a field defect that places the affected tissue at an increased risk of gastric cancer development<sup>[29]</sup>. Hypermethylation near a transcription start site, which can be cancer-specific and result in gene silencing, can be used as a diagnostic marker of malignancy in tissues or other samples, such as serum or ascites. In addition, hypermethylation at a region next to such a critical region might indicate an early signal of carcinogenesis.

### LOH

In differentiated carcinomas of the stomach, frequent LOH has been reported for several chromosomal arms, including 2q, 4p, 5q, 6p, 7q, 11q, 14q, 17p, 18q and 21q<sup>[7,70-73]</sup>. However, few reports have focused on the occurrence of LOH in undifferentiated carcinomas, probably due to the difficulty in performing LOH analysis on tissue samples with low tumor cellularity. Nonetheless, frequent LOH at 5q has been reported for both differentiated and undifferentiated tumor types at advanced stages<sup>[74,75]</sup>. Apart from a few exceptions, such as the *p53* gene on 17p, the target suppressor gene(s) in the LOH regions on these chromosomal arms remain(s) largely unknown. For example, *IRF-1* on 5q31.1 and *DPC4* (*Smad4*) on 18q21.1 are both located at commonly deleted regions identified in gastric cancer, but exhibit infrequent mutations in gastric cancer<sup>[70,75,76]</sup>. The methylation status of the *IRF-1* and *DPC4* (*Smad4*) gene promoter regions remains to be investigated.

### MSI

MSI is defined as the presence of replication errors in

simple repetitive microsatellite sequences due to defective DNA mismatch repair, and can be classified as either high-frequency (MSI-H), low-frequency (MSI-L) or stable (MSS)<sup>[77]</sup>. The prevalence of MSI in gastric cancer varies among different studies. While some reports suggest that differentiated carcinomas exhibit more frequent MSI than undifferentiated carcinomas<sup>[78]</sup>, other reports observe the opposite findings<sup>[79]</sup>. Again, these contradictory observations may be due to the frequent conversion of differentiated- to undifferentiated-type tumors<sup>[50]</sup>, as described for *p53* mutations. In a study where MSI analysis was restricted to early differentiated carcinomas (ordinary type), about 20% of tumors were classified as MSI-H<sup>[47]</sup>. In contrast, no evidence of MSI has been found in early undifferentiated carcinomas<sup>[17]</sup>. Gastric cancers with an MSI phenotype rarely exhibit structural alterations, such as mutations or LOH of tumor suppressor genes<sup>[46,47,80]</sup>, which suggests that the mutator and suppressor pathways are independent of each other at least in the early stages of gastric carcinogenesis.

### Promoter demethylation of *MAGE* and *synuclein-γ*

Melanoma antigen (*MAGE*)-encoding genes are expressed in various tumor types via demethylation of their promoter CpG islands, which are silent in all non-neoplastic tissues except for the testis and placenta. While the function of the *MAGE* peptides is not known, their tumor-specific expression is clearly of great significance to immunotherapy<sup>[81-83]</sup>. Demethylation of both the *MAGE-A1* and *-A3* promoters is more frequently observed in gastric cancer patients with advanced clinical stages. These patients also exhibit a higher incidence of lymph node metastasis compared to patients without demethylation<sup>[41]</sup>. Furthermore, patients exhibiting *MAGE-A1* and *-A3* promoter demethylation tend to have a worse prognosis, as assessed by the log rank test<sup>[41]</sup>. Demethylation of *MAGE-A1* and *-A3* tends to occur during the progressive stages of gastric cancer, and may therefore act as a prognostic factor for gastric cancer patients.

The *synuclein-γ* (*SNCG*) gene, also known as *breast cancer specific gene 1* (*BCSG1*), is a member of the synuclein neuronal protein family, along with *synuclein-a* (*SNCA*) and *synuclein-β* (*SNCB*)<sup>[84-86]</sup>. *SNCG* protein expression is highly tissue-specific, being expressed at presynaptic terminals in the brain and peripheral nervous system<sup>[85,86]</sup>. However, this tissue specificity is lost during breast and ovarian cancer disease progression<sup>[87]</sup>. While *SNCG* expression is normally silent in the breast and ovary, it becomes abundantly expressed in the vast majority of advanced-stage breast and ovarian cancers<sup>[87]</sup>. *SNCG* demethylation is also found to be more frequent in primary gastric cancers positive for lymph node metastasis than in metastasis-negative cancers, and more frequent in stage II-IV cancers than in stage I cancers<sup>[42]</sup>. An increased tendency for gastric cancer patients with poor prognoses to show *SNCG* demethylation compared to gastric cancer patients with normal methylation has also been reported<sup>[42]</sup>.

Global DNA hypomethylation is thought to occur during the early stages of tumor development in gastric and other tissues<sup>[37-40]</sup>. However, *MAGE-A1*

and -A3 demethylation are very rare in various organs obtained at autopsy from various age groups<sup>[41]</sup>, and only partial demethylation of *SNCG* is present in non-neoplastic gastric epithelia<sup>[42]</sup>. Therefore, we hypothesize that demethylation of these genes occurs during the progressive stages of gastric carcinogenesis, after global DNA hypomethylation.

## GENETIC AND EPIGENETIC ALTERATIONS IN PRECANCEROUS LESIONS

### Gastric adenoma/dysplasia

The histopathologic criteria for the diagnosis of gastric intramucosal neoplasia are not universal, and differences in the diagnostic criteria used by Japanese and Western pathologists have been recognized<sup>[88]</sup>. It is reasonable to suggest that the discrepant results obtained from the genetic analyses of lesions may be explained by the differences in histopathologic criteria, although a worldwide accepted histological classification has recently been proposed<sup>[89,90]</sup>. In my experience, gastric adenomas rarely exhibit genetic alterations, such as *p53* mutation, LOH, or MSI<sup>[10,13,34]</sup>, with mutations of *APC* gene being the only relatively frequent (20%) DNA structural alteration<sup>[91]</sup>. Indeed, *APC* gene mutations are more frequent in gastric adenomas than in differentiated or undifferentiated gastric carcinomas<sup>[17,46,54,64]</sup>. More recently, we reported that results of the Padova international classification<sup>[89]</sup> correlated with both molecular and cellular phenotypic profiles, and that *p53* and hMLH1 immunohistochemistry clearly discriminated these lesions<sup>[92]</sup>. Histopathologic observations have suggested that malignant transformation of gastric adenomas is infrequent, occurring in only 2.5% of conventional protruded and 5.0% of depressed adenomas<sup>[93]</sup>. However, detection of certain genetic alterations, such as *p53* mutations, LOH, or MSI, in adenomas may be indicative of malignant transformation<sup>[94]</sup>. It is noteworthy that gastric-type intramucosal neoplasia, often diagnosed as adenoma or dysplasia<sup>[95]</sup>, frequently shows a mutator defect<sup>[116]</sup>.

### Gastric intestinal metaplasia/non-neoplastic gastric epithelia

Intestinal metaplasia may be a precursor of differentiated carcinomas. This concept is supported by the finding that *p53* mutations are detected in gastric intestinal metaplasia, especially incomplete-type, in patients with gastric cancer<sup>[96]</sup>. Although frequent MSI has been reported in intestinal metaplasia<sup>[97]</sup>, there is little evidence of mismatch repair defects in this tissue<sup>[98]</sup>. *Helicobacter pylori* infection can accelerate the hypermethylation of genes such as *E-cadherin*<sup>[99]</sup>. Hypermethylation of tumor suppressor and tumor-related genes increases with age, and is thought to result in field defects in different organs<sup>[100]</sup>, although the significance of the hypermethylation appears to be dependent on the genomic region analyzed<sup>[69]</sup>, as described above for gastric cancer.

## CONCLUSIONS

The molecular pathways of gastric carcinogenesis are

dependent on the histological background, such that different genes are affected in different histologies. DNA structural alterations, including *p53* gene mutation and LOH, occur predominantly within intestinal metaplastic mucosa. Hypermethylation of tumor suppressor and tumor-related genes can occur in both metaplastic and native gastric epithelial cells, although at least some of the genes involved, such as *E-cadherin*, are more prone in the latter. Approximately 20% of differentiated carcinomas display evidence of mutator pathway tumorigenesis due to *hMLH1* hypermethylation. Demethylation of *MAGE* and *synuclein-γ* tends to occur during progressive disease stages. Thus, these genetic and epigenetic alterations can be used in the risk assessment, diagnosis and prognosis of gastric cancer.

### Abstract

Cadherin is an adhesion molecule and a superfamily of calcium-mediated membrane glycoproteins. E-cadherin is the prototype of the class E-cadherin that links to catenins to form the cytoskeleton. Recent evidence has shown that E-cadherin not only acts as an adhesive, but also plays important roles in growth development and carcinogenesis. It has been recently viewed as an invasion as well as a growth suppressor gene. This review summarizes the recent discoveries on E-cadherin and its role in gastric cancer. In particular, our work on E-cadherin in gastric cancer, including its relation with *Helicobacter pylori* and clinical applications, are described in detail.

### INTRODUCTION

Although decreasing in incidence, gastric cancer remains a major medical problem and is the second most common fatal cancer worldwide. In spite of intense interest and extensive investigations, its prognosis has not been improved significantly in recent years. The dramatic variations in the incidence of gastric cancer in different geographic areas and from one generation to the next have led to the hypothesis that the incidence of gastric cancer is determined largely by environmental rather than genetic factors. The identification and the subsequent classification of *Helicobacter pylori* (*H. pylori*) infection as type I carcinogen by the WHO sparked a significant understanding in the

etiology of gastric cancer. The current discovery of germline mutation at E-cadherin gene in familial gastric cancers and the findings of IL-1 polymorphisms with increased gastric cancer risk again turn the focus towards the studying of host genetics. The molecular studies of the host may give a definite proof of the etiological role of *H. pylori* in inducing gastric carcinoma.

Only a small fraction of all cancers arise in individuals who carry a germline defect conferring genetic predisposition. Nevertheless, many genes that underlie inherited cancer syndromes have more widespread roles in sporadic cancers, as a result of somatic mutations that arise during tumor initiation or progression. Hence, in this review paper, we shall focus on the E-cadherin gene, one of the candidate genes in gastric cancer, and the work we have done on E-cadherin in gastric carcinogenesis.

### E-CADHERIN

Cadherin is a superfamily of calcium-mediated membrane glycoproteins, with a molecular mass of 120 ku, forming one of the four classes of adhesion molecules<sup>[1-3]</sup>. Some common cadherins expressed by epithelial cells are E-cadherin, N-cadherin and P-cadherin. The intracellular domains of classical cadherins interact with  $\beta$ -catenin,  $\gamma$ -catenin (also called plakoglobin) and p120ctn to assemble the cytoplasmic cell adhesion complex (CCC) that is critical for the formation of extracellular cell-cell adhesion.  $\beta$ -catenin and  $\gamma$ -catenin bind directly to  $\alpha$ -catenin, which links the CCC to the actin cytoskeleton<sup>[4,5]</sup>. The cadherins are responsible for the homotypic cell-cell adhesion. However, knowledge gained in the recent few decades has shown that E-cadherin not only acts as an adhesive, but also plays important roles in growth development and carcinogenesis.

### E-CADHERIN AND CANCER

#### Role of E-cadherin in metastasis

E-cadherin is the prototype of the cadherin class. It is expressed in all epithelial cell types. Underexpression of the E-cadherin is found in gastric and other cancers, and correlates with infiltrative and metastatic ability<sup>[6]</sup>. It has been proposed that the loss of E-cadherin-mediated cell-cell adhesion is a prerequisite for tumor cell invasion and metastasis formation<sup>[7]</sup>. Re-establishing the functional cadherin complex, e.g. by forced expression of E-cadherin, results in a reversion from an invasive, mesenchymal, to a benign, epithelial phenotype of cultured tumor cells<sup>[7,8]</sup>. Hence, the E-cadherin gene is also called as an invasion

**Figure 1** Illustrated interaction between the cadherin-catenin complex and the APC protein. (A) In the absence of Wnt-1 and the presence of glycogen synthase kinase (GSK),  $\beta$ -catenin ( $\beta$ -cat) is stabilized and bound to cadherin or APC protein. Cadherin acts as a negative regulator of  $\beta$ -catenin by regulating the amount of free  $\beta$ -catenin. The free cytoplasmic  $\beta$ -catenin is degraded. (B) In the presence of Wnt-1, GSK is antagonized and mutant APC or tyrosine phosphorylated  $\beta$ -catenin cannot bind to each other, cytosolic free  $\beta$ -catenin concentrations rise, which leads to down-stream cell signalling and may be involved in carcinogenesis.

suppressor gene.

### Role of E-cadherin in oncogenesis

Recently, it has been postulated that the role of E-cadherin in carcinogenesis does not limit only to metastasis and invasion (Figure 1). It is now being increasingly recognized that there is also a possible role of E-cadherin in modulating intracellular signaling, and thus promoting tumor growth. There are several lines of evidence. Cadherin-mediated cell-cell adhesion can affect the Wnt-signaling pathway<sup>[9,10]</sup>.  $\beta$ -catenin (as well as  $\gamma$ -catenin) is usually sequestered by cadherins in the cadherin-catenin complex. Upon loss of E-cadherin function, non-sequestered, free  $\beta$ -catenin is usually phosphorylated by glycogen synthase kinase 3 $\beta$  (GSK-3 $\beta$ ) in the adenomatous polyposis coli (APC)-axin-GSK-3 $\beta$  complex and subsequently degraded by the ubiquitin-proteasome pathway. In many cancer cells, loss of function of the tumor suppressor APC, mutations in  $\beta$ -catenin or inhibition of GSK-3 $\beta$  by the activated Wnt-signaling pathway leads to the stabilization of  $\beta$ -catenin in the cytoplasm. Subsequently, it translocates to the nucleus, where it binds to the members of the Tcf/Lef-1 family of transcription factors and modulates expression of Tcf/Lef-1-target genes, including the proto-oncogene c-myc and cyclin D1. In addition, recent studies on familial gastric cancer indicate that E-cadherin can also act at a much earlier stage during tumor development. Mutations of the E-cadherin gene were found in three familial gastric cancer kindred from New Zealand<sup>[11]</sup> and this observation was confirmed in the kindred of European origin<sup>[12]</sup>. These results demonstrate that loss of function of E-cadherin may play a role in susceptibility to initial tumor development in addition to its role as an inhibitor of tumor invasion.

### EXPRESSION OF E-CADHERIN IN GASTRIC CANCER

The expression of E-cadherin has been studied by immunohistochemical method. Decreased expression has been observed in gastric cancer by various authors,

ranging from 17%<sup>[13]</sup> to 92%<sup>[14]</sup>, depending on the method and the definition used. The decreased expression of E-cadherin was mainly observed in diffuse type and less in intestinal type of gastric cancer. Direct correlation between E-cadherin and the grade of tumor differentiation has been observed in all these studies. In addition, it was shown in a study of 413 gastric cancers by Gabbert *et al.*<sup>[15]</sup> that patients with E-cadherin positive tumors had significantly better 3- and 5-year survival rates than patients with E-cadherin negative tumors. A similar trend of decrease in disease-free survival was also observed in other cancers exhibiting downregulation of E-cadherin<sup>[16]</sup>.

We have also studied the change in the expression of the E-cadherin complex along the Correa's cascade in gastric cancer by immunohistochemical staining<sup>[17]</sup>. We observed that the staining pattern, intensity and the percentage of cells with positive stains decreased along the Correa's cascade; that is, the staining was strong and membranous in normal gastric epithelium, but gradually decreased in intensity and percentage, as well as the pattern was changed towards cytoplasm in chronic atrophic gastritis, intestinal metaplasia, dysplasia and eventually to adenocarcinoma.

However, methods to evaluate, qualitatively or quantitatively, protein expression in biopsies from human tumors may have serious limitations because of sampling from heterogeneous tissue, non-stoichiometric labeling and subjective evaluation.

### MECHANISM OF INACTIVATION OF E-CADHERIN

#### Genetic inactivation

The E-cadherin gene can be genetically inactivated by a number of mechanisms. The first hit of a role for E-cadherin in tumor development, particularly in suppression of invasion, came from loss of heterozygosity studies on chromosome 16. Subsequently, mutations were reported in tumor samples in diffuse type gastric carcinomas<sup>[18]</sup>, gynecologic cancers<sup>[19]</sup>, and infiltrative lobular breast cancer<sup>[20,21]</sup>. In gastric cancer, E-cadherin mutations are common in

diffuse type carcinomas, but not seen in intestinal type<sup>[18]</sup>. The specificity of types of cancer affected by mutations of the E-cadherin gene, despite the prevalence of reduced E-cadherin expression in many cancer types, suggests that E-cadherin mutations may be of particular importance in the development of these tumors. In addition, mutations in diffuse gastric cancer<sup>[22]</sup> have been detected early in tumor development, suggesting a role in tumor suppression, in addition to invasion suppression. Further evidence for this comes from the observations that mutations of E-cadherin have also been observed in several kindred exhibiting familial gastric cancer<sup>[11,12]</sup>. Furthermore, at least one kindred exhibited both diffuse gastric cancer and early-onset breast cancer<sup>[11]</sup>.

### Inactivation by hypermethylation

In recent years, it has become increasingly apparent that increased methylation within the promoter regions of genes plays a key role in the inactivation of many important genes during the development of cancer<sup>[23]</sup>. Subsequently, numerous reports of E-cadherin promoter methylation, associated with reduced E-cadherin expression, have been published. Hypermethylation at E-cadherin has also been shown to play a role in familial gastric cancer, acting as the second hit (the first hit is either mutation or loss of heterozygosity) in inactivation of E-cadherin<sup>[24]</sup>.

We have previously shown that the immunostaining of E-cadherin decreases along the Correa's cascade; therefore, we went on to study the underlying mechanism. We found that the frequency of methylation at E-cadherin also increases along the Correa's cascade, with the highest frequency detected in the tumorous lesions and metastatic lesions<sup>[25]</sup>. The methylation frequency correlated with the tumor depth and node invasion. In addition, most of the decrease in immunostaining was accounted for by the presence of methylation at E-cadherin. More importantly, we also observed that *H pylori* infection was also associated with E-cadherin methylation.

In fact, the role of *H pylori* in the regulation of E-cadherin has been studied recently. It has been shown that *H pylori* infection is associated with downregulation of E-cadherin, probably by generating cell signaling events that counteract the normal function of protein kinase C<sup>[26,27]</sup>. The resulting increase in permeability mediated by the reduction in cell adhesion might allow *H pylori* antigens to reach the gastric lamina propria and activate the mucosal immune system, with resultant tissue damage.

In relation to the above findings, we therefore hypothesized that by eradicating *H pylori*, methylation at E-cadherin may disappear<sup>[28]</sup>. We performed a prospective randomized trial. Patients with dyspepsia and *H pylori* infection were randomized to receive *H pylori* eradication therapy (Group 1,  $n=41$ ) or no treatment (Group 2,  $n=40$ ) and were followed up prospectively. Gastric mucosae were taken for methylation assay at week 0 (before treatment) and week 6 (after treatment). Methylation was assessed using methylation-specific PCR. Methylation was detected in 46% (19/41) and 17% (7/41) at week 0 and 6, respectively in Group 1 ( $P=0.004$ ). 78.9% (15/19) specimens turned unmethylated after eradicating *H pylori*. Methylation was detected

in 47.5% (19/40) and 52.5% (21/40) at weeks 0 and 6, respectively in Group 2 ( $P=0.5$ ). Archived specimens with intestinal metaplasia with *H pylori* infection ( $n=22$ ) and without the infection ( $n=19$ ) were also retrieved for methylation analysis. But methylation frequency did not differ in *H pylori* positive or negative intestinal metaplastic specimens (72.7% *vs.* 63%,  $P=0.5$ ). Therefore, we postulated that *H pylori* eradication therapy could reverse methylation in patients with chronic gastritis only and may halt the process of gastric carcinogenesis.

### Postulated mechanism of helicobacter pylori infection for inducing methylation

Experimental data from *in vitro* studies support our contention that E-cadherin methylation might be related to *H pylori* infection. El-Omar *et al*<sup>[29]</sup> reported that interleukin-1 $\beta$  polymorphism that led to upregulation of interleukin-1 $\beta$  with *H pylori* infection was associated with increased risk of gastric cancer. Furthermore, Hmadcha *et al*<sup>[30]</sup> found that interleukin-1 $\beta$ , through the production of nitric oxide and the subsequent activation of DNA methyltransferase, might induce gene methylation. It is thus possible that *H pylori* induces methylation through the production of interleukin-1 $\beta$  and hence the downstream activation of nitric oxide and DNA methyltransferase, which subsequently led to an increased risk of E-cadherin methylation and hence gastric cancer<sup>[31]</sup>.

## OTHER REGULATORY MECHANISMS OF E-CADHERIN

Loss of E-cadherin function during tumor progression can also be caused by transcriptional repression binding to the CDH1-E box elements, e.g. by the repressors Snail<sup>[32,33]</sup> and Sip-1<sup>[34]</sup>. Tyrosine phosphorylation has also been previously implicated in the regulation of cadherin function: RTKs, such as EGFR, c-Met and FGFR, and the non-receptor tyrosine kinase, c-Src, phosphorylate E-cadherin, N-cadherin,  $\beta$ -catenin, -catenin and p120ctn, resulting in the disassembly of the cytoplasmic adhesion complex and a disruption of cadherin-mediated cell adhesion and cell scattering<sup>[35-37]</sup>.

## SOLUBLE E-CADHERIN

E-cadherin has a cleavage site near the transmembrane domain and artificially produces a soluble 80 ku amino-terminal fragment in the culture medium upon trypsin digestion in the presence of calcium<sup>[38]</sup>. This soluble E-cadherin fragment is considered to be a degradation product of the 120 ku intact E-cadherin generated by a calcium-dependent proteolytic action, and can be detected in the protein extract of tissue samples from peripheral blood and urine in normal subjects<sup>[39]</sup>. Serum soluble E-cadherin is reported to be increased in dermatological disorders (bullous pemphigoid, pemphigus vulgaris, psoriasis vulgaris), multi-organ failure, and various tumors like bladder cancer, prostate cancer, lung cancer and gastric cancer<sup>[39-43]</sup>. The role of soluble E-cadherin and its biological significance is still, at present, unclear. Recent studies indicate that, in inflammatory condition, serum

soluble E-cadherin is induced by inflammatory mediators and cytokines<sup>[44]</sup>; whereas in cancerous diseases, soluble E-cadherin is increased by cleavage of tissue E-cadherin due to overexpressed proteases<sup>[45]</sup>. The potential of soluble E-cadherin to be a prognostic marker in cancerous diseases has been shown in bladder cancer<sup>[40]</sup> and gastric cancer<sup>[46]</sup>.

We have examined the potential clinical application of E-cadherin. We first studied the correlation between E-cadherin immunostaining expression and the concentration in sera<sup>[47]</sup>. We found that normal strong membranous staining, e.g. in normal gastric epithelium, was associated with low levels of serum soluble E-cadherin, but a partially reduced; cytoplasmic staining, e.g. in intestinal type of gastric cancer, was associated with high levels; whereas complete absence of staining, e.g. in diffuse type of gastric cancer, was associated with low levels of soluble E-cadherin. We also found that soluble E-cadherin may be a potentially useful prognostic marker. High levels of soluble E-cadherin correlated with the depth of tumor invasion, as well as inoperability<sup>[48]</sup>. More importantly, levels higher than 10 000 ng/mL predicts survival less than 3 years in more than 90% of patients<sup>[47]</sup>. Currently, we are investigating the use of post-operative soluble E-cadherin levels to predict tumor recurrence in patients who have received curative surgery for gastric cancer.

## CONCLUSION

Being an adhesion molecule, E-cadherin plays an important role in invasion and metastasis in almost all kinds of epithelial malignancies, and hence is named invasion suppressor gene. However, recent studies have shown that E-cadherin actually plays an early and important role in carcinogenesis and acts as a tumor suppressor gene, particularly in gastric cancer. Further thorough understanding of the role of E-cadherin and its association with extracellular environment and intracellular functions will be extremely important. Potentially, reversing methylation at E-cadherin in the gastric epithelium in patients with *H pylori* infection may halt the process of future development of gastric cancer. In addition, soluble E-cadherin may be a useful prognostic marker for gastric cancer.

### Abstract

Metastatic gastric cancer remains a non-curative disease. Palliative chemotherapy has been demonstrated to prolong survival without quality of life compromise. Many single-agents and combinations have been confirmed to be active in the treatment of metastatic disease. Objective response rates ranged from 10-30% for single-agent therapy and 30-60% for polychemotherapy. Results of phase II and III studies are reviewed in this paper as well as the potential efficacy of new drugs. For patients with localized disease, the role of adjuvant and neoadjuvant chemotherapy and radiation therapy is discussed. Most studies on adjuvant chemotherapy failed to demonstrate a survival advantage, and therefore, it is not considered as standard treatment in most centres. Adjuvant immunochemotherapy has been developed fundamentally in Korea and Japan. A meta-analysis of phase III trials with OK-432 suggested that immunochemotherapy may improve survival of patients with curatively resected gastric cancer. Based on the results of US Intergroup 0116 study, postoperative chemoradiation has been accepted as standard care in patients with resected gastric cancer in North America. However, the results are somewhat confounded by the fact that patients underwent less than a recommended D1 lymph node dissection and the pattern of recurrence suggested a positive effect derived from local radiotherapy without any effect on micrometastatic disease.

Neoadjuvant chemotherapy or chemoradiation therapy remains experimental, but several phase II studies are showing promising results. Phase III trials are needed.

### TREATMENT OF ADVANCED GASTRIC CANCER

#### *Should chemotherapy be offered to patients with advanced gastric cancer?*

Traditionally, although responses to chemotherapy have been reported in up to 60% of patients in phase II trials, most patients developed drug resistance within few months, and median survival of treated patients usually ranged from 7 to 9 mo. These disappointing results together with the toxic effects derived from chemotherapy prompted to several investigators to evaluate the benefit of chemotherapy in terms of survival and/or quality of life compared with best supportive care alone. Four randomized phase III studies were conducted during the last decade, showing a survival advantage in favour of chemotherapy of about 6 mo<sup>[1-4]</sup>. In the light of these findings, chemotherapy should be offered to patients with metastatic gastric cancer in good general conditions. Even in those patients with asymptomatic disease, a similar survival advantage derived from early chemotherapeutic treatment has been shown as compared with conservative attitude and therapy only when symptoms appear<sup>[5]</sup>. This benefit was obtained without quality of life compromise.

#### *Which drugs can be considered active as single agents?*

Many traditional and modern drugs have been tested as single-agent in advanced gastric cancer. Table 1 shows those agents that have obtained  $\geq 10\%$  response rate. It is worth to remark that classical drugs were tested in the 1960s and 1970s and its true single-agent activity may be overestimated due to the methodology employed. In that sense, in the setting of a randomized trial reported in 1994, both epirubicin and 5-fluorouracil obtained less than 10% response rate<sup>[6]</sup>. Complete responses with single-agent therapy are uncommon, and partial responses ranged 10-20%, followed by a short period of time to disease progression.

#### *Combination therapy for advanced gastric cancer patients*

Several combination regimens have been developed with the aim of improving overall response rate and survival. Platinum compounds, 5-fluorouracil, and recently taxanes and irinotecan might be considered the mainstay of these

Table 1 Single agent activity in advanced gastric cancer

Agents	Response rate (%)
Mitomycin C	30
Doxorubicin	17
Epirubicin	19
Cisplatin	19
BCNU	18
5-Fluorouracil	21
Etoposide (oral)	21
Hydroxurea	19
UFT	27
Capecitabine	19
S-1	45
Paclitaxel	17-23
Docetaxel	17-29
CPT-11	18

combinations (Table 2).

**Fluorouracil-based combinations:** The FAM (fluorouracil-doxorubicin-mitomycin C) combination was widely used in the 1980s. After the first publication where the authors reported an overall response rate of 42%<sup>[7]</sup>, more than six hundred patients were treated with FAM or modified-FAM schedules reporting a cumulative response rate of 30%<sup>[8]</sup>. The concept of biochemical modulation of the activity of 5-FU led several authors to design schedules, such as FAMTX, FEMTX and EFL. In 1982, Klein *et al*<sup>[9]</sup> reported a response rate of 63%, administering sequentially high-dose methotrexate, with leucovorin rescue, and 5-FU followed by adriamycin (FAMTX) on day 15, with a median survival of 9 mo. In a subsequent study conducted by the EORTC with the same regimen, 22 out of 67 (33%) patients responded and nine of them achieved clinical complete responses. The median survival for all patients was 6 mo. Toxicity consisted mainly of leukopenia (WHO grade 4 in 14%), mucositis (WHO grade 3 in 11%), and alopecia<sup>[10]</sup>. When adriamycin was substituted by its analogue 4-epi-doxorubicin (FEMTX), no advantages were found in response rate or tolerance<sup>[2]</sup>. It is well known that 5-fluorouracil modulated by leucovorin combined with intravenous etoposide (EFL) is a well tolerated scheme, initially designed for elderly patients or those with cardiac risk. A phase II trial reported a 53% response rate, including 12% of complete responses<sup>[11]</sup>. Overall survival was 11 mo. The results of three modified-EFL regimens consisting of oral etoposide, oral leucovorin and either 5-FU continuous infusion or tegafur were controversial. Colleoni *et al*<sup>[12]</sup> and Feliu<sup>[14]</sup> reported 42% and 26% of partial remissions, and 8% and 9% complete responses respectively. Median survival times were 9.5 and 9 mo, respectively. Toxicity with these schedules was mild or moderate, mainly nausea and vomiting, and asymptomatic leukopenia. On the other hand, only 16% of patients treated with the entirely oral tegafur-containing schedule designed by Raderer *et al*<sup>[13]</sup> achieved partial remission, and overall survival was 6 mo. The investigators argued a low compliance due to severe emesis, in spite of prophylactic intake of 5-HT<sub>3</sub> receptor antagonists, to explain these disappointing results.

#### Combinations based on cisplatin/5-FU continuous

Table 2 Combination therapy for advanced gastric cancer

	Response rate (%)	Median survival (mo)
FU-based combinations		
FAM	30-42	6-9
FAMTX	33-63	6
ELF	53	11
Modified-ELF	16-42	6-9.5
Cisplatin-5-FU CI synergism		
PF	40	9-10
ECF	59-71	8.7
P-5-FU 48-h CI	50	9.3
P-5FU 24-h CI	58	11
Cisplatin-based combinations		
EAP	33-64	9
FLEP	35	8
FLEP-type	39	11
LV5FU2-P	27	13.3
Combinations including new drugs		
P-CPT11	41-58	9-12
LOHP-CPT11	50	8.5
CPT11-bolus 5-FU	22	7.6
CPT11- 5-FU CI	20	7
P-Xeloda	54.8	10.1
ECC	59	9.6
P-S-1	73-74	12
TPFU/LV	50	11-14
DP	37-56	9-11
DPF	51	9.3

CI: Continuous infusion.

**infusion (CI) synergism:** The *in vitro* synergy between cisplatin and 5-FU, especially in continuous infusion administration, led several investigators to test the combination of both drugs with or without the addition of a third active agent. About 40% response rate and median survival of 9-10 mo were reported with the combination of cisplatin and 5-FU CI for 5 d<sup>[15,16]</sup>. Higher response rates (71% and 59%) were achieved in two phase II trials with the combination of protracted continuous 5-FU infusion, cisplatin and epirubicin (ECF), but apparently with a similar overall survival<sup>[17,18]</sup>. The Spanish Group for the Treatment of Digestive Tumors (TTD) conducted a phase II study with cisplatin every 3 wk in combination with a weekly 48-h infusion of 5-FU. Responses were achieved in 50% of patients and median survival reached 9.3 mo<sup>[19]</sup>. In these schedules, moderate myelosuppression appeared as the most relevant side effect with few patients requiring hospitalization for neutropenic fever. A multicenter study showed that a weekly 5-FU 24-h continuous infusion modulated by leucovorin and combined with bimonthly cisplatin obtained a 58% response rate and 11 mo of median survival<sup>[20]</sup>.

**Others cisplatin-based combinations:** In 1989, a group of German investigators developed a combination regimen consisting of cisplatin + etoposide + doxorubicin (EAP). Responses were observed in 43 of 67 (64%) patients that included 21% clinical complete responses. Median survival time was 9 mo<sup>[21]</sup>. With exactly the same schedule employed by Preusser *et al*<sup>[8]</sup>, 36 previously untreated patients with advanced gastric cancer were

involved in a phase II trial at the Dana-Farber Cancer Institute. Only 33% objective responses, including 8% clinical complete responses were reported. Median survival for the entire group was 8 mo<sup>[22]</sup>. Their revision of published experience with EAP-like regimens over 262 patients revealed a mean response rate of 41%. Although EAP is an active regimen, it should be noted the high hematologic toxicity reported with this schedule. Deaths due to treatment-related toxicity have been reported in the majority of series, ranging from 6% to 20%. The FLEP schedule developed by our group combined bolus 5-FU modulated by folinic acid (FA) for three consecutive days with epirubicin and cisplatin on day 2. Objective responses were observed in 32 of 90 patients (35%), including 9% clinical complete remissions, and median survival time was 8 mo. Ten patients presented episodes of febrile neutropenia, but no toxic deaths were observed<sup>[23]</sup>. Almost double response rate was reported with an intensive weekly FLEP-modified schedule, but median survival achieved seemed to be slightly better if so<sup>[24]</sup>. Other FLEP-type schedule in which cisplatin and 5-FU/FA were combined with etoposide, taking advantage of the three drugs synergism, obtained 39% responses and a median survival of 7 mo<sup>[25]</sup>. A well known active regimen in metastatic colorectal cancer (LV5FU2), combined with bimonthly cisplatin infusion obtained one of the higher overall survival of 13.3 mo in patients with advanced gastric cancer<sup>[26]</sup>. Hematologic toxicity was the most common adverse event (42.9% grade 3 or 4) but less than 5% of patients experienced febrile neutropenia and no toxic deaths were observed. Nausea and vomiting were also frequent side effects, despite systematic prophylaxis.

### Combinations including new active drugs

Irinotecan shows a marked synergism with cisplatin as well as a lack of cross-resistance due to different mechanisms of action and a non-overlapping profile of adverse reactions. Shirao *et al*<sup>[27]</sup> reported a 41% response rate with a combination of irinotecan and cisplatin in a phase I-II trial. The recommended dose and schedule were 70 mg/m<sup>2</sup> of CPT-11 on days 1 and 15 and 80 mg/m<sup>2</sup> cisplatin on day 1 every 4 wk. The dose-limiting toxicity was neutropenia. A phase II study employing a combination of CPT-11 (70 mg/m<sup>2</sup>) plus cisplatin (80 mg/m<sup>2</sup>) in patients with metastatic gastric cancer achieved an overall response rate of 48%<sup>[28]</sup>. In Western countries, Ajani *et al*<sup>[29]</sup> obtained a very high response rate (58%) with a combination of irinotecan (65 mg/m<sup>2</sup>) plus cisplatin (30 mg/m<sup>2</sup>), both administered intravenously 1 d per week for 4 consecutive weeks, followed by a recovery period of two weeks. The median survival reported reached 9 mo. Compared with the classic cisplatin combination regimens, the introduction of CPT-11 as part of the treatment schedule increased the gastrointestinal toxicity. A recent pharmacokinetic study comparing two infusion schedules of irinotecan plus cisplatin suggested some advantages in favour of 24-h continuous infusion of CPT-11. The area under the plasma concentration-time curve of SN-38 was increased by 24-h infusion when compared with the 90-min infusion<sup>[30]</sup>. Irinotecan has also been combined with oxaliplatin as first-line treatment for locally advanced or metastatic

gastric cancer patients. Oxaliplatin 85 mg/m<sup>2</sup> followed by CPT-11 200 mg/m<sup>2</sup> as a 30-min i.v. infusion achieved an overall response rate of 50% and a median survival of 8.5 mo in a phase II multicentre study conducted in Greece<sup>[31]</sup>. A weekly irinotecan plus bolus folinic acid and bolus<sup>[32]</sup> or infusion<sup>[33]</sup> 5-FU combination did not improve the outcome in patients with advanced gastric cancer in a non-randomised comparison with other CPT-11 combinations. Capecitabine is a novel oral fluoropyrimidine carbamate that mimics continuous infusion of 5-FU. The combination of capecitabine and cisplatin has been proven to be active and well tolerated in patients with advanced gastric cancer, giving an overall response rate of 54.8% in the intention-to-treat analysis<sup>[34]</sup>. Evans *et al*<sup>[35]</sup> evaluated in a phase I trial the combination of epirubicin, cisplatin and capecitabine (ECC). With a fixed-dose of cisplatin 60 mg/m<sup>2</sup> and epirubicin 50 mg/m<sup>2</sup>, both every 3 wk, the recommended dose for capecitabine was 1 000 mg/m<sup>2</sup> per 12 h on an intermittent schedule (two weeks of treatment, followed by one week rest). An overall response rate of 59% and median survival of 9.6 mo have recently been reported in a phase II trial carried out in Korea<sup>[36]</sup>. S-1 is another fluoropyrimidine derivative developed mainly in Japan. A phase I/II study conducted by Koizumi *et al*<sup>[37]</sup> found a recommended dose for this combination of cisplatin 60 mg/m<sup>2</sup> on d 8 plus S-1 40 mg/m<sup>2</sup> b.i.d for 21 d, followed by a 2-wk rest. The response rate (74%) achieved was the highest published in the literature, and the median survival reached 12 mo. These encouraging results have been confirmed in another phase I/II trial carried out in Japan in which S-1 was administered orally at a dose of 80 mg/m<sup>2</sup> per d for 2 wk, followed by a 2-wk rest, plus cisplatin 70 mg/m<sup>2</sup> as the recommended dose. Among eleven evaluable patients for response, 8 achieved a partial response (73%) and 1 had stable disease. The main toxicities were neutropenia, nausea and anorexia, all of them not severe, reversible and manageable<sup>[38]</sup>. In Europe, the first phase II trial with S-1 as monotherapy for advanced gastric cancer revealed that the starting dose of 40 mg/m<sup>2</sup> was not tolerable due to significant diarrhoea. At 35 mg/m<sup>2</sup> twice daily a response rate of 26.1% was reported according to an independent radiology review<sup>[39]</sup>. A recent phase II trial conducted in the United States and Germany was presented at ASCO 2005, employing cisplatin 75 mg/m<sup>2</sup> on d 1 plus S-1 25 mg/m<sup>2</sup> p.o twice daily on d 1-21, followed by a 7-d of recovery<sup>[40]</sup>. Over 41 assessable patients, the overall confirmed response rate reached 51.2% and the median time to progression was 4.8 mo. The regimen showed a very favourable safety profile, with only 2.1% of patients suffering from febrile neutropenia and less than 15% experienced grade 3 or 4 gastrointestinal toxicities. A phase III trial comparing cisplatin plus S-1 *versus* cisplatin plus continuous infusion 5-FU is ongoing in Western countries. Similar results were reported by Iwase *et al*<sup>[41]</sup> in a phase II trial in which S-1 was given orally at 80 mg/m<sup>2</sup> daily for 14 d and cisplatin was administered as a 24-h continuous infusion on day 8. Many randomized trials consisting of an S-1 based regimen are now being evaluated in Japan. Moreover, 5-FU alone is being compared with the combination of cisplatin plus irinotecan and with S-1 alone in a three- arms controlled study. The accrual of

a study comparing S-1 *versus* S-1 plus cisplatin has recently been completed<sup>[42]</sup>.

Taxane-containing combinations have considerable activity in the treatment of gastric cancer. Kim *et al*<sup>[43]</sup> reported a 51% response rate with the combination of paclitaxel 175 mg/m<sup>2</sup> by 3-h, cisplatin 20 mg/m<sup>2</sup> per d for 5 d and 5-FU 750 mg/m<sup>2</sup> by 24-h continuous infusion for 5 d. In their treated population, there were patients included as second-line chemotherapy. Two consecutive studies from the University of Tuebingen Medical Center in Germany, in chemo-naïve advanced gastric cancer patients, employing weekly 24-h continuous intravenous infusion of 5-FU, modulated by leucovorin, plus 3-weekly cisplatin and either weekly or 3-weekly paclitaxel confirmed an overall response rate of 50% and survival times of 11 and 14 mo, respectively<sup>[44,45]</sup>. Docetaxel has also been combined with cisplatin, and in a three-drugs combination together with cisplatin and 5-FU. Two phase II trials combining docetaxel and cisplatin reported response rates of 37-56% and median survival times 9-11.5 mo<sup>[46,47]</sup>. Recently, Roth *et al*<sup>[48]</sup> have demonstrated that protracted infusion of 5-FU can be safely added to a docetaxel-cisplatin combination, showing a high response rate of 51%. Nevertheless, it should be remarked that although no treatment-related deaths were reported, 79% of patients experienced  $\geq$  grade 3 neutropenia and ten febrile neutropenia episodes were recorded. Grade 3 diarrhoea appeared in 19% of patients. The combination of docetaxel plus S-1 has recently been tested in Japan<sup>[49]</sup>, showing a high activity (52.1% response rate and 93.8% tumour control rate), but probably it would be necessary to add hematopoietic growth factors due to the high rate of grade 4 neutropenia (22.9%).

### **Which of these combinations could be considered as a standard treatment?**

Looking at the data of the phase II trials shown in Table 2, it can be concluded that we have made only marginal progress in the palliative treatment of advanced or metastatic gastric cancer. Despite a relatively high rate of objective responses achieved with cisplatin-based therapy and other combinations, including new agents, the time to treatment progression was usually short and the median survival ranged from 8 to 13 mo. Toxicity profile may be quite different depending on the schedule and it should be taken into account, mainly when great differences in progression-free survival and overall survival are unexpected. Relatively aggressive regimens, such as EAP-like, FLEP or DCF (Docetaxel-cisplatin-5-FU), commonly require regular use of colony-stimulating factors due to high medullar toxicity. ECF or cisplatin plus 5-FU CI seems to be less toxic but the need for central venous access and portable pumps make these schedules less comfortable. New oral fluoropyrimidines might play a role in the future to avoid central venous access.

Nowadays, data derived from randomized phase III studies do not convincingly support the use of a specific schedule as a standard treatment. During the early 1990s, especially in Europe, FAMTX became the gold standard because it was shown to be superior in overall survival when compared with the traditional FAM regimen (42 wk

*vs.* 29 wk)<sup>[50]</sup>. The results of five subsequent randomized trials comparing FAMTX or FAM *versus* cisplatin-based combinations (EAP, EEP, FLEP, and PF) were disappointing<sup>[51-55]</sup>. The EORTC trial comparing FAMTX *versus* PF *versus* a non-cisplatin combination (ELF) showed a low activity in the three arms ( $\leq 20\%$ ), no differences in toxicity profile and similar modest survival times below 8 mo<sup>[54]</sup>. The authors concluded that none of these schedules should be regarded as standard treatment for advanced gastric cancer and that new strategies should be found. The ECF regimen developed in United Kingdom was compared with FAMTX. Long-term results demonstrated that ECF yielded a significantly higher response rate (46% *vs* 21%,  $P=0.00003$ ), median survival (8.7 mo *vs* 6.1 mo,  $P=0.0005$ ) and two-year survival rates (14% *vs* 5%,  $P=0.03$ )<sup>[56]</sup>. However, the results are somewhat confounded by the fact that around one-third of patients included in both arms had locally advanced disease rather than metastatic disease. More patients in the ECF arm (12 out of 47) underwent surgery compared to the FAMTX arm (5 out of 51), and it is not clear in the study whether there were common criteria to perform a surgical rescue after neoadjuvant chemotherapy, reviewed by a surgical expert panel. On the other hand, ECF resulted in a more favourable toxicity profile than FAMTX. Therefore, many centres in Europe are now considering ECF as their standard practice. A later English study comparing ECF *versus* MCF (mitomicyn C, cisplatin and fluorouracil) over 574 eligible patients showed an equivalent response rate (42.4% for ECF *vs* 44.1% for MCF) as well as median survival times (9.4 mo for ECF *vs* 8.7 mo for MCF), although quality of life assessment suggested that ECF regimen was a more tolerable schedule<sup>[57]</sup>.

Promising results of phase II studies containing new drugs have prompted to confirm these outcomes in phase III randomized trials. Data of a phase III study comparing DCF (docetaxel-cisplatin-5-FU) *versus* PF (cisplatin-5-FU) reported a significant advantage for DCF in response rate (37% *vs* 25%) and time to progression (5.6 mo for DCF *vs* 3.7 mo for PF,  $P=0.0004$ )<sup>[58]</sup>. Overall survival was longer with DCF (risk reduction 23%,  $P=0.02$ ). Another randomized phase II study conducted by the SAKK Co-operative Group, comparing DCF *versus* DC *versus* ECF concluded that DCF is the more promising schedule and should be chosen for a formal comparison with ECF in a phase III study<sup>[59]</sup>. A recent three-arms randomized phase II study has compared LV 200 mg/m<sup>2</sup> (2-h infusion), followed by 5-FU 400 mg/m<sup>2</sup> bolus and 5-FU 600 mg/m<sup>2</sup> (22-h continuous infusion) on days 1 and 2, every 14 d (LV5FU2) *versus* LV5FU2 plus cisplatin 50 mg/m<sup>2</sup> or LV5FU2 plus CPT-11 180 mg/m<sup>2</sup>, and showed that the overall response rates were 13%, 27% and 40%, respectively<sup>[60]</sup>. The median progression-free survival (6.9 mo) and overall survival (11.3 mo) of the LV5FU2-irinotecan regimen were encouraging when compared with those of previous randomized studies. The accrual of a randomized phase III trial comparing irinotecan plus infusional 5-FU/LV *versus* cisplatin plus infusional 5-FU has been completed and the outcome is expected in the near future.

Finally, the ongoing REAL-2 study is testing the efficacy of oxaliplatin and capecitabine in a 2  $\times$  2 design. Six

**Table 3** Meta-analysis of randomized trials of adjuvant cytotoxic chemotherapy in gastric cancer

Author. <sup>Year</sup>	Number of patients/ number of trials included	Mortality risk ratio	95% confidence interval	P value
Hermans. <sup>1993</sup>	2 096/11	0.88	0.78-1.08	NS
Earle. <sup>1999</sup>	1 190/13	0.80	0.66-0.97	0.024
Mari. <sup>2000</sup>	3 658/20	0.82	0.75-0.89	<0.001
Panzini. <sup>2002</sup>	2 913/17	0.72	0.62-0.84	NA
Jannunger. <sup>2002</sup>	3 962/21	0.84	0.74-0.96	NA

hundred patients will be recruited and randomized to receive ECF *versus* EOF (epirubicin-oxaliplatin-5FU) *vs* ECX (epirubicin-cisplatin-capecitabine) *vs* EOX (epirubicin-oxaliplatin-capecitabine). An interim analysis presented at ASCO 2003 reported an interesting response rate of 52% for EOX compared with 31% for ECF, 33% for EOF and 35% for ECX<sup>[61]</sup>.

## COMPLEMENTARY TREATMENT FOR LOCALIZED GASTRIC CANCER

Surgery remains the only potentially curative treatment, though it is associated with a high rate of locoregional failure. The surgical aim is the achievement of a curative resection (R0), which implies the removal of the primary tumour with clear resection margins and the removal of the regional lymph nodes<sup>[62,63]</sup>.

There is an ongoing debate whether more extensive lymph node dissection (D2) improves survival when compared to less extensive lymph node dissection. The D2 dissection was developed from surgical practice in Japan. Retrospective studies from Japan, involving more than 10 000 patients, suggested that D2 dissection prolonged survival compared to limited resection<sup>[64-66]</sup>. However, two large phase III studies concluded that D2 dissection did not improve survival and was associated with higher surgical morbidity and mortality<sup>[67,68]</sup>. The complication rate of D2 dissection was reported to be higher in the Dutch trial than in the Japanese experience. Further studies should be designed to evaluate the extended nodular dissection.

Nevertheless, the effectiveness of surgical resection is poor. R0 resection can be only achieved in 40% of the cases. Globally, almost 60% of patients who undergo a R0 resection will relapse and succumb to their disease; consequently the overall 5-year survival rate of patients with resectable gastric cancer ranges from 10% to 30%<sup>[69,70]</sup>. The high risk of relapse after surgery has led to search strategies to prevent relapse and to improve survival for gastric cancer patients, as postoperative or adjuvant therapy strategies, or as preoperative or neoadjuvant approaches.

## ADJUVANT CHEMOTHERAPY

The outcome of gastric cancer is related to a high

incidence of both local recurrence and distant metastases after curative surgery, and has led to major efforts to explore different adjuvant therapies, such as adjuvant systemic chemotherapy, adjuvant peritoneal chemotherapy or adjuvant immunochemotherapy.

Gastric cancer would seem to be an ideal setting to test adjuvant cytotoxic regimens, as there are multiple significantly active chemotherapy drugs and combinations that show antitumoral activity in the metastatic disease. However, over the last three decades multiple phase III studies, including an observational arm, have been reported and failed to demonstrate a clear improvement in survival, and therefore, this strategy is far to be the standard management following curative surgery.

Before 1993, there were no analyses supporting the regular use of adjuvant chemotherapy for gastric cancer<sup>[71]</sup>. The minimal benefit of adjuvant cytotoxic chemotherapy alone has been published in several meta-analyses since 1993 (Table 3). The first meta-analysis published by Hermans *et al*<sup>[72]</sup> in 1993 revealed no conclusive value for adjuvant cytotoxic chemotherapy. Later on, a meta-analysis published by Earle *et al*<sup>[73]</sup> showed a marginal statistically significant, although clinically irrelevant, survival improvement for the adjuvant chemotherapy following surgical resection of gastric cancer. In 2000, Mari *et al*<sup>[74]</sup> concluded that chemotherapy might offer a small survival advantage in patients with curatively resected gastric cancer, however, the same authors pointed that, in regard to the limitations of literature-based meta-analyses, adjuvant chemotherapy must be considered as an investigational approach. The meta-analysis reported by Panzini *et al*<sup>[75]</sup> in 2002 showed that adjuvant chemotherapy resulted in a significant survival benefit in patients, though the authors suggested to confirm this conclusion in large prospective randomized trials. Finally, Jannunger *et al*<sup>[76]</sup> in 2002 did not recommend adjuvant chemotherapy as routine therapy in this setting.

Overall, there is insufficient evidence nowadays to recommend postoperative chemotherapy as adjuvant treatment.

As systemic postoperative chemotherapy has not been accepted as standard treatment, other adjuvant strategies have been explored for patients with curatively resected gastric cancer, as adjuvant immunochemotherapy and adjuvant intraperitoneal therapy.

The adjuvant immunochemotherapy approach has been developed, fundamentally, in Korea and Japan. The benefit of a streptococcal preparation (OK-432) immunochemotherapy in patients with curatively resected gastric cancer was assessed by a meta-analysis involving 1 522 patients from six clinical trials<sup>[77]</sup>. In these trials, chemotherapy was compared to the same chemotherapy plus immunotherapy. The 3-year survival rate was 67.5% in the immunochemotherapy group whereas 62.6% in the control group. The 3-year overall survival odds ratio was 0.81 (95% confidence interval: 0.65-0.99; *P*=0.044). The results of this meta-analysis suggested that immunochemotherapy with OK-432 after surgery may improve the survival of patients with curatively resected gastric cancer.

Intraperitoneal chemotherapy is a rational approach

**Table 4** Phase II studies of preoperative chemotherapy in localized gastric cancer

Author. <sup>Year</sup>	Number of patients	Neoadjuvant chemotherapy regimen	Adjuvant chemotherapy regimen	R0 rate	pCR	Median survival (mo)	2-yr survival rate (%)
Wilke. <sup>1989</sup>	34	EAP × 2	EAP × 2	29	5	18	26
Leichman. <sup>1992</sup>	38	CF × 2	Intraperitoneal	76	3	17	NR

	29	Surgery	None	62		13.1	NR

EAP: etoposide, doxorubicin and cisplatin; CF: cisplatin and 5-fluoruracil; EFP: etoposide, 5-fluoruracil and cisplatin; FAMtx: 5-fluoruracil, doxorubicin and methotrexate; pCR: pathological complete remission; NR: no reported

since the peritoneal cavity is the site of recurrence in more than half of the patients, and commonly the only one location of progression disease. In other tumours, such as ovarian cancer, in which peritoneal failure is common, clinical trials have demonstrated a small but significant advantage to intraperitoneal therapy<sup>[78,79]</sup>. Nevertheless, the trials reported in gastric cancer have been hampered by small size and limited statistical power and have not established a clear survival benefit from this strategy<sup>[80,82]</sup>.

## ADJUVANT CHEMORADIO THERAPY

Taking into account that surgical resection of gastric cancer is curative in less than 40% of cases, and the fact that both locoregional and distant relapses are common, adjuvant chemoradiotherapy is a rational approach for these patients. Several preliminary studies have shown promising results<sup>[83,84]</sup>. The most important trial in this setting is the US Intergroup 0116 phase III study. Five-hundred and fifty six patients with adenocarcinoma of the stomach and esophagogastric junction were randomized to surgery alone or surgery plus postoperative chemoradiation (1 cycle of 5-FU modulated by leucovorin, followed by concomitant 5-FU/LV and radiation therapy (45 Gy), and one month after the completion of radiotherapy, two 5-d cycles of 5-FU/LV)<sup>[85]</sup>. Eighty-five percent of patients in both arms had node-positive carcinoma (stage III or IV). The toxicity in the study arm was: 41% of patients experienced grade III and 32% grade IV toxicity, with a 1% of toxic deaths. Median overall survival was significantly improved in the experimental arm compared to the surgery alone group (36 mo *vs* 27 mo;  $P=0.005$ ). The 3-year overall survival (50% *vs* 41%) and 3-year relapse-free (48% *vs* 31%) survival were significantly better in the study group. The survival improvement was mostly related to the decrease in locoregional rather than distant failure. Based on the results of US Intergroup 0116 study, postoperative chemoradiation has been accepted as standard care in patients with resected gastric cancer in North America.

However, this study is limited for both the surgical procedures and the chemotherapy regimen employed. Fifty-four percent of patients underwent less than D1 dissection (only partial removal of the N1 nodes) and only

10% of patients underwent a D2 dissection. On the other hand, 5-FU/LV is not a chemotherapeutic option in the management of patients with advanced gastric cancer. The benefit of the Intergroup 0116 may have primarily derived from the use of radiation therapy, since local control was improved without any effect in distant control. These data support a potential benefit of this chemoradiation schedule after inadequate surgical resection. Further studies employing D1 or D2 dissection alone *versus* the same surgery plus adjuvant cisplatin/5-FU-based combinations plus radiation therapy are needed.

## NEOADJUVANT CHEMOTHERAPY

Neoadjuvant treatment, chemotherapy or chemoradiotherapy, has been tested in small studies. Preoperative chemotherapy may allow to improve in the R0 rate due to tumour down-staging, and also may contribute to eradicate micrometastasis. At present, neoadjuvant treatment is being tested in locally advanced non-resectable tumours and in those resectable tumours with a high risk of recurrence.

However, there are possible disadvantages of the neoadjuvant treatment. Patients with early gastric carcinoma (stages 0 and I) could be over-treated, and among the stages II-IV non-metastatic gastric cancers, the response to the preoperative therapy could be unsatisfactory; therefore, some patients could be exposed to an unnecessary morbidity, and furthermore, the success of surgical resection could be hampered. In this context, efforts to identify prognostic factors and more active and less toxic preoperative regimens are being searched.

Several small phase II trials with different cisplatin-based neoadjuvant chemotherapy regimens have been reported in the nineties, with the largest including only 59 patients (Table 4). The perioperative radiotherapy was not included in any trials, while postoperative systemic or intraperitoneal chemotherapy was administered in some of these trials. The median survival ranged from 16 to 48 mo, and was significantly better in those patients who underwent an R0 resection<sup>[86-91]</sup>. Beyond these small trials, phase III prospective clinical trials are needed.

The large phase III UK Medical Research Council Adjuvant Gastric Infusional Chemotherapy (MAGIC)

trial was the first well-powered phase III neoadjuvant chemotherapy study to assess the efficacy of perioperative chemotherapy<sup>[92]</sup>.

Five hundred and three patients with potentially resectable gastric cancer were randomized to both preoperative and postoperative EFC therapy chemotherapy *versus* surgery alone. EFC regimen consisted of epirubicin (50 mg/m<sup>2</sup>) and cisplatin (60 mg/m<sup>2</sup>) administered on day 1, and protracted venous infusion of 5-FU (200 mg/m<sup>2</sup> per d) on days 1 to 21, administered every 3 wk for three cycles before and after surgery. The results of this trial demonstrated statistically significant improvement of the study arm in disease-free survival (HR 0.7%, 95% confidence interval 0.56-0.88%) and a strong trend towards better overall survival compared to surgery alone (HR 0.8, 95% confidence interval 0.63-1.01). There were other important results from the MAGIC study. Although in the study group, the number of patients who underwent surgery was slightly lower (85% *vs* 92%), the rate of pathological complete response was significant better in this group (79% *vs* 69%, *P*=0.018), and the surgical morbidity and mortality were not compromised. Furthermore, there was a significant tumour down-staging.

However, it remains unclear how the neoadjuvant therapy may be integrated into the multimodality management of localized gastric cancer. Consequently, ongoing randomized controlled trials are evaluating this issue.

Meanwhile some clinicians may elect to offer patients preoperative chemotherapy. Taking into account, both INT-0116 study and MAGIC study, combining neoadjuvant and postoperative chemoradiation might result in improving the outcome of patients with resectable gastric cancer.

## NEOADJUVANT CHEMORADIOOTHERAPY

There are few phase I-II studies exploring the role of neoadjuvant chemoradiotherapy in resectable gastric cancer. In 2003, Roth *et al*<sup>[93]</sup> reported promising results of a phase I-II study with preoperative platinum and 5-FU plus radiotherapy in this setting. They found a 5% pathological complete responses, 80% resection rate without increasing the surgical morbidity, and 71% of 2-year survival<sup>[93]</sup>. Similar results were reported in a phase II study of MD Anderson group with 5-FU and concomitant preoperative radiotherapy<sup>[94]</sup>.

Other approach is the three-step therapy, involving preoperative chemotherapy, followed by concomitant chemoradiation and finally the surgical procedure. The MD Anderson group reported two phase II studies. In the former study, the patients received a combination of cisplatin and 5-FU, and then radiotherapy concomitant with 5-FU, achieving a 29% rate of pathological complete response and 80% rate of resectability<sup>[95]</sup>. In the latter study, a combination of paclitaxel, cisplatin and 5-FU was used as neoadjuvant chemotherapy, followed by concomitant radiotherapy plus 5-FU. The resectability rate reported was 100%, with 26% of resections showing no viable tumour in the pathologic examination<sup>[96]</sup>. Finally, some other trials are exploring other chemotherapeutic agents, such as docetaxel or irinotecan.

## CONCLUSIONS OF COMPLEMENTARY TREATMENT FOR LOCALIZED GASTRIC CANCER

Gastric cancer is a disease in which locoregional control is hardly achieved. The roles of adjuvant and neoadjuvant therapy have also been debated for a long time; there are some approaches that seem to be effective for the management of localized gastric cancer.

Currently, it remains unclear to agree the standard care, and even it differs in each country. In EEUU, adjuvant chemoradiation is considered the standard care and stands for the control arm for further trials. However, in Korea, the standard care is adjuvant immunochemotherapy. In Japan, a D2 lymph node dissection is the standard surgical procedure and the role of any adjuvant chemotherapy is controversial.

In Europe, there are the most different opinions. Some authors argue that following an optimal surgery (at least D1), none of the adjuvant strategies seem to be superior to surgery alone, but other authors do agree to the INT-0116 results.

On the other hand, the MAGIC trial added important information on adjuvant strategy, though it is required to wait for definitive survival results of the MAGIC and other phase III trials, to accept neoadjuvant chemotherapy as the new standard care. In addition, neoadjuvant chemoradiotherapy trials offer promising results and these schemes may be explored in large randomized phase III trials. Newer approaches to cancer management, including molecular-targeted therapies may be explored.

## Abstract

**AIM:** To examine the potency of 1,2,3,4,6-penta-O-galloyl- $\beta$ -D-glucose (PGG) as a hepatic heme oxygenase-1 (HO-1) inducer and its regulation in HepG2 cells.

**METHODS:** Expression of HO-1 and NF-E2-related factor 2 (Nrf2) and activation of mitogen-activated protein (MAP) kinases were analyzed by Western blot, immunofluorescence assay, and flow cytometry. Transfections of HO-1 gene, small interfering RNAs for HO-1 and Nrf2, and dominant-negative gene for MAP/extracellular signal-regulated kinase (ERK) were carried out to dissect the signaling pathways leading to HO-1 expression in HepG2 cells.

**RESULTS:** PGG up-regulated HO-1 expression and this expression conferred cytoprotection against oxidative injury induced by t-butyl hydroperoxide. Moreover, PGG induced Nrf2 nuclear translocation, which was found to be an upstream step of PGG-induced HO-1 expression, and ERK activation, of which pathway was involved in PGG-induced Nrf2 nuclear translocation, HO-1 expression and cytoprotection.

**CONCLUSION:** PGG up-regulates HO-1 expression by

## INTRODUCTION

Oxidative stress is the inappropriate exposure to reactive oxygen species (ROS), such as superoxide anion radicals and hydroxyl radicals. High levels of ROS cause damage to cells and are involved in several human pathologies, including liver cirrhosis and fibrosis<sup>[1,2]</sup>. Therefore, the use of compounds with antioxidant properties may help prevent or alleviate many diseases associated with ROS.

Because ROS formation is a naturally occurring process, the mammalian cells have developed several protective mechanisms to prevent ROS formation or to detoxify the ROS. These mechanisms employ molecules called antioxidants as well as protective enzymes<sup>[3]</sup>. Among the various cytoprotective enzymes, heme oxygenase-1 (HO-1) is recently highlighted by virtue of its hepatoprotective roles<sup>[4-6]</sup>.

The inducible HO-1 is a rate-limiting enzyme in heme catabolism, leading to the formation of carbon monoxide, iron, and biliverdin. Biliverdin is subsequently converted to bilirubin, a potent endogenous anti-oxidant<sup>[7]</sup>. There is a large body of evidence suggesting that HO-1 plays a key role in maintaining anti-oxidant homeostasis during cellular stress<sup>[7-9]</sup>. The induction of HO-1 gene is primarily

regulated at the transcriptional level, and its inducibility by various inducers is linked to the transcription factor NF-E2-related factor 2 (Nrf2)<sup>[9]</sup>.

Under normal conditions, Nrf2 is sequestered in the cytoplasm by binding to Keep1, an actin-binding protein<sup>[10]</sup>. Several stimuli cause the disruption of this complex, freeing Nrf2 for translocation to the nucleus and dimerization with basic leucine zipper transcription factors<sup>[11,12]</sup>. The mechanism by which Nrf2 is liberated from the Keep1-Nrf2 complex remains to be established. However, recent studies have suggested that the Nrf2 nuclear translocation requires the activation of the mitogen-activated protein kinases (MAPKs)<sup>[13]</sup>.

The three major MAPK pathways are represented by kinase cascades leading to activation of extracellular signal-regulated kinase (ERK), p38, and c-Jun N-terminal kinase (JNK)<sup>[14]</sup>. All three pathways appear to be involved to some extent in HO-1 expression and Nrf2 nuclear translocation in response to diverse stimuli<sup>[15-20]</sup>.

In view of the growing evidence that HO-1 provides hepatoprotection<sup>[4,6]</sup>, HO-1 expression by pharmacological modulator may represent a novel target for therapeutic intervention. Particularly, the identification of a non-cytotoxic inducer of HO-1 may maximize the intrinsic antioxidant potential of cells. Several antioxidants from plant origins have been reported to induce HO-1 expression in a variety of cells, including liver cells, and hence to resist to the oxidative stress<sup>[15-17, 21-24]</sup>.

1,2,3,4,6-penta-O-galloyl- $\beta$ -D-glucose (PGG), a bioactive tannin, is wide-spread and can be found in many medicinal plants<sup>[25]</sup>. Previously, we have demonstrated that PGG is a promising inducer of HO-1<sup>[26]</sup>. In this study, we aimed at examining the potency of PGG as a hepatic HO-1 inducer and its regulation in HepG2 cells. In addition, we examined the hepatoprotective significance of PGG-induced HO-1 against oxidant toxicity.

## MATERIALS AND METHODS

### Cell culture

HepG2 cells were obtained from ATCC (Manassas, VA) and maintained as monolayer cultures in F12 medium supplemented with 100 mL/L fetal bovine serum (FBS), 1.7 mg/mL sodium bicarbonate, 0.1 unit/mL insulin, 0.5 x minimal essential medium amino acid, 100 units/mL penicillin, and 100  $\mu$ g/mL streptomycin.

### Antibody, DNA and RNA

Antibodies to phospho (p)-ERK-1/2, p-JNK-1/2, p-p38, ERK-1/2, JNK-1/2, p38, and Nrf2, and small interfering (si) RNAs for HO-1 and Nrf2 plus siRNA transfection kit were obtained from Santa Cruz Biotechnology (Santa Cruz, CA). FITC-conjugated secondary antibody was purchased from BD PharMingen (San Diego, CA). Antibodies to HO-1, tubulin, and lamin B were obtained from Cell Signaling Technology (Beverly, MA). cDNAs encoding constitutively active (CA) and dominant negative (DN) mutants of MEK1 were kindly provided by Dr. K. Y. Choi (Yonsei University, Seoul, Korea). HO-1 cDNA was a kind gift from Dr. A. M. K. Choi (University of Pittsburgh, Pittsburgh, PA).

### PGG, inhibitors and reagents

PGG was isolated from the root of *Paeonia lactiflora*, as previously described<sup>[27]</sup>. U0126 and zinc protoporphyrin IX (ZnPP) were obtained from Promega (Madison, WI) and Porphyrin Products (Logan, UT), respectively. SP600125 was purchased from Calbiochem (San Diego, CA). SB203580 and other reagents were purchased from Sigma-Aldrich (St. Louis, MO).

### Reverse transcription polymerase chain reaction (RT-PCR)

Total RNA was isolated by using TRI Reagent<sup>TM</sup> (Sigma-Aldrich). First-strand cDNAs were synthesized from RNA using ImProm-II RT system (Promega). Then, PCR with Taq DNA polymerase (Promega) was performed for 27 cycles, and PCR products were analyzed by electrophoresis. The primers used for PCR amplification were 5'-ATGGATGATGATATCGCCGCG-3' and 5'-TCTCCATGTCGTCCAGTTG-3' ( $\beta$ -actin, 248 bp), as well as 5'-AAGATTGCCAGAAAGCCCTGGAC-3' and 5'-AACTGTCGCCACCAGAAAGCTGAG-3' (HO-1, 399 bp).

### Western blotting analysis and HO activity

Cells were solubilized in ice-cold 10 g/L Triton X-100 lysis buffer supplemented with protease and phosphatase inhibitors. After 30 min on ice, the lysates were clarified by centrifugation and the protein concentration was determined. Proteins were resolved with SDS-PAGE, transferred to nitrocellulose membranes, and probed with specific antibodies (diluted 1:1 000), followed by incubation with secondary antibody (diluted 1:5 000) for specific band detection. HO-1 activity was determined at the end of each treatment as described in our previous study<sup>[26]</sup>.

### Immunofluorescence assay

Cells were grown on Lab-Tek II chamber slides. The cells were fixed using formalin and permeabilized with cold acetone. Immunofluorescence was then performed using Nrf2 or HO-1 antibody and FITC-labeled secondary antibody. The cells were stained with DAPI (Sigma-Aldrich) to visualize the nuclei. A Zeiss Axiovert 200 fluorescent microscope fitted with a HV-Deo camera and the appropriate filters were used to capture the fluorescent images.

### Flow cytometry

Cells were washed three times with PBS, fixed with 40 g/L paraformaldehyde and permeabilized with 1 g/L saponin. HO-1 expression was determined by intracellular staining with HO-1 antibody labeling FITC-conjugated secondary antibody. The stained cells were analyzed using a FACSVantage flow cytometry (BD Biosciences, Franklin Lakes, NJ).

### Cell viability

Cell toxicity was estimated using the tetrazolium salt reduction test (MTT) after 4-h exposure to t-butyl hydroperoxide (t-Bt-HP; Sigma-Aldrich). After changing culture medium, MTT (5 mg/mL in PBS) was added to a plate. Cells were allowed to incubate for 3 h at 37°C in a

atmosphere containing 50 mL/L CO<sub>2</sub>. After solubilization of deposited MTT with dimethyl sulfoxide, absorbance was measured at 540 nm in a microplate reader.

### Transient transfection

HepG2 cells were plated in 6-well plates at a density of  $1.5 \times 10^5$  cells/well. After 24 h of plating, cells were transfected with expression plasmids using Lipofect-AMINE 2000 (Invitrogen), following the manufacturer's instructions. Briefly, cell culture medium was changed to a fresh medium before each transfection, 0.5  $\mu$ g of pRSV- $\beta$ -galactosidase plasmid was co-transfected for transfection efficiency normalization in each transfection, and total amount of DNA transfected in each well was adjusted to 4  $\mu$ g by using the empty vector pCDNA3.1. Cells were incubated with transfection mixture for 5 h and then cultured in fresh medium for an additional 36 h. Transfection for each siRNA was carried out with siRNA transfection kit (Santa Cruz Biotechnology), following the manufacturer's instructions. The transfected cells were grown for 36 h.

### Statistical analysis

Results were expressed as means  $\pm$  SE. Student's t-test was applied for comparison of the data.  $P < 0.05$  was considered statistically significant.

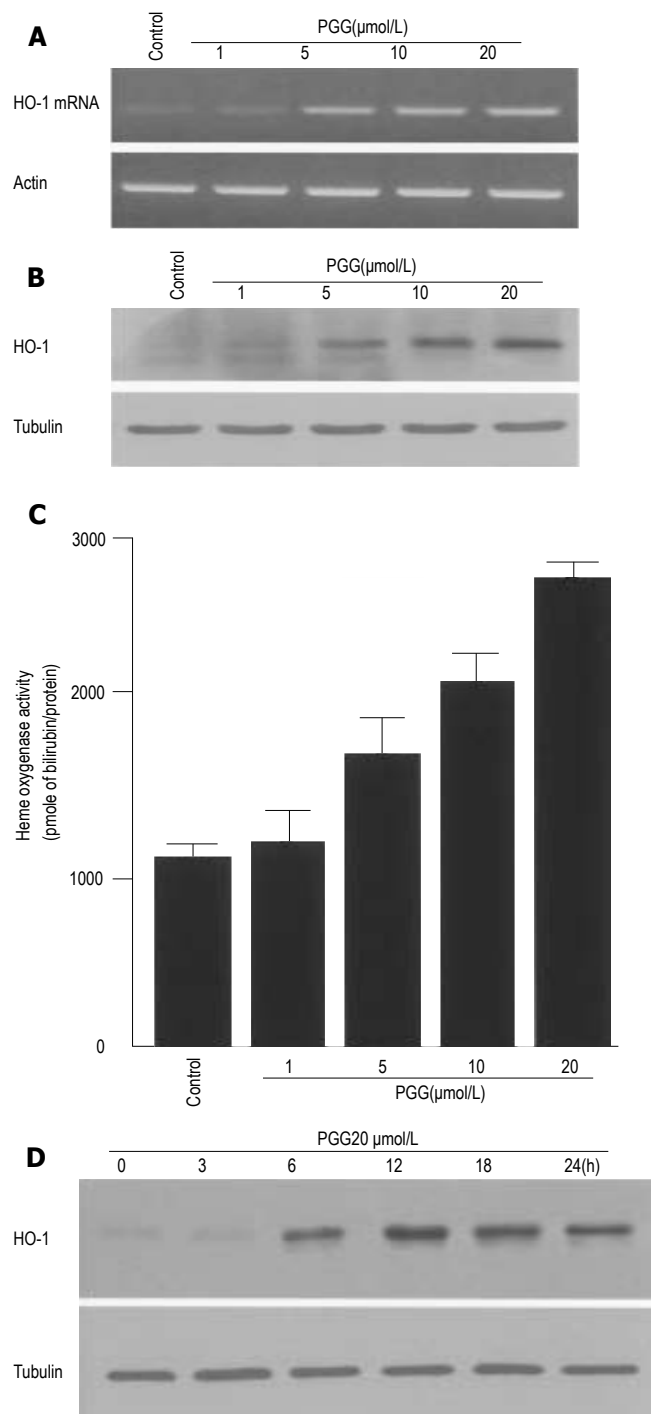

## RESULTS

### HO-1 mRNA and protein expressions by PGG

To determine the effects of PGG on HO-1 gene transcription, we used human HepG2 cells, which have been widely used in drug metabolism, chemoprevention and hepatoprotective studies<sup>[28]</sup>. HO-1 mRNA expression was analyzed by RT-PCR after treatment with PGG (1-20  $\mu$ mol/L) for 4 h. HO-1 mRNA expression was increased in a dose-dependent manner (Figure 1A). No significant toxicity was found to the cells at these concentrations of PGG (data not shown). To further determine whether PGG could induce HO-1 protein expression, cells were treated with different doses of PGG for 12 h. Treatment with PGG increased HO-1 protein expression in a dose-dependent manner (Figure 1B). In addition, HO activity was also increased in a dose-dependent manner (Figure 1C). In HepG2 cells treated with 20  $\mu$ mol/L of PGG, HO-1 expression was increased in a time-dependent manner, reaching a maximum at 12 h, followed by a decrease at 24 h (Figure 1D).

