## **HUMAN STUDIES - EVIDENCE FOR PLASTICITY OF BMDCS IN PATIENTS TRANSPLANTED WITH GENDER MISMATCHED BONE MARROW**

Human studies have confirmed that plasticity of BMDCs is not restricted to mice, and may be a physiologically relevant phenomenon in man as well. Studies, examining peripheral tissue of female patients transplanted with bone marrow derived from male donors, have shown that BMDCs from the donor can differentiate into skin, gut epithelium and mature hepatocytes<sup>[24,25]</sup>. Identification of the Y chromosome in cells of these tissues confirms that BMDCs can substantially repopulate the GI tract epithelium<sup>[25]</sup>, and this repopulation does not appear to be a rare event. Patients in these studies have some level of graft-versus-host disease, and the level of inflammation in the tissue correlates with the level of donor cell engraftment. These findings are consistent with the data derived from murine studies and suggest the inflammatory environment is crucial for optimal engraftment and differentiation of BMDCs. The fact that BMDCs have the capacity to differentiate along organ-specific lineages appropriate for the organ of engraftment, and are found in increasing num-

**Figure 3** An experimental mouse model for bone marrow transplantation and *H. felis*-induced gastric carcinoma.

bers during chronic inflammation (a condition associated with cancer), places these cells “in the right place, at the right time” to be candidates for the cancer stem cell.

#### Similarities between BMDCs and cancer cells

In addition to what appears to be of immense plasticity of cells within the bone marrow, BMDCs have other traits which make them attractive candidates for cancer stem cells. BMDCs have the capacity for self renewal, are long lived, are chemoresistant, and may be inherently mutagenic<sup>[26-29]</sup>. Intriguing is the fact that similar growth regulators and control mechanisms are involved in both cancer and stem cell maintenance. For example, proteins from the polycomb group, the epigenetic chromatin modifiers, are involved in both cancer development and maintenance of embryonic and adult stem cells<sup>[30]</sup>. Also, pathways used by bone marrow stem cells for trafficking appear to be exploited by tumor cells for metastasis<sup>[31]</sup>. For instance, chemokines and cytokines produced during chronic inflammation (such as SDF-1) influence the behavior and migration of cancer cells. These are the same chemokines and cytokines responsible for physiological stem cells homing back to the marrow cavity<sup>[32-36]</sup>. Identification of bone marrow stromal cell-derived growth inhibitor as a potent inhibitor of breast cancer cell migration, and the capability of this protein to induce cell cycle arrest and apoptosis in breast cancer stem cells further supports the use of similar growth mechanisms between stem and cancer cells<sup>[37]</sup>. Inflammation of the GI tract is associated with IL-6 and IL-8 production which initiate neutrophil infiltration<sup>[39]</sup>. Interestingly, IL-6 is also chemotactic for MSC<sup>[33]</sup>. Other cytokines and chemokines prominent in the setting of mucosal inflammation such as VEGF and MIP-1 $\alpha$  are also chemoattractants for MSC<sup>[33,34]</sup>. Receptors such as CXCR 2 and 4 are found on both cancer cells and stem cells, and influence the homing of stem cells, or invasion/metastases of cancer cells, suggesting a link between the two populations of cells. One might suppose that a mechanism similar to that used to regulate BMDC circulation and homing back to areas of bone may also facilitate migration and engraftment of BMDCs into peripheral tissues as a result

of chronic inflammation, if the peripheral tissue secretes the appropriate homing signals.

Additionally, immune escape has long been a perplexing property of cancer cells; MSCs have unique immunological properties in that they are not immunogenic, they do not stimulate alloreactivity, and they escape lysis by cytotoxic T cells and natural killer cells<sup>[39]</sup>. This inherent ability to evade immune recognition may explain why many cancer cells evade the host immune response.

#### BMDCs as the origin of epithelial cancer: helicobacter induced gastric cancer as a model system

We reasoned that BMDCs, as the ultimate uncommitted adult stem cell, might represent the ideal candidate for transformation, if placed in a favorable environment. We used the well-described *H. felis*/C57BL/6 mouse model of gastric cancer to test this theory<sup>[40]</sup>. This model is optimal for studying the role of stem cells in inflammatory-mediated cancers because C57BL/6 mice do not develop gastric cancer under controlled conditions. With *Helicobacter* infection, however, the gastric mucosa progresses through a series of changes including metaplasia and dysplasia, culminating in gastrointestinal intraepithelial neoplasia (GIN)<sup>[41]</sup> by 12-15 mo of infection, thus reiterating human disease, where gastric cancer in the absence of *Helicobacter* infection is unusual, while longstanding infection carries a significant (up to 1-3%) risk of gastric cancer<sup>[42-47]</sup>. In order to test the role for BMDCs in gastric cancer (Figure 3), C57BL/6J mice were myeloablated and transplanted with gender-mismatched bone marrow from mice that expressed a non-mammalian beta-galactosidase enzyme [C57BL/6J-*Gtosa26* (ROSA 26)], mice that expressed green fluorescent protein [C57BL/6J-*beta-actin-EGFP* (GFP)], or control C57BL/6J litter mates. Engraftment of ROSA26 BMDCs into the gastric mucosa was confirmed by several independent methods including detecting enzyme activity, specific B-galactosidase immunohistochemistry (IHC, two cytoplasmic markers) (Figures 4 and 5), and detection of LacZNeo fusion gene sequence (nuclear marker) by PCR within beta-galactosidase positive gastric glands isolated by laser capture microscopy. In those mice transplanted with GFP marrow, GFP was detected by fluorescence activated cell sorting of cytokeratin positive-single cell preparations, and GFP immunohistochemistry of tissue sections. X and Y chromosome fluorescent *in situ* hybridization (X and Y-FISH) was used as an additional means to detect BMDCs in gender mismatched transplants<sup>[40]</sup>.

As expected, acute *Helicobacter* infection was associated with an influx of bone marrow-derived inflammatory cells (Figure 4A - blue staining) into the tissue. At early time points, we did not detect any engraftment or differentiation of BMDCs to an epithelial cell phenotype. At 20 wk of infection, rare glands entirely replaced by BMDCs were isolated, suggesting that engraftment into the stem cell niche had occurred. These findings were more pronounced at 30 wk, where antralized glands and metaplastic cells at the squamocolumnar junction were entirely replaced by marrow-derived cells (Figures 4D and 4E). The severity of intraepithelial dysplasia increased over time, and by one year of infection, most mice developed invasive neoplastic glands. All of the intraepithelial neoplasia in mice infected

**Figure 4** Engraftment of donor-derived ROSA-26 marrow by x-gal staining. **A:** Mice transplanted with ROSA 26 marrow and infected with *H. felis* for 4 wk had donor-derived leukocytes (blue) infiltrating the gastric mucosa, and no engraftment into gland structures. **B and C:** A higher power view reveals myocytes and myofibroblasts in the submucosal tissue adjacent to vascular structures (arrows). **D:** After 30 wk of infection, marked architectural distortion is seen with antralization and appearance of metaplastic glands. Entire gland structures are derived from donor marrow (blue staining). Gland shown in panel D (arrow) is shown at higher power in **E**.

for 12-16 mo rose from donor marrow cells, strongly suggesting an inherent vulnerability of this population of cells to malignant progression. Progressive parietal and chief cell loss is a hallmark of chronic *Helicobacter* infection. Of the few parietal or chief cells which we isolated from the infected mice, none were derived from the bone marrow, strongly suggesting that marrow cells do not differentiate toward the parietal or chief cell phenotype under the experimental conditions that were used<sup>[40]</sup>.

Normal healing of the gastric mucosa after iatrogenic ulceration likewise did not require BMDCs<sup>[40]</sup>, nor did loss of specific cell lineages, such as targeted ablation of parietal cells, lead to marrow engraftment<sup>[40]</sup>. Rather, it seems that long standing inflammation and inflammatory mediated damage to the epithelium is required - an environment strongly linked to the development of cancer in many settings. In our *Helicobacter*-gastric cancer model, infection and inflammation reached a plateau at 8 wk; however, engraftment was not apparent until 20 wk, suggesting that events other than increased inflammation are responsible for engraftment. Between 8 and 20 wk, there is loss of the oxyntic glands, and a restructuring of the gastric architecture to include metaplastic cell lineages, re-

flecting the effects of an abnormal tissue milieu on rapidly proliferating cells<sup>[48]</sup>. Once engraftment began, however, the number of bone marrow-derived glands increased dramatically, suggesting that a threshold for recruitment had been reached<sup>[40]</sup>.

In addition to epithelial cells within the tumor, BMDCs also comprise a subset of cells within the tumor stroma and within seemingly uninvolved epithelium and subepithelial spaces adjacent to the tumors. We have recovered adipocytes (Figure 5C), fibroblast, endothelial cells and myofibroblasts (Figures 4B and 4C) derived from bone marrow precursors in areas adjacent to dysplasia and neoplasia.

Based on these experiments, we have proposed a new paradigm for epithelial cancer (Figure 6). Chronic tissue inflammation leads to tissue injury and with time, to tissue stem cell failure. Peripheral stem cell failure leads to recruitment and permanent engraftment of BMDCs into the tissue stem cell niche, where the BMDCs essentially take over the function of the tissue stem cell. In the setting of inflammation, specifically with Th1 type cytokines and an abnormal tissue environment (for example, one lacking chief and parietal cells), the BMDCs initiate differentia-

**Figure 5** Immunohistochemistry for bacterial beta-galactosidase confirms uniform signal in gastrointestinal neoplasia. Mice developed severe dysplasia and intraepithelial neoplasia derived from donor marrow, 12-15 mo after infection with *H. felis* (A) and (B). Immunohistochemistry for bacterial beta-galactosidase demonstrates cytoplasmic staining in dysplastic glands. A population of adipocytes in the submucosa are also stained for beta-galactosidase (arrow).

**Figure 6** A new paradigm proposed for epithelial cancer.

tion, but fail to regulate growth programs appropriately and progresses through stages of metaplasia and dysplasia. We speculate that the inappropriate retention of primitive growth programs in a stem cell forced to replicate may permit survival despite otherwise lethal mutations, thus allowing transformation. This new model brings together previously unexplained observations regarding the behavior of cancer, and presupposes that properties inherent to cancer such as their resistance to apoptosis, their unlimited growth potential and their ability for local spread and distant metastasis are fundamental to the origin of the cell, rather than traits acquired. The concept of cancer initiation and promotion can also be viewed within the context of this model. Initiation may represent BMDCs trafficking into the stem cell niche as a result of tissue stem cell damage. In the absence of continued inflammation and injury, these engrafted cells may behave in a way indistinguishable from endogenous tissue stem cells. Promotion may represent an additional stimulus received at a later time that allows sustained proliferation of BMDCs and transformation.

#### ***In vitro* experiments and animal models supporting the BMDC-epithelial cancer model**

In addition to the *Helicobacter*-gastric cancer model, other studies have begun to address the role of BMDCs in cancer using various *in vitro* and *in vivo* models. For example, BMDCs have been shown to localize to a known stem cell

niche within the epidermis known as the CD34 positive bulge region of the hair follicle, and clonally expand to repopulate portions of the epidermis, functioning as an epidermal stem cell<sup>[49]</sup>. Similar to our findings, engraftment of BMDCs to the stem cell niche is dramatically increased with injury severe enough to deplete peripheral stem cells in the region. However, these are short-term studies. Longer term studies utilizing carcinogen exposure will determine the eventual fate of these BMDCs, and determine if BMDCs in the stem cell niche behave differently from peripheral stem cells occupying the same niche. It is intriguing, however, to speculate the ultimate fate of these stem cells given the prevalence of BMDC-skin carcinoma in solid organ recipients (see below).

In addition to residing in the epithelial stem cell niche, bone marrow-derived myofibroblasts have been recovered within the colonic subepithelial compartments in both mice and human beings<sup>[50,51]</sup>. Interestingly, Direkze *et al.* observed that in the IL-10 knockout mouse model of colitis, up to 45% of subepithelial myofibroblasts were marrow derived<sup>[51]</sup>, suggesting that in the setting of chronic inflammation, damaged tissue is replaced by BMDCs. When the same group looked at tumor-associated myofibroblasts and fibroblasts, they also found a significant portion of these cells derived from bone marrow cells<sup>[50]</sup>. It is not clear from these data, if tumors recruit bone marrow cells into the stromal compartment or if resident myofibroblasts and fibroblasts derived from marrow contribute to tumor formation because of abnormal signaling behavior.

Adenocarcinoma of the distal esophagus (Barrett's adenocarcinoma) results from reflux-induced mucosal damage followed by healing with a metaplastic intestinal cell lineage. This intestinal metaplasia is prone to malignant degeneration and is another ideal model to test the role of BMDCs in inflammatory-mediated cancers. Using a rat model of Barrett's metaplasia, a significant contribution of BMDCs to the stroma and the metaplastic epithelium has been demonstrated, supporting a role for BMDCs in these pre-neoplastic lesions<sup>[52]</sup>. Though these findings have only been reported in an abstract form so far, this information is especially exciting because it provides evidence of direct BMDC involvement in carcinogenesis from both an additional species (rat) and tissue type (esophagus), providing

further support for our BMDC-epithelial cancer model.