### Cytoprotection by PGG-induced HO-1 against oxidative injury

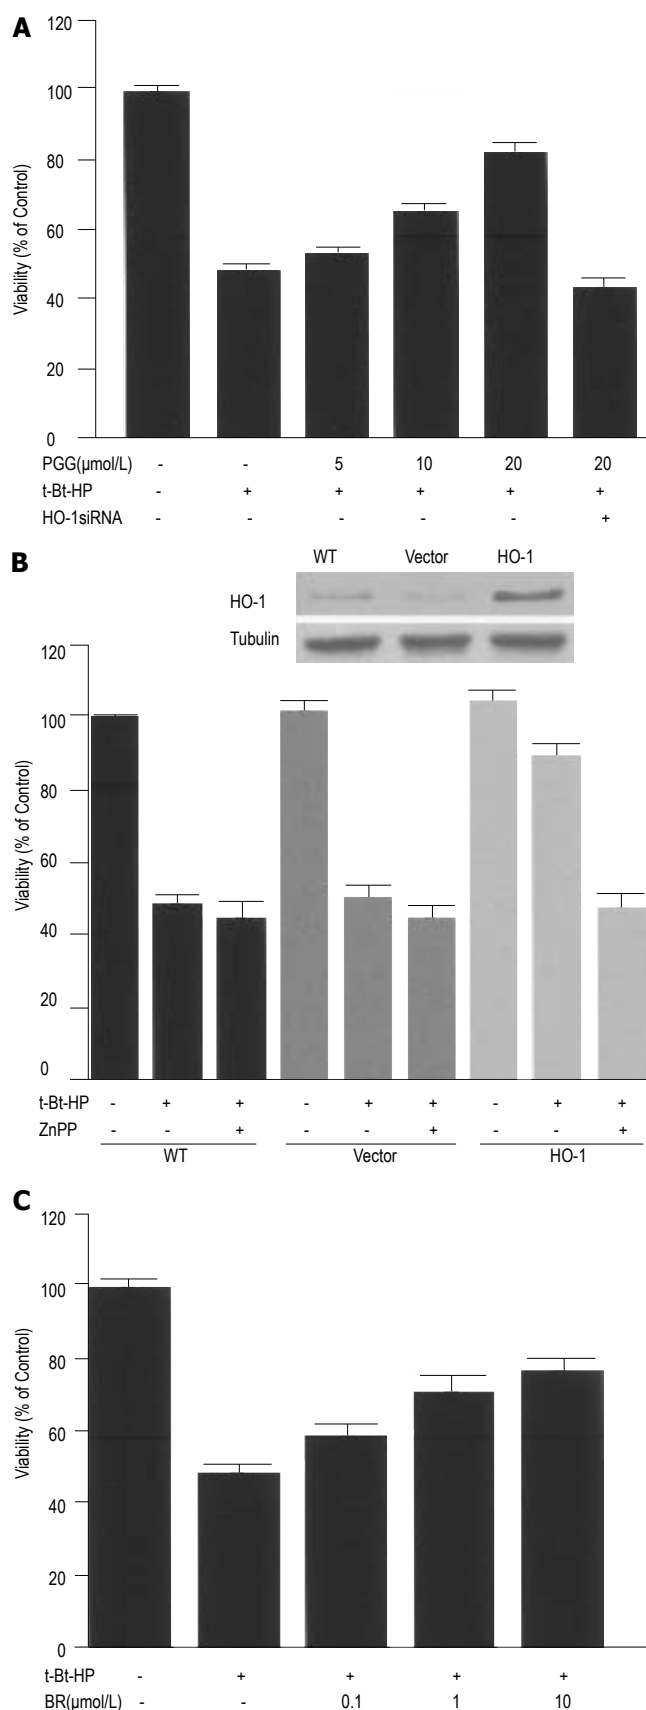

To examine whether HO-1 expression by PGG could cause HepG2 cells to become more resistant to oxidative injury, the cells were pre-treated with medium or PGG (5-20  $\mu$ mol/L) for 12 h. After changing culture medium, cells were exposed for 4 h to t-Bt-HP, a compound commonly used to induce oxidative stress in biological system<sup>[29]</sup>. Exposure to 100  $\mu$ mol/L of t-Bt-HP resulted in a marked reduction of cell viability. Pre-incubation with PGG for 12 h diminished t-Bt-HP toxicity in a dose-dependent manner and increased cell viability by 80% (Figure 2A).

**Figure 1** Effects of PGG on HO-1 mRNA and protein expression and HO activity in HepG2 cells. **A, B, C:** Cells were incubated with indicated concentrations of PGG for either 4 h (A) or 12 h (B and C); **D:** Cells were also incubated with 20  $\mu$ mol/L PGG for indicated times. Data are expressed as mean  $\pm$  SE of five independent experiments.

Cytoprotection by PGG was not detectable when the cells were transiently transfected with HO-1 siRNA (Figure 2A). Moreover, a similar cytoprotective effect was observed when the cells were transfected with HO-1 gene (Figure 2B). Blockage of the enzyme activity by ZnPP, a specific HO inhibitor, abolished HO-1-mediated cytoprotection (Figure 2B), suggesting that HO-1 metabolites could be of functional relevance of the observed protective action. Indeed, exogenously added bilirubin (0.1-10  $\mu$ mol/L),

**Figure 2** Effects of PGG-induced HO-1 on t-Bt-HP-induced toxicity in HepG2 cells. **A:** Cells transiently transfected with HO-1 siRNA were pre-incubated with indicated concentrations of PGG for 12 h, and exposed to 100 μmol/L t-Bt-HP for 4 h; **B:** Cells (WT) were transiently transfected with control vector (Vector) or HO-1 gene (HO-1), and then exposed to 100 μmol/L t-Bt-HP for 4 h in the absence or presence of 20 μmol/L ZnPP; **C:** Cells were exposed to 100 μmol/L of t-Bt-HP for 4 h in the absence or presence of indicated concentrations of bilirubin (BR). Data are expressed as mean ± SE of five independent experiments.

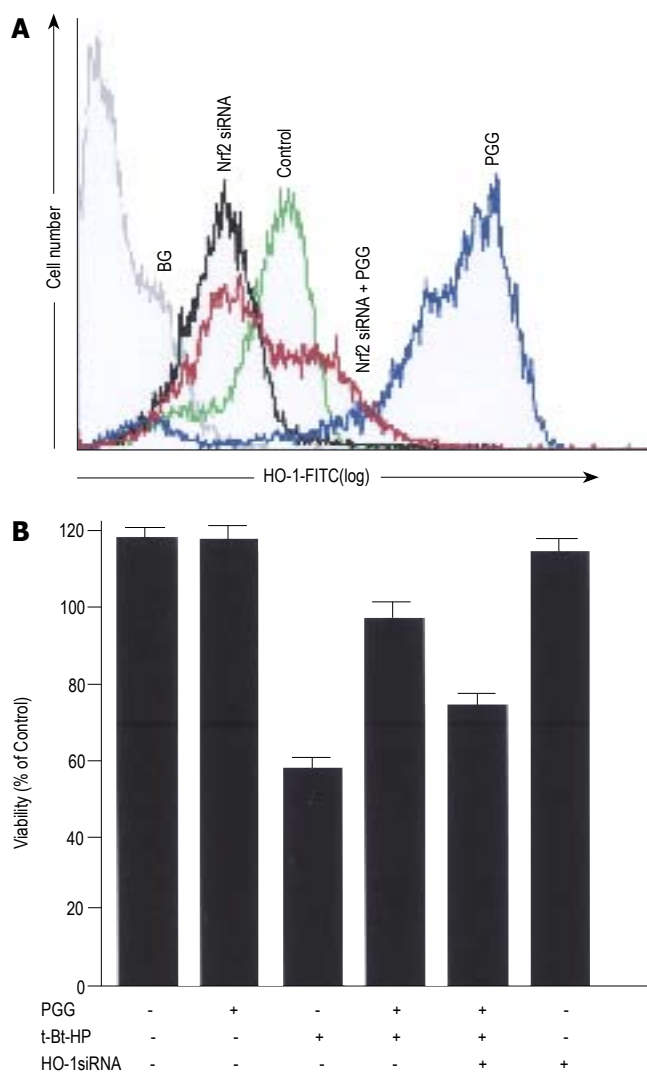

**Figure 3** Effects of PGG on Nrf2 nuclear translocation in HepG2 cells. **A:** After 2-h treatment with 20 μmol/L PGG; **B:** Cytoplasmic and nuclear extracts harvested from control cells and cells treated for indicated times with 20 μmol/L PGG, and Western blotting performed with antibodies for Nrf2, tubulin and lamin B.

one of three HO-1 metabolites, produced a substantial reduction of t-Bt-HP toxicity (Figure 2C). HO-1 siRNA and ZnPP alone had no significant effect on cell viability under these conditions (data not shown).

### Nrf2 nuclear translocation by PGG

In the mechanism of HO-1 expression, nuclear translocation of activated Nrf2 is an important upstream step<sup>[9,30]</sup>. To investigate whether PGG could induce Nrf2 translocation in HepG2 cells, an immunofluorescence assay was used to detect the distribution of Nrf2 in the cells treated with medium or PGG (Figure 3A). Approximately 20 μmol/L PGG was chosen to further determine the effects of PGG, because PGG at this concentration showed no significant toxicity (data not shown), caused a maximal increase in HO-1 expression (Figure 1) and also conferred a maximal cytoprotection (Figure 2). In untreated HepG2

**Figure 4** Effects of PGG-induced Nrf2 activation on HO-1 expression and t-Bt-HP-induced toxicity in HepG2 cells. **A:** Normal cells and the cells transiently transfected with Nrf2 siRNA were pre-incubated with 20  $\mu\text{mol/L}$  PGG for 12 h. HO-1 expression was determined by a flow cytometry. BG indicates background auto-fluorescence; **B:** Cells and transfected cells pre-incubated for 12 h with 20  $\mu\text{mol/L}$  PGG were exposed to 100  $\mu\text{mol/L}$  t-Bt-HP for 4 h. Data are expressed as mean  $\pm$  SE of five independent experiments.

cells, Nrf2 fluorescence was found to be distributed throughout the cells including cytoplasm and nucleus<sup>[15]</sup>. After treatment with PGG for 2 h, Nrf2 fluorescence was primarily concentrated in the nuclei (Figure 3A). To further confirm the Nrf2 nuclear translocation by PGG, cells were incubated with PGG for about 2 h. Using Western blot, Nrf2 proteins in the cytoplasm and nuclear compartments of the cells were analyzed. After treatment with PGG, Nrf2 protein in the cytoplasm was decreased, and Nrf2 protein in the nucleus was markedly increased (Figure 3B). In addition, PGG-induced HO-1 expression was significantly reduced by transient transfection with Nrf2 siRNA (Figure 4A), as quantified by a flow cytometry, and cytoprotection afforded by PGG was effectively abolished by Nrf2 siRNA (Figure 4B).

#### Involvement of ERK MAPK pathway in HO-1 expression by PGG

MAPKs have been reported to participate in the regulation

of HO-1 expression<sup>[15-20]</sup>. We examined the effects of PGG on MAPK activities in HepG2 cells. The cells were treated with medium or 20  $\mu\text{mol/L}$  PGG for about 2 h, and cell extracts were analyzed for phosphorylated and total MAPKs by Western blot. While the phosphorylated forms of all three MAPKs could be detectable even in the untreated cells, only the phosphorylated form of ERK was significantly increased by PGG (Figure 5A). Increased phosphorylation of ERK was detected within 30 min after treatment with PGG, and the amount of this kinase remained above the basal level for about 2 h. To address the role of individual MAPK pathway in HO-1 expression by PGG, we examined the effects of U0126, SB203580 and SP600125, specific inhibitors for ERK, p38 and JNK pathways, respectively, on HO-1 expression. Whereas inhibitor of either p38 or JNK had no effect on PGG-induced HO-1 expression, inhibitor for ERK MAPK pathway significantly reduced HO-1 expression (Figure 5B). In addition, we examined the effects of three MAPK inhibitors on PGG-induced cytoprotection. As expected, inhibitor for ERK MAPK pathway abolished PGG-induced cytoprotection, but inhibitors for p38 or JNK MAPK pathways did not (Figure 5C). The inhibitor for ERK alone had no significant toxicity under our experimental conditions (data not shown).

#### Involvement of ERK MAPK activation in Nrf2 nuclear translocation by PGG

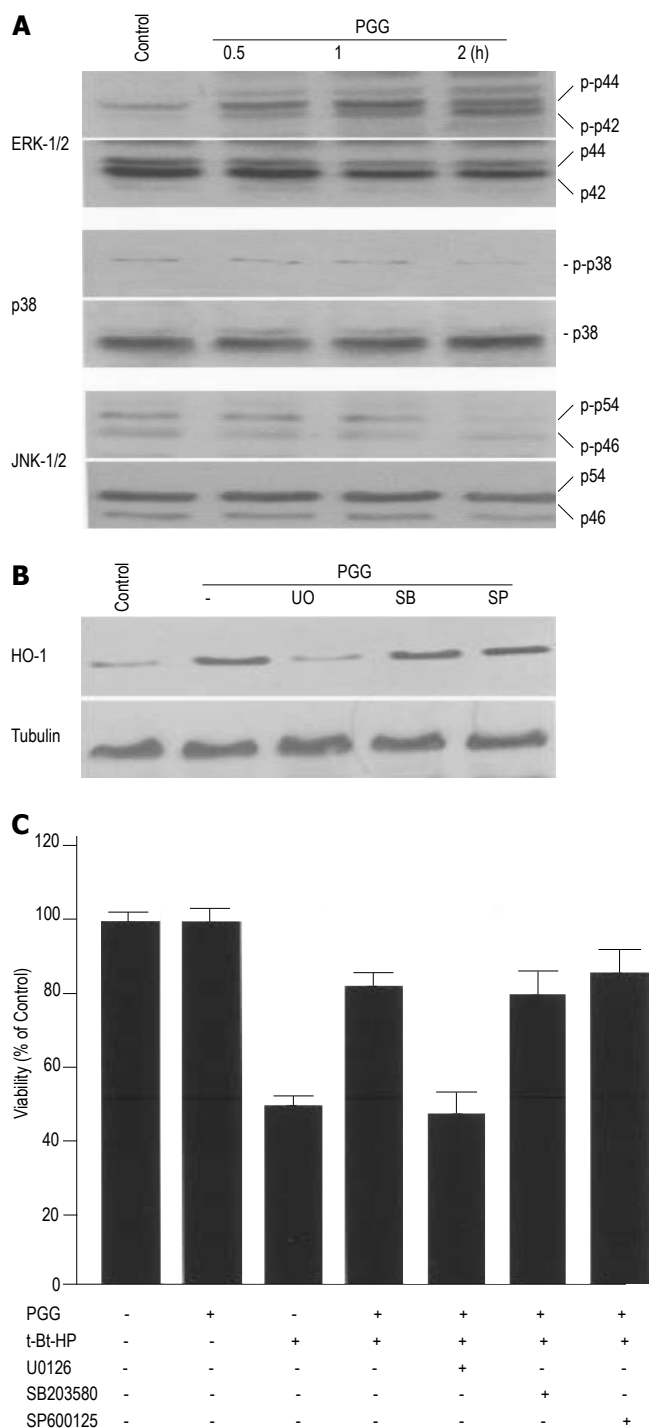

It has been reported that MAPK-directed phosphorylation is a requirement for Nrf2 nuclear translocation in HepG2 cells<sup>[31-33]</sup>. Thus, we examined whether MAPK pathway could be involved in the process by which PGG caused Nrf2 nuclear translocation. As shown in Figure 6A, inhibitor for ERK MAPK pathway, but not for p38 or JNK MAPK pathways, blocked PGG-induced Nrf2 nuclear accumulation. This was similar to the role of ERK inhibitor in PGG-induced HO-1 expression (Figure 5B) and cytoprotection (Figure 5C). To further evaluate the role of the ERK activation in PGG-induced Nrf2 nuclear translocation and HO-1 expression, we transfected DN-MEK1 and CA-MEK1 genes into HepG2 cells to selectively inhibit or activate the ERK pathway. In HepG2 cells, CA-MEK1 expression itself activated Nrf2 nuclear translocation and also HO-1 expression (Figure 6B). Moreover, PGG-induced cytoprotection (Figure 6C) and HO-1 expression (Figure 6D) were not observed when the cells were transfected with DN-MEK1 gene.

## DISCUSSION

We previously reported that PGG, one of bioactive tannins, induced HO-1 expression<sup>[26]</sup>. In this study, we aimed to examine the potency of PGG as a hepatic HO-1 inducer and its regulation in HepG2 cells. Our results showed that PGG induced HO-1 expression via stimulating Nrf2 nuclear translocation in an ERK-dependent manner, thereby exerting hepatoprotective effects.

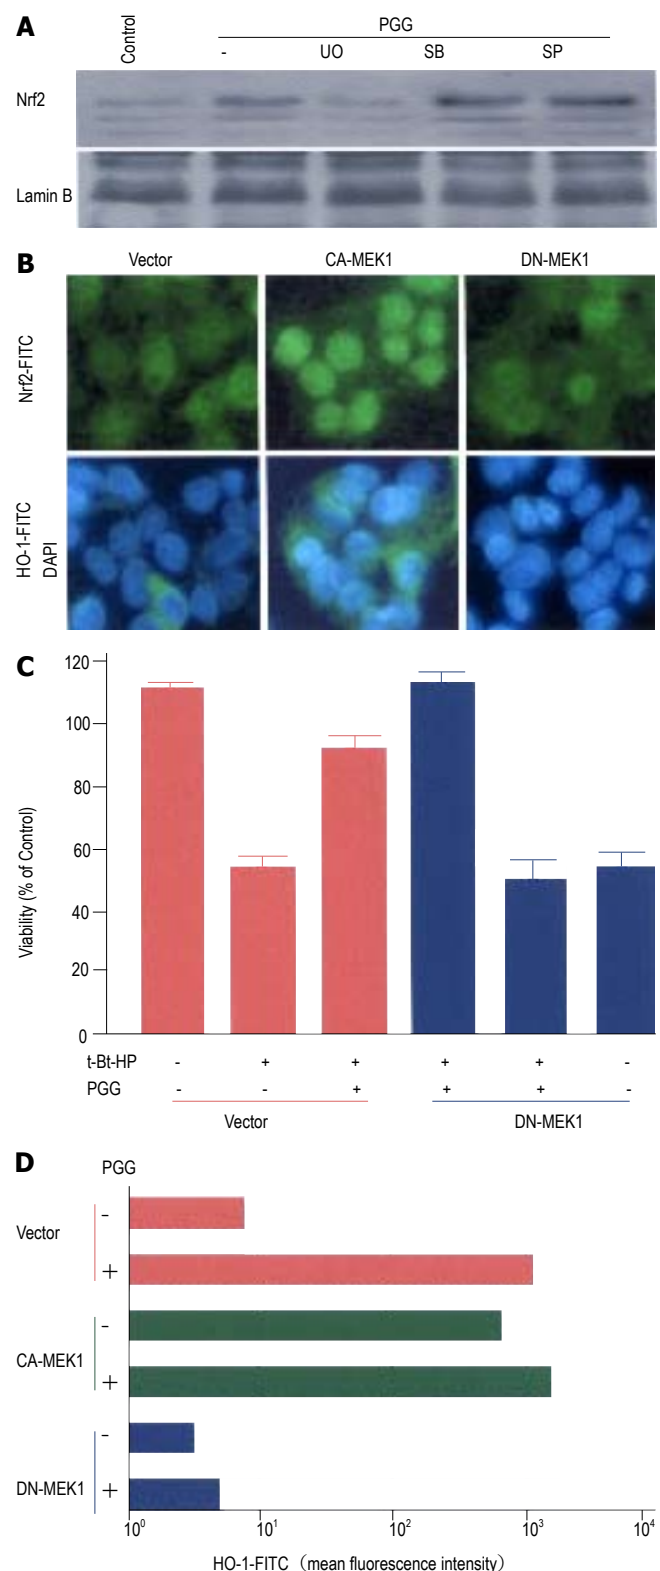

The cytoprotective properties of antioxidants have been partially ascribed to their ability to induce cytoprotective enzymes. Among the various cytoprotective enzymes,

**Figure 5** Effects of PGG-induced ERK activation on HO-1 expression and t-Bt-HP-induced toxicity in HepG2 cells. **A:** Cells were incubated with 20  $\mu\text{mol/L}$  PGG for indicated times, and Western blotting was performed with specific antibodies; **B:** Cells were incubated with 20  $\mu\text{mol/L}$  PGG for 12 h in the presence or absence of 10  $\mu\text{mol/L}$  U0123 (UO), 20  $\mu\text{mol/L}$  SB203580 (SB), or 20  $\mu\text{mol/L}$  SP600125 (SP), and Western blotting was performed with HO-1 antibody; **C:** Cells untreated or treated with PGG in the presence or absence of each specific inhibitor for 12 h were exposed to 100  $\mu\text{mol/L}$  t-Bt-HP for 4 h. Data are expressed as mean  $\pm$  SE of five independent experiments.

HO-1 expression has been considered to be an adaptive and beneficial response to oxidative stress in a wide variety of cells<sup>[4-9]</sup>. Here, we demonstrated that PGG at non-cytotoxic concentrations increased HO-1 mRNA and protein expressions as well as HO activity in HepG2 cells (Figure 1). The increase of HO-1 expression by

**Figure 6** Roles of PGG-induced ERK activation in Nrf2 nuclear translocation and t-Bt-HP-induced toxicity in HepG2 cells. **A:** Cells were incubated with 20  $\mu\text{mol/L}$  PGG for 2 h in the presence or absence of 10  $\mu\text{mol/L}$  U0123 (UO), 20  $\mu\text{mol/L}$  SB203580 (SB), or 20  $\mu\text{mol/L}$  SP600125 (SP), and nuclear extracts were harvested, following Western blotting analysis with Nrf2 antibody; **B:** Cells were transiently transfected with control vector (Vector), CA-MEK1 gene, or DN-MEK1 gene, stained with Nrf2 antibody (upper) or HO-1 antibody and DAPI (lower), and visualized using a fluorescent microscope; **C:** Cells transfected with control vector or DN-MEK1 gene were pre-incubated with 20  $\mu\text{mol/L}$  PGG for 12 h, and exposed to 100  $\mu\text{mol/L}$  t-Bt-HP for 4 h. Data are expressed as mean  $\pm$  SE of five independent experiments; **D:** Cells transfected with vector or each gene were incubated for 12 h in the absence or presence of 20  $\mu\text{mol/L}$  PGG. HO-1 expression was determined by a flow cytometry.

PGG conferred cytoprotection against t-Bt-HP-induced oxidative stress (Figure 2A), which was clearly confirmed by transfection of either HO-1 siRNA (Figure 2A) or HO-1 gene (Figure 2B). We also demonstrated that cytoprotection afforded by HO-1 was highly dependent on its enzyme activity (Figure 2B) and bilirubin, one of its enzymatic products (Figure 2C). Our results suggested that PGG-induced HO-1 expression might serve as one of the important mechanisms for its hepatoprotective effects.

While the induction of HO-1 has been extensively reported and is known to be regulated primarily at the level of gene transcription, the molecular mechanism(s) underlying this response is poorly understood. However, recent evidences have implicated Nrf2 in inducer-dependent activation of the HO-1 gene<sup>[9,30]</sup>. In our study, we found that PGG could activate Nrf2 in HepG2 cells. PGG increased not only Nrf2 nuclear translocation (Figure 3A), but also Nrf2 nuclear accumulation (Figure 3B). Using Nrf2 siRNA transfection method, we could show that the full expression of HO-1 by PGG required Nrf2 nuclear accumulation (Figure 4A). Along with this result, cytoprotection afforded by PGG was reduced by transient transfection with Nrf2 siRNA (Figure 4B). These results suggested that Nrf2 nuclear translocation might play a key role in PGG-induced HO-1 expression and cytoprotection.

MAPK pathways have been reported to be involved in HO-1 expression<sup>[15-20]</sup> and also in Nrf2-dependent transcription<sup>[31-33]</sup>. Our experiments designed to determine a possible role of MAPK pathways in PGG-induced HO-1 expression showed that PGG activated ERK pathway (Figure 5A). Additionally, the use of specific inhibitors for MAPK pathways confirmed the involvement of ERK, but not of p38 or JNK pathways, in PGG-induced HO-1 expression (Figure 5B) and cytoprotection (Figure 5C). These results suggested that ERK MAPK pathway might be important for PGG-induced HO-1 expression.

In light of our finding that ERK inhibitor blocked PGG-induced Nrf2 nuclear accumulation (Figure 6A), it is interesting to speculate that ERK pathway may play a role in regulating PGG-induced Nrf2 nuclear translocation. Our hypothesis is that addition of PGG may increase ERK activation in HepG2 cells, somehow to subsequently stimulate Nrf2 nuclear translocation. Increased Nrf2 in the nucleus may increase its DNA-binding activity, followed by HO-1 gene transcription eventually leading to HO-1 expression. This was confirmed by the transfection of HepG2 cells with CA-MEK1 or DN-MEK1 genes to selectively activate or inhibit the ERK pathway. Activation of the ERK pathway by CA-MEK1, even without further stimulation, was able to induce Nrf2-dependent HO-1 expression (Figure 6B). Blockage of the ERK pathway by DN-MEK1 abolished PGG-induced cytoprotection (Figure 6C) and HO-1 expression (Figure 6D). It is interesting that ERK activation is required for Nrf2 nuclear translocation during glutamate cysteine ligase modulatory gene expression by the antioxidant pyrrolidine dithiocarbamate in HepG2 cells<sup>[32,33]</sup>.

In summary, the antioxidant PGG can induce hepatic HO-1 expression in HepG2 cells, and this expression confers hepatoprotection against oxidative injury. PGG also induces Nrf2 nuclear translocation, which is an

upstream step of PGG-induced HO-1 expression, and activates ERK MAPK phosphorylation. ERK MAPK pathway is involved in PGG-induced Nrf2 nuclear translocation, HO-1 expression, and hepatoprotection. Thus, we speculate that PGG may be developed as a hepatic HO-1 inducer for therapeutic purposes. Despite the fact that up-regulation of HO-1 is sufficient to produce many beneficial outcomes in a variety of stressful condition<sup>[4-9]</sup>, we do not exclude the possibility that PGG will stimulate the expression of other defensive enzymes, probably depending on Nrf2 nuclear translocation, and that cellular and tissue protection will be achieved by virtue of the concerted action of the multiple pathways being activated.

## ACKNOWLEDGEMENTS

We gratefully acknowledge Dr. H. Oh for the isolation and purification of PGG, Dr. Augustine M. K. Choi for the kind gift of HO-1 gene, and Dr. K. Y. Choi for the gifts of DN-MEK1 and CA-MEK1 genes.

### Abstract

**AIM:** To examine whether peanut consumption is associated with a reduced risk of colorectal cancer in a prospective cohort with a 10-year follow-up.

**METHODS:** In 1990-1992, residents (12026 men and 11917 women aged 30 to 65 years) in 7 townships, Taiwan, were interviewed and recruited into a cancer-screening cohort and annually followed up. Colorectal cancer cases in this cohort were identified from cancer registry and death certificates. Incidence rates of this disease by the end of 2001 were calculated by gender for the primary study variable and covariates. The dietary intake was assessed by means of weekly food frequency measures, including frequently consumed food groups and folk dishes including sweet potato, bean products, peanut products, pickled foodstuffs, nitrated or smoked foodstuffs.

**RESULTS:** During the study period, 107 new colorectal cancer cases (68 men and 39 women) were confirmed. The multivariate Cox's proportional hazard model showed that the relative risk (RR) of peanut consumption was 0.73 [95% confidence interval (CI) = 0.44-1.21] for men and 0.42 (95% CI = 0.21-0.84) for women. However, frequent intake of pickled foodstuffs was harmful for women (RR = 2.15, 95% CI = 0.99-4.65). The risk of colorectal cancer was also elevated among cigarette smokers but not significant ( $P < 0.05$ ).

### INTRODUCTION

Etiological studies showed that more than 85% colorectal cancer cases are associated with environmental factors<sup>[1,2]</sup>, particularly the dietary factor<sup>[3]</sup>. Among dietary constituents implicating in colorectal carcinogenesis, consumption of vegetables and fruits has a beneficial effect<sup>[4]</sup>. But the effect of pulse (legume) consumption is conflicting<sup>[5]</sup>. An ecological study reported consumption of pulses is inversely related with colon cancer mortality of males in 38 countries (correlation coefficient = -0.7)<sup>[6]</sup>. Previous studies showed that components, such as folic acid, protease inhibitors, phytosterols (PS), saponins, inositol hexaphosphate (phytic acid, PA), isoflavones and resveratrol in grains, nuts and seeds may have anti-carcinogenic effects<sup>[7,8]</sup>. Several studies reported consumption of pulses is inversely related with colorectal cancer<sup>[9-12]</sup>, but other studies have failed to show this protective effect<sup>[13-16]</sup>. As a good source of PS, PA and resveratrol, peanut has been thought to have an effect against carcinogenesis<sup>[17]</sup>. The suppression effect of PS, PA and resveratrol on colon cancer has been supported *in vitro* and *in vivo* as well<sup>[18-20]</sup>. Whether the laboratory findings are relevant to the hypothetically protective effect of peanut on cancers remains unexplored.

Colorectal cancer has become the second most fatal malignancy in developed countries and the third most frequent cancer worldwide<sup>[21,22]</sup>. While the incidence rate of colorectal cancer also increases in Taiwan, the mortality rate of the disease has a 74% rise from 1993 to 2002.

Peanut is a common food in the world and in Taiwan as well. The association between peanut consumption and colorectal cancer has not been well studied. The purpose of this study was to determine the association between peanut consumption and colorectal cancer risk in a community-based cancer-screening cohort with a 10-year follow-up.

## MATERIALS AND METHODS

### Cohort recruitment and inclusion criteria

The details of this prospective cohort study conducted in 7 townships (Sanchi, Chutung, Potzu, Kaoshu, Makung, Hushi and Paihsa) and their precincts, Taiwan, have been described elsewhere<sup>[23]</sup>. A total of 23943 persons (12026 men and 11917 women) who were at least 30 years old and gave their consent to a baseline interview in person, physical examinations and annual follow-up activities, were recruited between July 1990 and June 1992 in this cohort study. At the same time, we conducted the laboratory tests of serum cholesterol and triglyceride for all participants.

### Questionnaire interviews

Well-trained public health nurses employed at local health stations in the study townships assisted to conduct home visits to all participants. With consent, structured questionnaire interviews were conducted for information regarding socio-demographic characteristics (age, gender, education level, ethnicity group, residential area, and

marital status), anthropometric measures (height and weight), cigarette and alcohol use, dietary consumption, personal and family history of cancers. Dietary intake was assessed by means of weekly food frequency measures (0-1, 2-3, and >3 meals/week), including frequently consumed food groups and folk dishes including sweet potato, bean products, peanut products, pickled foodstuffs, nitrated or smoked foodstuffs.

Cigarette smoking and alcohol drinking were evaluated by their amount and duration. Total cigarette smoking was estimated in terms of packs/year (packs per day multiplying the years of cigarette smoking in the follow-up). Alcohol drinking in data analyses used a dichotomous classification: yes versus no. Height and weight were measured once at the baseline. This study also collected information on reproductive health, including the use of oral contraceptives or intrauterine devices (never or ever use) and menopausal status (yes or no) for females.

### Follow-up and data linkage

All participants were annually followed up for their health status. In addition to the active follow-up by home visit or telephone interviews, data from the National Cancer Registry and death certificates were also used to identify and verify newly developed colorectal cancer and other types of cancer. Diagnoses of colorectal cancer were confirmed by reviewing the medical records and death certificates. Colon and rectal cancer cases were combined in this study because of the small sample size and potential for their mutual misclassification in some death certificates<sup>[24]</sup>.

### Statistical analysis

After exclusion of the participants with cancer occurred prior to the recruitment ( $n=1336$ ) or cancer cases ( $n=492$ ) other than colorectal cancer, a cohort of 22115 (92%) persons remained for the present study analysis. In addition to calculation of the incidence of the disease, the Cox's proportional hazard model was used to estimate the relative risk (RR) and 95% confidence interval (CI) associated with socio-demographic factors, cigarette and alcohol use, body mass index (BMI), cholesterol, triglyceride and diet. The association with menopause was also considered for women. None of the female cases was a smoker or a alcohol user, the RR due to these two factors was calculated only for men. Because of the limited sample size, diet consumptions and other covariates were mostly categorized into two or three strata in the data analysis. BMI was categorized into four strata (<24.2, 24.2-26.4, 26.4-28.2, >28.2 kg/m<sup>2</sup>). For incidence and RR calculation, the number of persons/year under observation was computed for each stratum of categorized risk factors. The dose-response relationship across the level of life style variables was observed by treating each ordinal-score variable as a continuous variable in proportional hazard regression. A score selection procedure (the highest likelihood score statistic) was used to determine the covariates included in the final multivariate Cox's proportional hazard model beginning with all lifestyle and dietary variables. All analyses were performed using the SAS version 8.2 software (SAS Institute, Inc., Cary, North Carolina). All statistical tests were two-sided.

## RESULTS

A total of 107 new cases of colorectal cancer (56 in the colon, 51 in the rectum) were found during the 10-year follow-up period until December 31, 2001. Table 1 shows the incidence rate of 34.8 per 10<sup>5</sup> persons/year for women and 62.5 per 10<sup>5</sup> persons/year for men. Most participants who received only elementary education or no school education had a greater incidence than persons who received 6 or more years of education. There were no significant relationships between colorectal cancer and ethnicity and marital status. Residents living in Potzu had a higher risk for the disease than those living in other areas but not significant ( $P = 0.08$ ).

The incidence of the disease was positively associated with BMI, serum cholesterol and cigarette smoking in men ( $P < 0.01$ , Table 2). The incidence increased from 54.7 per 10<sup>5</sup> persons/year in men with the BMI less than 24.2 kg/m<sup>2</sup> to 101.4 per 10<sup>5</sup> persons/year for those with the BMI greater than 28.6 kg/m<sup>2</sup>. In women, the incidence rate of colorectal cancer was related with their BMI, cholesterol and triglyceride level ( $P < 0.05$ , Table 3). The highest incidence rate in women was 70.2 per 10<sup>5</sup> persons/year for those with their BMI being 26.4-28.6 kg/m<sup>2</sup>. The results also showed that menopausal women had an increased risk for the disease with an incidence rate of 67.6 per 10<sup>5</sup> persons/year.

The analysis of food intake showed that the incidence rate of colorectal cancer was significantly increased in men

who had more sweet potatoes and in women who had more pickled foodstuffs (Table 4). Beneficial effects were of the consumption of peanut products observed in both sexes but not significant. There were no significant associations between the colorectal cancer risk and the consumption of bean products, nitrate and smoked foodstuffs in both sexes.

The score selection in the final multivariate Cox's proportional hazard analysis was completed with 5 final covariates including age, resident area, cigarette smoking, consumption of peanut products and BMI, which were potentially associated with the risk of the disease in men. For women, three potential covariates including age, consumption of peanut products and pickled foodstuffs were selected. Among these covariates, age was a significant factor for colorectal cancer in both sexes. Obese men living in Potzu had an increased risk for colorectal cancer. The RR was 1.98 (95% CI = 0.91-4.30) for the highest level of BMI (>28.6 kg/m<sup>2</sup> vs <24.2 kg/m<sup>2</sup>). Men who smoked cigarettes had an excess risk of 77% over non-smokers (RR = 1.77, 95% CI = 0.97-3.26). Women who had peanut products demonstrated a significant beneficial effect. The RR was 0.42 (95% CI = 0.21-0.84) for consuming 2+ meals/week compared with 0-1 meals/week. On the other hand, consumption of pickled foodstuffs also had a harmful effect on female colorectal cancer patients with a boarder line significance level (RR for +2 meals/week

versus 0-1 meals/week was 2.15, 95% CI=0.99-4.65) (Table 5).

## DISCUSSION

The present study had several weaknesses due the relatively short follow-up time (10 years), the lack of detailed information on meat, vegetables and fruits consumption, physical activity, family history of colorectal neoplasm, aspirin and other non-steroidal anti-inflammatory drug use, colon-cancer screening practices and the relatively small number of cases for a cohort study. However, this well-defined population-based prospective approach reduced the selection bias and strengthened the complete ascertainment of cancer cases in the study.

It was reported that colorectal cancer is related with the consumption of vegetables and fruits and that the intake of vegetables and fruits can moderately lower the risk for colorectal cancer<sup>[5,25,26]</sup>. This 10-year follow-up study was not able to examine the effect of the consumption of vegetables and fruits. However, our results support the hypothesis that the consumption of peanut protects those who consume peanut products against colorectal cancer. This finding indicates that some specific components in peanut inhibit the carcinogenic mechanisms of colorectal cancer. Peanut is a good source of phytosterols (PS)<sup>[17]</sup>, phytic acid (PA)<sup>[17,19,27]</sup> and resveratrol<sup>[28]</sup>, which is con-

**Table 5** Relative risk from multivariate analysis by Cox's proportional hazard model of the community-based cancer screening cohort (1991-2001)

<sup>1</sup>Relative risk; <sup>2</sup>95% Confidence interval; <sup>3</sup>Including Sanchi, Chutung, Kaoshu, Makung, Hushi and Paihsa; <sup>4</sup>Not included in the model.

sumed more in Asians (particularly in vegetarians) than in Westerns<sup>[7]</sup>. PS consists of approximately 80%  $\beta$ -sitosterol and 20% campesterol and stigmasterol<sup>[17]</sup>.  $\beta$ -sitosterol is the main component offering the protective effect against colon cancer by inhibiting HT-29 colon cancer cells<sup>[29]</sup>. The consumption of PS inhibits the development of chemically-induced colon tumors in rats<sup>[18]</sup>. In addition, PS consumption normalizes the hyper-proliferating state in rat and mouse colon cells<sup>[30]</sup>.

PA consisting of a myo-inositol ring and six symmetrically distributed phosphate moieties<sup>[19]</sup>, is a natural antioxidant in the form of metal chelate that decreases the catalytic reactivity of polyvalent transition metals<sup>[27]</sup> and has the anti-carcinogenic effect on colon cancer risk<sup>[19,31]</sup>. In addition, resveratrol is a natural phytoalexin in grapes, red wines and other grape products<sup>[32]</sup>, peanut and its products<sup>[28]</sup>. With a resorcin-type structure, resveratrol can inhibit cyclooxygenase-2 (COX-2) activities in colon cancer cells<sup>[33,34]</sup> and depress the growth of colorectal aberrant crypt foci<sup>[20]</sup>, suggesting a protective role in the carcinogenesis of colon cancer.

The association between peanut consumption and human colorectal cancer risk has not been well established. The present study provided cohort data suggesting a significant beneficial effect of peanuts in women. Though legume consumption offers protection against colon cancer<sup>[12]</sup>, PA and resveratrol are also candidate components in legumes offering this protection. This does not rule out the role of other components such as folic acid, calcium, dietary fiber, protease inhibitors, oligosaccharides, saponins and isoflavones in peanuts and legumes in protecting against colorectal cancer<sup>[35]</sup>.

Studies on cigarette smoking and colon adenoma rather than colorectal cancer have consistently reported an ele-

vated risk in the earlier twentieth century. However, recent prospective studies showed that smoking is positively related with colorectal cancer, especially in long-term heavy smokers<sup>[36,37]</sup>. Giovannucci *et al*<sup>[36]</sup> proposed that carcinogens in cigarette smoke might initiate colorectal tumors with an induction period of three to four decades. In our follow-up study, a moderately elevated risk was observed in male smokers with colorectal cancer cases. There is no authentic evidence that can explain why moderate smokers are at the highest risk for colorectal cancer.

We also found that the harmful effect of pickled foodstuff consumption was significantly associated with colorectal cancer in women. Pickled food intake has been considered as a probable risk factor for gastric cancer<sup>[38]</sup>. Our finding is in agreement with the result of a case-control study in Japan<sup>[39]</sup>. Pickled foodstuff rich in sodium is the main dish for folk vegetarians in Taiwan. However, its association with colorectal cancer has not been found in men, indicating a gender discrepancy.

Increased body mass has been associated with excess colorectal cancer mortality, especially in men<sup>[40]</sup>. A previous cases-control study conducted in Taiwan, has also reported a significant gender discrepancy in the risk associated with colorectal cancer<sup>[41]</sup>. These findings suggest that the mechanism underlying colorectal carcinogenesis is different between men and women. Gender difference should be considered in studies on the etiology of colorectal cancer.

In conclusion, high bean intake has a number of beneficial effects and high pickled foodstuff consumption may have a number of potentially adverse effects, but the evidence is yet insufficient. Frequent peanut intake can lower the risk for colorectal cancer in women. Intake of peanuts may have beneficial effect on other types of cancer and deserves further study.

## Abstract

**AIM:** To determine whether biliary cirrhosis could induce pancreatic dysfunction such as modifications in endothelial nitric oxide synthase (eNOS) expression and whether the regulation of eNOS could be altered by the regulatory proteins caveolin and heat shock protein 90 (Hsp90), as well as by the modifications of calmodulin binding to eNOS.

**METHODS:** Immunoprecipitations and Western blotting analysis were performed in pancreas isolated from sham and cirrhotic rats.

**RESULTS:** Pancreatic injury was minor in cirrhotic rats but eNOS expression importantly decreased with the length (and the severity) of the disease. Because co-immunoprecipitation of eNOS with both Hsp90 and caveolin similarly decreased in cirrhotic rats, eNOS activity was not modified by this mechanism. In contrast, cirrhosis decreased the calmodulin binding to eNOS with a concomitant decrease in eNOS activity.

**CONCLUSION:** In biliary cirrhosis, pancreatic injury is minor but the pancreatic nitric oxide (NO) production is significantly decreased by two mechanisms: a decreased expression of the enzyme and a decreased binding of calmodulin to eNOS.

## INTRODUCTION

Chronic bile duct ligation (BDL) in rats induces severe cirrhosis associated with extra-hepatic organ dysfunction in heart<sup>[1]</sup>, lung<sup>[2, 3]</sup>, and extrahepatic vessels such as aorta<sup>[4, 5]</sup> and mesenteric artery<sup>[6]</sup>. Chronic BDL also induces pulmonary injury associated with hypoxemia and pulmonary vasodilatation due to an excess production of endothelial nitric oxide (eNO)<sup>[2, 3]</sup>. In aorta and mesenteric artery from BDL rats, hyporeactivity to vasoconstrictors also originates from NO overproduction<sup>[4-6]</sup>. Pancreas may suffer from hemodynamic consequences of cirrhosis, but information on eNOS expression and regulation in this splanchnic organ is missing.

In all types of cirrhotic livers, although eNOS protein expression is increased or decreased, the activity is uniformly decreased<sup>[7-10]</sup>. The reason for the decrease in hepatic NO bioavailability remains unclear. One explanation is that caveolin expression, a negative regulatory protein of eNOS, increases during cirrhosis and alters enzyme activity<sup>[10]</sup>. However, such negative post-translational regulation of eNOS is not unique.

In isolated endothelial cells, transcriptional and post-transcriptional mechanisms regulating eNOS have been described. Although eNOS activity is associated with changes in Ca<sup>2+</sup> concentrations within endothelial cells, increase in Ca<sup>2+</sup> concentration alone is not sufficient to modify enzyme activity<sup>[11]</sup>. Binding of calmodulin (CaM) and flow of electrons from the reductase to the oxygenase domains of the enzyme are dependent on phosphorylation and dephosphorylation of various residues of eNOS. Additionally, proteins such as caveolin and heat shock protein 90 (Hsp90) associate with eNOS and modify the enzyme activity as well as its intracellular localization<sup>[12, 13]</sup>. eNOS is co-localized with regulatory proteins and other molecules of the signal transduction pathway to form an "eNOS signaling complex" that modulates NO production<sup>[11]</sup>. For example, eNOS co-localizes with kinases that phosphorylate eNOS on the <sup>495</sup>Thr residue with a concomitant decrease in enzyme activity<sup>[11, 14, 15]</sup>.

The aim of our study was to determine whether biliary cirrhosis could induce pancreatic dysfunction including

modifications in eNOS expression as observed in other extrahepatic organs and modify the regulation of eNOS by regulatory proteins and modifications in eNOS phosphorylation.

## MATERIALS AND METHODS

### Animals

Sprague-Dawley rats were used in this study and divided into 3 groups, which underwent BDL 15, 30 and 60 days respectively before experiment and were designated as BDL-15, BDL-30 and BDL60 groups respectively.

### Induction of biliary cirrhosis

Cirrhosis was induced 15, 30 and 60 days before the experiments. After laparotomy under 2-3% isoflurane anesthesia, Sprague-Dawley rats had a double ligation of the common bile duct with section between the two ligatures. The bile duct was ligated close to the liver to avoid pancreatic duct obstruction. Sham rats had laparotomy without bile duct ligation and were studied 15 days later. Normal rats with no laparotomy served as controls. The protocol was approved by the Animal Welfare Committee of the University of Geneva.

### Histologic examination

Tissues were collected from 15 rats ( $n=3$  in each group), and 3- $\mu$ m thick paraffin sections were stained with hematoxylin and eosin as well as the Gomori technique.

### Western blotting analysis

Pancreatic tissues were homogenized in lysis buffer containing 50mM Tris HCl, 0.1mM EGTA, 0.1mM EDTA, 1% NP-40, 1% protease inhibitor cocktail, 1% phosphatase inhibitor, cocktails I and II (Sigma). Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and Western blotting analysis were performed using minigels (BioRad, Switzerland). Protein extracts (100  $\mu$ g) were separated on a 10% (eNOS and hsp90) or a 12% (caveolin and calmodulin) polyacrylamide gel. After the gel was transferred to a polyvinylidene difluoride membrane (Millipore, Volketswil, Switzerland), the membrane was blocked with PBS containing 5% nonfat dry milk (1 h at room temperature) and incubated overnight at 4°C with specific antibodies. The membrane was washed four times with PBS containing 0.2% Tween 20 and incubated for 1 h with an alkaline phosphatase-conjugated second antibody. After washed, protein was detected by chemiluminescence (Immune-Star, Bio-Rad) according to the manufacturer's instructions. Molecular weight markers and positive controls were included for each experiment. Films were scanned using an ImageScanner densitometer equipped with the Labscan and Image Quant software (Amersham Biosciences). An equal quantity of protein stained with Ponceau Red was loaded on each line before the blocking was assessed.

### Immunoprecipitation

Immunoprecipitation (IP) was performed by incubating 500  $\mu$ g or 5 mg of protein extracts with antibodies directed to the native protein eNOS and the immune complexes

were precipitated with protein G-sepharose beads (Sigma, Buchs, Switzerland). Complexes were washed twice in lysis buffer. The samples were boiled in loading buffer (Laemmli sample buffer, BioRad) to elute the bound proteins. Total or phosphorylated eNOS, Hsp90, caveolin and calmodulin were detected by Western blot. Antibodies used included mouse monoclonal anti-eNOS and rabbit polyclonal anti-caveolin-1 from BD Biosciences-Pharmingen (Basel, Switzerland), rat monoclonal anti-Hsp90 from Stressgen (Bioggio, Switzerland), mouse monoclonal anti-calmodulin from Upstate (Lake Placid, New-York) and goat polyclonal anti-phospho-eNOS-Thr<sup>495</sup> from Santa Cruz Biotechnology (Santa Cruz, California).

### Immunostaining

Samples of pancreas ( $n=3$  in each group) were fixed in neutral buffered formalin for 24 h, processed and embedded in paraffin. Sections (3- $\mu$ m thick) were cut and mounted on Superfrost/plus slides, then deparaffinized. The sections were treated with 1mM EDTA (pH=8) to quench endogenous alkaline phosphatase activity. Non-specific binding was blocked by incubating sections in 1% BSA-Tris buffer for 30 min. Sections were then incubated with the primary antibody (rabbit polyclonal anti-caveolin-1 from BD Biosciences-Pharmingen) diluted in BSA-Tris buffer for 1 h. Control sections were incubated in BSA-Tris buffer without the first antibody and showed no immunostaining. After rinsing with Tris, the sections were incubated with alkaline phosphate-labeled polymer (DAKO Envision system) for 10 min and rinsed with Tris between each step. The antigen-antibody complex was visualized using the substrate chromogen solution containing 0.2 mM levamisole for 5-10 min. Sections were subsequently counterstained with Mayer's hematoxylin solution for 2 min and rinsed in distilled water and then in 37 mM ammonia solution (10 times), rinsed in distilled water for 2 min and coverslipped with mounted media glycerol (DAKO). Images were obtained under Zeiss microscope (Zeiss, Zürich, Switzerland) using a Nikon COOLPIX995 camera and processed using the Coll view image and Photoshop software.

A similar technique was used to stain Hsp90 in pancreatic tissues with monoclonal mouse anti-Hsp90 (Stressgen) and eNOS with rabbit polyclonal anti-eNOS (BD Biosciences-Pharmingen). Monoclonal mouse anti-Hsp90 was incubated overnight.

### cGMP measurement

Pancreatic cGMP was measured by competitive immunoassay according to the instructions of the manufacturer (R&D systems, Wiesbaden-Nordenstadt, Germany).

### Statistical analysis

Data for densitometric measurements were given as mean  $\pm$  SD and difference between groups was determined with a Kruskal-Wallis or Mann-Whitney test for non-parametric variables.  $P<0.05$  was considered statistically significant.

## RESULTS

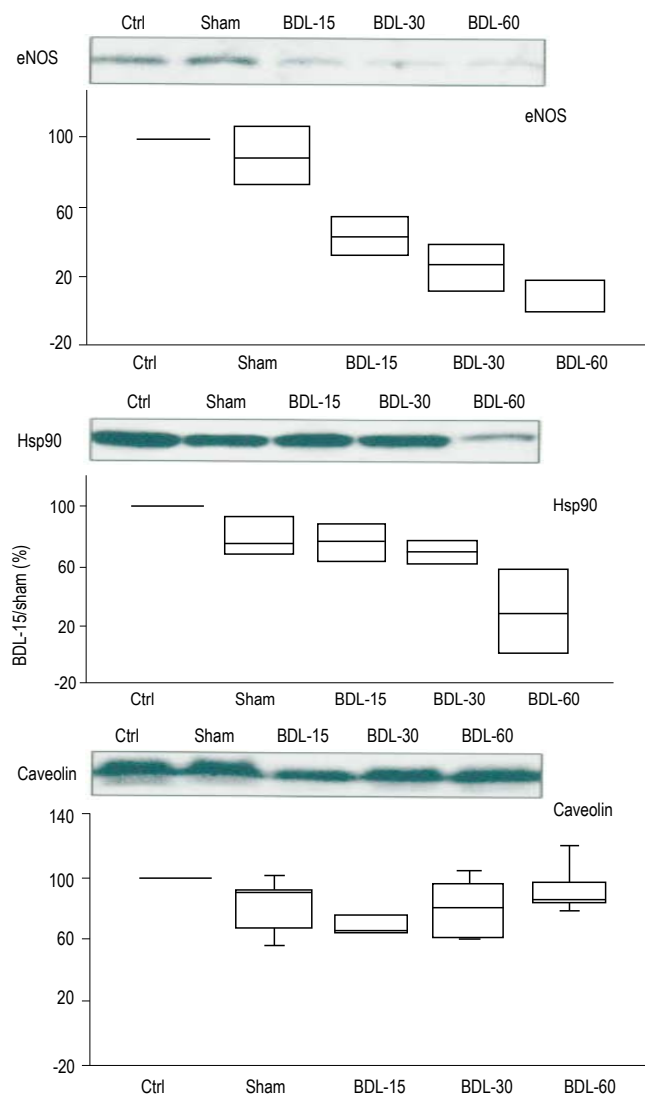

### Pancreatic injury and biliary cirrhosis

Chronic bile duct ligation induced severe hepatic

**Figure 1** Pancreatic tissues from sham and BDL-60 rats were stained with hematoxylin and eosin (panels A and C) and Gomori (panels B and D). In panels A and C, magnification is 100x and 400x (upper: small vessel; middle: acini; lower: Langerhans islet) and in panels B and D, magnification is 400x. The extracellular matrix was enlarged in pancreas isolated from BDL-60 rats and most of the enlarged extracellular matrix consisted of edema. No increase in reticulin fibers was observed with the Gomori technique.  $n = 3$  in each group.

**Figure 2** Endothelial nitric oxide synthase (eNOS), heat shock protein 90(Hsp90), and caveolin expression in pancreatic lysates isolated from control (Ctrl), sham rats, and rats with bile duct ligation (BDL) 15, 30, and 60 days before tissue collection (left panel). Densitometry (right panels) was measured in  $\geq 4$  rats in each group.

**Figure 3** Immunostaining of caveolin (I) in pancreas isolated from BDL-30 rat. Caveolin was detected in epithelial cells lining the pancreatic ductules (C), cells within the islets of Langerhans (D), and in the apex of acinar cells (B). Caveolin was also present in endothelial lining cells in veinules (A), microvessels surrounding acini (B), and microvessels inside Langerhans islets (D). Immunostaining of Hsp90 (II) in pancreas isolated from BDL-15 rat. Hsp90 was present in epithelial cells lining the pancreatic ductules (C), cells within the islets of Langerhans (D), and in the apex of acinar cells (B). Hsp90 was also present in endothelial lining cells in veinules (A). Immunostaining of endothelial nitric oxide synthase (III) in pancreas isolated from BDL-15 rat. The protein was present in endothelial lining cells (B) and cells within the islets of Langerhans (D). In aorta isolated from BDL-60 rats (A), eNOS is more heavily stained. Magnification is 400x.

diseases as evidenced by the increase in serum bilirubin and aspartate aminotransferase concentrations (Table 1). In contrast, serum amylase concentration was

**Tble 1** Hepatic tests and serum amylase concentrations in sham-operated rats and rats with BDL (mean  $\pm$  SD)

	Sham	BDL-15	BDL-30	BDL-60	
ALAT (IU/L)	34 $\pm$ 22	60 $\pm$ 43	76 $\pm$ 52	56 $\pm$ 11	$P=0.55$
ASAT (IU/L)	67 $\pm$ 40	194 $\pm$ 50	718 $\pm$ 328	262 $\pm$ 95	$P=0.005$
Total bilirubin ( $\mu$ mol/L)	5.3 $\pm$ 6.1	154.0 $\pm$ 9.2	120.7 $\pm$ 22.5	183.5 $\pm$ 28.1	$P<0.0001$
Amylase (UI/L)	1268 $\pm$ 113	1313 $\pm$ 115	1439 $\pm$ 293	2161 $\pm$ 299	$P=0.019$

ALAT = alanine aminotransferase; ASAT = aspartate aminotransferase.

**Figure 4** Endothelial NO synthase (eNOS) immunoprecipitation from pancreatic extracts. Immunoprecipitates were Western blotted with Hsp90, caveolin, and eNOS antibodies. Pancreatic proteins were collected from sham rats and rats which had a 15 days bile duct ligation (BDL-15).

slightly increased only in rats with BDL 60 d before the experiment.

Pancreatic injury was minor in rats with BDL. On histological examinations, the only modification was the enlargement of the interstitial space in rats with BDL 60 days before the experiment (BDL-60 rats, Figure 1A).

No pancreatic necrosis was observed at any time point. The enlarged extracellular matrix consisted of edema because reticulin fibers surrounding acini in sham rats did not increase in BDL-60 rats (Figure 1B).

### Expression of endothelial NO synthase and its regulatory proteins

eNOS expression was significantly decreased in BDL-15, BDL-30 and BDL-60 rats ( $P=0.003$ ).

The two regulatory proteins of eNOS, Hsp90 (positive regulatory protein of eNOS) and caveolin (negative regulatory protein of eNOS), had different evolution. Hsp90 expression was maintained at the beginning of the disease but significantly decreased in BDL-60 rats ( $P=0.02$ ) while caveolin expression slightly decreased in BDL-15 rats but recovered in BDL-30 and BDL-60 rats ( $P=0.05$ ) (Figure 2).

### Protein immunostaining

The localization of caveolin in pancreas is illustrated in Figure 3.

Caveolin was present in epithelial cells lining the pancreatic ductules, cells within the islets of Langerhans

**Figure 5** Calmodulin and <sup>495</sup>Thr-P-eNOS expression in pancreatic lysates isolated from control (Ctrl), sham rats, and rats with bile duct ligation (BDL) 15, 30, and 60 days before tissue collection. Densitometry was measured in  $\geq 4$  rats in each group. Liver homogenate serves as control.

and in the apex of acinar cells. Caveolin was also present in endothelial lining cells in veinules, microvessels surrounding acini and microvessels within Langerhans islets. Hsp90 was present in epithelial cells lining the pancreatic ductules, cells within the islets of Langerhans and in the apex of acinar cells. Hsp90 was also present in endothelial lining cells in veinules. Immunostaining of eNOS was weak in comparison to caveolin and Hsp90. Endothelial NOS was present only in endothelial cells and cells within the islets of Langerhans. In aorta isolated from BDL-60 rats (used as positive controls), eNOS was more easily detected.

### Co-immunoprecipitation of eNOS, caveolin and Hsp90 in sham and BDL-15 rats

Hsp90 and caveolin were co-immunoprecipitated with eNOS in pancreas isolated from sham and BDL-15 rats (Figure 4).

Because in BDL-15 rats, the reduction in coimmunoprecipitation of Hsp90 and caveolin was similar to the decrease in eNOS expression ( $P=0.74$ ), eNOS activity was not modified by this mechanism in BDL-15 rats. Co-immunoprecipitation from pancreas isolated from BDL-30 and BDL-60 rats was not available because the amount of eNOS protein in samples was too low.

### Calmodulin and <sup>495</sup>Thr-P-eNOS expression

In pancreatic lysates, <sup>495</sup>Thr-P eNOS was not detectable

at any time point, though the phosphorylated eNOS was easily detected in the liver (Figure 5).

Expression of CaM was evident and did not differ between groups ( $P=0.95$ ). In BDL-15 rats, the co-immunoprecipitation of eNOS with CaM decreased while  $^{495}\text{Thr}$ -P eNOS became detectable.

Interestingly, the cGMP concentration in pancreatic tissue was slightly lower in BDL-15 rats than in sham rats (62 pmol/g vs 90 pmol/g protein,  $P=0.086$ ).

## DISCUSSION

Our study showed that pancreatic injury was mild in rats with chronic biliary cirrhosis. Nevertheless, the expression of eNOS importantly decreased with the duration (and the severity) of the disease. The regulation of eNOS by Hsp90 and caveolin was not modified by a 15-day BDL but cirrhosis decreased the CaM binding to eNOS with a concomitant phosphorylation of the enzyme on  $^{495}\text{Thr}$  residue, suggesting that the activity of the enzyme decreases through this regulatory pathway. Consequently, besides liver, lungs and extrahepatic vessels, pancreas is another organ in which eNOS regulation is markedly impaired by cirrhosis.

### Chronic biliary cirrhosis

BDL is frequently used to induce chronic biliary cirrhosis in rats. In this model, the severity of hepatic injury increases with the duration of BDL. This model is also characterized by extra-hepatic injuries. Chronic BDL is associated with severe cardiomyopathy<sup>[1]</sup>. Vasoconstriction to phenylephrine or vasodilatation to acetylcholine decreases in large vessels such as aorta<sup>[5, 16, 17]</sup>, mesenteric<sup>[18]</sup> and pulmonary arteries<sup>[3]</sup>. Additionally, the modifications observed in lungs from BDL rats mimic the hepatopulmonary syndrome that complicates human cirrhosis<sup>[3]</sup>. In the present study, we described for the first time a slight pancreatic injury that appeared only 2 months after BDL.

### BDL and eNOS expression

Organ dysfunction during biliary cirrhosis includes modification in NO release. eNOS expression has been investigated in livers from normal and BDL rats and the expression is similar in control and BDL-24 rats<sup>[19]</sup>. Modifications in eNOS expression have also been found in extrahepatic organs isolated from rats with BDL. For example, in aortic rings isolated from BDL-28 rats, eNOS protein expression is increased. For example, in aortic rings isolated from BDL-28 rats, eNOS protein expression is increased<sup>[20]</sup>. These results have been confirmed in rats sacrificed at different time points (BDL-21 and BDL-30 rats)<sup>[5, 21]</sup>. The expression of eNOS in pulmonary arteries isolated from BDL-28 rats is also increased<sup>[3, 22]</sup>. The high staining of eNOS observed in aorta isolated from BDL-60 rats (Figure 3) might confirm these findings.

In our study, we used the BDL model of cirrhosis. However, additional experimental models exist, including chronic ingestion of CCl<sub>4</sub> that also shows a dysregulation of eNOS<sup>[8]</sup>. Though BDL rats develop hepatic cirrhosis with systemic vasodilatation and hepatopulmonary

syndrome as observed in humans<sup>[3]</sup>, the results obtained in BDL rats should be extrapolated to humans with cautions.

eNOS has already been detected in normal pancreas<sup>[23-25]</sup>. For the first time, we showed that eNOS expression significantly decreased in pancreas collected from BDL-15 rats with a further decrease associated with the duration of bile duct ligation. Interestingly, we localized eNOS in endothelial cells and cells within the islets of Langerhans. However, the staining was weak, suggesting that eNOS has a low expression in native pancreas.

### eNOS regulation in native tissues

The regulation of eNOS is a process determined by a cascade of events, including changes in (1) NOS mRNA and protein levels, (2) association of eNOS with regulatory proteins in the signaling complex, (3) changes in intracellular location of the enzyme and (4) phosphorylation of serine, threonine and tyrosine residues. Though many of these steps have been relatively well elucidated in *in vitro* models and in cell lines overexpressing one or more components of the signaling complex, much more work is required to determine which modification plays a dominant role in the regulation of eNOS activity in native tissues.

In our experimental study, the two regulatory proteins of eNOS, Hsp90 and caveolin, had a different evolution. Caveolin expression slightly decreased in BDL-15 rats but recovered in BDL-30 and BDL-60 rats. The reason for the transient decrease is unclear. In contrast, in livers from BDL rats, caveolin expression increases<sup>[10]</sup>. In normal pancreas, caveolin is detectable in membrane preparations<sup>[26]</sup>. Caveolin-1 has been identified in exocrine cells and secretagogues known to stimulate secretions in exocrine cells also release caveolin<sup>[27]</sup>. However, the function of secreted caveolin in pancreas is unknown. We also identified caveolin in epithelial cells lining the pancreatic ductules, cells within the islets of Langerhans, endothelial cells lining veinules, microvessels surrounding acini and inside Langerhans islets.

In our study, Hsp90 expression was maintained at the beginning of the disease but significantly decreased in BDL-60 rats. Hsp90 is constitutively expressed at high concentration in normal pancreas and the expression does not increase during acute pancreatitis<sup>[28]</sup> or hyperthermia<sup>[29, 30]</sup>. In the present study, we showed for the first time, the localization of Hsp90 in epithelial cells lining the pancreatic ductules, cells within the islets of Langerhans, acinar cells and endothelial cells in veinules.

In BDL livers, co-immunoprecipitation of caveolin with eNOS increases and this binding is associated with a decreased eNOS activity<sup>[10]</sup>. Co-immunoprecipitation of Hsp90 with eNOS was not investigated in this study. In pancreas from BDL-15 rats, the co-immunoprecipitation of eNOS with both caveolin and Hsp90 similarly decreased, suggesting that the two regulatory proteins have no effect on pancreatic eNOS activity.

### Co-immunoprecipitation of eNOS with CaM and eNOS phosphorylation on Thr residue

Phosphorylation of eNOS on the  $^{495}\text{Thr}$  residue in isolated endothelial cells is associated with a decrease in enzyme

activity. The link between phosphorylation and NO production can be explained by the interference with the binding of CaM to the CaM-binding domain of eNOS [11, 14, 15]. Changes in <sup>495</sup>Thr phosphorylation are generally associated with stimuli such as bradykinin, histamine and Ca<sup>2+</sup> ionophores. In endothelial cells, these Ca<sup>2+</sup> elevating agonists decrease <sup>495</sup>Thr phosphorylation of eNOS with a concomitant increased binding of CaM to the CaM-binding site of eNOS.

Interestingly, we showed a similar regulatory mechanism induced by cirrhosis in native pancreas. The <sup>495</sup>Thr-phosphorylated form of eNOS undetectable in normal pancreas (in contrast to normal liver) appeared in pancreas from cirrhotic rats. Concomitantly, the increased expression of <sup>495</sup>Thr-P-eNOS was associated with a decreased binding of CaM to eNOS.

Besides the regulatory proteins and CaM, other proteins are likely to interfere with the regulation of eNOS in the pancreas [13]. Phosphorylation of <sup>1179</sup>Ser is another well-identified mechanism activating the enzyme. These regulatory pathways and probably many others concomitantly modify eNOS activity. Although we found a decreased cGMP concentration in pancreas from BDL-15 rats, the numerous pathways regulating eNOS preclude the modifications of eNOS activity to the decreased binding of CaM.

In conclusion, co-immunoprecipitation of Hsp90 and caveolin with eNOS has no effect on eNOS activity while the binding of CaM to eNOS decreases with a likely concomitant decrease in eNOS activity. Besides liver, lungs and extra-hepatic vessels, pancreas is another organ with its eNOS expression modified by cirrhosis.

### INTRODUCTION

Erythropoietin (EPO) is a glycoprotein (molecular weight = 34 ku) produced in adult kidney and the fetal liver that regulates growth, differentiation, and survival of erythroid progenitors<sup>[1]</sup>. The effects of EPO are transduced via EPO receptors (EPO-R), members of the cytokine receptor superfamily, that are primarily expressed on the cell surface of erythroid cells<sup>[2]</sup>.

Prior to 1990, morbidity and mortality due to hemorrhagic lesions in dialysis patients was relatively high<sup>[3,4]</sup>. However, the impact of this complications has been attenuated by the advent of EPO which is used for treatment of renal anemia and by the marked reduction in the incidence peptic ulcer disease due to the eradication of *H pylori*. Studies on gastric mucosal defense factors have focused on the protective role of gastric mucosal blood flow, oxygen supply, and radical oxygen suppression, and the importance of ferrous ions in the gastric mucosa has also been demonstrated<sup>[5,6]</sup>. However, direct effects of EPO on the gastric mucosa have not fully been investigated.

Recently, the effect of recombinant human erythropoietin (rhEPO) on cellular proliferation has been examined in human umbilical vein endothelial cells (HUVEC)<sup>[7]</sup> and bovine pulmonary artery endothelial cells<sup>[8]</sup>. The growth of these cells was stimulated by EPO. Further, we have previously demonstrated the growth promoting effects of EPO on porcine gastric mucosal vascular endothelial cell<sup>[9]</sup>. These effects may improve the gastric lesions found in dialysis patients through the neovascularization in mucosal tissue.

Okada *et al*<sup>[10]</sup> reported that EPO stimulated proliferation of rat gastric-derived cell lines via EPO-R expressed on these cells. Although these rat stomach

### Abstract

**AIM:** To analyze the localization of erythropoietin receptor on gastric specimens and characterize the effects of erythropoietin on the normal gastric epithelial proliferation using a porcine gastric epithelial cell culture model.

**METHODS:** Erythropoietin receptor was detected by RT-PCR, Western blotting and immunohistochemistry. Growth stimulation effects of erythropoietin on cultured gastric mucosal cells were determined by ELISA using bromodeoxyuridine (BrdU).

**RESULTS:** Erythropoietin receptor was detected on cultured porcine gastric mucosal epithelial cells. Erythropoietin receptor was also detected histochemically at the base of gastric mucosal epithelium. BrdU assay demonstrated a dose-dependent increase in growth potential of cultured porcine gastric mucosal epithelial cells by administration of erythropoietin, as well as these effects were inhibited by administration of anti-erythropoietin antibody ( $P < 0.01$ ).

**CONCLUSION:** These findings indicate that erythropoietin has a potential to proliferate gastric mucosal epithelium via erythropoietin receptor.

**Figure 1** Expression of pepsin, MUC5AC and proton-pump in cultured gastric epithelial cells observed by double immunolabelling. A confocal microscopic image demonstrates the FITC-positive anti-pepsin-positive cells (A) and Texas Red-positive anti-MUC5AC-positive cells (B) in the same area. The anti-pepsin-positive cells, which co-express MUC5AC, are indicated yellow (C). A confocal microscopic image also demonstrates the FITC-positive anti-pepsin-positive cells (D) and Texas Red-positive anti-proton pump-positive cells (E) in the same area. The anti-pepsin-positive cells which co-express proton pump are indicated yellow (F). Scale bars indicate 100  $\mu$ m.

**Figure 2** RT-PCR analysis of EPO-R in cultured gastric epithelial cells. 207 bp products are detected. MWM; molecular weight marker.

derived cells were morphologically epithelioid, they were also immortalized with very short doubling times, which suggests that these cells had undergone transformation and possess characteristics that differ from normal gastric epithelium. Indeed, many types of tumor cells express EPO-R and show increased growth in response to EPO exposure *in vitro*<sup>[11]</sup>. Therefore, the goal of the present study was to analyze the localization of EPO-R on gastric epithelium and to characterize the effects of EPO on the normal gastric epithelium using a porcine gastric epithelial cell culture model.

## MATERIALS AND METHODS

### Reagents

Collagenase and EDTA were purchased from Wako Pure Chemicals (Tokyo, Japan). Keratinocyte-SFM medium, modified Eagle medium (MEM), Dulbecco's modified minimum essential medium, trypsin, newborn calf serum, TRIzol reagent and penicillin-streptomycin mixture were purchased from Gibco BRL (Gland Island, NY). Human

recombinant basic fibroblast growth factor was purchased from InterGen (Purchase, NY). rhEPO (Epoetin Beta) was purchased from Chugai Pharmaceutical Co. (Tokyo, Japan). Monoclonal anti-porcine H<sup>+</sup>/K<sup>+</sup> ATPase antibody was purchased from Affinity Bioreagents (Golden, CO). Anti-porcine stomach pepsin goat antibody was purchased from Polysciences (Warrington, PA). Monoclonal anti-human gastric mucin antibody (MUC5AC) was purchased from NeoMarkers (Union City, CA). Rabbit anti-human EPO-R antibody was kindly provided by collaborative researcher: Dr. M. Higuchi of Chugai Pharmaceutical Co. (Tokyo, Japan). Isotype matched rabbit IgG against anti-EPO antibody was from Chemicon (Temecula, CA). Horseradish peroxidase-labeled rabbit IgG antibody was purchased from Zymed Laboratories Inc. (South San Francisco, CA). Texas Red labeled anti-mouse IgG and FITC-labeled anti-goat IgG were purchased from Vector Laboratories (Burlingame, CA).

### Cell culture

Porcine gastric mucosal epithelial cells were separated by the method with modification which has been developed for the cultivation of human pulmonary epithelial cells<sup>[12]</sup>. Fetal porcine gastric mucosa was digested with 0.1% collagenase, and cells obtained were seeded onto plastic dishes in plain medium (Dulbecco's minimum essential medium supplemented with 10% newborn calf serum, 100 U/mL of penicillin and 100  $\mu$ g/mL of streptomycin) and incubated at 37 °C. The viability of the separated cells was about 80%–90%. After the epithelial cell colonies grew large enough, other cells were detached from the dish manually with a small piece of silicon rubber under the phase contrast microscopy. The colonies were collected with small grass cylinder (internal diameter 10 mm) and 0.05% trypsin-0.02% EDTA, and the cells were seeded onto new dishes using the growth medium (keratinocyte-SFM containing 10% new born calf serum and 10 ng/mL of basic fibroblast growth factor). The culture medium was changed twice a week. The cells were passaged in the

**Figure 3** Western blotting analysis of EPO-R in cultured gastric epithelial cells. EPO-R is detected as a predicted size. The intensity of signals is dependent on anti-EPO-R antibody dilution.

**Figure 4** Immunolocalization of EPO-R and MUC5AC on porcine gastric mucosa. Immunolocalization of EPO-R as well as gastric mucin MUC5AC is detected in epithelial cells. ( $\times 60$ ).

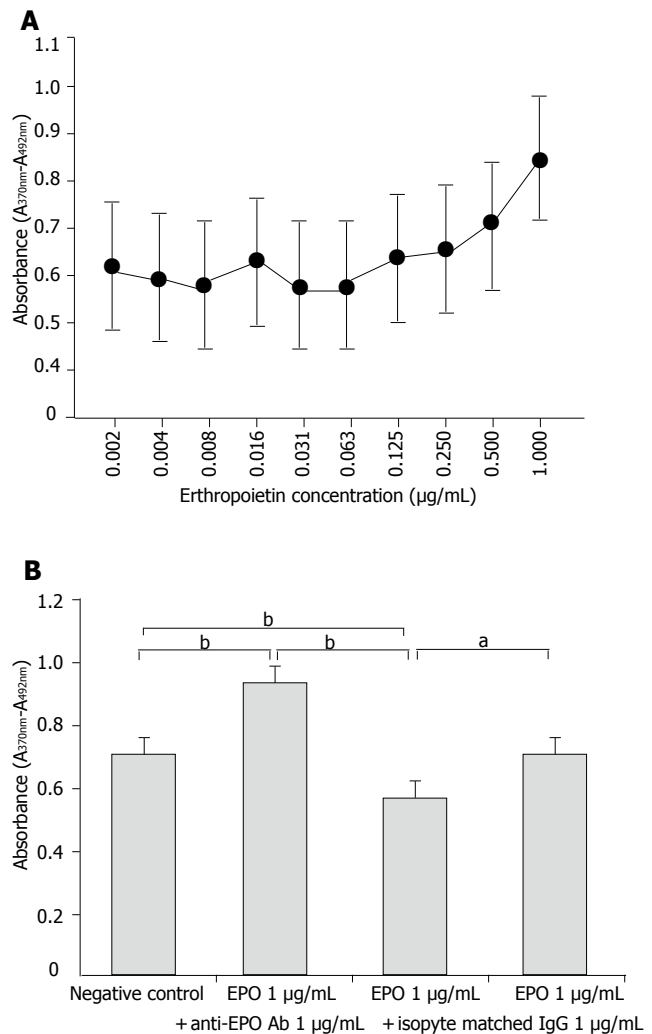

split at the ratio 1:4 and were used in younger generation (passages 6-7).

#### Identification of gastric mucosal epithelial cells in culture

Cells were also identified as gastric epithelial cells by double staining with anti-porcine H<sup>+</sup>/K<sup>+</sup> ATPase antibody, anti-pepsin antibody and anti-gastric mucin antibody in order to identify for gastric parietal cells, chief cells and mucin-producing cells, respectively. Cell growth assessed by the overnight bromodeoxyuridine (BrdU) uptake showed that about 60% of the cells retained growth potential and the population doubling time was about 36 h in these culture conditions.