### Human data supporting the BMDC-epithelial cancer model

In human beings, the incidence of solid tumors is significantly increased following bone marrow transplantation<sup>[53]</sup> and may be related to persistent chronic inflammation of graft *vs.* host disease. The data on BMDCs in human cancers, however, have been conflicting. First, it is difficult to examine the contribution of donor marrow to tumor formation in human beings because of a paucity of cell markers to consistently identify autologous BMDCs or donor cells after BM transplantation. The most reliable marker we have to date is identification of the sex chromosomes in sex mismatched transplants. However, there are inherent difficulties with using Y-chromosome identification. X/Y fluorescent *in situ* hybridization (FISH) analysis of archived tumors is estimated to miss more than 50% of Y-positive cells due to sectioning bias, where only a portion of the nucleus and thus only a portion of the chromosomes are included in the tissue section. Additionally, females with a history of carrying a male fetus may show peripheral blood chimerism confounding interpretation of data, and eliminating this population from the study. Also, tumors identified within a short time after transplant may reflect the effects of immunosuppression on previously undetected early malignancy and not newly formed tumors, and may explain why some studies conclude tumors in these patients are host derived<sup>[54]</sup>, while other studies demonstrate a definite contribution of donor's-BMDCs<sup>[55]</sup>. Studies utilizing larger numbers of patients followed for longer periods of time will better address this new and controversial area, and determine if the BMDCs are confined to the stroma, involved in angiogenesis or constitute the epithelial component of the tumor mass in human beings.

In addition to patients receiving bone marrow transplants, recipients of solid organ transplants also have a higher incidence of secondary malignancy. Interestingly, in solid organ transplant recipients, hematopoietic cells of donor origin are often found in the circulation, indicating that hematopoietic stem cells are transferred with the transplanted organ<sup>[56,57]</sup>. These transferred stem cells have been shown to give rise to Kaposi sarcoma (KS), a vascular tumor<sup>[58]</sup>, and skin carcinoma<sup>[59]</sup>. The detected KS lesions occurred distal to the graft site, and formed presumably via mobilization of donor progenitor cells with subsequent transformation at a distant site. Donor-derived stem cells contribute to skin carcinomas, and have been recovered as components of squamous cell carcinoma, basal cell carcinoma, actinic keratosis, keratoacanthomas and benign cutaneous lesions<sup>[59]</sup>, attesting to the great potential for abnormal differentiation of these cells. BMDCs as terminally differentiated cells in other organs including hepatic endothelial cells, hepatocytes and biliary epithelial cells<sup>[60]</sup>, suggesting that these cells may play a role in transformation within these organs as well, if subjected to the appropriate environmental conditions.

### CONCLUSION

One of the greatest and most elusive challenges in cancer biology has been to identify the cellular origin of cancer.

We have identified the bone marrow stem cell as the cell of origin of Helicobacter-induced gastric cancer in a mouse model, radically altering our current view of gastric cancer formation in particular, and of inflammation-mediated cancers in general. The concept of BMDC plasticity is being increasingly recognized and validated by independent groups. Our recent observation that BMDCs are the origin of Helicobacter-induced gastric cancer<sup>[40]</sup> combined with supporting observations of BMDCs in other tumors such as benign and malignant tumors of the skin<sup>[59]</sup>, Kaposi sarcoma<sup>[58]</sup> Barretts' adenocarcinoma of the esophagus<sup>[52]</sup> as well as demonstration of BMDCs as constituents of tumor stroma and tumor vascular structures<sup>[51-55]</sup> suggests exciting approaches for cancer therapy. If the propensity for BMDCs to transform is based on inappropriate regulation of immature growth programs, with growth programs left "turned on" rather than the previously held concept of mutation driven-reactivation of programs, can we target these pathways? Undoubtedly, genetic mutations have occurred which are irreversible; but if we can target and switch off inappropriately activated growth cascades, perhaps we can push these damaged cells into apoptosis or enhance the sensitivity to conventional chemo- and radiotherapy. These approaches may lead to novel and more efficacious cancer therapy.

Presently, our laboratory is involved in identifying the cell population within the bone marrow capable of cancer formation as well as defining the homing and differentiation signals which allow these cells to access to gastric mucosa, and to differentiate as metaplastic and dysplastic cells. Studies designed to determine if fusion is a means of bone marrow cell integration into gastric mucosa and gastric cancer are underway. The applicability of these findings to other epithelial cancers will be tested as well as our ability to control the growth of these cells by manipulations of the local tissue environment. These efforts are aimed at identifying cell-specific targets for chemotherapy. Findings from these studies will radically alter our approach to the treatment of gastric cancer as well as other solid tumors, and offer hope for improved survival and potential cure.

### Abstract

Surgery is currently the only potentially curative treatment for gastric cancer. Since the inception of the gastrectomy for cancer of the stomach, there has been debate over the bounds of surgical therapy, balancing potential long-term survival with perioperative morbidity and mortality. This review delineates the current role of surgery in preoperative staging, curative resection, and palliative treatment for gastric cancer.

### INTRODUCTION

Gastric cancer is one of the most common malignancies in the world and is a leading cause of cancer death. Despite some recent advances in neoadjuvant therapy, studies generally have failed to show any improvement in overall or relapse-free survival following adjuvant therapy. Surgical therapy remains as the most effective modality in treating gastric cancer. The goal of this review is to evaluate the optimal role and impact of surgery in regards to staging, resection of primary, regional and locally advanced disease, and palliation of symptoms in patients with incurable gastric cancer.

### STAGING

Laparoscopy has emerged as an essential staging modality prior to gastric resection, identifying unresectable disease in a significant number of patients deemed resectable by current radiographic and endoscopic modalities. The

diagnostic yield of laparoscopy has been improved by the addition of laparoscopic ultrasound and peritoneal cytology.

Stell *et al*<sup>[1]</sup> compared 103 patients with gastric adenocarcinoma who underwent preoperative staging with ultrasound (US), computed tomography (CT), and laparoscopy. Histologic confirmation was obtained at laparotomy ( $n=65$ ) or with percutaneous liver biopsy during laparoscopy ( $n=27$ ). The sensitivity, specificity, and accuracy of laparoscopy in detecting hepatic metastases ( $n=27$ ) was 96%, 100%, and 99%, respectively. Laparoscopy had a sensitivity of 53%, a specificity of 100%, and an accuracy of 65% in detecting nodal metastasis ( $n=49$ ). Peritoneal metastases were histologically confirmed in 13 patients, and laparoscopy was 69% sensitive, 100% specific, and 94% accurate.

Burke *et al*<sup>[2]</sup> reviewed 103 patients who were deemed free from intra-abdominal metastases by CT scan and subsequently underwent laparoscopy. A control group who underwent laparotomy for possible gastric resection and subsequently found to have M1 disease was also reviewed. Laparoscopy accurately staged 94% of these patients. Histologic evidence of metastasis was obtained in 32 patients during laparoscopy. Of the 71 patients who were M0 by laparoscopy, 65 were confirmed by laparotomy. Of the six false negatives, three were missed peritoneal metastases, and three were missed distant nodal metastases, two of which were identified after resection. Of the 32 patients who were M1 on laparoscopy, 4 had chemotherapy followed by resection, 3 had further palliative procedures, and 1 had a mini-laparotomy for additional specimen. The remaining 24 patients went on to have no further operation. When comparing these 24 patients to the control group of 60 patients with M1 disease on laparotomy, the hospital stay was significantly shorter. There was one complication in the laparoscopy group and eight in the laparotomy group; however, this did not reach significance. The authors concluded that laparoscopy is a valuable staging tool that can spare patients with asymptomatic M1 disease a laparotomy, and identify those patients who may benefit from neoadjuvant therapy.

The addition of laparoscopic US has improved the yield of laparoscopy for staging gastric cancer. Hulscher *et al*<sup>[3]</sup> reviewed the utility of laparoscopic US in staging 48 patients with gastric carcinoma of the cardia and esophageal invasion. All of these patients were staged with endoscopic US, percutaneous US of the neck and abdomen, conventional chest radiograph and bronchoscopy if there was extensive proximal invasion. Metastatic

disease was detected and histologically confirmed in 11 patients (23%), 7 detected with laparoscopy alone, and an additional 4 detected by laparoscopic US. Of the patients who went on to laparotomy, two were found to have posterior liver metastases, and two to have unresectable lymph nodes at the base of the celiac axis. Three of these four lesions were detected laparoscopically, but were either not amenable to biopsy due to position, or were negative on laparoscopic biopsy. The authors concluded that laparoscopy is a valuable staging tool for gastric adenocarcinoma of the cardia, and that the addition of US increases the yield, avoiding laparotomy in 23% of patients.

Peritoneal cytology obtained at laparoscopy has proven to be a predictor of post-operative mortality in patients undergoing curative (R0) resection. Bentrem *et al*<sup>[4]</sup> reviewed 371 patients who underwent staging laparoscopy with peritoneal washings and subsequent R0 resection as a combined procedure. Twenty-four patients (6%) had positive cytology, defined as the presence of adenocarcinoma cells, regardless of quantity. Positive cytology without evidence of macroscopic M1 disease was associated with advanced preoperative T stage and advanced AJCC stage, but not preoperative N stage. The median survival for patients with positive cytology was 15 mo, compared to 98.5 mo for those with negative cytology. On multivariate analysis, preoperative T stage, preoperative N stage, primary tumor site, and peritoneal cytology were significant predictors of survival, with positive cytology showing the highest risk ratio. The authors have altered their practice in response to this information, performing staging laparoscopy as a separate procedure in patients considered high risk (T3/4 and AJCC stage II/III). Those patients found to have positive cytology were then referred for chemotherapy followed by possible resection with intraperitoneal chemotherapy.

Laparoscopy and laparoscopy US are currently accepted as standard pre-operative staging tools. Laparoscopy is significantly more accurate than US and CT in detecting hepatic, nodal and peritoneal metastases. Reports suggest minimal added morbidity and no mortality from laparoscopy. Peritoneal cytology is not widely accepted as a screening tool; however, this is a topic of growing research interest.

## EXTENT OF GASTRIC RESECTION

### *Distal gastric adenocarcinoma*

The extent of gastric resection for distal lesions had been debated, and the traditional view that total gastrectomy (TG) is required for all gastric lesions has been challenged. Gouzi *et al*<sup>[5]</sup> conducted a multicenter randomized trial comparing TG to subtotal gastrectomy (SG) enrolling 169 patients with resectable lesions of the gastric antrum. Patients with macroscopic lymph node involvement of the cardioesophageal or splenopancreatic region were excluded from the study. TG consisted of TG with Roux-en-Y esophagojejunostomy. Splenectomy was not routinely performed; however, the TG group had an unspecified higher splenectomy rate than the SG group. SG consisted of a distal gastrectomy and Billroth II gastrojejunostomy.

Both procedures included a total omentectomy, and lymph node dissection extended to the pyloric, left gastric, hepatic, and cardiac nodes. The groups were well matched for tumor size, extent of invasion, and lymph node stage. There was a post-operative mortality of 2.4%, with three deaths in the SG group and one death in the TG group. The non-lethal complication rate was 33% in the TG group and 34% in the SG group. Lymph node involvement and serosal extension were significantly associated with 5-year survival; however, extent of resection was not. The authors concluded that TG or SG could be performed with equal morbidity and mortality, but that TG offered no added survival benefit. A major criticism of this study was that it was underpowered to detect a difference between the groups, as 200 patients were originally calculated to show a difference of 20%.

In a larger trial, Bozzetti *et al*<sup>[6]</sup> also performed a randomized trial comparing TG to SG in 618 patients with resectable tumors at least 6 cm from the cardia. Patients were enrolled if they had tumors of the distal half of the stomach without evidence of metastatic disease, were under 75 years of age and in good health, and had no previous gastric resection or chemotherapy. Patients were further assessed at laparotomy for a minimum distance from the tumor to the cardia and no evidence of peritoneal, D3 lymph node metastasis or extension into adjacent organs. Patients were randomized intra-operatively to TG or SG. Both operations were performed with a D2 lymphadenectomy. Splenectomy was left to the discretion of the operating surgeon. Patients were then followed regularly for a median follow-up of 72 mo in the SG group and 75 mo in the TG group. Five-year survival was 65.3% in the SG, and 62.5% in the TG group, suggesting that type of resection had no influence on the survival. Site of tumor, wall invasion, extension of surgery including splenectomy, and relative frequency of metastatic lymph nodes were significant predictors of survival. Given the lack of survival benefit, the authors concluded that SG was the preferred operation for distal gastric cancer, provided that a proximal margin of at least 6 cm could be obtained, because it is technically less demanding, results in a lower splenectomy rate, and is associated with better quality of life (QOL).

QOL is a very important outcome after gastrectomy. For tumors of the distal stomach, given the current data suggesting equivalent morbidity and survival for TG and SG, the procedure with the best QOL profile is preferred. Davies *et al*<sup>[7]</sup> compared the QOL of patients following TG to those after SG. These authors compared 46 patients who had undergone an R0 resection. Twenty-six underwent TG and 21 underwent SG. Five questionnaires were used: the Rotterdam symptoms checklist, the Troidl index, the hospital anxiety and depression scale, the activities of daily living score, and the Visick grade. Patients were questioned before the operation and at 1, 3, 6, and 12 mo. There was no difference in QOL prior to the operation or at 1, 3 or 6 mo; however, patients undergoing SG had a significantly higher QOL at 1 year. The authors thus concluded that, given equivalent survival, SG is the operation of choice for tumors of the distal stomach.

Based on data that accrued in prospective, randomized

trials, it is now accepted that SG is an appropriate oncologic operation for distal adenocarcinoma.