#### EPO-R gene expression on gastric mucosal epithelial cells

**Analysis of EPO-R by RT-PCR:** EPO-R gene expression in porcine gastric mucosal epithelial cells ( $1 \times 10^7$ ) was analyzed by RT-PCR. Total RNA was extracted using TRIzol reagent. RNA samples were treated with RNase-free DNase I at 37°C for 30 min to eliminate genomic DNA contamination. RNA was purified with 1 volume of phenol:chloroform (5:1). RT-PCR was performed by RNA PCR Kit (AMV) ver. 2.1 (Takara, Japan). Briefly, 1  $\mu$ g of RNA was primed with random primers and reverse transcribed using reverse transcriptase in a final volume 20  $\mu$ L. 5  $\mu$ L of this mixture was PCR-amplified in a 25  $\mu$ L reaction using Takara Taq DNA polymerase. The following PCR priming sets were used under PCR conditions of 94°C for 45 s, 58°C for 1 min, and 72°C for 2 min. EPO-R: forward primer (5'-AGC TGT GGC TGT ACC AAA CTG A-3'), reverse primer (5'-ACT TGT

**Figure 5** Evaluation of erythropoietin effects on cultured gastric epithelial cells. (A) BrdU assay shows a dose-dependent effect of EPO on growth stimulation of porcine gastric mucosal epithelial cells. (B) Growth stimulation effects of EPO on gastric mucosal epithelial cells. Treatment with EPO (closed bar) significantly increased cell growth. This effect is inhibited by anti-EPO neutralizing antibody (hatched bar), not by isotype matched IgG (dotted bar). Results are expressed as the means  $\pm$  SD of six different experiments. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$ .

CCA GCA CCA GGT AGG T-3'); number of cycles: 36, 40, and 44. All PCR products were separated on ethidium bromide-stained gel.

#### Analysis of EPO-R by Western blotting

Porcine epithelial cells ( $0.5 - 1 \times 10^7$ ) were cultured in modified Eagle's medium (MEM) containing 10% fetal calf serum (FCS) for 48 h. EPO (1  $\mu$ g/mL) was added, and the cells were incubated for an additional 24 h. The cells were homogenized in cold buffer. The protein concentration was measured by DC protein assay kit (Bio-Rad, CA) according to the manufacturer's instruction. Aliquots of 50  $\mu$ g protein were applied each lane of 10% SDS-polyacrylamide gel and electrophoresed. After electrophoresis, samples were transferred onto PVDF membrane (Millipore, MA). The filter was then incubated with anti-human EPO-R monoclonal antibody (diluted 1:100, 1:500, 1:1000 and 1:2000 respectively). Reaction product was demonstrated using ECL-plus Kit (Amersham.

Bioscience, UK). For a negative control experiment, the primary antibody was omitted from the solution.

### **Analysis of EPO-R in the tissues by Immunohistochemical staining**

Stomachs were resected from pig fetuses and dissected along the greater curvature. The gastric mucosa was visually inspected, removed from the anterior wall, fixed in 10% formalin, embedded in paraffin, and cut into 5  $\mu$ m sections. Primary antibodies against EPO-R and MUC5AC were used in the immunohistochemical staining. Tissue sections were incubated overnight with primary antibodies at 4°C and then treated with horse radish peroxidase-labeled rabbit IgG antibody for 1hr at room temperature. The immunoreactive products were visualized with DAB staining (ABC method). Counterstaining was performed with hematoxylin. For negative controls, the primary antibody was replaced with rabbit or mouse nonimmune serum. Double staining for EPO-R and MUC5AC was performed with DAB staining (ABC method) followed by Ni-DAB staining (PAP method). For negative controls, the protocol was similar to that used for single staining.

### **Growth stimulation effects of EPO on cultured porcine gastric mucosal epithelial cells**

Cultured porcine gastric mucosal epithelial cells were incubated with Keratinocyte-SFM containing 20% newborn calf serum. EPO (0.002, 0.004, 0.008, 0.016, 0.031, 0.063, 0.125, 0.25, 0.5, 1  $\mu$ g/mL) was added to the supernatant to evaluate the dose-dependent effects on growth potential of the gastric mucosal cells.

To evaluate the specificity of EPO effects, four sets of groups were established: 1) untreated cultures; 2) EPO 1  $\mu$ g/mL treated cultures; 3) EPO 1  $\mu$ g/mL + anti-EPO antibody 1  $\mu$ g/mL treated cultures; and 4) EPO 1  $\mu$ g/mL + nonspecific antibody (rabbit IgG) 1  $\mu$ g/mL treated cultures. Quantification of cell growth was measured by ELISA using BrdU.

Cultures and quantitative analysis were performed using 96-well plates (Nunc, Naperville, IL). Medium was prepared for each experimental group and aliquoted (50  $\mu$ L/well) into 6 wells per group. The gastric mucosal epithelial cells were adjusted to a density of  $1 \times 10^5$  cells/mL, and 50  $\mu$ L were aliquoted into each well and incubated (5000 cells/well) for 4 d. In accordance with a cell proliferation ELISA protocol, 10  $\mu$ L/well of BrdU solution was added, and incubation was continued for 24 h. After discarding the supernatants, 200  $\mu$ L/well of fixation reagent was added for 30 min to fix the cells and denature the DNA. After discarding the supernatants, 100  $\mu$ L/well of anti-BrdU peroxidase solution was added and followed by incubation for 1 h. After discarding the supernatants and washing, 100  $\mu$ L/well of substrate solution was added and incubated for 30 min, and absorbance at 370 nm (control wavelength, 492 nm) was assessed.

### **Statistical analysis**

All results are expressed as mean  $\pm$  SE. Statistical comparisons were made using the Student *t*-test or Welch's *t*-test after the analysis of variances. The results were considered significantly different at  $P < 0.05$ .

## **RESULTS**

### **Identification of gastric mucosal epithelial cells in culture**

Cells were identified as gastric epithelial cells by double staining with anti-proton pump antibody, anti-pepsin antibody and anti-gastric mucin antibody in order to identify for gastric parietal cells, chief cells and mucin-producing cells, respectively (Figure 1). In the most cells, immunofluorescence showed double positive staining for anti-pepsin antibody and anti-proton pump antibody or for anti-pepsin antibody and anti-gastric mucin antibody.

### **EPO-R gene expression on gastric mucosal epithelial cells**

**RT-PCR:** EPO-R was detected on the cultured porcine gastric mucosal epithelial cells. 207 bp products were detected (Figure 2).

### **Western blotting**

We examined the expression of EPO-R protein in porcine epithelial cells by Western blotting. EPO-R protein expression was detected as a predicated size. The intensity of signals was dependent on anti-EPO-R antibody dilution (Figure 3).

### **Immunohistochemical staining of EPO-R in the gastric tissue**

EPO-R showed a punctate expression pattern at the base of gastric mucosal epithelial cells. MUC5AC was observed in the mucosal cell reticulum. Double staining was performed to examine the correlation between mucosal epithelial expression of EPO-R and presence of glycoproteins, which are an important component of the mucosal barrier. The findings were positive for EPO-R in the foveolar epithelial cells that were also positive for MUC5AC (Figure 4)

### **Growth stimulation effects of EPO on gastric mucosal epithelial cells**

BrdU assay demonstrated a dose-dependent increase in growth potential of cultured porcine gastric mucosal epithelial cells at EPO doses ranging from 0.002 to 1  $\mu$ g/mL. Evaluation of EPO dose dependence in this study showed the greatest growth potential at 1  $\mu$ g/mL (Figure 5A) compared to untreated cultures, cultures treated with EPO showed statistically significant growth stimulation. In contrast, co-culturing with EPO antibody showed a significant growth inhibition effect. On the other hand, there was no significant inhibition effect of cell growth with a nonspecific antibody. These findings suggested that growth stimulation by EPO of gastric mucosal cells was mediated via EPO-specific receptors (Figure 5B).

## **DISCUSSION**

The incidence of gastrointestinal bleeding is higher in hemodialysis patients than in the general population. The advent and use of histamine-2 ( $H_2$ ) receptor blockers and proton pump inhibitors (PPIs) has resulted in a small decrease in gastrointestinal bleeding events in hemodialysis

patients, but the use of EPO therapy for treatment of anemia associated with renal failure has led to a more dramatic decrease in this complication for reasons that were previously unclear. Decreased blood supply secondary to anemia leads to low local oxygen concentrations in the gastric mucosa and results in formation of gastric lesions in dialysis patients<sup>[3,4,6]</sup>. Thus an increase in red blood cell production in response to EPO may reduce the incidence of hemorrhagic lesions by increasing oxygen delivery to the gastric mucosa. However, the present study suggests that the direct effect of EPO to gastric mucosa may also mediate the efficacy of EPO therapy found in dialysis patients.

The EPO gene was cloned and recombinant human EPO was purified in 1985, followed by identification of EPO-R on erythroid cells using iodine-labeled EPO. The EPO-R density on the surface of erythroid cells is low, ranging from a few hundred to a few thousand per cell. In the hematopoietic system, EPO-R is mainly expressed at the stage of late erythroid progenitor cells,<sup>[13]</sup> and the number of receptors decreases with differentiation into mature erythrocytes. In addition to erythroid progenitors, EPO-R is expressed on megakaryocytes<sup>[14]</sup>, vascular smooth muscle cells<sup>[15]</sup>, endothelial cells<sup>[7]</sup>, skeletal myoblasts<sup>[16]</sup>, neural cells<sup>[17]</sup>, renal cells<sup>[18]</sup>, ischemic retinal cells<sup>[19]</sup> and in the epicardium and pericardium<sup>[20]</sup>. Further, studies of the digestive tract have shown EPO-R mRNA in hepatic stromal cells in fetal mice<sup>[21]</sup>, and EPO-R protein has been found in the intestinal villi during development in humans and rats.<sup>[22,23]</sup> Okada *et al*<sup>[10]</sup> investigated whether EPO stimulated gastric mucosal development *in vitro* in a rat gastric mucosal cell line (RGM-1) and reported that EPO produced a dose-dependent increase in thymidine uptake and c-myc gene expression. In addition, RT-PCR confirmed EPO-R gene expression, thus showing a direct growth effect on RGM-1 cells. It should be noted, however, that RGM-1 may represent transformed cell line rather than normal gastric epithelial cells. We previously demonstrated EPO-R mRNA expression in cultured porcine gastric mucosal microvascular endothelial cells<sup>[9]</sup>.

In the present study, we confirmed the EPO-R mRNA in the cultured normal gastric epithelial cells. In addition, we used immunohistochemical analysis in the tissue sections to demonstrate EPO-R immunoreactivity in gastric mucosa cell, predominantly in foveolar epithelial cells. These data suggests that EPO may play a direct role in modulating normal gastric mucosal cells.

The dose-dependent effects of EPO on mucosal epithelial cell growth were observed at doses up to 1 µg/mL. Treatment of the porcine gastric mucosal epithelial cells with EPO clearly resulted in increased cell growth. The increase was inhibited by co-culturing with anti-EPO antibody, with significantly lower growth than in cells co-cultured with nonspecific antibody (rabbit IgG), which suggests that the growth stimulation effect of EPO is a direct and specific effect on the gastric mucosal epithelial cells.

EPO may have direct action on other types of mucosal and stromal cells. A previous study reported that treatment of rats with EPO before surgical anastomosis increased anastomosis strength and improved healing<sup>[24]</sup>. Further,

in a retrospective study in premature rats, treatment with EPO decreased the incidence of experimentally-induced necrotizing enteritis<sup>[25,26]</sup>. In addition, treatment with EPO, both orally and parenterally, increased jejunal villus surface area. As compared to a control group, villus length was increased in groups treated with oral or parenteral EPO<sup>[27]</sup>. These findings indicate that EPO has a trophic action on the small intestine. EPO also stimulates growth of hepatic stromal cells in fetal mice, and furthermore, there is a dose-dependent effect. These results are consistent with data from the present study performed in gastric mucosal cells. EPO-specific mucosal cell growth is a noteworthy finding in our study, and the present study suggests EPO may prevent hemorrhagic gastric lesions in dialysis patients by a systemic hematopoietic effect and by a local effect on the gastric mucosa. EPO directly and specifically stimulated gastric mucosal epithelial cell proliferation.

### Abstract

**AIM:** To assess the effect of iron reduction after phlebotomy in rats with "normal" hepatic iron concentration (HIC) on the progression of hepatic fibrosis, as a result of bile duct ligation (BDL).

**METHODS:** Rats underwent phlebotomy before or after sham operation or BDL. Animals undergone only BDL or sham operation served as controls. Two weeks after surgery, indices of hepatic damage and fibrosis were evaluated.

**RESULTS:** Phlebotomy lowered HIC. Phlebotomy after BDL was associated with body weight increase, lower hepatic weight, less portal hypertension, less periportal necrosis, less portal inflammation, lower hepatic activity index score and higher albumin levels. On the other hand, phlebotomy before BDL was associated with body weight decrease and hepatic activity index score increase. Phlebotomy after sham operation was not associated with any hepatic or systemic adverse effects.

**CONCLUSION:** Reduction of HIC after induction of liver damage may have beneficial effects in BDL rats. However, iron deficiency could induce impairment of liver function and may make the liver more susceptible to insults like BDL.

**Key words:** Iron; Phlebotomy; Bile duct ligation; Hepatic activity index; Rat.

### INTRODUCTION

Chronic liver injury due to various causes may result in hepatic fibrosis, which can lead to cirrhosis and end-stage liver failure<sup>[1]</sup>. Currently, there are no proven therapeutic options designed to delay or reverse the progression of hepatic fibrosis. Iron overload is a relatively common finding in many patients with a variety of end-stage liver diseases, who have no evidence of genetic hemochromatosis<sup>[2, 3]</sup>. In such patients the presence of hepatic siderosis is associated with more advanced liver dysfunction, more rapid decompensation and decreased survival<sup>[4]</sup>.

The pathogenesis of hepatic fibrosis in patients with iron overload is not well understood. Four possible mechanisms have been suggested. (1) Iron *per se* is as an inducer of fibrosis even in the absence of necrosis and inflammation, and may act as a profibrogenic agent that stimulates the deposition of collagen by hepatic stellate cells<sup>[5]</sup>. (2) Iron, as a mediator of hepatocellular necrosis and local inflammation, may activate the peroxidative process, produce oxygen-free radicals, lipid peroxidation damage to protein and DNA and stimulation of fibrosis<sup>[6-11]</sup>. (3) Iron, as an inducer of fibrosis, may act in conjunction with other hepatotoxins<sup>[6]</sup>. It has been suggested that mild to moderate hepatic iron concentration (HIC) increase in patients and animals with various liver diseases, like non-alcoholic steatohepatitis, hepatitis C virus (HCV) infection and alcoholic liver disease, may exacerbate liver injury and accelerate the development of hepatic fibrosis<sup>[12-20]</sup>. Moreover in HCV positive patients undergoing liver transplantation, HIC increase in the donor liver (graft) is associated with fibrosis progression<sup>[21]</sup>. (4) Iron overload may alter hepatic extracellular matrix degradation<sup>[22]</sup>. In patients with hemochromatosis, the ratio between serum concentration of matrix metalloproteinases (MMP's) 1-3 and tissue inhibitor of metalloproteinase 1 is reduced as compared to controls. Iron reduction therapy causes increase in MMP's 2 and 3 serum concentration<sup>[22]</sup>.

In the liver, iron is present in a few forms: ferritin,

**Table 1** Weights and phlebotomy volume in different groups of rats (mean  $\pm$  SE)

hemosiderin, heme and as low molecular weight iron (LMWI). It is thought that part of LMWI bound to weak chelators like ATP and AMP, is readily available to induce tissue damage<sup>[23]</sup>. This fraction of iron is probably the most susceptible to reduction after iron reduction therapy.

Iron depletion has been reported to improve metabolic derangement in patients with non-alcoholic fatty liver disease, liver damage and response to drug therapy in patients with chronic HCV infection<sup>[13, 24-27]</sup>. Menstruating women with chronic HCV infection who are iron deficient have lower aminotransferase levels and improved liver histology when compared to age-matched menstruating females who are not iron deficient<sup>[28]</sup>. The possibility of altering the natural history and clinical course of HCV infection and to improve the response to anti-viral therapy (interferon monotherapy) has led to the recommendation to consider iron reduction therapy (phlebotomy) in patients with HCV infection as an adjuvant therapy to the other therapeutic modalities, even if HIC is normal or only mildly elevated<sup>[29,30]</sup>. Plebotomy is safe in most HCV-infected patients who are usually not iron deficient<sup>[31]</sup>. In HCV-infected patients in whom ribavirin is combined

<sup>1</sup>*P*  $\leq$  0.003 vs BDL only.

with interferon, HIC does not influence the response to therapy<sup>[32]</sup>. However, it is not yet known whether phlebotomy may improve the sustained virological response or histological score in these patients. Patients with chronic cholestatic liver disease do not usually have hepatic iron overload<sup>[4]</sup>. Moreover, no information exists as to the effect of iron reduction in subjects with cholestatic liver diseases with no increase ("normal levels") of HIC.

The aim of the present work was to assess the effect of iron reduction after phlebotomy on the HIC in rats with "normal" iron stores and to evaluate whether reduction of HIC may decrease the hepatic damage and slow the progression of hepatic fibrosis induced by bile duct ligation (BDL).

## MATERIALS AND METHODS

Forty male Sprague Dawley rats (Harlan, Israel), weighing 180-223 g, were studied. Rats were housed in regular cages situated in an animal room at 24°C with a 12-h light-dark cycle. Rats were maintained on standard rat chow (Kofflok, Tel Aviv, Israel) and with free access to tap water. The Ethics Review Committee for Animal Experimentation of the Hebrew University Hadassah Medical School approved all the animal studies described

herein. BDL was performed as previously described<sup>[33]</sup>. Under ketamine anesthesia (100 mg/kg, intramuscular) a median laparotomy was done, the common bile duct was exposed, doubly ligated with 3/0 silk and sectioned between ligatures. The abdominal cavity was closed with two suture lines. In sham operated (SO) rats the portal area and liver hilum were exposed, the common bile duct was isolated and gently mobilized.

Three groups of animals were studied: (1) Control group of BDL (*n*=9) and SO (*n*=5) rats; (2) Post-procedure phlebotomy group of BDL (*n*=8) and SO (*n*=4) rats. These rats were phlebotomized on a daily basis for five consecutive days, from the fourth to the ninth post-operative days. Phlebotomy was done through a tail vein with 21-gauge needles under light ether anesthesia; (3) Pre-procedure phlebotomy group of BDL (*n*=8) and SO (*n*=6) rats. These rats were phlebotomized on a daily basis for five consecutive days from the ninth to the fourth days before the surgical procedure (BDL or sham operation).

Two weeks after the surgical procedure rats were anesthetized with ether. The abdominal cavity was opened by midline incision, and blood was drawn from the inferior vena cava, centrifuged, aliquoted and frozen. Serum albumin, bilirubin, calcium, phosphor, liver enzymes, kidney function tests and electrolytes were measured by the dry chemistry method (Kodak, Rochester, NY, USA). Serum iron (SI) as determined by Guanidine/FerroZinc method (Cobas Integra 700). Transferin was determined using the immunoturbidimetric method (Cobas Integra 700). The liver and spleen were removed and weighed. Sections from the liver of each animal included in the study were taken for histological evaluation, determination of HIC, myeloperoxidase (MPO) activity, prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) generation and hydroxyproline (HP) content.

### Liver histology

Sections from the liver of each animal were fixed in phosphate-buffered formaldehyde, embedded in paraffin, and 5-μm thick sections were prepared. Sections were stained with hematoxylin and eosin for evaluation of necroinflammatory grading and Masson's trichrome stains for fibrosis and architectural changes. Histological

<sup>1</sup>*P*≤0.0001, <sup>2</sup>*P*≤0.012 vs BDL only; <sup>3</sup>*P*≤0.016 vs sham only.

grading of BDL-induced liver damage was assessed by a modification of the Knodell score<sup>[34]</sup>. Each specimen was examined for the following features and scored by points of increment from 0-4, according to the severity of the findings as follows: periportal necrosis: none = 0, mild = 1, moderate = 2, marked = 3, severe = 4; portal inflammation: none = 0, mild = 1, moderate = 2, marked = 3, severe = 4; lobular necrosis: none = 0, mild = 1, moderate = 2, marked = 3, severe = 4; fibrosis: none = 0, portal expansion = 1, septal formation = 2, marked bridging fibrosis = 3, cirrhosis = 4. Hepatic activity index (HAI) was calculated for each rat by summation of the points of these four parameters. In addition, bile duct proliferation was assessed in each specimen by allocating points of increment from 0-4, according to the severity of the findings. Histological evaluation of the pathological specimens was done on a blind basis by our pathologist. Reliable correlation was seen in repeated and blinded histological evaluation of the specimens.

### Determination of PGE<sub>2</sub>

One hundred and fifty mg of liver tissue was placed in preweighed tubes containing 1.0 mL of phosphate buffer (50 mmol/L, pH 7.4). The liver was minced with scissors and centrifuged in an Eppendorf centrifuge for 10 s. The pellet was resuspended in 1.0 mL of the above buffer, incubated for 1 min in a vortex mixer. Indomethacin (10 μg) was added and the tubes were centrifuged for 60 s. The supernatant was kept at -20°C until radioimmuno-assay was performed. The ability of liver tissue to generate PGE<sub>2</sub> was expressed as ng/g wet tissue weight. PGE<sub>2</sub> generation was determined by radioimmunoassay as previously described<sup>[33]</sup>.

### Determination of MPO activity

Liver tissue (200 mg) was homogenized three times for 30 s each time at 4°C with a polytron (Kinematica GmbH, Krietz-Lucern, Switzerland) in 1.0 mL of ice-cold 0.5% hexadecyltrimethylammonium bromide in 50 mmol/L phosphate buffer, pH 6.0. The polytron probe was rinsed twice with 1.0 mL of the buffer and the washing was added to the homogenate. The homogenate was then sonicated for 10 s, freeze-thawed three times and centrifuged for 15 min at 40 000 r/min. An aliquot of the supernatant was

**Table 6** Serum iron and transferrin in different groups of rats (mean  $\pm$  SE)

Subgroup	n	Serum iron ( $\mu$ g/dL)	Transferrin (mg/dL)
Sham only	5	163 $\pm$ 21	446 $\pm$ 46
Sham and phlebotomy later	4	144 $\pm$ 38	459 $\pm$ 17
Phlebotomy and sham later	6	160 $\pm$ 20	482 $\pm$ 103
BDL only	9	205 $\pm$ 71	640 $\pm$ 128
BDL and phlebotomy later	8	197 $\pm$ 57	732 $\pm$ 65
Phlebotomy and BDL later	8	215 $\pm$ 116	701 $\pm$ 83

taken for determination of enzyme activity according to Bradley *et al.*<sup>[35]</sup>. The correlation coefficient based on 10 standard curves was  $r=0.98$  and inter assay variation was  $0\pm 1.65\%$  (mean  $\pm$  SE,  $n=57$ ).

### Determination of hepatic iron content

Hepatic non-heme iron concentration was measured by the method of Torrance and Bothwell<sup>[36]</sup>.

### Determination of hepatic hydroxyproline content

Hepatic hydroxyproline content was measured by the method described by Woessner<sup>[37]</sup>.

### Statistical analysis

Data were expressed as mean  $\pm$  SE. Group variance was analyzed by the Kruskal-Wallis test, followed by the Mann-Whitney test for multiple comparisons to allow pair-wise testing for significant differences between groups.  $P\leq 0.05$  was considered statistically significant.

## RESULTS

### Effect of bile duct ligation

Two weeks after BDL all rats were jaundiced, had lesser weight gain, greater liver and spleen weight than SO rats (Table 1). BDL rats also had higher serum levels of liver enzymes, higher bilirubin and lower albumin levels, higher fibrosis score, higher hepatic HP content, higher hepatic activity index and higher bile duct proliferation score than SO rats (Table 2, Tables 3 and 4 and Figure 1). No change in HIC and content or SI and transferrin were observed as a result of BDL (Tables 5 and 6).

### Effect of phlebotomy

Phlebotomy after surgical procedure (SO or BDL) resulted in a decrease of HIC and content. The change was more pronounced in BDL rats than in SO rats. Rats that were phlebotomized before the surgical procedure had higher HIC than those undergone phlebotomy after the surgical procedure (Table 5). No change in SI and transferrin was noted in any group as a result of phlebotomy (Table 6).

Phlebotomy after BDL was associated with body weight increase, higher albumin levels and lower hepatic PGE<sub>2</sub> generation at sacrifice compared to BDL only rats (Tables 1-3). Moreover, periportal necrosis, portal inflammation, fibrosis scores, total HAI and hepatic HP content decreased in rats that were phlebotomized after BDL, although the results did not reach statistical significance. Phlebotomy before BDL was associated

**Figure 1** Hepatic activity index (HAI) in the study groups; <sup>a</sup> $P<0.02$  vs BDL only.

(when compared to BDL only rats) with a similar weight loss. Periportal necrosis, portal inflammatory activity and fibrosis score were higher in this group than in the BDL only group. However, while the difference in value for each variable was not statistically significant, the combination of variables (HAI) was significant ( $12.17 \pm 1.93$  vs  $7.22 \pm 3.49$ ,  $P\leq 0.018$ , Figure 1). Surprisingly, hepatic PGE<sub>2</sub> generation and MPO activity in the rats that had phlebotomy before BDL were lower than those in the BDL only group.

When both phlebotomy groups undergone BDL were compared, the group that had phlebotomy after the procedure had a better outcome: weight gain, higher albumin level, lower hepatic weight ( $P=0.029$ ), less portal hypertension (determined as lower spleen weight) ( $P=0.029$ ), less periportal necrosis ( $P=0.008$ ) and portal inflammation ( $P=0.008$ ) and lower total HAI score ( $P=0.008$ , Tables 1-3, Figure 1).

## DISCUSSION

The role of iron in the progression of hepatic damage in various clinical and experimental conditions has usually been studied by iron loading<sup>[14,16,18-20]</sup>, or by iron depletion in situations where mild to moderate iron overload is present<sup>[13,24,25,30]</sup>. In the present study, we examined the effect of reduction of "normal" hepatic iron stores on liver function and histology in rats subjected to BDL. This situation may be more relevant and analogous to and may mimic more closely the common clinical conditions where most of the patients with non-hemochromatosis and non-end-stage liver diseases do not have iron overload<sup>[13]</sup>.

In the present study we were able to demonstrate that it was possible to reduce HIC by phlebotomy and that such a procedure after sham operation was not associated with hepatic adverse events. Liver disease developed in the rats after two weeks of BDL was not associated with HIC increase. Phlebotomy before the surgical procedure was associated with HIC reduction but not with SI or transferrin reduction. The changes in liver histology (mainly necrosis and inflammation) following the HIC reduction indicated that hepatic iron might not have a role in the fibrosis process after BDL<sup>[38]</sup>. Alternatively, we may also speculate that further reduction of HIC by more

aggressive phlebotomy would have an effect on fibrosis. Since SI and transferrin levels did not change following phlebotomy, we assume that the phlebotomy process performed in our rats was not sufficient to alter the course of the fibrosis process. Although no change was observed in fibrosis score, phlebotomized rats after BDL exhibited favorable effects. These rats had body weight increase, higher albumin levels and lower hepatic necroinflammatory activity. Iron deficiency induced by iron chelation may reduce the severity of inflammation in joints and in the gastrointestinal tract<sup>[39, 40]</sup>.

HIC was only mildly reduced in the rats undergone phlebotomy before the surgical procedure compared to the BDL only rats. Only the total amount of iron per whole liver was reduced significantly. This could be due to the ability of rats to absorb iron during the time interval between the last phlebotomy session and the sacrifice of the rats (18 d). This may indicate that phlebotomy has a transient effect and that continuous phlebotomy sessions over time should be done in order to sustain a beneficial effect. In cirrhotic subjects an increased iron absorption due to increased duodenal expression of iron transporter, divalent metal transporter 1 has been reported<sup>[41]</sup>. However this phenomenon does not exist in rats with cholestatic liver disease.

Phlebotomy had a favorable effect on the rats after BDL, but a definite negative effect before BDL. The latter rats lost weight and had a worse HAI (a worse score in periportal necrosis and portal inflammation) as compared to the other BDL groups. A similar trend of changes was observed in the rats subjected to phlebotomy before sham operation. Iron deficiency may affect various organs including eccentric cardiac hypertrophy in rats<sup>[42]</sup> and various hepatic enzyme functions<sup>[43]</sup>. Anemic patients with early cirrhosis may have worse hemodynamic parameters (lower systemic vascular resistance, increased cardiac index and hepatic venous pressure gradient) than non-anemic control patients<sup>[44]</sup>. Increased blood hemoglobin may attenuate splanchnic vasodilatation in portal hypertensive subjects by nitric oxide inactivation<sup>[44]</sup>. In our study, the rats undergone phlebotomy before BDL had the highest splenic weight (a marker of portal hypertension). Based on this finding we may speculate that deterioration of hemodynamic parameters in these rats is associated with activation of the renin-angiotensin system. This system may have a role in hepatic fibrosis in BDL rats<sup>[45]</sup>.

Hepatic PGE<sub>2</sub> generation and MPO activity were used as adjuvant markers for hepatic inflammatory activity in our study, and decreased PGE<sub>2</sub> generation was observed in the BDL groups undergone phlebotomy. This is unexpected as iron is known to down-regulate PGE<sub>2</sub> generation in various tissues<sup>[46, 47]</sup>. Higher PGE<sub>2</sub> levels were also expected in the BDL groups with increased hepatic inflammatory changes. This is similar to the results in our previous study of rats to BDL and colitis, in which colonic PGE<sub>2</sub> generation was reduced as compared with a control group<sup>[33]</sup>. One may speculate that cyclooxygenase activity or even phospholipase A<sub>2</sub> activity may be defective in rats with experimental liver disease<sup>[33, 48]</sup>.

As MPO is found primarily in neutrophil granules, it is a marker of neutrophil content and influx into tissues<sup>[49]</sup>. Our previous study in BDL rats with colitis

found that mucosal inflammation is correlated with MPO activity<sup>[33]</sup>. In the present study, however no correlation was found between the hepatic inflammatory changes and hepatic MPO activity. Decreased MPO activity in the Carrageenan model of inflammation in rats with acute cholestasis due to bile duct resection has been reported<sup>[50]</sup>. Additional defects of neutrophil function in BDL rats, like impairment of adhesion, defective phagocytosis, increased superoxide generation and chemotaxis, and increased number of neutrophil counts, have been reported<sup>[50-53]</sup>. Iron deficiency *per se*, may also impair neutrophil function and MPO activity and cause a selective defect in the process of inflammation<sup>[54, 55]</sup>. Iron repletion improves some of the above functions<sup>[54]</sup>. In this study, hepatic MPO activity was the lowest in the rats undergone phlebotomy before the surgical procedure. However there was no clear correlation between HIC, hepatic MPO activity and hepatic inflammation.

In summary, hepatic iron depletion in rats after a liver insult like BDL, may have beneficial effects. "Hepatic iron deficiency" may make the liver more vulnerable to insults such as laparotomy or BDL. Hepatic PGE<sub>2</sub> generation and hepatic MPO activity are not reliable markers for hepatic inflammation in rats with cholestatic liver disease.

### Abstract

**AIM:** To evaluate the contrast-enhanced endosonography as a method of differentiating inflammation from pancreatic carcinoma based on perfusion characteristics of microvessels.

**METHODS:** In 86 patients with suspected chronic pancreatitis (age:  $62 \pm 12$  years; sex: f/m 38/48), pancreatic lesions were examined by conventional endoscopic B-mode, power Doppler ultrasound and contrast-enhanced power mode (Hitachi EUB 525, SonoVue<sup>®</sup>, 2.4 mL, Bracco) using the following criteria for malignant lesions: no detectable vascularisation using conventional power Doppler scanning, irregular appearance of arterial vessels over a short distance using SonoVue<sup>®</sup> contrast-enhanced technique and no detectable venous vessels inside the lesion. A malignant lesion was assumed if all criteria were detectable [gold standard endoscopic ultrasound (EUS)-guided fine needle aspiration cytology, operation]. The criteria of chronic pancreatitis without neoplasia were defined as no detectable vascularisation before injection of SonoVue<sup>®</sup>, regular appearance of vessels over a distance of at least 20 mm after injection of SonoVue<sup>®</sup> and detection of arterial and venous vessels.

**RESULTS:** The sensitivity and specificity of conventional EUS were 73.2% and 83.3% respectively for pancreatic cancer. The sensitivity of contrast-enhanced EUS increased to 91.1% in 51 of 56 patients with malignant pancreatic lesion and the specificity increased to 93.3% in 28 of 30 patients with chronic inflammatory pancreatic disease.

### INTRODUCTION

Endoscopic ultrasound is a diagnostic method with a high sensitivity for detection of small pancreatic lesions and can rule out carcinomas in almost all patients without chronic pancreatitis<sup>[1,2]</sup>. However, the differential diagnosis of pancreatic lesions, especially malignant neoplasia in patients with chronic pancreatitis is always difficult.

Differentiation between malignant and benign lesions in the liver is possible in many cases through analysis of its organ specific vascularity (portal vein/sinusoidal) using liver specific contrast media<sup>[3,4]</sup>. In contrast to the liver with its organ specific (portal vein/sinusoidal) blood supply, the pancreas does not contain pancreatic specific vasculature. Therefore, the differentiation of malignant from benign pancreatic lesions seems to remain an unsolved problem today though technology is improved. The same problem arises using computerized tomography (CT) and magnetic resonance imaging (MRI)<sup>[5-7]</sup>. In patients with chronic pancreatitis the specificity of differentiation between malignant and benign lesions in the pancreas is reported to be as low as 33%-75%<sup>[8,9]</sup>.

However, the introduction of endoscopic ultrasound-guided fine needle aspiration has made this easier<sup>[10-12]</sup>. The gold standard is still surgery in combination with pathological examination of histological specimens. Nevertheless an improved non-invasive method of detecting malignant tissue is preferable. In the present study, contrast-enhanced endoscopic ultrasound was used to differentiate between benign and malignant pancreatic lesions.

## MATERIALS AND METHODS

### Patients

A total of 120 patients (age:  $61 \pm 18$  years; sex: f/m 56/64) who showed undifferentiated pancreatic lesions in ultrasound and computed tomography were included into the present study. Reference imaging examinations (e.g. computed tomography, magnetic resonance imaging and positron emission tomography [PET]) were performed as part of the clinical work-up of the patients. Patients with mucinous cyst adenoma ( $n=1$ ), serous cyst adenoma ( $n=5$ ), serous cyst adenocarcinoma ( $n=4$ ) and neuroendocrine tumours ( $n=6$ ) were excluded from the study. Contrast-enhanced endoscopic ultrasound was not performed in seven patients due to severe heart failure NYHA III/IV, a contraindication for SonoVue®. The image quality was inadequate in one patient due to severe pancreatic lipomatosis. Furthermore, the lesion could not be reached in 10 patients by the biopsy needle. Finally, 86 patients (age:  $62 \pm 12$  years; sex: f/m 38/48) were included in the study.

Informed consent according to the ethical guidelines from Helsinki was obtained from all patients after the patients were informed of the purpose of the study before ultrasound examination was started.

### Methods

Endoscopic ultrasound was performed using an electronic linear ultrasound probe (Pentax FG 38 UX; Hitachi EUB 525). The pancreas was examined as previously described<sup>[13]</sup>. As contrast enhancing agent, SonoVue® (Bracco, Milano, Italy) was applied in all patients. During the procedure all patients were monitored as previously described<sup>[14,15]</sup>.

### Conventional B-mode and power Doppler scanning

The imaging criteria of chronic pancreatitis have been recently discussed<sup>[16,17]</sup>. All patients received transabdominal examination as previously described<sup>[18]</sup>. In this study the specificity and sensitivity of endoscopic ultrasound were tested before and after injection of the contrast-enhancing agent SonoVue® in differentiating focal chronic pancreatitis from pancreatic carcinoma. Tumour location, morphology, echogenicity and size were documented. If a lesion was detected, vascularity and possible vessel infiltration were evaluated using conventional endoscopic power Doppler ultrasonography in comparison to the surrounding pancreatic tissues and regarded as hyper-, iso- or hypovascular.

The pulse repetition frequency and wall filters were individually adjusted to enable the detection of parenchymal and intratumoral vessels and to avoid artefacts such as "blooming". To detect vascular complications such as portal vein thrombosis, the portal vein was also investigated in variable scans. If any echogenic material was found in the lumen of the portal vein, power Doppler was used to detect flow inside the material. If flow was detected, pulsed wave Doppler analysis was performed to differentiate between pulsatile arterial and non-pulsatile (portal-) venous perfusion. In addition, the following criteria for malignant lesions were used: irregular lesion without clear structure, stenosis of pancreatic duct with prestenotic duct dilatation

and infiltration of vessels or surrounding organs.

### Contrast-enhanced power Doppler scanning

In a prestudy, Levovist and SonoVue® were compared in 10 consecutive patients, which demonstrated best results in imaging pancreatic perfusion using SonoVue (2.4 mL). Therefore, contrast-enhanced ultrasound was applied using SonoVue® 2.4 mL (BR1, Bracco, Italy) to evaluate if this contrast application could improve the characterisation of tumour vascularity. SonoVue® (2.4 mL) was injected following a flash of 10 mL saline solution via a catheter (12 mm in diameter or larger) into a cubital vein. Hitachi EUB 525 was used. Continuous scanning was performed with its pulse repetition frequency set at 7 kHz to gain optimal signals as low as possible but to avoid artefacts with an adjusted wall filter. In contrast to the technique described by Becker *et al.*<sup>[13]</sup>, we combined the analysis of the detected vessels with pulse wave (pw) Doppler analysis. The sonograms were stored on videotapes and re-evaluated blind to the clinical settings using a semiquantitative scoring system to evaluate the vascularity during different phases of perfusion.

Criteria of chronic pancreatitis without neoplasia were defined as no detectable vascularisation or regular appearance of vessels over a distance of at least 20 mm before and after injection of SonoVue® and detection of arterial and venous vessels in the contrast-enhanced phase.

Criteria for malignancy were no detectable vascularisation before injection of SonoVue®, irregular appearance of arterial vessels over a short distance after injection of SonoVue® and no detection of venous vessels in the lesion. A malignant lesion was assumed if all criteria were detectable.

The whole procedures were stored on videotapes. The criteria of benign and malignant pancreatic tumour using contrast-enhanced power Doppler are summarized in (Table 1)

### Endoscopy-guided puncture

EUS-guided fine needle aspiration was performed in all patients. The patients with benign diseases were followed up for at least 12 mo. After detection of the lesion by endoscopic ultrasound, the diagnostic criteria of endoscopic ultrasound were used to get a primary diagnosis. Then the lesion was investigated with the help of power Doppler mode before and after the application of 2.4 mL SonoVue® for over 3 min and the secondary diagnosis was established. At the end of the procedure all lesions were punctured with a 22 G fine needle aspiration system (Cook Deutschland GmbH, Mönchengladbach, Deutschland) to confirm the diagnosis using cytology. For optimization of the cytology results more than 6 needle passes of the lesion were used as previously described<sup>[10,19]</sup>. The material was spread out on to a normal microscopic glass platelet and dried by air. Then, a blood stain (May-Gruenwald/Giemsa) was made. In case of remaining tissue, the tissue biopsy was fixed in formalin for histological examination. A malignant process was assumed if the result of cytological examination was Papanicolaou IV or V or the histological examination was positive for malignant tissue. A benign process was assumed if the result of

**Table 1 Endosonographic criteria for differentiation between malignant and benign diseases**

Kind of lesion	Vessel architecture using conventional power mode	Arterial or venous vessels in the lesion using continuous duplex scanning	Vessel architecture using contrast-enhanced power mode
Pancreatic cancer	No visible vascularisation	Only arterial vessels	Irregular, chaotic vessels
Focal pancreatitis	Nearly no visible vascularisation	Both arterial and venous vessels in the lesion	Regular with no changing diameter

**Table 2 Endoscopic findings in B-mode ultrasound in patients with pancreatic carcinoma and focal chronic pancreatitis**

		Pancreatic carcinoma	Chronic pancreatitis
Good quality of imaging		56	30
Localization	Head	35	25
	Corpus	12	4
	Tail	9	1
Size (cm -SD)		3.8 (1.09)	3.02 (0.94)
Echogenicity	Hypoechoic	41	3
	Mixed echoic	15	27
Borders	Clear	15	25
	Irregular	41	5
Structure	Irregular	41	5
	Regular	15	25
Ducts	Dilated	39	6
	Not dilated	17	24
Lymphnodes	Visible	15	4
	Not present	41	26
Invasion	Visible	23	0
	Not visible	33	30

cytological examination was Papanicolaou I or II.

### Final diagnostic methodology

After detection of the lesion by endoscopic ultrasound and the use of contrast-enhanced Doppler sonography, the final diagnosis was achieved by endoscopy-guided puncture. The material was immediately evaluated and re-puncture was performed if the material was not representative. Re-puncture was successful in 17 patients. Surgery was performed in 19 patients leading to concordant results. There was an inoperable tumour in the following diagnostic procedures (for example metastasis of lung, condition of the patient etc.) or no other sign of pancreatic cancer in all other patients. If the operation was refused, we re-examined the patients with assumed chronic pancreatitis 6 and 12 mo after the diagnosis. In case of no signs of malignant tumour 12 mo after the initial diagnosis, pancreatic cancer was ruled out.

## RESULTS

### Final diagnosis

Final diagnosis was obtained by endoscopy-guided puncture in all 86 patients. Furthermore the diagnosis was confirmed by surgery in 19 patients and by re-examination after 6 and 12 mo in all other patients with suspect chronic pancreatitis.

### Conventional B-mode and power Doppler scanning

Adequate visualisation of the pancreas and the suspected lesion could be achieved in all patients. The diagnosis was

confirmed by conventional B-mode and power Doppler endoscopic ultrasound in 41 of 56 patients using more then 2 of the previously described 3 B-mode ultrasound criteria for malignant lesions. The sensitivity was 73.2%. The diagnosis was confirmed in absence of the mentioned criteria in 25 of 30 patients with focal chronic pancreatitis. The specificity was 83.3%. However, these results were comparable to other reports<sup>[8]</sup>. The findings are shown in (Table 2).

### Contrast-enhanced power Doppler scanning

The main criteria for malignant lesions were the complete absence of venous vessels by using power Doppler in combination with pw-Doppler examination of the lesion within 3 min after contrast enhancer application. The quality of imaging was acceptable if the time was long enough to scan all visible vessels by pw-Doppler. In this study, application of the contrast enhancer SonoVue had to be repeated in 4 patients to achieve adequate image quality. In addition, using the criteria of Becker *et al*<sup>[13]</sup>, hypervascularity was observed in the area of interest in 26 patients and hypovascularity in 4 patients with chronic pancreatitis (specificity 86.6%). Hypervascularity was observed in 10 patients and hypoperfusion in 46 patients pancreatic carcinoma (sensitivity 82.1%).

The diagnosis was confirmed in 51 of 56 patients with pancreatic carcinoma using the main criteria of malignant vascularisation with a sensitivity of 91.1%. The diagnosis was confirmed in 28 of 30 patients with focal chronic pancreatitis using the criteria of benign vascularisation with a specificity of 93.3%. The results are shown in Figure 1. Typical endoscopic ultrasound images after injection of contrast enhancer SonoVue<sup>®</sup> in power Doppler mode are demonstrated in Figures 2 and 3.

## DISCUSSION

Contrast-enhanced techniques provide information on vascularity and blood flow in normal and pathological tissues. The use of 2<sup>nd</sup> generation contrast agents in combination with low mechanical index techniques can improve the transabdominal application of contrast-enhanced techniques allowing real-time imaging with or without three dimensional reconstruction. In contrast to the frequently applied transabdominal technique<sup>[20,21]</sup> there are only a few reports on contrast-enhanced endoscopic ultrasound<sup>[13,22-24]</sup>. Endoscopic ultrasound has been widely used in the past 20 years while real time contrast using low mechanical index (MI) is still restricted to the transabdominal application. In the present study, we showed that contrast-enhanced power Doppler ultrasonography in combination with power Doppler analysis could improve the differentiation between malignancy and chronic pancreatitis.

The pressure inside ductal adenocarcinoma of the pan-

**Figure 1** Endoscopic ultrasound image of chronic pancreatitis. Regular vascularisation is shown with detection of venous vessels using contrast-enhanced power Doppler scanning in combination with power Doppler.

**Figure 2** Endoscopic ultrasound image of ductal adenocarcinoma of the pancreas. Irregular vascularisation is shown with detection of only arterial and no venous vessels using contrast-enhanced power Doppler scanning in combination with pw-Doppler.

creas is higher due to surrounding fibrous tissues, which could explain the observed phenomenon that only arterial signals can be displayed in patients with malignancy with contrast-enhanced Doppler techniques, whereas both arterial and venous signals can be displayed in patients with chronic pancreatitis.

We rarely observed detectable vascularity and irregular vessel architecture in almost all patients with pancreatic carcinoma after application of the contrast-enhancing agent SonoVue®. However, both venous and arterial vessels were detectable in benign lesions. In contrast, only arterial vessels were observed in malignant lesions. The sensitivity in the discrimination between benign and malignant pancreatic lesions increased from 73.2% by endoscopic ultrasound to 91.1% using contrast-enhanced power Doppler ultrasound combination with power Doppler endoscopic ultrasound. In addition, the specificity increased from 83.3% to 93.3%. The analysis of contrast enhancing vessels in the pancreatic masses by power Doppler ultrasound in combination with power-Doppler endoscopic ultrasound is superior to the analysis of the intensity of vascularisation by power Doppler ultrasound only as demonstrated by Becker *et al*<sup>[13]</sup>.

The different vessel structures in malignant tissue are in accordance with a recently published study analysing the

**Figure 3** Results of contrast-enhanced endoscopic ultrasound in differentiation between pancreatic carcinoma and focal pancreatitis.

architecture of vessels in pancreatic carcinoma in rats<sup>[25]</sup>. However, Weskott *et al*<sup>[26]</sup> reported that venous vessels are rarely found in malignant lymph nodes.

Bhutani *et al*<sup>[9]</sup> have observed an effect of Levovist® imaging on abdominal vessels in pigs. In 1998, Hirooka *et al*<sup>[22]</sup> demonstrated that lesions in gallbladder and pancreas can be visualized using the contrast enhancer Albunex®, focal pancreatitis and pancreatic carcinoma can be differentiated by analysing the contrast enhancement. They also reported that patients with focal chronic pancreatitis reveal enhancement whereas patients with pancreatic carcinoma have no enhancement<sup>[25]</sup>.

Recently, Nomura *et al*<sup>[24]</sup> showed that improved staging of oesophageal and gastric cancer after application of an ultrasound contrast enhancer leads to better visualisation of the gut layers. Up to now there is only one study using contrast-enhanced endoscopic ultrasound with a 2<sup>nd</sup> generation contrast agent<sup>[13]</sup>. Rickes *et al*<sup>[27]</sup> have reported a similar finding.

In addition to their observations, we observed contrast enhancement of the 2<sup>nd</sup> generation contrast agent SonoVue® in both benign and malignant pancreatic lesions. To confirm our results we used endosonography-guided fine needle aspiration of the lesions. Endoscopic ultrasound-guided fine needle aspiration has become a highly valuable technique for acquisition of cytologic specimens in pancreatic diseases in the last 10 years. False-positive EUS-FNA cytologies do occur but seldom<sup>[28]</sup> in large series of EUS-FNA for pancreatic masses. EUS-FNA provides a cytologic diagnosis of 80%-94% malignancies<sup>[29-32]</sup>.

In our study, the successful rate was 90% (successful fine needle aspiration of pancreatic masses in 86 of 96 patients), which is in accordance with the literature. The 22 G fine needle aspiration system allowed histological examination of the specimens in 8% of the cases. Up to now no patient with chronic pancreatitis developed pancreatic cancer during the 12-mo follow-up. The cytological results could be confirmed in all the 19 patients undergone surgery.

The method is limited by hindered passage through the pylorus and depth of penetration. As all the new methods are concerned, a certain training factor has to be taken into account since a steady and targeted transducer manipula-

tion is the prerequisite for optimal image documentation. Sometimes, severe lipomatosis of pancreas reduces image quality. It must be mentioned that the best results can be achieved using the present method. For equal results in modern sonographic systems, changes in the pre-settings of colour Doppler are required.

To date, ultrasonography is the most commonly used imaging modality in many countries. The advantages of endoscopic ultrasound (e.g. lack of radiation exposure, relatively low cost) are countered by its operator-dependency. Endoscopic ultrasound using contrast-enhancing agents may improve our understanding of the morphologic imaging methods through additional analyses of the functional criteria like perfusion with better characterization of tumours, lymph node staging and organ infiltration. The improved image (video) documentation enhances confidence in the method.

In conclusion, contrast-enhanced endoscopic ultrasound improves the differentiation between chronic pancreatitis and pancreatic carcinoma and seems to be a useful method in clinical practice.

tonin given in advance of L-Arg significantly reduced the pancreatic CAT activity relative to that in the rats treated with L-Arg alone. In the liver, L-Arg significantly increased the lipid peroxidation level, and the glutathione peroxidase and Cu/Zn-SOD activities, whereas the Mn-SOD activity was reduced as compared to the control rats. Melatonin pre-treatment prevented these changes.

**CONCLUSION:** Melatonin is an antioxidant that is able to counteract some of the L-Arg-induced changes during acute pancreatitis, and may therefore be helpful in the supportive therapy of patients with acute necrotizing pancreatitis.

### Abstract

**AIM:** To determine the effect of melatonin pre- and post-treatment on the severity of L-arginine (L-Arg) -induced experimental pancreatitis in rats.

**METHODS:** Male Wistar rats (25) were divided into five groups. Those in group A received two injections of 3.2 g/kg body weight L-Arg i.p. at an interval of 1 h. In group MA, the rats were treated with 50 mg/kg body weight melatonin i.p. 30 min prior to L-Arg administration. In group AM, the rats received the same dose of melatonin 1 h after L-Arg was given. In group M, a single dose of melatonin was administered as described previously. In group C the control animals received physiological saline injections i.p. All rats were exsanguinated 24 h after the second L-Arg injection.

**RESULTS:** L-Arg administration caused severe necrotizing pancreatitis confirmed by the significant elevations in the serum amylase level, the pancreatic weight/body weight ratio (pw/bw), the pancreatic IL-6 content and the myeloperoxidase activity, relative to the control values. Elevation of the serum amylase level was significantly reduced in rats given melatonin following L-Arg compared to rats injected with L-Arg only. The activities of the pancreatic antioxidant enzymes (Cu/Zn-superoxide dismutase (Cu/Zn-SOD) and catalase (CAT)) were significantly increased 24 h after pancreatitis induction. Mela-

### INTRODUCTION

Acute necrotizing pancreatitis is a disease with a high mortality and no efficient treatment is available for it at present. Oxygen- and nitrogen-derived free radicals (FRs) and lipid peroxidation play an important role in the development of local inflammation and systemic complications during acute pancreatitis<sup>[1-6]</sup>. They damage the lipid membranes, structural and enzymatic proteins and DNA of the cells. The major target of FRs is polyunsaturated fatty acids of the lipid-rich membranes. Lipid peroxidation results in loss of the membrane fluidity and integrity, leading to cell death. Numerous antioxidants have recently been examined for their protective properties against oxidative damage in acute pancreatitis and have been shown to moderate the changes in several parameters of the disease<sup>[7-10]</sup>. We presumed that a compound with strong antioxidant properties and also anti-inflammatory features might exert a beneficial effect on the outcome of severe experimental pancreatitis.

The pineal product, melatonin, is known to play a role

in the regulation of circadian rhythm and in the seasonal reproduction of certain species. Melatonin is also important as regards the physiology of the retina and the immune system<sup>[11]</sup>. The antioxidant activity of melatonin has recently received significant attention. Although its level is low in the blood, a strong correlation has been observed between this level and the antioxidant capacity of serum both *in vitro* and *in vivo*<sup>[12, 13]</sup>. Since melatonin is strongly lipophilic, its intracellular concentration may be several times higher than that in serum<sup>[14]</sup>. Various body fluids likewise contain melatonin levels that are orders of magnitude higher than those measured in blood<sup>[15]</sup>.

Melatonin can detoxify OH, ONOO-, NO and peroxy radicals directly by electron donation, stimulate the activities of scavenger enzymes, including glutathione peroxidase (GPx), superoxide dismutase (SOD) and catalase (CAT), and protect these proteins from inactivation by the above-mentioned radicals<sup>[11, 16-18]</sup>. The inhibition of nitrogen monoxide synthase (NOS) by melatonin leads to a reduction in the amount of NO generated<sup>[19, 20]</sup>. Moreover, melatonin exerts an anti-inflammatory effect by inhibiting nuclear factor kappa B (NF- $\kappa$ B)<sup>[21]</sup>, a transcription factor with a central role in the development of inflammatory diseases. By blocking the activation of NF- $\kappa$ B, melatonin depresses the synthesis of inflammatory cytokines such as interleukin-6 (IL-6), tumor necrosis factor-alpha (TNF-alpha) and adhesion molecules.

The protective effects of melatonin have been documented in experimental models of numerous diseases where oxidative damage is a component. In the central nervous system, melatonin is protective in experimental models of stroke, Alzheimer, Parkinson and Huntington diseases, and fetal brain injury, and improves the outcome of hypoxia/reperfusion-induced heart, liver, retina and gut injuries<sup>[22-27]</sup>. Melatonin additionally contributes to the improvement of inflammatory diseases, including endotoxic and circulatory shock<sup>[23, 28]</sup>.

In an earlier study, Qi and colleagues<sup>[29]</sup> showed that in mild cerulein-induced edematous pancreatitis pharmacological doses of melatonin protect against the injury caused by FRs. Melatonin decreased the edema in the pancreas and stomach, and also the extent of lipid peroxidation in the pancreas. Jaworek *et al*<sup>[30]</sup> demonstrated that even the circadian changes in physiological levels of melatonin reduce the severity of experimental pancreatitis<sup>[30]</sup>.

L-Arg-induced pancreatitis is an experimental model of severe necrotizing acute pancreatitis. Twenty-four h after intraperitoneal (i.p.) injection of L-Arg, inflammation of the tissue is confirmed by histology and characteristic changes of the laboratory parameters. The model is highly reproducible, noninvasive and produces dose-dependent acinar necrosis, and is therefore ideal for studying the pathogenesis of acute pancreatitis<sup>[31-35]</sup>.

The protective effect of melatonin in severe L-Arg-induced pancreatitis in rats has not been investigated to date. We hypothesized that administration of pharmacological doses of melatonin might improve the outcome of L-Arg-induced necrotizing pancreatitis in rats. To test this, we measured a variety of parameters related to pancreatic damage by L-Arg when melatonin was given before or after L-Arg.

Table 1 Agents used in the 5 groups of rats

Group	Time: 0 h	Time: 0,5 h	Time: 1,5 h	Time: 2,5 h	Time: 25,5 h
C	P.s. 1 mL	P.s. 1 mL	P.s. 1 mL		exsanguination
A	P.s. 1 mL	Arginine 3.2 g/kg	Arginine 3.2 g/kg		exsanguination
AM	Arginine 3,2 g/kg	Arginine 3.2 g/kg		Melatonin 50 mg/kg	exsanguination
MA	Melatonin 50 mg/kg	Arginine 3.2 g/kg	Arginine 3.2 g/kg		exsanguination
M	Melatonin 50 mg/kg	P.s. 1 mL	P.s. 1 mL		exsanguination

## MATERIALS AND METHODS

### Experimental protocol

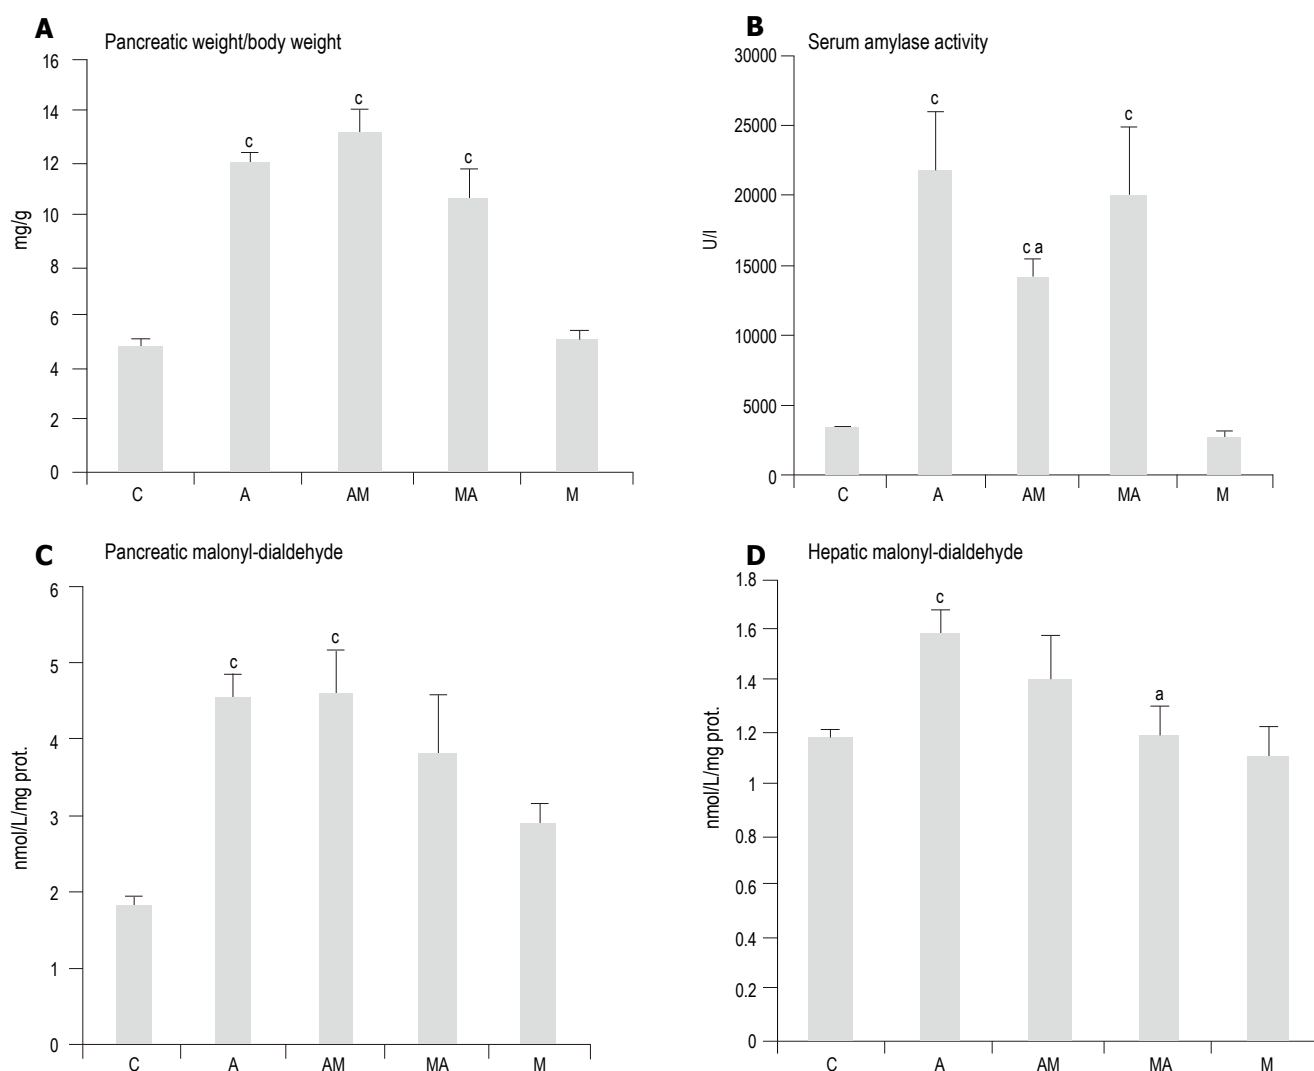

Male Wistar rats (weighing 200-250 g) were kept at constant room temperature (25°C) in a 12h light-dark cycle with free access to water and standard laboratory chow (Biofarm, Zagyvaszárszó, Hungary). The study was approved by the Ethical Committee on Animal Experiments at the University of Szeged.

After one week of acclimatization, the rats were divided into five groups ( $n=5$  per group). In group A, pancreatitis was induced with 3.2 g/kg body weight L-Arg (Sigma-Aldrich, Budapest, Hungary) i.p. twice at an interval of 1 h. Rats in group MA were treated with a single dose of 50 mg/kg body weight melatonin (Helsinn, Biasca, Switzerland) i.p. 30 min prior to L-Arg administration. Rats in group AM received the same dose of melatonin 1 h after the second injection of L-Arg. In group M, a single dose of melatonin was administered. Rats in group C served as control animals and received i.p. injections of physiological saline. Twenty-four h after the last L-Arg injection, the rats were anesthetized with 44 mg/kg pentobarbital (Sanofi Phylaxia, Budapest, Hungary) and exsanguinated through the abdominal aorta. The pancreas, liver and lungs were quickly removed and frozen at -70°C until use (Table 1).

### Assays

The pancreatic weight/body weight ratio was evaluated as an estimate of the degree of pancreatic edema. For serum amylase activity, blood samples were centrifuged for 20 min at 2500 r/min. Serum amylase activities were determined by a colorimetric kinetic method (Dialab, Vienna, Austria). Concentration of the lipid peroxidation marker malonyl dialdehyde (MDA) was measured after the reaction with thiobarbituric acid as previously described<sup>[36]</sup>. Total SOD activity was determined on the basis of the inhibition of epinephrine-adenochrome autoxidation<sup>[37]</sup>. Mn-SOD activity was measured via the extent of autoxidation in the presence of  $5 \times 10^{-3}$  mol/L KCN<sup>[38]</sup>. Cu/Zn-SOD activity was obtained by deducting the Mn-SOD from the total SOD activity. CAT activity was determined spectrophotometrically at 240 nm by the method of Beers and Sizer<sup>[39]</sup> and expressed in Bergmeyer units (BU) (1 BU - decomposition of 1 g H<sub>2</sub>O<sub>2</sub>/min at 25°C). GPx activity was determined by the "chemical" method using cumene

**Figure 1** Effects of melatonin (50 mg/kg) treatment on the pancreatic weight/body weight ratio (p.w./b.w.) (A), serum amylase activity (B), amount of malonyl-dialdehyde in the pancreas (C) and liver (D) in L-arginine-induced (2 x 3.2 g/kg) acute pancreatitis. Means  $\pm$  SE of results on 5 animals in each group are shown. <sup>a</sup> $P < 0.05$  vs group A; <sup>c</sup> $P < 0.05$  vs group C.

hydroperoxide and reduced glutathione as substrates of GPx<sup>[40]</sup>. Total glutathione (GSH) was measured spectrophotometrically with Ellman's reagent<sup>[41]</sup>. The level of leukocyte infiltration into the tissue was quantified by measurement of pancreatic myeloperoxidase (MPO) activities by the method of Kuebler *et al*<sup>[42]</sup>.

### Preparation of cytosolic fraction

The cytosolic and nuclear fractions were separated by the method of Dignam *et al*<sup>[43]</sup>. In brief, 250-300 mg of pancreatic tissue was lysed on ice in a hypotonic buffer in a Dounce homogenizer. The buffer contained 10 mmol/L HEPES (pH 7.9), 1.5 mmol/L MgCl<sub>2</sub> 10 mmol/L KCl and was supplemented before use with 1mmol/L phenylmethylsulfonyl fluoride, 4 mmol/L benzamidine, 100 IU/mL aprotinin and 1 mmol/L dithiothreitol (DTT). After incubation for 25 min on ice, Nonidet P-40 was added to a final concentration of 0.3-0.4% (v/v). The samples were vortexed and incubated on ice for 2 min. The homogenates were centrifuged at 13000 r/min for 50 s and the supernatants (cytosolic fraction) were collected for determination of protein and IL-6 concentrations.

### Pancreatic cytokine concentration

Pancreatic IL-6 concentration in the cytosolic fraction was measured with an ELISA kit (Bender Medsystem, Vienna, Austria) according to the manufacturer's instructions and corrected for the protein content of the tissue. Protein concentration in the tissues was determined by the method of Lowry *et al*<sup>[44]</sup>.

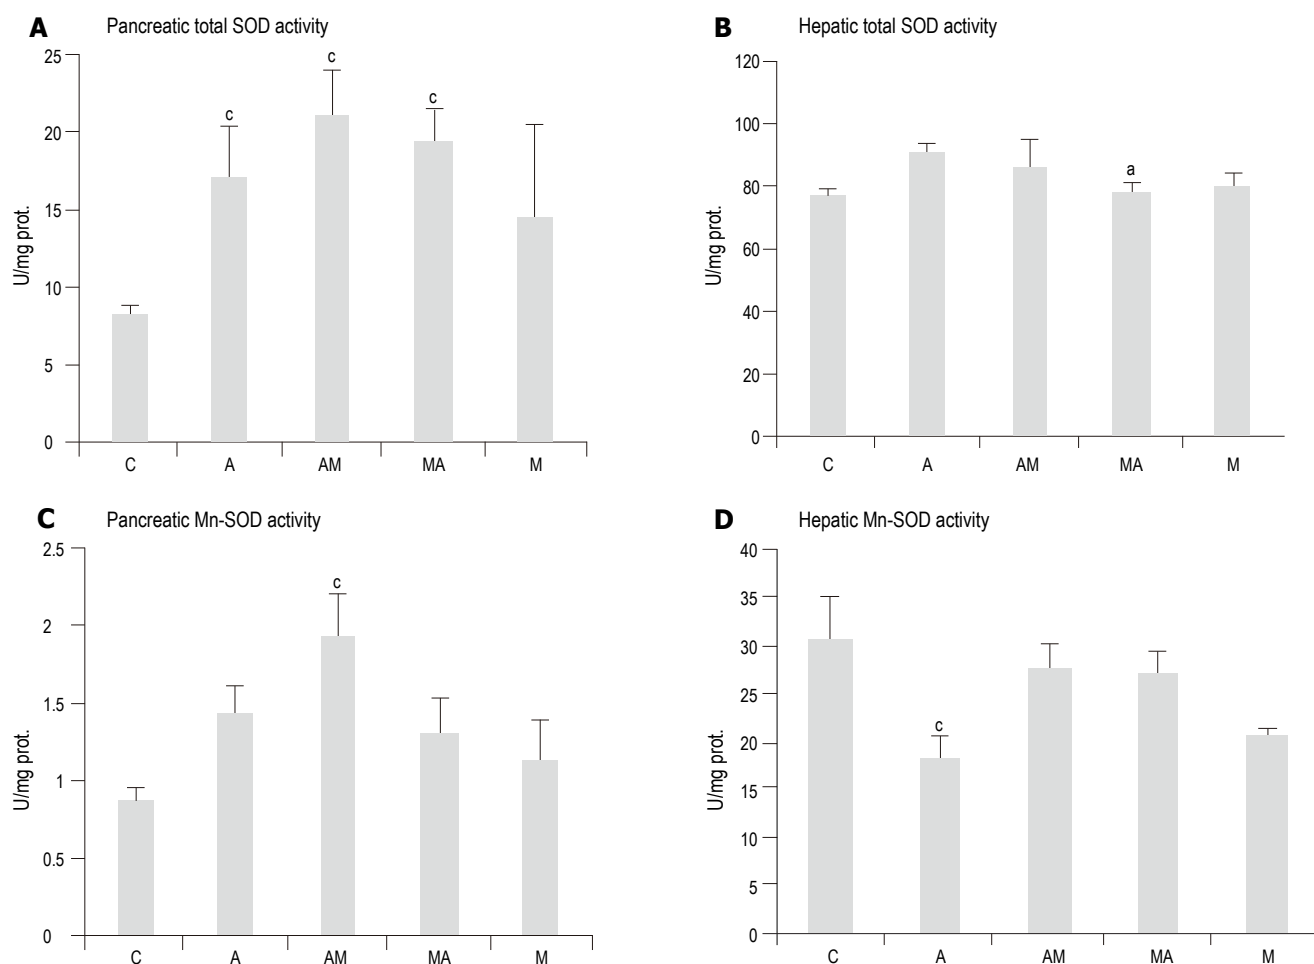

### Histological examination

A portion of the pancreas was fixed in 8% neutral formaldehyde solution and embedded in paraffin. Tissue slices were stained with hematoxylin and eosin and examined under light microscope. Slices were coded and examined blind by a pathologist for the grading of histological alterations.

### Statistical analysis

One-way ANOVA and LSD *post hoc* analysis were performed to test for significant differences among the five experimental groups. Results were expressed as mean  $\pm$  SE.  $P < 0.05$  was considered statistically significant.

**Figure 2** Effects of melatonin (50 mg/kg) treatment on the total SOD and Mn-SOD activities of the pancreas (A, C) and liver (B, D) in L-arginine-induced (2 x 3.2 g/kg) acute pancreatitis. Means  $\pm$  SE of results on 5 animals in each group are shown. \* $P < 0.05$  vs group A; <sup>c</sup> $P < 0.05$  vs group C.

## RESULTS

Melatonin treatment alone caused no significant alterations in the measured parameters as compared to those in the control rats.

The pancreatic weight/body weight ratio was significantly higher in the L-Arg-treated rats than in the control group. Melatonin given before or after L-Arg, did not influence the degree of edema (Figure 1A).

The serum amylase activity in all L-Arg-injected rats was significantly elevated relative to the control. Melatonin posttreatment significantly reduced the amylase activity as compared to the treatment only with L-Arg (Figure 1B).

The concentration of lipid peroxidation product MDA in the pancreas was increased in the rats treated with L-Arg or with L-Arg followed by melatonin. When melatonin was given before L-Arg, the MDA level was not significantly changed compared to that in the control group (Figure 1C). The amount of MDA in the liver of animals given L-Arg was significantly increased compared to that in the control group. Melatonin pretreatment significantly reduced the concentration of the lipid peroxidation product (Figure 1D).

The pancreatic total SOD activity was significantly increased as a result of L-Arg administration and the effect was not modified by pre- or post-treatment with melatonin

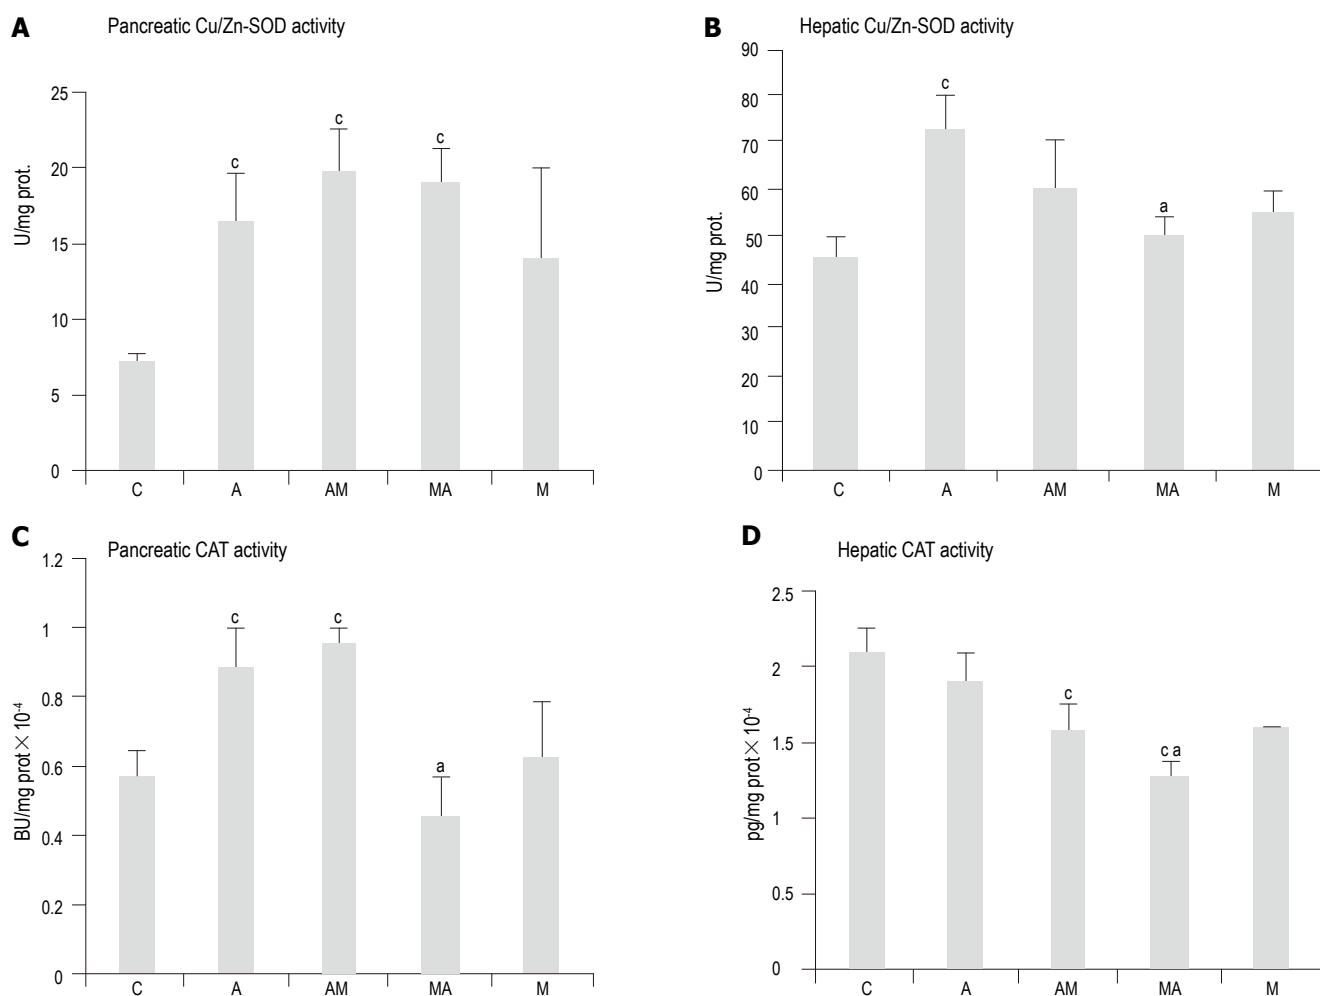

(Figure 2A). The hepatic total SOD activities in the L-Arg-treated groups were not significantly different from those in the control rats, but the L-Arg-treated rats having previously received melatonin exhibited a significantly lower SOD activity than those injected only with L-Arg (Figure 2B).