### Proximal gastric adenocarcinoma

The extent of resection needed to achieve cure in tumors of the gastroesophageal junctions has been a topic of much debate. Ito *et al*<sup>[8]</sup> reviewed patients with Siewert type II or III carcinoma of the gastric cardia in an attempt to discern the optimal surgical approach. Eighty-two patients were included in the study, 59 with type II and 23 with type III lesions. The surgical approach varied, with 33% undergoing total esophagectomy, 29% undergoing extended gastrectomy with thoracotomy, and 38% undergoing extended gastrectomy without thoracotomy. There was no significant difference in the type of procedure between type II and III lesions. There was no significant difference in post-operative mortality; however, there was a higher post-operative morbidity associated with total esophagectomy as compared to extended gastrectomy with or without thoracotomy (33% *vs* 11%). The addition of a thoracotomy to extended gastrectomy did not have an impact on post-operative morbidity (13% *vs* 10%). There was a significantly higher incidence of microscopic residual disease at the proximal margin in the extended gastrectomy group with or without thoracotomy as compared to the total esophagectomy group (38% *vs* 7%). The mean follow-up was 34 mo and 5-year survival for the entire group was 33%. Multivariate analysis revealed that patient's age over 65, lymph node metastases, and absence of an R0 resection were adversely associated with survival. There was no survival difference between the different types of resection despite a higher incidence of positive proximal margins in the extended gastrectomy group. Based on these results, showing R0 status and nodal status to be predictors of survival, the authors made the following recommendations: (1) A minimum proximal margin of 6 cm and distal margin of 4 cm should be obtained. (2) A minimum of 15 lymph nodes should be sampled. The type of surgical approach should be tailored to fit the individual patient with these goals in mind.

TG is the traditional treatment for proximal gastric cancer; however, this has been recently challenged as well. Harrison *et al*<sup>[9]</sup> reviewed 98 patients with proximal gastric cancer who underwent gastric resection via an abdominal approach, excluding all patients who underwent esophagogastrectomy. Of these 98 patients, 65 underwent proximal gastrectomy (PG), and 33 underwent TG. There was no difference in post-operative mortality (6% *vs* 3%). Post-operative morbidity data was not analyzed; however, there was no difference in the length of hospital stay. There was no significant difference in time to recurrence or first site of recurrence. The 5-year survival rate was not significantly different between the TG and PG groups with a mean follow-up of 30 mo (43% for PG *vs* 41% for TG). The authors concluded that either procedure can be performed safely without sacrificing long-term survival.

The optimal approach for carcinoma of the gastroesophageal junction or gastric cardia is still a topic of debate. The over-riding factor, regardless of the type of resection, is the ability to obtain a margin-negative resection.

## EXTENT OF LYMPH NODE DISSECTION

The extent of lymphadenectomy is one of the most controversial topics in gastric cancer surgery. The Japanese developed an extensive classification system for the regional lymph nodes and a systematic method of dissection referred to now as the D2 resection. This method is described in detail by Maruyama *et al*<sup>[10]</sup>, who also reviewed the Japanese National Cancer Center experience with gastric resection over the period from 1963 to 1985. The authors reported an improvement over this time span in 5-year survival for resected patients from 44.3% to 61.6%. Most of this improvement was attributed to early gastric cancer screening established at a national level; however, they do report an increase in survival over this time period with respects to specific stage, T stage, and N stage.

Shiu *et al*<sup>[11]</sup> reviewed the results of gastric resection and lymphadenectomy for gastric cancer at Memorial Sloan Kettering Cancer Center over a 20-year period. They analyzed the outcomes of 210 patients and attempted to identify risk factors for mortality. On multivariate analysis, they identified non-pyloric tumor site and greater than three positive lymph nodes as pathologic risk factors. They also identified positive microscopic margins, inadequate lymphadenectomy, and TG as independent surgical risk factors for mortality. Adequate lymphadenectomy was defined as one and a half lymph node levels beyond the furthest level of lymph node disease. For example, patients with N0 disease would require a dissection including the N1 and part of N2 nodes.

This data from a Western center as well as the Japanese data were cited to justify extended lymphadenectomy, a practice which was not commonplace in the West. Multiple clinical trials were performed to look at the morbidity, mortality, and long term survival of a D2 dissection in Western centers.

The best known trial to evaluate lymphadenectomy was from the Dutch Gastric Cancer Group. Bonenkamp *et al*<sup>[12]</sup> published their results from a randomized controlled trial comparing D1 and D2 gastrectomy in 80 Dutch hospitals over 5 years. D1 resection was defined as containing only the N1 (perigastric) nodes. D2 resection was defined as encompassing the N2 nodes. The spleen and distal pancreas were resected in 11 (3%) of D1 resections and 30 (37%) of D2 resections. The type of gastrectomy, TG *vs* SG, as well as the method of reconstruction were left to the preference of the surgeon. Surgeons were instructed in the technique with video classes, and eight visiting Japanese surgeons were present to supervise all D2 resections. Seven hundred and seven patients underwent resection with intention to treat, and 632 were found to have an R0 resection, and thus followed for evidence of recurrence. These authors reported a statistically significant difference in post-operative mortality (4% *vs* 10%) and complication rate (25% *vs* 43%) for D1 *vs* D2 resection. The 5-year survival rate was 45% for the D1 group and 47% for the D2 group, which was not statistically significant. The 5-year risk of relapse was 43% in the D1 group and 37% in the D2 group, which also was not statistically significant. Subgroup analysis, however, showed that in patients who

did not require splenectomy or pancreatectomy, there was a significantly lower 5-year risk of relapse. The conclusions drawn from this article were that D2 lymphadenectomy was associated with a higher morbidity and mortality without offering a long-term survival benefit, and thus it was not recommended. The sub-group analysis also questioned the benefit of distal pancreatectomy or splenectomy.

A concomitant British trial was also performed over the same time period. Cuschieri *et al*<sup>[13]</sup> reported the results of a randomized study comparing D1 to D2 resections. Four hundred patients were randomized. In this trial a D1 resection consisted of the removal of all lymph nodes within 3 cm of the tumor and D2 resection consisted of the standard resection of the omental bursa, the hepatoduodenal nodes for antral lesions and the splenic artery, splenic hilar, and retropancreatic nodes by distal pancreatectomy for middle and upper third lesions. They reported similar post operative morbidity and mortality data to that of the Dutch study for the D2 resection group, and showed no difference in the 5-year survival (35% *vs* 33%) or risk of recurrence. As in the Dutch trial, the British trial showed that resection of the spleen and pancreas was independently associated with decreased survival.

Both of these large randomized studies showed no benefit from a D2 resection; however, each also raises the question: is there a role of D2 resection without pancreatico-splenectomy? Two current studies attempt to answer that question.

Edwards *et al*<sup>[14]</sup> compared D1 resection to D2 resection sparing the pancreas and spleen in a total of 118 patients. The study was not randomized, as one surgeon performed all the D1 resections (*n* = 36) at one hospital and the other surgeon performed all the D2 resections (*n* = 82) at another hospital in the same region of Wales. Splenectomy and pancreatectomy were performed only for evidence of direct invasion of tumor. They reported similar operative mortality (8.3% *vs* 7.3%) and a significant 5-year survival advantage for the D2 resection group (32% *vs* 59%), which was most evident in the patients with stage III disease (8% *vs* 33%). Extent of lymphadenectomy was independently associated with increased survival on multivariate analysis. The authors concluded that a modified D2 resection sparing resection of the pancreas and spleen offers a survival advantage over a D1 resection with no increase in short-term morbidity or mortality.

Recent phase II data from a multicenter trial conducted in Italy showed acceptable morbidity and mortality with good 5-year survival following pancreas-preserving D2 resection<sup>[15]</sup>. The Italian Gastric Cancer Study Group enrolled 191 patients, and pancreas-preserving D2 resection was performed with an operative mortality of 3.1%, morbidity of 20.9%, and 5-year survival rate of 55%. These numbers compare favorably to the Japanese experience, and suggest that pancreas-preserving D2 may offer a survival benefit; however, the randomized comparison to D1 resection has not yet been performed.

Data from Japan concerning mortality and 5-year survival after gastrectomy had been criticized for being retrospective in nature. A D1 gastrectomy is considered

as a non-curative operation in Japan; thus, it would not be performed in any randomized trial. Sano *et al*<sup>[16]</sup> are conducting a randomized trial comparing standard D2 resection to extended para-aortic lymphadenectomy. This is the first randomized prospective study to come from Japan. The selection criteria of the surgeons and the selected centers should be mentioned. Only surgeons with over 100 D2 gastrectomies, and only centers with over 80 gastrectomies a year were selected for the trial. This is in stark contrast to the Dutch and British trials which did not require a set training period to master the “learning curve” of the procedure. The spleen was resected in all the cases where TG was performed, and the pancreas was resected only in cases of direct invasion. The morbidity and mortality data for this trial have been released. The overall morbidity of a D2 resection was 20.9%, with a mortality of 0.8%. The conclusions that can be drawn from this study, pending the 5-year survival data, are that D2 resection can be performed at specialized centers by surgeons with ample experience with low morbidity and mortality.

Based on the current data, it appears that a modified D2 lymphadenectomy, sparing the spleen and pancreas when possible, can be performed safely and may offer the best chance for long-term survival; however, the randomized controlled data to support this argument is currently in progress.

## EXTENDING RESECTION TO ADJACENT ORGANS

D2 resection with splenectomy and distal pancreatectomy was performed by many centers in Japan to facilitate dissection of lymph nodes around the splenic artery with early reports suggesting improved survival<sup>[10]</sup>. The utility of extended resection was later called into question by many Japanese and Western surgeons. Otsuji *et al*<sup>[17]</sup> reviewed 128 patients who underwent TG for gastric adenocarcinoma of the middle or proximal stomach. Of these, 35.9% underwent pancreaticosplenectomy, 44.6% splenectomy, and 19.5% gastrectomy alone. Pancreaticosplenectomy increased the risk of pancreatic fistula significantly. Five-year survival for the pancreaticosplenectomy group, the splenectomy group and the gastrectomy alone group were 40.7%, 55.9%, and 54.2%, respectively; however, on multivariate analysis pancreaticosplenectomy and splenectomy alone were not independently associated with survival. The conclusions drawn from this study were that extension of TG to include pancreaticosplenectomy or splenectomy increases the risk of complications without improving survival.

Kasakura *et al*<sup>[18]</sup> reviewed 1 938 gastric resections over 18 years and also concluded that splenectomy and distal pancreatectomy do not have an impact on survival and are associated with an increased incidence of complications. Of these 1 938 patients, 78 underwent splenectomy (S), 105 underwent splenectomy/pancreatectomy (PS), and 1 755 underwent gastrectomy alone. The PS and S groups were associated with a higher percentage of proximal tumors and TG, higher T stage, higher N stage, and worse histologic grade. There were more severe post-operative

complications in the PS and S groups over the gastrectomy alone group, with a higher rate of pancreatic fistula, intra-abdominal abscess, and anastomotic leak. There was also a higher rate of local recurrence in the S and PS groups. When analyzed by UICC stage; however, no difference in 5-year survival for stage II, III, or IV tumors was detected. Gastrectomy alone was found to have higher 5-year survival for T2 tumors; however, for T3 and T4 tumors, there was no difference. Conclusions from this study were that long-term survival is not affected by splenectomy or pancreatectomy and these procedures should not be performed solely to aid in lymph node dissection. The spleen should only be resected when there are clearly positive lymph nodes in the splenic hilum and around the splenic artery, and the pancreas should only be resected when there is direct invasion of tumor.

Resection of adjacent organs for local invasion was advocated in the early Japanese literature<sup>[10]</sup>; however, this practice also has been analyzed extensively in the past decade. Shchepotin *et al*<sup>[19]</sup> reviewed 353 patients with T4 gastric cancer who underwent gastrectomy combined with resection of adjacent organs. Of these patients, 89% had histologically confirmed invasion. TG was performed in 32.9% of patients and SG in 67.1%. The extent of lymph node dissection was the same in all patients, consisting of dissection of all perigastric nodes, nodes along the celiac axis, hepatic artery, and proximal splenic artery. The transverse colon was resected in 45%, the tail of the pancreas and spleen in 42.5%, the left hepatic lobe in 28.5% and the head of the pancreas in 10.5%. The complication rate was 31.2%, and mortality rate was 13.6%. Combined 5-year survival was 25%; however, when this was broken down into node positive or node negative T4 lesions, 5-year survival changed significantly. Node negative T4 patients had a 37% 5-year survival, whereas node positive T4 patients had only a 15% survival. From these data, the authors continued to advocate extended resection of adjacent organs in the resection of gastric cancer for cure.

Martin *et al*<sup>[20]</sup> showed that extended organ resection could be performed with acceptable morbidity (4%) and 5-year survival (32%). Two hundred and sixty-eight patients with locally advanced gastric cancer underwent gastrectomy with adjacent organ resection and D2 lymphadenectomy. The type of gastrectomy was variable; however, there was a higher incidence of adjacent organ resection in the TG group. Spleen alone was the most common resection ( $n=123$ ), followed by spleen/pancreas ( $n=38$ ), spleen/colon ( $n=18$ ), pancreas alone ( $n=12$ ), and colon alone ( $n=16$ ). As would be expected, there was a higher percentage of T3/T4 tumors and N2/N3 lymph node metastases in the organ resection group. Perioperative mortality was not significantly different, 3.6% in the gastrectomy group and 3.7% in the gastrectomy with organ resection group. There was a higher rate of recurrence in the gastrectomy with organ resection group (52% *vs* 42% at 24 mo follow-up), and significantly lower median survival (32 mo *vs* 63 mo) on univariate analysis. On multivariate analysis, however, only T-stage, N-stage and overall stage were predictors of survival. The authors concluded that resection of adjacent organs is important

to achieve an R0 resection and can be done with minimal morbidity; however, careful selection of clinically T4 tumors should be performed to limit unnecessary organ resection in early stage gastric cancer.

Resection of adjacent organs in conjunction with gastrectomy can increase survival with minimal additional morbidity in a highly selected patient population.

## POSITIVE MARGINS

Patients with recurrence after resection of gastric cancer uniformly have a rapid decline. The risk factors for recurrence, and the rate and pattern of recurrence has been examined. In a recent retrospective review of 367 patients who underwent an R0 resection with subsequent recurrence, the rate and pattern of recurrence was examined<sup>[21]</sup>. The majority of the patients (65%) had T3 lesions, 46% had N1 nodal disease, and 54% were AJCC stage III. The type of gastric resection was highly variable, with the highest percent being esophago-proximal resections (45%). The extent of lymphadenectomy was also variable, with the majority being D2 (68%). The rate of locoregional, peritoneal, and distant metastases was 54%, 51%, and 29% respectively, with significant overlap of these three. Seventy-nine percent had recurred within two years and 94% by four years. The median time to death from diagnosis of recurrence was 6 mo. The pattern of recurrence was not associated with survival time; however, T stage, N stage, age and presentation with symptoms were all predictors of decreased survival. Advanced T stage, distal location, diffuse Lauren's subtype, and female gender were significantly associated with peritoneal metastases. Proximal location and male gender were associated with locoregional recurrence. Proximal location, early T stage, and intestinal Lauren's subtype were associated with distal recurrence. There was no significant pattern of recurrence associated with overall stage, extent of lymphadenectomy, nodal status, or extension of resection to adjacent organs.

There is no surgical therapy for recurrent gastric cancer; however, the question of re-excision for positive margins at primary resection has been raised. Survival for patients with microscopically positive margins has been shown to be significantly shorter than those with clear margins<sup>[25]</sup>. In a recent review of 259 patients who underwent gastrectomy with curative intent, 22 had microscopically positive resection line margins<sup>[22]</sup>. Positive margins were associated with tumor location and differentiation. There was a significantly lower 5-year survival for the patients with positive margins (18% *vs* 45%); however, when this was stratified for lymph node status, the patients with positive lymph nodes had a significantly lower survival. The authors concluded that, given the very poor prognosis associated with positive margins, re-laparotomy may be justified in those patients with node-negative disease.

## PALLIATIVE SURGERY FOR GASTRIC CANCER

Despite improved clinical outcomes associated with earlier diagnosis, more accurate staging, and decreased surgical morbidity and mortality, the overall prognosis of gastric

cancer remains poor because many patients are incurable at presentation. A complete R0 resection remains the most powerful indicator of survival, but is obtained in only 50% of those presenting for resection of a primary gastric cancer<sup>[20,23]</sup>. For those patients who present with stage IV disease, cure measured by 5-year survival is exceedingly rare and is not a realistic treatment goal<sup>[2,24-32]</sup>. Because of the low cure rate and the advanced stage at which many patients present, palliative strategies and symptom management remain an essential component in the total care of the patient with gastric cancer<sup>[33]</sup>.

Palliation of symptoms caused by any advanced cancer demands the highest level of surgical judgment. Although an important part of the surgical decision making process requires consideration of risk in terms of treatment-related toxicity, morbidity, and mortality, attention to this element should not be the predominant factor in making decisions about palliative therapy. Decisions are made best on endpoints such as the probability and durability of symptom resolution, the impact on overall QOL, and pain control. Deliberations must consider the medical condition and performance status of the patient, the extent and prognosis of the cancer, the availability and success of non-surgical management, cost effectiveness and the individual patient's quality and expectancy of life. Knowledge about the need to repeat a specific therapy or requirements to manage additional symptoms can give further information about the potential for symptom-free survival and what additional care will be needed. Therapy for symptoms must remain flexible and individualized to continually meet the patient's unique and ever changing needs<sup>[34-36]</sup>. Surgical palliation of advanced gastric cancer may include resection or bypass, alone or in combination with endoscopic or percutaneous interventions. Such interventions have been proposed not only to improve symptom control, but also to eliminate potential complications (bleeding, obstruction, pain, perforation, and debilitating ascites) caused by the primary tumor<sup>[37,38]</sup>.

In 1958, Lawrence and McNeer demonstrated that palliative gastric resections effectively relieve symptoms in patients with incurable gastric cancer. Because of high rates of associated perioperative morbidity and mortality and the brief period of anticipated survival, however, the authors suggested that a TG in patients with incurable gastric cancer was rarely a worthwhile palliative procedure<sup>[39]</sup>. This conclusion was supported by Remine in 1979 who also suggested that TG was not a satisfactory palliative operation<sup>[40]</sup>. Later series, however, showed improved symptom relief with gastrectomy compared to gastroenterostomy, without increasing complication rates<sup>[41,42]</sup>. Others have based their support for palliative gastric resections primarily on improved survival data and have proposed that it should be performed whenever technically possible<sup>[43,44]</sup>. Because of decreasing perioperative complications, some authors now suggest that total palliative gastrectomy and esophagogastrectomy is justified in selected patients<sup>[45-49]</sup>.

The effective and appropriate use of palliative surgical interventions in patients with gastric cancer remains controversial. Recommendations from the literature are contradictory and often based on the retrospective

evaluation of suboptimal data. A highly variable and imprecise understanding of the goals and indications of palliative surgery, poorly defined patient groups, and a reliance on inappropriate endpoints contributes to this confusion. The designation of patients as "palliative" is commonly based on the extent of disease (ranging from gross disease at operation to postoperative margin status) rather than a sound definition encompassing factors associated with good palliative therapy. Even though the value of a palliative procedure should be judged by its ability to control symptoms, reports often fail to utilize validated QOL or pain assessment instruments and rarely consider the durability of potential palliative benefits<sup>[25]</sup>. These factors limit useful interpretation of most prior studies on palliative procedures for gastric cancer. The impact of such deficiencies in the literature has been demonstrated by a recent analysis of the Memorial Sloan-Kettering Gastric Cancer Database. Important differences among the patients undergoing a non-curative gastric cancer were demonstrated when a sound and reproducible definition of palliative surgery was applied. Significant differences between overall survival, primary tumor sites, staging, degrees of nodal and metastatic disease, and the types of procedures performed support the differentiation between palliative and non-palliative designations<sup>[49]</sup>.

Conclusions over the effectiveness of palliative operations in the gastric cancer literature are often based, incorrectly, on incremental survival differences. Caution must be taken when evaluating survival data in patients following a palliative intervention. Palliative care ideally selects treatment that will maximize QOL and minimize complications. Consideration of anticipated survival helps to define a period during which the requirements of effective symptom control must be met and may be useful when considering the risk-benefit ratio for an individual patient<sup>[50,51]</sup>. Although increased survival may be a secondary goal of a palliative procedure, it is inappropriate to select a palliative procedure solely based on improved duration of survival<sup>[36]</sup>. Based on patients grouped by extent of disease rather than palliative intent, The Dutch Gastric Cancer Group has suggested that differences in overall survival following "palliative" gastric resections may be beneficial in patients with tumor load restricted to one metastatic site<sup>[52]</sup>. Such conclusions about the value of palliative gastrectomy are premature because they fail to consider the associated risks, benefits, and expected durability of the procedure<sup>[33,49]</sup>.

To compare the impact of potentially achievable gains associated with palliative surgery, non-curative gastrectomies were analyzed with a partitioned survival analysis<sup>[33,53]</sup>. The technique, which has been generally used to evaluate chemotherapy trials, analyzes treatment by defining relevant clinical health states and comparing their duration with regard to treatment, toxicity and relapse. The analysis provided by this methodology is well suited to evaluate surgical palliation, especially in conditions such as gastric cancer, in which treatment-related toxicity plays such an important role in both the literature and in clinical decision-making<sup>[33,54]</sup>. Palliative gastric resections previously have been associated with considerable operative morbidity (54%) and mortality (6%)<sup>[49]</sup>. Duration in the time without

symptoms or toxicity (TWiST) state was found to be significantly decreased (8.5 mo *vs* 2.1 mo,  $P=0.04$ ) in patients experiencing a major postoperative complication (requiring invasive interventions, unplanned ICU admission, or permanent disability). Complications have a considerable influence on the patients' limited survival by not only increasing time in a hospitalized setting but also by diminishing the QOL. Concerns about potential complications such as bleeding, obstruction or perforation have led some to propose prophylactic gastric resections in patients with advanced, asymptomatic gastric cancer. Sarela *et al* have shown in patients with known metastatic disease identified on laparoscopy; however, that complications requiring emergency or urgent palliative operations were rare in patients not receiving a prophylactic resection for incurable gastric cancer<sup>[55]</sup>.

Since palliative gastrectomies are associated with significant perioperative morbidity and mortality, the authors recommend deliberate palliative resection only in carefully selected patients with severe symptoms<sup>[34,50,54,55]</sup>.

### Abstract

Gastric cancer is one of the most common tumors worldwide. The therapeutic outcome of conventional therapies is inefficient. Thus, new therapeutic strategies are urgently needed. Gene therapy is a promising molecular alternative in the treatment of gastric cancer, including the replacement of defective tumor suppressor genes, the inactivation of oncogenes, the introduction of suicide genes, genetic immunotherapy, anti-angiogenic gene therapy, and virotherapy. Improved molecular biological techniques and a better understanding of gastric carcinogenesis have allowed us to validate a variety of genes as molecular targets for gene therapy. This review provides an update of the new developments in cancer gene therapy, new principles, techniques, strategies and vector systems, and shows how they may be applied in the treatment of gastric cancer.

### INTRODUCTION

Gastric cancer is the fourth most common malignancy worldwide with an estimated 934 000 new cases that was reported in 2002 and the second most common cause of death from cancer (700 000 deaths annually). Almost two-thirds of the cases occur in developing countries and 42% in China alone<sup>[1]</sup>. The prognosis of gastric cancer is poor with an estimated relative 5-year survival rate of less than 20%<sup>[2]</sup>. The efficacy of current therapeutic approaches such as surgery, hormone, radio- and chemotherapy is

limited. Thus, new therapeutic approaches are urgently needed. Cancer is an acquired genetic disease developing in a multi-step process. Mutations of genes related to growth control, apoptosis, invasion and metastasis form the molecular genetic basis of malignant transformation and tumor progression<sup>[3]</sup>. The characterization of dysregulated genes like the tumor suppressor p53, which are critical for carcinogenesis, and a better understanding of the molecular basis for tumor-host interaction led to significant progress in the development of new therapeutic agents. More than 15 years ago, gene therapy emerged as a new therapeutic approach and has meanwhile become an important strategy in cancer treatment. Cancer is by far the most frequent of all indications addressed by gene therapy (60% of all clinical trials<sup>[3]</sup>), underlining the expectations raised by this new therapeutic option. The original concept of cancer gene therapy was further developed into two branches as a result of different strategies of therapeutic benefit: molecular cancer therapy and virotherapy. Molecular cancer therapy can be defined as a therapeutic technique, which aims at the introduction of nucleic acids into cancer patients' cells in order to modulate the gene expression profile of the target cells and thereby eradicate the tumor<sup>[4]</sup>. In contrast, virotherapy is a new concept of gene therapy that uses replication-competent oncolytic viral vectors (OVV) with viro-oncolytic potency for targeted tumor cell destruction<sup>[5]</sup>.

There are different ways to modulate tumor growth by gene therapeutic strategies. These include direct destruction of tumor cells, inhibition of tumor angiogenesis and tumor cell spread and activation of the host immune response against the tumor. Although all these approaches showed promising anti-tumor effects in pre-clinical investigations, clinical trials have often been disappointing, since they demonstrated only slight therapeutic benefit. Thus, a major breakthrough is still needed in gene therapy of cancer. Nevertheless, clinical trials proved the relative safety of human cancer gene therapy. The application of vectors and the expression of transgenes are generally well tolerated and the low risk of severe side effects seems to be calculable.

The main problem of the relative inefficiency of cancer gene therapy continues to be the low *in vivo* efficiency of gene delivery into the target tumor cells, leading to low expression of therapeutic genes and thus limited curative effects. Several factors seem to be responsible for this, among them the presence of anatomic barriers inhibiting the efficient transfer of vectors from circulation to target cells and the low expression of vector-specific target receptors on the cancer cells causing reduced

cellular uptake of viral vectors. Moreover, immunological responses of the host against the vectors and the rapid clearance of vectors from circulation after intravascular administration may be important factors preventing efficient gene transfer<sup>[6-8]</sup>. In the last few years, great efforts have been made to overcome these limitations. Especially the development of OVV<sup>[9]</sup> and vectors with enhanced tumor-specific targeting<sup>[10,11]</sup> together with improved vector application protocols have led to a significant enhancement of vector-mediated gene delivery. Furthermore, the use of new powerful molecular techniques like RNA interference (RNAi)<sup>[12]</sup> and the detection of new target genes are hopeful signs for improving human cancer by gene therapy. In the present paper, we review new trends in gene therapy and update their application in gastric cancer.