Relative to the level in the control rats, the pancreatic Mn-SOD activity was significantly elevated in animals given L-Arg followed by melatonin (Figure 2C). The Mn-SOD activity in the liver was significantly decreased as a consequence of L-Arg injections. Melatonin given before or after L-Arg prevented the reduction of Mn-SOD activity (Figure 2D).

As compared to the levels in the control rats, the pancreatic Cu/Zn-SOD activities were significantly elevated in all L-Arg-treated groups (Figure 3A). Relative to the control levels, the hepatic Cu/Zn-SOD activity was significantly increased in rats that received only L-Arg, this change was prevented by melatonin given before or after the L-Arg injections (Figure 3B).

The pancreatic CAT activity was significantly increased in the rats given only L-Arg injections and also in those given L-Arg followed by melatonin, relative to that in the control rats. However, in the rats pretreated with melatonin the changes in CAT activity were prevented (Figure 3C). As compared to the level in the control rats, the hepatic

**Figure 3** Effects of melatonin (50 mg/kg) treatment on the Cu/Zn-SOD and CAT activities of the pancreas (A, C) and liver (B, D) in L-arginine-induced (2 x 3.2 g/kg) acute pancreatitis. Means  $\pm$  SE of results on 5 animals in each group are shown. \* $P < 0.05$  vs group A; <sup>c</sup> $P < 0.05$  vs group C.

CAT activities were significantly reduced in the rats treated with melatonin before or after L-Arg, whereas in the rats given only L-Arg the CAT activity was unchanged (Figure 3D).

The pancreatic GSH level was not significantly influenced by any of the treatments (Figure 4A). GPx activity was not detectable in the pancreas of the rats in this study. In comparison with the level in the control rats, hepatic GPx activities were significantly elevated in the rats treated only with L-Arg and in the rats given melatonin following L-Arg, but not in the rats pretreated with melatonin (Figure 4B).

The pancreatic MPO activity was significantly increased in the L-Arg-treated rats compared to that in the control rats. This response was reduced by melatonin given before or after L-Arg injections (Figure 4C).

Relative to the level in the control rats, the pancreatic IL-6 concentration was significantly elevated in the L-Arg-injected animals (Figure 4D).

Histological investigation confirmed the development of severe necrotizing pancreatitis in all rats given L-Arg, with no discernible differences between the groups.

## DISCUSSION

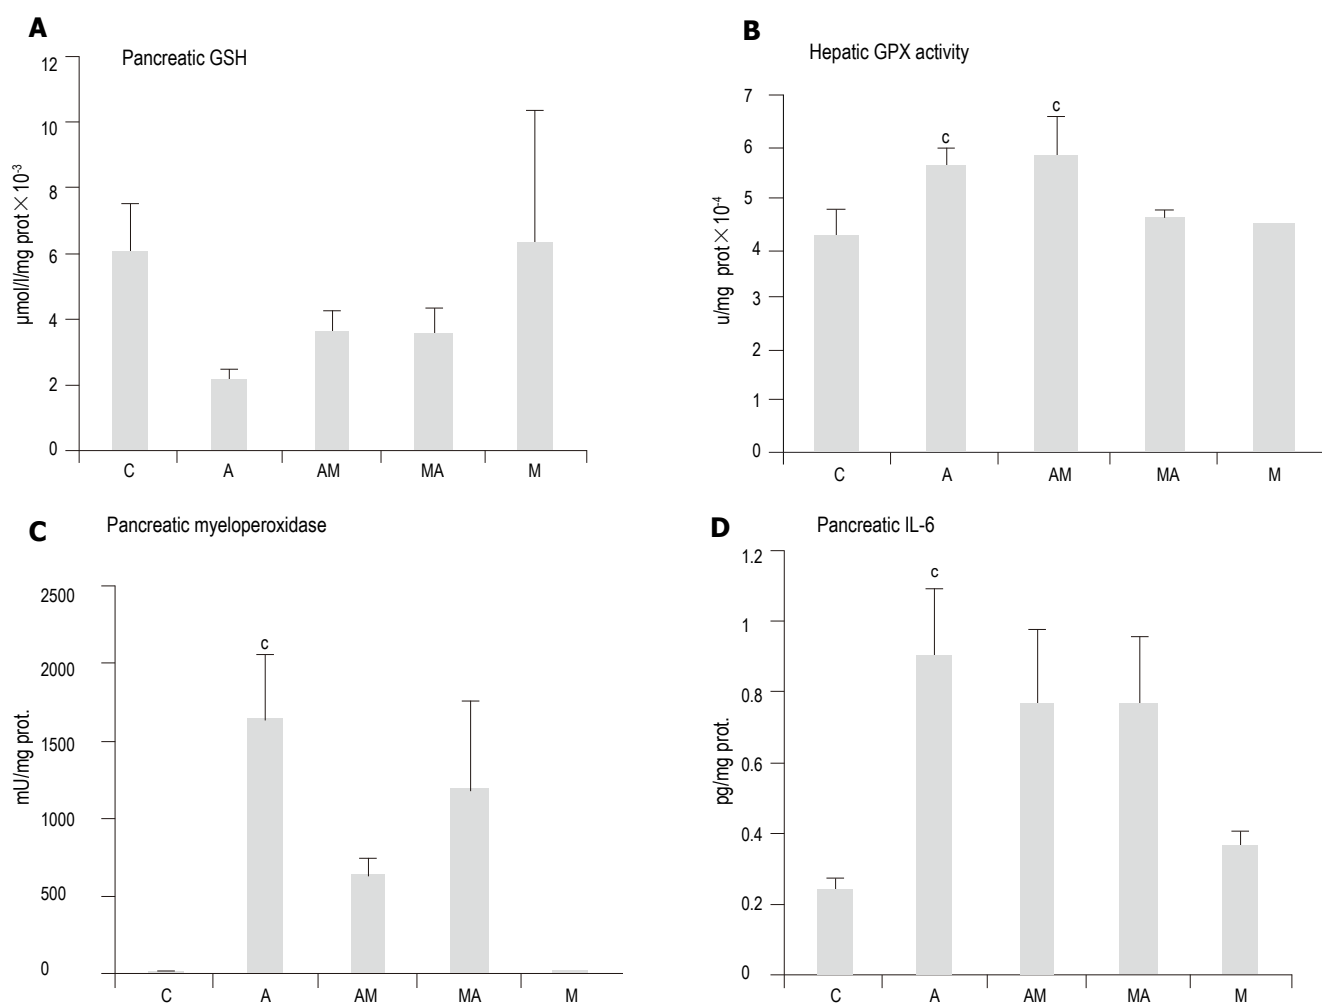

This study demonstrated the antioxidant effect of

melatonin during L-Arg-induced severe necrotizing pancreatitis. The dose of 50 mg/kg melatonin was chosen according to literary data and a pilot-study investigating the effect of different doses of melatonin on the pancreatic weight/body weight ratio and the serum amylase activity [22,28-29]. In contrast to Qi and colleagues who used repeated injections of melatonin, we could detect the beneficial effect of the drug after administration of a single dose in the same order of magnitude [29]. Melatonin beneficially influenced the serum amylase activity, the free radical scavenger enzyme activity in the liver and pancreas as well as the lipid peroxidation level in the liver.

L-Arg-induced pancreatitis is a slowly-developing experimental model in which characteristic laboratory changes are observed 24 h after induction of the disease. By this time, administration of high doses of L-Arg can cause severe necrotizing pancreatitis, as observed in the current study and confirmed by the significant elevation of the serum amylase activity, edema of the pancreas and the increased level of lipid peroxidation marker MDA. The significantly higher MPO activity and the increased amount of pro-inflammatory cytokine IL-6 in the pancreas document the initiation of an inflammatory process in the pancreas.

Elevation of the serum amylase activity is one of the characteristic parameters of acute pancreatitis. The activ-

**Figure 4** Effects of melatonin (50 mg/kg) treatment on the pancreatic GSH content (A), liver GPx activity (B), pancreatic myeloperoxidase activity (C) and pancreatic IL-6 content (D) in L-arginine-induced (2 × 3.2 g/kg) acute pancreatitis. Means ± SE of results on 5 animals in each group are shown. \*P < 0.05 vs group A; °P < 0.05 vs group C.

ity of this enzyme begins to rise 12 h after administration of L-Arg and peaks at around 24 h. At this point, the level of serum amylase activity correlates with the severity of acinar destruction. In our experiment administration of melatonin following the induction of pancreatitis can significantly reduce the activity of this enzyme in serum.

Infiltrating leukocytes and mediators released by these cells are known to play a pivotal role in the amplification of the inflammatory process. One of the inflammatory cytokines that is important in the development of L-Arg-induced pancreatitis is IL-6. In the present study, the level of IL-6 and the MPO activity proved to be significantly elevated in the L-Arg-treated rats. However, the previously reported anti-inflammatory effect of melatonin could not be clearly demonstrated in severe necrotizing pancreatitis [45].

Lipid peroxidation in the pancreas and distant organs is a process mediated by free radicals. Detection of these radicals is difficult because of their high reactivity and short half-life. Accordingly, we measured the activities of free radical scavengers and the degree of lipid peroxidation in order to assess the extent of free radical damage during this inflammatory process. In our experimental setting we did not focus on the detection of early events of acute pancreatitis, such as decreased scavenger enzyme activities

and enzyme-activating effects of melatonin, which took place during the first 6-12 h of the disease. We rather wanted to demonstrate the long-lasting effect of a single dose of melatonin on the fully developed illness.

The current study revealed that melatonin pretreatment significantly attenuated the lipid peroxidation in the liver of the rats. Changes in Cu/Zn-SOD, Mn-SOD and GPx activities in the liver were reduced by melatonin, whereas in the pancreas the beneficial effect was less pronounced and manifested only in the changes of CAT activity. In the pancreas, H<sub>2</sub>O<sub>2</sub> generated by SOD can serve as a substrate of GPx or CAT. This explains the CAT activity elevation and the lack of GPx activity in the pancreas. The differences observed between the examined organs can be explained by the fact that the basal activities of scavenger enzymes are 10-fold higher in the liver than in the pancreas. The antioxidant effect of melatonin is therefore easier to demonstrate in the liver of animals. These differences in scavenger activities explain why melatonin pretreatment can reduce the lipid peroxidation in the liver, but not in the pancreas. The low scavenger activities are probably one reason for the high mortality associated with acute pancreatitis.

In conclusion, melatonin is able to counteract some of the L-Arg-induced changes in laboratory parameters of

acute pancreatitis. Even a single injection of melatonin can beneficially influence serum amylase activity and lipid peroxidation level in the liver, but can not prevent histological damage to the pancreas. Since melatonin has a very short half-life, repeated injections or continuous infusion may be necessary to develop its full effect. Multiple organ failure is the main reason for pancreatitis-associated mortality. As melatonin reduces hepatic damage caused by L-Arg, it is possible that continuous infusion of the substance may be beneficial in preventing multiple organ damage as a complication of acute necrotizing pancreatitis.

## Abstract

**AIM:** To investigate the role of oxidative injury in pancreatitis-induced hepatic damage and the effect of antioxidant agents such as melatonin, ascorbic acid and *N*-acetyl cysteine on caerulein-induced pancreatitis and associated liver injury in rats.

**METHODS:** Thirty-eight female Wistar rats were used. Acute pancreatitis (AP) was induced by two i.p. injections of caerulein at 2-h intervals (at a total dose of 100 µg/kg b.wt). The other two groups received additional melatonin (20 mg/kg b.wt) or an antioxidant mixture containing L(+)-ascorbic acid (14.3 mg/kg b.wt.) and *N*-acetyl cysteine (181 mg/kg b.wt.) i.p. shortly before each injection of caerulein. The rats were sacrificed by decapitation 12 h after the last injection of caerulein. Pancreatic and hepatic oxidative stress markers were evaluated by changes in the amount of lipid peroxides measured as malondialdehyde (MDA) and changes in tissue antioxidant enzyme levels, catalase (CAT) and glutathione peroxidase (GPx). Histopathological examination was performed using scoring systems.

**RESULTS:** The degree of hepatic cell degeneration, intracellular vacuolization, vascular congestion, sinusoidal dilatation and inflammatory infiltration showed a significant difference between caerulein and caerulein+melatonin ( $P=0.001$ ), and caerulein and caerulein+L(+)-ascorbic acid+*N*-acetyl cysteine groups ( $P=0.002$ ). The degree of acinar cell degeneration, pancreatic edema, intracellular vacuolization and inflammatory infiltration showed a significant difference between caerulein and

caerulein+melatonin ( $P=0.004$ ), and caerulein and caerulein+L(+)-ascorbic acid+*N*-acetyl cysteine groups ( $P=0.002$ ). Caerulein-induced pancreatic and liver damage was accompanied with a significant increase in tissue MDA levels ( $P=0.01$ ,  $P=0.003$ , respectively) whereas a significant decrease in CAT ( $P=0.002$ ,  $P=0.003$ , respectively) and GPx activities ( $P=0.002$ ,  $P=0.03$ , respectively). Melatonin and L(+)-ascorbic acid+*N*-acetyl cysteine administration significantly decreased MDA levels in pancreas ( $P=0.03$ ,  $P=0.002$ , respectively) and liver ( $P=0.007$ ,  $P=0.01$ , respectively). Administration of these agents increased pancreatic and hepatic CAT and GPx activities. Melatonin significantly increased pancreatic and hepatic CAT ( $P=0.002$ ,  $P=0.001$ , respectively) and GPx activities ( $P=0.002$ ,  $P=0.001$ ). Additionally, L(+)-ascorbic acid+*N*-acetyl cysteine significantly increased pancreatic GPx ( $P=0.002$ ) and hepatic CAT and GPx activities ( $P=0.001$ ,  $P=0.007$ , respectively).

**CONCLUSION:** Oxidative injury plays an important role not only in the pathogenesis of AP but also in pancreatitis-induced hepatic damage. Antioxidant agents such as melatonin and ascorbic acid+*N*-acetyl cysteine, are capable of limiting pancreatic and hepatic damage produced during AP via restoring tissue antioxidant enzyme activities.

## INTRODUCTION

Acute pancreatitis (AP) is an inflammatory disease characterized by tissue edema, acinar necrosis, hemorrhage and fat necrosis as well as inflammation and perivascular infiltration in the pancreas<sup>[1,2]</sup>. In experimental pancreatitis induced by supramaximal doses of the cholecystokinin (CCK) analogue, caerulein, the secretory block is subse-

quently followed by lysosomal degradation of intercellular organelles within autophagic vacuoles in acinar cells and a marked interstitial edema<sup>[3-6]</sup>. AP is usually considered as an autodigestive disease, in which in addition to premature intracellular protease activation<sup>[7]</sup>, other mechanisms such as oxidative stress have also been shown to be involved in the development of AP<sup>[6,8-11]</sup>.

AP is a multi-system disease with alterations not only in the pancreas but also in liver, lungs and kidneys, which may lead to distant organ dysfunction and death<sup>[12,13]</sup>. The liver is a critical organ for metabolic homeostasis and toxic substance clearance and plays an important role in the systemic response to critical illness<sup>[14]</sup>. Recently, a number of studies have suggested that pancreatitis-associated ascitic fluid (PAAF) plays a critical role in inducing hepatocyte injury by inducing hepatocyte apoptosis<sup>[14-16]</sup>. PAAF induces liver injury by direct hepatocyte injury and death independent from locally produced Kupffer-cell-derived cytokines and PAAF-induced liver injury is mediated by heat-stable factors other than pancreatic enzymes<sup>[16]</sup>. Though the role of oxidative stress in AP has been studied in several animal models<sup>[2,6,11,17]</sup> and in humans<sup>[18]</sup>, few data are available regarding AP-induced hepatic oxidative stress<sup>[19]</sup>.

Previous reports have indicated that antioxidant agents such as melatonin, retinol, ascorbic acid and *N*-acetyl cysteine have beneficial effects in the treatment of caerulein-induced AP<sup>[18,20-22]</sup>. This study was undertaken to examine the role of oxidative stress in the pathogenesis of AP and AP-induced hepatic damage as well as the protective effect of antioxidant agents against caerulein-induced pancreatic and liver injury.

## MATERIALS AND METHODS

### *Animals and experimental protocol*

Thirty-eight female Wistar rats weighing 280-350 g were used. Animals were fed with standard rat chow and tap water *ad libitum*. They were maintained in a 12 h light/12 h dark cycle at 21°C.

AP was induced by two i.p. injections of caerulein (Sigma-Aldrich Co., Taufkirchen, Germany) at a total dose of 100 µg/kg b.wt. at 2-h intervals, each injection containing 50 % of the dose. A control group received four i.p. injections of 0.9% saline at 2-h intervals. To evaluate the effect of antioxidant agents, the rats were divided into two additional groups. One group was treated with caerulein (100 µg/kg b.wt) and melatonin (Sigma, St Louis, MO, USA) (20 mg/kg b.wt) and the other group was treated with the same dose of caerulein and an antioxidant mixture containing L(+)-ascorbic acid (Mallinckrodt Baker B.V., Deventer, Holland) (14.3 mg/kg b.wt.) and *N*-acetyl cysteine (Sigma, St. Louis MO, USA) (181 mg/kg b.wt.). Melatonin was dissolved in absolute ethanol and further diluted in saline, with 1 % final concentration of ethanol. Therapeutic agents were administered i.p. shortly before each injection of caerulein. The rats were sacrificed by decapitation 12 h after the last injection of caerulein.

For light microscopy, pieces from central part of the pancreas and right lobe of the liver were rapidly removed and divided into two pieces. The first part of

tissue samples was placed in 10% buffered formalin and prepared for routine paraffin embedding. The other part of tissue samples was stored at -80°C for determination of MDA, GPx and CAT.

Animal experiments were performed in accordance with the guidelines for animal research from the National Institute of Health and approved by the Committee of Animal Research at Inonu University, Malatya, Turkey.

### *Histological examination*

Five-µm thick sections of tissues were cut, mounted on slides, stained with hematoxylin-eosin (H-E) and examined under a Lyca DFC280 light microscope by Leica Q Win and Image Analysis System (Leica Micros Imaging Solutions Ltd.; Cambridge, U.K). Assessment of tissue alterations in 20 different fields for each section was conducted by an experienced histologist who was unaware of the treatment. Pancreatic damage was scored by grading acinar cell degeneration, interstitial inflammation, edema and hemorrhage with a maximum score of 12. Schmidt's standards<sup>[1]</sup> were modified as follows. Grading for edema was scaled as 0: absent or rare; 1: edema in the interlobular space; 2: edema in the intralobular space; 3: isolated-island shape of pancreatic acinus. Inflammation was scored as 0: absent; 1: mild; 2: moderate; 3: severe. Acinar cell degeneration was scaled as 0: absent; 1: focal (<5 %); 2: and/or sublobular (<20 %); 3: and/or lobular (>20 %). Parenchyma hemorrhage was scored as 0: absent; 1: mild; 2: moderate; 3: severe. Hepatic damage was scored (0 to 3) by grading hepatocyte necrosis, intracellular vacuolization, vascular congestion and sinusoidal dilatation. The maximum score for inflammatory infiltration was 12.

### *Biochemical determination*

After decapitation, the trunk blood was collected and centrifuged for measurements of serum aspartate aminotransferase (AST), alanine aminotransferase (ALT), lactic dehydrogenase (LDH), total and direct bilirubin. Amylase. Lipase levels were determined spectrophotometrically using an automated analyzer (Olympus AU 600, Diamond Diagnostic, Holliston, USA). All chemicals were obtained from Sigma (Sigma, St Louis MO, USA).

### *Preparation of tissue homogenates*

After being cut into small pieces on ice, tissues were homogenized in 1/5 (w/v) phosphate-buffered saline. Homogenates were divided into two portions. One part was directly used for immediate MDA measurement. The other part was sonicated four times for 30 s at 20 s intervals using a VWR Bronson scientific sonicator (VWR Int. Ltd. Merch House Pool, UK). Then, homogenates were centrifuged at 20000 g for 15 min in Beckman L8-70M ultracentrifuge (Rotor SW-28; Beckman L8-70M Ultracentrifuge, München, Germany). Supernatants were separated and kept at -40°C for enzyme activity measurement. Care was taken to keep the temperature at -4°C throughout the preparation of homogenates and supernatants.

### *Determination of protein concentration*

Protein determination in supernatants was done according to Lowry and Rosebrough<sup>[23]</sup> using BSA as standard. A

**Figure 1** Histopathological changes in pancreatic and hepatic specimens

**A:** Obvious acinar cell degeneration, edema and inflammation in caerulein group.

**B:** Acinar cell degeneration and fat necrosis in caerulein group.

**C:** Hepatocyte necrosis, vascular congestion, sinusoidal dilatation and inflammatory infiltration in caerulein group.

**D:** Prominent intracellular vacuolization in hepatic specimens from caerulein group.

**Table 1** Scores for pancreatic and hepatic damage in different groups (mean  $\pm$  SE)

Group	Scores for pancreatic damage	Scores for hepatic damage
Control	0.00 $\pm$ 0.00	0.00 $\pm$ 0.00
Caerulein	6.16 $\pm$ 0.67 <sup>a</sup>	6.28 $\pm$ 0.56 <sup>a</sup>
Caerulein + melatonin	2.14 $\pm$ 0.70 <sup>c</sup>	1.14 $\pm$ 0.26 <sup>c</sup>
Caerulein + antioxidant mixture	1.85 $\pm$ 0.45 <sup>c</sup>	1.42 $\pm$ 0.36 <sup>c</sup>

<sup>a</sup> $P < 0.005$  vs control; <sup>c</sup> $P < 0.005$  vs caerulein.

Shimadzu 1601 UV/VIS spectrophotometer (Shimadzu, Kiyoto, Japan) with a connected PC and a Grand LTD 6G thermo stability unit adjusted to  $37 \pm 0.1^\circ\text{C}$  was employed for all spectrophotometric assays.

#### Assay of CAT activity

CAT activity was measured in supernatants by the method of Luck<sup>[24]</sup>. The decomposition of the substrate  $\text{H}_2\text{O}_2$  was monitored spectrophotometrically at 240 nm. Specific activity was defined as micromole substrate decomposed per minute per milligram of protein (i.e. U/mg protein). CAT levels were expressed as a micromole per milligram of protein (U/mg/protein).

#### Assay of GPx activity

GPx activity was measured according to Lawrence and Burk<sup>[25]</sup>. In brief, 1.0 mL of 50 nmol/L PBS solution (pH 7.4) including 5 mmol/L EDTA, 2  $\mu\text{mol/L}$  NADPH, 20  $\mu\text{mol/L}$  GSH, 10  $\mu\text{mol/L}$   $\text{NaN}_3$  and 23 mU of glutathione reductase was incubated at  $37^\circ\text{C}$  for 5 min. Then 20  $\mu\text{L}$  of 0.25 mmol/L  $\text{H}_2\text{O}_2$  solution and 10  $\mu\text{L}$  of supernatant were added to the assay mixture. The change in absorbance at 340 nm was monitored for 1 min. A blank with all ingredients except for supernatants was also monitored. Specific activity was calculated as micromole NADPH consumed

per minute per milligram of protein (i.e. U/mg protein) using an appropriate molar absorptivity coefficient ( $6220 \text{ M}^{-1} \text{ cm}^{-1}$ ). GPx levels were expressed as a micromole per milligram of protein (U/mg protein).

#### Measurement of tissue MDA levels

The level of MDA in tissue homogenate was determined using the method of Uchiyama and Mihara<sup>[26]</sup>. Half a milliliter of homogenate was mixed with 3 mL  $\text{H}_3\text{PO}_4$  solution (1 % v/v) followed by addition of 1 mL thiobarbituric acid solution (0.67 % w/v). Then the mixture was heated in water bath for 45 min. The colored complex was extracted into n-butanol and absorption at 532 nm was measured using tetramethoxypropane as standard. MDA levels were expressed as a nanomol per milligram of protein (nm/mg protein).

#### Statistical analysis

Statistical analysis was carried out using the SPSS 10.0 statistical program (SPSS Inc., Chicago, IL, USA). All data were expressed as mean  $\pm$  SE. For the analysis of histological scores and enzyme levels Mann Whitney-U test and *t* test were used.  $P < 0.05$  was considered statistically significant.

## RESULTS

All animals survived until the end of the experiment. Animals from control group presented no histological alterations. The pancreatic specimens from the caerulein treated group showed some histopathological changes such as acinar cell degeneration, edema and inflammation (Figure 1A, Figure 1B). The liver specimens from this group also showed histopathological alterations such as hepatocyte necrosis and intracellular vacuolization vascular congestion, sinusoidal dilatation and inflammatory infiltration (Figure 1C, Figure 1D). Histopathological scores of the groups are summarized in Table 1. In the groups treated

**Figure 2** Histopathological evidence of pancreatic and hepatic damage

**A:** Normal histological appearance except for minimal infiltration in caerulein + melatonin group.

**B:** Normal histological appearance except for minimal edema in caerulein + L(+)-ascorbic acid + N-acetyl cysteine group.

**C:** Normal histological appearance in caerulein + melatonin group.

**D:** Two small areas of necrosis and cell infiltration in caerulein + L(+)-ascorbic acid + N-acetyl cysteine group.

**Table 2** MDA, CAT and after treatment GPx levels in pancreatic tissues of different groups after treatment (mean  $\pm$  SE)

Groups	MDA (nmol/mg pr)	CAT (U/mg pr)	GPx (U/mg pr)
Control	1.74 $\pm$ 0.23	10.29 $\pm$ 0.68	0.59 $\pm$ 0.05
Caerulein	2.63 $\pm$ 0.22 <sup>a</sup>	2.78 $\pm$ 0.28 <sup>b</sup>	0.10 $\pm$ 0.00 <sup>b</sup>
Caerulein + melatonin	1.90 $\pm$ 0.17 <sup>c</sup>	15.63 $\pm$ 0.67 <sup>e</sup>	1.72 $\pm$ 0.29 <sup>e</sup>
Caerulein + antioxidant mixture	1.30 $\pm$ 0.15 <sup>e</sup>	7.02 $\pm$ 1.84	1.15 $\pm$ 0.18

<sup>a</sup> $P < 0.05$  vs control; <sup>c</sup> $P < 0.05$  vs caerulein; <sup>e</sup> $P < 0.005$  vs caerulein; <sup>b</sup> $P < 0.005$  vs control.

with caerulein+melatonin and caerulein + L(+)-ascorbic acid + N-acetyl cysteine, histopathological evidence of pancreatic and hepatic damage was markedly reduced (Figure 2). The degree of hepatic cell degeneration, intracellular vacuolization, vascular congestion, sinusoidal dilatation and inflammatory infiltration showed a significant difference between groups treated with caerulein and caerulein + melatonin ( $P = 0.001$ ), caerulein and caerulein + L(+)-ascorbic acid + N-acetyl cysteine ( $P = 0.002$ ). The degree of acinar cell degeneration, pancreatic edema, intracellular vacuolization and inflammatory infiltration showed a significant difference between groups treated with caerulein and caerulein + melatonin ( $P = 0.004$ ), caerulein and caerulein + L(+)-ascorbic acid + N-acetyl cysteine ( $P = 0.002$ ). Caerulein-induced pancreatitis and liver damage were accompanied with a significant increase in tissue MDA levels ( $P = 0.01$ ,  $P = 0.003$ , respectively) whereas a significant decrease in CAT ( $P = 0.002$ ,  $P = 0.003$ , respectively) and GPx activities ( $P = 0.002$ ,  $P = 0.03$ , respectively). MDA, CAT and GPx levels measured in pancreatic and hepatic tissues of all groups are summarized in Tables 2 and 3 respectively. Administration of melatonin and L(+)-ascorbic acid + N-acetyl cysteine significantly decreased

**Table 3** MDA, CAT and GPx levels in liver tissues of different groups after treatment (mean  $\pm$  SE)

Group	MDA (nmol/mg pr)	CAT (U/mg pr)	GPx (U/mg pr)
Control	7.00 $\pm$ 2.29	3.20 $\pm$ 0.83	0.72 $\pm$ 0.25
Caerulein	20.89 $\pm$ 10.13 <sup>a</sup>	1.09 $\pm$ 0.35 <sup>a</sup>	0.33 $\pm$ 0.09 <sup>b</sup>
	9.66 $\pm$ 3.65 <sup>c</sup>	3.69 $\pm$ 1.35 <sup>e</sup>	0.50 $\pm$ 0.12 <sup>c</sup>
Caerulein + antioxidant mixture	10.49 $\pm$ 3.03 <sup>c</sup>	3.12 $\pm$ 1.02 <sup>e</sup>	0.61 $\pm$ 0.26 <sup>c</sup>

<sup>a</sup> $P < 0.005$  vs control; <sup>c</sup> $P < 0.05$  vs caerulein; <sup>e</sup> $P < 0.005$  vs caerulein; <sup>b</sup> $P < 0.05$  vs control.

MDA levels in pancreas ( $P = 0.03$ ,  $P = 0.002$ , respectively) and liver ( $P = 0.007$ ,  $P = 0.01$ , respectively) while increased pancreatic and hepatic CAT and GPx activities. Melatonin significantly increased pancreatic and hepatic CAT ( $P = 0.002$ ,  $P = 0.001$ , respectively) and GPx activities ( $P = 0.002$ ,  $P = 0.001$ ). Additionally, L(+)-ascorbic acid + N-acetyl cysteine significantly increased pancreatic GPx ( $P = 0.002$ ) and hepatic CAT and GPx activities ( $P = 0.001$ ,  $P = 0.007$ , respectively).

Caerulein administration resulted in a significant increase in serum AST ( $P < 0.02$ ), ALT ( $P = 0.009$ ), LDH ( $P = 0.002$ ), total bilirubin ( $P = 0.001$ ), direct bilirubin ( $P = 0.001$ ), amylase ( $P = 0.02$ ) and lipase ( $P = 0.002$ ) levels (Tables 4 and 5). Both melatonin and ascorbic acid + N-acetyl cysteine reduced these levels. Ascorbic acid + N-acetyl cysteine caused a significant decrease in ALT level ( $P = 0.01$ ). Additional administration of melatonin and ascorbic acid + N-acetyl cysteine resulted in a significant decrease in both total and direct bilirubin ( $P = 0.001$ ).

## DISCUSSION

The present study was undertaken to confirm the role of reactive oxygen species (ROS) in the pathogenesis

**Table 4** AST, ALT, LDH, total and direct bilirubin levels in different groups after treatment (mean  $\pm$  SE)

Group	AST (U/L)	ALT (U/L)	LDH (U/L)	Total bilirubin (mg/dL)	Direct bilirubin (mg/dL)
Control	186.85 $\pm$ 19.5	53.71 $\pm$ 2.39	4088.43 $\pm$ 510.5	0.02 $\pm$ 0.02	0.01 $\pm$ 0.01

of caerulein-induced acute pancreatitis and pancreatitis-induced hepatic damage. The exact pathogenesis of AP is not fully understood, but a large body of evidence suggests that pancreatic damage depends upon the toxic effect of ROS<sup>[18,27]</sup>. However, few data are available regarding AP-induced hepatic oxidative stress<sup>[19]</sup>.

It is shown that acinar cells produce large amounts of ROS at early stage of AP in rats<sup>[17]</sup>. Highly reactive ROS directly attacks lipids, proteins in the biological membranes and cause their dysfunction<sup>[28]</sup>. Under normal conditions, a natural system of scavengers and antioxidants counteracts the cytotoxicity of ROS produced from molecular oxygen in the mitochondria. When the production of ROS is increased in AP by activated leukocytes, the capacity of intrinsic defense mechanism leads to alteration in cytoskeleton of acinar cells and damage of cell membranes<sup>[27]</sup>. Degradation of polyunsaturated fatty acids in cell membranes by ROS results in the destruction of membranes and formation of MDA, which is an indicator of ROS generation<sup>[29]</sup>. Disruption of the cytoskeleton leads to disturbance of intracellular transport of digestive enzymes and their premature activation and damage in acinar cells<sup>[30]</sup>. Large amounts of ROS and activated pancreatic enzymes leaked from the broken cells injure capillary endothelium. Increased capillary permeability contributes to edema<sup>[27]</sup>. It is suggested that PPAA contributes to hepatocyte injury by inducing hepatocyte apoptosis during AP. Barlas *et al*<sup>[19]</sup> reported that ROS plays an import role in the pathogenesis of pancreatitis-induced hepatic damage.

In this study we measured the levels of MDA, a product of lipid peroxidation, and endogenous scavengers CAT and GPx in pancreatic and hepatic tissues. Caerulein-induced pancreatitis and liver damage were accompanied with a significant increase in tissue MDA levels ( $P < 0.05$ )

whereas a significant decrease in CAT and GPx activities ( $P < 0.05$ ). These findings demonstrate that lipid peroxidation is not only dramatically enhanced within pancreatic tissue but also within hepatic tissue. Elevated MDA as an offense system and lowered CAT and GPx activities as a defense system play an important role in the development of pancreatic and liver injury.

Previous reports indicate that treatment with antioxidant agents such as melatonin<sup>[19,20,22]</sup>, N-acetylcysteine, ascorbic acid<sup>[21]</sup>, SOD, CAT and deferoxamine<sup>[31]</sup>, has beneficial effects on caerulein-induced AP. Melatonin can directly neutralize a number of free radicals and reactive oxygen and nitrogen species<sup>[32-34]</sup> and stimulate several antioxidative enzymes (superoxide dismutase, glutathione peroxidase)<sup>[32]</sup>. Free radical scavengers and antioxidants neutralize and/or metabolically remove reactive species from cells before they carry out their destructive activities<sup>[33]</sup>. While the antioxidative actions of most molecules are limited by their specific intercellular distribution, antioxidative actions of melatonin include the protection of lipids in cell membranes, proteins in cytosol and DNA in nuclei. Furthermore, melatonin can crossover all morphophysiological barriers and enter all cells in the organism<sup>[35]</sup>. In the present study, treatment with melatonin and N-acetylcysteine + ascorbic acid mixture significantly decreased histopathological damage score in both pancreas and liver. Additionally these therapies decreased tissue MDA levels but increased tissue CAT and GPx activities. Histopathological changes correlated with biochemical changes.

In conclusion, oxidative injury plays an important role not only in the pathogenesis of AP but also in pancreatitis-induced hepatic damage. Antioxidant agents such as melatonin and ascorbic acid + N-acetyl cysteine, are capable of limiting pancreatic and hepatic damage produced during AP *via* restoring tissue antioxidant enzyme activities.

### Abstract

**AIM:** To investigate the effects of *Reishi mushroom*, *Ganoderma lucidum* extract (GLE), on liver fibrosis induced by carbon tetrachloride (CCl<sub>4</sub>) in rats.

**METHODS:** Rat hepatic fibrosis was induced by CCl<sub>4</sub>. Forty Wistar rats were divided randomly into 4 groups: control, CCl<sub>4</sub>, and two GLE groups. Except for rats in control group, all rats were administered orally with CCl<sub>4</sub> (20%, 0.2 mL/100 g body weight) twice a week for 8 weeks. Rats in GLE groups were treated daily with GLE (1 600 or 600 mg/kg) via gastrogavage throughout the whole experimental period. Liver function parameters, such as ALT, AST, albumin, and albumin/globulin (A/G) ratio, spleen weight and hepatic amounts of protein, malondialdehyde (MDA) and hydroxyproline (HP) were determined. Histochemical staining of Sirius red was performed. Expression of transforming growth factor  $\beta$ 1 (TGF- $\beta$ 1), methionine adenosyltransferase (MAT1) 1A and MAT2A mRNA were detected by using RT-PCR.

**RESULTS:** CCl<sub>4</sub> caused liver fibrosis, featuring increase in plasma transaminases, hepatic MDA and HP contents, and spleen weight; and decrease in plasma albumin, A/G ratio and hepatic protein level. Compared with CCl<sub>4</sub> group, GLE (600, 1 600 mg/kg) treatment significantly increased plasma albumin level and A/G ratio ( $P < 0.05$ ) and reduced the hepatic HP content ( $P < 0.01$ ). GLE (1 600 mg/kg) treatment markedly decreased the activities of transaminases ( $P < 0.05$ ), spleen weight ( $P < 0.05$ ) and hepatic MDA content ( $P < 0.05$ ); but increased hepatic protein level ( $P < 0.05$ ). Liver histology in the GLE (1 600 mg/kg)-treated rats was also improved ( $P < 0.01$ ). RT-PCR analysis showed that GLE treatment decreased the expression of TGF- $\beta$ 1 ( $P < 0.05-0.001$ ) and changed the expression of MAT1A ( $P < 0.05-0.01$ ) and MAT2A ( $P < 0.05-0.001$ ).

**CONCLUSION:** Oral administration of GLE significantly reduces CCl<sub>4</sub>-induced hepatic fibrosis in rats, probably

by exerting a protective effect against hepatocellular necrosis by its free-radical scavenging ability.

### INTRODUCTION

Reishi mushroom, *Ganoderma lucidum* (Fr.) Krast (Polyporaceae), is a well-known Chinese crude drug used clinically in East Asia. The fruit bodies are used for the treatment of neurasthenia, deficiency fatigue, insomnia, bronchial cough in elderly people and carcinoma<sup>[1]</sup>.

A number of animal studies have indicated that water or ethanol extracts of *G. lucidum* showed protective actions against acute hepatitis in rats or mice<sup>[2-4]</sup>. Other reports had previously indicated that triterpenoids isolated from *G. lucidum* possessed the protective effect against acute hepatitis caused by CCl<sub>4</sub><sup>[5,6]</sup>. Furthermore, Park et al.<sup>[7]</sup> demonstrated that, in rats, polysaccharides extracted from *G. lucidum* could antagonize liver fibrosis caused by biliary obstruction. These results demonstrate that *G. lucidum* possesses a protective effect in the liver.

Liver fibrosis is the common end-stage of most chronic liver disease, regardless of etiology, and its progression leads to cirrhosis and liver cancer<sup>[8]</sup>. Although the exact mechanisms of pathogenesis in liver cirrhosis are still obscure, the role of free radicals and lipid peroxides has attracted considerable attention<sup>[9]</sup>. It has been found that metabolism of CCl<sub>4</sub> involves the production of free radicals through its activation by drug-metabolizing enzymes located in the endoplasmic reticulum<sup>[10]</sup>. CCl<sub>4</sub> is capable of causing liver lipid peroxidation, resulting in liver fibrosis<sup>[11]</sup>.

Data from *in vitro* and *in vivo* studies have indicated that *G. lucidum* has potent antioxidative and radical-scavenging effects<sup>[3,12-15]</sup>, which contribute to hepatoprotection<sup>[3,15]</sup>. Nevertheless, to our knowledge, no reports have recorded the effect of *G. lucidum* on chronic hepatitis. In the present study, we therefore investigated the effect of extracts

of *G. lucidum* on chronic CCl<sub>4</sub>-induced liver fibrosis.

## MATERIALS AND METHODS

### Preparation of test substance

Crude *G. lucidum* extract (GLE), which also contains cracked spores of *G. lucidum*, was obtained from the Taiwan branch of the American company NuSkin Pharmanex. GLE was suspended in distilled water and administered orally to each rat at a volume of 1 mL/100 g body weight. To guarantee reproducibility of pharmacological experiments, we assayed the total triterpene content of GLE.

### Determination of total triterpenes in GLE by HPLC

GLE (100 mg) was extracted with ethyl acetate and then evaporated to dryness under vacuum. The residue was dissolved in methanol and diluted to 2 mL. The sample solutions were filtered through a 0.45-μm filter before HPLC analysis as follows. HPLC instrument: Waters 2690 separation unit plus Waters 996 PDA; column: Phenomenex Luna C18(2); flow rate: 1.0 mL/min; detection: absorption at 252 nm; gradient solvent system: CH<sub>3</sub>CN+0.1% trifluoroacetic acid. The total peak area for a retention time of 8.0-38.0 min was used to calculate total triterpenes. The peak area of ganoderic acid A (Shanghai R&D, Pharmanex) was used as standard. This method showed that the total triterpene content of GLE was over 6%.

### Animals

Male Wistar rats were obtained from the National Laboratory Animal Breeding and Research Center, National Science Council, and fed with a standard laboratory diet and tap water *ad libitum*. Experimental animals were housed in an air-conditioned room at 22-25°C and a 12 h light/dark cycle. Rats were allowed free access to powdered feed and mains water that was supplied through an automatic watering system. When they reached 250-300 g, forty rats were divided randomly into 4 groups, such as control, model and two GLE treatment groups, according to body weight 1 d before administration of the test substance. All animals received humane care and the study protocols were in compliance with Institutional Guidelines for the use of laboratory animals.

### CCl<sub>4</sub>-induced liver fibrosis

Liver fibrosis was induced by oral administration of 0.2 mL/100 g body weight of CCl<sub>4</sub> (200 mL/L; diluted in olive oil) twice a week for 8 wk. Animals received CCl<sub>4</sub> only (model group), CCl<sub>4</sub> with GLE (600 or 1 600 mg/kg per day) throughout whole experimental period. During CCl<sub>4</sub> administration, the time interval between CCl<sub>4</sub> and GLE administration was at least 5 h to avoid disturbance in absorption of each substance. At the end of the experimental period, rats were sacrificed under ether anesthesia and blood was withdrawn from the abdominal artery. Liver and spleen were quickly removed, weighed after washing with cold normal saline and removing excess moisture. The largest lobe of liver was divided into four parts, which were then used as follows: (1) submerged

in 100 mL/L neutral formalin for the preparation of pathological sections; (2) frozen directly in liquid nitrogen for transcript analysis; (3) after weighing, the liver was completely dried at 100 °C for the determination of collagen content; and (4) remaining samples were stored at -80 °C as reserves.

### Assessment of liver functions

Whole blood was centrifuged at 4 700 r/min at 4 °C for 10 min to separate the plasma. Aspartate aminotransferase (AST) and alanine aminotransferase (ALT), albumin and total protein were determined spectrophotometrically with an automatic analyzer (Cobas Mira; Roche, Rotkreuz, Switzerland) using commercially available kits (Roche Diagnostics).

### Assays for hepatic protein, lipid peroxidation and hydroxyproline

Livers were homogenized in 9 vols ice-cold 0.15 mol/L KCl and 1.9 mmol/L ethylenediaminetetraacetic acid. Liver protein concentration was measured according to Lowry *et al*<sup>[16]</sup> using bovine serum albumin as standard. Lipid peroxidation was measured by the methods of Ohkawa *et al*<sup>[17]</sup> using 2-thiobarbituric acid. Lipid peroxidation was expressed as the amount of malondialdehyde/mg protein.

Hydroxyproline determination followed a method designed by Neuman and Logan<sup>[18]</sup>. After hydrolysis, dried liver tissue was oxidized by H<sub>2</sub>O<sub>2</sub> and colored by p-dimethylaminobenzoaldehyde; and absorbance was determined at 540 nm. The amount of hydroxyproline was expressed as μg/g tissue.

### RNA extraction and RT-PCR analysis

Total RNA was isolated from rat livers using the acid guanidium thiocyanate-phenol-chloroform extraction methods, as described by Chomczynski and Sacchi<sup>[19]</sup>. A total of 5 μg RNA from each liver sample was subjected to reverse transcription (RT) by using MMuLV reverse transcriptase in a 50 μL reaction volume. Aliquots of the reverse transcription mixture were used for amplification by polymerase chain reaction (PCR) of fragments specific to transforming growth factor-β1 (TGF-β1), methionine adenosyltransferase 1A (MAT1A) and MAT2A using the primer pairs listed in (Table 1). The levels of expression of all transcripts were normalized to that of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA in the same tissue sample. The primer pairs for TGF-β1 and GAPDH were designed by Wolf *et al*<sup>[20]</sup>. In addition, the primer pairs for MAT1A and MAT2A were designed using the Primer select program<sup>[21]</sup>. The identities of the resultant PCR products were confirmed by sequence analysis. The cycling parameters were 30 min at 55°C for cDNA first strand synthesis, and 5 min at 95°C, 1 min at 55°C and 1 min at 72 °C for 32 cycles in a Perkin Elmer 9700 Gene Amp PCR system. The PCR product was electrophoresed on a 20 g/L agarose gel recorded by Polaroid film, and the bands were quantitated by using densitometry.

### Pathological examinations

After formalin fixation, tissue samples were sliced, embedded in a standard manner and stained with Sirius

<sup>a</sup>*P* < 0.05 vs CCl<sub>4</sub> + H<sub>2</sub>O group; <sup>b</sup>*P* < 0.001 vs control group.

red. Fibrosis was graded according to the method of Ruward *et al.*<sup>[22]</sup> as follows: Grade 0 = normal liver; grade 1 = increase of collagen without formation of septa; grade 2 = formation of incomplete septa from portal tract to central vein (septa that do not interconnect with each other); grade 3 = complete but thin septa interconnecting with each other, so as to divide the parenchyma into separate fragments; and grade 4 = as grade 3, except with thick septa (complete cirrhosis). To avoid sampling error, all biopsies were obtained from the same lobe and these semi-quantitative grades were performed by the observer without knowledge of sample treatment.

### Statistical analysis

Data were presented as mean  $\pm$  SD. All other experimental data, except the pathological findings, were analyzed by one-way analysis of variance using the Dunnett's test. Liver histopathological examination data were analyzed by the Kruskal-Wallis non-parametric test, followed by a Mann-Whitney *U*-test. A *P* value < 0.05 was considered statistically significant.

## RESULTS

### Body weight and weights of liver and spleen

Treatment with CCl<sub>4</sub> caused a significant decrease in the body weight of rats as compared with control rats. There were no differences in the body weight of rats in the CCl<sub>4</sub> alone and CCl<sub>4</sub> + GLE groups. The final body weights for control and CCl<sub>4</sub>-treated groups were 474.5  $\pm$  26.7 and 405.4  $\pm$  31.6 g, respectively.

CCl<sub>4</sub> treatment obviously caused splenomegaly in the rats, demonstrating that the weight of spleen in the CCl<sub>4</sub>-treated group was about 290% of the control group (Table 2). On contrary, GLE (1 600 mg/kg) significantly reduced the weight of spleen induced by CCl<sub>4</sub> (Table 2). Moreover,

Table 2 Effect of GLE on weight of liver and spleen in CCl<sub>4</sub>-treated rats

Group	Dose (mg/kg)	Liver (g)	Spleen (g)
Control	-	15.1 $\pm$ 1.8	0.90 $\pm$ 0.11
CCl <sub>4</sub> + H <sub>2</sub> O	-	16.6 $\pm$ 3.3	2.58 $\pm$ 0.32 <sup>b</sup>
CCl <sub>4</sub> + GLE	600	16.7 $\pm$ 2.2	2.21 $\pm$ 0.36
	1600	18.2 $\pm$ 2.0	2.09 $\pm$ 0.56 <sup>a</sup>

<sup>a</sup>*P* < 0.05 vs CCl<sub>4</sub> + H<sub>2</sub>O group; <sup>b</sup>*P* < 0.001 vs control group.

Table 4 Effect of GLE on plasma albumin concentration and A/G ratio in CCl<sub>4</sub>-treated rats

Group	Dose (mg/kg)	Albumin (g/dL)	A/G ratio
Control	-	3.35 $\pm$ 0.15	1.22 $\pm$ 0.07
CCl <sub>4</sub> + H <sub>2</sub> O	-	2.33 $\pm$ 0.21 <sup>b</sup>	0.75 $\pm$ 0.04 <sup>b</sup>
CCl <sub>4</sub> + GLE	600	2.73 $\pm$ 0.18 <sup>a</sup>	0.87 $\pm$ 0.07 <sup>a</sup>
	1600	2.70 $\pm$ 0.25 <sup>a</sup>	0.88 $\pm$ 0.13 <sup>a</sup>

<sup>a</sup>*P* < 0.05 vs CCl<sub>4</sub> + H<sub>2</sub>O group; <sup>b</sup>*P* < 0.001 vs control group.

CCl<sub>4</sub> did not change liver weights, and no effect of GLE on the liver weight was observed.

### Effects of GLE on biochemical parameters

As shown in (Table 3), CCl<sub>4</sub> treatment resulted in a significant increase in plasma AST and ALT activities as compared to the control group. Oral administration of GLE (1 600 mg/kg) significantly reduced the CCl<sub>4</sub>-induced increase in AST and ALT activities.

The plasma albumin content and A/G ratio in CCl<sub>4</sub>-treated groups were significantly lower than that in the control group. The CCl<sub>4</sub>-induced decrease in plasma albumin concentration and A/G ratio were significantly increased following the administration of GLE (600 and 1 600 mg/kg; Table 4).

### Hepatic protein, malondialdehyde and hydroxyproline concentrations

CCl<sub>4</sub>-induced liver fibrosis in rats resulted in a significant decrease in hepatic protein content compared to the control group. GLE (1 600 mg/kg) attenuated the decrease of hepatic protein level induced by CCl<sub>4</sub> (Table 5).

CCl<sub>4</sub> induced liver fibrosis in the rats, accompanied by a marked elevation of malondialdehyde and hydroxyproline concentrations. GLE (600 and/or 1 600 mg/kg) could lower the increase in hepatic malondialdehyde and hydroxyproline content (Table 5).

### TGF- $\beta$ 1, MAT1A and MAT2A mRNA expression

Fragments specific to TGF- $\beta$ 1, MAT1A and MAT2A were amplified by using RT-PCR (Figure 1). Values from densitometric analysis, after normalization against the corresponding GAPDH transcript, were expressed as the TGF- $\beta$ 1:GAPDH, MAT1A:GAPDH and MAT2A:GAPDH ratios (Table 6). CCl<sub>4</sub> treatment could significantly increase the levels of both TGF- $\beta$ 1 and MAT2A. The administration of GLE (600 or 1600 mg/kg) significantly decreased the expression of TGF- $\beta$ 1 and

Control	–	0.18 ± 0.03	4.34 ± 0.081	0.29 ± 0.02
CCl <sub>4</sub> + H <sub>2</sub> O	–	22.17 ± 7.20 <sup>f</sup>	1.75 ± 0.46 <sup>f</sup>	4.95 ± 0.21 <sup>f</sup>
CCl <sub>4</sub> + GLE	600	16.99 ± 3.26 <sup>a</sup>	3.07 ± 1.15 <sup>a</sup>	1.68 ± 0.14 <sup>d</sup>
	1600	4.83 ± 0.48 <sup>d</sup>	3.83 ± 1.35 <sup>b</sup>	0.56 ± 0.03 <sup>d</sup>

<sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01, <sup>d</sup>*P* < 0.001 *vs* CCl<sub>4</sub> + H<sub>2</sub>O group; <sup>f</sup>*P* < 0.001 *vs* control group.

MAT2A mRNA. In contrast, the level of MAT1A mRNA was significantly decreased by CCl<sub>4</sub> treatment. However, treatment with GLE significantly increased the level of MAT1A mRNA.

### Pathological changes

As shown in Figure 2, CCl<sub>4</sub> induced liver lesions in rats. Sirius red stain showed clear nodular fibrosis (Figure 2B). Treatment with GLE (1 600 mg/kg) showed a marked improvement in the pathological changes to these tissues (Figure 2C and Table 7).

## DISCUSSION

The present study revealed the beneficial effect of GLE in prevention of liver fibrosis induced by CCl<sub>4</sub> treatment. An improvement brought about by GLE was also seen in plasma biochemical parameters.

CCl<sub>4</sub> treatment caused hepatocellular damage in rats, as indicated by a drastic increase in both plasma ALT and AST levels after CCl<sub>4</sub> administration. Rats treated with GLE showed a protection against CCl<sub>4</sub>-induced hepatotoxicity, with the levels of both plasma AST and ALT being reduced.

It is well known that adenosylmethionine-dependent methylation is central to many biological processes<sup>[23]</sup>. Methionine adenosyltransferase (MAT) is a key enzyme for liver methionine metabolism, which catalyzes the synthesis of S-adenosylmethionine<sup>[24]</sup>. In mammalian tissue, three different forms of MAT (MAT I/III and MAT II) have been identified, which are the product of two different genes (MAT1A and MAT2A). MAT1A is primarily restricted to adult liver<sup>[25]</sup>. MAT2A is high in fetal liver,

**Figure 1** Effect of GLE on mRNA expression of TGF-β1, MAT1A and MAT2A in hepatic tissue. M: DNA marker

decays at birth to negligible levels and, in the adult liver, increases during regeneration after partial hepatectomy<sup>[26–28]</sup>. Thus, in response to liver injury, MAT1A expression is switched off and MAT2A expression is switched on. Consistent with this, the expression of MAT1A was found to be reduced in the livers of rats with chronic CCl<sub>4</sub> injury, whereas the expression of MAT2A increased. In this study, we also found that the changes in MAT expression in chronic CCl<sub>4</sub>-injured rats were reduced by GLE treatment. These results further support the fact that GLE possesses a hepatoprotective effect.

The liver synthesizes not only the protein it needs, but also produces numerous export proteins. Among the latter, plasma albumin is the most important<sup>[29]</sup>. Export proteins are synthesized on polyribosomes bound to the rough endoplasmic reticulum of the hepatocytes. In contrast, protein destined for intracellular use is synthesized on free polyribosomes rather than bound polyribosomes<sup>[29]</sup>. In this experiment, CCl<sub>4</sub> induced liver fibrosis in rats and it appeared to cause a decrease in both hepatic protein and plasma albumin contents. GLE clearly reduced the decrease in protein content in the liver and albumin content in the plasma; thus it was shown to ameliorate the decline in liver synthesis function caused by CCl<sub>4</sub>-induced fibrosis.

Immunoglobulin is synthesized by immunocytes and hyperglobulinemia is found in hepatocellular disorders, appearing as an inflammatory reaction of liver<sup>[30]</sup>. In the present experiments, we observed CCl<sub>4</sub>-induced chronic liver lesions in rats and also a decrease in A/G ratio. GLE could clearly lessen the decrease in the A/G ratio caused by CCl<sub>4</sub>, thereby exhibiting suppressive actions on liver

**Table 7** Effect of GLE on CCl<sub>4</sub>-induced liver fibrosis in rats

Group	Dose (mg/kg)	Score of hepatic fibrosis					Average
		0	1	2	3	4	
Control	–	10	0	0	0	0	0

inflammation caused by CCl<sub>4</sub>.

It is well known that liver fibrosis is a result of increased collagen synthesis<sup>[31]</sup>; hydroxyproline is the characteristic component in collagen<sup>[32]</sup>. The amount of collagen can be reflected by determining hydroxyproline concentration and can be used to express the extent of fibrosis<sup>[32]</sup>. In this experiment, when CCl<sub>4</sub> was administered to induce liver fibrosis, the hydroxyproline contents in liver obviously increased. Interestingly, GLE could reduce hydroxyproline concentration, indicating that it could lessen the actions of hepatic fibrosis caused by CCl<sub>4</sub>, which was further proved by histopathological inspection.

When the liver is damaged, it can initiate regenerative actions<sup>[33]</sup>, thus increasing the weight of liver. If it was heavily damaged, however, liver fibrosis and cirrhosis appear resulting in liver atrophy<sup>[34]</sup>. Therefore, the change in weight of liver can not directly predict the pathological process in chronic liver injuries.

Liver fibrosis leads to blockage of blood flow into the liver and causes portal hypertension. It also influences blood flow to the spleen and gives rise to splenomegaly<sup>[35]</sup>. In this study, CCl<sub>4</sub> induced chronic hepatic fibrosis and splenomegaly, but GLE could improve splenomegaly, indicating that GLE possesses actions in ameliorating fibrosis.

Increased free radical production and lipid peroxidation

have been proposed as a major cellular mechanism involved in CCl<sub>4</sub> hepatotoxicity<sup>[10]</sup>. Furthermore, a close relationship has been reported between lipid peroxidation and fibrogenesis in rats, in which fibrosis was induced by CCl<sub>4</sub> administration<sup>[11]</sup>. Our results also confirmed these findings that hepatic lipid peroxidation increases during hepatic fibrogenesis. Moreover, we observed that GLE inhibited CCl<sub>4</sub>-induced hepatic lipid peroxidation. These results indicated that GLE might inhibit lipid peroxidation and consequently attenuate the development of liver fibrosis. Numerous studies have indicated that *G. lucidum* extracts are good free-radical scavengers<sup>[12–14]</sup>, suggesting that the ameliorative effects of GLE on liver fibrosis induced by CCl<sub>4</sub> are due, at least in part, to its free-radical scavenging ability.

TGF-β1 is a profibrogenic cytokine as it directly stimulates extracellular matrix production by both endothelial and stellate cells<sup>[36,37]</sup>. Increased levels of TGF-β1 mRNA expression have been found in patients with liver fibrosis as well as in experimental models of liver fibrosis<sup>[38,39]</sup>. Blockade of TGF-β1 synthesis or signaling is a primary target for the development of antifibrotic approaches, and modern hepatology has facilitated the design of drugs removing this causative agent<sup>[40]</sup>. In this study, CCl<sub>4</sub> treatment increased while GLE treatment significantly reduced TGF-β1 mRNA expression, suggesting that GLE might ameliorate liver fibrosis via reducing TGF-β1 secretion.

In conclusion, oral administration of GLE is effective in the reduction of chronic liver injury, probably via a protective effect against hepatocellular necrosis by its free-radical scavenging ability.

## Abstract

**AIM:** To characterize the consequences of short-term exposure to luminal bile on mucosal mast cell reactions in a canine model, and to determine the effects of systemic phosphatidylcholine pretreatment in this condition.

**METHODS:** Twenty mongrel dogs were used for experiments. Group 1 ( $n=5$ ) served as a saline-treated control, while in group 2 ( $n=5$ ) the esophagus was exposed to bile for 3 h. In group 3 ( $n=5$ ) the animals were pretreated with 7-nitroindazole to inhibit the neuronal isoform of nitric oxide synthase. In group 4 ( $n=5$ ) phosphatidylcholine solution (50 mg/kg) was administered iv before the biliary challenge. Mucosal microcirculation was observed by intravital videomicroscopy. Myeloperoxidase and nitric oxide synthase activities, the degrees of mast cell degranulation and mucosal damage were evaluated via tissue biopsies.

**RESULTS:** Exposure to bile evoked significant mast cell degranulation and leukocyte accumulation. The red blood cell velocity and the diameter of the postcapillary venules increased significantly. The tissue ATP content and constitutive nitric oxide synthase activity decreased, while the inducible nitric oxide synthase activity increased significantly as compared to the control values. 7-nitroindazole treatment significantly exacerbated the mucosal mast cell degranulation and tissue damage. In contrast, phosphatidylcholine pretreatment prevented the bile-induced ATP depletion, the inducible nitric oxide synthase and myeloperoxidase activity and the mast cell degranulation increased.

**CONCLUSION:** The neuronal nitric oxide synthase - mast cell axis plays an important role in the esophageal mucosal defense system. Systemic phosphatidylcholine pretreatment affords effective protection through ameliorating the bile-induced ATP depletion and

secondary inflammatory reaction.

## INTRODUCTION

During acute regurgitation or prolonged gastroesophageal reflux episodes, the esophageal epithelial layer is exposed to various noxious luminal agents. Gastric acid has been shown to play a crucial role in the development of esophagitis, but regurgitated bile could also be linked to various detrimental mucosal reactions, including ATP depletion and permeability alterations<sup>[1,2]</sup>. Bile salts can damage the epithelium both directly and indirectly, and may alter the function of cells. Given that mast cells (MCs) are involved in stress-induced gastrointestinal reactions, it seems reasonable to assume that the effects of bile involve MCs. Indeed, it has been shown *in vitro* that bile acids induce concentration-dependent MC degranulation in correlation with their lipophilicity and surface activity<sup>[3]</sup>.

A number of MC-specific reactions in the gastrointestinal tract may be linked to the activity of constitutively expressed nitric oxide synthase (NOS). A relative lack of NO can activate both MCs and leukocytes, and MC degranulation *per se* can bring about leukocyte accumulation and other characteristics of local inflammation<sup>[4,5]</sup>. NOS system consists of three distinct isoforms: neuronal NOS (nNOS), inducible NOS (iNOS), and endothelial NOS (eNOS). Both eNOS and nNOS are constitutively expressed, but nNOS is predominant in the gastrointestinal tract<sup>[6,7]</sup>. Although the above line of reasoning suggests that MCs and nNOS-derived NO could be closely associated with mucosal homeostasis, the relative contributions of the different NOS isoforms to the reflux-caused inflammatory responses of the esophagus are unclear. In the first part of our study, therefore, we examined the consequences of an acute

biliary challenge on NOS activation and mucosal MC reactions by performing detailed microcirculatory, histological and biochemical analyses. As we hypothesized that bile-induced inflammatory response critically involves NO, we determined the consequences of nNOS inhibition in this setting.

In addition to this pathomechanism investigation, another aim was to outline a means of modulating the outcome of biliary mucosal irritation. It is clearly recognized that a mixed or biliary reflux is more harmful than gastric acid alone, but to date there are no effective pharmacological therapies for bile-induced esophagitis. Nevertheless, various lines of indirect evidence have suggested that phosphatidylcholine (PC) may be protective during this condition. It was postulated in early *in vitro* studies that PC in aqueous media may protect against the membrane damage caused by bile salts<sup>[8, 9]</sup>. In stress conditions the hydrolysis of endogenous membrane PC leads to release of phosphatidic acid and choline. Choline is anti-inflammatory and is actively transported into the epithelial cells<sup>[10]</sup>. Moreover, choline could form part of a defense mechanism which may operate in biological systems against oxido-reductive stress<sup>[11]</sup>.

Accordingly, in the second part of our study we set out to establish whether systemic PC administration can protect the esophageal mucosa by acting as an anti-inflammatory agent in bile-induced esophagitis.

## MATERIALS AND METHODS

The experiments were performed in adherence to the NIH guidelines for the use of experimental animals. The study was approved by the Ethical Committee for the Protection of Animals in Scientific Research at the University of Szeged.

### Surgical preparation

The experiments were performed on 20 inbred mongrel dogs (average weight  $12 \pm 3$  kg) under sodium pentobarbital anesthesia (30 mg/kg iv). Small supplementary doses of pentobarbital were administered when necessary. The left femoral artery and vein were cannulated for recording the mean arterial pressure and blood sampling, respectively. The animals were placed in a supine position on a heating pad for maintenance of the body temperature between 36°C and 37°C, and received an infusion of Ringer's lactate at a rate of 10 mL/(kg h) during the experiments.

Following a collar incision, the cervical esophagus with intact neurovascular connections was dissected free, and an approximately 8-10-cm segment of the middle portion was then occluded at both ends with atraumatic clips. The objective of the videomicroscope (Cytoscan A/R, Cytometrics, PA., USA) was placed into the esophagus lumen for continuous observation of the microcirculation. A second polyvinyl tube (0.5 mm i. d.) was secured with purse-string sutures for administration of the test compounds.

### Experimental protocol

Surgery was followed by a 30-min recovery period for cardiovascular stabilization, and 7.0 mL isotonic saline

(pH 7.4) was then injected into the lumen of the dissected esophagus for 30 min in order to determine the baseline variables. The esophageal segment was next filled with test solution (7.0 mL) for 180 min. At the end of the experiment, a biopsy was taken from the esophageal segment, together with a tissue sample from the aboral intact part of the esophagus, with a freeze-clamp technique for determination of the tissue adenosine triphosphate (ATP) concentrations, and additional biopsies were performed to measure the tissue myeloperoxidase (MPO) and NOS isoform activities, and to determine the extent of MC degranulation and structural damage.

The animals were randomly allotted into 4 groups. Group 1 ( $n=5$ ) served as saline-treated control, while in groups 2-4 the effects of bile were investigated. In group 2 ( $n=5$ ) the animals were treated with canine bile alone. Bile obtained from 3 healthy dogs was pooled and stored at -20°C, and diluted freshly (pH 6.5) before the experiments. Bile was diluted with same volume of saline and solution was warmed up to 37°C before administration. Group 3 ( $n=5$ ) was treated with 5 mg/kg 7-nitroindazole (7-NI, Sigma Chem., USA) in 0.3mL/min iv infusion 20 min before bile administration. In group 4 ( $n=5$ ) the animals received 50 mg/kg iv PC infusion 20 min before bile treatment. Five percent PC solution (soybean lecithin, MW: 785, phospholipon 90, Phospholipid GmbH, Cologne, Germany) was freshly prepared according to the description of the manufacturer. Briefly, PC solution contained deoxycholate (2.3%), NaOH (0.24%), benzyl alcohol (0.82%), NaCl (0.22%), and ethanol (0.27%) in distilled water. The intraluminal volume load was identical in all groups studied.

### Measurements

Central venous pressure and mean arterial pressure were measured continuously with Statham P23Db transducers and registered with a computerized data-acquisition system (Haemosys 1.17, Experimetria Ltd., Budapest, Hungary). Arterial blood gases were measured with a blood gas analyzer (AVL Compact 2, Graz, Austria).

### Intravital video-microscopy

The intravital OPS technique (Cytoscan A/R, Cytometrics, PA, USA) was used for continuous visualization of the microcirculation of the esophageal mucosa. This technique utilizes reflected polarized light at the wavelength of the isosbestic point of oxy- and deoxyhemoglobin (548 nm). Since polarization is preserved in reflection, only photons scattered from a depth of 2-300  $\mu$ m contribute to the image formation. A 10x objective was introduced into the intestinal lumen, and the microscopic images were recorded with a S-VHS video recorder (Panasonic AG-TL 700). Videomicroscopic observations were made at specific anatomic locations at a depth of approximately 200  $\mu$ m. Microcirculatory evaluation was performed off-line by frame-to-frame analysis of the videotaped images. Capillary red blood cell velocity (RBCV,  $\mu$ m/s), vessel diameter (VD,  $\mu$ m) changes in postcapillary venules and relative vessel area (RVA, length of perfused nutritive capillaries per total capillary length of a standard observation area) were determined in 3 separate fields by

means of a computer-assisted image analysis system (IVM Pictron, Budapest, Hungary). Changes in venular wall diameter were determined by following identifiable visual landmarks within the vessel wall. All microcirculatory evaluations were performed by one investigator (EG).

### ATP measurement

A whole-thickness sample was taken from the esophagus with a Wollenberg forceps cooled in liquid nitrogen, and the tissue was stored at  $-70^{\circ}\text{C}$ . The sample was weighed, placed into a 3-fold volume of trichloroacetic acid (6% w/v), homogenized for 1 min, and centrifuged at 5000 g/min. The supernatant was neutralized with saturated potassium carbonate solution. The ATP concentration was measured spectrophotometrically according to Lamprecht *et al* [12]. The method is based on the principle that  $\beta$ -nicotinamide adenine dinucleotide phosphate is used up in an enzymatic reaction catalyzed by glucose-6-phosphate dehydrogenase and hexokinase.

### NOS activity measurements

NO formation in esophageal tissue was measured by the conversion of [ $^3\text{H}$ ] L-citrulline from [ $^3\text{H}$ ] L-arginine according to the method of Szabo *et al* [13]. Briefly, tissue homogenates were centrifuged at 24 000 g/min for 20 min at  $4^{\circ}\text{C}$  and the supernatant was loaded into centrifugal concentrator tubes (Amicon Centricon-100; 100 000 MW cut-off ultrafilter). The tubes were centrifuged at 1000 g/min for 150 min and the concentrated supernatant was washed out from the ultrafilter with 300  $\mu\text{L}$  homogenizing buffer. The samples were incubated with a cation-exchange resin (Dowex AG 50W-X8,  $\text{Na}^+$  form) for 5 min to deplete endogenous L-arginine. The resin was separated by centrifugation at 1500 g/min for 10 min and the supernatant containing the enzyme was assayed for NOS activity. For the  $\text{Ca}^{2+}$ -dependent NOS (cNOS) activity, 50  $\mu\text{L}$  enzyme extract and 100  $\mu\text{L}$  reaction mixture (pH 7.4, containing 50 mmol/L Tris-HCl buffer, 1 mmol/L NADPH, 10  $\mu\text{mol/L}$  tetrahydrobiopterin, 1.5 mmol/L  $\text{CaCl}_2$ , 100 U/mL calmodulin and 0.5  $\mu\text{Ci}$  [ $^3\text{H}$ ] L-arginine (ICN Biomedicals, specific activity 39 Ci/mmol) were incubated together for 30 min at  $37^{\circ}\text{C}$ . The reaction was stopped by the addition of 1 mL ice-cold HEPES buffer (pH 5.5) containing 2 mmol/L EGTA and 2 mmol/L EDTA. Measurements were performed with boiled enzyme and the NOS inhibitor N- $\omega$ -nitro-L-arginine (3.2 mmol/L) to determine the extent of [ $^3\text{H}$ ] L-citrulline formation that was independent of the NOS activity.  $\text{Ca}^{2+}$ -independent NOS activity (iNOS) was measured without Ca-calmodulin but with EGTA (8 mmol/L). Reaction mixture (1 mL) was applied to Dowex cation-exchange resin (AG 50W-X8,  $\text{Na}^+$  form) and eluted with 2 mL distilled water. The eluted [ $^3\text{H}$ ] L-citrulline activity was measured with a scintillation counter (Tri-Carb Liquid Scintillation Analyze 2100TR/2300TR, Packard Instrument Co, Meriden, Ct., USA) and referred to the protein content.

### Tissue MPO activity

The activity of MPO, a marker of tissue leukocyte infiltration, was measured from mucosal biopsies by the method of Kuebler *et al* [14]. Briefly, the tissue was

homogenized with Tris-HCl buffer (0.1 mmol/L, pH 7.4) containing 0.1 mM polymethylsulfonyl fluoride to block tissue proteases, and then centrifuged at 2000 g/min at  $4^{\circ}\text{C}$ . The MPO activities of the samples were measured at 450 nm (UV-1601 spectrophotometer, Shimadzu, Japan), and the data were referred to the protein content.

### Light microscopy

Esophageal biopsy samples were rapidly placed into ice-cold Carnoy's fixative, embedded in paraffin, sectioned (6  $\mu\text{m}$ ) and stained with hematoxylin-eosin. Histological analysis was performed in coded sections by one investigator (MB). Mucosal injury was graded on the 0-100 esophageal mucosal damage score of Lanis *et al* [15] with the following criteria: epithelial changes (epithelial splitting, erosion and ulceration): maximal score 40; inflammation (intraepithelial leukocytes and cellular hyperplasia): maximal score 40; vascular lesions (edema, congestion and hemorrhage): maximal score 20.

Counting of polymorphonuclear leukocytes (PMN) was performed on coded sections by two independent investigators (TL, EG). Five nonoverlapping fields were observed in each section, and in each field an average of 4 consecutive measurements was used to calculate average PMN count with a semiquantitative scoring system. PMN counts were determined in the epithelium, submucosa, muscle layer and adventitia with the following criteria: grade 0, no PMNs in the given structure; grade 1, 1-10 PMNs; grade 2, 11-100 PMNs; grade 3: > 100 PMNs.

### Histology for mast cells

The sections were stained with acidic toluidine blue (pH 0.5) and alcian blue-safranin O (Sigma Chem. USA, pH 0.4). Positively stained MCs were quantitated in 10 fields. The counting was performed in coded sections at an optical magnification of  $\times 400$  by two independent investigators (EG and TL). Loss of intracellular granules and stained material dispersed diffusely within the lamina propria were taken as evidence of MC degranulation. For each animal, 5 fields were chosen at random, and the number of degranulated and intact MCs was counted. All counts were pooled for each treatment, and the percentage of degranulated MCs was calculated.

### Statistical analysis

Data analysis was performed with a statistical software package (SigmaStat for Windows, Jandel Scientific, Erkrath, Germany). Nonparametric methods were used. Friedman repeated measure analysis of variance on ranks was applied within the groups. Time-dependent differences from the baseline were assessed by Dunn's method. Differences between groups were analyzed with Kruskal-Wallis one-way analysis of variance on ranks, followed by Dunn's method for pairwise multiple comparison. In the Table and Figures, median values and 75<sup>th</sup> and 25<sup>th</sup> percentiles are given.  $P < 0.05$  was considered statistically significant.

## RESULTS

The baseline values of the macrohemodynamic variables

**Table 1** Effects of various intraluminal treatments on the mean arterial pressure (MAP), heart rate (HR) and red blood cell velocity (RBCV,  $\mu\text{m/s}$ ) and venular diameter (VD,  $\mu\text{m}$ ) of the esophageal mucosa.

M=median value, 25p and 75p=25<sup>th</sup> and 75<sup>th</sup> percentiles, respectively. <sup>a</sup> $P<0.05$  vs -30-min values, <sup>c</sup> $P<0.05$  vs saline-treated group, <sup>e</sup> $P<0.05$  vs bile-treated group.

did not differ significantly in the different groups and there were no significant hemodynamic changes as compared to the control values during the experimental period (Table 1). The mean arterial pressure in the bile+7-NI or PC-treated groups was not significantly different ( $P>0.05$ ) from that in the saline-treated group as a whole (Table 1).

Venules of  $35 \pm 10 \mu\text{m}$  in diameter were the largest fraction of the vessels and arterioles were seen only very rarely. The baseline level of RBCV in the various groups ranged 560 - 680  $\mu\text{m/s}$ , and in the control group the RBCV did not change during the experiments (Table 1). However, the RBCV was increased significantly after 3-h exposure to bile with or without 7-NI or PC pretreatment. The median value was 813, 886 and 787  $\mu\text{m/s}$  after bile, bile with 7-NI, and bile with PC pretreatment, respectively.

The inner boundary of the venular wall was easily distinguishable and an exact comparison of inner diameter changes was possible. The median vessel diameter was significantly greater in bile-treated group 2 as compared to the saline-treated control, and increased from the baseline value of 33  $\mu\text{m}$  to 44  $\mu\text{m}$ . Administration of 7-NI before bile treatment prevented this increase. PC pretreatment resulted in a significant vessel diameter elevation as

compared to the control group, but the diameter changes in this group were significantly lower than those in the bile-treated group (Table 1).