## TUMOR SUPPRESSOR GENES

The most obvious way to target growth regulation in cancer cells is to introduce tumor suppressors that may be inactivated in tumors. The replacement of p53, which is the most commonly inactivated tumor suppressor and mutated in about 60% of human gastric cancers, has emerged as an attractive treatment option, both alone and combined with conventional chemotherapy<sup>[13,14]</sup>. Introduction of the p53 gene via a recombinant adenovirus has been shown to inhibit the growth of gastric cancer cells with mutated p53 *in vitro* and *in vivo*<sup>[15,16]</sup>. The pro-apoptotic function of p53 depends on the transactivation of genes such as Bax, Apaf-1, Fas, and PTEN, whose own expression or activity may be abnormal in tumor cells<sup>[17]</sup>. Consequently, the Bax gene may serve as a good alternative to p53 for cancer gene therapy, not only because it has been shown to kill cancer cells irrespective of their p53 status, but also because it may increase their sensitivity to other anti-tumor treatments<sup>[18]</sup>. Moreover, the adenoviral expression of the initiator caspase-8 leads to the selective induction of apoptosis in detached gastric tumor cells *in vitro* and *in vivo*, thus displaying anti-metastatic potential in gastric cancer<sup>[19]</sup>. All these signaling molecules work through a common pathway involving activation of the effector caspase 3. Thus, recombinant expression of caspase 3 leads to the induction of apoptosis in gastric cancer cells<sup>[20]</sup>. Moreover, the introduction of wild-type p16INK4A, another tumor suppressor and cell cycle regulator in gastric cancer cells harboring a p16 mutation, may also be a feasible approach to efficient tumor growth control and chemosensitization<sup>[21]</sup>. Finally, the replacement of Fhit, a tumor suppressor often inactivated in gastric cancer, decreases sensitivity to carcinogens and induces apoptosis in gastric tumor cells *in vivo*. Therefore, restoring Fhit expression by viral transduction may be a promising strategy for both the prevention and therapy of gastric tumors<sup>[22]</sup>.

## SUICIDE GENES

This strategy relies on the conversion of non-toxic substances (prodrugs) into physiologically active agents by means of non-mammalian enzymes. These suicide enzymes are over-expressed in neoplastic cells as a

result of successful transfection with their genes<sup>[23]</sup>. The most widely used suicide gene/prodrug system is the herpes simplex virus (HSV) thymidine kinase (HSV-tk)/ganciclovir (GCV) system that can convert the prodrug GCV into phosphorylated GCV. The phosphorylated GCV inhibits cellular DNA synthesis and leads to the killing of cancer cells via apoptotic and non-apoptotic mechanisms<sup>[24,25]</sup>. One of the powerful features in these systems is the “bystander effect”, the mechanism by which the toxic metabolites are transferred from transduced cells to neighboring cancer cells via gap junctions or apoptotic vesicles. The bystander effect drastically enhances the tumor-killing capacity of the HSV-tk/GCV system<sup>[26,27]</sup>. Several studies were undertaken to evaluate the potential of suicide gene therapy in gastric cancer. In alpha-fetoprotein (AFP)-producing gastric tumors, the adenovirus-mediated expression of HSV-tk by an AFP enhancer/promoter element selectively eliminated AFP-positive, but not AFP-negative cell lines when treated with ganciclovir<sup>[28]</sup>. This approach may be a promising tumor-selective treatment option for AFP-positive gastric tumors with a very poor prognosis. A similar approach involves the expression of recombinant *E. coli* cytosine deaminase (CD) in gastric cancer cells together with the administration of 5-fluorocytosine (5-FC). 5-FC is given orally and converted to 5-fluorouracil in the tumor cells expressing CD. In attempts to increase the specificity of suicide gene therapy, CD expressed from gastric cancer cell-specific promoters SEL1L and TP1 was shown to cause efficient cytotoxic effects in combination with 5-FC<sup>[29]</sup>. An earlier attempt with tumor-specific and more efficient CD/5-FC gene therapy was carried out using the Cre/loxP regulation system. Ueda *et al.*<sup>[30]</sup> constructed an adenovector-expressing Cre recombinase from a carcinoembryonic antigen (CEA) promoter and a second vector expressing CD under the control of the CAG promoter. The double infection with both vectors rendered CEA-producing gastric cancer cells 13 times more sensitive to 5-FC than the single infection with a vector expressing CD from the CEA promoter. Consequently, anti-tumor efficacy *in vivo* was also significantly enhanced by using the Cre/loxP system compared to the single infection with the vector directly expressing CD under the control of the CEA promoter. Finally, recombinant expression of the bacterial enzyme nitroimidazole reductase gene together with the administration of the prodrug CB1954 was evaluated in a phase I and pharmacokinetic study with the intention of treating gastric cancer<sup>[31]</sup>.

## ANTI-ANGIOGENESIS GENE THERAPY

Tumor angiogenesis plays an important role in the growth of solid tumors and the formation of metastases. Angiogenesis is a multi-level process including endothelial cell proliferation, migration, basement membrane degradation, and lumen reorganization. It is stimulated by several factors secreted from both host and tumor cells. The principal growth factors driving angiogenesis include, among others, the vascular endothelial growth factor (VEGF), the basic fibroblast growth factor, and the hepatocyte growth factor (HGF)<sup>[32]</sup>. Thus, there are various

potential targets for anti-angiogenic cancer gene therapy. In contrast to other genetic treatments, anti-angiogenic gene therapy does not necessarily require direct and selective transduction of target genes into cancer cells, but rather transduction around the tumor to create an anti-angiogenic environment<sup>[33]</sup>. This advantage helps to overcome the limitations of the currently available vector systems, which often lack adequate transduction efficiency in cancer cells. Several studies were undertaken to evaluate the potential of anti-angiogenic gene therapy in gastric cancer. One study demonstrated that, if expressed from adenovector-transduced peritoneal mesothelial cells, the soluble VEGF receptor sFlt-1 is able to inhibit the peritoneal dissemination of gastric cancer *in vivo* and consequently prolong the survival of treated animals<sup>[33]</sup>. Another study evaluated the therapeutic efficacy of the HGF antagonist NK4, which is known for its inhibitory effects on several angiogenic pathways. Application of an NK4-expressing adenovector inhibited the formation of both peritoneal metastases and intra-tumor vessels in gastric cancer *in vivo*<sup>[34]</sup>. New potential targets for anti-angiogenic gene therapy of gastric cancer were recently discovered. Meng *et al*<sup>[35]</sup> and Xue *et al*<sup>[36]</sup> showed that silencing Raf-1 and Rac1 GTPase, which are critical factors in hypoxia-induced gene activation of several angiogenesis factors, results in downregulation of the angiogenesis-promoting factors VEGF and Hif-1 $\alpha$  and upregulation of the tumor suppressors and angiogenesis inhibitors p53 and VHL. Furthermore, downregulation of Raf-1 and Rac1 GTPase leads to tumor cell apoptosis and significantly inhibits cell proliferation. Similarly, Stoeltzing *et al*<sup>[37]</sup> showed that direct suppression of Hif-1 $\alpha$  resulted in decreased secretion of VEGF, thereby impairing tumor growth, angiogenesis and vessel maturation *in vivo*.

## GENETIC IMMUNOTHERAPY

Genetic immunotherapy aims at improving the host's immune response to a particular tumor and is currently one of the most promising gene therapeutic options for cancer. The function of the immune system is very complex and its activation in gene therapeutic settings can be achieved by employing different strategies<sup>[38]</sup>. One of the most common strategies in immunotherapy of cancer is the use of mediators of the immune system. Among them, IL-2, IL-12, INF- $\gamma$ , GM-CSF and TNF- $\alpha$  have raised special attention and several trials have proved their efficacy in cancer gene therapy<sup>[39-42]</sup>. New developments indicate further improvement of the benefit, if cytokine therapy is combined or used with other gene therapeutic options. For example, synergistic anti-tumor effects were achieved by simultaneous expression of IL-2 and INF- $\gamma$ <sup>[40]</sup> or by combining an oncolytic adenovirus (oAdV) with IL-12 immunotherapy<sup>[43]</sup>.

Based on this knowledge, studies were carried out in order to prove the efficacy of immunotherapy in combination with other gene therapeutic strategies in gastric cancer. Zhang *et al*<sup>[44-46]</sup> evaluated the anti-tumor effects of the HSV-tk/GCV system together with the expression of recombinant IL-2 or TNF- $\alpha$  in gastric cancer. In contrast to their disappointing results *in vitro*<sup>[46]</sup>,

they observed enhanced anti-tumor effects by HSV-tk/GCV suicide gene therapy combined with recombinant TNF- $\alpha$  expression *in vivo*<sup>[44]</sup>. Using a similar protocol, another group found strongly enhanced anti-tumor effects after coexpression of IL-2, GM-CSF and HSV-tk/GCV in a gastric cancer model *in vivo*<sup>[47]</sup>. These results strongly indicate the potential impact of combined cytotoxic and immunomodulatory gene therapy in gastric cancer. Other immunotherapeutics also demonstrated their potential efficacy in gastric cancer. For example, it was shown that the expression of recombinant intercellular adhesion molecule (ICAM)-2 prolonged the survival of mice with peritoneal metastases of gastric cancer<sup>[48]</sup>. Meng *et al*<sup>[49]</sup> tested the recently discovered gastric carcinoma-specific tumor-associated antigen MG7-Ag in a *Salomonella typhimurium* vaccine against gastric cancer. In detail, they constructed a recombinant gene vaccine consisting of the MG7-Ag mimotope fused with HBcAg, a protein from HBV enhancing the immunogenicity of its antigens. Oral application of the vaccine *in vivo* led to increased formation of MG7-Ag antibodies, reduced average tumor weight compared to the controls and prevented tumor growth in one of five immunized mice, thereby indicating some protective effects of the vaccine<sup>[50]</sup>.

## GENE SILENCING APPROACHES

Inappropriately expressed genes are a major cause of uncontrolled cell growth. Thus, the specific downregulation of (onco)gene expression leading to tumor growth inhibition is a promising approach in cancer gene therapy<sup>[51]</sup>. Several years ago, double-strand RNA molecules homologous to the sequence of the target gene were shown to induce post-transcriptional gene silencing (PTGS) in a sequence-specific manner. This mechanism was designated as RNAi<sup>[52]</sup>. The process of PTGS is initiated by small interfering (si) RNA molecules, which have a length of 21-23 nucleotides<sup>[12]</sup>. In mammalian cells, siRNAs are incorporated into a large protein complex, the RNA-induced silencing complex, leading to precise degradation of complementary mRNA targets<sup>[53]</sup>. Due to its extraordinary efficiency, target gene specificity and simplicity of construction, siRNA technology has gained considerable attention as a new tool for gene knockdown and, hence, therapeutic use in cancer gene therapy. Chemically synthesized or *in vitro*-transcribed siRNAs are widely used for *in vitro* anti-cancer studies, while their use *in vivo* revealed several problems. Major limitations *in vivo* are the generally low transduction efficiency and short half-life. Furthermore, synthetic siRNAs preferentially transduce the liver after systemic application<sup>[54]</sup>, rendering them useless for systemic cancer gene therapy. These obstacles may be overcome by the expression of siRNA from viral vectors. Currently, adenoviral, retroviral and adeno-associated virus vectors have been shown to efficiently express siRNAs resulting in strong downregulation of the target gene<sup>[55-57]</sup>. In this setting, vector-based expression systems were further developed, enabling tissue-specific and inducible siRNA expression by the use of tissue specific promoters<sup>[58]</sup> and pharmacologically regulated gene expression systems<sup>[55]</sup>.

Furthermore, siRNA expressed from viral vectors seems to be more stable than synthetic siRNA<sup>[59]</sup>. Several studies were undertaken to evaluate siRNA technology in gastric cancer. Hong *et al.*<sup>[60]</sup> constructed a eukaryotic vector expressing siRNA against new zinc ribbon (ZNRD1) gene, which promotes a multi-drug resistant phenotype in gastric cancer through the upregulation of permeability-glycoprotein. After transfection of a ZNRD1 siRNA, a dramatic reduction of ZNRD1 was observed accompanied by a significantly enhanced sensitivity to vincristine, adriamycin and etoposide. Further studies proved the high efficiency of siRNA-mediated gene silencing in gastric cancer cells *in vitro*<sup>[35,59,61-63]</sup>. Continuous development of siRNA technology warrants further investigations of its future therapeutic use in gastric cancer *in vivo*.

Further approaches for the downregulation of tumor genes in gastric cancer, including anti-sense-RNA<sup>[64]</sup>, anti-sense oligonucleotides<sup>[65,66]</sup>, ribozymes<sup>[67]</sup>, and dominant negative forms of tumor proteins<sup>[37,68]</sup>, have also been investigated and may be of potential clinical value in the gene therapy of gastric cancer. While anti-sense strategies preferentially aim at blocking the translation of a target mRNA by complementary binding to its specific mRNA, dominant negative mutant alleles compete with their endogenous homologs for binding in a protein complex, leading to the inhibition of protein function. For example, the insulin-like growth factor (IGF) I receptor is involved in carcinogenesis and proliferation. Its blockade by adenovector-mediated expression of a truncated dominant negative IGF was shown to sensitize gastric tumor cells for chemotherapy and to suppress their peritoneal dissemination *in vivo*<sup>[68]</sup>. In another study, Kim *et al.*<sup>[66]</sup> showed that downregulation of anti-apoptotic protein bcl-2 by administering bcl-2 anti-sense oligonucleotides significantly increased the sensitivity of gastric cancer to chemotherapeutics *in vivo*.

## VIROTHERAPY

The limited efficiency of replication-deficient viral vectors to transduce cancer cells and express effector genes *in vivo* led to the development of a new vector generation called OVV. In contrast to replication-deficient viral vectors, the primary replication cycle of OVV causes viro-oncolysis of initially infected tumor cells, resulting in the release of progeny virions followed by the infection of adjacent cells and the infection and destruction of further tumor mass<sup>[69]</sup>. Thus, OVV are intended to ultimately destroy a tumor although only a small percentage of tumor cells was initially infected. Furthermore, progeny virions can spread systemically by circulation<sup>[70]</sup> and infect tumor cells remote from the primary replication site of OVV, thus enhancing the potential therapeutic efficacy in metastatic cancer.