The *in vivo* interference of bile treatment with ATP production of the esophageal mucosa was evaluated (Figure 1). There were no significant differences in tissue ATP levels between the intact and treated parts of the esophagus in the saline-treated control group (data not shown). There was a statistically significant fall (45%) in the ATP content of the esophageal tissue after bile treatment (saline: M=4.43  $\mu\text{mol/mg}$  protein, 25p=4.21, 75p=4.76; bile: M=2.42  $\mu\text{mol/mg}$  protein, 25p=1.66, 75p=2.61) by the end of the observation period, and this change was not affected by 7-NI treatment. Following PC treatment, the ATP content was significantly maintained in the mucosa as compared to bile treatment alone (M=3.82, 25p=3.56, 75p=4.28), and this value was not significantly different from the corresponding value in the saline-treated group.

Figure 2 demonstrates the changes in esophageal cNOS and iNOS activities. The activity of cNOS was significantly depressed after bile treatment, and this change was accompanied with a significant increase (6-fold) in

**Figure 1** Effects of bile (black box), PC+bile (gray box) and 7-NI+bile (checked box) on the ATP content of esophageal mucosa. The plots demonstrate the median (horizontal line in the box), the 25<sup>th</sup> (lower whisker) and 75<sup>th</sup> (upper whisker) percentiles, respectively. <sup>a</sup> $P < 0.05$  between groups vs saline-treated control group. <sup>c</sup> $P < 0.05$  between bile+7-NI-treated and bile+PC-treated groups vs bile-treated group values.

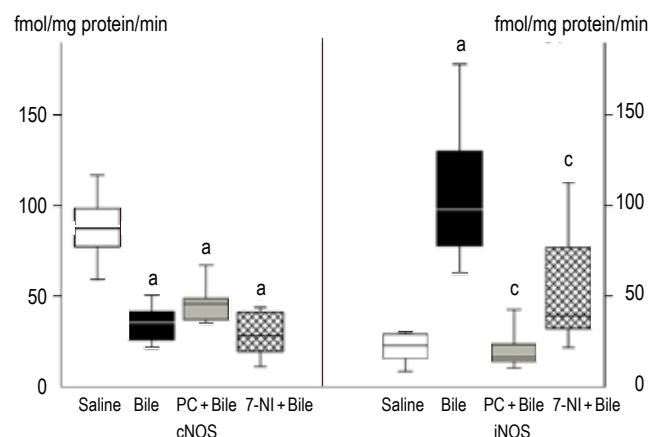

**Figure 3** Myeloperoxidase (MPO) activity in the esophageal mucosa 180 min after treatment. The plots demonstrate the median (horizontal line in the box), the 25<sup>th</sup> (lower whisker) and 75<sup>th</sup> (upper whisker) percentiles, respectively. <sup>a</sup> $P < 0.05$  between groups vs saline-treated control group values. <sup>c</sup> $P < 0.05$  between bile+7-NI-treated and bile+PC-treated groups vs bile-treated group values.

iNOS activity. The cNOS activity was not altered by PC or 7-NI pretreatment. However, the esophageal iNOS activity was significantly lower after PC pretreatment as compared to bile treatment alone. 7-NI treatment resulted in a somewhat lower increase (2.6-fold) in iNOS activity, as compared to the value in the bile-treated group.

The MPO data demonstrated that leukocyte accumulation was significantly increased in mucosae of the bile-treated and 7-NI pretreated groups as compared to the saline-treated group (Figure 3). Bile alone resulted in a 2.5-fold ( $M = 209.4$ ,  $25p = 136.6$ ,  $75p = 259.6$ ) rise in MPO activity, and a further increase was observed after 7-NI+bile administration ( $M = 315.4$ ,  $25p = 182.4$ ,  $75p = 441.8$ ). PC pretreatment significantly decreased bile-induced MPO activity.

Histological scoring of leukocyte infiltration was performed by two independent viewers (the inter-observer

**Figure 2** Changes in constitutive (left panel) and inducible NOS (right panel) activities [fmol (mg protein)<sup>-1</sup>min<sup>-1</sup>] in esophageal tissue from saline-treated (empty box), bile-treated (black box), bile+PC-treated (gray box) and bile+7-NI-treated (checked box) animals. The plots demonstrate the median (horizontal line in the box), the 25<sup>th</sup> (lower whisker) and 75<sup>th</sup> (upper whisker) percentiles, respectively. <sup>a</sup> $P < 0.05$  between groups vs saline-treated control group values. <sup>c</sup> $P < 0.05$  between bile+7-NI-treated and bile+PC-treated groups vs bile-treated group values.

**Figure 4** Mast cell degranulation (%) in the esophageal mucosa 180 min after treatment. The plots demonstrate the median (horizontal line in the box) and the 25<sup>th</sup> (lower whisker) and 75<sup>th</sup> (upper whisker) percentiles. <sup>a</sup> $P < 0.05$  between groups vs saline-treated control group values. <sup>c</sup> $P < 0.05$  between bile+7-NI-treated and bile+PC-treated groups vs bile-treated group values.

variation was less than 15%, and these data showed good correlation with MPO results). In saline-treated group the extravasation of PMNs was negligible (range of scores: 1-3;  $M = 2$ ). Exposure to bile resulted in a significant ( $P < 0.05$ ) accumulation of PMNs (range: 4-6;  $M = 5$ ). In PC pretreated animals the PMN infiltration was significantly decreased and the scores did not differ significantly from the control values (range: 1-3;  $M = 3$ ). Bile + 7-NI treatment increased the degree of PMN infiltration and resulted in a grade 7 score (range: 7-9).

The effects of bile and various pretreatments on the mucosal MC degranulation are presented in Figure 4. In the control group, 35% of the MCs were degranulated. Exposure to bile resulted in a significant degranulation ( $M = 79.6\%$ ,  $25p = 75.0$ ,  $75p = 84.6$ ) relative to the control group. In the PC-pretreated group, the percentage of degranulated MCs ( $M = 54.3\%$ ,  $25p = 42.2\%$ ,  $75p = 66.7\%$ )

**Figure 5** Photomicrographs of esophageal wall from groups 1-4 (H&E staining). **A:** control group (saline treatment, original magnification x 224), **B:** bile treatment (epithelial damage and subepithelial edema, original magnification x 112), **C:** bile-treated group (significant leukocyte infiltration in the muscle layers and adventitia, original magnification x 112), **D:** bile + 7-NI treatment (extreme leukocyte infiltration in the adventitia, original magnification x 224), and **E:** bile + PC treatment (no significant change in the esophageal wall, original magnification x 56x; the arrow in the right upper corner shows the muscle layer of the same field (original magnification x 400); the interstitial capillaries are filled with PMNs, but only few extravasated PMNs are present).

was significantly lower than that after bile treatment alone. The nNOS inhibition evoked a marked stimulation of MC degranulation over that due to bile treatment alone. In the 7-NI+bile-treated group, the degranulation of mucosal MCs was nearly complete ( $M = 87.5\%$ ,  $25p = 65.6\%$ ,  $75p = 95.6\%$ ).

Biopsy samples from the saline-treated control group exhibited an average grade of injury of 5 (range of scores: 0-20) on the Lanas scale. In these sections, the luminal surface was always lined by a continuous layer of epithelial cells, while the vessels usually presented with empty lumina (Figure 5A). The 180-min bile exposure induced significant mucosal damage ( $P < 0.01$ ), with a median value of 58 (range: 50-70). Deep lesions were observed with disruption and desquamation of the epithelial layer (Figures 5B and 5C). Extensive intraepithelial and subepithelial leukocytosis and connective tissue damage were the general characteristics. Submucosal edema, hemorrhage and vasodilatation were apparent. Semiquantitative evaluation of the samples from the 7-NI+bile-treated animals revealed a significant exacerbation of the mucosal injury ( $P < 0.01$ ) and an injury score of 68 (range 60-90). A tendency toward more intense injury was always manifested. Severe epithelial damage and exfoliation of the surface epithelium were present, and the deeper tissue layers were more strongly involved in a generalized inflammatory reaction. In most cases, transmural inflammatory infiltrations, vasodilation and subepithelial connective tissue edema were observed (Figure 5D).

Administration of PC did not significantly influence the superficial tissue damage, but the reactive mucosal changes were different from those observed in the bile-treated group. In general, the degree of epithelial damage and the

nature of reactive epithelial changes were similar to those observed in the bile-treated group 2, but there was no evidence of severe subepithelial inflammation. Submucosal damage was often patchy, mild and severe lesions were commonly observed within the same section and hemorrhage was rarely observed. The general image of tissue damage was somewhat improved, but this group had a median grade of injury of 50 (range: 40-75), a value not significantly different ( $P > 0.01$ ) from the corresponding value for the bile-treated group.

## DISCUSSION

Regurgitation of the duodenogastric content may lead to esophageal dysfunction and tissue damage in the long run, but acute biliary reflux likewise correlates with the presence of severe esophagitis and esophageal ulceration in critically ill and mechanically ventilated patients<sup>[16]</sup>. Appropriate treatment or prevention of this condition clearly presupposes an understanding of the pathogenesis of regurgitation-induced lesions and the nature of inflammatory complications.

The results of our *in vivo* study indicate that bile may target several potentially interconnected pathways, leading to mucosal barrier impairment. Intraluminal bile reduced ATP content of the exposed tissues, decreased cNOS activity, increased iNOS activity, evoked a parallel rise in MC degranulation and leukocyte accumulation, and induced severe structural alterations. These effects were potentiated by 7-NI, a selective inhibitor of the nNOS isoform.

NO plays a central role in the maintenance of resting esophageal mucosal blood flow, but it has been shown

that the reactive responses to luminal deoxycholate are not NO-dependent<sup>[17, 18]</sup>. In our experiments the acute biliary challenge elicited characteristic microcirculatory changes in the esophageal mucosa, as demonstrated by intravital videomicroscopy. Both the venular diameter and RBCV increased, which shows that a substantial venodilator influence is present in the mucosa, despite cNOS inhibition. This finding is seemingly controversial. Nevertheless, it is clear that other mechanisms or mediators could compensate for the absence of cNOS-derived NO. Nonspecific inhibitors of NOS generally increase the intestinal epithelial permeability, these changes are attributed to the destabilizing effects of NO deficit on MCs<sup>[4, 19]</sup>.

It is reasonable to suggest that MC-related histamine is a likely candidate in this process. Mucosal mast MCs are a unique cellular source of both preformed and *de novo* synthesized mediators, and MC-induced reactions contribute to postischemic mucosal permeability alterations and flow response in the gastrointestinal tract<sup>[5, 20]</sup>. Moreover, it has been shown that bile acids are able to degranulate MCs and induce histamine release from mucosal MCs both *in vitro* and *in vivo*<sup>[3, 21]</sup>. It has further been reported that MC-derived histamine is involved in esophageal and gastric vasodilatation during acid-induced injury<sup>[22]</sup>. This type of vasodilation could protect the mucosa against further injury and appears to be mediated by calcitonin gene-related peptides (CGRP)<sup>[23]</sup>. Thus, it is reasonable to suggest that bile-induced venodilatory response is closely associated with MC degranulation.

The current study also showed that bile potently inhibits the constitutive, Ca<sup>2+</sup>-dependent isoforms of NOS, even though the activity of the inducible isoform increased over time. The latter phenomenon could be a compensatory event of cNOS inhibition, or an aftermath of inflammatory stimuli, as iNOS has been shown to be present in macrophages and MCs too. The functioning of inducible, Ca<sup>2+</sup>-independent iNOS is closely related to the activation of NF- $\kappa$ B, and it has recently been shown that the iNOS mRNA expression increases within 30 min after an inflammatory challenge. Moreover, even physiological levels of deoxycholic acid are capable of inducing NF- $\kappa$ B and NF- $\kappa$ B target gene expression<sup>[24]</sup>.

Although the lowered ATP generation could be an important factor for the acute decrease in cNOS activity, the intracellular biochemical mechanisms mediating this injury are not completely understood. It has been speculated that unconjugated di- and trihydroxy bile acids cause damage by binding to and crossing cell membranes to enter cells. However, it has recently been shown that the  $\beta$ -chain of ATP synthase, a principal protein complex in the mitochondrial inner membrane, is also present at the cellular surface and plays a decisive role in the regulation of cell homeostasis. At the mitochondrial level, the potential toxicity of bile acids may cause cytochrome C release and Fas-dependent hepatocyte apoptosis or necrosis, and inhibit the activities of complexes I and III of the mitochondrial respiratory chain<sup>[25]</sup>. However, because of their detergent properties, bile acids are inherently cytotoxic and their direct toxicity to isolated hepatocyte mitochondria has also been demonstrated<sup>[26]</sup>.

Some evidence additionally attests to the importance of direct effects of bile on MCs. It has been shown that lipophilic bile acids possess concentration-dependent cytotoxicity toward MCs, causing histamine release *in vitro*<sup>[3]</sup>. Similarly, *in vivo* bile acids induce secretion in the small intestine by a mechanism involving histamine-mediated processes and MC degranulation<sup>[27, 28]</sup>. However, Fihn *et al*<sup>[29]</sup> demonstrated that MC degranulation and NO release are not involved in the mechanism of deoxycholic acid-induced increase in epithelial permeability in rat small intestine<sup>[29]</sup>. As the secretory effect of conjugated bile acids is observed only in association with an increase in mucosal permeability, a possible explanation could be that a permeability-enhancing factor is necessary to permit access of these charged large molecules to the basolateral membrane or to the subepithelium, where they can then exert their secretory effect. In our study, 7-NI treatment significantly amplified bile-induced tissue damage and caused further MC degranulation. Since 7-NI has a higher affinity for nNOS than for the eNOS isoform<sup>[30]</sup>, the residual responses to 7-NI might be mediated by a previously unblocked part of the nNOS isoform. This also suggests that bile principally inhibits eNOS, and partially sustained nNOS activity is able to counteract, or at least diminish the harmful effects of bile. This underlines the role of nNOS-derived NO in the maintenance of esophageal homeostasis.

Beside increases in blood flow, acute biliary challenge was found to be accompanied with leukocyte recruitment. In many ways, constitutively produced NO is anti-inflammatory, as it modulates the adhesive interaction between leukocytes and endothelium, and reduces MC reactivity. Thus, it could be hypothesized that decreased local ATP level, cNOS inhibition and relative lack of NO could account for the mucosal MC degranulation and the intramural blood flow increase, and these factors may play a concerted role in the process of leukocyte accumulation.

In the PC-pretreated animals, on the other hand, the bile-elicited ATP decrease, cNOS inhibition and MC degranulation were significantly attenuated. The question therefore arises as to which process may be of critical significance in the mechanism of mucosal protection after PC treatment. PC is a ubiquitous membrane-forming entity and the most prominent phospholipid species in the gastrointestinal tract. PC is present in the bile, *in vitro* and *in vivo* experiments have demonstrated that topical PC physically protects the intestinal mucosa against injurious actions of bile salts by forming less toxic mixed micelles<sup>[31]</sup>. Nevertheless, the experimental results and clinical experience suggest that PC could function as an active substance under certain *in vivo* conditions. The therapeutic effect of dietary PC in preventing esophageal strictures due to alkali-induced esophageal burns has been demonstrated in rats<sup>[32]</sup>, and parenteral PC and lyso-PC could prolong survival in experimental sepsis models<sup>[33, 34]</sup>. PC is taken up by phagocytic cells, and accumulates in inflamed tissues<sup>[35]</sup>. Little is known about the transport of the molecule, but phosphatidylcholine transfer protein (PCTP) accelerates the intermembrane transfer of phospholipids in an energy-independent way. Choline, a metabolite of PC and a precursor of organic osmolyte

betaine, is actively transported by a choline carrier described in intestinal epithelial and endothelial cells of the blood-brain barrier<sup>[36]</sup>.

It is widely believed that the biological efficacy of PC depends on the fatty acid moiety<sup>[37]</sup>. In contrast, some studies have revealed that the protective role of PC is independent of fatty acids, and it may be assumed that the active principle is choline. Phospholipase-D is activated by almost all stress factors resulting in the release of phospholipid metabolites, and several of these factors could be of importance in stress-induced defense reactions<sup>[38]</sup>. Indeed, it has been shown that PC metabolites might relieve a potentially dangerous increase in the ratio of NADH/NAD<sup>+</sup> (reductive stress), a predisposing cause of oxidative damage<sup>[11]</sup>. This reaction sequence could explain the still incompletely understood essential role of choline in diet and its preventive efficacy in a number of experimentally induced pathologies associated with a redox imbalance. It may be assumed that the endogenous pool of these metabolites may become exhausted under exogenous provocation and that an exogenous supply might help to replenish and strengthen the endogenous protective mechanism.

In conclusion, our data suggest that nNOS-MC axis plays an important role in the mucosal defense system of the esophagus. Elucidation of the mechanisms by which bile acids induce mucosal dysfunction is complicated by the intrinsic complexity of esophageal tissue, which is made up of many different, but interacting cell types. Whether the findings in this experimental model are applicable to humans remains to be established. However, these data together with previous observations suggest a therapeutic potential for parenteral PC with a view to decreasing the harmful consequences on bile-induced tissue reactions.

## ACKNOWLEDGMENT

The authors thank Dr. Miklos Ghyczy for fruitful discussions, Mr. Armin Wendel (Phospholipid GmbH, Cologne, Germany) for the generous supply of PC, and Drs. László Tiszlavicz and István Németh for the histology analysis.

### Abstract

**AIM:** To study the expression of vascular endothelial growth factor A (VEGF-A) and VEGF-C and to determine whether the presence of VEGF-A and VEGF-C was associated with the clinicopathologic characteristics of pancreatic cancer.

**METHODS:** VEGF-A and VEGF-C mRNA transcripts were examined by Northern blot in 6 human pancreatic cancer cell lines and 8 normal pancreatic tissues and 8 pancreatic carcinoma specimens. The expression of VEGF-A and VEGF-C proteins was examined by Western blot in the tested cell lines and by immunohistochemical stain in 50 pancreatic carcinoma samples.

**RESULTS:** VEGF-A and VEGF-C mRNA transcripts were present in all the 6 human pancreatic cancer cell lines. Immunoblotting revealed the presence of VEGF-A and VEGF-C proteins in all the cell lines. Northern blot analysis of total RNA revealed 3.0-fold and 3.6-fold increase in VEGF-A and VEGF-C mRNA transcript in the cancer samples, respectively. Immunohistochemical analysis confirmed the expression of VEGF-A and VEGF-C in cancer cells within the tumor mass. Immunohistochemical analysis of 50 pancreatic cancer tissue samples revealed the presence of VEGF-A and VEGF-C immunoreactivity in 50% and 80% of the cancer tissue samples, respectively. The presence of VEGF-A in these cells was associated with larger tumor size and enhanced local spread ( $\chi^2=6.690$ ,  $P=0.035<0.05$ ) but was not associated with decreased patient survival. However, the presence of VEGF-C in the cancer cells was associated with increased lymph node metastasis ( $\chi^2=5.710$ ,  $P=0.017<0.05$ ),

but was not associated with decreased patient survival. There was no correlation between the expression of VEGF-A and VEGF-C in the same cancer cells.

**CONCLUSION:** VEGF-A and VEGF-C are commonly overexpressed in human pancreatic cancer and may contribute to tumor growth and lymph node metastasis. There is no relationship between the expression of VEGF-A and VEGF-C in pancreatic cancer.

### INTRODUCTION

Though the mortality rate of pancreatic cancer has decreased and the survival rate of pancreatic cancer patients is improved after surgery, the 1-year survival rate after diagnosis of pancreatic cancer remains below 20% and the 5-year survival rate is only 3%<sup>[1,2]</sup>. One reason for this poor prognosis is the propensity of pancreatic cancer to metastasize. Pancreatic carcinoma is characterized by its aggressive local invasion of adjacent structures, perineural invasion and early lymph node and liver metastasis<sup>[3-5]</sup>. Lymph node metastasis and blood vessel invasion are the definitive factors of the prognosis after resection<sup>[6,7]</sup>.

Angiogenesis plays an important role in the development, growth and metastasis of carcinoma in mammals<sup>[8]</sup>. It is also important to consider the possible impact of lymphangiogenesis (development of lymphatic vessels) on cancer growth and metastasis<sup>[4]</sup>. In fact, tumor spread is dependent on both the angiogenic and lymphangiogenic systems. Many carcinomas metastasize through the lymphatic system, whereas others spread mainly hematogenously.

VEGF-A has a potent mitotic activity specific to vascular endothelial cells<sup>[9,10]</sup>, suggesting that VEGF-A

contributes to the pathologic angiogenesis associated with solid tumors. Recently VEGF-B to -E showing homology to VEGF-A have been identified<sup>[11-13]</sup>. Among these, VEGF-C possessing approximately 30% identity with VEGF, has been shown to induce specific lymphatic endothelial proliferation and hyperplasia of the lymphatic vasculature by binding to its specific receptor flt-4<sup>[11, 12, 14-16]</sup>. VEGF-C may also be an important factor regulating the mutual paracrine relationship between tumor cells and lymphatic endothelial cells not only in primary tumor but also in adjacent normal tissue.

We have previously reported that VEGF-C and its receptor are overexpressed in pancreatic cancer<sup>[17]</sup>. We now report the coexpression of VEGF-A and VEGF-C in human pancreatic cancer.

## MATERIALS AND METHODS

### Cell culture

ASPC-1, CAPAN-1, MIA-PaCa-2 and PANC-1 human pancreatic cancer cells were obtained from the American Type Culture (Rockville, MD, USA). COLO-357 and T3M4 human pancreatic cancer cells were a gift from R. S. Metzger at Duke University. Cells were grown in monolayer culture containing humidified 50ml/L CO<sub>2</sub> and 95% air at 37°C. ASPC-1, CAPAN-1 and T3M4 cells were grown in RPMI-1640 medium. COLO-357, MIA-PaCa-2 and PANC-1 cells were grown in Dulbecco's modified Eagle's medium (DMEM). Media contained 10% fetal bovine serum, 100 U/mL penicillin and 100 µg/mL streptomycin.

### Tissues for Northern blot analysis

Normal pancreatic tissue and pancreatic cancer tissue samples were frozen in liquid nitrogen and stored at -80°C for RNA extraction.

### Tissues for immunohistochemistry

Pancreatic cancer tissue samples were obtained from 50 patients (35 men and 15 women; mean age, 64.3 ± 10.8 years; range, 48-81 years) undergoing surgery for pancreatic cancer. The tumors were classified as previously described<sup>[18]</sup>. Histologically, there were 15 well, 31 moderately and 4 poorly differentiated adenocarcinomas. There were 0 stage I, 3 stage II, 9 stage III and 38 stage IV tumors. Tissue samples were fixed in 10% paraformaldehyde solution for 18-24 h and embedded in paraffin.

### Cloning and labeling of VEGF-A and VEGF-C probes

Reverse-transcription polymerase chain reaction (RT-PCR) was carried out using RT-PCR kit according to the manufacturer's instructions. Briefly, total RNA was extracted from human placenta using the acid guanidinium thiocyanate method. The prepared RNA (1 µg) was mixed with reverse transcription reagents in a total volume of 20 µL, incubated for 30 min at 42 °C into first-strand cDNA. One µL cDNA was used for PCR amplification. The upstream primer for VEGF-A was 5'-CTC ACC TGC TTC TGA GTT GC-3', and the downstream primer was 5'-TTC TCT GCC TCC ACA ATG G-3' with an expected size of 319 bp. The upstream primer for VEGF-C was 5'-CGGGATCCACGGCTTATGCAAGCAAA-3', and the

downstream primer was 5'-CGGAATTCAACACAGTT TTCCATAATAGA-3' with an expected size of 1167 bp. Amplification conditions were denaturation at 94 °C for 5 min, followed by 32 cycles of denaturation at 95 °C for 1 min, annealing at 55 °C for 1 min, extension at 72 °C for 1 min. The PCR products were electrophoresed on 1.5% agarose gels and the target bands containing the specific cDNA were cut down and purified using an ultraclean DNA purification kit (Mo Bio Laboratories, Solana Beach, CA, USA.) according to the manufacturer's instructions. The accuracy of the RT-PCR products was confirmed by sequencing of cloned cDNA. The prepared cDNA probes were labeled by PCR-DIG labeling mix according to the manufacturer's instructions.

### Northern blot analysis

Total RNA was extracted from human tissue samples and human pancreatic cancer cell lines using the acid guanidinium thiocyanate method. RNA was fractionated on 0.8% agarose/2.2% formaldehyde gels, electrotransferred onto nylon membranes and cross-linked by ultraviolet irradiation<sup>[19]</sup>. The blots were prehybridized in hybridization buffer for 1 h at 42 °C, hybridized with the indicated DIG-labeled cDNA probes overnight at 42°C, and washed twice for 5 min with 2×SSC/SDS (0.1%) at room temperature, twice for 15 min with 0.1×SSC/SDS (0.1%) at 68°C. DIG-labeled nucleic acids were detected with CSPD according to the manufacturer's instructions at room temperature. Briefly, after rinsed in washing buffer, the membrane was incubated for 30 min in blocking solution and anti-DIG-AP conjugate, respectively. Then the membrane was washed twice in washing buffer for 15 min and in detection buffer for 5 min and incubated for 5 min in CSPD solution. The damp membrane was sealed in a hybridization bag, incubated for 15 min at 37 °C and exposed to radiographic film for 15 min at room temperature. Equivalent loading of RNA in each lane was confirmed by hybridizing the total RNA with a β-actin cDNA. All cDNAs were labeled with DIG as above. Densitometric analysis of the signals were performed with a gel imaging system.

### Immunoblotting

Human pancreatic cancer cells were solubilized in lysis buffer containing 50 mmol Tris, 150 mmol NaCl, 1 mmol ethyleneglycoltetraacetic acid, 1% NP40, 1% sodium deoxycholate, 1 mmol sodium banadate, 50 mmol sodium flupride, 2 mmol EDTA (pH 8.0), 100 µg/mL benzamidine, 50 µg/mL aprotinin, 10 µg/mL leupeptin, 10 µg/mL pepstatin A, and 1 mmol phenylmethylsulfonyl fluoride. Proteins were subjected to sodium dodecyl sulfatepolyacrylamide gel electrophoresis and transferred to Immobilon P membrane. Membranes were incubated for 90 min with highly specific anti-VEGF-A or anti-VEGF-C polyclonal antibody, then washed and incubated with a horseradish peroxidase-coupled secondary goat anti-rabbit antibody for 60 min. After washing, antibodies were visualized by enhanced chemiluminescence. Equivalent loading of protein in each lane was confirmed by hybridizing the total protein with β-actin.

**Figure 1** Expression of VEGF-A (A) and VEGF-C (B) in six human pancreatic cancer cell lines. Lane 1: COLO-357; lane 2: MIA-PaCa-2; lane 3: PANC-1; lane 4: T3M4; lane 5: ASPC-1; lane 6: CAPAN-1.

### Immunohistochemistry

The same anti-VEGF-A and anti-VEGF-C polyclonal antibodies were used for immunohistochemical analysis. Paraffin-embedded sections (4  $\mu$ m) of pancreatic cancer and noncancerous pancreatic tissues were subjected to immunostaining using the streptavidin-peroxidase technique. After deparaffinization, antigen retrieval was performed by immersing the sections in 10 mmol citrate buffer (pH 6.0) and heated twice in a microwave oven (95  $^{\circ}$ C) for 5 min each time. Endogenous peroxidase activity was blocked by incubation with 1% hydrogen peroxide in distilled water for 10 min. Tissue sections were incubated with normal donkey serum for 20 min at room temperature and then incubated with polyclonal anti-VEGF-A antibody (2  $\mu$ g/mL) or anti-VEGF-C antibody (2  $\mu$ g/mL) in normal donkey serum for 2 h at room temperature. Bound antibodies were detected with biotinylated goat anti-rabbit IgG secondary antibody and streptavidin-peroxidase complex, using diaminobenzidine tetrahydrochloride as the substrate. The sections were counterstained with Mayer's hematoxylin and incubated with nonimmunized rabbit IgG or without primary antibodies, which did not yield positive immunoreactivity.

**Figure 2** Northern blot analysis of VEGF-A and VEGF-C expression in human pancreatic tissues.

Scoring was carried out by two independent observers blinded to the patient's status. Positive staining was defined as the presence of VEGF-A and VEGF-C immunoreactivity in at least 10% of the cancer cells.

### Statistical analysis

Differences in distribution of VEGF-A or VEGF-C were determined using the  $\chi^2$  test. Kaplan-Meier survival analysis was used to estimate survival time and log-rank test was used to compare differences in survival time between VEGF-A positive and negative groups or between VEGF-C positive and negative groups<sup>[20]</sup>.  $P < 0.05$  was considered statistically significant.

## RESULTS

### Expression of VEGF-A and VEGF-C in human pancreatic cancer cell lines

Northern blot analysis of total RNA isolated from pancreatic cancer cell lines indicated that the 6 cell lines expressed the 4.1 kb VEGF-A transcript and 2.4 kb VEGF-C transcript (Figures 1A and 1B). Immunoblotting with a highly specific anti-VEGF-A or anti-VEGF-C antibody revealed an approximately  $M_r$  43000 band (occasionally also a  $M_r$  41000 band) of VEGF-A protein or  $M_r$  55000 band (occasionally proteolytic forms of  $M_r$  41000 molecules) of VEGF-C protein in all the cell lines (Figures 1 A and 1B). Both  $M_r$  43000 band and  $M_r$  41000 band corresponded to the VEGF165 isoform homodimer.

### Expression of VEGF-A and VEGF-C mRNA in human pancreas

Northern blot analysis of total RNA isolated from human pancreatic tissue revealed the 4.1 kb VEGF-A transcript and the 2.4 kb VEGF-C transcript in all normal pancreatic tissue samples and cancer tissue samples (Figure 2). Densitometric analysis of the autoradiograms indicated that the levels of 4.1 kb VEGF-A transcript and 2.4 kb VEGF-C transcript were approximately 3.0-fold and 3.6-fold higher in pancreatic cancer tissues in comparison with normal pancreatic tissues.

**Figure 3** Immunohistochemical analysis of VEGF-A (A) and VEGF-C (B) expression in human pancreatic cancer tissues. In the pancreatic cancers, moderate to strong VEGF-A and VEGF-C immunoreactivity was present in the cytoplasm of cancer cells,  $\times 400$ .

### Expression of VEGF-A and VEGF-C protein in human pancreatic tissue

The same anti-VEGF-A or anti-VEGF-C antibody was used to localize VEGF-A or VEGF-C immunohistochemically. In the normal pancreatic tissue, moderate VEGF-A and VEGF-C immunoreactivity was present in the cytoplasm of endocrine islet cells, a weak immunoreactivity in some ductal cells within the small ductules and in a few acinar cells (data not shown). In the pancreatic cancer tissue, moderate to strong VEGF-A and VEGF-C immunoreactivity was present in the cytoplasm of many cancer cells (Figures 3A and 3B). Among the 50 pancreatic cancer cases, 25 (50%) were positive for VEGF-A and 40 (80%) for VEGF-C immunoreactivity in the cytoplasm of cancer cells.

### Correlation between VEGF-A and VEGF-C expression and patient survival

$\chi^2$  analysis indicated that the presence of VEGF-A in cancer cells was associated with a statistically significant increase in tumor size and local extension (T category). However, there was no correlation between the presence of VEGF-A in cancer cells and lymph node metastasis or distant metastasis or tumor stage or histological grade of cancers (Table 1). The presence of VEGF-C in cancer cells was associated with a statistically significant increase in the presence of lymph node metastasis (N category), but there was no correlation between the presence of VEGF-C in cancer cells and other factors (Table 1). The

mean survival time of the VEGF-A negative and positive groups was  $20.80 \pm 15.00$  months and  $16.04 \pm 9.00$  months respectively. Thus, the survival time of patients with VEGF-A positive tumors was shorter. However, Kaplan-Meier analysis and log-rank test indicated that there was no significant difference in survival between these two groups (Figure 4A). The mean survival time of VEGF-C negative and positive groups was  $30.7 \pm 14.00$  months and  $15.4 \pm 10.00$  months respectively. The survival time of patients with VEGF-C positive tumors was shorter. But Kaplan-Meier analysis and log-rank test indicated that there was no significant difference in survival between these two groups (Figure 4B).

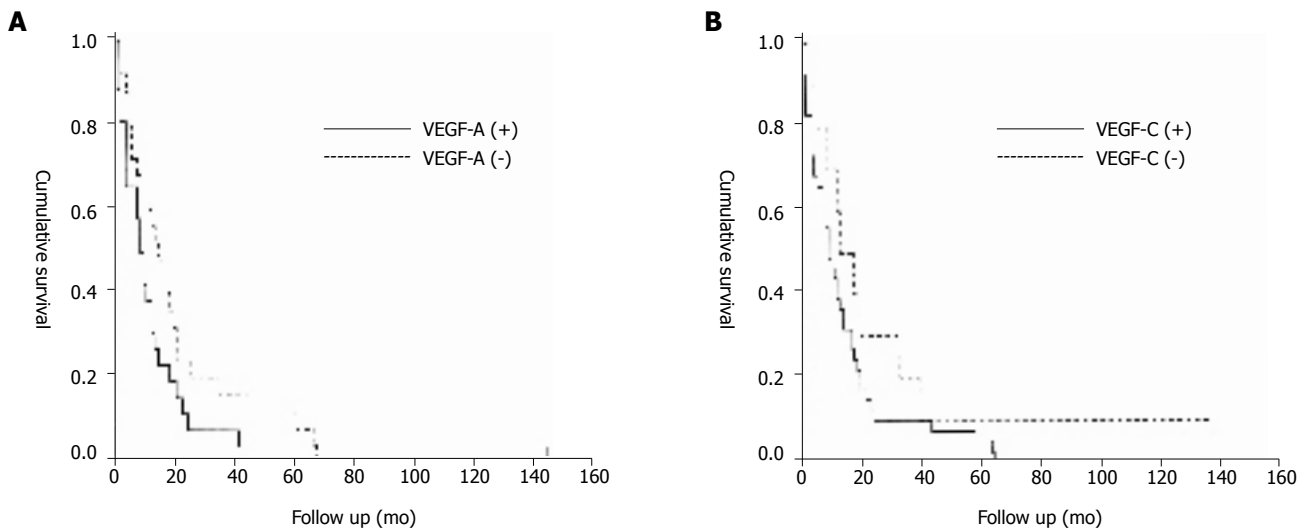

### Correlation between VEGF-A and VEGF-C expression in pancreatic cancer

There was no correlation between VEGF-A and VEGF-C expression in pancreatic cancer (Table 2).

## DISCUSSION

Recently, VEGF-B to -E showing homology to VEGF-A have been identified<sup>[11-13]</sup>. Among these, VEGF-C has

**Figure 4** Survival curve. **A:** Cumulative survival (Kaplan-Meier) plot of the postoperative survival period of patients whose pancreatic tumors exhibited cytoplasmic VEGF-A immunostaining (solid line) versus those whose tumors were negative for VEGF-A (broken line), ( $P=0.184$ ); **B:** Cumulative survival (Kaplan-Meier) plot of the postoperative survival period of patients whose pancreatic tumors exhibited cytoplasmic VEGF-C immunostaining (solid line) versus those whose tumors were negative for VEGF-C (broken line), ( $P=0.159$ ).

a high degree (approximately 30%) of homology to VEGF(-A)<sup>[11, 12, 14-16]</sup>. VEGF-A plays an important role in tumor growth and metastasis<sup>[21-23]</sup>. VEGF-C is a ligand for VEGF-A receptor 3 (flt-4) expressed mainly in endothelia of lymphatic vessels and induces specific lymphatic endothelial proliferation and hyperplasia of the lymphatic vasculature<sup>[11, 24]</sup>.

Expression of VEGF-A and VEGF-C was detected in normal and cancer tissues in the present study. Overexpression of VEGF-A has been reported in mammary, colorectal, liver, gastric and pancreatic malignancies<sup>[21, 22, 25-27]</sup>. Expression of VEGF-A and its receptor KDR correlates with vascularity, proliferation and metastasis of colonic cancer<sup>[22]</sup> and with vessel count and tumor stage of gastric cancer<sup>[26]</sup> as well as with growth of pancreatic cancer. Recent studies demonstrated that expression of VEGF-C in various human tumors, including lymphoma, melanoma, fibrosarcoma, squamous cell carcinoma, breast cancer, gastric cancer, colorectal cancer, pancreatic cancer and hepatocellular carcinoma<sup>[17, 28-34]</sup>. VEGF-C is expressed only in lymph node-positive breast cancer<sup>[29]</sup>. Gastric cancer patients with a high expression of VEGF-C protein have a much poorer prognosis than those with a low VEGF-C expression<sup>[14]</sup>. VEGF-C promotes lymph node metastasis of rectal cancer<sup>[30]</sup>. Expression of VEGF-C and its receptor flt-4 correlates with lymphangiogenic process and metastasis of pancreatic cancer<sup>[17]</sup>.

The present study showed that VEGF-A and VEGF-C expression was abnormal in pancreatic cancer *in vivo*. Northern blot analysis revealed a single 4.1 kb VEGF-A mRNA transcript and a single 2.4 kb VEGF-C mRNA transcript in all normal and pancreatic cancer tissue specimens, as well as 3.0-fold and 3.6-fold increase of VEGF-A and VEGF-C mRNA transcripts in pancreatic cancer tissue specimens, indicating that both VEGF-A and VEGF-C are overexpressed in pancreatic cancer. The distribution of VEGF-A and VEGF-C in normal and

cancerous tissue specimens was different. In the normal pancreas, VEGF-A and VEGF-C were relatively abundant in endocrine islets, less frequently present in ductal cells and only occasionally present in acinar cells. In contrast, VEGF-A and VEGF-C were abundant in ductal-like cancer cells of pancreas. VEGF-A is a specific mitogen toward endothelial cells and VEGF-C is a specific mitogen to lymphatic endothelial cells, suggesting that VEGF-A has a potential to act in a paracrine manner on endothelial cells within the pancreatic tumor mass, leading to enhanced angiogenesis and tumor growth, while VEGF-C has a potential to act in a paracrine manner on lymphatic endothelial cells within the pancreatic tumor mass, leading to enhanced invasion to lymphatic vessels and lymph node metastasis. Cancer with active lymphangiogenesis could be predisposed to metastatic spread via the lymphatic system, resulting in a poor survival rate. It appears that tumor cells need to penetrate the lymphatic endothelium twice to translocate into the interstitium of a lymph node. Because lymphatic vessels have no tight junctions or continuous basal laminae, their penetration may only require tumor cell adhesion to the endothelium and transmigration through intracellular gaps between lymphatic endothelial cells. VEGF-A can increase microvascular permeability by enhancing the transmigration activity of vesicular-vacuolar organelles<sup>[32-34]</sup>. VEGF-C and flt-4 may be components of a paracrine signaling network between cancer cells and the endothelium and may be involved in modifying the permeabilities of both blood and lymphatic vessels and metastasis<sup>[35]</sup>.

Univariate analysis of the immunohistochemical data demonstrated that the presence of VEGF-A and VEGF-C in pancreatic cancer cells was associated with tumor size and lymph node metastasis respectively, indicating that VEGF-A and VEGF-C contribute to pancreatic tumor growth and lymphatic metastasis *in vivo*. Though the survival time was shorter in patients with VEGF-A and VEGF-C positive tumors, this correlation was not statisti-

cally significant. Niedergethmann *et al.*<sup>[36]</sup> and Kuwahara *et al.*<sup>[37]</sup> reported that the survival time of patients with pancreatic ductal carcinoma showing high expression of VEGF-A is significantly shorter than that of those with low or no expression of VEGF-A. Kurahara *et al.*<sup>[38]</sup> reported that VEGF-C and VEGF-D expression in tumor cells is significantly associated with the 5-year survival rate of patients with pancreatic head cancer. In our study, VEGF-A or VEGF-C did not emerge as an independent prognostic parameter. Moreover, our previous study showed that the survival time of patients with VEGF-C positive tumors is shorter<sup>[17]</sup>. Because the majority of patients in the present study had no detectable metastatic disease at the time of surgery, whether VEGF-A or VEGF-C expression correlates with enhanced propensity of pancreatic cancer to metastasize remains unknown. Further studies are needed.

## Abstract

**AIM:** To study the role of N-acetylcysteine (NAC) as a protective agent in rifampicin (RMP)-induced oxidative hepatic injury of young rats.

**METHODS:** Hepatic injury was produced by giving 50mg/kg body weight/day of RMP for 3 wk. A dose of NAC (100mg/kg body weight/day) was given in combination with RMP intraperitoneally. Analysis of lipid peroxidation, thiol levels, cytochrome P<sub>450</sub>, superoxide dismutase (SOD), catalase, glutathione peroxidase, reductase and transferase were estimated in liver along with the body weight, liver weight and histological observations.

**RESULTS:** RMP exposure resulted in no change in body and liver weight while antioxidative enzymes were altered but the non protein thiol (GSH) status was well preserved. Cytochrome P<sub>450</sub> system and peroxidation of lipids were induced by RMP exposure. Partial protection was observed with NAC against RMP-induced changes in liver, which was evidenced from the prevention of increase in lipid peroxidation and the reduction in SOD and catalase enzyme levels.

**CONCLUSION:** NAC protects young rats against RMP-induced oxidative hepatic injury.

## INTRODUCTION

Tuberculosis is one of the major health problems in developing countries like India. Most adult deaths in India are due to vascular diseases or pulmonary tuberculosis<sup>[1]</sup>. Steel *et al*<sup>[2]</sup> reported that clinical hepatitis occurs in 1.1% of adults receiving RMP containing regimens. Occasional cases of RMP-associated hepatitis have been reported in patients not receiving isoniazid (INH) treatment<sup>[3]</sup>. The actual incidence of RMP-induced hepatitis remains unclear because RMP is always used in combination with other antitubercular drugs.

The mechanism of RMP-induced liver injury is not yet fully understood. Gangadharan<sup>[4]</sup> showed that RMP causes a direct toxic injury to the hepatocytes. This has been confirmed in experimental rats by Sodhi *et al*<sup>[5]</sup>. Hepatotoxicity still remains a definite yet unpredictable risk during treatment of tuberculosis patients, suggesting that diminution of protective mechanisms and enhancement of destructive mechanism might be important in RMP-induced hepatotoxicity.

It is well established that by augmenting cellular antioxidative defense system especially non protein thiols, i.e. glutathione (GSH), cells can be protected against oxidative injuries produced by various drugs<sup>[6]</sup>. Among the possible antioxidant chemicals, NAC known to be non-toxic has been used in the treatment of various disorders<sup>[7, 8]</sup>. The present study was designed to see whether NAC could protect against RMP-induced oxidative hepatic injury in an experimental model.

## MATERIALS AND METHODS

### Animals

Young male Wistar rats weighing about 150-200 g were selected in the present study. Animals were fed with standard rat pellet diet (Aashirwad Industries, Chandigarh) and water *ad libitum*.

### Drugs

NAC was obtained from Sigma Chemical Company, USA. RMP and NAC were administered intraperitoneally (i.p) to animals. RMP solution was prepared by dissolving the powder in sterile distilled water and then the pH was

adjusted to 3.0 with 0.1 N HCl to have a clear solution<sup>[9]</sup>. Similarly, NAC was dissolved in sterile distilled water. The volume of sterile water injected either alone or containing drugs, was kept constant (4.0mL/kg body weight/day) in all the treatments.

A dose of NAC (100 mg/kg body weight/day) was selected when the animals treated with this dose did not exhibit any histopathological liver injury at the end of the treatment schedule.

### Study protocol

Forty animals were divided into four groups (10 each group) and injected with RMP and / or NAC (dissolved in sterile water) for a period of three weeks.

Animals in control group were injected with sterile water alone. Animals in RMP group were injected with 50mg/kg body weight/day of RMP alone after dissolved in sterile distilled water. Animals in RMP+NAC group were injected with RMP (50mg/kg body weight/day) and NAC (100mg/kg body weight/day). Animals in NAC group were treated with NAC at a dose of 100mg / kg body weight / day.

Animals were fasted for 12 h before sacrificed by cervical dislocation under light anesthesia and weighed on d 0 and 10 and at the time of sacrifice. Their liver tissues were excised and cooled in an ice-bath after weighed. Liver tissues were perfused with ice-cold saline. Homogenate and post mitochondrial supernatant were prepared as previously described<sup>[5]</sup>. Crude homogenate (20%) was prepared in 100mmol/L phosphate buffer and used to estimate thiols (total and protein-bound) and lipid peroxidation. The homogenate was then centrifuged at 10000r/min for 20 min at 4°C. The post mitochondrial supernatant (PMS) was separated from the pellet by decantation and pellet was discarded. All enzyme assays were carried out using PMS fraction.

Estimation of thiols was carried out according to the method of Sedlak and Lindsay<sup>[10]</sup>. Lipid peroxidation was measured by the method of Ohkawa *et al*<sup>[11]</sup>. Cytochrome P<sub>450</sub> was assayed using the method of Omura and Sato<sup>[12]</sup>. The method of Kono<sup>[13]</sup> was adopted to estimate superoxide dismutase. Activity of catalase was measured by the method of Luck<sup>[14]</sup>. Glutathione peroxidase, glutathione reductase and glutathione transferase were estimated using the methods of Flohe and Gungler<sup>[15]</sup>, Carlberg *et al*<sup>[16]</sup> and Habig *et al*<sup>[17]</sup>, respectively. Proteins were estimated using bovine serum albumin as standard by the method of Lowry *et al*<sup>[18]</sup>.

### Histopathological investigation

Small pieces of liver tissue from sacrificed animals were preserved in 10% formal saline. Light microscopy was performed after slides were routinely stained with haematoxylin and eosin (H&E).

### Statistical analysis

Data were analysed by analysis of variance (ANOVA) followed by multiple comparison using Dunnett's procedure to compare all groups against control and Student-Newman-Keul's procedure to compare the pair wise of all groups.

An approval from Postgraduate Institute of Medical

Education and Research Ethical Committee was obtained before the animal experimentation.

## RESULTS

Analysis of variance showed that inter-group variation in body weight and the effect of treatment on body weight were not significant. Relative liver weight (g/100 g body weight) of experimental animals was not affected by any of the treatments. Animals treated with RMP had comparable liver weight ( $4.75 \pm 0.75$ g) to animals treated with RMP+NAC ( $4.85 \pm 0.67$ g).

Mortality in RMP treatment group was decreased from 30% (3/10) to 10% (1/10) when NAC was co-administered with RMP.

Essentially normal morphology was observed in all 10 control animals (100%) (Figure 1). Hepatotoxicity was produced by i.p. injection of RMP at a dose of 50mg / kg body weight / day over a period of three weeks as evidenced by the presence of changes such as hepatocytic necrosis and portal triaditis. Nine out of 10 (90%) animals treated with RMP showed histological lesions, 7 out of 10 (70%) animals had moderate degree of portal triaditis (Figure 2A) and 2 out of 10 (20%) had spotty necrosis with portal triaditis (Figure 2B). Only 1 out of 10 (10%) animals treated with RMP showed normal morphology.

Animals co-exposed to RMP+NAC exhibited lower degrees of histological lesions such as mild to moderate portal triaditis and spotty necrosis. Control animals treated with NAC alone had no change in liver histology.

Hepatic thiols were significantly increased ( $P < 0.05$ ) after treatment with RMP, while NAC had no effect on total and bound thiols when animals were treated with RMP+NAC. Multiple comparisons using Newman-Keul's procedure did not reveal any significant change in treated groups with respect to non protein thiols (GSH) (Table 1).

Lipid peroxidation was significantly ( $P < 0.001$ ) enhanced in animals exposed to RMP compared to the controls. Simultaneous administration of NAC and RMP prevented the enhancement of lipid peroxidation compared to control animals ( $P < 0.05$ ). But the values of lipid peroxidation in RMP+NAC-treated animals were higher ( $P < 0.05$ ) than those in the controls (Table 2). There was no significant difference in LPO values between NAC-treated group and controls.

Superoxide dismutase (SOD) was decreased significantly ( $P < 0.001$ ) in RMP-treated animals compared to controls. Supplementation of NAC to RMP treated animals significantly prevented the reduction of superoxide dismutase while no effect of NAC was observed in control group (Table 2).

Catalase activity was significantly decreased in RMP-treated animals as compared to controls ( $P < 0.001$ ). Supplementation of NAC to RMP-treated animals prevented the lowering of catalase levels. However, animals treated with NAC in combination with RMP had significantly lower ( $P < 0.001$ ) enzyme levels compared to the controls while NAC alone had no effect on catalase activity in control group (Table 2).

Levels of glutathione-S-transferase were significantly higher ( $P < 0.001$ ) in RMP-treated group than in controls.

**Table 1** Effect of RMP treatment (50 mg/kg/day for 3 wk) and NAC (100 mg/kg/day for 3 wk) on total, protein-bound and non-protein thiols in rats ( $\mu\text{mole/g}$  liver) (mean  $\pm$  SD)

Group	Total thiols	Protein bound	Non protein thiols (GSH)
Control	13.42 $\pm$ 0.52	10.09 $\pm$ 0.45	3.23 $\pm$ 0.42
RMP	16.77 $\pm$ 0.61 <sup>a</sup>	13.49 $\pm$ 0.42 <sup>a</sup>	2.98 $\pm$ 0.61
RMP + NAC	17.17 $\pm$ 0.78 <sup>b</sup>	13.92 $\pm$ 0.51 <sup>b</sup>	3.37 $\pm$ 0.72
NAC	13.44 $\pm$ 0.50	9.55 $\pm$ 0.25	3.42 $\pm$ 0.43

<sup>a</sup> $P < 0.05$  vs control, <sup>b</sup> $P < 0.001$  vs control.**Table 3** Effect of RMP treatment (50 mg/kg/day for 3 wk) and NAC (100 mg/kg/day for 3 wk) on glutathione peroxidase, glutathione reductase and cytochrome P<sub>450</sub> (nmol/min/mg protein) (mean  $\pm$  SD)

Group	Glutathione peroxidase	Glutathione reductase	Cytochrome P <sub>450</sub>
Control (C)	458.37 $\pm$ 45.19	25.37 $\pm$ 3.82	0.431 $\pm$ 0.050
RMP	287.18 $\pm$ 39.82W <sup>b</sup>	27.01 $\pm$ 2.75	0.540 $\pm$ 0.039 <sup>b</sup>
RMP + NAC	385.99 $\pm$ 50.47 <sup>a</sup>	27.47 $\pm$ 3.27	0.509 $\pm$ 0.042 <sup>a</sup>
NAC	474.07 $\pm$ 37.92	26.93 $\pm$ 4.01	0.412 $\pm$ 0.047

<sup>a</sup> $P < 0.05$  vs control, <sup>b</sup> $P < 0.001$  vs control.

Supplementation of NAC to RMP-treated animals prevented the increase of GST activity. GST level in NAC-treated animals was comparable to that in the controls (Table 2).

Glutathione peroxidase activity was significantly ( $P < 0.001$ ) decreased after RMP treatment. NAC in combination with RMP could prevent the decrease of glutathione peroxidase activity but was still significantly lower than that in the controls ( $P < 0.05$ ). NAC had no effect on this enzyme in control group (Table 3).

Glutathione reductase did not significantly increase in the RMP-treated animals compared to the controls. Supplementation of NAC to RMP-treated and control groups had comparable enzyme activities to non RMP-exposed animals (Table 3).

Cytochrome P<sub>450</sub> was induced in RMP-treated animals ( $P < 0.001$ ). Supplementation of NAC to RMP-treated and control animals had no effect on cytochrome P<sub>450</sub> in the present study. The values in RMP+NAC group were comparable to those in RMP-treated animals (Table 3).

## DISCUSSION

Rat model was used to study the hepatotoxic effect of RMP and hepatoprotective effect of NAC. Rats have been successfully used to establish RMP-induced hepatotoxicity models<sup>[9,19]</sup>. Our earlier studies have shown that oxidative stress is the mechanism of RMP-induced hepatotoxicity in experimental rats<sup>[5]</sup>.

In the present study, hepatotoxicity was produced by RMP at a dose of 50 mg/kg body weight/day for three weeks. The dose is very high compared to that in the

**Table 2** Effect of RMP treatment (50 mg/kg/day for 3 wk) and NAC (100 mg/kg/day for 3 wk) on lipid peroxidation, catalase, superoxide dismutase, glutathione-S-transferase (nmol/min/mg protein) in rats (mean  $\pm$  SD)

Group	Lipid peroxidation (nmol MDA/g tissue /10min)	Catalase ( $\mu\text{mol/min/mg}$ protein)	superoxide dismutase (IU)	Glutathione-S-transferase using EA
Control	120.47 $\pm$ 9.3	310.32 $\pm$ 31.2	17.92 $\pm$ 2.25	13.94 $\pm$ 2.27
RMP	163.52 $\pm$ 22.6 <sup>b</sup>	204.92 $\pm$ 28.6 <sup>b</sup>	11.71 $\pm$ 1.39 <sup>b</sup>	18.58 $\pm$ 1.52W <sup>b</sup>
RMP + NAC	138.71 $\pm$ 13.2W <sup>a</sup>	269.48 $\pm$ 19.5W <sup>a</sup>	14.38 $\pm$ 2.47W <sup>a</sup>	15.92 $\pm$ 1.38 <sup>a</sup>
NAC	103.59 $\pm$ 12.9	317.51 $\pm$ 38.7 <sup>a</sup>	16.47 $\pm$ 2.80	14.59 $\pm$ 2.18

<sup>a</sup> $P < 0.05$  vs control, <sup>b</sup> $P < 0.001$  vs control.**Figure 1** Normal morphology of rat liver (H&E, X 55).

treatment of tuberculosis in human subjects, because higher doses are required for animals like rats as they metabolize the drugs at a faster rate<sup>[20]</sup>.

In the present study, the drugs used had no effect on body weight and relative liver weight of the animals. This is consistent with what has been reported earlier<sup>[21]</sup>.

Cytochrome P<sub>450</sub> mediates generation of reactive metabolites of drugs and their covalent binding to hepatic macromolecules is the most accepted mechanism of RMP-induced hepatic injury<sup>[22]</sup>. RMP is a potent inducer of cytochrome P<sub>450</sub> and enhances the covalent binding of reactive metabolites of acetyl hydrazine to the macromolecules of hepatocytes<sup>[21]</sup>.

In the present study, free radicals formed either by the reaction of drug's radicals with oxygen or by the interaction of superoxide radicals with hydrogen peroxide seemed to initiate lipid peroxidation in RMP-treated rats, suggesting that increased lipid peroxidation might be associated with cellular damage. NAC combined with RMP prevented significantly the peroxidation of lipids in animals exposed to RMP either directly or through non-protein thiols (GSH) by scavenging the radicals. The scavenging ability of NAC has also been reported during cancer chemotherapy<sup>[23,24]</sup>. From these studies and results of the present study, it can be concluded that the protective effect of NAC may be due to the radicals scavenged by NAC.

SOD, catalase and glutathione peroxidase constitute a

**Figure 2** Portal triaditis (A) and spotty necrosis (B) in rats treated with RMP (H&E, X55)

mutually supportive team of antioxidative enzymes which provide a defense against reactive oxygen species. In the present study, SOD decreased significantly in RMP-exposed animals. The activities of  $H_2O_2$  scavengers, catalase and glutathione peroxidase, decreased significantly after RMP treatment. Similar results have been reported by Sodhi *et al*<sup>[5]</sup>. The decline in these enzymes in the present study could be explained by the fact that excess superoxide radicals may inactivate  $H_2O_2$  scavengers, thus resulting in inactivation of SOD<sup>[25]</sup>.

In the present study, co-administration of NAC and RMP partially prevented decrease in catalase and glutathione peroxidase activities, which might be due to incomplete scavenging of radicals by NAC, resulting in partial protection of these enzymes. As NAC reacts with scavenging radicals slowly, residual superoxide radicals might interact with  $H_2O_2$  resulting in the formation of OH radicals. This is supported by the fact that lower increase in lipid peroxidation was observed in NAC+RMP co-exposed animals as compared to RMP-treated animals. Jaya *et al*<sup>[26]</sup> have also reported that anti-peroxidative enzymes can be partially restored with NAC in rats exposed to alcohol and paracetamol.

It was reported that thiols increase significantly after RMP treatment, which might be due to the increased protein content<sup>[28]</sup>.

GSH constitutes approximately 90% of total hepatic

thiols, which could explain the maintained GSH levels in RMP-exposed animals in the present study. Supplementation of NAC also failed to increase the threshold levels of GSH. These results are inconsistent with Yao *et al*<sup>[27]</sup> who failed to demonstrate a significant rise of GSH in livers of rats treated with NAC.

In the present study, glutathione used in scavenging hydroxyl radicals stimulated glutathione reductase activity, thereby maintaining nearly normal GSH. NAC failed to decrease glutathione reductase activity in RMP-exposed animals. These results might be due to stimulation of glutathione reductase activity by the low level of glutathione and or a negative feedback inhibition by the normalization of GSH levels in NAC treated animals.

GST activity against EA was stimulated in animals treated with RMP and RMP+NAC. GST is specific for removal of peroxidation products and induction of this enzyme might be in response to lipid peroxidation so as to remove the highly toxic materials from cellular milieu. Adachi *et al*<sup>[28]</sup> reported that RMP can induce GST activity in rats.

The histopathological patterns of liver injury in the present study are similar to the earlier findings<sup>[9, 29]</sup>. Sodhi *et al*<sup>[5]</sup> also showed that patchy necrosis occurs in RMP-treated animals. In the present study, NAC failed to protect completely against RMP-induced hepatic injuries but it protects completely against hepatic injuries in rats after treatment with INH+RMP<sup>[30]</sup>.

In conclusion, RMP exposure to animals does alter the profile of antioxidant enzymes while non-protein thiol status can be well preserved. The protective effect of NAC on RMP-induced hepatic injury might be due to prevention of lipid peroxidation as well as decline in superoxide dismutase in animals exposed to RMP and NAC. However, partial hepatotoxicity due to RMP might be due to some other mechanisms of injury.

## ACKNOWLEDGEMENTS

Lupin Laboratories, India, was acknowledged for supplying the purified RMP powder as a gift.

### Abstract

**AIM:** To investigate the correlation between ASCA and presence of mucosal *S. cerevisiae* DNA in a population of CD, ulcerative colitis (UC) patients and controls.

**METHODS:** *S. cerevisiae*-specific primers and a fluorescent probe were designed for a 5' exonuclease real time PCR (TaqMan™) assay, which is a homogenous system using a fluorescent-labelled probe for the detection of PCR product in real time. We analyzed the relation of the PCR results with the ASCA findings in a group of 76 inflammatory bowel disease (IBD) patients (31 CD, 45 UC) and 22 healthy controls (HC).

**RESULTS:** ASCA (*IgA* or *IgG*) were positive in 19 (61%) patients with CD, 12 (27%) with UC and none of the HC. PCR amplification was inhibited and excluded from the final results in 10 (22%) UC patients, 7 (22%) CD patients, and 6 (30%) HC. In only 15 of the mucosal samples, *S. cerevisiae* DNA was detected by real time PCR, including 7 (29%) in CD, 7 (19%) in UC, 1 (6%) in HC. In 4 CD and in 4 UC patients, ASCA and mucosal *S. cerevisiae* were positive. Mucosal *S. cerevisiae* was present in combination with negative ASCA *IgA* and *IgG* in 3 UC, and 3 CD patients.

**CONCLUSION:** We conclude that since the presence of *S. cerevisiae* in colonic mucosal biopsy specimens is very rare, ASCA is unlikely to be explained by continuous exposure to *S. cerevisiae* in the mucosa. Therefore, ASCA formation must occur earlier in life and levels

### INTRODUCTION

Inflammatory bowel disease (IBD) is characterized by a chronic relapsing intestinal inflammation. The causes of IBD are unknown but genetic, environmental, immunological, and microbial factors may be involved. Results from studies on animals suggest that the intestinal flora participates in the initiation and perpetuation of IBD<sup>[1]</sup>.

*Saccharomyces cerevisiae* is the most common species of the genus *Saccharomyces*. It is used in baker's yeast and readily finds its way into our foods<sup>[2]</sup>. Several case-series describe serious *S. cerevisiae* infections in immune-compromised patients, usually following treatment with broad-spectrum antibiotics<sup>[3-6]</sup>. Opportunistic infections by viral and fungal agents have been described as occurring in rare cases of ulcerative colitis (UC). Only one case describes diarrhea associated with *S. cerevisiae* cultured in the stool specimen of an UC patient<sup>[7]</sup>. So far, no studies have been published concerning the presence of *S. cerevisiae* in the intestinal tissue of patients with IBD. *S. cerevisiae* specific primers and a fluorescent probe were designed for a 5' exonuclease real time PCR (TaqMan™) assay. This method provides high specificity and sensitivity for detecting *S. cerevisiae* DNA but is hampered by the difficulties arising from DNA extraction of *Saccharomyces* species.

In 1988, the presence of anti-*Saccharomyces cerevisiae* antibodies (ASCA) in patients with Crohn's disease (CD) was firstly described<sup>[8]</sup>. The ASCA test for diagnosing CD has a sensitivity of 72% and a specificity of 82%<sup>[9-12]</sup>. The underlying cause of generating *S. cerevisiae* antigens

supporting the specific antibody response in CD is still unknown. ASCA are thought to result from a specific antibody response to the *S. cerevisiae* cell wall mannan (phosphopeptidomannans). It is unknown whether this is a direct response towards the yeast itself or an epiphenomena with a similar immunologic response towards another antigen. It is postulated that the yeast wall cell mannan may mimic a high mannose-containing molecule towards which the antibody is directed inducing a hypersensitivity reaction during inflammation<sup>[12,13]</sup>.

## MATERIALS AND METHODS

### Patients

Seventy-six patients with IBD (45 UC, 31 CD) and 22 healthy age- and sex-matched controls regularly visiting the Departments of Gastroenterology from the VU University Medical Center, Amsterdam, the Netherlands, a third line referral center, and St Anna Hospital, Geldrop, the Netherlands, a regional hospital, were enrolled in the study. IBD patients with clinical complaints compatible with active inflammation of the mucosa were screened for the study, but both IBD patients with active inflammation as well as quiescent disease assessed by macroscopic endoscopic findings were included in the study. The diagnosis of CD and UC was based on standard endoscopic, histological, and radiographic features<sup>[14]</sup>. Disease localization and activity, demographical data and medication were documented. Fifty-four percent of UC patients and 42% of CD patients was treated with immunosuppressive medication (Table 1). None of the patients was treated with probiotics containing *S. boulardii*. However, they were not requested to use a diet low of *S. cerevisiae* either.

During sigmoidoscopy, 2 mucosal biopsy specimens were obtained from the sigmoid and directly snap frozen in liquid nitrogen and then stored at -18°C until further analysis. In addition, blood samples were drawn for detection of ASCA antibodies.

This study was approved by the Medical Ethical Committee of the VU University Medical Center, Amsterdam, the Netherlands.

### ASCA ELISA

ASCA IgA and IgG were determined by commercially available ELISA kits (Inova, Uniprom Diagnostics BV, Krimpen aan de IJssel, the Netherlands). The antigen consists of phosphopeptidomannan (PPM) extracted from *S. cerevisiae*. ASCA ELISAs were performed according to the manufacturer's instructions. ASCA results were expressed as arbitrary units with a cut-off for positivity of 25 U/mL as advised by the manufacturer and described elsewhere<sup>[15]</sup>. Serum was considered positive if either IgA or IgG or both were positive. Serum was considered negative if both IgA and IgG ASCA were negative.

### DNA isolation

Biopsy specimens were pretreated with 200 µL of 5 g/L collagenase A (Roche Diagnostics, Almere, Nederland B.V.) and incubated at 37°C overnight with continuous shaking. Subsequently, each biopsy was divided into two equal cell

fractions. One fraction was spiked with 20 colony forming units/µL *S. cerevisiae*. Both fractions were incubated for 90 min at 37°C with 600 µL of sorbitol buffer and 200 U of lyticase (Sigma-Aldrich, Steinheim, Germany), prior to the isolation of chromosomal DNA with the DNeasy™ Tissue Kit (Qiagen, Hilden, Germany), according to the manufacturer's instructions. The end volume after the extraction of the DNA from the biopsy specimen was 100 µL. The control fraction of the biopsy specimen contained 20 CFU equivalents/µL (elution concentration).

*S. cerevisiae* specific primers and a fluorescent probe for a 5' exonuclease RT PCR (TaqMan™) assay were designed with the Primer Express software package (Applied Biosystems, Foster City, CA, USA). This assay is a homogeneous system with a fluorescent double-labeled probe for the quantitative detection of PCR product. This provides a rapid automated combined PCR amplification and detection system with no post-amplification manipulation of amplicons, thereby considerably reducing the risk of contamination. Coupled with a quick, simple DNA extraction method, this protocol allows for rapid specification of clinical isolates. Amplification reactions were carried out in a total volume of 25 µL. Reaction mixtures contained 1x universal master mix (Applied Biosystems), 300 nmol of *Saccharomyces* forward primer (5'- GAA ATG CCA CCG TGA ATG C), 300 nmol of *Saccharomyces* reverse primer (5'-CTT TGG TGG TGA TCC TCT ATG ATT G) and 100 nmol of labeled probe (FAM - TGG CAC CAT GAA CCC TAG CGT CGT T - TAMRA), and 5 µL of DNA. To prevent inhibition, 5 g/L bovine serum albumin (BSA) (Sigma-Aldrich, Steinheim, Germany) was added to the PCR mixtures. Amplification was carried out after an incubation for 2 min at 50°C and for 10 min at 95°C, followed by 45 cycles at 95°C for 15 s, and at 60°C for 1 min. These reactions were performed on an ABI Prism 7000 Sequence Detection System (SDS) (Applied Biosystems, Figure 1).

### Statistics

SDS software was used for analysis of the data obtained from RT-PCR results, and *t*-test with separate variance estimates were used to test differences between patients with CD, UC and controls.

## RESULTS

ASCA (IgA or IgG) were identified in 19 (61%) CD patients, 12 (27%) UC patients and none of the HC. Of the patients, 42% of CD patients and 54% of UC patients were using immunosuppressive medication (Table 2).

To determine the sensitivity of real time PCR, *S. cerevisiae* cells were cultured and the amount of colony forming units (CFU) were counted. After DNA isolation a dynamic range, based on the related amount of DNA (CFU equivalents) was made from 10 to 10<sup>5</sup> (Figure 2).

Specificity of the PCR for *S. cerevisiae* was examined by comparing the results of pure *S. cerevisiae* DNA and *S. cerevisiae* DNA mixed with DNA isolated from 10 different bacteria (*Bacteroides vulgatus*, *Bifidobacterium adolescentis*, *Clostridium difficile*, *Lactobacillus acidophilus*, *Propionibacterium acnes*, *Actinomyces viscosus*, *Enterococcus faecalis*, *Fusobacterium*

Figure 1 Annealing cycles of *S. cerevisiae*Figure 2 Dilution series of *S. cerevisiae*

*nucleatum*, *Escherichia coli*, *Streptococcus pyogenes*, *Listeria monocytogenes*, *Listeria ivanovi*), belonging to the normal gut flora and 6 different *Saccharomyces* species (*S. boulardii*, *S. unisporus*, *S. kluyveri*, *S. pastorianus*, *S. paradoxus*, *S. servazii*). In addition, this DNA mixture neither influenced the sensitivity nor the specificity of the *S. cerevisiae* amplification (data not shown). Among the 15 mucosal biopsies, *S. cerevisiae* DNA was detected in 7 (29%) CD patients, 7 (19%) UC patients, 1 (6%) HC. The amount of *S. cerevisiae* DNA was low and varied. Positive values were to be found between 37-38 CFU equivalents. Inhibition during amplification occurred in 8 (18%) UC patients, 7 (22%) CD patients and 6 (30%) HC.

Furthermore, 25% (4/16) CD patients and 33% (4/12) UC patients showed positivity for both ASCA and mu-

cosal *S. cerevisiae* DNA. In 12% (3/25) UC and 38% (3/8) CD patients, mucosal *S. cerevisiae* DNA was present in combination with negative ASCA *IgA* and *IgG* (Tables 3 and 4).

## DISCUSSION

ASCA (*IgA* or *IgG*) were positive in 19 (61%) CD patients, 12 (27%) UC patients and none of the HC. Out of the 15 mucosal biopsies, RT PCR demonstrated the presence of *S. cerevisiae* DNA in 7 (29%) CD patients, 7 (19%) UC patients, and 1 (6%) HC. No significant correlation could be found between ASCA and the presence of *S. cerevisiae* DNA isolated from mucosal biopsies.

Frequencies of ASCA reported in literatures range from 39-76% for CD patients, 5-15% for UC patients to 0-5 % in controls<sup>[8, 11, 12, 16-23]</sup>. In this study ASCA positivity in the UC group was high (27%) as compared to earlier ASCA studies from our group and reported frequencies in literature.

The presence of ASCA appears not to be related to disease activity<sup>[23]</sup>. Therefore, we assume that our selection of patients (clinical complaints compatible with active disease) is not likely to influence ASCA status or the presence of *S. cerevisiae*. Forty-two percent of CD patients and 54% of UC patients were using immunosuppressive agents in this cohort (Table 1). This high percentage of patients using immunosuppressive agents reflects the overall disease activity of our patient population, being relatively severe. However, use of immunosuppressive agents does not explain the high frequency of ASCA in our UC population since most ASCA-positive UC patients did not use this type of medication. Therefore, it can be hypothesized that healing of the mucosa with the use of immunosuppressive agents will lead to decreasing ASCA levels, as has been reported in the treatment of children with active CD<sup>[22]</sup>. ASCA were detected with well-validated commercially available kits that have been described in previous studies<sup>[9]</sup>.

Mucosal permeability appears increased in active CD as a consequence of direct effects of pro-inflammatory molecules and transmigrating neutrophils. However, considerable controversy exists regarding a primary genetically

Table 2 RT-PCR and ASCA results in relation to medication

determined defect in epithelial barrier function<sup>[24-26]</sup>.

In a small study<sup>[27]</sup>, intestinal permeability, tested by a cellobiose/mannitol test, was raised in 6 (37%) of the CD patients and in 11% of their relatives. This altered intestinal permeability was unrelated to sex, age, disease activity, localization, duration, treatment schedule, as well as to serum ASCA positivity, a rather stringent subdivision in such a small patient group. Although an interesting finding, this makes interpretation difficult. Furthermore, genetic polymorphisms were not taken into account.

ASCA is not related to mucosal disintegrity, because ASCA is independent of disease activity<sup>[28]</sup>. Elevated serum levels of ASCA did not primarily seem to result from a defect of the gut barrier<sup>[29]</sup>. These data fit in with the hypothesis that a relationship between antibody responses toward microbial antigens and complicated small bowel diseases reflect the interplay between a genetically susceptible host and relevant luminal flora, as has been suggested before, relating intestinal permeability to environmental factors, and ASCA generation to genetic predisposition<sup>[23]</sup>.

To our knowledge, this is the first study describing the presence of *S. cerevisiae* DNA in intestinal mucosa of IBD patients by using RT-PCR. The presence of ASCA antibodies could not be correlated with mucosal *S. cerevisiae* DNA in biopsy specimens taken during sigmoidoscopy although the RT-PCR test is highly sensitive and specific. Every individual sample was checked for inhibition by a simultaneous spiked amplification. Inhibition during amplification occurred in 8 (18%) UC patients, 7 (22%) CD patients and 6 (30%) HC. Extraction of DNA from yeast requires special enzymes to remove the cell wall<sup>[30]</sup>. Theoretically, excluding a number of patients from the total patients due to inhibition of the RT-PCR amplification may influence the results, particularly taking into account the relatively small study population. However, amplification problems were equally distributed in all groups. Furthermore, one could hypothesize that the presence of *S. cerevisiae* is higher in ileal mucosa than in the sigmoid since higher ASCA levels were detected in CD patients with ileal localization of disease<sup>[28]</sup>. Preliminary RT-PCR data from our group show comparable numbers of *S. cerevisiae* in the left and right side of the colon consistent with a equally distributed presence of *S. cerevisiae* throughout the (distal) intestinal tract (Akol, personal communication). Interbiopsy variability between multiple biopsies taken at the same

localization was low. Therefore, our results were unlikely to be biased by neither the number of biopsy specimens nor the localization from where the biopsies were obtained.

The presence of mucosal *S. cerevisiae* DNA with concomitant negative serum ASCA IgA and IgG in one UC and two CD patients can not be explained by the intestinal leakage hypothesis. This finding corroborates the hypothesis that ASCA formation is an epiphenomenon (in genetically susceptible individuals) rather than the result of antigenic challenge by intestinal presence of *S. cerevisiae* in leaking mucosa. On the contrary, we postulate that since the presence of *S. cerevisiae* DNA in mucosal biopsy specimens is very rare, presence of ASCA can not be explained by antigenic exposure to *S. cerevisiae*.

Another hypothesis is that everyone encounters *S. cerevisiae* early in life. In some patients, the (transitory) *S. cerevisiae* presence may lead to ASCA formation, particularly in people prone to develop CD. Only in a small percentage of people, life-long colonisation may be the result, comparable to what has been documented in other species such as *Clostridium difficile*. Although intra-individual, longitudinal determination values of ASCA were not tested in this study, ASCA formation may be initiated early in life and perpetuate thereafter as described in adult populations<sup>[31]</sup>. In contrast, ASCA levels decrease after treating active inflammation in children with CD<sup>[22,32,33]</sup>. These differences between stable ASCA values in an adult population and decreasing ASCA values in a paediatric population have recently been described for a population with coeliac disease<sup>[34]</sup>, pointing at differences in antigen handling/immunologic response in children and adults.

In conclusion, our study demonstrates no any correlation between the presence of ASCA antibodies and mucosal *S. cerevisiae* DNA. Although the study population was small, this finding underscores the hypothesis that ASCA antibodies are not solely formed as a reaction on the mannan from the yeast cell wall but rather is an epiphenomenon with a similar immunologic response towards another, yet unidentified antigen.

## ACKNOWLEDGEMENTS

Xander Huijsdens is kindly acknowledged for designing the primer-probe combinations for *S. cerevisiae*. Furthermore, we thank Teun Boekhout from the CBS in Utrecht for providing the *Candida* species for testing the specificity

of the PCR. We also thank Uniprom Diagnostics BV, Krimpen aan de IJssel, the Netherlands for providing the ASCA kits.