The restriction of OVV replication to cancer cells is a central concern of OVV development. This aim has been achieved by genetic engineering of viral vector genomes (e.g. in herpes- and adenoviruses) either by driving of viral genes essential for virus replication by tumor-specific promoters<sup>[71,72]</sup> or by inserting mutations into viral genes that abolish their function for viral replication in normal cells but not in tumor cells<sup>[73]</sup>. Other OVV with inherent

oncolytic potency acquire tumor-selective replication competence through defects or dysregulation of cellular genes in cancer cells (e.g. Newcastle virus and vesicular stomatitis virus)<sup>[74,75]</sup>.

Several studies have demonstrated that replication of OVV is 100- to 1 000-fold attenuated in normal cells compared to cancer cells. As shown in oAdVs, OVV safety can be further increased by pharmacological regulation of viral replication, using the rapamycin<sup>[76]</sup> or the Tet-On gene expression system<sup>[77,78]</sup> to regulate adenoviral E1A. This now opens the door to permanent external control of OVV during the treatment of patients. Various genetically engineered OVV and viruses with inherent oncolytic properties have recently been explored as anti-cancer agents, among them adenovirus<sup>[9,79,80]</sup>, HSV<sup>[81-83]</sup>, retroviruses<sup>[84]</sup>, vaccinia virus<sup>[41]</sup>, autonomous rodent parvovirus<sup>[85]</sup>, vesicular stomatitis virus<sup>[86]</sup>, Newcastle virus<sup>[87]</sup>, and reoviruses<sup>[88-89]</sup>. Of these, HSV and adenovirus are the most widely studied ones. ONYX-015 was the first tested oAdV and is to date the most commonly used oAdV in clinical trials. Deletion of the adenoviral E1B-55kD enables the replication of ONYX-015 in cells with a defective p53 pathway and minimizes its replication in cells with a functionally active p53 pathway<sup>[9]</sup>. Thus, ONYX-015 is unable to replicate in normal cells, but strongly replicates in cancer cells. Several clinical trials have demonstrated the efficacy of ONYX-015 in patients with cancer. Strongest anti-tumor responses were observed in patients with squamous cell cancer of the head and neck<sup>[90,91]</sup>, but responses to hepatocellular carcinoma<sup>[92]</sup>, hepatobiliary tumors<sup>[93]</sup>, and advanced pancreatic cancer<sup>[94]</sup> were reported, whereas no response was observed in patients with advanced ovarian cancer<sup>[95]</sup>. Two phase I/II clinical trials have provided evidence for the efficacy of ONYX-015 in metastatic gastrointestinal cancer<sup>[96,97]</sup>. Reid *et al.*<sup>[96]</sup> administered ONYX-015 by hepatic artery infusion combined with 5-fluorouracil and leucovorin in 27 patients with both primary gastrointestinal carcinoma and liver metastases. The treatment was well tolerated showing only mild or moderate flu-like symptoms, including fever, myalgia, asthenia and/or chills. Virus replication was demonstrated and three partial responses, four minor responses and nine stable diseases were documented as therapeutic outcome. In another study, patients with advanced sarcomas, among them patients with gastrointestinal stromal tumors, were given an intratumoral injection of ONYX-015 combined with MAP chemotherapy. The treatment was well tolerated and there was no significant toxicity. One of the six patients treated showed a partial response with an approximately 70% reduction of tumor size, and in four patients the disease stabilized<sup>[97]</sup>. Other oncolytic viruses like HSV, Newcastle virus and vaccinia virus also demonstrated their viro-oncolytic efficacy in clinical trials with cancer patients<sup>[41,98,99]</sup>. On the other hand, the studies revealed therapeutic limitations of the currently available OVV. Often, only a minority of patients shows a response, which is only partial and transient in most of the cases<sup>[5,97]</sup>. Obviously, there are several major limitations to the therapeutic potential of OVV. The key problems are low infectivity, replication rate and cytolytic activity of OVV.

To overcome these limitations, measures have therefore been taken to further develop OVV. The low transduction efficiency of oAdV due to low coxsackie-adenovirus receptor (CAR) expression can be enhanced by modifying the fiber proteins. This can be achieved by adding foreign peptides to the HI loop or the C-terminus of the fiber knob<sup>[100,101]</sup> or by substituting fibers of adenoviral 2 and 5 with fibers derived from other adenoviruses, which bind to receptor molecules other than CAR<sup>[102,103]</sup>. These strategies seem to be promising for the treatment of gastric cancer as well, since gastric cancer cells express low amounts of CAR, making it resistant to adenoviral infection<sup>[100]</sup>. Recently published data demonstrate that oAdV with RGD motif in the HI-loop of the fiber-knob region or replacing its adenovirus type 5 knob by an adenovirus type 3 knob has a stronger anti-tumor effect than unmodified oAdV in a gastric cancer model *in vivo*<sup>[100]</sup>. Another study investigated re-targeting a doubly-ablated adenovector to the epithelial cell adhesion molecule (EpCAM) by introducing a bi-specific single-chain antibody to EpCAM. EpCAM is highly expressed in gastric cancer but not in gastric epithelium. Consequently, the vector was highly selective for primary gastric tumors, while transduction of normal gastric epithelium and liver was low<sup>[104]</sup>.

Another way to improve the efficacy of OVV is combining OVV treatment with conventional and other gene therapeutic strategies. Preclinical and clinical data demonstrate that OVV-induced tumor cell killing can be strongly enhanced by the expression of therapeutic transgenes from OVV like anti-angiogenic factors, suicide genes, or tumor suppressor genes and simultaneous treatment with conventional chemo- and radiotherapy<sup>[43,96,105-110]</sup>.

## PROSPECTS

Gene therapy has become a generally accepted new therapeutic tool in the treatment of cancer. More and more cancer patients profit from its use due to the progress made in the development of vector systems and gene therapeutic strategies. Thus, cancer gene therapy will increase its importance as a therapeutic tool even though many problems still need to be solved. One of the most important issues affecting the possible clinical application of gene therapy is the need to ensure the highest possible safety levels. Many clinical investigations have demonstrated that the currently available vector systems are well tolerated and side effects are acceptable. However, the use of retroviral vectors is discussed controversially, since 3 of 11 children with X-linked severe combined immunodeficiency, who were treated with a retrovirus, developed uncontrolled T-lymphocyte proliferation in a French gene therapy trial.

The major problem of cancer gene therapy that still remains is the relatively poor therapeutic outcome. This problem is not restricted to a specific tumor entity, but is rather a general problem. There may be many reasons for this, but it is widely agreed that this is mainly due to the relative resistance of cancer cells to introduce foreign material combined with low transgene expression *in vivo*. Thus, improved vector systems and application protocols

will continue to be the biggest issues to be dealt with in cancer gene therapy in the next few years. However, important progress to overcome these limitations has already been made by the development of OVVs and vectors with increased tumor cell tropism.

Great progress has also been made in the development of gene therapeutic strategies in gastric cancer. New vector systems as well as the evaluation of new target genes and gene therapeutic strategies have substantially improved the chances for successful treatment of gastric cancer by gene therapy. The next challenge will be to test the results gained thus far in clinical studies.

**CONCLUSION:** The activation of NF- $\kappa$ B plays an important role in the pathogenesis of lung injury induced by intestinal I/R through upregulating the neutrophil infiltration and lung ICAM-1 expression. PDTC as an inhibitor of NF- $\kappa$ B can prevent lung injury induced by intestinal I/R through inhibiting the activity of NF- $\kappa$ B.

### Abstract

**AIM:** To investigate the role of nuclear factor kappa B (NF- $\kappa$ B) in the pathogenesis of lung injury induced by intestinal ischemia/reperfusion (I/R), and its effect on intercellular adhesion molecule-1 (ICAM-1) expression and neutrophil infiltration.

**METHODS:** Twenty-four Wistar rats were divided randomly into control, I/R and pyrrolidine dithiocarbamate (PDTC) treatment groups,  $n = 8$  in each. I/R group and PDTC treatment group received superior mesenteric artery (SMA) occluding for 1 h and reperfusion for 2 h. PDTC group was administrated with intraperitoneal injection of 2% 100 mg/kg PDTC 1 h before surgery. Lung histology and bronchia alveolus lung fluid (BALF) protein were assayed. Serum IL-6, lung malondialdehyde (MDA) and myeloperoxidase (MPO) as well as the expression level of NF- $\kappa$ B and ICAM-1 were measured.

**RESULTS:** Lung injury induced by intestinal I/R, was characterized by edema, hemorrhage and neutrophil infiltration as well as by the significant rising of BALF protein. Compared to control group, the levels of serum IL-6 and lung MDA and MPO increased significantly in I/R group ( $P = 0.001$ ). Strong positive expression of NF- $\kappa$ B p65 and ICAM-1 was observed. After the administration of PDTC, the level of serum IL-6, lung MDA and MPO as well as NF- $\kappa$ B and ICAM-1 decreased significantly ( $P < 0.05$ ) when compared to I/R group.

### INTRODUCTION

Intestinal I/R is not necessarily limited to the intestine itself, but involves severe destruction of distant tissue. It is known that intestinal I/R is an important event in the pathogenesis of multi-system organ failure syndrome, especially acute respiratory distress syndrome which is the leading cause of death in critically ill patients<sup>[1-4]</sup>. The mechanism of lung injury induced by intestinal I/R is complex. Proinflammatory cytokines and chemokines exert their effects via a direct toxic action on target cells<sup>[5]</sup>, ICAM-1 and neutrophil infiltration play an important role in lung injury induced by intestinal I/R<sup>[6]</sup>. However, recent studies showed that these proinflammatory mediators play a role in gene induction<sup>[7-9]</sup>. NF- $\kappa$ B upregulates most of these mediators<sup>[10-12]</sup>, but it is not known how NF- $\kappa$ B is activated and ICAM-1 is expressed in lung injury induced by intestinal ischemia.

This study was to evaluate the role of NF- $\kappa$ B in the pathogenesis of lung injury induced by intestinal I/R and the effect of pyrrolidine dithiocarbamate (PDTC) on lung neutrophil infiltration and expression of ICAM-1.

### MATERIALS AND METHODS

#### Animals

Male Wistar rats (From Animal Center of Dalian Medical

University, Dalian, China) weighing 200-240 g were used in this study. All rats had free access to standard laboratory chow and water in accordance with institutional animal care policies.

### Experimental design

The rats were anesthetized with intraperitoneal administration of 10% chloral hydrate, 350 mg/kg, laparotomized and randomly divided into three experimental groups ( $n=8$  in each): sham operation group (control group) undergoing full surgical preparation including isolation of SMA without occlusion; I/R group: ischemia was induced for 1 h and reperfusion for 2 h after SMA was isolated and ischemia was occluded<sup>[13]</sup>; PDTC treatment group undergoing full surgical preparation including isolation of SMA with intraperitoneal administration of 2% PDTC 100 mg/kg 1 h before the operation. The rats in control and I/R groups were treated with an equal volume of normal saline solution. All animals were killed after 2 h of reperfusion. Blood samples were obtained for analysis. Lung tissues were harvested immediately for detection.

### Lung histology and bronchia alveolus lung fluid (BALF) assay

The harvested right middle lobe of the lung was fixed in 40 g/L formaldehyde. After being embedded in paraffin, 4- $\mu$ m-thick sections were stained with hematoxylin and eosin for light microscopy. Pathological injury score was evaluated according to Chiu's method<sup>[14]</sup>. BALF was collected according to the process of Cox<sup>[15]</sup> and centrifuged at 1 000 r/min for 10 min. The protein in the supernatant was measured using assay kit (Nanjing Jincheng Corp., China) following the manufacturer's instructions and expressed as g/L.

### Serum IL-6 assay

The serum level of IL-6 was determined using an RIA kit (Radioimmunity Institute of PLA General Hospital, Beijing, China) according to the manufacturer's instructions and expressed as ng/L.

### Lung MDA and MPO assay

The right base lobe of lung was harvested and immediately homogenized on ice in 5 volumes of normal saline. The homogenates were centrifuged at 1 200 r/min for 10 min. The malondialdehyde (MDA) and myeloperoxidase (MPO) content in the supernatants were measured using MDA and MPO assay kit (Nanjing Jincheng Corp., China) following the manufacturer's instructions and expressed as nmol/mg and U/g, respectively.

### Lung NF- $\kappa$ B and ICAM-1 immunohistochemical analysis

Formalin-fixed and paraffin-embedded lung specimens were stained with SP immunohistochemistry technique for NF- $\kappa$ B and ICAM-1 detection. Experiments were performed following the manufacturer's instructions. Five-micron sections were dewaxed in xylene, cultured in 3% hydrogen peroxide to eliminate intrinsic peroxidase and quenched in normal goat serum for 30 min, then incubated

overnight at 4°C with polyclonal rabbit anti-rat NF- $\kappa$ B p65 and ICAM-1 antibody (NeoMarkers Corp. and Boster Corp., Ltd., respectively) against purified recombinant NF- $\kappa$ B or ICAM-1. Then anti-rabbit immunoglobulin and streptavidin conjugated to horseradish peroxides were added. Finally, 3,3'-diaminobenzidine was used for color development and hematoxylin was used for counter staining. The results were evaluated semi-quantitatively according to the percentage of positive cells in five high power fields at 400 multiple signal magnification.

### Western blot analysis of NF- $\kappa$ B and ICAM-1

Cellular plasma and nuclear protein were extracted from frozen lung tissue with protein extraction kit (Pierce, Meridian Road, Rockford, IL, USA) according to the manufacturer's instructions. Protein concentrations were determined by Coomassie blue dye-binding assay (Nanjing Jincheng Corp, China). Samples were mixed with loading buffer and boiled for 5 min. Thirty micrograms of protein (nuclear protein for NF- $\kappa$ B p65, plasma protein for ICAM-1) was loaded into each lane of 10% SDS-PAGE gel electrophoresis at 100 V for 4 h. After electrophoresis, the proteins were electroblotted onto NC membranes (Millipore, Bedford, MA, USA) at 9 V for 30 min. Nonspecific binding was blocked by incubation in phosphate-buffered saline (PBS) containing 0.1% Tween 20 (PBS-T) and 5% skim milk. The transferred membranes were incubated overnight at 4°C with rabbit polyclonal antibodies NF- $\kappa$ B p65 and ICAM-1 (NF- $\kappa$ B p65 at 1:1 000 dilution, ICAM-1 at 1:500 dilution) against rat in PBS-T containing 5% skim milk. After washing thrice in PBS-T, the membranes were incubated with anti-rabbit IgG (Zhongshan Bio., China) conjugated to horseradish peroxidase at a dilution 1:2 000 in PBS-T containing 5% skim milk for 1 h at 37°C. After three additional washes with PBS-T, the signals were visualized by DAB assay kit (Maixin-bio, China) and analyzed with a gel imaging system (Kodak system EDAS120).

### Statistical analysis

All data were expressed as mean  $\pm$  SD. Statistical analysis was performed using *F*- and *Q*-tests.  $P < 0.05$  was considered statistically significant.

## RESULTS

### Lung pathological and BALF changes

The lung histological structure was normal in control group, while the lung tissues were obviously damaged with edema, hemorrhage, and inflammatory cell infiltration in I/R group. There was a significant difference between I/R and control group in pathological score ( $P < 0.01$ ) and BALF content. After the administration of PDTC, the pathological score of lung injury and BALF content was improved significantly when compared to I/R group ( $P < 0.05$ , Table 1).

### Serum IL-6 level

Compared to control group, serum IL-6 level was significantly increased in I/R group ( $P < 0.01$ , Table 2).

**Table 1 Protein content of lung lavage fluid in different groups (mean±SD)**

Groups	n	Lung lavage fluid (g/L)
Control group	8	0.8769 ± 0.1622
I/R group	8	1.2462 ± 0.3303 <sup>b</sup>
PDTC group	8	0.9299 ± 0.2573 <sup>a</sup>

<sup>a</sup>*P*<0.05 vs I/R group, <sup>b</sup>*P*<0.01 vs control.**Table 2 Serum IL-6 level in different groups (mean±SD)**

Groups	n	IL-6 (ng/L)
Control group	8	22.51 ± 6.10
I/R group	8	42.85 ± 7.35 <sup>b</sup>
PDTC group	8	28.08 ± 7.55 <sup>a</sup>

<sup>a</sup>*P*<0.05 vs I/R group, <sup>b</sup>*P*<0.01 vs control.

Compared to I/R group, serum IL-6 level was significantly decreased in PDTC treatment group (*P*<0.05).

#### Lung MDA and MPO assay

Compared to control group, lung MDA and MPO significantly increased in I/R group (*P*<0.01). Compared to I/R group, lung MDA and MPO significantly decreased in PDTC treatment group (*P*<0.01, Table 3).

#### Immunohistochemical analysis of lung NF-κB and ICAM-1

The expression of NF-κB p65 and ICAM-1 in control group showed light brown immunostaining in cytoplasm and no staining in the nuclei. The significant positive expressions of NF-κB p65 and ICAM-1 as strong brown staining in cytoplasm and nuclei were observed in I/R group (*P*<0.01). Compared to I/R group, the positive rates of NF-κB p65 and ICAM-1 expression decreased significantly in PDTC group (*P*<0.01, Figures 1 and 2).

#### Western blot analysis of NF-κB and ICAM-1

Western blot showed weak NF-κB p65 and ICAM-1 positive signals in the lungs of control group. In contrast, significant increase of NF-κB p65 and ICAM-1 protein expression was found in I/R group (*P*<0.01). Compared to I/R group, the signals weakened significantly in PDTC group (*P*<0.05, Figure 3 and Table 4).

## DISCUSSION

Previous studies have identified many mediators involved in the pathogenesis of lung injury induced by intestinal I/R<sup>[16,17]</sup>, which exert their effects via a direct toxic action on lung tissue. Recent studies showed that these mediators such as NO, ROS, TNF-α, and ICAM-1 can be regulated by NF-κB. NF-κB is a rapid response transcription factor, which is maintained in the cytoplasm and consists of two subunits of 50 and 65 ku bound to an inhibitor protein, I-κB. This phosphorylated inhibitor unit is tagged by ubiquitin for subsequent proteolysis, and then the free NF-κB complex is able to translocate into the nuclei

**Table 3 Lung MDA and MPO level in different groups (mean±SD)**

Groups	n	MDA (nmol/mg)	MPO (U/g)

where it transactivates target genes<sup>[18,19]</sup>. As a consequence, activated polymorphonuclear neutrophils (PMNs) and pro-inflammatory cytokines (TNF-α, ILs) are released into the systemic circulation, interact with the vascular endothelium of distant organs, primarily the lungs, contributing to the systemic inflammatory response<sup>[20]</sup>. ICAM-1 is a member of the immunoglobulin superfamily, which is inducible by NF-κB and inflammatory cytokines such as IL-1β and TNF-α. ICAM-1 might be upregulated to involve the adhesion and infiltration of leukocytes into the injured site<sup>[21]</sup>. MPO resides in PMNs and its activity reflects the level of accumulation of PMNs.

In our study, 1 h of intestinal ischemia followed by 2 h of reperfusion induced lung injury manifested as a significant increase of BALF content and pathological injury score as well as PMN infiltration. These changes were parallel to the level of lung NF-κB p65, suggesting that the activation of NF-κB is involved in the pathogenesis of lung injury induced by intestinal I/R. As a consequence, activated PMNs and pro-inflammatory cytokines (such as IL-6) are released into the systemic circulation, and interact with the vascular endothelium of organs. Endothelial adhesion molecules expressed on the surface of endothelial cells (such as ICAM-1) play a key role in neutrophil chemoattraction, adhesion and emigration from the vasculature to the tissue, contributing to the systemic inflammatory response and organ injury<sup>[22,23]</sup>. The production of ROS, such as lung MDA and MPO (an index of tissue neutrophil count) was observed in I/R group. NF-κB upregulates neutrophil infiltration and expression of ICAM-1. PDTC, as an antioxidant, is involved in its ability to inhibit NF-κB<sup>[24-26]</sup> via the stabilization of I-κB-α<sup>[27]</sup> or via the inhibition of the ubiquitin-proteasome pathway<sup>[28]</sup>. In our study, PDTC reduced the neutrophil infiltration, lung expression of ICAM-1 and MPO activity, which can prevent the development of lung injury.

In conclusion, activation of NF-κB plays an important

role in the pathogenesis of lung injury induced by intestinal I/R by upregulating the neutrophil infiltration and lung ICAM-1 expression. PDTC can prevent lung injury induced by intestinal I/R by inhibiting the activity of NF- $\kappa$ B.

## Abstract

**AIM:** To establish a novel coculture system for ex vivo expansion of umbilical cord blood(UCB) hematopoietic progenitors using thrombopoietin (TPO)/Flt-3 ligand (FL)-transduced human marrow-derived mesenchymal stem cells (tfhMSCs) as feeder.

**METHODS:** UCB CD34<sup>+</sup> cells were isolated and cultured using four culture systems in serum-containing or serum-free medium. Suitable aliquots of cultured cells were used to monitor cell production, clonogenic activity, and long-term culture-initiating culture (LTC-IC) output. Finally, the severe-combined immunodeficient (SCID) mouse-repopulating cell (SRC) assay was performed to confirm ability of the cultured cells to reconstitute long-term hematopoiesis.

**RESULTS:** There were no significant differences in the number of total nucleated cells among different culture systems in serum-containing medium during 21-d culture. However, on d 14, the outputs of CD34<sup>+</sup> cells, CFU-C and CFU-GEMM in tfhMSCs coculture system were significantly enhanced. LTC-IC assay demonstrated that the tfhMSCs coculture system had the most powerful activity. The severe-combined immunodeficient (SCID) mouse repopulating cell (SRC) assay confirmed extensive ability of the expanded cells to reconstitute long-term hematopoiesis. Furthermore, PCR analysis demonstrated the presence of human hematopoietic cells in the bone marrow and peripheral blood cells of NOD/SCID mice.

**CONCLUSION:** The TPO/FL-transduced hMSCs, in combination with additive cytokines, can effectively expand hematopoietic progenitors from UCB in vitro and the tfhMSCs coculture system may be a suitable system for ex vivo manipulation of primitive progenitor cells under contact culture conditions.

## INTRODUCTION

Hematopoietic stem cells (HSCs) are generally defined as cells having the self-renewing potential and the capacity to give rise to differentiated cells of all hematopoietic lineages<sup>[1]</sup>. Therefore, HSC transplantation is performed for complete healing of hematologic disorders and as a supportive therapy after high-dose chemotherapy against malignant diseases. HSCs can be collected from peripheral blood (PB), bone marrow (BM), and umbilical cord blood (UCB). Human UCB is thought to contain a high number of primitive hematopoietic cells, because the number of severe combined immunodeficiency (SCID)-repopulating cells (SRCs) in nonobese diabetic/SCID (NOD/SCID) mice that had received transplants from UCB was higher than that in NOD/SCID mice that had received transplants from other sources<sup>[2-4]</sup>. Moreover, the frequency of graft-versus-host disease, which is a severe side effect of HSC transplantation in patients, is reduced among patients receiving transplants from UCB<sup>[5]</sup>, and UCB can be obtained from the cord-blood bank network. However, the total number of UCB HSCs harvested from one donor's UCB is limited and is not sufficient for HSC transplantation in an adult patient. To overcome this problem, attention has been increasingly focused on

ex vivo expansion of HSCs. Many approaches have been reported during the last decade, and they can be divided into 2 categories. The first category is treatment of HSCs with various combinations of cytokines. Treatment with the following combinations of cytokines increased the progenitor/stem cell population by 2- to 30-fold in the relatively short period of 10 to 14 d: Flt-3 ligand (FL), stem cell factor (SCF), and thrombopoietin (TPO); SCF, granulocyte-colony stimulating factor (G-CSF), and megakaryocyte growth and development factor (MGDF); FL, SCF, G-CSF, interleukin-3 (IL-3), and interleukin-6 (IL-6); and FL, SCF, and IL-6<sup>[6-9]</sup>. However, it is difficult to maintain HSC activity in long-term cultures even if the total number of hematopoietic cells could be expanded. Hence, these methods could be improved for use in clinical settings. The second category involves using stromal cells. It has been reported that the SCID-repopulating activity (SRA) of human HSCs could be maintained by coculture with murine stromal cells for 7 wk<sup>[10]</sup>, and that the SRA could be maintained by coculture with the AGM-S3 stromal cell line for 4 wk<sup>[11]</sup>. MS-5 expanded SRCs for 2 wk<sup>[12]</sup>, FBMD-1 expanded cobblestone area-forming cells by 90-fold<sup>[13]</sup>; HESS-5 expanded SRCs for only 5 d<sup>[14,15]</sup>. Contact between HSCs and stromal cells is important for maintaining the function of HSCs<sup>[16,17]</sup>. However, when human HSCs are cocultured with nonhuman stromal cells, the expanded human HSCs might have a risk of being exposed to an unknown viral contamination in animal stromal cells.

Several methods of ex vivo expansion using human primary stromal cells were reported<sup>[18,19]</sup>. When HSCs were cocultured with human primary stromal cells, the HSCs were expanded for 2 to 4 wk. However, in general, when human primary somatic cells divide in an in vitro culture, the telomeric DNA at the end of the chromosome shortens at each cell division. Then, the replication of human primary cells slows (aging occurs), and the cells finally cease to divide (crisis phase)<sup>[20,21]</sup>. To obtain a sufficient number of primary stromal cells for use on a clinical scale, we have to harvest BM many times, and we cannot ignore the burden on the donor. To solve this problem, trials to establish human stromal cell lines using transduction of viral antigens such as human papillomavirus (HPV) E6/E7 and simian virus 40 (SV40) large T have been reported<sup>[22-24]</sup>. These stromal cells could maintain HSCs, but the possibility of transformation was mentioned<sup>[25]</sup>.

Recently, it was shown that Mesenchymal stem/progenitor cells in human UCB and placenta could support ex vivo expansion of CD34<sup>+</sup> hematopoietic stem cells<sup>[26,27]</sup>. However, no report has investigated whether transduced human marrow-derived mesenchymal stem cells (hMSCs) could be useful in ex vivo expansion of UCB hematopoietic progenitors. Previous research has shown that TPO and FL, the two early-acting cytokines, could lead to significant expansion of HSC populations, including long-term culture-initiating cells (LTC-IC). Our group have introduced TPO and FL genes into cultured hMSCs by retroviral vector transfer and demonstrated long-term expression in vitro and in vivo. In this study, we attempted to establish a coculture system for ex vivo

expansion of UCB hematopoietic progenitors using TPO/FL-transduced hMSCs (tfhMSCs) as feeder. As a result, tfhMSCs is capable of expanding UCB hematopoietic cells in synergy with extra cytokines *in vitro*.