### Abstract

**AIM:** To study the relationship between particularly interesting new cysteine-histidine rich protein (PINCH) expression and clinicopathological factors in Chinese colorectal cancer patients.

**METHODS:** The expression of PINCH was examined by immunohistochemistry in 141 samples of primary colorectal adenocarcinoma and 92 normal samples of colorectal mucosa. Eighty of the cases had both primary tumour and normal mucosa from the same patients.

**RESULTS:** PINCH was expressed in the stroma of normal mucosa and tumours. PINCH expression in tumour-associated stroma was increased compared to normal mucosa in both unmatched cases ( $n = 141$ ,  $X^2 = 85.79$ ,  $df = 3$ ,  $P < 0.0001$ ) and matched cases ( $n = 80$ ,  $X^2 = 45.86$ ,  $df = 3$ ,  $P < 0.0001$ ). Among 135 tumours with visible invasive margin, 86 (64%) showed stronger PINCH expression at the invasive margin than in the intratumoural stroma. The frequency of PINCH strong expression in mucinous and signet-ring cell carcinomas was higher (52%) compared to non-mucinous carcinomas (29%,  $X^2 = 5.13$ ,  $P = 0.02$ ). We did not find that PINCH expression was related to patient's gender, age, tumour location, tumour size, gross status, histological type, differentiation, invasion depth, lymph node status and Dukes' stage ( $P > 0.05$ ).

### INTRODUCTION

Studies have shown the importance of stromal tissue in regulating the physiological processes of the body. Disruption of stromal-epithelial interactions and cell adhesion alters cellular signalling, which influences proliferation, angiogenesis, differentiation, motility, death, genomic integrity and other phenotype in the cells and tissues<sup>[1-3]</sup>. Extra-cellular matrix (ECM) adhesion is a fundamental process that controls a variety of cellular processes including cell shape changes and migration. Cell-ECM interactions are mediated by a selective group of membrane and cytoplasmic proteins at the ECM contact sites. Integrin-linked kinase (ILK) is a multidomain protein that plays an important role at ECM adhesion sites<sup>[2-7]</sup>.

PINCH is a LIM domain adapter protein. The PINCH gene is located on chromosome 2q12.2. PINCH and ILK components function as an adaptor protein connecting the growth factor-signalling pathways with the integrin-signalling pathway. It is found in focal adhesions, large cellular complexes that link extracellular matrix to the actin cytoskeleton interacting with ILK and Nck2. PINCH has been implicated as a platform for multiple protein-protein interactions mediating integrin signalling within focal adhesions<sup>[4, 7-11]</sup>.

In the present study, the expression of PINCH was immunohistochemically studied in 141 samples of primary colorectal adenocarcinoma and 92 normal mucosa samples. The aims were to investigate the expression of PINCH in

normal mucosa and primary tumours in Chinese colorectal cancer patients and to identify the relationship between PINCH expression and clinicopathological variables including patient's gender, age, tumour location, tumour size, gross status, histological type, grade of differentiation, invasive depth, metastasis in the lymph nodes and Dukes' stages.

## MATERIALS AND METHODS

### Patients

Tumour samples were collected from 141 patients with colorectal adenocarcinoma diagnosed at Department of Pathology, Tangshan Worker's Hospital, China, between 2000 and 2002. The study also included 92 normal mucosa samples, 80 of which were matched with the tumours, i.e., from the same patients. Normal samples were taken from the margin of the distant resection being histologically free from pre-tumour and tumour. None of the patients received preoperative radiotherapy or chemotherapy. The patient's gender, age, tumour location, tumour size, gross status, histological type, grade of differentiation, invasive depth, lymph node status and Dukes' stages were obtained from surgical and pathological records. The mean age of the patients was 56 years (range, 30–80 years). Tumours of the caecum, ascending and transverse colon were defined as proximal tumours and tumours of the descending and sigmoid colon and rectum were defined as distal tumours. The mean tumour size was 4.9 cm (range, 0.8–20 cm). Tumours were graded as better (well + moderate) and worse (poor) differentiation. All samples were examined by two pathologists.

### Immunohistological staining and evaluation

The preparation, specificity and reliability of the rabbit polyclonal PINCH antibody (obtained kindly from Professor Ann Rearden, Department of Pathology, University of California, La Jolla, CA) used in this study have been described previously [10, 11].

The paraffin-embedded tissue sections (5 µm) were deparaffinised in xylene and rehydrated in graded ethanol. In order to expose masked epitopes, the sections were boiled in 0.01 mol/L Tris-EDTA buffer (pH 9.0) in a high pressure-cooker, kept at room temperature for 30 min and washed with phosphate-buffered saline (PBS, pH 7.4). The activity of endogenous peroxidase was blocked in 0.5% H<sub>2</sub>O<sub>2</sub> in methanol for 10 min and washed with PBS. The sections were incubated with the 2 µg/mL primary PINCH antibody at 4 °C overnight and washed with PBS. The sections were incubated with polymer enhancer for 20 min, then with polymerized HRP-anti mouse/rabbit IgG antibody for 30 min and rinsed in PBS between the incubation steps. After washed with PBS, peroxidase reaction was performed by use of 3,3'-diaminobenzidine for 5 min [Elivision TM plus polyer HRP (mouse/rabbit) IHC kit, Fuzhon Maixin Biology Technology Limited Company, Fuzhou, China]. After counterstained with haematoxylin, the sections were dehydrated and mounted. Normal mucosa and the matched primary tumours were stained in the same run of immunostaining to avoid bias on the pattern and intensity of the staining. Sections known to show

strong immunostaining for PINCH were used in each run receiving either the primary antibody or PBS as positive and negative controls. In all the staining procedures, the positive controls showed staining clearly and there was no staining in the negative controls.

PINCH immunostaining was independently examined by two pathologists in a blinded fashion without knowledge of the clinical and pathological information. To avoid artificial effect, the staining on the margins of sections and areas of poorly presented morphology were not counted. The intensity of PINCH staining in stroma was graded as negative (no positive cells), weak (<5% positive cells), moderate or strong staining. In cases with discrepant results, a consensus score was reached after re-examination.

### Statistical analysis

The chi square method was used to test the relationship between the frequencies of PINCH expression in normal mucosa and tumour as well as between PINCH expression in tumour and clinicopathological variables. All *P* values cited were two-sided and *P*<0.05 was considered statistically significant.

## RESULTS

PINCH was expressed in the stroma in both normal

**Figure 1** PINCH immunohistochemical staining in normal mucosa (A), adenocarcinoma (B), tunica adventitia of blood vessel (C), peripheral nerve fascicles (D) and stronger expression of PINCH at the invasion edge than in the inner area (E), and at the invasion edge of mucinous carcinoma (F).

**Figure 2** Frequency of PINCH immunohistochemical staining in 92 normal mucosa and 141 tumour samples.

mucosa and tumour samples, mainly in cytoplasm of fibroblasts and myofibroblasts, a proportion of endothelial cells in the tumour vasculature and peripheral nerves (Figure 1). Among 135 tumours with visible margin, 86 (64%) showed stronger PINCH expression at the invasive edges than in the intratumoural stroma, 31 (23%) showed opposite evidence, the remained 18 (13%) showed the same staining intensity. There was no PINCH expression in normal epithelial and tumour cells (Figure 1).

PINCH expression was negative in 50 (54%), weak in 9 (10%), moderate in 27 (29%) and strong in 6 (7%) in 92 normal mucosa samples, and in 5 (4%), 31 (22%), 57 (40%) and 48 (34%) respectively in 141 tumour samples. The expression was significantly increased in tumour samples compared to normal mucosa samples ( $\chi^2 = 85.79$ ,  $df = 3$ ,

$P < 0.0001$ , Figure 2). Even in the 80 matched cases of normal mucosa samples (51%, 10%, 33% and 6%) and tumours (5%, 20%, 43% and 33%), the significance was still remained ( $\chi^2 = 45.86$ ,  $df = 3$ ,  $P < 0.0001$ ).

Since the clinicopathological features of tumours with negative, weak and moderate staining were similar, they were combined as one group (weak group) to compare with strong group in statistical analyses. Table 1 summarises the expression of PINCH in relation to patient's gender, age, tumour location, tumour size, gross status, histological type, grade of differentiation, invasive depth, lymph node status and Dukes' stage. The result showed that the frequency of strong PINCH expression was higher in mucinous/signet-ring cell carcinomas (52%) than in non-mucinous carcinomas (29%,  $\chi^2 = 5.13$ ,  $P = 0.02$ , Table 1). Figure 1 shows a mucinous carcinoma with PINCH expression. The frequency of strong PINCH expression in Dukes C+C+D tumour (45%) tended to be higher than that in Dukes' A + B tumour (30%,  $\chi^2 = 2.65$ ,  $P = 0.10$ ). It was also shown that patients with lymph node metastasis seemed to have higher PINCH expression (44%) than those without metastasis (30%,  $\chi^2 = 2.50$ ,  $P = 0.11$ ). We did not find other relationships between the expression of PINCH and clinicopathological variables ( $P > 0.05$ , Table 1).

## DISCUSSION

In the present study, we observed that PINCH presented in fibroblasts, myofibroblasts, a proportion of endothelial cells of the tumour vasculature and peripheral nerves. The expression of PINCH was especially strong in stroma at the invasive edges of tumours compared to the intratumoural stroma, suggesting that PINCH as a biological factor, may be involved in the angiogenesis and invasiveness of tumour. This evidence may partly

explain why strong PINCH expression is associated with a poor prognosis in colorectal cancer patients<sup>[12]</sup>. In the present study, the frequency of strong PINCH expression was significantly higher in mucinous and signet-ring cell carcinomas than in non-mucinous carcinomas, which may also explain why PINCH expression is related to a poor clinical outcome. Studies demonstrated that patients with mucinous colorectal carcinomas have a worse prognosis than those with non-mucinous carcinomas<sup>[13-15]</sup>, indicating that mucins interfere with immunologic recognition of tumour cells by masking antigenic epitopes with sialic acid residues and inhibiting lymphocyte infiltration<sup>[16]</sup>. We have previously reported that there is less inflammatory infiltration in colorectal cancer with strong PINCH expression<sup>[12]</sup>.

PINCH is directly associated with ILK and Nck-2 proteins that are downstream effectors of integrin and growth factor signalling. Some of these growth factors, such as PDGF-mediated tumour-stromal interactions are important to tumour growth. PINCH is required for ILK localisation to integrin-containing adherens junctions where ILK regulates fibronectin matrix assembly<sup>[4, 6, 7, 9-12]</sup>, suggesting that PINCH protein may increase the upregulated growth factor signalling in stromal cells and a marker for stroma angiogenesis and invasion of tumour cells.

PINCH protein is involved in integrin-mediated cell-ECM interactions, where the different mechanisms or different genetic pathways may develop different histological types of tumour by specific classes of carcinogens. In this context, the expression of PINCH may be associated with the phenotype of epithelial cells in the colorectum. The frequency of K-ras mutation and microsatellite instability is higher in mucinous carcinomas than in non-mucinous carcinomas<sup>[17-20]</sup>. In contrast, mucinous carcinomas exhibit significantly less p53 mutation and protein<sup>[20-23]</sup>. These results lead to the hypothesis that K-ras and microsatellite instability may influence mucus production or degradation, resulting in the development of mucinous carcinoma. In contrast to non-mucinous tumours, the development of mucinous carcinomas may be independent from p53 alteration. Thus, PINCH may be another factor involved in the development of mucinous carcinomas.

In conclusion, the expression of PINCH was upregulated in colorectal cancers, and especially at the margin of the tumours, and further was related to mucinous carcinomas. The results suggest that expression of PINCH may be involved in the tumorigenesis and aggressiveness of colorectal cancers.

## ACKNOWLEDGEMENTS

The authors thank Professor Ann Rearden at the Department of Pathology, University California, CA, USA, for providing the PINCH antibody, and Dr. Yu-Xin Gu for helping in the experiment.

## Abstract

**AIM:** To investigate the roles of lymphocytes in the development of dextran sulfate sodium-induced colitis.

**METHODS:** Using various doses of dextran sulfate sodium (DSS), we induced colitis in wild-type B6 control and Rag-1 knockout (H-2<sup>b</sup> haplotype) mice, and evaluated the colitis in terms of symptomatic and histologic parameters, such as weight loss, survival, severity of diarrhea, shortage of colon length and histological changes. Symptomatic parameters were checked daily and histological changes were scored.

**RESULTS:** Although development of colitis in Rag-1 knockout mice treated with high dose (5%) of DSS was comparable to that in B6 control mice, colitis progression was much more tolerable in Rag-1 knockout mice compared to than in B6 mice treated with low dose (1.5%) DSS. Symptomatic parameters as well as histopathologic changes were improved in Rag-1 knockout mice.

**CONCLUSION:** These results indicate that the presence of lymphocytes contributes to colitis progression at low dose of DSS stimulation. Lymphocytes may play roles as an aggravating factor in DSS-induced colitis.

## INTRODUCTION

Despite many years of researches, the pathogenesis of human inflammatory bowel disease (IBD) remains poorly understood<sup>[1]</sup>. Clinical studies are limited to the patients with established disease; therefore, early events of the disease are difficult to approach. Several experimental models of colitis have been introduced to study factors that can induce chronic inflammation and investigate the evolution of colitis from the initial pathologic event to its final clinical manifestation. One of these models is based on the oral administration of dextran sulfate sodium (DSS) in the drinking water of mice, which results in an acute and chronic colitis with some morphological changes similar to human ulcerative colitis<sup>[2]</sup>. In addition, this model has been shown to respond to the anti-colitis drugs, such as sulfasalazine, olsalazine and mesalazine, that are used in human ulcerative colitis and have several immunomodulating functions<sup>[3]</sup>.

The pathogenic mechanism of this colitis is attributed to its direct toxic effects to colonic epithelial cells<sup>[4]</sup>, namely their relative independence from lymphocyte-mediated responses. Thus, in DSS-induced colitis, it is reported that mice lacking T cells, B cells, and NK cells can still develop colitis in response to DSS<sup>[5]</sup>. However, some studies showed the contradictory results, which suggest that lymphocytes play roles in the development of DSS-induced colitis. In acute stages of DSS-induced colitis, T cell response consists of polarized Th1 response, but in later and more chronic phase of inflammation, a mixed Th1/Th2 response occurs<sup>[6]</sup>. NKT cells, in contrast to the above CD4 T cells, were reported to play a protective role in DSS-induced colitis<sup>[7]</sup>.

In this study, we investigated the role of lymphocytes in the development of DSS-induced colitis using Rag-1 knockout (KO) mice and found that the severities of the DSS-induced colitis were dramatically decreased in Rag-1 KO mice.

## MATERIALS AND METHODS

### Animals

Eight-week-old male C57BL/6 (B6, H-2<sup>b</sup>-haplotype) and

Rag-1 knockout (Rag-1 KO, H-2<sup>b</sup>-haplotype) mice were purchased from Orient (Chunduk, Korea) and Jackson laboratory (Bar Harbor, ME, USA), respectively. The mice housed in a specific pathogen-free condition at Hallym University (Chuncheon, Korea) for at least 6 weeks for adaptation to the environmental changes. All mice used in this study were 14 and 16 weeks of age. All experimental animals were cared for, maintained, and terminated in accordance with the Hallym University Guidelines.

### Colitis model

Colitis was induced by addition of 1.5% DSS (M.W. 36,000-50,000; MP Biomedicals, Irvine, CA) to drinking water for 15 d. Animals were monitored daily for loss of body weight, diarrhea, and survival for 15 d. The severity of diarrhea was evaluated as the following scores<sup>[8]</sup>: no diarrhea = 0; mild diarrhea = 2; severe watery diarrhea = 3; mild diarrhea with blood = 4; and severe watery diarrhea with blood = 8. At 15 d or when mice had lost more than 20% of their initial body weight after DSS administration, they were sacrificed.

### Histopathological analysis

Colons were removed, fixed in 100 mL/L neutral formalin, embedded in paraffin, sectioned at 4- $\mu$ m thickness and stained with hematoxylin and eosin (HE). Colonic epithelial damage was assigned scores as follows: 0 = normal; 1 = hyperproliferation, irregular crypts, and goblet cell loss; 2 = mild to moderate crypt loss (10-50%); 3 = severe crypt loss (50-90%); 4 = complete crypt loss, surface epithelium intact; 5 = small- to medium-sized ulcer (<10 crypt widths); and 6 = large ulcer ( $\geq$ 10 crypt widths). Infiltration with inflammatory cells was assigned scores separately for mucosa (0 = normal, 1 = mild, 2 = modest, 3 = severe), submucosa (0 = normal, 1 = mild to modest, 2 = severe), and muscle/serosa (0 = normal, 1 = moderate to severe). Scores for epithelial damage and inflammatory cell infiltration were added, resulting in a total scoring range of 0-12<sup>[9]</sup>. All analyses were performed "blind."

### Statistical analysis

Data were expressed as mean  $\pm$  SE. An unpaired Student's *t* test was used to examine differences in the extent of weight loss, the survival time, and histology scores. This statistical analysis was determined using GraphPad Prism (GraphPad Software, Inc., San Diego, CA). A *P* value less than 0.05 was considered statistically significant.

## RESULTS

To test the role of lymphocytes in the development of DSS-induced colitis, we administrated various doses of DSS orally into wild-type control and Rag-1 KO mice and investigated the clinical and pathological findings. We could not detect any differences between B6 control and Rag-1 KO mice when treated with high dose (5%) of DSS. However, the progression of colitis significantly slowed down in Rag-1 KO mice treated with low dose (1.5%) of DSS. To evaluate the disease activity, we observed the symptomatic parameters, including body weight loss, survival rate and diarrhea. The control B6

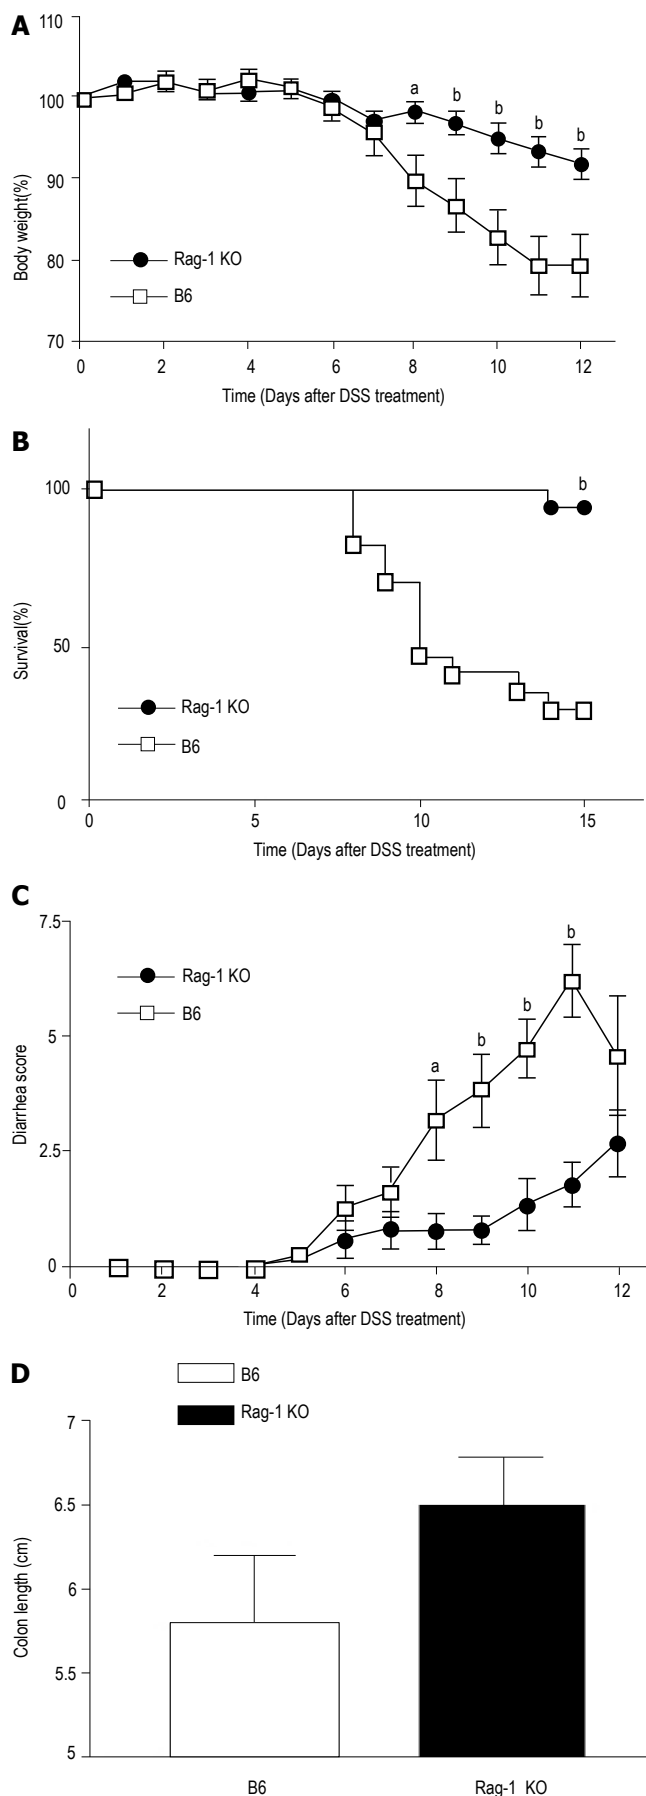

mice administered with oral DSS lost body weight, almost  $20 \pm 3.79\%$  ( $n=10$ ) in 12 d. In contrast, the absence of lymphocyte in Rag-1 KO mice significantly prevented the loss of body weight caused by the treatment of DSS, the decrement being  $7.98 \pm 1.79\%$  ( $n=14$ ,  $P<0.005$  vs control B6 mice/DSS administration). The differences of body weight began to be statistically significant 8 d after DSS administration and maintained through the experiments (Figure 1A). In addition to weight loss, the survival rates and clinical signs were also different between two groups. At the end of the study, while 65% of control mice died or lost weight more than 20%, only 5.5% (1/18) of Rag-1 KO mice lost weight more than 20% (Figure 1B). Furthermore, the severity of diarrhea after DSS treatment was scored according to the scale described in the Materials and Methods. In control B6 group, DSS caused severe diarrhea, which peaked around day 10, and the average score at day 10 reached the level of  $5.545 \pm 0.55$  ( $n=11$ ). In comparison, the grade of diarrhea was improved significantly in Rag-1 KO mice, with the average score of  $1.36 \pm 0.54$  ( $n=14$ ,  $P<0.0001$  vs B6 mice-DSS, Figure 1C). Next, to identify the morphological changes induced by DSS treatment, we examined the changes in the colon. In macroscopic examination, we found that the colons in Rag-1 KO mice treated with DSS were less shortened, although it was not statistically significant (Figure 1D). In addition, macroscopic examination showed fewer intra-abdominal adhesion and less erythematous colons in Rag-1 KO mice (not analyzed statistically).

The severity of colonic inflammation was evaluated further by histopathologic examinations. As shown in Figures 2A-2F, wild-type animals often had massive infiltration of mixed inflammatory cells in mucosa and submucosa with epithelial denudation, disruption of mucosal architecture, ulceration, and muscular thickening. In contrast, inflammatory infiltrates were diminished in the colonic mucosa of Rag-1 KO mice, and many areas appeared intact, implying that the effects of lymphocytes in DSS-induced colitis is detrimental. We scored the histological alterations (histology score, HS) as described in the Materials and Methods<sup>[9]</sup> and demonstrated that the differences in histology between two groups were statistically significant (Figure 2G). The HS in wild-type B6 mice treated with DSS ( $7.80 \pm 0.82$ ) was significantly higher than that in Rag-1 KO mice treated with DSS ( $3.850 \pm 0.63$ ,  $P=0.0005$ ). Taken together, our results suggest that lymphocytes play detrimental roles in the development of DSS-induced colitis.

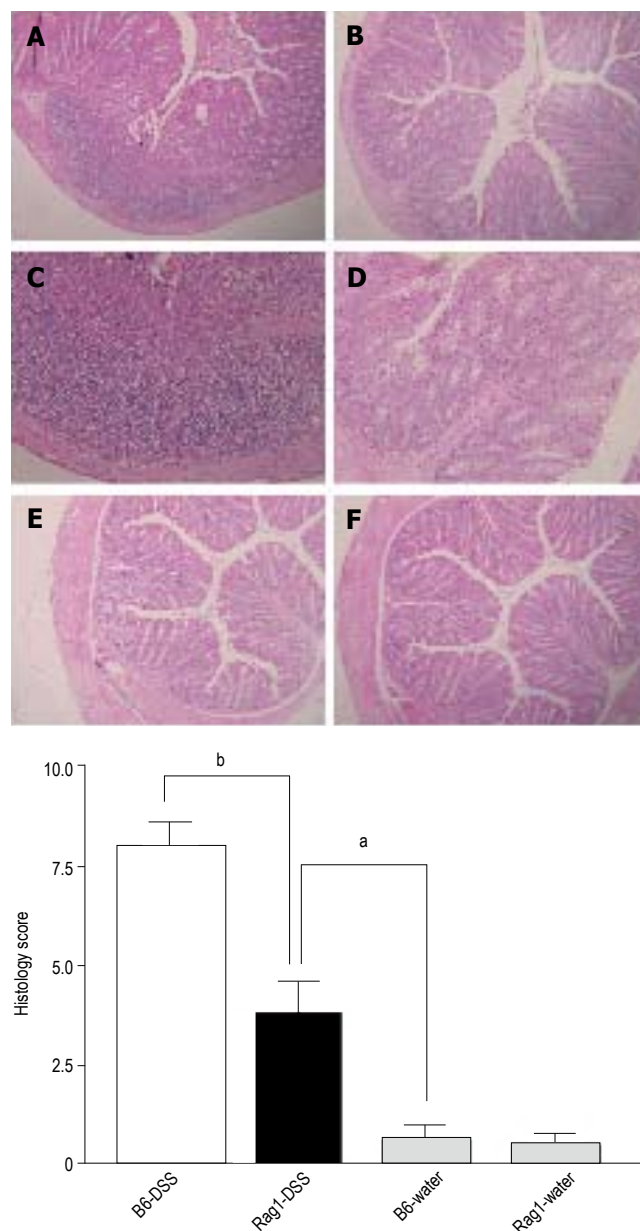

## DISCUSSION

Oral administration of DSS for several days leads to colonic epithelial lesions and acute inflammation characterized by the presence of neutrophils and macrophages within damaged segments. The reason for the deleterious effects of DSS is not well understood, however, epithelial cell toxicity, increased epithelial cell permeability, and macrophage activation have been proposed as potential mechanism<sup>[10]</sup>. In addition, it has been controversial whether the development of DSS-induced colitis is affected by the presence of

**Figure 1** Rag-1 deficient mice showing resistance to develop of DSS-induced colitis. Weight loss (A), mortality (B), the severity of diarrhea (C) and shortage of colon (D) after 1.5% DSS administration were analyzed. Each study group contained > 10 mice. Data shown represent mean values obtained from four independent experiments (\* $P < 0.05$ ; \*\* $P < 0.01$ ).

**Figure 2** Hematoxylin and eosin (HE) staining of colons obtained from B6 and Rag-1 KO mice treated with or without DSS. A, C: B6 mice treated with DSS (X100 and 160); B, D: Rag-1 KO mice treated with DSS (X100 and 160); E: B6 mice treated with water (X100); F: Rag-1 KO mice treated with water (X100); G: Quantitative histopathologic assessment of DSS-induced colitis activity showing a significant suppression in Rag-1 KO mice compared to the B6 control mice. Samples were collected from B6 control and Rag-1 KO mice treated with 1.5% DSS (open and solid bar, respectively), or water (stripped bars). Data are expressed as mean  $\pm$  SE and represent > 10 mice per group (\* $P < 0.05$ ; \*\* $P < 0.01$ ).

lymphocytes<sup>[1]</sup>. To test the role of lymphocyte in the pathogenesis of DSS-induced colitis, we observed the development and clinical course of DSS-induced colitis in both Rag-1 KO and B6 control mice and clearly showed that the absence of lymphocyte suppressed DSS-induced colitis at low dose DSS stimulation.

However, while the overall severities were significantly reduced in Rag-1 KO mice, the inflammatory changes and the shortage of the colons were also observed in Rag-1 KO mice compared to that in wild-type B6 control mice. In addition, we could not detect any differences in clinical courses and morphological changes between Rag-1 KO

and B6 control mice when treated with high dose of DSS (5%, data not shown). Taken together, these results suggest that the roles of lymphocytes are dispensable in DSS-induced colitis initiation and considered as an aggravating factor under the presence of weak insults (low dose of DSS)<sup>[1]</sup>. Our hypothesis is also supported by a previous paper which showed that adoptive transfer of primed T cells from DSS-treated mice by itself did not induced colitis but aggravated DSS-induced colitis, in contrast to the data from TNBS-treated Th1-type colitis model<sup>[11]</sup>.

Given the contribution of lymphocyte to DSS-induced pathology, the data presented here lead to the question of “how”. At the moment, this question can only be answered in general terms by the following suggestions: DSS is known to be directly toxic to colonic epithelial cells and disruption of colonic epithelial barriers allows monocytes-macrophages in lamina propria to enter the activation phase<sup>[10]</sup> and then macrophages uptake and present foreign peptide into T cells in addition to the secretion of pro-inflammatory cytokines. The activated T cells contribute to DSS-induced pathology as an aggravating factor.

In summary, our results show that lymphocytes play a crucial role in the induction of DSS-induced colitis resembling human ulcerative colitis as aggravating factors.

### Abstract

**AIM:** To cost-effectively express the 23-ku pE2, the most promising subunit vaccine encoded by the E2 fragment comprising of the 3'-portion of hepatitis E virus (HEV) open reading frame 2 (ORF2) in plastids of tobacco (*Nicotiana tabacum* cv. SR1), to investigate the transgene expression and pE2 accumulation in plastids, and to evaluate the antigenic effect of the plastid-derived pE2 in mice.

**METHODS:** Plastid-targeting vector pRB94-E2 containing the E2 fragment driven by rice *psbA* promoter was constructed. Upon delivery into tobacco plastids, this construct could initiate homologous recombination in *psaB-trnFM* and *trnG-psbC* fragments in plastid genome, and result in transgene inserted between the two fragments. The pRB94-E2 was delivered with a biolistic particle bombardment method, and the plastid-transformed plants were obtained following the regeneration of the bombarded leaf tissues on a spectinomycin-supplemented medium. Transplastomic status of the regenerated plants was confirmed by PCR and Southern blot analysis, transgene expression was investigated by Northern blot analysis, and accumulation of pE2 was measured by ELISA. Furthermore, protein extracts were used to immunize mice, and the presence of the pE2-reactive antibodies in serum samples of the immunized mice was studied by ELISA.

**RESULTS:** Transplastomic lines confirmed by PCR and Southern blot analysis could actively transcribe the E2 mRNA. The pE2 polypeptide was accumulated to a level as high as 13.27 µg/g fresh leaves. The pE2 could

stimulate the immunized mice to generate pE2-specific antibodies.

**CONCLUSION:** HEV-E2 fragment can be inserted into the plastid genome and the recombinant pE2 antigen derived is antigenic in mice. Hence, plastids may be a novel source for cost-effective production of HEV vaccines.

### INTRODUCTION

Hepatitis E is a water-borne disease caused by hepatitis E virus (HEV) in many tropical and subtropical areas. Over 50 outbreaks have been reported since its first epidemic in Delhi, India, documented in 1955 and 1956<sup>[1]</sup>. It accounts for more than 50% of acute viral hepatitis among young adults in developing countries with a fatality rate of 1-3% in non-pregnant patients and up to 20% in pregnant women<sup>[2]</sup>. Consequently, it is a serious threat to public health and has an urgent need of effective vaccines.

HEV appears as a 27-30-nm virus-like particle. It has a ≈ 7.5-kb linear, single-stranded, a positive-sense RNA made up of a short 5'-noncoding region, a 3'-poly(A) tail, and three overlapping open reading frames (ORFs)<sup>[3,4]</sup>. ORF1 extends approximately 5 kb from the 5'-end and encodes a polyprotein with functional motifs typical of RNA-dependent RNA polymerase, RNA helicase, papain-like cysteine proteinase and methyltransferase. ORF2 is made up of several dozens of base pairs downstream of the ORF1 and extends approximately 2 kb to the termination codon that is 200-300 bp from the 3'-poly (A) residues. ORF2 contains a consensus signal peptide sequence at its amino terminus and a capsid-like region similar to that seen with other virus capsid proteins. ORF3 partially

overlaps the ORF1 and ORF2, and encodes a 123-aa polypeptide with the possible role of a cytoskeletal anchor site for the assembly of virus particles<sup>[5]</sup>.

Since killed and attenuated vaccines for hepatitis E are not available due to a lack of culture system for HEV production, recombinant proteins represent the best hope for subunit vaccines. The ORF2-encoded protein has been shown to be the most promising candidate because the only neutralizing epitope identified to date is mapped to its carboxy-terminal region between aa 578-607<sup>[6]</sup>. To explore the possibility that these subunit vaccines could be produced through recombinant protein approach, ORF2 fragments have been expressed in prokaryotes<sup>[7]</sup>, insect cells<sup>[8]</sup>, animal cells<sup>[9]</sup>, and transgenic plants<sup>[10]</sup>. Satisfactory accumulations of the ORF2 proteins in bacterial<sup>[7]</sup> and animal cells<sup>[9]</sup> have been achieved. However, if the vaccines are to be produced in such systems, a relatively higher expense may be encountered. In insect cells<sup>[11]</sup> and nuclear transformed tomatoes<sup>[10]</sup>, the ORF2-encoded peptides are accumulated at much lower levels (1-2 mg/L and 48-61 ng/g fresh weight, respectively). Hence, a technique for cost-effective large-scale production of the ORF2 subunit vaccines plays an important role in the control of hepatitis E.

Plastids are unique organelles in plants. Each plant cell accommodates up to 10 000 copies of the plastid genome, indicating the potential of using transplastomic plants to express foreign proteins at elevated levels<sup>[12]</sup>. To obtain high-level accumulation of the ORF2-encoded pE2 peptide (aa 394-607), we inserted its corresponding cDNA sequence, the *E2* fragment<sup>[7]</sup>, into the plastid genomes of tobacco plants (*Nicotiana tabacum* cv. SR1). The *E2* fragment was expressed satisfactorily at RNA and protein levels, and the plastid-produced pE2 was found to be antigenic in mice. Our results suggest that plastid transformation may be an economical alternative for large-scale production of edible HEV vaccines.

## MATERIALS AND METHODS

### Modification of chloroplast transformation vector pVSR326

A polylinker (upper strand, 5'-CATGGCCGC-GGGGGCCCGCTAGCAGGCCTG CGGCCGCATC-GATGAGCT-3'; lower strand, 5'-CATCGATGCGGCC-GCAGG CCTGCTAGCGGGCCCCCGCGGC-3') was cloned in *NcoI*-*SacI* site of pVSR326 (GenBank accession no.: AF527485). The obtained pVSR326 derivative was digested by *SacI* and inserted with a (His)<sub>5</sub> fragment (upper strand: 5'-GCGGGGTT CTCATCATCATCATCATG-GTCCGC-3'; lower strand: 5'-GGACCATGATGATGATGATGATGAGAACCCCGCGC-3'). The resultant plasmid was termed pMLVHisA.

### Construction of chloroplast-targeting vector pRB94-E2

A 0.8-kb *E2* fragment originally obtained from a conserved region near the 3'-terminal of the ORF2 in a Chinese HEV strain (GenBank accession no.: D11092) was released by *Bam*HI-*Eco*RI digestion of pGEX-E2<sup>[13]</sup> and cloned in the corresponding site in pBluescript KS. Then the 0.8-kb fragment was removed from the resulting plasmid by *Spe*I-*Cla*I digestion before it was cloned into the *Nbe*I-*Cla*I site in pMLVHisA. This pMLVHisA derivative was digested by *Xba*I and *Kpn*I to produce a cassette of

“rice *psbA* promoter-*E2*-rice *psbA* terminator” which was then inserted into the corresponding site in pRB94<sup>[14]</sup>. The resulting construct, termed pRB94-E2, has two cassettes: “rice *psbA* promoter-*E2*-rice *psbA* terminator” for pE2 production, and “tobacco *rrn* promoter-*aadA*-tobacco *psbA* terminator” for expressing the spectinomycin-degrading aminoglycoside 3'-adenyltransferase. These two cassettes were flanked by a 1.5-kb *trnG-psbC* arm and a 1.9-kb *psaB-trnM* arm (nt 36 835-38 314 and 38 326-40 205, respectively, in tobacco plastid genome, GenBank accession no.: Z00044) (Figure 1A). These two arms were for homologous recombination upon delivery of pRB94-E2 into chloroplasts.

### Plant material

Seeds of tobacco SR1 were germinated on MS medium (Sigma, St. Louis, USA) plus 3% sucrose and 0.6% agar (Sigma). After the seedlings were grown for 3-4 wk, the leaves were placed on petri-dishes with RMOP medium<sup>[15]</sup> for one day before being bombarded with a PDS-1000/He Biolistic® Particle Delivery System (Bio-Rad).

### Chloroplast transformation

DNA for plastid transformation was prepared using the High Purity Plasmid Maxiprep System (Marligen Bioscience Inc., USA). One microgram of pRB94-E2 plasmid was used to coat 1 mg of 0.6-μmol/L diametric tungsten particles (M13, Bio-Rad) according to the standard procedure. The coated particles were bombarded at 1100 *psi* to tobacco leaves on petri-dishes. One milligram of the coated particle was used for each bombardment. The bombarded leaves were kept on the same petri-dishes for 24 h before being cut into ≈1 cm<sup>2</sup> pieces and put on RMOP plus 500 μg/mL spectinomycin dihydrochloride. Spectinomycin-resistant shoots emerged in about a month, and their leaves were used as explants for subsequent rounds of regeneration until homoplasmy was achieved.

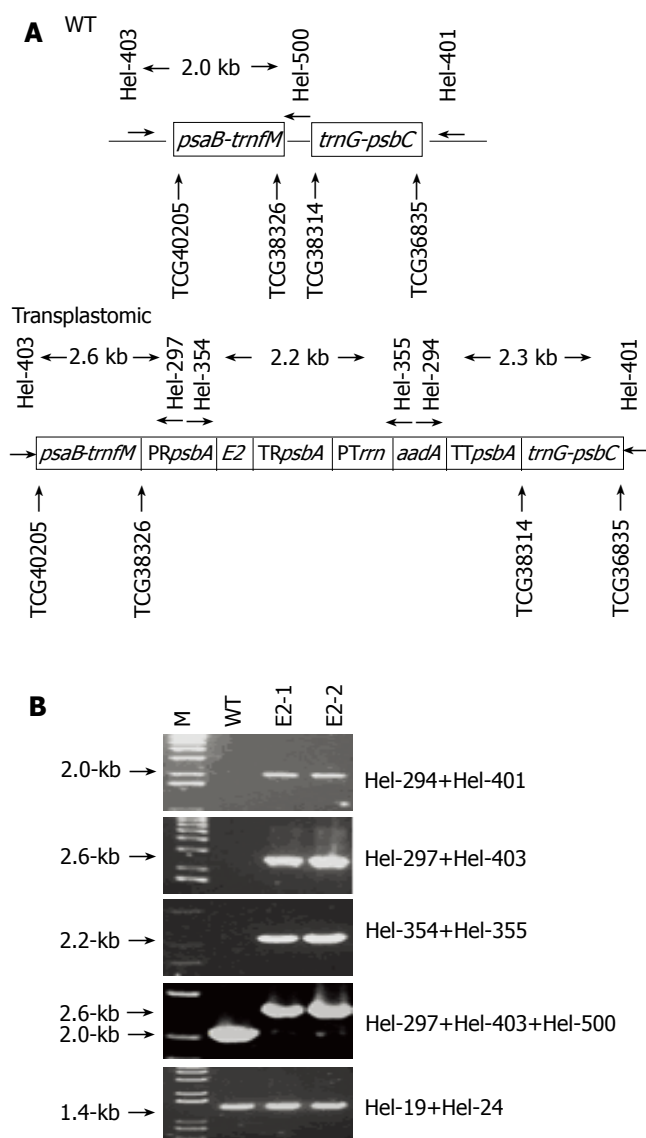

### PCR

Primer pairs (Hel-297/Hel-403, Hel-294/Hel-401 and Hel-354/Hel-355) capable of differentiating WT and transplastomic genomes (Table 1 and Figure 1A) were used. In addition, Hel-19/Hel-24 was used for the amplification of a 1.4-kb fragment in the endogenous *rbcL* gene from both the WT and the transplastomic plants. Thirty-five cycles of PCR were performed using the *Taq* DNA polymerase (Promega). PCR products were separated on a 0.8% agarose gel for visualization under UV illumination after ethidium bromide staining.

### Southern blot analysis

Genomic DNA was digested by *Nco*I and *Kpn*I, separated on a 0.8% agarose gel and transferred onto a GeneScreen Plus® membrane (PerkinElmer), before separate hybridization to four <sup>32</sup>P-labeled DNA probes (P1, P2, P3, and P4 in Figure 2A). Hybridization was performed overnight at 65°C in a buffer containing 250 mmol/L NaCl, 7% SDS and 125 mmol/L phosphate, pH 7.0. After hybridization, blots were washed twice (10 min each) at room temperature in 2×SSC plus 0.5% SDS, and once at 65°C for 15min in 0.2×SSC plus 0.1% SDS. Blots were then

**Figure 1** Transplastomy of the spectinomycin-resistant plants. **A:** Maps of WT and transplastomic genomes in the area of two arms (*psaB-trnFM* and *trnG-psbC*) for homologous recombination. Horizontal arrows indicate locations and orientations of different primers. The sizes of PCR products are shown in kb. Arrows pointing upwards denote nucleotide positions in the tobacco chloroplast genome (TCG) in accordance with GenBank accession no. Z00044. *PRpsbA*: rice *psbA* promoter; *TRpsbA*: rice *psbA* terminator; *PTrrn*: tobacco *rrn* promoter; *TTpsbA*: tobacco *psbA* terminator. **B:** Agarose gel pictures of PCR products. Primers used for generating each product are given to the right of the panels. Arrows indicate sizes of the PCR products in kb. Primer pair Hel-19/Hel-24 amplified a 1.4-kb fragment in the *rbcl* gene presenting in both the WT and the transplastomic plants.

exposed to X-ray.

### Northern blot analysis

RNA samples were prepared from leaves of WT and transplastomic plants. Seven micrograms of the isolated RNA was separated on 1.2% agarose gel, blotted onto a membrane and hybridized to four <sup>32</sup>P-labeled DNA probes (P4, P5, P6, and P7 in Figure 3A). The *aadA*-specific probes (P4) were the same as those used for Southern blot analysis, while "*psbA-Prn*" (P6) and *trnFM* (P7) probes were made with templates generated by PCR using primer pairs of Hel-720/Hel-721 and Hel-348/Hel-399, respectively (Table 1). Hybridization and washing conditions were the

same as in Southern blot analysis.

### Enzyme-linked immunosorbent assay (ELISA)

HEV antigen ELISA Kit and standard pE2 antigen were purchased from Beijing Wantai Biological Pharmacy Enterprise Co., Ltd., Beijing, China. Total soluble protein (TSP) from weighed WT and transplastomic plant tissues (leaves and seeds) was extracted with a non-denaturing buffer [50 mmol/L Tris-HCl (pH 8.5), 10 mmol/L sodium acetate, 100 MgCl<sub>2</sub>, 1 mmol/L EDTA and 1 mmol/L PMSF]. After protein quantification with the Bradford agent, 1 µg leaf TSP and 5 µg seed TSP were used for ELISA. Antigen concentrations expressed as nanogram pE2 per microgram TSP were calculated using an ELISA standard curve established with a serial dilution of the standard pE2 antigen. These concentrations were further converted to microgram pE2 per gram fresh tissue using the protein yield (µg TSP/g fresh weight) as multiplication factor. The average values for these factors from three independent assays were 20.95 ± 3.95 and 10.79 ± 1.40 mg TSP/g fresh seeds and leaves, respectively.

### Mice immunization with plastid-derived pE2

Four-week old BALB/c mice were divided into four groups. Each mouse in the first group was subcutaneously injected with 100 µL of PBS solution, the second group with 100 µg of TSP from WT plant, the third group with 100 µg of TSP from the E2-1 leaves, and the fourth group with 10 µg of TSP (equivalent to ≈ 1 µg pE2) from *E. coli* expressing the pE2 polypeptide. Injection was performed once a week for three consecutive weeks. One week after the last infection, serum samples were collected for pE2-specific antibody detection.

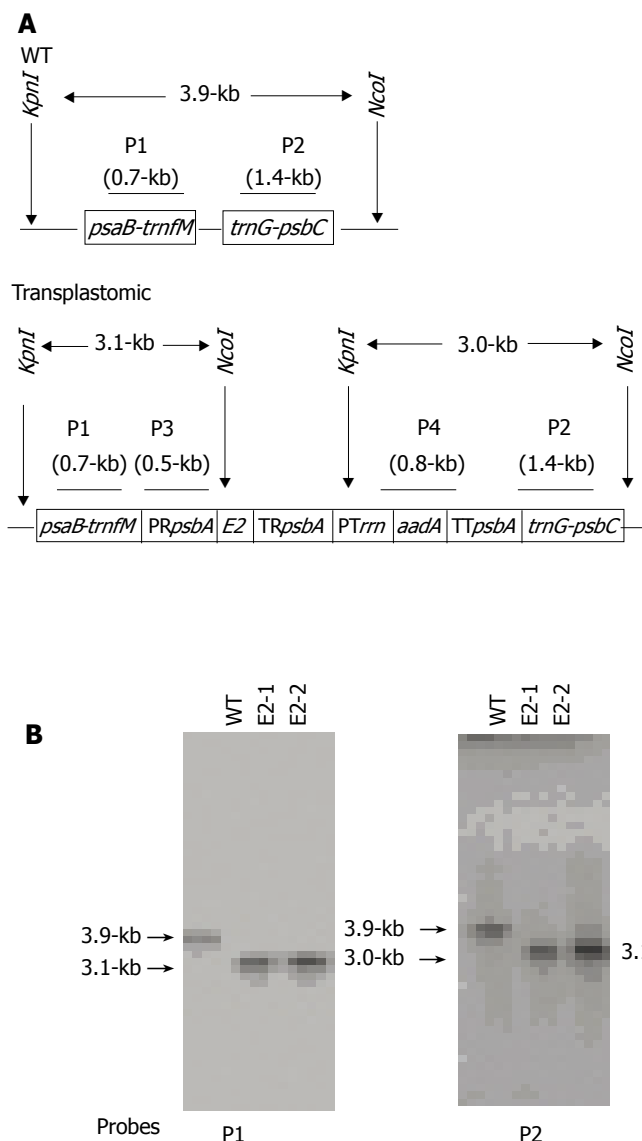

Serum samples were diluted five times with coating buffer (0.015 mol/L sodium carbonate, 0.025 sodium bicarbonate, pH 9.6). Fifty microliters of the diluted samples were added to a 96-well microplate and incubated at 4 °C overnight. After the coating buffer was removed, the wells were blocked with 5% non-fat milk in PBS supplemented with 0.5% Tween 20 for 2 h, which was followed by four washes with 200 µL PBS plus 0.5% Tween 20. Then 200 ng of the pE2 antigen (Beijing Wantai Biological Pharmacy Enterprise Co., Ltd.) diluted in 50 µL PBS plus 0.5% Tween 20 was added and incubated at 37 °C for 1 h. After the uncaptured pE2 was removed and the wells were washed five times, 100 µL of HRP-conjugated monoclonal anti-HEV antibodies (Beijing Wantai Biological Pharmacy Enterprise Co., Ltd.) were added. After incubation at 37 °C for 30 min, the antibody solution was removed and the wells were washed five times. Then 50 µL chromogen A and 50 µL chromogen B were added to the well and the plate was incubated at 37 °C for 2 h. After color development, 50 µL stop solution was added and absorbance at 450 nm (*A*<sub>450</sub>) was measured with equal volume of mixture of chromogen A and chromogen B as reference.

## RESULTS

### Generation of transplastomic tomato plants

The vector pRB94 was reported to have an increased chloroplast-targeting efficacy<sup>[14]</sup>. Hence we used its backbone

**Figure 2** Transformed plastid genomes revealed by Southern blot analysis. **A:** Maps of WT and transplastomic genomes showing the positions of *KpnI* and *NcoI* sites, and areas to which different probes hybridize. The restriction fragment lengths are given in kb. **B:** DNA gel blot analysis confirming transgene integration into chloroplast genomes. DNA was digested by *KpnI* and *NcoI*. The blots were hybridized with probes targeting the *psaB-trnFM* arm (P1), *trnG-psbC* arm (P2), rice *psbA* promoter (P3) and *aadA*-coding region (P4). Arrows indicate the sizes of the hybridized DNA fragments in kb.

and made a construct pRB94-E2 for tobacco chloroplast transformation in this study.

Two shoots were obtained after culturing the bombarded leaf pieces in spectinomycin-containing RMOP medium for about a month. The shoots were selected for two more generations in the same RMOP medium. They were then transferred to grow in greenhouse after root development in a hormone-free MS medium. The resulting plants were named E2-1 and E2-2.

### PCR analysis

To confirm whether the spectinomycin-resistant E2-1 and E2-2 were transplastomic, PCR were performed with primer pairs that could only amplify DNA fragments that resulted from homologous recombination (Table 1 and Figure 1A) for which three pairs were used. The first pair (Hel-297/Hel-403) could produce a 2.6-kb product that resulted from recombination in the *psaB-trnFM* arm, the second (Hel-294/Hel-401) a 2.0-kb fragment as a result

<sup>1</sup>Positions are indicated in accordance with the numbering of the tobacco plastome sequence (accession no. Z00044); <sup>2</sup>Positions are indicated in accordance with the numbering of the pRB94 vector (accession no. AJ312392); <sup>3</sup>Positions are indicated in accordance with the numbering of pVSR326 vector (accession no. AF527485).

of recombination in the *trnG-psbC* arm, and the third (Hel-354/Hel-355) a 2.2-kb fragment from the rice *psbA* promoter to the *aadA*-coding sequence. All the three pairs produced PCR products of expected sizes from E2-1 and E2-2 DNA samples (Figure 1B), indicating that homologous recombination occurred and the *E2*- and *aadA*-expressing cassettes were co-integrated and stayed intact in the plastid genomes.

### Southern blot analysis

To confirm the transgene integration and to determine the homoplasmic status, DNA of both the WT and transplastomic plants in the greenhouse was digested by *KpnI* and *NcoI*, and subjected to Southern blot analysis with probes hybridizing to the *psaB-trnFM* arm (P1), *trnG-psbC* arm (P2), rice *psbA* promoter (P3), and *aadA*-coding region (P4). Restriction fragments and their lengths in kb for both the WT and transplastomic genomes are shown in Figure 2A. When probes P1 and P2 were used, the WT

**Figure 3** Transgene expression investigated by Northern blot analysis. **A:** Map of the transplastomic genome with areas to which different probes hybridize. Lengths of possible transcripts are shown in kb. **B:** RNA blot analysis for characterization of different transcripts. RNA blots were hybridized with probes targeting the *aadA*-coding region (P4), HEV pE2-coding sequence (P5), junction between the rice *psbA* terminator and tobacco *rrn* promoter (P6) and tobacco *trnM* (P7). Arrows to the left of the panels denote lengths of RNA in kb. Normalization of RNA loading was demonstrated by ethidium bromide staining of the RNA gel.

revealed a 3.9-kb band, while the transplastomic plants produced bands of 3.1- and 3.0-kb, respectively (Figure 2B). Absence of the 3.9-kb band in the transplastomic plants indicated homoplasmy. When probes P3 and P4 were used, the transplastomic plants showed the expected 3.1- and 3.0-kb bands, respectively (Figure 2B). These results supported the data from PCR (Figure 1) and confirmed that both *E2*- and *aadA*-expressing cassettes were transformed into the chloroplast genome, and the transplastomic plants achieved homoplasmy.

#### Northern blot analysis

In the E2-1 and E2-2 plants, the transgenes were actively transcribed. When the blot bearing RNAs from both the WT and the transplastomic plants was hybridized with *E2*-specific probes P5 (Figure 3A), three bands (0.7-, 1.1- and 2.6-kb) were detected in the transplastomic plants (bands a, c, and d, Figure 3B), indicating that *E2*-containing transcripts were terminated at multiple locations. When the same blot was hybridized with *aadA* probes P4, a 2.6-kb band and a 0.9-kb band appeared (Figure 3B). The 2.6-kb band represented run-through transcripts initiated from the rice *psbA* promoter, since it could be detected by *E2*-specific probes P5, but not by *trnM*-targeting probes P7 (Figure 3B). The 0.9-kb band was the *aadA* transcripts plus 0.1-kb 5'-UTR between the *rrn* promoter and *aadA*-coding

**Table 2** Accumulation of pE2 leaves and seeds of WT and transplastomic plants (mean  $\pm$  SD)

Plant	Tissue	pE2

ND: Non-detectable.

fragment. To determine the initiation sites for the 0.7- and 1.1-kb transcripts, probe P7 was used. In this case, only the 0.7-kb band was revealed (band a, Figure 3B). Therefore, the 0.7-kb transcripts were initiated from *trnM*, while the 1.1-kb transcripts were solely from the *E2*-expressing cassette, which consisted 0.2-kb *psbA* 5'-UTR, 0.8-kb *E2* and the remaining polylinker sequences ( $\approx$  0.1-kb).

#### Accumulation of pE2 polypeptide in transplastomic tobacco plants

To investigate if the pE2 antigen was produced in E2-1 and E2-2, TSP extracted from both plants was used in a pE2-specific ELISA assay. An ELISA standard curve was established using different amounts of standard pE2 and used for quantifying the pE2 expressed as amount of fresh pE2 per gram. As high as 13.27 and 0.46  $\mu$ g of pE2 were detected in leaves and seeds, respectively (Table 2). In comparison with the concentrations (47.9 ng/g fresh leaf tissue and 61.2 ng/g fresh fruit) of the same pE2 antigen expressed in tomato nuclear transformants<sup>[10]</sup>, this study achieved over 200-fold increase in leaf pE2 content (Table 2). This elevated level of pE2 accumulation faithfully demonstrated that plastid transformation was superior to nuclear engineering for the production of HEV vaccines.

#### Antigenicity of plastid-derived pE2 in mice

To investigate if the plastid-derived pE2 proteins were

**Table 3** Antigenicity of plastid-derived pE2 in mice

Group	A450	
	Expt A	Expt B
PBS	0.117	0.137

<i>E. coli</i> TSP	1.367	2.620

antigenic, TSP from leaves of transplastomic plant E2-1 was subcutaneously injected into mice once a week for three consecutive weeks. One week after the last injection, serum samples were collected for antibody detection.

The pE2 polypeptides produced in plastids were antigenic when injected into four-week old BALB/c mice, according to ELISA that specifically detected pE2-reactive antibodies (Table 3). In addition, in consistent with reports from other groups<sup>[7,16]</sup>, bacterially-expressed pE2 could also stimulate mice to produce the corresponding antibodies (Table 3). Therefore, plastids were an ideal compartment for the production of antigenic pE2 proteins.

## DISCUSSION

The unique biological property of plastid-containing plant cells is the high ploidy degree of plastid genomes<sup>[17]</sup>. Unlike nuclei, plastids provide an environment where foreign gene activity is not subjected to positional effect and epigenetic silencing. Thus, plastid transformation has the potential to steadily express foreign proteins at elevated level. Compared to the pE2 content in nuclear transformed tomatoes<sup>[10]</sup>, this study resulted in a dramatic increase in pE2 accumulation and demonstrated that plastid transformation was substantially superior to its nuclear counterpart for pE2 production. High-level pE2 expression in tobacco plastids did not affect growth rates, flowering, seed setting or any other morphological features (data not shown), indicating that no apparent pleiotropic effects occur on the transplastomic plants.

The pE2 can interact with one another to form homodimers that are strongly recognized by serum samples from hepatitis E patients<sup>[13]</sup> and highly immunogenic in monkeys<sup>[7]</sup> and rats<sup>[16]</sup>. These findings reveal two important aspects about the HEV subunit vaccines. The first aspect is that carboxy terminus of the ORF2-encoded major structural protein possesses good antigenicity, and the other aspect is that conformation of these subunit vaccines is crucial in antibody stimulation and in antibody-antigen interaction. Plastid-derived pE2 should therefore possess the right conformation in order to be functional.

Plastids do offer an ideal compartment for foreign proteins to have functional folding. Examples include plastid-expressed nontoxic B subunit of *E. coli* heat-labile enterotoxin<sup>[18]</sup> and human somatotropin<sup>[19]</sup>. The pE2 expressed in this study reacted with the pE2-specific conformational antibody in the HEV antigen ELISA kit. Such a reaction could be abolished in the presence of SDS and when heating was applied to denature the protein

(data not shown), suggesting that the plastid-derived pE2 possesses functional conformation.

Antibodies cross-reacting with pE2 were detected in serum samples of mice immunized with plastid-derived pE2 in this study. This is consistent with reports that antigenic pE2 can be produced from bacteria<sup>[7,16]</sup>, and confirms that plastids are a cheaper source for the production of HEV vaccine.

The feasibility of pE2 as a broad-type antigen against HEV has been manifested by several observations. First, with the exception of a Mexican isolate and a USA isolate, the 0.8-kb pE2-coding sequence used in this study shares more than 90% homology with the corresponding sequences in other HEV isolates<sup>[7]</sup>. Second, though at least four genotypes have been identified, HEV is antigenically conserved and so far only one serotype has been identified<sup>[1]</sup>. Third, all naive macaques infected with HEV genotypes 1, 2, 3, and 4 have been reported to produce antibodies to the ORF2 polypeptides, one of which is comprised of aa 458-607<sup>[20]</sup>, shorter than the plastid-produced pE2 (aa 394-607) in this study. Hence, we may anticipate that the pE2 peptide in its proper conformation can stimulate antibodies against all the four reported genotypes.

Plastid-encoded genes are typically organized into polycistronic transcription units that give rise to overlapping RNAs. Though the significance of this complicated mode of expression is unknown, the intergenic sequences involved should not possess the typical function of strong terminators. The multiple bands detected with the E2-specific probes (P5) indicate that transcripts initiated from the rice *psbA* promoter could pass through the rice *psbA* terminator. This run-through transcription might actually contribute to the synthesis of the *aadA*-encoded protein, since *aadA*-specific probes revealed much less initiation of the *aadA* transcripts from the tobacco *rrn* promoter. The same *rrn* promoter was able to satisfactorily initiate *aadA* transcription, when the E2 fragment in the pRB94-E2 vector was replaced by the bacterial *uidA* gene (data not shown). Whether proximal DNA sequences influence activity of the *rrn* promoter is unclear at present.

While this study has proved the feasibility of expressing immunogenic pE2 in plastids, the tobacco plant is nevertheless inedible and a transgenic tobacco-based vaccine that can be administered by subcutaneous injection is a feasibility supported by the present work. For hepatitis B, an edible plant-based oral vaccine has been demonstrated in animals<sup>[21]</sup>. Introduction of the pE2-coding sequences into the plastid genomes of edible plants such as tomato, lettuce and carrot would thus be more desirable to test if an oral-based vaccine for hepatitis E could be realized. In tomatoes, foreign protein has been shown to express in fruit chromoplasts<sup>[14]</sup>. This example provides assurance for the production of edible vaccines through plastid transformation.

In conclusion, transplastomic tobacco plants expressing the antigenic HEV pE2 peptide at elevated level can be successfully generated and it is possible to produce pE2 in edible plant parts for the purpose of immunizing human beings against HEV infection.

## ACKNOWLEDGMENTS

The authors thank Professor Ralph Bock for providing the pRB94 chloroplast transformation vector, and Drs S. Leelavathi and V.S. Reddy for providing the pVSR326 plasmid and their help in the early stage of this study. The authors also thank the laboratory of Professor M.H. Ng (Department of Microbiology, University of Hong Kong) for the gift of the plasmid pGEX-E2.

### Abstract

**AIM:** To analyze the results and complications of intra-operative enteroscopy (IOE) by investigating a series of selected patients with bleeding suspected to originate from the small intestine.

**METHODS:** Eighty-one patients (mean age: 65 years) including 40 males (49.4%) and 41 females (50.6%) with obscure gastrointestinal bleeding underwent IOE between 1990 and 2004. The patients were identified from a database and data were selected from the patients' charts retrospectively. All the patients had undergone at least one non-diagnostic esophagogastroduodenoscopy, colonoscopy, standard enteroscopy and a negative abdominal ultrasound scan before IOE.

**RESULTS:** The median minimal hemoglobin level in the patients was 59+15g/L and 72.8% of the patients required transfusion of packed erythrocytes previously. A bleeding source was detected in 68 (84%) of the patients during IOE. Angiodysplasias were found in 44 patients (54.3%) and 9 patients (11.1%) were affected by ulcers in the small intestine. A tumor in the small intestine was detected in another 6 patients. The treatment consisted of argon-plasma-coagulation, surgical suture or limited resection in most of the patients.

**CONCLUSION:** Intra-operative enteroscopy is still used for the diagnosis of suspected small bowel bleeding. Recent developments such as wireless capsule endoscopy and double balloon enteroscopy, may lead to the replacement of IOE in the future.

### INTRODUCTION

In most patients suffering from gastrointestinal bleeding, a bleeding source can be detected using upper endoscopy or colonoscopy. However, the small intestine is a source of bleeding in up to 5% of patients<sup>[1,2]</sup>. The diagnostic and therapeutic approach to patients with bleeding originating from the small intestine still remains a challenge to all physicians involved in their care.

Several endoscopic and non-endoscopic techniques have been developed for detection of the bleeding sites in the small intestine and their use depends on the severity and time parameters of hemorrhage<sup>[3]</sup>. In the last few years, wireless capsule endoscopy<sup>[4,5]</sup> and double-balloon enteroscopy<sup>[6,7]</sup> have closed the diagnostic gap between colonoscopy and push-enteroscopy for many of the patients. However, intra-operative enteroscopy is still a diagnostic approach that offers the complete endoscopic work-up of the entire small intestine as well as the detection of extramural lesions and the definitive endoscopic or surgical therapy during the same session<sup>[8-11]</sup>.

The aim of our study was to analyze the results of intra-operative enteroscopy for the diagnosis of gastrointestinal bleeding of obscure origin by investigating a large consecutive series of patients in a third referral center.

### MATERIALS AND METHODS

Between 1990 and 2004, 81 consecutive patients with bleeding of obscure origin underwent intra-operative enteroscopy in our department. Patients undergone IOE were identified from a database of the Department of Gastroenterology. The patient charts were analyzed retrospectively with respect to the basic data, such as previously performed examinations, need for transfusion, type of

**Table 1 Basic data of the 81 consecutive patients (mean  $\pm$  SD)**

Patients ( <i>n</i> )	81
Age (Yrs)	65 $\pm$ 20,8
Female ( <i>n</i> )	41 (50.6%)
Transfusion need (%)	72.8
Minimal hemoglobin level	5.9 $\pm$ 1.5 g/dL

bleeding (overt or obscure), endoscopic findings through IOE, therapeutic procedures performed and short-term outcome after IOE until discharge from the hospital. Basic patient data are given in Table 1.

All the patients had at least one episode of gastrointestinal tract bleeding with need for transfusion (obscure or overt bleeding), recurrent minor bleeding episodes without transfusion requirement or chronic iron-deficiency-anemia with suspected bleeding of obscure origin. All the patients were subjected to an endoscopic work-up of the colon and the upper gastrointestinal tract before IOE. They all underwent standard enteroscopy (using a sonde-type or push-type enteroscope (Olympus SIF-100 or XSIF-140Q)) and an abdominal ultrasound scan to exclude malformations of the larger abdominal vessels and/or larger tumors in the abdomen. In a large number of patients, additional methods such as barium enema, MR-enteroclysm and angiography or scintigraphy, were applied prior to IOE.

Intra-operative enteroscopy was routinely carried out under general anesthesia. After a median laparotomy, the small intestine was opened through an incision in the middle third. A surgeon placed the endoscope (Olympus PCF-20; PCF-160 HI or CF-Q140) through a sterile sleeve in the intestine. The endoscope was then pushed up to the duodenum and down into the cecum. If a bleeding source was detected, the lesion was treated endoscopically (e.g. argon-plasma-coagulation) or surgically (e.g. resection) during the same session.

Data were entered with a standard program (Microsoft Excel) and analyzed by the statistical module. Data were expressed as median and range if not stated elsewhere. The study was conducted in accordance with the Declaration of Helsinki.

## RESULTS

The median minimal hemoglobin level before IOE was 59  $\pm$  15 g/L and 72.8% of the patients received at least two units (0-50) of packed erythrocytes.

The patients had a median of 4 EGDs and underwent colonoscopies before the IOE procedure. All the patients were subjected to at least one push-type enteroscopy and/or abdominal ultrasound, 80% of them had a non-diagnostic small bowel enema (Figure 1). During the push-enteroscopy prior to IOE, single small angiodysplasias were found in 5 cases within reach of the enteroscope and treated with argon plasma coagulation. IOE found additional angiodysplasias. One additional patient had a non-bleeding small ulcer in the upper jejunum and was exam-

**Figure 1** Proportion of patients undergone different endoscopic procedures before intra-operative endoscopy.

ined intraoperatively because of ongoing hemorrhage.

Intra-operative enteroscopy was able to visualize the complete small intestine in all the patients. A bleeding source was detected in 68 (84%) of the patients. Angiodysplasia was found in 44 (54.3%) patients and ulcer in 9 patients (11.1%). The ulcer might be due to the use of non-steroidal anti-rheumatics (NSAR) and the presence of Crohn's disease. Using IOE, we found tumors of the small intestine not identified previously in 6 patients (7.4%) of the study group. Four of the tumors were malignant, namely 1 B-cell lymphoma, 2 neuroendocrine tumors, 1 gastrointestinal stromal tumor. Two additional tumors were benign, namely 1 Peutz-Jeghers polyp and 1 giant hyperplastic polyp. Four patients of the series had a Meckel's diverticulum, two of them having a Meckel's scintigraphy prior IOE without any signs of a Meckel's diverticulum. Three patients had large diverticula of the jejunum or ileum, which were presumed to be the site of bleeding. Additional diagnoses included Dieulafoy's ulcer in the cecum (missed by the previously performed colonoscopy) and bleeding from anastomotic vessels after cholecystojejunostomy. Intra-operative enteroscopy was non-diagnostic in 13 patients (16%) (Figure 2).

All patients with a positive finding during IOE were treated. Angiodysplasias were treated with argon-plasma-coagulation (APC) ( $n = 20$ ), with a combination of APC and surgical suture in case of large malformations ( $n = 18$ ), or with surgical resection of a small part of the small intestine ( $n = 6$ ) in case of multiple angiodysplasias located in well-defined areas of the ileum. Both the tumors and all the large diverticula were completely resected in all the 6 patients during the IOE session.

One of the patients, an 84-year-old woman with recurrent blood loss originating from the small intestine and a minimal hemoglobin level of 43 g/L, had an intra-abdominal abscess due to a leakage at the incision site of the small intestine. She was re-operated two days after the IOE and recovered soon without further problems. There was no mortality due to the intra-operative enteroscopy or its sequelae during her hospital stay (Figure 3).

**Figure 2** Diagram of the main diagnoses acquired during IOE. Angiodysplasia was the most frequent finding. Other findings were one Dieulafoy ulcer in the cecum (not-diagnosed during a previous colonoscopy). Three patients had a Meckel's diverticulum and 3 patients had a large diverticulum in the ileum ( $n=1$ ) or jejunum ( $n=2$ ).

## DISCUSSION

The management of patients with obscure gastrointestinal bleeding remains a diagnostic and therapeutic challenge to all physicians involved in their care<sup>[3]</sup>. After non-diagnostic upper and lower endoscopy, the use of peroral push-type enteroscopy has been the diagnostic standard procedure for many years<sup>[12,13]</sup>.

Push enteroscopy is still the method of choice for suspected small intestinal bleeding as it is easy to perform and is available in several endoscopic centers. Push-enteroscopy provides the option for a broad spectrum of diagnostic and therapeutic endoscopic procedures, including biopsies, argon-plasma-coagulation, injection methods and even removal of polyps<sup>[13]</sup>. However, this technique is limited with respect to the insertion depth due to the tortuous nature of the small intestine and looping in the stomach. In most cases, only the upper and middle part of the jejunum can be reached and the diagnostic harvest is thus limited. In several series for which push-enteroscopy was used for the diagnosis of a bleeding source, the rate of the diagnostic findings ranges 15-53%, depending on the timing of endoscopy, the type of enteroscope and the clinical setting<sup>[5,13-15]</sup>.

For many years, IOE has been the only method for evaluating the mucosal surface of the complete small intestine. This procedure is limited to patients who are operative candidates and have recurrent or severe bleeding episodes<sup>[16]</sup>, since IOE is an invasive procedure requiring general anesthesia. Several methods for IOE such as peroral approach, transanal and direct intubation through a surgical incision of the small intestine are now available. The latter is method used in our series and allowed for the examination of the entire small intestine in all the patients. In general, the diagnostic yield of IOE is high when patients are highly selected for such procedures. It was reported that IOE can detect 70-80% sources of bleeding<sup>[17]</sup>. In our series, a probable or definite bleeding source was found in 68 (84%) of the 81 patients. The IOE procedure allowed for the endoscopic or surgical treatment of the lesions during the same session in all our patients.

**Figure 3** Typical angiodysplasia in the ileum diagnosed during IOE.

The most common finding by IOE was angiodysplasia with a rate of 54.3%. In several other series investigated for small intestinal bleeding, angiodysplasias are the most common findings too and local treatment results in the reduction of blood loss in a substantial portion of patients<sup>[15,18,19]</sup>.

Four of the 81 patients had previously non-diagnosed malignant tumors of the small intestine and 6 additional patients were affected by a Meckel's diverticulum or a large small intestinal diverticulum as a bleeding source. These conditions required operative treatment rather than endoscopic treatment even if they were within the reach of the scope. In our series, we encountered only one major complication during hospital stay (intra-abdominal abscess formation). Most published series present a comparable low morbidity rate and no mortality<sup>[8-11,20]</sup>. Though the accuracy and diagnostic yield of IOE are high the procedure should be regarded as the last resort for patients with unexplained obscure gastrointestinal bleeding due to its invasive nature<sup>[21]</sup>.

Wireless capsule endoscopy and double-balloon enteroscopy constitute new methods for the diagnosis of patients with obscure gastrointestinal bleeding. Capsule endoscopy allows for non-invasive visualization of the entire small intestine in a substantial portion of patients. It was reported that it has a high diagnostic yield of angiodysplasia, ulcer and active bleeding in selected populations of obscure gastrointestinal bleeding<sup>[5]</sup>. A recently published Italian multi-center study on capsule endoscopy examined 100 patients with obscure gastrointestinal bleeding and yielded 47% positive and 15% suspicious findings<sup>[22]</sup>. The timing of capsule endoscopy is important: in patients with ongoing overt bleeding during the examination, the findings are positive in 92%. When capsule endoscopy was performed more than 10 d after an overt bleeding episode, the diagnostic rate decreased to 12%. However, in 21% of cases, the cecum was not reached, and in 5% of the cases, asymptomatic retention of the capsule occurred. Capsule endoscopy is limited in its use because biopsies and interventional treatment procedures are not possible and the localization of findings is sometimes difficult. A two-center-study showed that the sensitivity of capsule endoscopy (compared by IOE as a criterion) is 95%, the positive and negative predictive values are 95% and 86%, respectively<sup>[23]</sup>.

Double balloon enteroscopy (DBE) is a new diagnostic option that has the potential to replace intra-operative enteroscopy in the near future<sup>[7]</sup>. It allows for endoscopic visualization of the entire small intestine in a substantial portion of patients. The technical principle of DBE is an alternating push and pull procedure<sup>[6]</sup>.

Initial data from Japan and Germany show encouraging results, with a high diagnostic yield of DBE in patients with suspected small bowel diseases. However, in only 10-15% patients, visualization of the complete small intestine is possible. Two procedures, beginning perorally and then transanally, are required for a substantial portion of patients. The procedure is time-consuming. In patients having undergone previous surgical operations of the abdomen, a complete examination of the small intestine is not be possible because of adhesions. As this method is carried out without general anesthesia and its nature is less invasive compared to IOE, repeated DBE is possible even in older patients and in those with recurrent bleeding.

Studies comparing IOE with DBE have not yet been conducted. Such studies may never be performed because patients with a diagnostic DBE do not need an IOE and vice versa. Nevertheless, further studies should be carried out to redefine the role of the invasive IOE procedure in the new era of wireless capsule endoscopy and double-balloon enteroscopy.

### Abstract

**AIM:** There is strong evidence that interleukin-11 (IL-11) is involved in the regulation of tumor progression, cellular growth and differentiation. Recently, interleukin-11 receptor (IL-11R) has been detected on some cancer cells. In this study, we investigated the expression of IL-11 and IL-11R in colorectal adenocarcinoma.

**METHODS:** To elucidate the involvement of IL-11 and IL-11R $\alpha$  in human intestinal adenocarcinomas, we examined 115 cases of surgically resected human colonic adenocarcinoma and 11 cases of adenoma by immunohistochemistry and Western blotting.

**RESULTS:** Among 115 cases of adenocarcinoma, 100 cases (87.0%) showed positive staining in the cytoplasm of carcinoma cells for the IL-11, and 87 cases (75.6%) were positive for the IL-11R $\alpha$ . Six cases (54.5%) and four cases (36.4%) of 11 adenomas were positive for IL-11 and IL-11R $\alpha$ , respectively. The expression of IL-11R $\alpha$  correlated with the histological differentiation ( $P=0.033503$ ), the depth of tumor invasion ( $P=0.006395$ ), Dukes' classification ( $P=0.015648$ ) and lymphatic invasion ( $P=0.003865$ ). However, the expression of IL-11R $\alpha$  was not correlated with the venous invasion and the presence of lymph node metastasis. The expression

of IL-11 was not correlated with any clinicopathological factors. In Western blot analysis, two human colorectal carcinoma cell lines and four tissues of surgically resected human carcinoma expressed both IL-11 and IL-11R $\alpha$  proteins.

**CONCLUSION:** IL-11 and IL-11R $\alpha$  are highly expressed in human colorectal adenocarcinoma and the IL-11R $\alpha$  expression is correlated with clinicopathological factors. These findings suggest that the expression of IL-11R $\alpha$  is an important factor for the invasion of human colorectal adenocarcinoma.

### INTRODUCTION

Colorectal cancer is one of the most common neoplasms and is a significant cause of morbidity and mortality<sup>[1,2]</sup>. Consequently, colorectal carcinoma is one of the best characterized examples of multistep progression in which activation of oncogenes, such as the K-ras gene<sup>[3]</sup>, and inactivation of tumor suppressor genes, such as APC, DCC and p53<sup>[4-7]</sup> take place. The prognosis of colorectal cancer patients is based on the depth of tumor cell invasion and the presence of lymph node metastasis. Recently, it has been suggested that the occurrence and progression of cancer is related to the activation of some cytokines and/or an intracellular signaling pathway. But the development and progressive mechanism of the colorectal cancer is not fully understood.

IL-11 was cloned from the primate stromal cell line PU-34 and was initially considered to be a hematopoietic

cytokine<sup>[8,9]</sup>. It was found later to have effects on non-hematopoietic systems, and to act on many different cells and tissues, which included stimulation of megakaryocyte maturation, platelet production, and growth stimulation of CD34+ hematopoietic progenitor cells<sup>[8,9]</sup>. This cytokine has also been shown to mediate inhibition of adipogenesis<sup>[10]</sup> and stimulation of osteoclasts<sup>[11]</sup>, and acts as a cytoprotective agent of gut mucosa during treatment with radiation and chemotherapy and in models of inflammatory bowel disease<sup>[12-15]</sup>.

The IL-11 receptor (IL-11R) is a member of the gp130-dependent receptor group, which includes the receptors for interleukin-6 (IL-6), leukemia inhibitory factor (LIF), ciliary neurotrophic factor and oncostatin M, and it has been associated with various unique biological actions<sup>[16]</sup>. IL-11-induced signaling is mediated by the formation of a receptor complex, composed of two molecules each of IL-11, two subunits of the IL-11R $\alpha$ , and gp130. An important signaling system activated by the IL-11R $\alpha$  and other members of this receptor family is the PI3

kinase pathway, MAP kinase pathway and the Janus kinase signaling transducer and activator of transcription (Jak-STAT) pathway<sup>[17]</sup>.

Recent studies have shown that IL-11R expression was not only present in megakaryocytes, osteoclasts and colon epithelium but also in breast, ovarian and prostate cancers<sup>[18-20]</sup>. This suggested that it was theoretically possible that IL-11 could affect the growth of tumor cells. In contrast, one study showed that IL-11 may be involved in the normal growth control in the intestinal epithelium, which suggests that the inhibition by IL-11 is lost during carcinogenic transformation<sup>[21]</sup>. In addition, another study showed that IL-11 appears unlikely to stimulate the growth of the most common solid tumors<sup>[22]</sup>. Since, IL-11 could become a therapeutically important compound for providing supportive care for patients who receive cancer chemotherapy, it is important to establish that IL-11 does not stimulate growth of tumor cells.

In this study, we investigated the expression of IL-11 and IL-11R $\alpha$  in human colorectal adenocarcinoma and compared that with the clinicopathological factors to elucidate the relationship of IL-11 and IL-11R in colorectal carcinoma.

## MATERIALS AND METHODS

### Human colorectal tissues and cell lines

Human colorectal tissues were obtained from fresh surgical samples or paraffin-embedded blocks as described previously. All specimens were obtained from patients operated at Nagasaki University Hospital between 1998 and 2003. We examined 115 cases of human colorectal adenocarcinoma and 11 cases of adenoma as benign lesions with moderate dysplasia. Each tumor was assigned a histological type according to the Japanese Classification of Colorectal Carcinoma by the World Health Organization classification<sup>[23]</sup> and a depth grading of infiltration according to the TNM staging system by the American Joint Commission on Cancer<sup>[24]</sup>. 24 mucosal carcinomas (Tis), 11 submucosal infiltrative carcinomas (T1), 10 carcinomas invading proprial muscle layers (T2), 48 carcinomas reaching the subserosa (T3), and 22 carcinomas penetrating the serosal surface (T4) were examined. Histologically, 57 were well-differentiated adenocarcinomas (wel), 46 were moderately-differentiated adenocarcinomas (mod), 5 were poorly differentiated adenocarcinomas (por), and 7 were mucinous carcinomas (muc) (Table 1).

Colo320DM (adenocarcinoma) and DLD-1 (adenocarcinoma) cell lines derived from human colorectal cancer were obtained from the Human Health Resources Bank (Osaka, Japan). All cell lines were incubated at 37 °C in a humidified incubator containing 5% CO<sub>2</sub> and 95% air. Colo320DM was maintained in RPMI 1640 (Invitrogen Corp., Carlsbad, CA, USA) supplemented with heat-inactivated 10% fetal calf serum (Invitrogen Corp.). DLD-1 was maintained in DMEM/F-12 (Invitrogen Corp.) supplemented with 10% fetal calf serum.

### Immunohistochemistry

Formalin-fixed and paraffin-embedded tissues were cut

**Figure 1** Immunohistochemical staining for the IL-11 and IL-11R $\alpha$  in human colorectal carcinoma. (A) is for IL-11, and (B) is for IL-11R $\alpha$ . IL-11 and IL-11R $\alpha$  show strong cytoplasmic and membranous expression.

into 4  $\mu$ m sections, deparaffinized in xylene and rehydrated in phosphate-buffered saline. Deparaffinized sections were preincubated with normal bovine serum to prevent nonspecific binding, and then incubated overnight at 4°C with an optimal dilution (0.1  $\mu$ g/mL) of a primary polyclonal rabbit antibody against human IL-11 (H-169) and IL-11R $\alpha$  (N-20). Each antibody was bought from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA, USA). The slides for IL-11 were then sequentially incubated with a horseradish-conjugated goat antirabbit immunoglobulin G antibody. And the reaction products were resolved using a diaminobenzidine (DAB; DAKO, Carpinteria, CA, USA). The slides for IL-11R $\alpha$  were sequentially incubated with an alkaline phosphatase-conjugated goat antirabbit immunoglobulin G antibody, and the reaction products were resolved using a mixture of 5-bromo-4-chloro-3-indolyl phosphate and nitroblue tetrazolium chloride (BCIP/NBT; DAKO). Primary antibodies preabsorbed with excess recombinant IL-11 and IL-11R $\alpha$  peptides (Santa Cruz Biotechnology, Inc.), respectively, were used as negative controls. Prostatic cancer tissues<sup>[19]</sup> served as the internal positive control for IL-11 and IL-11R $\alpha$  immunostaining. Analysis of the immunohistochemical staining was performed independently by two investigators (K. Yamazumi and T. Nakayama). IL-11 and IL-11R $\alpha$  expression was classified into three categories depending on the percentage of cells stained: -, 0 to 10% positive cells; +, 10 to 50% positive tumor cells; and ++, > 50% positive tumor cells.

#### Western blot analysis

Western blot analysis for IL-11 and IL-11R $\alpha$  expressio was

**Figure 2** Demonstration of IL-11 and IL-11R $\alpha$  in colorectal carcinoma cells and tissues by Western blotting. All of colorectal carcinoma cells, carcinoma tissues and normal mucosa expressed both IL-11 and IL-11R $\alpha$ . (N: normal mucosa, T: human colorectal cancer tissue).

performed on four human colorectal carcinoma tissues, normal mucosal tissues and two colorectal carcinoma cell lines. Human colorectal tissues were obtained within 1 hour of surgery and immediately frozen. The tissues were then suspended in RIPA buffer (50 mmol/L Tris, 150 mmol/L NaCl, 1% NP-40, 1% sodium deoxycholate and 0.05% SDS, pH 7.4), broken into pieces on ice and subjected to three freeze-thaw cycles. The insoluble cell debris was removed by centrifugation at 14000 r/min at 0°C for 10 min. The supernatant was collected and the protein concentration was quantified using a protein assay reagent (Bio-Rad Laboratories, Hercules, CA). The proteins (20  $\mu$ g) were separated by polyacrylamide gel electrophoresis (PAGE) under denaturing and reducing conditions, and then transferred to a Hybond ECL nitrocellulose membrane (Amersham Biosciences, Buckinghamshire, UK). The membranes were rinsed in TBS, blocked with 5% low-fat dried milk in TBS containing 0.1% Tween 20 (TBS-T), and then incubated for 1 h at room temperature with a 1  $\mu$ g/mL dilution of the anti-human IL-11 or IL-11 receptor  $\alpha$  antibody (Santa Cruz Biotechnology, Inc.). After extensive washing of the membranes with TBS-T, they were incubated for 1 h with a 1:1000 dilution of the horseradish-peroxidase-conjugated donkey anti-rabbit immunoglobulin G (Santa Cruz Biotechnology, Inc.) in TBS-T containing 3% low-fat dried milk. The membranes were washed and developed with a horseradish peroxidase chemiluminescence detection reagent (ECL Plus System, Amersham Bioscience), and then exposed to Hyperfilm ECL (Amersham Bioscience).

#### Statistical analysis

The Stat View II program (Abacus Concepts, Inc., Berkeley, CA) was used for statistical analyses. Analyses comparing the degrees of IL-11 or IL-11R $\alpha$  expression were performed by Spearman's correlation coefficient by rank test or Mann-Whitney's *U* test methods.

## RESULTS

IL-11 was localized in the cytoplasm of the carcinoma cells (Figure 1A), and IL-11R $\alpha$  was localized both in the membrane and the cytoplasm, mainly in the membrane (Figure 1B). No staining with anti-IL-11 or anti-IL-11R $\alpha$  was seen in the negative controls for tissue staining. Although normal epithelium and stromal tissue around tumors expressed IL-11 and IL-11R $\alpha$ , the expression in these tissues were more faint than that in the carcinoma cells.

Immunohistochemical results are summarized in the Table 1. Among 115 cases of adenocarcinoma, 100 cases

(87.0%) showed positive staining for the IL-11, and 87 cases (75.6%) were positive for the IL-11R $\alpha$ . Among 10 cases of normal colorectal mucosa, 5 cases (50.0%) expressed IL-11 and 4 cases (40.0%) were positive for IL-11R $\alpha$ . And there were significant differences between IL-11 and IL-11R $\alpha$  expression and in between normal mucosa and adenocarcinoma ( $P=0.001883$ ,  $P=0.00196$ , respectively). Among 11 cases of adenoma, 6 cases (54.5%) were expressed IL-11 and 4 cases (57.1%) of adenoma were positive for IL-11R $\alpha$ , and there were significant differences of IL-11 or IL-11R $\alpha$  expressions between adenoma and adenocarcinoma ( $P=0.023291$ ,  $P=0.000833$ , respectively).

IL-11 and IL-11R $\alpha$  were expressed more intensely in the invasive than the superficial parts of the carcinoma. The expression of IL-11R $\alpha$  correlated significantly with histological differentiation ( $P=0.000833$ ), depth of tumor invasion ( $P=0.006395$ ), Dukes' classification ( $P=0.015648$ ) and lymphatic invasion ( $P=0.003865$ ) (Table 1). However, there was no correlation with lymph node metastasis and venous invasion. On the other hand, there was no correlation between IL-11 expression and clinicopathological factors.

IL-11 and IL-11R $\alpha$  expression was also detected in two colorectal carcinoma cell lines and all of four human carcinoma tissues by Western blot analysis (Figure 2). The IL-11 protein of 19.1 Kd was clearly detected in all of the two cell lines and four carcinoma tissues. The IL-11R $\alpha$  expression was detected in the two cell lines and four carcinoma tissues at various levels. IL-11 and IL-11R $\alpha$  proteins were also expressed in normal mucosa but were more intense in the cancer tissue than in the normal mucosa (Figure 2).

## DISCUSSION

IL-11 is well known as a hematopoietic cytokine. However, the expression of IL-11 has also been observed in many types of cells, such as fibroblasts, chondrocytes, synovial epithelium, bronchial epithelium and colonic epithelium<sup>[15,25,26]</sup>, and it has been shown that IL-11 has various actions on hepatic, stromal, epithelial, neural and osteoclastic cells<sup>[27]</sup>. Recent studies have shown that IL-11R was not only expressed in megakaryocytes, osteoclasts and colon epithelium but also in breast cancer, ovarian cancer and prostate cancer<sup>[12-14]</sup>. In this study, we have demonstrated for the first time that IL-11 and IL-11R $\alpha$  are expressed in the human colorectal mucosa, colorectal cancer tissue and cell lines. Both IL-11 and IL-11R $\alpha$  were expressed simultaneously in the carcinoma cell. Therefore, it is suggested that the tumor cell may respond to the IL-11 in an autocrine and/or paracrine fashion to promote the invasion of tumors.

There were statistically significant correlations between the expression of IL-11R $\alpha$  and histological differentiation, tumor invasion and lymphatic invasion. These results suggest that IL-11R $\alpha$  is involved in the regulation of cellular differentiation and tumor progression in human colorectal carcinoma. Recently, the expression of IL-11R $\alpha$  has been reported in carcinoma of the breast, ovary and prostate<sup>[12-14]</sup>. We suggest that IL-11 might play an important role in the progression of carcinomas.

IL-11 is known as the activator of the JAK/STAT pathway through GP130<sup>[11]</sup>. A recent study showed that STAT3 signaling directly regulates tumor invasion and metastasis<sup>[28]</sup>. And other GP130-dependent cytokines, such as IL-6 and LIF, have been reported to have connections with several tumors<sup>[29-33]</sup>. Especially, the tumor-promoting and invasion activity of IL-6 has been well studied<sup>[30-32]</sup>. IL-11 also shares the GP130 connection, and in one report it was noted that a complex of the soluble IL-11 receptor and IL-11 act as an IL-6-type cytokine<sup>[34]</sup>. Thus, it is suggested that IL-11 may stimulate colorectal carcinoma cell growth and invasion through activation of the GP130/STAT-3 signaling pathway.

Recently, it was suggested that IL-11 could become a therapeutically important molecule in supportive care of cancer patients who receive chemotherapy<sup>[35]</sup>, and another study showed that IL-11 appears unlikely to stimulate the growth of the most common solid tumors<sup>[16]</sup>. However, in this study, we have demonstrated that IL-11 may up-regulate the activity of colorectal carcinoma cell growth and/or invasion, so it is necessary to pay very careful attention to the therapeutic use of IL-11.

In conclusion, we have demonstrated that IL-11R $\alpha$  is an important factor involved in the invasion of human colorectal adenocarcinoma. However, the roles of IL-11 and IL-11R in human colorectal carcinoma remain unclear and await further study.

## ACKNOWLEDGEMENTS

We are grateful to Mr. Toshiyuki Kawada (Nagasaki University Graduate School of Biomedical Sciences) for his excellent immunohistochemical and molecular biological assistance.

### Abstract

**AIM:** To investigate the efficacy of angiotensin II receptor antagonist on hepatic stellate cells (HSCs) activation in the patients with non-alcoholic steatohepatitis (NASH).

**METHODS:** Seven patients with NASH were prescribed losartan, a selective angiotensin II type 1 receptor antagonist (50 mg/d) for 48 wk. Liver biopsies were performed both at the entry and end of the study in all patients. Quiescent and activated HSCs were identified by double immunostaining using anti-p75 and  $\alpha$ -smooth muscle actin antibodies, and the number of each phenotype was counted. Similarly, the liver specimens obtained from the eight patients with non-alcoholic fatty liver (NAFL) were also examined as controls.

**RESULTS:** In NASH hepatic tissues, activated HSCs were dominantly distributed as compared with those in NAFL. The 48-wk losartan treatment induced a remarkable decrease in activated HSCs and a mild increase in quiescent phenotypes.

**CONCLUSION:** Our data suggest the crucial involvement of HSCs in anti-fibrotic effect of angiotensin II receptor antagonist on patients with NASH.

### INTRODUCTION

Non-alcoholic steatohepatitis (NASH) is a distinct clinical entity characterized by steatosis, varying degrees of lobular inflammation and fibrosis in the liver, and this disease can potentially progress<sup>[1,2]</sup>. Previous data showed that about 20% of the patients developed to liver cirrhosis<sup>[3]</sup> and several cases of hepatocellular carcinoma are related to NASH<sup>[4]</sup>. Although the causes of NASH are not well defined, hepatic stellate cell (HSC) is suggested to play a pivotal role in the progression of hepatic fibrosis as other chronic liver diseases<sup>[5,6]</sup>. Stimulated HSCs transform into myofibroblast-like cell, and produce a large amount of extracellular matrix components, resulting in the formation of fibrosis<sup>[7]</sup>. However, to our knowledge, the efficacy of any treatments for NASH on the activation of HSCs has not been reported yet. Recently, we have demonstrated that losartan, a selective angiotensin II type 1 receptor antagonist, improved hepatic necroinflammation and fibrosis in patients with NASH<sup>[8]</sup>. Based on our results, we hypothesized that an angiotensin II receptor antagonist inhibits the progression of hepatic fibrosis through the inactivation of HSCs in NASH. In this study, we, therefore, investigated the efficacy of long-term losartan treatment on HSCs in patients with NASH.

### MATERIALS AND METHODS

#### Patients

Seven patients with both NASH and hypertension, which was defined as a systolic blood pressure over 140 mmHg

**Table 1** Characteristics and biochemical data of patients with non-alcoholic fatty liver (NAFL) and non-alcoholic steatohepatitis (NASH) before losartan treatment

Parameters	NAFL (n=8)	NASH (n=7)
Age (yr) Male/female	59 (34-76) 4/4	59 (41-65) 2/5
BMI (kg/m <sup>2</sup> )	24.5 (21.4-31.4)	26.1 (22.6-36.7)
SBP (mmHg)	130 (92-156)	148 (127-171)
DBP (mmHg)	78 (54-96)	90 (71-100)
AST (IU/L)	54 (42-70)	84 (20-128)
ALT (IU/L)	72 (56-110)	132 (54-138)
γ-GTP (IU/L)	30 (17-43)	53 (42-127) <sup>a</sup>
TC (mg/dL)	209 (169-254)	222 (160-319)
TG (mg/dL)	128 (86-198)	124 (65-295)
FBS (mg/dL)	95 (86-112)	109 (97-132) <sup>a</sup>
Ferritin (ng/mL)	111 (30-264)	199 (54-379)
HA (ng/mL)	46.5 (10.0-78.3)	89.4 (12.3-197.0)
IV collagen (ng/mL)	2.7 (2.0-3.5)	5.2 (3.1-9.9) <sup>a</sup>

Values are expressed as median (range). <sup>a</sup>*P* < 0.05 *vs* NAFL; BMI: body mass index; SBP: systolic blood pressure; DBP: diastolic blood pressure; AST: aspartate aminotransferase; ALT: alanine aminotransferase; γ-GTP: γ-glutamyl transpeptidase; TC: total cholesterol; TG: triglyceride; FBS: fasting blood glucose; HA: hyaluronic acid; IV collagen: type IV collagen 7S.

and/or a diastolic blood pressure over 90 mmHg, and eight patients with non-alcoholic fatty liver (NAFL) were enrolled into this study. A detailed alcohol history was taken by at least two physicians and confirmed by at least one close relative who lived with the patient. All patients consumed less than 40 g of alcohol per week, and were negative for hepatitis B serological tests, antibody to hepatitis C virus or any autoantibodies, including anti-nuclear antibody, and anti-mitochondrial antibody. Serum ceruloplasmin and α1-antitrypsin levels were normal in all patients. Four patients in NASH group and three in NAFL group were obese (body mass index > 25); four in NASH and one in NAFL had diabetes mellitus; two in NASH and four in NAFL had impaired glucose tolerance; three in NASH and four in NAFL had hyperlipidemia; and one patient in each group had hyperuricemia. Four of eight patients with NAFL group had hypertension.

### Study design

At the entry of the study, some of the patients had already been on medication, including benzodiazepines, calcium antagonists or anticoagulants for at least 12 mo. These therapeutic regimens were not changed after an induction of losartan treatment in patients with NASH. No patient was taking any angiotensin converting enzyme inhibitors or angiotensin II receptor antagonists before the study. Laboratory examination showed abnormally high serum transaminase and γ-glutamyl transpeptidase concentrations in all patients. A liver biopsy was performed prior to entry of the study, which revealed a moderate to severe lobular steatosis in both groups. On the other hand, various degrees of hepatic necroinflammation and fibrosis were demonstrated only in NASH group. After the estimation at the entry, patients with NASH were prescribed losartan at a dose of 50 mg/d for 48 wk, and a physical and laboratory examination were monitored every 4 wk. A liver biopsy was repeated at the end of the study in the patients with

**Figure 1** Expression of HSCs in patients with NASH and NAFL (× 400). Liver sections were immunostained with both monoclonal anti-p75 antibody and monoclonal anti-α-SMA antibodies. Although most perisinusoidal HSCs were quiescent form (arrow heads) in NAFL, a number of arrow head were detected in the patient with NASH (arrow heads).

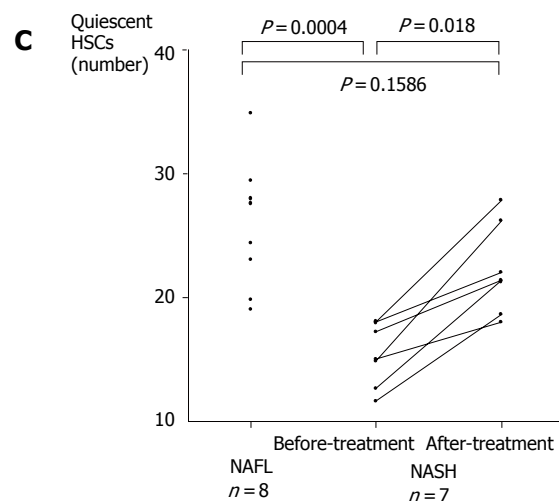

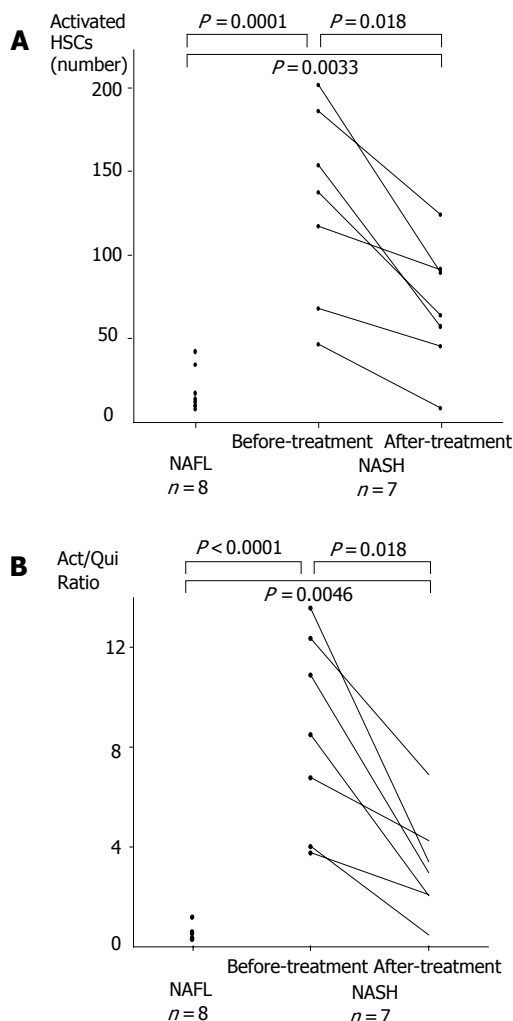

**Figure 2** Significant decrease of activated and quiescent HSCs by 48-wk losartan treatment in a patient with NASH (double immunostaining with anti-p75 and α-SMA antibodies, × 200).

NASH. The Ethical Committee of Asahikawa Medical College for Clinical Study approved all protocols, and informed consents were obtained from all patients.

### Liver histology

Hematoxylin & eosin and Azan stainings were performed on fixed histological sections. Two experienced hepatopathologists graded necroinflammation and staged fibrosis in a blinded fashion according to the Grading and Staging system of NASH proposed by the American Association for the Study of Liver Diseases<sup>[9]</sup>. To identify HSCs, double immunostaining was performed using monoclonal anti-p75 (a low affinity nerve growth factor receptor) antibody (Novocastra, Newcastle, UK) and monoclonal anti-α-smooth muscle actin (α-SMA) antibody (Dako, Kidlington, UK) as previously described<sup>[10,11]</sup>. Color development was achieved with BCIP/NBT for p75 and DAB for α-SMA, and counter-staining was performed using direct fast red. Activated HSCs were distinguished from quiescent HSCs by their myofibroblast-like form and the disappearance of fat vesicles in cytoplasm<sup>[7]</sup>. The numbers of both activated and quiescent HSCs were blindly counted by two independent pathologists and averaged in five fields per slide at

**Figure 3** Average numbers of HSCs in five fields per slide at x200 magnification. **A:** number of activated HSCs; **B:** averaged ratio of activated HSCs to quiescent HSCs (Act-/Qui- Ratio: a ratio of activated HSCs to quiescent HSCs); **C:** averaged number of quiescent HSCs.

and circular cell bodies containing lipid droplets in the cytoplasm, were dominantly distributed, and active forms of HSC were rarely observed. On the other hand, activated HSCs (myofibroblast-like phenotype), characterized by enlarged cell bodies, fewer lipid droplets and the presence of membranous processes, were conspicuously scattered in NASH liver tissues. These activated HSCs were preferentially associated with areas of fibrosis (Figure 2). The number of activated HSCs and ratio of activated/quiescent HSCs in NASH liver tissues were significantly higher as compared with those in NAFL liver tissues (Figures 3A and 3B). On the other hand, the number of quiescent HSCs was significantly lower in NASH liver tissues as compared with those in NAFL liver tissues (Figure 3C). In patients with NASH, the number of activated HSCs in the liver sections with mild necroinflammation (grade 1) was significantly lower as compared with those with moderate to severe necroinflammation (grades 2 and 3) [grade 1: 57 (46-68); grades 2 and 3: 153 (117-201),  $P < 0.05$ ]. Although the number of activated HSCs in the liver sections with mild fibrosis (stages 1 and 2) tended to be lower as compared with those with severe fibrosis (stages 3 and 4), there was no statistically significant difference [stages 1 and 2: 68 (46-185); stages 3 and 4: 145 (117-201)].

The number of activated HSCs and the ratio of activated/quiescent HSCs were significantly decreased after 48-wk losartan treatment (Figures 3A and 3B). On the other hand, quiescent HSCs slightly increased after losartan treatment (Figure 3C). There was no significant correlation between the decrease rate of activated HSCs and the improvement of hepatic pathologic findings after losartan treatment.

## DISCUSSION

In the present study, we demonstrated that the activated HSCs and the ratio of activated/quiescent HSCs in NASH hepatic tissues were significantly higher as compared with those in NAFL, and activated HSCs in NASH livers were

× 200 magnification.

## Statistical analysis

Data were expressed as median values with ranges. Mann-Whitney *U*-test was used to compare two independent data, and Wilcoxon rank sum test was used for paired data. A *P* value  $< 0.05$  was considered statistically significant.

## RESULTS

Before the study, serum  $\gamma$ -glutamyl transpeptidase, type IV collagen 7 S and fasting blood glucose levels in NASH group were significantly higher as compared with NAFL group. Although body mass index, serum transaminase, hyaluronic acid, ferritin and triglyceride levels in the NASH group tended to be higher as compare with the NAFL group, there was no statistically significant difference (Table 1). No side effect was noted, and the body mass index was unchanged during the losartan treatment in patients with NASH. The necroinflammatory grade and stage of fibrosis diagnosed by liver biopsies were improved after losartan treatment [for grade: pretreatment, 2 (1-3), posttreatment, 1 (1-2),  $P < 0.05$ ; for stage: pretreatment, 3 (1-4), posttreatment, 2 (1-4),  $P < 0.05$ ].

HSCs were identified in the perisinusoidal area of both NAFL and NASH liver sections (Figure 1). In NAFL liver tissues, quiescent forms of HSC, characterized by small

preferentially localized along fibrotic area. The number of activated HSCs tended to be correlated with the necroinflammatory grade and fibrotic stage. This result was very consistent with previous studies that demonstrated the activation of HSCs in NASH<sup>[5,6]</sup>, and suggested that the hepatic necroinflammation activated and proliferated HSCs, and led to progress the hepatic fibrosis in NASH. In contrast, Wasington *et al*<sup>[6]</sup> reported no difference in the number of activated HSCs between NASH and NAFL. This discrepancy may be due to the difference of employed procedure for identifying activated HSCs. Although we judged activated HSCs by their distinctive form and disappearance of fat vesicle, together with double staining with anti-p75 and  $\alpha$ -SMA antibodies, they identified activated HSCs only by positive staining for  $\alpha$ -SMA. Since recent studies demonstrated that both activated and quiescent HSCs expressed  $\alpha$ -SMA<sup>[10,11]</sup>, activated HSCs identified by their procedure may include quiescent phenotypes.

We also investigated the changes of HSCs after 48-wk losartan treatment in patients with NASH. Both the number of activated HSCs and the ratio of activated/quiescent HSCs were significantly decreased, and quiescent HSCs were slightly increased by losartan treatment concurrently with the improvement of hepatic fibrosis. The depletion of activated HSCs might be due to inactivation of activated HSCs<sup>[12]</sup>, or disappearance of activated HSCs by apoptosis<sup>[10]</sup>. An increase of quiescent HSCs after losartan treatment supported the former mechanism. However, an increase in quiescent HSCs was relatively small as compared with a decrease in activated HSCs after losartan treatment, suggesting that the latter mechanism may be dominant in a depletion of activated HSCs. Because it is difficult to recruit patients with both NASH and hypertension, and only seven patients were evaluated in this study, significant correlation between the decrease rate of activated HSCs and the improvement of hepatic pathologic findings after losartan treatment was not observed. However, our present data strongly suggested a causative role of HSCs in hepatic fibrosis of NASH.

Although detailed mechanisms for the suppressive effect of angiotensin II receptor antagonist on HSC activation could not be well defined in this study, we hypothesize that there are two different pathways. The first may be the direct inhibition to HSCs. Studies have revealed that an activated HSC expresses angiotensin II type 1 receptor<sup>[13]</sup>, and synthesizes angiotensin II by itself<sup>[14]</sup>. Locally generated angiotensin II enhances the activation and proliferation of HSCs through autocrine and paracrine mechanisms<sup>[15]</sup>. Losartan inhibited activated HSCs possibly through the blocking of angiotensin II type 1 receptors expressed on the surface of HSCs. In accordance with this mechanism, angiotensin II receptor antagonist may have a therapeutic efficacy on other chronic liver diseases that HSCs are involved in the progression of hepatic fibrosis, including viral hepatitis, alcoholic liver injury, or autoimmune liver diseases<sup>[16-18]</sup>. Actually, Terui *et al*<sup>[19]</sup> reported that losartan improved the hepatic fibrosis in chronic type C hepatitis.

Another mechanism of the angiotensin II receptor antagonist may be the indirect inhibition of HSCs mediated through the improvement of hepatic necroinflammation. Chronic hepatic inflammation enhances the production of

transforming growth factor- $\beta$ 1 (TGF- $\beta$ 1) from Kupffer cell and inflammatory cells<sup>[20]</sup>. TGF- $\beta$ 1 is a multifunctional and ubiquitous cytokine, and in chronic liver diseases, this peptide plays a causative role in hepatic fibrogenesis through the activation of HSCs. We demonstrated that the patients with NASH had elevated plasma TGF- $\beta$ 1 levels that were reversed by  $\alpha$ -tocopherol<sup>[21]</sup>. Moreover, we have recently reported that losartan improves hepatic necroinflammation concurrently with a reduction of plasma TGF- $\beta$ 1 levels in the patients with NASH<sup>[8]</sup>. Angiotensin II is known to aggravate several pathogenic factors of NASH, such as insulin resistance, oxidative stress and hepatic iron overload<sup>[22-24]</sup>. In fact, our previous studies demonstrated that serum ferritin levels were significantly decreased and hepatic iron deposition disappeared in some patients with NASH after losartan treatment<sup>[8]</sup>. Angiotensin II receptor antagonist may also suppress the HSC activation through the decrease of TGF- $\beta$ 1.

In conclusion, inhibiting the action of angiotensin II by losartan results in a remarkable depletion of activated HSCs and a mild increase of quiescent HSCs, thereby suggesting the important involvement of HSCs in anti-fibrotic effect of angiotensin II receptor antagonist on the patients with NASH.

## Abstract

**AIM:** To analyze the hemodynamic and respiratory effects of propofol on patients undergoing gastroscopy and colonoscopy.

**METHODS:** In this prospective study, conducted over a period of three years, 1,104 patients referred for a same day GI endoscopy procedure were analyzed. All patients were given a propofol bolus (0.5-1.5 mg/kg). Arterial blood pressure (BP) was monitored at 3 min intervals and heart rate and oxygen saturation (SpO<sub>2</sub>) were recorded continuously by pulse oximetry. Analyzed data acquisition was carried out before, during, and after the procedure.

**RESULTS:** A statistically significant reduction in mean arterial pressure was demonstrated ( $P < 0.001$ ) when compared to pre-intervention values, but severe hypotension, defined as a systolic blood pressure below 60 mmHg, was noted in only 5 patients (0.5%). Oxygen saturation decreased from 96.5% to 94.4 % ( $P < 0.001$ ). A critical decrease in oxygen saturation ( $< 90\%$ ) was documented in 27 patients (2.4%).

**CONCLUSION:** Our results showed that propofol provided good sedation with excellent pain control, a short recovery time and no significant hemodynamic side effects if carefully titrated. All the patients (and especially ASA III group) require monitoring and care of an anes-

## INTRODUCTION

Gastrointestinal endoscopy remains to date an essential diagnostic and therapeutic tool. Patient comfort during the procedure is of paramount importance for successful completion of the examination<sup>[1,2]</sup>. A significant subset of patients is unable to tolerate gastrointestinal endoscopic procedures without sedation<sup>[3,4]</sup>. Midazolam and benzodiazepines are most commonly used, often in combination with pethidine, whereas anesthetic agents are less frequently used because oversedation may induce respiratory depression, hypotension, and other cardiopulmonary complications.<sup>[5-8]</sup> Optimal administration of conscious sedation and patient monitoring during endoscopy has not been adequately emphasized so far<sup>[9]</sup>.

The optimal strategy of conscious sedation should be tailored to the individual patient, based on the experience of the gastroenterologist and anesthesiologist. Oversedation may induce respiratory depression and delayed recovery in elderly patients and in those with inherent cardiopulmonary compromise. Hypoxemia and hypotension represent the majority of complications observed, especially in upper intestinal endoscopy<sup>[11]</sup>, and may occur more frequently during endoscopic procedures than during anesthesia.

Gastrointestinal procedures require careful patient monitoring especially in the high-risk patient population. Patient vital signs have been monitored in less than 25.9% of cases, in the published literature<sup>[9]</sup>.

Table 1 ASA physical status classification

ASA group	Procedure			Total
	Colonoscopy	Gastroscopy	Both procedures	
I	335	209	165	709
II	172	90	98	360
III	14	11	10	35
Total	521	310	273	1104

ASA-American Society of Anesthesiology.

The purpose of this study was to analyze the hemodynamic and respiratory effects of propofol on patients undergoing gastroscopy and colonoscopy and thus determine whether the monitoring and care of an anesthesiologist is required.

## MATERIALS AND METHODS

### Patients

We analyzed 1 104 patients (639 women and 465 men) admitted for a same day colonoscopy (521 patients), gastroscopy (310 patients) or both procedures (273 patients). The study was conducted prospectively over a three year period, from the 1<sup>st</sup> January 2001 to the 1<sup>st</sup> January 2004, at the Bates Clinic in Zagreb, Croatia. The median age of our patients was 53 years (range 17-88). Age, sex, body weight, blood pressure, heart rate, electrocardiogram, oxygen saturation, as well as patient history including current medication were recorded. We used the American Society of Anesthesiology classification system (ASA grades I-IV) to stratify patients by risk prior to the gastrointestinal procedure. Seven hundred and nine patients were in ASA group I (healthy patients), 361 in ASA II (patients with disease of one body system), and 35 in ASA III (patients with disease of more than one body system) (Table 1). After written informed consent had been obtained, an intravenous cannula was inserted. All patients were monitored throughout the procedure by the anesthesiologist.

### Procedure

The patients were given an intravenous propofol (2,6-diisopropylphenol, Diprivan, Astra Zeneca, USA) bolus (0.5-1.5 mg/kg). The required dose was calculated by the anesthesiologist based on the patient's weight, age, physical condition, and estimated duration of procedure. A mean dose of 135 mg (60-480 mg/kg) of propofol was administered. After an initial dose of 0.5-1.5 mg/kg (ASA I and II) or 0.25-0.5 mg/kg in patients ASA class III or over 70 years, the additional bolus injection was administered to maintain the sedation if needed. Supplemental nasal oxygen was administered at 4 l/min during the procedure. Oxygen saturation and heart rate were monitored continuously by pulse oximetry and blood pressure was recorded at three minute intervals. These values were obtained before, during and after the endoscopic procedure (Table 2). Following the completion of the procedure, the patients were transferred to a recovery room and were closely observed for 30 min. The anesthesiologist recorded an overall pain score (using graded questionnaire describing pain

Table 2 Data on basic laboratory parameters measured before, during and after GI procedures

Parameter	Findings in patients (mean <sup>±</sup> /SD)			Number of monitored patients		
	Before procedure	During procedure	After procedure	Before procedure	During procedure	After procedure
SBP (mmHg)	140.8 <sup>±</sup> 26.0	112.2 <sup>±</sup> 25.3	114.6 <sup>±</sup> 23.7	1 096	880	1 037
DBP (mmHg)	80.6 <sup>±</sup> 13.3	68.4 <sup>±</sup> 14.1	70.1 <sup>±</sup> 12.9	1 096	880	1 035
HR (beats/min)	88.4 <sup>±</sup> 19.1	81.3 <sup>±</sup> 14.3	80.1 <sup>±</sup> 13.9	1 012	888	1 049
SpO <sub>2</sub> (%)	96.5 <sup>±</sup> 2.9	94.4 <sup>±</sup> 4.1	95.3 <sup>±</sup> 3.4	997	885	1 046

as: no pain, mild, moderate and severe pain), complications and recovery time.

### Statistical analysis

Contingency tables were made for qualitative data and distribution parameters (mean, standard deviation, minimum and maximum) were calculated for all measured variables (systolic and diastolic blood pressure, heart rate, oxygen saturation and propofol per kg body weight). Paired t-test was used to test differences between pairs of values for all measured hemodynamic variables before, during and after the procedure.

## RESULTS

We analyzed arterial blood pressure, oxygen saturation and heart rate (Table 2). Blood pressure and heart rate decreased during the procedure ( $P < 0.0001$ ) and increased after ( $P < 0.0001$ ) an initial value. Our results showed that propofol in dosages of 0.5-1.5 mg/kg decreased the systolic blood pressure from 149.8 to 112.2 mmHg, diastolic blood pressure from 80.6 to 68.4 mmHg and heart rate from 88.4 to 81.3 beats/min. Hypotension, defined as a blood pressure below 60 mmHg, was recorded in 5 patients and they received a 500 mL normal saline bolus. Bradycardia, defined as a heart rate less than 50/min, was recorded in 7 patients (0.6%) and they received 0.5 mg of atropine. All medications were administered by the attending anesthesiologist. Oxygen saturation also decreased during the procedure from 96.5% to 94.4% ( $P < 0.001$ ). Oxygen saturation of less than 90% was documented in 27 patients (2.4%). Seven of them were in ASA class III with cardiopulmonary disease, 14 patients with hypertension and obesity and 6 patients were older than 80 years. All hypoxemic episodes occurred in patients undergoing an upper GI examination. No episodes of apnea occurred and mechanical ventilation was not employed in any of our patients. The hypoxemia proved to be transient in all the patients. In our study 3 patients developed ventricular premature beats whereas 5 patients went into a supraventricular tachycardia with a ventricular rate exceeding 140 beats/min. The endoscopic procedures themselves caused no complications. Total

colonoscopy was achieved in all but 6 patients who had subtotal stenosis. None of our patients reported any pain. Median recovery time was 7 min (range 5-15). Five patients had nausea but no intervention was needed. There were no serious respiratory or hemodynamic complications.

## DISCUSSION

Our choice of agent for the establishment of conscious sedation was propofol, a short acting anesthetic agent. In comparison with conventional sedation using midazolam or benzodiazepines, it provides a considerably more rapid onset of action and shorter recovery time<sup>[10,19,20]</sup>. We believe it is a safe alternative for patients undergoing endoscopic procedures. In this study, none of the patients sedated with propofol reported any pain, and the mean recovery time was 7 min (5-15 min).

The choice of sedative in GI procedures is largely operator dependent, but generally consists of benzodiazepines used either alone or in combination with an opiate<sup>[5-8]</sup>. Such combination may increase the risk of oxygen desaturation and cardiorespiratory complications<sup>[2,4,9]</sup>. Trojan *et al*<sup>[14]</sup> demonstrated that the residual effects of midazolam on psychomotor function could be documented for at least 1 h after its administration. Paradoxical reactions, including hyperactive or aggressive behavior have been reported<sup>[4]</sup>. The anesthetic agents, such as droperidol, propofol and general anesthesia are reserved for patients who remain uncooperative on standard regimens or who are perceived to be at high risk for agitation unless a deeper level of sedation is achieved<sup>[15-17]</sup>. General anesthesia is used most commonly in children. Sedation with midazolam, benzodiazepines, analgetics and propofol was administered in many studies by the nurse and the endoscopist<sup>[10,14,18-20]</sup>. In certain settings, assistance from an anesthesiologist may be required. Some authors suggest that GI procedures without sedation are satisfactory<sup>[4,6,9,18]</sup>, but in our previous study<sup>[21]</sup> we showed that 50% of patients without sedation reported the procedure as painful.

Our results showed that propofol in dosages of 0.5-1.5 mg/kg decreased the systolic and diastolic blood pressure and heart rate during the procedure and increased after an initial value. Hypotension and respiratory depression represent the majority of the complications observed<sup>[10,11,22-24]</sup>. In our study only 5 patients had hypotension and 7 patients developed bradycardia. Most of these patients were obese with cardiopulmonary disease and a compromised general physical condition (ASA class III). Electrocardiographic changes during GI procedures, especially gastroscopy, are common and reported in patients with known heart disease as well as otherwise healthy patients<sup>[24]</sup>. Approximately a half of all the complications observed during gastroscopy are of cardiopulmonary origin<sup>[11]</sup>. These rhythm abnormalities in 7 patients were of short duration and caused no hemodynamic compromise.

Monitoring of cardiopulmonary function during endoscopic procedures is of outmost importance and we believe that a significant reduction in morbidity and mortality can thus be achieved. The most widely used

definition of hypoxemia is an oxygen saturation of below 90% and monitoring of oxygen saturation is more sensitive than a clinical detection of cyanosis. Respiratory complications with oxygen desaturation were recorded in 2.4% patients in our study. We prevented hypoxemia with administration of supplementary of 4l/min oxygen. Numerous studies have documented the occurrence of hypoxemia during endoscopy<sup>[6,12,23-24]</sup>. They reported cardiopulmonary complications with oxygen desaturations in 40-60% of patients with sedation, and some studies have reported desaturation in 40% of unsedated patients<sup>[23]</sup>. Obesity, pulmonary disease, age and mechanical airway obstruction worsened hypoxemia. Their recommendation consisted of pulse oximetry monitoring. Intermittent oxygen desaturation is also common during sleep in normal subject<sup>[25]</sup>. Others showed that hypoxemia can be prevented by providing supplemental oxygen<sup>[5,23]</sup>. Gastrointestinal societies in the United States and United Kingdom issued guidelines for monitoring and oxygen administration<sup>[23,24]</sup>. All patients, and especially those in ASA III group, require monitoring and care of an anesthesiologist. Our results showed that propofol provided good sedation and short recovery time. The procedure is rendered painless and no significant respiratory or hemodynamic deteriorations have been observed. Monitoring of blood pressure, heart rate, ECG and oxygen saturation is necessary, as is supplemental administration of oxygen. While some authors recommended that sedation with propofol by nonanesthetists or nurses<sup>[10]</sup> are acceptable, we believe that conscious sedation administration and monitoring by an anesthesiologist with an inherent high index of suspicion for potential complications might be a safer strategy.

## Abstract

**AIM:** To evaluate the utility of local tumor therapy combined with percutaneous transhepatic biliary drainage (PTBD) for malignant obstructive biliary disease.

**METHODS:** A total of 233 patients with malignant biliary obstruction were treated in our hospital with PTBD by placement of metallic stents and/or plastic tubes. After PTBD, 49 patients accepted brachytherapy or extra-radiation therapy or arterial infusion chemotherapy. The patients were followed up with clinical and radiographic evaluation. The survival and stent patency rate were calculated by Kaplan-Meier survival analysis.

**RESULTS:** Twenty-two patients underwent chemotherapy (11 cases of hepatic carcinoma, 7 cases of pancreatic carcinoma, 4 cases of metastatic lymphadenopathy), and 14 patients received radiotherapy (10 cases of cholangiocarcinoma, 4 cases of pancreatic carcinoma), and 13 patients accepted brachytherapy (7 cases of cholangiocarcinoma, 3 cases of pancreatic carcinoma, 4 cases of metastatic lymphadenopathy). The survival rate of the local tumor treatment group at 1, 3, 6, and 12 months was 97.96%, 95.92%, 89.80%, and 32.59% respectively, longer than that of the non treatment group. The patency rate at 1, 3, 6, and 12 months was 97.96%, 93.86%, 80.93%, and 56.52% respectively. The difference of patency rate was not significant between treatment group and non treatment group.

**CONCLUSION:** Our results suggest that local tumor therapy could prolong the survival time of patients with

## INTRODUCTION

Percutaneous transhepatic biliary drainage (PTBD) is a well-established interventional radiological procedure used in patients with malignant obstructive jaundice, especially in inoperable patients<sup>[1-4]</sup>. We treated 233 cases with PTBD from January 1995 to October 2002, 49 of these patients were further treated for local tumors after PTBD. The therapeutic results are reported here.

## MATERIALS AND METHODS

From January 1995 to October 2002, 233 consecutive patients (92 females and 141 males, age ranged from 29 to 91 years, mean age of 63.6 years) with malignant biliary obstruction were treated in our hospital with transhepatic placement of metallic stents and/or plastic tubes. The diagnosis and poor prognosis of the patients were established by various imaging methods (US, CT, MRI) and biliary brush cytology or puncture biopsy. Forty-four of these individuals were diagnosed with pancreatic carcinoma, 89 with cholangiocarcinoma, 54 with metastases originating from a variety of primary sites and the remaining 46 with hepatic carcinoma. The obstructing lesion predominantly involved both the right and left main hepatic ducts in 106 patients and the common hepatic and/or proximal common bile duct in 127 patients.

### *Procedure of percutaneous transhepatic biliary drainage*<sup>[3]</sup>

After routine percutaneous transhepatic cholangiography,

the obstructing lesions were traversed using Terumo guide-wire techniques. If the guide wire could not pass the stricture, the external catheter was retained. Once the guide wire crossed the lesion and entered the bowel, we could deploy the stent or an internal-external catheter. When a stent was needed, a catheter with a side-arm sheath was employed to inject contrast material over the wire for accurate delineation of the upper and lower margins of the obstructing lesion. After the diagnostic catheter was removed, an 8-10F sheath with a side arm and a homeostasis valve was placed over the wire into the bile duct to allow retrieval of the stent in the event of malfunction of the stent delivery system. The side arm could provide a convenient portal for the injection of contrast material into opacity in the biliary ducts, which could facilitate stent positioning. Eight-millimeter balloons were used in most cases, but 10-mm balloons were required occasionally. Dilation before stent placement as a routine procedure was performed in most of the patients.

### Local tumor therapy

Transcatheter arterial chemoembolization (TACE) of all hepatic arteries, celiac and superior mesenteric arteries and their branches should be adequately opacified and all feeding arteries should be carefully identified. We performed TACE initially with infusion of 1000 mg 5-FU, 40~80 mg cisplatin or 200~400 mg carboplatin, 10~20 mg mitomycin or 20~60 mg pharmorubicin, sometimes added 5~15 mL lipiodol with 20~60 mg pirarubicin. We followed up the patients for one or two months with computer tomography, and made TACE 1-3 times.

**External irradiation:** Cobalt-60 source was used with a total integral dose of 6000cGy at the target length of 1cm, 200cGy per day for 30 d.

**Intraluminal brachytherapy:** After deployed the stent, we detained a coaxial guider located at the stenosis of endoprosthesis to undergo after-loading treatment. The intraluminal brachytherapy using the high dose rate iridium-192 ( $^{192}\text{Ir}$ ) sources was performed to deliver an integral dose of 3000cGy, 500cGy each time, two times a day for 3 d, and standard points were established at 1.0 cm.

### Data analysis

Follow-up of each patient was based on outpatient examinations and telephone interviews. The clinical symptoms, phantom change and laboratory examination were recorded. Survival was determined from the time of PTBD. The patent time was defined as the interval between PTBD and obstructive jaundice recurrence. If occlusion did not occur during a patient's life time, the patent period was considered equal to the survival period. Jaundice recurrence was defined as the symptom of jaundice recurred after it subsided and met one of the followings: cholangiography, CT or US demonstrating redilation of bile duct and combined serum bilirubin concentration/total serum bilirubin concentration  $\geq 35\%$ , or serum bilirubin increased after its obvious drop ( $>100\mu\text{mol/L}$ ) or after it was lower than half of its original level. The survival and stent patency were calculated by Kaplan-Meier survival analysis. Analysis of data was performed with SPSS/PC version 8.0.

## RESULTS

PTBD was successfully performed in all the patients. Stent placement was conducted in 136 cases. Of these 136 patients, 100 were treated with only 1 stent, 20 cases with 2 stents for bilateral drainage and 16 with 2 stents for long strictures. The other 97 patients received plastic catheters. The serum level of total bilirubin reduced from  $349.2 \pm 155.6 \mu\text{mol/L}$  to  $178.9 \pm 141.2 \mu\text{mol/L}$  after PTBD ( $t = 17.90$ ,  $P = 0.000$ ).

Forty-nine patients (16 females and 33 males, age ranged from 38 to 83 years, a mean age of 64.4 years) accepted local tumor treatment. Twenty-two patients underwent chemotherapy (11 cases of hepatic carcinoma, 7 cases of pancreatic carcinoma, 4 cases of metastasis), one patient died within 1 month because of re-obstruction in bile duct and poor conditions, others received two or three times of treatment for chemical infusion. Fourteen patients received external beam radiation therapy (10 cases of cholangiocarcinoma, 4 cases of pancreatic carcinoma), and 13 patients accepted brachytherapy (7 cases of cholangiocarcinoma, 3 cases of pancreatic carcinoma, 3 cases of metastatic lymphadenopathy). Obstruction occurred at the hilum in 20 cases while 14 cases received multi-drainage, and at the lower common bile duct in 29 cases. Among the 20 patients with obstruction at the hilum, 8 cases received chemotherapy, 6 external beam radiotherapy, and 6 intraluminal brachytherapy. Among the 29 patients with obstruction at the lower common bile duct, 14 cases received chemotherapy, 8 external beam radiotherapy, and 7 intraluminal brachytherapy.

Total serum bilirubin in those who received local tumor treatment reduced from  $324.04 \pm 166.21 \mu\text{mol/L}$  (mean  $\pm$  SD) to  $87.38 \pm 70.96 \mu\text{mol/L}$  ( $t = 11.54$ ,  $P < 0.001$ ). Total serum bilirubin reduced more than 50% in 42 patients and more than 25% in 7 patients. ALT was decreased from  $129.3 \pm 112.8 \text{ IU/L}$  to  $54.0 \pm 48.5 \text{ IU/L}$  ( $t = 4.01$ ,  $P < 0.001$ ), GGT was decreased from  $576.4 \pm 396.9 \text{ IU/L}$  to  $238.8 \pm 235.4 \text{ IU/L}$  ( $t = 5.58$ ,  $P < 0.001$ ) and ALP was decreased from  $687.9 \pm 685.1 \text{ IU/L}$  to  $291.5 \pm 247.1 \text{ IU/L}$  ( $t = 3.47$ ,  $P = 0.001$ ).

Patients with obstruction at the lower common bile duct had more chances to receive local tumor therapy. Stent deployment made it possible for patients to receive further treatment (Table 1).

No severe complication occurred after the procedures. One patient with stent placement died within 1 month because of bile duct re-obstruction and poor conditions. Five patients were still alive during follow-up, and the survival time was 10.5 months (median), and the 1-, 3-, 6- and 12-month survival rate was 97.96%, 95.92%, 89.80%, 32.59%, respectively. Twelve patients who received chemotherapy had re-obstruction during follow-up. Eight patients subsequently developed occluded stents that were treated with one or more additional interventions such as placement of additional stents ( $n = 2$ ) or placement of temporal external drainage ( $n = 6$ ). Four patients who received catheter drainage had replacement of the plastic catheter. One patient appeared to have distal tumor overgrowth and one exhibited both proximal overgrowth and intraluminal filling defects and three patients developed sludge and debris within

Table 1 Factors of PTBD

the stent. Seven patients who developed an intraluminal filling defect in stent or catheter did not have any cytological or histological evidence. Two patients who received intraluminal brachytherapy and 2 who received external

irradiation had re-obstruction during follow-up, which was eliminated by balloon dilation. The patency time was 14 mo (median). The patency rate at 1, 3, 6, and 12 mo was 97.96%, 93.86%, 80.93%, and 56.52%, respectively. While the 1-, 3-, 6- and 12- mo survival rate of non-therapy group was 84.24%, 56.97%, 26.40%, and 5.52% respectively, and the patency rate at 1, 3, 6, and 12 months was 94.15%, 84.89%, 66.29%, and 35.73% respectively. The median survival time was significantly longer in the local treatment group than in the no-adjuvant therapy group respectively (Log rank = 46.34,  $P < 0.001$ ) (Figure 1). Though the patency rate of treatment group was higher than that of non-therapy group, there was no significant difference between these two groups (Log rank = 2.38,  $P = 0.123$ , Figure 2)

## DISCUSSION

Surgical therapy of malignant obstructive jaundice includes a curative resection or a palliative operation of the tumor. Unfortunately, the surgical cure rate of pancreatic, bile duct and gall bladder carcinoma, and hepatic carcinoma is lower than 5%<sup>[5,6]</sup>. Since the resectability of pancreatic cancer remains below 30%<sup>[7]</sup>, palliative treatment is recommended for patients with unresectable tumor. Interventional radiologists play an important role in the management of patients with malignant biliary obstruction. Biliary drainage is usually used as the initial treatment because of overt cholangitis. All procedures were performed using fluoroscopic guidance alone in our study. Early and effective biliary drainage might be necessary in this group of patients with limited hepatic function to improve the prognosis<sup>[8]</sup>. PTBD for inoperable malignant obstructive jaundice is a widely used palliative procedure<sup>[1-3]</sup>.

Yan<sup>[9]</sup> pointed out that bile drainage as a palliative therapy for malignant obstructive jaundice could not prolong the survival time, but can improve life quality. Successful biliary drainage after biliary decompression is associated with improvement in quality of life<sup>[10]</sup>. However, PTBD could provide access to the intrahepatic and extrahepatic bile ducts<sup>[11-13]</sup>.

Since PTBD alleviates icterus and improves liver reserve function, patients with tumor could have more chances to receive chemotherapy or radiotherapy or photodynamic therapy<sup>[14]</sup> or radiofrequency ablation<sup>[15]</sup>. But how to choose system chemotherapy and artery infusion chemotherapy may be a question. Xia and Wang<sup>[16]</sup> reported that intra-artery treatment is more effective than system chemotherapy. Also radiotherapy can improve the survival<sup>[17]</sup>. Huang *et al*<sup>[18]</sup> demonstrated that radiotherapy is an effective adjuvant strategy in those who have a limited response to TACE or have a poor liver reserve function.

Occlusion of the stent by overgrowth of proximal or distal ends can be easily demonstrated and identified. In some cases, the defects consist of desquamated cells, mucus, and sludge. It has been speculated that these defects may be caused by tumor ingrowth through the meshes of the stent<sup>[19]</sup>. Drug infusion via supplying artery and embolization therapy have been used in clinical practice as an effective way of suppressing the growth of malignant tumors<sup>[20-23]</sup>. Further tumor therapy may improve the patency of stent and survival<sup>[24-26]</sup>.

TACE therapy could increase common bile duct obstruction due to tumor thrombi<sup>[27]</sup>. External beam radiation therapy may be beneficial in some patients with unresectable icteric-type HCC<sup>[28, 29]</sup>. When combined with other conventional therapies (such as TACE), radiation therapy may play an important role in the treatment of HCC<sup>[30, 31]</sup>.

In conclusion, PTBD is an effective palliative procedure for improving malignant obstructive jaundice.

## Abstract

Hepatopulmonary syndrome (HPS) is defined as a clinical triad including liver disease, abnormal pulmonary gas exchange and evidence of intrapulmonary vascular dilatations. We report a 61-year-old male presented with fatigue, long-lasting fever, loss of weight, signs of portal hypertension, hepatosplenomegaly, cholestasis and progressive dyspnoea over the last year. Clinical, laboratory and histological findings confirmed the diagnosis of granulomatous hepatitis. HPS due to hepatic granuloma-induced portal hypertension was proved to be the cause of severe hypoxemia of the patient as confirmed by contrast-enhanced echocardiography. Reversion of HPS after corticosteroid therapy was confirmed by a new contrast-enhanced echocardiography along with the normalization of cholestatic enzymes and improvement of the patient's conditions. This is the first case of complete reversion of HPS in a non-cirrhotic patient with hepatic granuloma, indicating that intrapulmonary shunt in liver diseases is a functional phenomenon and HPS can be developed even in miscellaneous liver involvement as in this case.

## INTRODUCTION

Hepatopulmonary syndrome (HPS) is defined as the triad of advanced liver disease, hypoxemia ( $P_{aO_2} < 70$  mmHg or increased alveolar-arterial oxygen gradient  $> 20$  mmHg) while breathing room air, and evidence of intrapulmonary vascular dilatations (IPVDs) resulting in an excess perfusion for a given state of ventilation irrespective of the presence or absence of cardiopulmonary disease<sup>[1,2]</sup>. HPS is a quite common condition in patients with advanced liver diseases as it has been reported in approximately 10-20% of candidates for liver transplantation<sup>[3]</sup>. The incidence rate of IPVDs in patients with end-stage liver disease is 13-47%<sup>[4]</sup> and 10% in normoxemic patients with early liver cirrhosis<sup>[5]</sup>. However, the prevalence of HPS according to the above mentioned criteria ranges from 5% to 30%<sup>[2,6,7]</sup>. Though the majority of patients with HPS have developed cirrhosis and portal hypertension, the presence of HPS is occasionally reported in cases of portal hypertension without the existence of cirrhosis. Actually, HPS has been reported in patients with Budd-Chiari syndrome<sup>[8]</sup> and acute<sup>[9]</sup> or chronic viral hepatitis<sup>[4]</sup>.

In this paper, we describe a non-cirrhotic patient with granulomatous hepatitis presented with signs of HPS, which responded completely to corticosteroid administration.

## CASE REPORT

A 61-year-old man was admitted to our department because of low-grade fever (up to 38°C), weakness, fatigability, loss of weight (10 kg during the last 8 mo) and progressive dyspnoea over the last year. The patient reported pruritus in the last 20 d and low exercise tolerance. He was an

**Figure 1** Liver histopathology shows an epithelioid granuloma without central necrosis. The granuloma is consisted of epithelioid macrophages and some chronic inflammatory cells. There is also a multinucleated giant cell (Hematoxylin and eosin staining x 40).

ex-smoker (80 packs a year) until 8 months earlier and had a 40-year history of alcohol abuse (over 100g of alcohol daily).

On admission, he was pale and well orientated, his temperature was 37.4°C, his pulse rate was 60 per minute and his blood pressure was 110/60 mmHg. Physical examination revealed profound dyspnoea with a high respiratory rate (30 per minute), platypnea and cyanosis, jaundice, hepatosplenomegaly without the presence of ascites, palmar erythema, digital clubbing and extended cutaneous spider naevi on the upper half of the body. Pulmonary auscultation and heart sounds were normal without murmurs or gallops. Further physical examination was unremarkable.

Laboratory test on admission showed mild normochromic-normocytic anaemia with 35% haematocrit, 118g/L haemoglobin,  $3.48 \times 10^{10}$ /L reticulocytes and normal platelet count ( $16.8 \times 10^9$ /L). White blood cells were  $3.5 \times 10^9$ /L with 57.4% segmented granulocytes, 29.5% lymphocytes and 9.9% monocytes. Peripheral blood smear was normal. Abnormal biochemical parameters were 67mg/dL urea, 1.47mg/dL creatinine, 11.0mg/dL serum calcium, 3.2mg/dL total bilirubin, 1.26mg/dL direct bilirubin, 348 U/L alkaline phosphatase (ALP) (upper normal <104 U/L), 516 U/L  $\gamma$ -glutamyltranspeptidase ( $\gamma$ -GT) (upper normal <40 U/L), 73U/L aspartate aminotransferase (AST) (upper normal <40U/L) and 43U/L alanine aminotransferase (ALT) (upper normal <40 U/L). Urinalysis revealed specific gravity of 1.010, pH 6.0, 1-2 red blood cells/HPF, 0-1 white blood cell/HPF, without casts, 760 mg/24h proteinuria and elevated urine calcium excretion (326 mg/24h) accompanied with reduced creatinine clearance (38.7mg/dL). Electrocardiography and chest X-ray radiography were normal. Upper gastrointestinal endoscopy revealed first-degree oesophageal varices and mild portal gastropathy.

Sequential bacterial cultures of blood, urine and marrow were negative for tuberculosis bacilli, brucellosis or other bacterial and fungal infectious diseases. Serology for hepatitis A, B, C and human immunodeficiency virus infections was negative. Abdominal ultrasound did not reveal lymphadenopathy, ascites or hepatic nodules.

Abdominal dynamic spiral computed tomography (CT) confirmed the presence of hepatosplenomegaly. Serum immunoglobulin M was mildly elevated (269mg/dL; upper normal limit: 249mg/dL) but antimitochondrial antibodies by ELISA, Western blot and indirect immunofluorescence (IIF) using commercial and in-house substrates were negative. Antinuclear autoantibodies using IIF were also negative. Liver biopsy revealed multiple non-caseating epithelioid granulomas and mild perisinusoidal fibrosis without any histological sign of cirrhosis (Figure 1). Multiple non-caseating granulomas were also found in the bone marrow biopsy specimen. High resolution CT of the chest was normal. Bronchoalveolar lavage fluid revealed the presence of lymphocytes mainly T-cells in 94% with a CD4/CD8 ratio of 2. Transbronchial biopsy was negative for granulomas. The above clinical, laboratory, histological and radiological findings indicated that idiopathic granulomatous hepatitis was the most likely diagnosis though the diagnosis of systemic sarcoidosis without apparent involvement of the lungs could not be rule out.

Arterial blood gas analysis (while breathing room air) showed hypoxemia with arterial oxygen tension ( $P_{aO_2}$ ): 53 mmHg;  $P_{aCO_2}$ : 27.9 mmHg; pH: 7.48; bicarbonate: 21mM;  $PA-aO_2$ : 66.7 mmHg. Supplemental 100% oxygen was administered and  $P_{aO_2}$  was elevated to 153 mmHg. Arterial blood gases while breathing room air became worse at the upright position ( $P_{aO_2}$ : 49 mmHg,  $P_{aCO_2}$ : 23.9 mmHg, pH: 7.42, bicarbonate: 15.5mmol/L) while improved at supine position. The observed orthodeoxia was compatible to the clinical improvement noted during supine position (platypnea). Spirometry revealed findings of chronic obstructive pulmonary disease of stage I, according to Global Initiative for Chronic Obstructive Lung Diseases (GOLD) classification<sup>[10]</sup>: FVC: 4.14 lt (110 % pred), FEV1: 2.68 lt (90 % pred), FEV1/FVC: 65%, FEF25-75%: 1.43 L/sec (42 % pred). The diffusion capacity test showed a moderately reduced DL, CO/VA: 0.75 (56% pred).

Contrast-enhanced echocardiography with agitated saline showed microbubble opacification in the left atrial after six heart beats later of the right heart chamber opacification in the absence of intracardiac septal defects, confirming the presence of intrapulmonary shunt (Figures 2A and 2B). Technetium 99m-labelad macroaggregated albumin scanning was also positive for IPVDs (increased uptake of radionuclide over the kidneys and brain), confirming the diagnosis of HPS on the basis of portal hypertension due to hepatic granulomas.

The patient started to receive methylprednisolone (32 mg daily) and continuous home oxygen therapy (2L/min) for at least 18 hours per day. Three months later, his performance status was excellent and arterial blood gas analysis (while breathing room air) was almost normal ( $P_{aO_2}$ : 85 mmHg,  $P_{aCO_2}$ : 36.2 mmHg, pH: 7.43, bicarbonate: 25.4mmol/L with  $PA-aO_2$  19.7 mmHg). Thirteen months after his first evaluation, he was still on methylprednisolone (4 mg daily). His performance status was very good with his blood gas, liver function and calcium concentration within normal limits. In addition, after treatment the spleen was not palpable, a new upper gastrointestinal endoscopy was normal and a new contrast-enhanced echocardiography revealed no intrapulmonary shunt (Fig-

**Figure 2** Contrast-enhanced echocardiography image of the patient before (A, B) and after (C, D) corticosteroid treatment for granulomatous hepatitis. A, C: Microbubble appearance in the right heart chamber (RA and RV) after the bolus infusion of agitated saline; B: Microbubble opacification in the left heart chambers (LA and LV) is not detected after six to eight heart beats; D: Microbubble opacification in the left heart chambers (LA and LV) is not detected after six to eight heart beats.

ures 2C and 2D).

## DISCUSSION

This case report describes a patient with HPS due to portal hypertension as a result of granulomatous hepatitis. Though the most common causes of granulomatous hepatitis are infections and systemic sarcoidosis, we were not able to confirm such a diagnosis (due to the absence of lung involvement). Indeed, liver involvement in sarcoidosis is not unusual as 50-80% of patients are affected but almost all of them have also lung disease<sup>[11]</sup>. However, to the best of our knowledge, this is the first case of complete reversion of HPS after corticosteroid treatment in a non-cirrhotic patient suffering from portal hypertension due to idiopathic granulomatous hepatitis.

HPS is a well-known complication in patients with advanced liver disease. Its major signs and symptoms include the presence of dyspnoea (particularly in exertion), cyanosis, digital clubbing, platypnea and orthodeoxia (a decrease in  $P_{aO_2}$  of more than 3 mmHg when the patient moves from the supine to the standing position)<sup>[12-14]</sup>. The pathogenesis of HPS is well delineated<sup>[1]</sup>. The syndrome occurs as a result of precapillary and capillary pulmonary vascular dilatations, causing apparent right-to-left intrapulmonary shunting, though there is no true anatomic shunt<sup>[15, 16]</sup>. However, the capillaries may become dilated to 500  $\mu$ m in diameter (normal range 8-15  $\mu$ m)<sup>[16, 17]</sup>. Hypoxemia arises due to a combination of ventilation and perfusion mismatching, oxygen diffusing limitation and intrapulmonary shunting<sup>[13, 16, 18]</sup>. These intrapulmonary vascular abnormalities in advanced liver cirrhosis are attributed to an excess production of vasodilators that affect the lung vascular system via porto-systemic shunt, with nitric oxide as the most likely mediator<sup>[19]</sup>. The above hypothesis is in accordance with the complete reversion of the syndrome when liver transplantation is successful in patients with end-stage

liver disease and HPS<sup>[12, 15, 16, 19]</sup>.

However, it was reported that HPS occurs occasionally in non-cirrhotic cases of portal hypertension<sup>[4, 8, 9]</sup> and could completely reverse after the causative agent is eradicated<sup>[8, 9]</sup>. Under this context, we believe that in our case the corticosteroid treatment of granulomatous hepatitis led to the reversion of HPS via an improvement of portal hypertension as the presence of liver granuloma per se can result in the development of sinusoidal portal hypertension irrespective of the presence or absence of cirrhosis.

Staging of the severity of HPS is important because severity influences survival and is useful in determining the timing and risks for liver transplantation. A classification of the severity of HPS based on oxygenation abnormalities in four stages has been proposed<sup>[1, 6]</sup>. According to this classification our patient had severe HPS as he presented with 49 mmHg  $P_{aO_2}$  while breathing room air, 153 mmHg  $P_{aO_2}$  when supplemental oxygen was admitted and a significant elevation of  $PA-aO_2$ . Contrast-enhanced echocardiography is the standard method for the diagnosis of HPS<sup>[12]</sup>. Technetium 99m-labeled macroaggregated albumin scanning is another method of detecting IPVDs<sup>[20]</sup> and can be used to quantify the magnitude of shunting.

In conclusion, to the best of our knowledge this is the first case study to describe complete reversion of HPS due to granulomatous hepatitis. We consider that the clinical and laboratory improvement of severe HPS in this case is due to the treatment response, leading to an improvement of portal hypertension as attested by the complete normalization of cholestatic enzymes, the absence of oesophageal varices and the shrinkage of spleen after corticosteroid administration. The absence of cirrhosis proved by liver biopsy may be a determinant factor for the reversion of HPS. It seems that HPS can be reversed (alleviation of dyspnea, improvement of hypoxemia) when liver function and portal hypertension are improved.

This further supports the fact that the development of intrapulmonary shunt in liver diseases is mainly a functional phenomenon and HPS can be observed even in miscellaneous liver involvement as in this case.

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7<sup>th</sup>, 14<sup>th</sup>, 21<sup>st</sup> and 28<sup>th</sup> of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

**Published by**  
The WJG Press

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297mm×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations.

#### Online submission

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to [wjg@wjgnet.com](mailto:wjg@wjgnet.com) for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

#### Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4(297 mm×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or \*.rtf format to:

#### Editorial Office

##### *World Journal of Gastroenterology*

Editorial Department: Apartment 1066, Yishou Garden,  
58 North Langxinzhuang Road,  
PO Box 2345, Beijing 100023, China  
E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)  
<http://www.wjgnet.com>

### MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

#### Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished,

disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

#### Abstract

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

#### Key words

Please list 3-10 key words that could reflect content of the study.

#### Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

#### Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126×76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

#### Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

#### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P*<0.05, <sup>b</sup>*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P*<0.05 and <sup>d</sup>*P*<0.01 are used. Third series of *P* values can be expressed as <sup>e</sup>*P*<0.05 and <sup>f</sup>*P*<0.01. Other notes in tables or under illustrations should be expressed as <sup>1</sup>*F*, <sup>2</sup>*F*, <sup>3</sup>*F*; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

#### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

### PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

### Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>)

### Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

### Format

Standard journal article (list all authors and include the PubMed ID [PMID] where applicable)

- 1 **Das KM**, Farag SA. Current medical therapy of inflammatory bowel disease. *World J Gastroenterol* 2000; 6: 483-489 [PMID: 11819634]
- 2 **Pan BR**, Hodgson HJF, Kalsi J. Hyperglobulinemia in chronic liver disease: Relationships between *in vitro* immunoglobulin synthesis, short lived suppressor cell activity and serum immunoglobulin levels. *Clin Exp Immunol* 1984; 55: 546-551 [PMID: 6231144]
- 3 **Lin GZ**, Wang XZ, Wang P, Lin J, Yang FD. Immunologic effect of Jianpi Yishen decoction in treatment of Pixu-diarrhoea. *Shijie Huaren Xiaobao Zazhi* 1999; 7: 285-287

Books and other monographs (list all authors)

- 4 **Sherlock S**, Dooley J. Diseases of the liver and biliary system. 9th ed. Oxford: Blackwell Sci Pub, 1993: 258-296

Chapter in a book (list all authors)

- 5 **Lam SK**. Academic investigator's perspectives of medical treatment for peptic ulcer. In: Swabb EA, Azabo S. Ulcer disease: investigation and basis for therapy. Marcel Dekker, 1991: 431-450

Electronic journal (list all authors)

- 6 **Morse SS**. Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1):24 screens. Available from: URL: <http://www.cdc.gov/ncidod/EID/eid.htm>

### Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

### Statistical data

Present as mean  $\pm$  SD and mean  $\pm$  SE.

### Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as *r* (in italics), degree of freedom as  $\gamma$  (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

### Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose)  $6.4 \pm 2.1$  mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5  $\mu$ g/L; CO<sub>2</sub> volume fraction, 50 mL/L CO<sub>2</sub> not 5% CO<sub>2</sub>; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

### Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

### Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindIII*, *BamHI*, *Kpn I*, *Kpn I*, etc.

Biology: *Helicobacter pylori*, *H pylori*, *E coli*, etc.

## SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

### Language evaluation

The language of a manuscript will be graded before sending for revision.

- (1) Grade A: priority publishing;
  - (2) Grade B: minor language polishing;
  - (3) Grade C: a great deal of language polishing;
  - (4) Grade D: rejected.
- The revised articles should be in grade B or grade A.

### Copyright assignment form

It is the policy of *WJG* to acquire copyright in all contributions. Papers accepted for publication become the copyright of *WJG* and authors will be asked to sign a transfer of copyright form. All authors must read and agree to the conditions outlined in the Copyright Assignment Form (which can be downloaded from <http://www.wjgnet.com/wjg/help/9.doc>).

### Final check list for authors

The format is at: <http://www.wjgnet.com/wjg/help/13.doc>

### Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: <http://www.wjgnet.com/wjg/help/10.doc>

### Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

### Publication fee

Authors of accepted articles must pay publication fee.

## World Journal of Gastroenterology standard of quantities and units

Number	Nonstandard	Standard	Notice
1	4 days	4 d	In figures, tables and numerical narration
2	4 days	four days	In text narration
3	day	d	After Arabic numerals
4	Four d	Four days	At the beginning of a sentence
5	2 hours	2 h	After Arabic numerals
6	2 hs	2 h	After Arabic numerals
7	hr, hrs,	h	After Arabic numerals
8	10 seconds	10 s	After Arabic numerals
9	10 year	10 years	In text narration
10	Ten yr	Ten years	At the beginning of a sentence
11	0,1,2 years	0,1,2 yr	In figures and tables
12	0,1,2 year	0,1,2 yr	In figures and tables
13	4 weeks	4 wk	
14	Four wk	Four weeks	At the beginning of a sentence
15	2 months	2 mo	In figures and tables
16	Two mo	Two months	At the beginning of a sentence
17	10 minutes	10 min	
18	Ten min	Ten minutes	At the beginning of a sentence
19	50% (V/V)	500 mL/L	
20	50% (m/V)	500 g/L	
21	1 M	1 mol/L	
22	10 μM	10 μmol/L	
23	1N HCl	1 mol/L HCl	
24	1N H <sub>2</sub> SO <sub>4</sub>	0.5 mol/L H <sub>2</sub> SO <sub>4</sub>	
25	4rd edition	4 <sup>th</sup> edition	
26	15 year experience	15- year experience	
27	18.5 kDa	18.5 ku, 18 500u or M:18 500	
28	25 g.kg <sup>-1</sup> /d <sup>-1</sup>	25 g/(kg·d) or 25 g/kg per day	
29	6900	6 900	
30	1000 rpm	1 000 r/min	
31	sec	s	After Arabic numerals
32	1 pg L <sup>-1</sup>	1 pg/L	
33	10 kilograms	10 kg	
34	13 000 rpm	13 000 g	High speed; g should be in italic and suitable conversion.
35	1000 g	1 000 r/min	Low speed. g cannot be used.
36	Gene bank	GenBank	International classified genetic materials collection bank
37	Ten L	Ten liters	At the beginning of a sentence
38	Ten mL	Ten milliliters	At the beginning of a sentence
39	umol	μmol	
40	30 sec	30 s	
41	1 g/dl	10 g/L	10-fold conversion
42	OD <sub>260</sub>	A <sub>260</sub>	"OD" has been abandoned.
43	One g/L	One microgram per liter	At the beginning of a sentence
44	A260 nm <sup>b</sup> P<0.05	A <sub>260</sub> nm <sup>a</sup> P<0.05	A should be in italic. In Table, no note is needed if there is no significance instatistics: <sup>a</sup> P<0.05, <sup>b</sup> P<0.01 (no note if P>0.05). If ther is a second set of P value in the same table, <sup>c</sup> P<0.05 and <sup>d</sup> P<0.01 are used for a third set: <sup>a</sup> P<0.05, <sup>b</sup> P<0.01.
45	<sup>*</sup> F=9.87, <sup>§</sup> F=25.9, <sup>#</sup> F=67.4	<sup>1</sup> F=9.87, <sup>2</sup> F=25.9, <sup>3</sup> F=67.4	Notices in or under a table
46	KM	km	kilometer
47	CM	cm	centimeter
48	MM	mm	millimeter
49	Kg, KG	kg	kilogram
50	Gm, gr	g	gram
51	nt	N	newton
52	l	L	liter
53	db	dB	decibel
54	rpm	r/min	rotation per minute
55	bq	Bq	becquerel, a unit symbol
56	amp	A	ampere
57	coul	C	coulomb
58	HZ	Hz	
59	w	W	watt
60	KPa	kPa	kilo-pascal
61	p	Pa	pascal
62	ev	EV	volt (electronic unit)
63	Jonle	J	joule
64	J/mm <sup>3</sup>	kJ/mol	kilojoule per mole
65	10×10×10cm <sup>3</sup>	10 cm×10 cm×10 cm	
66	N·km	KN·m	moment
67	x±s	mean±SD	In figures, tables or text narration
68	Mean±SEM	mean±SE	In figures, tables or text narration
69	im	im	intramuscular injection
70	iv	iv	intravenous injection
71	Wang et al	Wang <i>et al.</i>	
72	EcoRI	EcoRI	<i>Eco</i> in italic and RI in positive. Restriction endonuclease has its prescript form of writing.
73	Ecoli	<i>E.coli</i>	Bacteria and other biologic terms have their specific expression.
74	Hp	<i>H pylori</i>	
75	Iga	<i>Iga</i>	writing form of genes
76	igA	IgA	writing form of proteins
77	~70 kDa	~70 ku

## Abstract

Non-alcoholic fatty liver disease (NAFLD) encompasses a wide spectrum of fat-induced liver injury, ranging from relatively benign steatosis to cirrhosis and liver failure. The presence of obesity and insulin resistance is strongly associated with non-alcoholic fatty liver and confers on it a greater risk of histologically advanced disease. There is a growing concern in the medical profession as the prevalence of this disease continues to rise in parallel with the rise in obesity and the metabolic syndrome. Treatment options are limited and dietary weight loss is often advised. Low fat diets are difficult to adhere to and recent studies have shown the potential of low carbohydrate diets for weight loss and improving insulin resistance. Thus far, no study has evaluated the effect of low carbohydrate diets on NAFLD. Future studies will be required to address this question and others with regards to the nutritional adequacy and long-term side effects of these diets.

## INTRODUCTION

In the 1970s, patients undergoing jejunoileal bypass surgery

for morbid obesity were noted to develop steatohepatitis and even liver failure following rapid weight loss<sup>[1]</sup>. Their liver histology was similar to that seen in alcoholics, with macrovesicular steatosis, Mallory hyaline, focal hepatocyte necrosis, mixed lobular inflammation and fibrosis<sup>[2]</sup>. Similar findings were later described in obese patients without significant alcohol consumption. In 1980, Ludwig *et al*<sup>[3]</sup> coined the term 'non-alcoholic steatohepatitis' (NASH) to describe these findings. Since then, interest in the disease has grown exponentially in keeping with its rising prevalence. NASH was initially thought to be a benign condition largely limited to middle-aged obese women with diabetes. However, recent studies have shown it to be a far more complex disease that is found in men, women and even children. The spectrum of disease ranges from pure steatosis alone to NASH with hepatic fibrosis, cirrhosis, hepatocellular carcinoma, liver failure and even death<sup>[4-6]</sup>. Estimates suggest that 20-30% of adults in Western countries may have NAFLD and about 10% of these individuals meet criteria for diagnosis of NASH<sup>[7]</sup>. NAFLD is now recognized as the most common cause of chronically elevated liver transaminases<sup>[8,9]</sup> and may be the most common liver disorder<sup>[10]</sup>. Obesity is the single most common condition found in association with NAFLD. Other features of the metabolic syndrome, such as hyperinsulinemia, hypertriglyceridemia and hypertension, also play a significant pathophysiologic role in its development.

In general, NAFLD in the absence of NASH is an indolent disease with a benign course. However, as noted, end stage liver disease may occur as a consequence of NASH. The seriousness of this condition is demonstrated by the fact that approximately 50% of patients develop fibrosis, 15% develop cirrhosis and 3% may advance to liver failure requiring transplantation<sup>[11]</sup>. NASH is now being recognized as the underlying cause of most cases of cryptogenic cirrhosis<sup>[12,13]</sup>. The natural history of NAFLD is poorly understood, and it is not known why some patients progress to cirrhosis, while others do not. However, obesity and insulin resistance have been shown to be associated with more histological advanced disease.

The aim of this article is to review the role of the metabolic syndrome, especially insulin resistance and obesity in the development of NAFLD, to discuss the effect of weight loss on NAFLD and, finally, to evaluate popular diets and compare them with regard to their effects on the metabolic syndrome and NAFLD.

## NASH AND METABOLIC SYNDROME

Fatty liver is commonly associated with obesity and insulin resistance. The increasing incidence of NAFLD closely parallels these conditions. There is abundant data showing a relationship between obesity and NAFLD. Wanless *et al*<sup>[14]</sup> in an autopsy study of 351 patients found that 70% of obese patients had liver steatosis, and the degree of steatosis was proportional to the degree of obesity. The authors also found steatohepatitis in 18.5% and severe fibrosis in 13.8% of markedly obese patients, compared to steatohepatitis in 2.7% and severe fibrosis in 6.6% of lean people. A prospective study performed by Klain *et al*<sup>[15]</sup> evaluated liver biopsies from 100 consecutive morbidly obese patients undergoing Roux-en-Y gastric bypass. Histological abnormalities were found in 98% of biopsies, and ranged from mild fatty infiltration through inflammatory change to fibrosis and cirrhosis<sup>[15]</sup>. Data from 90 patients with NASH demonstrated insulin resistance in 85% of them<sup>[16]</sup>. An Italian study evaluated the risk factors associated with hepatic steatosis. A total of 257 participants were assigned to one of four categories: Controls, teetotalers with normal body mass index (BMI); obese teetotalers; heavy drinkers (> 60 g of alcohol per day) with normal BMI; and heavy drinkers with obesity. The prevalence of steatosis on ultrasound increased from 16% in controls to 46% in heavy drinkers, 76% in obese individuals and 95% in patients with both obesity and heavy alcohol intake. Compared with controls, steatosis was more common by 2.8-fold in heavy drinkers, 4.6-fold in obese persons and 5.8 fold in obese heavy drinkers. In heavy drinkers, obesity increased the risk of steatosis 2.0-fold, while heavy drinking was associated with only a 1.0-fold increased risk in obese subjects<sup>[17]</sup>. The authors concluded that steatosis was more strongly associated with obesity than with heavy drinking.

Evidence of an etiologic association between NAFLD and metabolic syndrome (hyperglycemia, central obesity, hypertension, hypertriglyceridemia and low HDL-cholesterol) has been shown in both obese and non-obese patients<sup>[18]</sup>. Studies also have shown that patients with NASH are more insulin resistant than patients with fatty liver alone<sup>[19]</sup>. Given the wealth of data supporting it, many researchers now consider NAFLD to be a hepatic manifestation of the metabolic syndrome, instead of a primary liver disease<sup>[16,20]</sup>. Chitturi *et al*<sup>[21]</sup> tested the hypothesis that insulin resistance is an essential requirement for the development of NASH, and that a high association between insulin resistance and liver disease is relatively specific for NASH. Sixty-six patients with NASH were studied. Insulin resistance was found in virtually all patients (98%) and was seen in both lean and overweight patients. A subset of 36 patients with less severe NASH were compared to 36 age- and sex-matched patients with chronic hepatitis C. The prevalence of insulin resistance was significantly higher in those with NASH than in comparable cases of HCV (75% *vs* 8.3%)<sup>[21]</sup>. Marchesini *et al*<sup>[19]</sup> studied liver biopsies in patients with NAFLD. Based on histology, these were classified as having NASH *vs* pure fatty liver. The investigators found that 88% of patients with NASH had metabolic syndrome

compared with 53% in patients with pure fatty liver<sup>[19]</sup>. Marceau *et al*<sup>[22]</sup> investigated the relationship between liver pathology and the metabolic syndrome. Five hundred fifty one severely obese patients undergoing anti-obesity surgery were studied. Steatosis was found in 86%, fibrosis in 74%, steatohepatitis in 24% and unexpected cirrhosis in 2%. With each addition of the components of metabolic syndrome, the risk of steatosis increased exponentially from 1- to 99-fold<sup>[22]</sup>. In a series of 505 severely obese patients evaluated before gastropasty, prevalence of steatosis was significantly higher in patients with impaired glucose tolerance or type II diabetes as compared with non-diabetics. The severity of steatosis was positively correlated with BMI, fasting plasma glucose, insulin and triglyceride concentrations, as well as serum ALT, AST and GGT levels<sup>[23]</sup>.

Issues regarding the nature of hyperinsulinemia in NASH have been raised. It has been questioned as to whether hyperinsulinemia and insulin resistance occur as part of the metabolic syndrome or whether liver damage itself leads to chronic hyperinsulinemia and insulin resistance from impaired insulin degradation, as is seen in cirrhosis. Chitturi *et al*<sup>[21]</sup> compared the patients with NASH and mild or absent fibrosis with age- and sex-matched patients with HCV, and found that the patients with NASH showed more attributes of insulin resistance than the controls. They had much higher levels of insulin resistance, serum insulin and C-peptide levels. However, the serum C-peptide/insulin ratio was similar in both groups<sup>[21]</sup>. Pagano *et al*<sup>[24]</sup> addressed the same question, comparing 19 patients with histologically mild NASH, who had functionally competent livers with 19 normal subjects. Patients with NASH showed marked hyperinsulinemia and insulin resistance as compared with controls, however, the hepatic insulin extraction was similar in both groups<sup>[24]</sup>. These two studies showed that insulin hypersecretion, and not just impaired insulin degradation, was the basis for hyperinsulinemia in NASH.

The overall incidence of NASH in the severely obese is reported to range from 25-36.4%<sup>[25-27]</sup>. The prevalence of obesity in the Western world has shown a large increase in the last 20 years. The data of the National Health and Nutrition Examination Survey (NHANES II, 1976-1980) showed a prevalence of 14.5%. By NHANES III (1988-1994), this number had increased to 22.5%, and the data of NHANES 1999-2000 showed a prevalence of 30.5%<sup>[28]</sup>. Significantly, this number could reach 40% by the year 2025<sup>[29]</sup>. A similar increase in the number of patients with type 2 diabetes is expected. By some estimates, 29 million people or 7.2% of the population will have type 2 diabetes by the year 2050<sup>[30]</sup>. Of grave concern is the increasing incidence of obesity in children and adolescents. Given these statistics, the incidence of NASH will rise significantly in the coming years and so will hepatic complications arising from it.

Factors responsible for the development of NAFLD in obese patients are not clear, and the exact mechanism of its progression to fibrosis and cirrhosis has yet to be elucidated. However, our understanding of disease pathogenesis has advanced significantly. Insulin resistance is thought to be a primary pathophysiologic mechanism

in development of fatty liver. Current understanding of the pathogenesis is as follows: Insulin resistance and visceral obesity lead to a hepatic influx of free fatty acids, resulting in increased triglyceride synthesis and decreased triglyceride export. This leads to hepatic steatosis. At this stage, patients have the relatively benign condition of NAFLD. Some of these patients will go on to steatohepatitis. It is unclear why only a small fraction will advance to NASH and what is the exact impetus for this advance. One proposal is that these lipid-laden hepatocytes are susceptible to a “second-hit”<sup>[31]</sup>. The exact mechanism of this second-hit is unknown. In NASH, as in alcoholic hepatitis, oxidative stress and lipid peroxidation have emerged as the most likely candidates. This “hit” occurs via increased mitochondrial beta-oxidation of the free fatty acids, production of reactive oxygen species and depletion of antioxidants glutathione and vitamin E. This depletion of anti-oxidants hampers reactive oxygen species inactivation, and increases the deleterious effects on the mitochondria. Oxidative stress also results in abnormal cytokine production, especially TNF- $\alpha$  through up-regulation of nuclear translocation of transcription factor nuclear factor  $\kappa$ B. This combination of lipid peroxidation and cytokine production results in hepatocyte death.

Another proposed mechanism of development of NASH includes a primary mitochondrial abnormality, as proposed by Sanyal *et al.*<sup>[32]</sup>. This defect, otherwise clinically silent, leads to increased mitochondrial beta oxidation and production of reactive oxygen species in the presence of insulin resistance.

Yang *et al.*<sup>[33]</sup> have demonstrated that obesity itself may cause progression to steatohepatitis by causing Kupffer cell dysfunction and sensitizing the hepatocytes to endotoxin, suggesting that the progression of liver disease may depend on the extent of fatty infiltration<sup>[33]</sup>.

Iron, a strong oxidative agent, has also been proposed as a factor causing the second-hit. Elevated serum ferritin and insulin resistance on those levels have been noted in patients with NASH, as well as increased prevalence of C282Y and H63D mutations in the HFE gene<sup>[34,35]</sup>. However, evidence that hepatic insulin resistance plays a significant role in fibrosis was found in only one study, and recent studies suggested that increased ferritin levels were likely markers of severe histologic damage and not iron overload<sup>[36]</sup>. Leptin production by activated hepatic stellate cells has also been considered an important factor in the progression of fatty liver disease and development of fibrosis<sup>[37]</sup>. Supporting evidence is furnished by genetically leptin-deficient ob/ob mice, which do not develop fibrosis even when fed a methionine-choline-deficient diet.

## OBESITY AND INSULIN RESISTANCE AS PREDICTORS OF FIBROSIS

The natural history of NAFLD is not well known, but it is known that prognosis varies according to histologic type. Matteoni *et al.*<sup>[5]</sup> conducted a retrospective study to compare clinical characteristics and outcomes of patients with different types of NAFLD. Patients were separated into four histologic types: Simple fatty liver; steatohepatitis;

steatonecrosis; and steatonecrosis plus either Mallory hyaline or fibrosis. Cirrhosis and liver-related death were seen almost exclusively in patients with steatonecrosis with or without Mallory hyaline or fibrosis<sup>[5]</sup>. The study also confirmed that the prognosis of simple steatosis is favorable.

A number of risk factors for more histologically advanced disease have been identified. These include central weight distribution and metabolic syndrome. Dixon *et al.*<sup>[38]</sup> studied 105 severely obese individuals undergoing bariatric surgery, and showed that hyperinsulinemia and increased insulin resistance were associated with adverse histologic findings. The study found that C-peptide was the best predictor of advanced fibrosis (stage 3-4) and that patients with advanced fibrosis had significantly higher C-peptide levels. The insulin resistance index and systemic hypertension were independently associated with advanced NAFLD. Insulin resistance was found to be the best predictor of zone 3-centric steatosis, inflammation and fibrosis. Interestingly, this study found that moderate alcohol consumption reduced the risk of NAFLD by decreasing insulin resistance. Angulo *et al.*<sup>[39]</sup> studied liver biopsies from 144 patients with NASH. In multivariate analysis, older age (>45 years), obesity, diabetes mellitus and an AST/ALT ratio >1 were significant predictors of severe fibrosis (bridging/cirrhosis). The investigators concluded that this subgroup would benefit most from liver biopsy and investigational therapies<sup>[39]</sup>. Researchers in France investigated 93 obese patients, and found that age  $\geq 50$  years, BMI >28 kg/m<sup>2</sup>, triglycerides >1.7 mmol/L and ALT >2 times normal value were independently associated with septal fibrosis<sup>[40]</sup>. A univariate analysis showed that diabetes and impaired glucose tolerance were significantly associated with fibrosis. Another recent study evaluating steatosis in chronic hepatitis C found that an increased BMI had a role in pathogenesis of steatosis in chronic hepatitis C, and that this may contribute to fibrosis<sup>[41]</sup>. Studies by both Marceau *et al.*<sup>[22]</sup> and Willner *et al.*<sup>[16]</sup> showed that patients with cirrhosis were more obese than those without cirrhosis. In addition, Marceau *et al.*<sup>[22]</sup> found the presence of diabetes to be the strongest predictor of cirrhosis. Finally, a recent investigation of NAFLD and the metabolic syndrome showed that the presence of metabolic syndrome carried a high risk for NASH among NAFLD patients, and was also associated with a high risk of severe fibrosis<sup>[19]</sup>.

Thus, features of the metabolic syndrome like obesity, insulin resistance and hypertriglyceridemia are not only predisposing factors for NASH, but are also risk factors for more severe fibrosis and advanced disease.

## TREATMENT OPTIONS

In light of the increasing incidence of NAFLD-associated comorbid conditions and NAFLD itself, as well as increased awareness of adverse outcomes associated with steatohepatitis, a number of treatment options are being explored. These combine specific therapies for NAFLD as well as the management of comorbid conditions. Therapies that have been evaluated include lifestyle changes such as

diet and exercise, antioxidants like vitamin E and betaine, cytoprotective agents such as ursodeoxycholic acid, lipid-lowering agents, anti-diabetics, weight-loss agents like orlistat and iron reduction therapy, i.e. phlebotomy. The management of associated conditions, such as diabetes, obesity and hyperlipidemia, is especially important, given their association with more advanced liver disease. This may be achieved by optimizing medical treatment of these conditions, as well as through weight loss strategies.

## EFFECT OF WEIGHT LOSS ON NAFLD

Because obesity is the most commonly associated condition with NAFLD, weight loss has traditionally been the most commonly suggested intervention. Patients are encouraged to lose weight through exercise and dietary fat restriction. Exercise is of great value as it reduces weight by preferentially decreasing visceral obesity while preventing the loss of muscle mass. It also enhances muscle insulin sensitivity even in the absence of weight loss. A number of studies suggest that NAFLD may improve after weight loss. Improvement in liver biochemistry and ultrasonographic appearance is a consistent finding with moderate weight reduction. However, serum aminotransferases are unreliable markers for follow-up, and do not provide accurate data on prognosis. Worsening of fibrosis can occur even as the levels of transaminases decline<sup>[42]</sup>. A few studies have evaluated and shown histologic improvement.

The effects of weight reduction on hepatic tests and physical findings were studied in a retrospective review of thirty-nine obese patients without primary liver disease. A weight loss of >10% corrected abnormal liver tests, decreased hepatosplenomegaly and resolved some stigmata of liver disease<sup>[43]</sup>. Early case series showed that improved liver chemistry and histology was evident with even a modest reduction in weight, as considerable extra weight persisted in the subjects under evaluation<sup>[44,45]</sup>.

Drenick *et al*<sup>[46]</sup> studied liver biopsies of 41 obese patients undergoing massive weight reduction (>100 lb). Biopsies were obtained at various stages before, during and after weight loss. Based on the method of weight loss, patients were divided into three groups, including prolonged fasting, low-calorie dieting and intestinal bypass surgery. In the non-surgical groups, a transient increase in hepatocellular degeneration and focal necrosis was noted along with progressive diminution of fatty infiltration during weight loss. However, late biopsies revealed normal histology. In patients who underwent intestinal bypass, biopsies variously revealed massive fatty changes, cholestasis, polynuclear inflammatory infiltrates, diffuse fibrosis, bile-duct proliferation and fatal hepatic necrosis<sup>[46]</sup>. These findings relating to jejunoileal bypass have been demonstrated in several studies<sup>[47-49]</sup>. This surgical procedure has been abandoned in favor of safer weight-loss surgery.

In a study of twenty-five obese Japanese subjects<sup>[50]</sup>, fifteen underwent a program of restricted diet and exercise for a period of three months, while ten did not. Patients in the intervention group showed a significant decrease in BMI, aminotransferases, total protein, cholinesterase, total

cholesterol and fasting plasma glucose levels. In addition, steatosis was significantly improved on liver biopsy in these patients. The ten patients in the control group did not show any change in biochemical parameters or liver histology.

Regular body weight and biological measurements were obtained from 505 severely obese patients before and after undergoing gastroplasty<sup>[24]</sup>. There was a high prevalence of biologic abnormalities associated with the metabolic syndrome at baseline. After a mean follow-up of  $21 \pm 14$  mo post-surgery, significant reductions in biological markers of metabolic syndrome, such as blood glucose, insulin, and triglycerides, were noted. Also, total cholesterol, uric acid and fibrinogen and ALT levels were reduced, along with an increase in HDL cholesterol levels. Data on children with NASH, who underwent weight reduction, also showed improvement in biochemical and ultrasonographic findings<sup>[51,52]</sup>.

The effect of weight loss on NAFLD was studied in 36 obese patients. Paired liver biopsies were obtained, the first at the time of laparoscopic adjustable gastric band placement and the second after weight reduction. Initial biopsies showed steatosis alone in 12 patients and NASH in 23 patients. Initial fibrosis score of 2 or more was noted in 18 patients. Follow-up biopsies were obtained at  $25.6 \pm 10$  mo after surgery. Weight loss resulted in a significant improvement in liver histology, with repeat biopsies showing NASH in only 4 patients and a fibrosis score of 2 or more in only 3 patients. Greater improvement was seen in patients who had been diagnosed with metabolic syndrome prior to surgery<sup>[53]</sup>.

Knobler *et al*<sup>[54]</sup> suggested that NAFLD is not only associated with biochemical abnormalities of the metabolic syndrome, but it responds to their amelioration. Forty-eight patients with chronically elevated liver enzymes with clinical, ultrasound, and histologic findings consistent with fatty liver were evaluated. Most of the patients were overweight or obese (64%), 44% had diabetes mellitus, 29% had impaired glucose tolerance, and 17% were hyperinsulinemic. Dietary intervention was the primary mode of weight loss. This was supplemented by oral hypoglycemic or lipid-lowering drugs as needed. The results showed moderate weight loss (3.7 kg), improvement in fasting plasma glucose and lipid levels. An improvement in liver enzymes was noted in 96% patients with normalization in 50% patients.

In a recent pilot study, ten obese patients with NASH were treated with orlistat in addition to diet for weight reduction over a period of 6 mo<sup>[55]</sup>. BMI, liver enzymes, hemoglobin A1c, fasting lipids, glucose and liver histology were assessed at baseline and at completion of the study. Mean weight loss was 22.7 lb. There was a significant decrease in the BMI, and levels of hemoglobin A1c, ALT, AST. Steatosis improved in six patients and fibrosis in three patients. Hickman *et al*<sup>[56]</sup> found that modest weight loss through exercise and dietary intervention resulted in sustained improvements not only of ALT and fasting insulin levels, but also of health-related quality of life.

The above data demonstrates that NAFLD and NASH improve significantly with weight reduction. However, this must be done in a controlled manner over a period

of time, as rapid weight loss may lead to exacerbation of liver disease. This has been shown following drastic weight reduction through diet as well as through bariatric surgery. Forty-one patients who had weight loss on a very-low-calorie diet showed improvement in fatty change on liver biopsy. However, 24% developed portal inflammation or fibrosis. These were patients who underwent a very rapid weight reduction ( $>1.6$  kg per week)<sup>[57]</sup>. Liver biopsies obtained from patients undergoing gastroplasty for morbid obesity were compared before surgery and after weight loss (mean  $32 \pm 19$  kg). There was a significant decrease in the prevalence of steatosis (38% of patients after weight loss *vs* 83% before). However, an increase in the prevalence of hepatitis was observed after significant weight reduction (26% of biopsies after weight loss *versus* 14% before)<sup>[58]</sup>. The pathogenesis appears to be massive mobilization of fatty acids from visceral stores, which reach the liver via the portal vein and may be toxic to the liver. Therefore, initial target weight reduction should be 10% of baseline weight and should not exceed 1.6 kg/wk.

## POPULAR DIETS

The effects of many popular diets on fatty liver are not known. However, metabolic improvements related to dietary weight reduction may favorably influence NASH. If dietary intervention can positively affect insulin resistance and other features of the metabolic syndrome, it would be important to know which particular diet is most beneficial. Conventional diets usually fall into two main categories. Those that alter the macronutrient composition of the diet and those that limit overall energy intake.

### Alterations in macronutrient composition

Diets that promote weight loss by emphasizing their macronutrient make-up, as opposed to caloric intake, include low-fat and low-carbohydrate diets. Low-fat diets are traditionally the most recommended by medical professionals. Over time, these have been shown to be safe, cardio-protective and effective in weight loss. Adherence, however, has been a problem. Energy density of food is an important consideration. This refers to the energy (calories) in a given weight of food. Weight loss from a low-fat diet may be due to the low energy density of the diet. Both carbohydrates and proteins have an energy density of 4 kcal/kg, compared to 9 kcal/kg for fats. Researchers for the National Weight Control Registry found that members who maintained successful weight loss, consumed less energy and a lower percentage of energy from fat when compared to the general population<sup>[59]</sup>. The low-fat (30%) diet is advocated by the National Cholesterol Education Program and by the American Heart Association.

Low carbohydrate diets have been popular periodically over the last several decades, and are currently undergoing a resurgence. An NPD survey on diet trends in the United States showed that in early 2004 about 9% of the population was on a low carbohydrate diet. These diets limit the composition and/or amount ( $<100$  g/d) of carbohydrates, with an increase in dietary protein and

fat. They are marketed as low carbohydrate, high protein diets, although they could also be called low carbohydrate, high fat diets. A diet high in carbohydrates results in an increase in blood glucose, insulin and triglycerides, all of which are risk factors for the development of NAFLD. Carbohydrate restriction leads to ketosis resulting not only in weight loss, but also a decrease in blood glucose, insulin and triglyceride levels. Studies have shown these diets to be effective in short-term weight loss<sup>[60,61]</sup>. Early weight loss is a result of diuresis associated with ketone and urea nitrogen excretion<sup>[62]</sup>. However, over time, weight loss is a result of loss of body fat. Proponents believe that these diets have a high satiety level, which make them easier to adhere to. This is very important, as dietary adherence is one of the main challenges faced by dieters. Questions with regard to their nutritional adequacy and long-term effects have been raised. In the short-term, these diets have been found to be safe.

Popular low carbohydrate diets include the Atkins, South Beach and the Zone diets. Originally published by Dr. Robert Atkins in 1972 (Dr. Atkins diet revolution), the Atkins diet is the most popular low carbohydrate diet in the United States. Weight reduction is achieved in four phases. The first phase is an induction diet which limits carbohydrates to 20 g/d, but allows unlimited amounts of fat. In phase two, there is ongoing weight loss with easing of the carbohydrate restriction. Through phases three and four, pre-maintenance and maintenance, individuals determine the amount of carbohydrate they can consume while maintaining their weight loss<sup>[63]</sup>. The South Beach diet consists of 3 phases, gradually increasing in proportion of carbohydrates and emphasizes good carbohydrates and fats. The Zone diet recommends a low carbohydrate, high protein diet, with macronutrient intake in the 40:30:30 ratio, i.e. 40% calories from carbohydrates, 30% from protein and 30% from fat.

### Reduction in energy intake

Studies have found that weight loss on a calorie-restricted diet is due to decreased energy intake and not nutrient composition. Golay *et al.*<sup>[64]</sup> evaluated the effect of diets that were equally low in energy, but widely different in amounts of fat and carbohydrate over a 6-wk period. No significant difference in amount of weight loss was noted<sup>[64]</sup>. Alford *et al.*<sup>[65]</sup> studied the effects of three different diets with a fixed caloric intake of 1 200 kcal/d. They found no significant difference in weight loss among diets with 25%, 45%, 75% carbohydrate. The authors concluded that weight loss is the result of reduction in caloric intake in proportion to caloric requirements. Schlundt *et al.*<sup>[66]</sup> found greater weight loss with a low-fat, calorie-restricted diet when compared to a low-fat, *ad libitum* carbohydrate intake diet. A systematic review of low carbohydrate diets by Freedman *et al.*<sup>[67]</sup> found weight loss to be associated with energy restriction and not carbohydrate restriction. It is likely that individuals on diets that alter macronutrient composition (low fat or low carbohydrate) actually lose weight because of a concurrent reduction in energy intake.

## LOW-CARBOHYDRATE *VERSUS* LOW-FAT DIETS: EFFECTS ON BIOCHEMICAL MARKERS OF METABOLIC SYNDROME AND NAFLD

As mentioned previously, dietary weight reduction has been shown to have a positive effect on biochemical markers of the metabolic syndrome. This may translate into a positive effect on NAFLD. Encouraging histologic findings have been noted in these patients. Therefore, it is important to compare the various diets and determine which, if any, is most beneficial in NAFLD.

Low-carbohydrate diets have long been considered fad diets by the medical profession. Several questions have been raised regarding their weight loss potential and possible adverse effects. Public interest continues unabated, and books detailing low carbohydrate lifestyles are regulars on best seller lists. A number of studies have been published in recent years evaluating the effects of low-carbohydrate diets on weight loss as well as on metabolic markers, comparing these diets to traditional low-fat diets. However, none has compared their effects on liver histology and NAFLD. Effects on obesity and biomarkers of the metabolic syndrome will be reviewed, given their important etiologic association with NAFLD.

In an uncontrolled study, Westman *et al*<sup>[68]</sup> showed that in mildly obese, motivated persons, a very low-carbohydrate diet led to sustained weight loss during a 6-mo period. Positive effects were also noted on the serum lipid profile, with a decrease in triglycerides, total and low-density lipoprotein cholesterol and an increase in high-density lipoprotein cholesterol levels. More recently, several randomized controlled trials comparing various diets have been published. Brehm *et al*<sup>[69]</sup> studied the effects of a very low-carbohydrate diet on body composition and cardiovascular risk factors. Fifty three healthy, obese women were randomized to 6 mo of an *ad libitum* very low-carbohydrate diet *versus* a calorie-restricted low-fat diet. The very low carbohydrate group had more weight loss ( $8.5 \pm 1.0$  *vs*  $3.9 \pm 1.0$  kg,  $P < 0.001$ ) without any deleterious effect on cardiovascular risk factors. Foster *et al* randomized 63 non-diabetic obese subjects to a low carbohydrate (Atkins) *versus* a conventional diet (low fat, high carbohydrate, calorie-restricted diet). The Atkins group had more weight loss at 3 mo ( $-6.8 \pm 5.0$  % *vs*  $-2.7 \pm 3.7$ %) and 6 mo ( $-7.0 \pm 6.5$  % *vs*  $-3.2 \pm 5.6$ %), but at 12 mo the difference between the 2 groups was not significant ( $-4.4 \pm 6.7$  % *vs*  $-2.5 \pm 6.3$ %). The low carbohydrate group was associated with a greater decrease in triglycerides and a greater increase in high-density lipoprotein cholesterol levels. No difference in the total of low-density lipoprotein cholesterol levels was seen between the both groups. Insulin sensitivity increased in both groups without any significant difference between groups<sup>[61]</sup>. In a study by Samaha *et al*<sup>[60]</sup>, 132 severely obese subjects with a mean body mass index (BMI) of 43 (diabetes mellitus in 39% and metabolic syndrome in 43%) were randomized to a low-carbohydrate or a low-fat, calorie-restricted diet. At 6 mo, the low carbohydrate group had more weight loss ( $-5.8 \pm 8.6$  kg *vs*  $-1.9 \pm 4.2$  kg

and a greater decrease in triglyceride levels ( $-20 \pm 43$  % *vs*  $-4 \pm 31$ %). In non-diabetics, the insulin sensitivity improved more, and in diabetics, fasting glucose levels decreased more in the low carbohydrate group<sup>[60]</sup>. No adverse effects on the serum lipid levels were observed. The 12-mo data from this study was published in 2004. Weight loss between the two groups at this point was no longer significant. The favorable metabolic response to the low-carbohydrate diet, however, persisted<sup>[70]</sup>. A recently published study of 120 overweight, hyperlipidemic subjects showed similar findings. At 24 wk, the low carbohydrate (Atkins) group had greater weight loss (mean  $-12.9$  % *vs*  $-6.7$ %,  $P < 0.001$ ). Effects on triglyceride and high-density lipoprotein cholesterol levels were also more favorable with the low-carbohydrate diet<sup>[71]</sup>. Comparison of the National Cholesterol Education Program (NCEP) diet with a modified low-carbohydrate diet (low in total carbohydrates but higher in complex carbohydrates, protein and monounsaturated fat) showed a significantly greater weight loss in the modified low-carbohydrate diet over a period of 12 wk. This study did not show any significant difference between groups in blood lipid levels<sup>[72]</sup>. A low-carbohydrate diet over 12 wk was also found to be more effective than a low-fat diet for weight loss in overweight adolescents without adversely affecting their lipid profile<sup>[73]</sup>. In comparing 4 popular diets (Atkins, Zone, Weight Watcher's and Ornish) over one year, all were found to reduce weight modestly, and to have a significant reduction in low-density lipoprotein/high-density lipoprotein cholesterol ratio. No significant difference was noted between diets, and no diet-related adverse effects were noted<sup>[74]</sup>. Evaluation of 3 different diets in overweight, insulin-resistant women showed greater weight reduction from the Atkins and Zone diets when compared to a conventional low-fat diet. A greater reduction in triglycerides and waist circumference was also noted with these diets. A significant increase in low-density lipoprotein levels was noted in 25% of subjects on the Atkins diet, whereas this was seen in only 13% of subjects on the low-fat diet and 3% of those on the Zone diet<sup>[75]</sup>. Improvement in characteristics of the metabolic syndrome as demonstrated by a decrease in triglycerides, triglyceride/high-density lipoprotein ratio, postprandial lipemia and increase in low-density lipoprotein particle size was shown in overweight men on a very low-carbohydrate diet<sup>[76]</sup>. Similarly, improved insulin sensitivity and prevention of HDL cholesterol decline were noted in overweight men<sup>[77]</sup>.

Results from these studies suggest that a low-carbohydrate diet results in weight loss and may even be more effective than a conventional, low-fat diet in the short-term period. Greater weight loss may be the result of the monotony and simplicity of the diet inhibiting appetite and food intake<sup>[78]</sup>. Enhanced satiety, palatability and novelty of the diet may also play a role<sup>[60,70]</sup>. There has been great concern regarding negative effects on renal function, bone health and cancer risk. Some studies showed that low-carbohydrate diets had a higher incidence of minor side-effects, such as constipation, headache, halitosis, muscle cramps, diarrhea, rash and general weakness<sup>[71]</sup>. The major concern of an adverse effect on serum lipids, renal and cardiovascular health was not realized in these

studies. Again, these studies have relatively short follow-up periods, and the effect on low-density lipoprotein cholesterol levels remains uncertain, and requires further study. Caution must be exercised in subjects with baseline abnormal low-density lipoprotein cholesterol levels. Effects on biochemical markers associated with the metabolic syndrome appear to be more favorable with low-carbohydrate diets. In general, these diets show greater improvements in insulin sensitivity, triglyceride and high-density cholesterol levels. It is possible that for patients with the metabolic syndrome, a low-carbohydrate diet may be more advantageous. This, in turn, may positively affect NAFLD.

## CONCLUSION

As the prevalence of obesity increases, so will that of the metabolic syndrome and NAFLD. It is now recognized that the consequences of NAFLD are not always benign. While pure steatosis alone is generally an indolent disease, steatohepatitis can be a progressive disease leading to cirrhosis and even liver failure. The etiologic association between NAFLD and the metabolic syndrome is so well established that NAFLD is considered a hepatic manifestation of the disease. Obesity and insulin resistance are associated with more histologically advanced disease. Given this scenario, it is important to develop new strategies to treat and prevent NASH. While it is known that dietary weight loss improves markers of the metabolic syndrome and data also suggest that judicious weight loss affects the liver favorably in NAFLD, the best dietary approach is yet unknown. Traditionally, a low-fat diet has been recommended, but recent studies, show greater short-term weight loss and greater improvement in markers of the metabolic syndrome without significant adverse effects with low-carbohydrate diets. This raises the question of whether low-carbohydrate diets should be recommended as part of a weight loss strategy for our patients. At this point, questions regarding the nutritional adequacy and long-term safety remain. While studies have evaluated the effect of these diets on weight loss, cardiovascular and metabolic marker studies are needed to evaluate the effect of these diets specifically on NAFLD.

### Abstract

The incidence and mortality of gastric cancer have fallen dramatically in US and elsewhere over the past several decades. Nonetheless, gastric cancer remains a major public health issue as the fourth most common cancer and the second leading cause of cancer death worldwide. Demographic trends differ by tumor location and histology. While there has been a marked decline in distal, intestinal type gastric cancers, the incidence of proximal, diffuse type adenocarcinomas of the gastric cardia has been increasing, particularly in the Western countries. Incidence by tumor sub-site also varies widely based on geographic location, race, and socio-economic status. Distal gastric cancer predominates in developing countries, among blacks, and in lower socio-economic groups, whereas proximal tumors are more common in developed countries, among whites, and in higher socio-economic classes. Diverging trends in the incidence of gastric cancer by tumor location suggest that they may represent two diseases with different etiologies. The main risk factors for distal gastric cancer include *Helicobacter pylori* (*H pylori*) infection and dietary factors, whereas gastroesophageal reflux disease and obesity play important roles in the development of proximal stomach cancer. The purpose of this review is to examine the epidemiology and risk factors of gastric cancer, and to discuss strategies for primary prevention.

### INTRODUCTION

Overall, gastric cancer incidence and mortality have

fallen dramatically over the past 70 years<sup>[1]</sup>. Despite its recent decline, gastric cancer is the fourth most common cancer and the second leading cause of cancer-related death worldwide<sup>[2,3]</sup>. In 2000, about 880 000 people were diagnosed with gastric cancer and approximately 650 000 died of the disease<sup>[4]</sup>.

The two main tumor sites of gastric adenocarcinoma are proximal (cardia) and distal (noncardia). Despite a decline in distal gastric cancers, proximal tumors have been increasing in incidence since the 1970s, especially among males in the Western countries<sup>[5,6]</sup>. These gastric tumor types predominate in populations from different geographic locations, racial and socio-economic groups. They may also differ in genetic susceptibility, pathologic profile, clinical presentation, and prognosis. The observed differences between gastric cancers by anatomic site suggest that they are distinct diseases with different etiologies. Detailed epidemiological analyses of their demographic trends and risk factors will help guide future cancer control strategies.

### PATHOLOGIC CONSIDERATIONS

About 90% of stomach tumors are adenocarcinomas, which are subdivided into two main histologic types: (1) well-differentiated or intestinal type, and (2) undifferentiated or diffuse type. The intestinal type is related to corpus-dominant gastritis with gastric atrophy and intestinal metaplasia, whereas the diffuse type usually originates in pangastritis without atrophy.

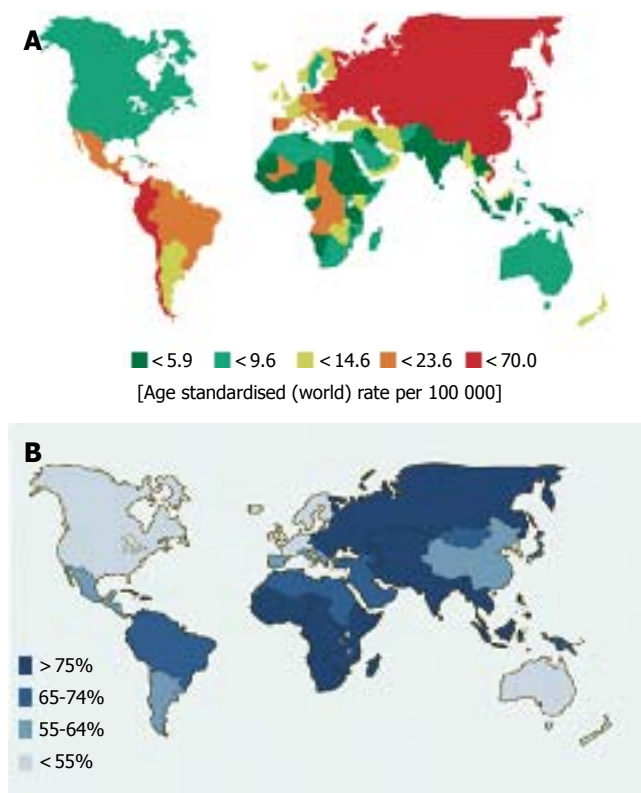

The intestinal type is more common in males, blacks, and older age groups, whereas the diffuse type has a more equal male-to-female ratio and is more frequent in younger individuals<sup>[7,8]</sup>. Intestinal type tumors predominate in high-risk geographic areas, such as East Asia, Eastern Europe, Central and South America, and account for much of the international variation of gastric cancer<sup>[9]</sup>. Diffuse type adenocarcinomas of the stomach have a more uniform geographic distribution<sup>[10]</sup>. A decline in the incidence of the intestinal type tumors in the corpus of the stomach accounts for most of the recent decrease in gastric cancer rates worldwide<sup>[11]</sup>. In contrast, the incidence of diffuse type gastric carcinoma, particularly the signet ring type, has been increasing<sup>[12]</sup>.

### DEMOGRAPHIC TRENDS

#### Time trends

In the 1930s, gastric cancer was the most common cause of cancer death in US and Europe. During the past 70 years, mortality rates have fallen dramatically

**Figure 1** (A) Incidence of stomach cancer in males. (B) Prevalence of *H. pylori* infection in asymptomatic adults. (Data adopted from Parkin *et al.*<sup>[6]</sup>.)

in all developed countries largely due to unplanned prevention. However, in the past 30 years, the incidence of gastric cardia adenocarcinoma rose by five- to six-fold in developed countries<sup>[13-19]</sup>. Gastric cardia tumors now account for nearly half of all stomach cancers among men from US and UK<sup>[6,20]</sup>. There has also been a rising trend in esophageal adenocarcinoma, in which obesity, gastroesophageal reflux disease (GERD), and Barrett's esophagus are major etiologic factors. Gastric cardia cancers share certain epidemiologic features with adenocarcinomas of the distal esophagus and gastroesophageal (GE) junction, suggesting that they represent a similar disease entity.

### Geographic variation

Gastric cancer incidence rates vary by up to ten-fold throughout the world. Nearly two-thirds of stomach cancers occur in developing countries<sup>[4]</sup>. Japan and Korea have the highest gastric cancer rates in the world<sup>[21,22]</sup>. High-incidence areas for noncardia gastric adenocarcinoma include East Asia, Eastern Europe, and Central and South America<sup>[20,23]</sup>. Low incidence rates are found in South Asia, North and East Africa, North America, Australia, and New Zealand (Figure 1A).

In Japan, gastric cancer remains the most common type of cancer among both men and women. Age-standardized incidence rates in Japan are 69.2 per 100 000 in men and 28.6 per 100 000 in women<sup>[3]</sup>. In contrast to the increasing incidence of proximal tumors in the West, distal tumors continue to predominate in Japan. However, even in Japan, the proportion of proximal stomach cancers has increased among men<sup>[24]</sup>.

Migrant populations from high-risk areas such as Japan show a marked reduction in risk when they move to low-incidence regions such as the US<sup>[25]</sup>. Subsequent generations acquire risk levels approximating those of the host country<sup>[20,23]</sup>.

### Sex, race, and age distribution

Noncardia gastric cancer has a male-to-female ratio of approximately 2:1<sup>[20,23]</sup>. Incidence rates are significantly higher among blacks and lower socio-economic groups, and in developing countries<sup>[20]</sup>. Incidence rises progressively with age, with a peak incidence between 50 and 70 years.

In contrast, for gastric cardia carcinomas, men are affected five times more than women and whites twice as much as blacks<sup>[26]</sup>. In addition, the incidence rates of proximal gastric cancers are relatively higher in the professional classes<sup>[27]</sup>. Different rates of genetic polymorphisms according to tumor sub-site suggest variation in susceptibility to stomach cancer by tumor location<sup>[28]</sup>. These findings suggest that noncardia and cardia adenocarcinomas are distinct biological entities.

## SURVIVAL

For the past few decades, gastric cancer mortality has decreased markedly in most areas of the world<sup>[29,30]</sup>. However, gastric cancer remains a disease of poor prognosis and high mortality, second only to lung cancer as the leading cause of cancer-related death worldwide. In general, countries with higher incidence rates of gastric cancer show better survival rates than countries with lower incidence<sup>[31]</sup>. This association is largely due to a difference in survival rates based on tumor location within the stomach. Tumors located in the gastric cardia have a much poorer prognosis compared to those in the pyloric antrum, with lower 5-year survival and higher operative mortality<sup>[32]</sup>.

In addition, the availability of screening for early detection in high-risk areas has led to a decrease in mortality. In Japan where mass screening programs are in place, mortality rates for gastric cancer in men have more than halved since the early 1970s<sup>[33]</sup>. When disease is confined to the inner lining of the stomach wall, 5-year survival is on the order of 95%. In contrast, few gastric cancers are discovered at an early stage in US, leading to 5-year relative survival rates of less than 20%<sup>[34]</sup>. Similarly in European countries, the 5-year relative survival rates for gastric cancer vary from 10% to 20%<sup>[35,36]</sup>. Host-related factors may also affect prognosis, as a US study demonstrated that gastric cancers in persons of Asian descent had a better prognosis compared to non-Asians<sup>[37]</sup>.

## RISK FACTORS

Gastric cancer is a multifactorial disease. The marked geographic variation, time trends, and the migratory effect on gastric cancer incidence suggest that environmental or lifestyle factors are major contributors to the etiology of this disease.

### *Helicobacter pylori* infection

*H. pylori* is a gram-negative bacillus that colonizes the stomach and may be the most common chronic bacterial

infection worldwide<sup>[38]</sup>. Countries with high gastric cancer rates typically have a high prevalence of *H pylori* infection, and the decline in *H pylori* prevalence in developed countries parallels the decreasing incidence of gastric cancer<sup>[39,40]</sup> (Figure 1B). In US, the prevalence of *H pylori* infection is <20% at the age 20 years and 50% at 50 years<sup>[41]</sup>. In Japan, it is also <20% at 20 years, but increases to 80% over the age of 40 years<sup>[42]</sup> and in Korea, 90% of asymptomatic adults over the age of 20 years are infected by *H pylori*<sup>[43]</sup>. The increase in prevalence with age is largely due to a birth cohort effect rather than late acquisition of infection. *H pylori* infection is mainly acquired during early childhood, likely through oral ingestion, and infection persists throughout life<sup>[44]</sup>. Prevalence is closely linked to socio-economic factors, such as low income and poor education, and living conditions during childhood, such as poor sanitation and overcrowding<sup>[45-49]</sup>.

The association between chronic *H pylori* infection and the development of gastric cancer is well established<sup>[50-53]</sup>. In 1994, the International Agency for Research on Cancer classified *H pylori* as a type I (definite) carcinogen in human beings<sup>[54]</sup>. In Correa's model of gastric carcinogenesis, *H pylori* infection triggers the progressive sequence of gastric lesions from chronic gastritis, gastric atrophy, intestinal metaplasia, dysplasia, and finally, gastric adenocarcinoma<sup>[55]</sup>. Several case-control studies have shown significant associations between *H pylori* seropositivity and gastric cancer risk, with about a 2.1- to 16.7-fold greater risk compared to seronegative individuals<sup>[56-62]</sup>. Prospective studies have also supported the association between *H pylori* infection and gastric cancer risk<sup>[50-52,63]</sup>. Perhaps the most compelling evidence for the link between *H pylori* and gastric cancer comes from a prospective study of 1 526 Japanese participants in which gastric cancers developed in 2.9% of infected people and in none of the uninfected individuals<sup>[64]</sup>. Interestingly, gastric carcinomas were detected in 4.7% of *H pylori*-infected individuals with non-ulcer dyspepsia.

The vast majority of *H pylori*-infected individuals remain asymptomatic without any clinical sequelae. Cofactors, which determine that *H pylori*-infected people are at particular risk for gastric cancer, include bacterial virulence factors and proinflammatory host factors. Gastric cancer risk is enhanced by infection with a more virulent strain of *H pylori* carrying the cytotoxin-associated gene A (*cagA*)<sup>[65,66]</sup>. Compared to *cagA*- strains, infection by *H pylori cagA*+ strains was associated with an increased risk of severe atrophic gastritis and distal gastric cancer<sup>[67-70]</sup>. In the Western countries, about 60% of *H pylori* isolates are *cagA*+<sup>[71]</sup>, whereas in Japan, nearly 100% of the strains possess functional *cagA*<sup>[72,73]</sup>. Host factors associated with an increased risk of gastric cancer include genetic polymorphisms which lead to high-level of expression of the proinflammatory cytokine, interleukin-1β<sup>[74,75]</sup>.

The effects of *H pylori* on gastric tumor development may vary by anatomical site. The falling incidence of *H pylori* infection and noncardia gastric cancer in developed countries has been diametrically opposed to the rapid increase in the incidence of gastric cardia adenocarcinoma<sup>[76]</sup>. Based on a meta-analysis of prospective cohort studies, *H pylori* infection was associated

with the risk of noncardia gastric cancer, but not cardia cancer<sup>[77]</sup>. Other studies demonstrated a significant inverse association between *H pylori* infection, particularly *cagA*+ strains, and the development of gastric cardia and esophageal adenocarcinomas<sup>[78,79]</sup>. In the Western countries, where the prevalence of *H pylori* infection is falling, GERD and its sequelae are increasing. Studies have shown that severe atrophic gastritis and reduced acid production associated with *H pylori* infection significantly reduced the risk of GERD<sup>[80-83]</sup>. However, recent studies have found conflicting results on whether *H pylori* eradication therapy increases the risk of esophagitis and gastric cardia adenocarcinoma<sup>[84-91]</sup>. Thus, the protective effect of *H pylori* against cardia tumors remains controversial.

### Dietary factors

It is unlikely that *H pylori* infection alone is responsible for the development of gastric cancer. Rather, *H pylori* may produce an environment conducive to carcinogenesis and interact with other lifestyle and environmental exposures. There is evidence that consumption of salty foods and *N*-nitroso compounds and low intake of fresh fruits and vegetables increases the risk of gastric cancer. *H pylori* gastritis facilitates the growth of nitrosating bacteria, which catalyze the production of carcinogenic *N*-nitroso compounds<sup>[92]</sup>. In addition, *H pylori* infection is known to inhibit gastric secretion of ascorbic acid, which is an important scavenger of *N*-nitroso compounds and oxygen free radicals<sup>[93]</sup>.

Salt-preserved foods and dietary nitrite found in preserved meats are potentially carcinogenic. Intake of salted food may increase the risk of *H pylori* infection and act synergistically to promote the development of gastric cancer. In animal models, ingestion of salt is known to cause gastritis and enhance the effects of gastric carcinogens<sup>[94,95]</sup>. Mucosal damage induced by salt may increase the possibility of persistent infection with *H pylori*<sup>[96]</sup>. Several case-control studies have shown that a high intake of salt and salt-preserved food was associated with gastric cancer risk<sup>[97-103]</sup>, but evidence from prospective studies is inconsistent<sup>[104-107]</sup>. *N*-nitroso compounds are carcinogenic in animal models and are formed in the human stomach from dietary nitrite. However, case-control studies have shown a weak, nonsignificant increased risk of gastric cancer for high vs low nitrite intake<sup>[97,108-110]</sup>. Prospective studies have reported significant reductions in gastric cancer risk arising from fruit and vegetable consumption<sup>[111-114]</sup>. The worldwide decline in gastric cancer incidence may be attributable to the advent of refrigeration, which led to decreased consumption of preserved foods and increased intake of fresh fruits and vegetables.

Animal studies have shown that polyphenols in green tea have antitumor and anti-inflammatory effects. In preclinical studies, polyphenols have antioxidant activities and the ability to inhibit nitrosation, which have been implicated as etiologic factors of gastric cancer<sup>[115-117]</sup>. Although various case-control studies have shown a reduced risk of gastric cancer in relation to green tea consumption<sup>[118-121]</sup>, recent prospective cohort studies found no protective effect of green tea on gastric cancer risk<sup>[122-125]</sup>.

Obesity	+	?
Tobacco	+	+

NOTE: ++, strong positive association; +, positive association; -, negative association; ?, ambiguous studies.

### Tobacco

Prospective studies have demonstrated a significant dose-dependent relationship between smoking and gastric cancer risk<sup>[126,127]</sup>. The effect of smoking was more pronounced for distal gastric cancer, with adjusted rate ratios of 2.0 (95% CI, 1.1-3.7) and 2.1 (95% CI, 1.2-3.6) for past and current smokers, respectively<sup>[128]</sup>. There is little support for an association between alcohol and gastric cancer<sup>[129]</sup>.

### Obesity

Obesity is one of the main risk factors for gastric cardia adenocarcinoma<sup>[130,131]</sup>. Obesity can promote GE reflux disease which predisposes to Barrett's esophagus, a metaplastic precursor state for adenocarcinoma of the esophagus and GE junction<sup>[132,133]</sup>. A Swedish study found that the heaviest quarter of the population had a 2.3-fold increased risk for gastric cardia adenocarcinoma compared to the lightest quartile of the population<sup>[134]</sup>. A recent prospective study from US found that body mass index was significantly associated with higher rates of stomach cancer mortality among men<sup>[135]</sup>. Thus, risk factors positively associated with adenocarcinoma of the esophagus and gastric cardia include obesity, GE reflux, and the presence of Barrett's esophagus. A summary of the main differences between cardia and noncardia gastric cancer can be found in Table 1.

### Other

Less common risk factors for gastric cancer include radiation<sup>[136]</sup>, pernicious anemia<sup>[137]</sup>, blood type A<sup>[138]</sup>, prior gastric surgery for benign conditions<sup>[139]</sup>, and Epstein-Barr virus<sup>[140-142]</sup>. In addition, a positive family history is a significant risk factor, particularly with genetic syndromes such as hereditary nonpolyposis colon cancer and Li-Fraumeni syndrome<sup>[143-145]</sup>.

## PREVENTION OF GASTRIC CANCER

### Lifestyle modifications

Because gastric cancer is often associated with a poor

prognosis, the main strategy for improving clinical outcomes is through primary prevention. Reduction in gastric cancer mortality is largely due to unplanned prevention. The widespread introduction of refrigeration has led to a decrease in the intake of chemically preserved foods and increased consumption of fresh fruits and vegetables<sup>[98,146]</sup>. A decline in the prevalence of *H pylori* infection may be due to improvements in sanitary and housing conditions, as well as the use of eradication therapy<sup>[54]</sup>. In addition, reduced tobacco smoking at least in males may have contributed to the decline in gastric cancer incidence<sup>[147]</sup>. Therefore, modifiable risk factors, such as high salt and nitrite consumption, low fruit and vegetable intake, cigarette smoking, and *H pylori* infection, may be targeted for prevention.

### *Helicobacter pylori* eradication

Public health measures to improve sanitation and housing conditions are the key factors in reducing the worldwide prevalence of *H pylori* infection. *H pylori* eradication therapy is another potential strategy for gastric cancer chemoprevention. A 7 to 14 d course of two antibiotics and an antisecretory agent has a cure rate of about 80% with durable responses<sup>[148]</sup>. However, higher reinfection rates are seen in developing countries after people have had effective eradication therapy<sup>[149]</sup>. In Japanese patients treated for early gastric cancer, *H pylori* eradication therapy resulted in a significantly lower rate of gastric cancer recurrence<sup>[150]</sup>. A randomized controlled chemoprevention trial showed that antimicrobial therapy directed against *H pylori* or dietary supplementation with antioxidants increased the regression rate of gastric atrophy and intestinal metaplasia compared to placebo<sup>[151]</sup>. In a randomized, placebo-controlled primary prevention trial conducted in a high-risk region of China, 1 630 healthy carriers of *H pylori* infection were randomized to a 2-wk course of eradication treatment or placebo<sup>[152]</sup>. Although the incidence of gastric cancer was similar in both groups after 7.5 years of follow-up, post hoc analysis of a subgroup of *H pylori* carriers without precancerous lesions at baseline showed a significant decrease in the development of gastric cancer with eradication therapy.

Several large-scale chemoprevention trials of *H pylori* eradication therapy with gastric cancer endpoints are ongoing. Potential downsides of widespread eradication therapy in asymptomatic carriers include developing antibiotic-resistant strains of *H pylori* and perhaps increasing the risk of GERD and adenocarcinoma of the esophagus and gastric cardia.

### Antioxidants

High intake of antioxidants, such as vitamins C and E and  $\beta$ -carotene, may have a protective effect on the risk of gastric cancer. High serum levels of  $\alpha$ -carotene,  $\beta$ -carotene, lycopene, and vitamin C were significantly associated with reduced risk of gastric cancer in a cohort from Shanghai, China<sup>[153]</sup>. A randomized trial in Linxian, China showed a reduced risk of both cardia and noncardia gastric cancers in individuals supplemented with a combination of selenium,  $\beta$ -carotene, and  $\alpha$ -tocopherol<sup>[154]</sup>. However, a randomized trial from

Finland showed no association between  $\alpha$ -tocopherol or  $\beta$ -carotene supplementation and the prevalence of gastric cancer in elderly men with atrophic gastritis<sup>[155]</sup>. Another prospective study from the US Cancer Prevention Study II cohort found that vitamin supplementation did not significantly reduce the risk of stomach cancer mortality<sup>[156]</sup>. Therefore, dietary supplementation may only play a preventive role in populations with high rates of gastric cancer and low intake of micronutrients.

### COX-2 inhibitors

Cyclooxygenase-2 (COX-2) plays a role in cell proliferation, apoptosis, and angiogenesis, and may be involved in gastric carcinogenesis<sup>[157,158]</sup>. Increasing levels of COX-2 are present in the progression from atrophic gastritis to intestinal metaplasia and adenocarcinoma of the stomach<sup>[159]</sup>. Exposure to cigarette smoke, acidic conditions, and *H pylori* infection all induce COX-2 expression<sup>[160-162]</sup>. Furthermore, McCarthy *et al.* showed that COX-2 expression in the antral mucosa was reduced in the epithelium after successful eradication of *H pylori*<sup>[163]</sup>.

Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) are thought to inhibit cancer cell growth primarily through the inhibition of COX-2, and evidence is mounting that COX-2 inhibitors may be beneficial in preventing upper gastrointestinal malignancies. Compared to colorectal cancer, the association between NSAID use and the development of gastric cancer has been studied less extensively<sup>[164-166]</sup>. A recent meta-analysis showed that NSAID use was associated with a reduced risk of noncardia gastric adenocarcinoma<sup>[167]</sup>. Thus, COX-2 inhibitors may provide a chemopreventive strategy against gastric carcinogenesis.

### Endoscopic screening and surveillance

Because of the high risk of gastric cancer in Japan, there has been a national endoscopic surveillance program within the commercial workforce. Annual screening with a double-contrast barium technique and endoscopy is recommended for persons over the age of 40 years<sup>[168]</sup>. With mass screening, about half of gastric tumors are being detected at an early stage in asymptomatic individuals and the mortality rate from gastric cancer has more than halved since the early 1970s<sup>[33]</sup>. An intervention study in China is underway which involves a comprehensive approach to gastric cancer prevention, including *H pylori* eradication, nutritional supplements, and aggressive screening with double contrast X-ray and endoscopic examination. In the first four years after intervention, the relative risk of overall mortality with this intervention for a high-risk group was 0.51 (95% CI, 0.35-0.74)<sup>[169]</sup>. This study suggests that targeting high-risk populations for aggressive screening and prevention may decrease gastric cancer mortality.

### CONCLUSION

In summary, cardia and noncardia gastric cancers exhibit unique epidemiologic features characterized by marked geographic variation, diverging time trends, and differences based on race, sex, and socio-economic status. *H pylori*

infection and dietary factors appear to be the main causative agents for distal gastric cancer, whereas GERD and obesity play a primary role in proximal gastric cancer. Future directions in primary prevention should target modifiable risk factors in high-risk populations. In the planning and evaluation of gastric cancer control activities, detailed demographic analyses will inform future screening and intervention studies.

## Abstract

Cancer commonly arises at the sites of chronic inflammation and infection. Although this association has long been recognized, the reason has remained unclear. Within the gastrointestinal tract, there are many examples of inflammatory conditions associated with cancer, and these include reflux disease and Barrett's adenocarcinoma of the esophagus, Helicobacter infection and gastric cancer, inflammatory bowel disease and colorectal cancer and viral hepatitis leading to hepatocellular carcinoma. There are several mechanisms by which chronic inflammation has been postulated to lead to cancer which includes enhanced proliferation in an endless attempt to heal damage, the presence of a persistent inflammatory environment creating a pro-carcinogenic environment and more recently a role for engraftment of circulating marrow-derived stem cells which may contribute to the stromal components of the tumor as well as the tumor mass itself. Here we review the recent advances in our understanding of the contributions of circulating bone marrow-derived stem cells to the formation of tumors in animal models as well as in human beings.

## INTRODUCTION

The association between cancer and inflammation has been recognized for over 2 000 years<sup>[1,2]</sup>. Virchow recognized that many tumors arise in a setting of chronic inflammation, and later, Dvorak aptly described cancer as "wounds that do not heal"<sup>[3]</sup>. It is estimated that up to 15% of cancers worldwide are associated with chronic infection<sup>[4]</sup> and there are many more examples throughout the body of cancer associated with inflammation of unclear etiology. Within the GI tract, examples include esophageal adenocarcinoma arising in the setting of Barrett's metaplasia, gastric cancer occurring secondary to Helicobacter infection, colorectal cancer occurring in longstanding inflammatory bowel disease and hepatocellular carcinoma secondary to viral hepatitis (Table 1). There are several mechanisms by which inflammation and a cycle of chronic injury/repair has been postulated to lead to cancer, including the push for continued proliferation, an abnormal inflamed-stromal environment, and more recently we recognize a role for engraftment of circulating marrow-derived stem cells, which may contribute to the stromal components of the tumor as well as the epithelial component of the tumor mass itself.

## INFLAMMATION: THE RELATIONSHIP BETWEEN TISSUE INJURY, REPAIR AND CANCER

Proliferation of cells alone is not sufficient to cause cancer, rather proliferation in the setting of altered growth signals from inflammatory cell infiltrates and DNA damaging agents released from infiltrating leukocytes promote malignant degeneration. Wound healing, which requires subversion of usual growth programs, mobilization and migration of cells and a heightened resistance to apoptosis, embodies all the properties of malignant cells with one exception, that is, healing is self limited. Successful wound healing results in restoration of tissue integrity and resolution of inflammation, reinstating homeostatic growth control. The tissue environments of longstanding unrelenting chronic infection or idiopathic chronic inflammation are persistent states of inadequate wound healing. Within this setting, inflammatory cells produce highly reactive oxygen and nitrogen species, which interact with cellular DNA inducing point mutations, deletions or rearrangements. Usually DNA damage such as this triggers

Table 1 Infection and inflammation associated with cancers

Cause	Site
Chewing tobacco/oral irritation	Oral cancers
Smoking/chronic bronchitis	Lung
Asbestos	Mesothelioma
Reflux disease	Barretts' adenocarcinoma of the esophagus
Chronic Helicobacter infection	Gastric adenocarcinoma and lymphoma
Chronic pancreatitis	Pancreatic cancer
Opisthorchis sinensis infection (liver fluke)	Cholangiocarcinoma
Viral hepatitis	Hepatocellular carcinoma
Ulcerative colitis and Crohn's disease	Colorectal carcinoma
Human papilloma virus	Anogenital carcinomas
Schistosomiasis	Bladder cancer
Pelvic inflammatory disease	Ovarian cancer
Chronic osteomyelitis	Osteosarcoma
Chronic scar tissue	"Scar" cancer arising in the lung, skin and other areas of scarring

apoptosis. However, in areas of chronic inflammation and repair, growth programs are corrupted and the environment is poised to allow replication and survival of cells, which under normal situations would either be quiescent or lost to apoptosis. Allowing cells to continually divide in an environment conducive to DNA damage may result in the accumulation of genetic defects and the emergence of malignant cells.

Which cell is the target of malignant transformation has been the area of much debate. Original thought was that a terminally differentiated cell would acquire enough genetic damage to replicate endlessly. This would require multiple genetic alterations in key cell signaling cascades to allow autonomous growth. A more likely scenario, however, is that these cells would undergo apoptosis or be sloughed off as a normal part of organ turnover prior to "backing up" the differentiation ladder sufficiently to acquire independent growth. More recently, focus has been on tissue-derived stem cells as the source of cancer. Tissue stem cells possess several important features making them attractive candidates for malignant degeneration. These include long life span, relative apoptosis resistance and ability to replicate for extended periods of time. In the setting of chronic inflammation, progenitor or stem cells within the peripheral tissue are forced to undergo multiple rounds of cell division predisposing to the accumulation of mutations. While restricted progenitors or even differentiated cells can still become transformed, in most cases, it has been believed that early stem cells are the targets of transformation.

If one looks at areas of high proliferative capacity (high BrdU or PCNA staining in tissue) as the stem cell zone, then this theory of peripheral stem cells as the cells of origin of cancer must be reconciled with the fact that this supposed stem cell compartment is often the most damaged and depleted by agents thought to be carcinogens<sup>[5]</sup>. With chronic inflammation leading to atrophic changes attributed to peripheral stem cell exhaustion, the very cell thought to be transformed is lost - leading us to investigate if an alternate stem cell compartment is responsible for peripheral cancers arising in the setting of inflammation. In order to understand this concept, and why the bone marrow-derived stem cell (BMDC) is a "logical choice"

**Figure 1** A proposed model for the cancer stem cell. The cancer stem cell replicates itself asymmetrically, thus maintaining one daughter stem cell identical to itself. This remains in a relatively quiescent state. The asymmetric division also produces another daughter cell with a high proliferative rate which rapidly divides to sustain the tumor mass.

**Figure 2** Conventional versus stem cell-targeted chemotherapy. Conventional chemotherapy and radiotherapy targets rapidly dividing cells, and may shrink tumor mass substantially. However, the stem cell (gray), which is relatively quiescent, is not affected. Regrowth of tumor from surviving stem cell leads to regrowth of tumor and treatment failure. Chemotherapy targeted at the stem cell would remove the source of new cell growth, and allow residual cells within the tumor to be targeted with chemotherapy, differentiating agents or therapy aimed at inducing apoptosis, thus successfully eliminating the tumor.

for a cancer stem cell, we need to understand a few points about cancer stem cells, and BMDCs in general.

### Stem cells in cancer - cancer as an abnormal organ

A tumor mass can be compared to an abnormal organ; in that it is composed of a heterogeneous mixture of cell types and of cells possessing different proliferative capacities and different levels of differentiation. Tumor cells are admixed with fibroblasts, endothelial cells and inflammatory cells comprising the tumor stroma. This tumor stroma is being increasingly recognized as a critical contributor to malignant growth and survival of the tumor mass; however, stromal cells themselves are usually not malignant. Likewise, not all cells within a tumor are malignant - meaning not all cells can form tumors if transplanted at another site, or into a secondary host. In fact, the majority of cells within a tumor are incapable of independent growth and are readily susceptible to apoptosis. Only a small fraction of cells within a tumor are capable of independent growth, and fulfill the criteria described for cancer stem cells<sup>[6-8]</sup>. These cells have metastatic potential, form tumors in secondary hosts and are believed to be responsible for continual renewal of cells within the tumor mass. These cells are likely to proliferate slowly and asymmetrically,

self renewing the stem cell population and giving rise to daughter cells, which proliferate to sustain tumor growth (Figure 1). Conventional anti-cancer chemotherapy and radiotherapy target rapidly dividing daughter cells, affecting the bulk of the tumor mass, but leave the cancer stem cell intact, explaining the often rapid recurrence of tumor bulk, once therapy is stopped (Figure 2). At present, the most pressing issue for cancer research is to identify the cancer stem cell and exploit its unique characteristics with targeted therapies.

### **Bone marrow stem cells**

BMDCs are a heterogeneous group of cells isolated from the bone marrow which are capable of repopulating the hematopoietic system of a lethally irradiated immunologically compatible secondary host. These cells have been divided into at least two main categories; the hematopoietic and mesenchymal stem cells (MSC). Hematopoietic stem cells are traditionally regarded as the cells which give rise to the formed elements of the blood and have been used extensively in human bone marrow transplantation. Thus, hematopoietic stem cells have been extensively studied and defined with regard to surface markers, growth characteristics and repopulation potential<sup>[9]</sup>. Less well defined are the MSC. This term MSC, as defined in the literature, is the heterogeneous population of cells isolated as the adherent population, when total marrow is placed in culture<sup>[10]</sup>. These cells give rise to adipocyte, chondrocyte, cells of osteocyte lineages and the marrow mesenchyma, which is vital for optimal hematopoiesis<sup>[11-13]</sup>.

Work from multiple laboratories demonstrates surprising roles for marrow-derived stem cells in addition to hematopoiesis, stressing that the potential for differentiation may be much greater than originally believed. Markers defining cell subpopulations within the marrow are not standardized in these studies, making direct comparison of data between laboratories challenging; however, one thing remains consistent - cells within the bone marrow have a markedly greater differentiation potential than originally believed. For the purposes of this discussion, the term BMDCs will be broadly used to refer to cells derived from the marrow, and will encompass hematopoietic stem cells, MSC multipotent progenitor cells and whole marrow.

### ***In vitro* and *in vivo* studies-plasticity of BMDCs**

Multiple and elegant studies from independent groups have shown quite clearly that bone marrow stem cells can differentiate along multiple diverse lineage pathways<sup>[14-17]</sup>. These findings challenge the conventional view that bone marrow stem cells give rise only to the marrow mesenchyma or formed elements in the peripheral blood. *In vitro*, BMDCs have been shown to differentiate at the single cell level and acquire characteristics of mesoderm, neuroectoderm and endoderm<sup>[15,16]</sup>. These cells appear to use culture environmental factors to guide lineage decisions. Strikingly, *in vivo* studies in the mouse model have confirmed this plasticity. Elegant studies utilizing transplanted single cells demonstrate differentiation along multiple lineages, supporting a central role for the local tissue environment in dictating differentiation of stem cells, confirming that a single cell is multipotent, and supporting the assertion

that experimental findings demonstrating multiple cell lineage differentiation is not due to circulating tissue specific progenitor cells, but rather to a single multipotent cell. In these studies, multiple types of epithelial cells have been shown to be derived from BMDCs including epithelium of the lung, gastrointestinal tract and skin after transplantation of a single bone marrow-derived stem cell<sup>[14]</sup>. This is not a transient event, as cells can be recovered nearly a year after transplantation. In the gastrointestinal tract, engrafted cells are seen as isolated epithelial cells in the gastric pits of the stomach, the small intestinal villi, the colonic crypt, and rarely in the esophagus. Under these experimental conditions, cells were recovered as single differentiated epithelial cells, and did not appear to engraft into the stem cell niche as clonal expansion was not seen. Infusion of labeled BMDCs into a non-irradiated host, also led to the engraftment (*albeit* to a lesser degree) and differentiation as epithelial cells of the liver, lung and gut in a similar pattern to that seen with marrow ablation and transplantation<sup>[15]</sup>, demonstrating that engraftment and differentiation are true physiological events and not merely artifacts of irradiation and experimental manipulation. While epithelial cell damage is not necessary for engraftment, studies support the notion that damage to the epithelium increases engraftment.

The mechanism by which the marrow-derived cells acquire the appropriate phenotype of epithelial cells is not known, with evidence supporting both direct differentiation or fusion with a peripheral cell<sup>[18-21]</sup>. The method of engraftment and differentiation may be specific to the individual tissues and/or may depend on the mechanism of injury inducing engraftment. Irrespective of the mechanism involved, BMDCs have been shown to engraft and take on the function of cells within the peripheral tissues<sup>[16,18-23]</sup>.