## MATERIALS AND METHODS

### **Analysis of expression of the TPO and FL gene by enzyme-linked immunosorbent assay**

Untransduced and TPO/FL-transduced hMSCs (tfhMSCs) were cultured in minimal essential medium  $\alpha$  (MEM- $\alpha$ ; HyClone, Logan, UT, USA) supplemented with 100 mL/L fetal bovine serum (FBS; GibcoBRL, Grand Island, NY, USA) at 37°C with 50 mL/L CO<sub>2</sub> in humidified air. For assaying TPO and FL secretion, untransduced hMSCs and/or tfhMSCs were passaged when cells reached 90% confluence by transferring  $2.5 \times 10^6$  to  $5.0 \times 10^6$  cells into a 75-cm<sup>2</sup> flask with 12 mL of hMSCs medium. Twenty-four hours later, 1 mL of culture supernatant was collected and stored at -80°C. The assay was performed in triplicate using the TPO and FL ELISA kit (BioSource International, Camarillo, CA, USA). The level of TPO and FL was normalized to the level of endogenously expressed IL-6 measured with an IL-6 ELISA kit (BioSource International) using the procedures suggested by manufacturer. Plates were read on a microplate reader (Bio-Rad Laboratories, Hercules, CA, USA) and the data were analyzed using Microsoft Excel.

### **UCB sample collection and CD34<sup>+</sup> cell purification**

UCB were collected from normal full-term pregnancies according to the regulations of the Research Ethics Committee of Women's Hospital, School of Medicine Zhejiang University. Mononuclear cells (MNC) were isolated using Ficoll-Hypaque ( $1.077 \pm 0.001$  Kg/L, Sigma, St. Louis, MO), washed, and resuspended in Iscove's modified Dulbecco's medium (IMDM; HyClone, Logan, UT) supplemented with 100 mL/L fetal bovine serum (FBS; GibcoBRL, Grand Island, NY). CD34<sup>+</sup> cell purification utilized positive selection using the *miniMACS* immunomagnetic separation system (Miltenyi Biotec GmbH, Glodbach, Germany) according to the manufacturer's instructions. Briefly, MNCs were suspended in buffer containing phosphate-buffered saline (PBS), 5 mL/L bovine serum albumin (BSA; Sigma), and 2 mmol/L EDTA (BSA-EDTA-PBS), and incubated for 15 min with monoclonal hapten-conjugated anti-CD34 antibody (clone: QBEND/10) and human Ig to prevent nonspecific binding. Washed cells were resuspended in BSA-EDTA-PBS and incubated for 15 min with colloidal super-paramagnetic microbeads conjugated to an anti-hapten antibody. After labeling, the cell suspension was passed through a column (VS<sup>+</sup> separation column) held within a magnetic field causing CD34<sup>+</sup> cells to be retained in the column. CD34<sup>+</sup> cells were collected by removal of the column from the magnet and washing with BSA-EDTA-PBS. Ninety-six percent or more of the enriched cells were CD34<sup>+</sup> by flow cytometric analysis.

### **Human cytokines**

Recombinant human TPO, granulocyte-macrophage

colony-stimulating factor (GM-CSF), and erythropoietin (EPO) were purchased from Peprotech (London, UK). IL-3 and IL-6 was purchased from RELIATech GmbH (Braunschweig, Germany). Recombinant human SCF was a gift from Amgen Biologicals (Thousand Oaks, CA). Recombinant human FL was purchased from R&D Systems (Minneapolis, MN). The final concentrations of cytokines were as follows: TPO, 50 µg/L; FL, 50 µg/L; IL-3, 20 µg/L; IL-6, 20 µg/L; SCF, 50 µg/L; GM-CSF, 10 µg/L; and EPO, 3 000 U/L.

### Culture systems

Stroma-free culture and coculture with tfhMSCs or hMSCs were performed in culture media in 24-well microplates (Costar, Bethesda, MD). Serum-containing liquid culture was carried out using a medium containing 125 mL/L horse serum (HS; HyClone), 125 mL/L FBS, 10<sup>-4</sup> mol/L 2-mercaptoethanol (Sigma), 2 mmol/L L-glutamine (Sigma) and IMDM supplemented with 10<sup>-6</sup> mol/L hydrocortisone (Sigma) with or without feeder layer. In the coculture, tfhMSCs or hMSCs were seeded at 1 × 10<sup>5</sup> cells per well with MEM-α supplemented with 100 mL/L FBS. After obtaining a confluent feeder layer, cells were washed five times and subjected to γ-irradiation at a dose of 12 Gy. the medium was then changed for coculture. Totally 20 000 UCB CD34<sup>+</sup> cells were expanded for 21 d under four conditions: 1) tfhMSCs coculture system (tfhMSCs + SCF + IL-3 + IL-6 + GM-CSF); 2) hMSCs coculture system (hMSCs + TPO + FL + SCF + IL-3 + IL-6 + GM-CSF); 3) cytokines culture system (TPO + FL + SCF + IL-3 + IL-6 + GM-CSF); 4) hMSCs (TPO/FL-free) culture system (hMSCs + SCF + IL-3 + IL-6 + GM-CSF). On d 7 and 14 of culture, the medium in each well was removed and replaced with fresh medium. On d 7, 14 and 21 of culture, aliquots of cultured cells were harvested and subjected to cell count, clonal cell culture, and flow cytometric analysis when contamination of stromal cells in the harvested cells was negligible (< 2%) by microscopic visualization. On d 14, cultured cells were harvested and subjected to LTC-IC assay and SRC assay. Short-term (7 d) serum-free liquid culture was carried out using StemPro<sup>TM</sup>-34SFM (GibcoBRL) supplemented with StemPro<sup>TM</sup>-34 Nutrient Supplement (GibcoBRL), 2 mmol/L L-glutamine, and penicillin/streptomycin (GibcoBRL).

### Immunophenotyping by flow cytometry

Aliquots of cells were suspended in EDTA-BSA-PBS and incubated with mouse IgG (InterCell Technologies, Hopewell, NJ) to block nonspecific binding. Cells were then reacted for 15 min with FITC- and PE-conjugated monoclonal antibodies at 4°C. Unbound antibodies were removed by two washes, and cells were resuspended in EDTA-BSA-PBS. Stained cells were then passed through a nylon mesh filter and subjected to two-color flow cytometric analysis. Cells labeled with FITC- and PE-conjugated mouse isotype-matched antibodies were used as negative controls. The analysis was performed using an FACsort flow cytometer (Becton Dickinson, San Jose, CA) with CELLQUEST<sup>TM</sup> software (Becton Dickinson). At least 10 000 events were acquired for each analysis.

Antibodies used were as follows: FITC-conjugated CD14, CD15, CD19, CD33, CD34, and CD41; PE-conjugated CD38 and CD45 antibodies. Glycophorin A antibodies were from Immunotech (Marseille, France). CD14, CD33, and CD45 antibodies were from Pharmingen (San Diego, CA) and all others were from Becton Dickinson. Furthermore, in some experiments, aliquots of cultured cells were subjected to three-color flow cytometric analysis to assess the lineage commitment of progenitors. Samples were incubated for 15 min with biotin-conjugated anti-CD34 (Immunotech, Marseille, France). Cells labelled with a biotin-conjugated mouse isotype-matched antibody were used as a negative control. After washing, cells were labeled with streptavidin PerCP (Becton Dickinson), PE-conjugated anti-CD38, and various FITC-conjugated monoclonal antibodies. Three-color flow cytometry was performed using an FACSCalibur (Becton Dickinson) with CellQuest software (Becton Dickinson).

### Colony-forming cell assay (CFC assay)

Aliquots from initial UCB samples or cultured cells were incubated in methylcellulose media at concentrations of 1-2 × 10<sup>5</sup> cells/L for purified CD34<sup>+</sup> cells and 5-10 × 10<sup>5</sup> cells/L for cultured cells in 35-mm tissue culture dishes (Costar). One milliliter of culture mixture contained 12 mL/L 1500 cp methylcellulose (Sigma), MEM-α, 10 g/L deionized fraction V BSA (Sigma), 10<sup>-4</sup> mol/L 2-mercaptoethanol, 300 mL/L fetal calf serum (JRH Biosciences, Lenexa, KS), EPO, IL-3, SCF, GM-CSF, and cells. Dishes were incubated at 37°C in a humidified atmosphere with 50 mL/L CO<sub>2</sub> in air. All cultures were done in triplicate. Total colony-forming units in culture (CFU-C) and mixed colonies containing erythroid and myeloid cells and megakaryocytes (CFU-GEMM) consisting of 50 or more cells were scored under an inverted microscope at 21 d of culture. To assess the accuracy of in situ identification, individual colonies were lifted with an Eppendorf micropipette under direct microscopic visualization, spread on glass slides using a cytocentrifuge and studied with May-Grunwald-Giemsa staining.

### Long-term culture-initiating cell assay (LTC-IC assay)

LTC-IC assay was performed as described by Sutherland *et al.*<sup>[28]</sup>, with slight modifications. Briefly, bone marrow stromal cells derived from hematologically normal donors were seeded at 10<sup>5</sup> cells per well in 96-well flat-bottomed plates (Costar) with MEM-α supplemented with 100 mL/L FBS. After obtaining semiconfluent feeder layers, stromal cells were irradiated with 15-Gy using a <sup>60</sup>Co γ-irradiator. CD34<sup>+</sup> cell subpopulations purified from UCB or those isolated from cultured cells by sorting with an FACSVantage (Becton Dickinson) were seeded at limiting dilution on the feeder layer in serum-containing media. For each evaluation, at least three cell concentrations were used with 24 replicates per concentration. Culture plates were incubated at 37°C with 50 mL/L CO<sub>2</sub> in air and weekly changes of medium. After 5 wk of culture, cells were assayed for CFU-C in methylcellulose medium. Colonies were scored 2 wk later. The frequency of wells in which there were no clonogenic progenitors was determined

**Figure 1** Maintenance of TPO and FL production *in vitro*. TPO (A) and FL (B) levels secreted from tfhMSCs and untransduced hMSCs and endogenous IL-6 levels were assayed in the medium after 2, 4, 6, and 8 passages in culture. The level of TPO and FL in the supernatant was normalized to the level of endogenous IL-6 and the ratio was plotted for passage number. In addition, the absolute values (ng/100 000 cells/24 h) of TPO, FL and IL-6 are shown (arrow). Data were obtained from triplicate ELISA measurements. a=untransduced hMSCs; b=tfhMSCs.

according to the number of the initial input population. Poisson statistics were applied to the single-hit model and the frequency of LTC-IC was calculated with the maximum likelihood estimator.

### SCID-repopulating cells assay (SRC assay)

SRC assay was performed as previously described<sup>[29]</sup>, with slight modifications. Briefly, 8-wk-old male NOD/Shi-scid (NOD/SCID) mice were obtained from the Central Institute for Experimental Animals, Shanghai Institutes for Biological Sciences, CAS. All animals were handled under sterile conditions and maintained under microisolators in the animal facility located at Zhejiang Academy of Medical Sciences. Human hematopoietic cells at the indicated doses were transplanted by tail-vein injection into sublethally irradiated mice (350 cGy using a linear accelerator). Cells were co-transplanted with irradiated (15 Gy using a <sup>60</sup>Co  $\gamma$ -irradiator) nonrepopulating CD34<sup>+</sup> cells as accessory cells. Mice were killed 7 wk after transplantation, and the bone marrow (from the femurs and tibiae) and peripheral blood cells (from the retro-orbital venous plexus using heparin-coated micropipettes) were harvested. The

presence of human hematopoietic cells was determined by detection of cells positively stained with FITC-conjugated antihuman CD45 using flow cytometry. Polymerase chain reaction (PCR) analysis using human Alu sequence primers (5' - GTGGGCGACAGAACGAGATTCTAT; 5' - CTCCTACTTGGAGACAGGTTCA) was also performed to confirm flow cytometric results.

### Statistical analysis

Results are expressed as mean  $\pm$  SD. Statistical comparisons were performed using the two-sided Student's *t*-test. Iterative approximation of Newton's method was performed using Microsoft Visual Basic 6.0 software.

## RESULTS

### Analysis of expression of TPO and FL gene from tfhMSCs and untransduced hMSCs

We transduced hMSCs with the secreted cytokine TPO and FL, which allows direct quantitation of the extracellular product. Human MSCs were transduced with a retroviral vector (pLXINTF) expressing TPO, FL and neomycin followed by selection in the presence of G418 for 2 wk. Cultures were maintained and expanded further for up to 8 passages. Twenty-four hours after each replating aliquots of supernatant from tfhMSCs and untransduced hMSCs was removed for measurement of secreted TPO and FL. The TPO and FL secretion value obtained was normalized to the secretion value obtained for endogenous human IL-6 measured in the same sample aliquot. The absolute values for each cytokine are shown in Figure 1. We chose IL-6 as the control cytokine because expression was in a range similar to that of the transduced gene product and previous data showed similar expression of IL-6 from hMSCs over time in hMSC cultures<sup>[30]</sup>.

We observed TPO transgene expression from tfhMSCs and untransduced hMSCs averaging  $175 \pm 85$  and  $25 \pm 11$  ng/ $10^5$  cells/24 h respectively (Figure 1A) and FL transgene expression averaging  $190 \pm 99$  and  $31 \pm 12$  ng/ $10^5$  cells/24 h respectively (Figure 1B); Endogenous IL-6 protein levels averaging  $6 \pm 2$  ng/ $10^5$  cells/24 h. The cytokine ratio (transduced/endogenous) of tfhMSCs demonstrated a 14- to 36-fold and 22- to 41-fold increase respectively in TPO and FL secretion over endogenous IL-6 expression. The results demonstrate that *in vitro* transgene expression from tfhMSCs was maintained for at least three months in culture.

### Assessment of the supportive effects of tfhMSCs on proliferation of UCB primitive progenitor cells (PPC) in synergy with extra cytokines

To determine whether tfhMSCs was capable of supporting *ex vivo* expansion of UCB-derived hematopoietic cells, four culture systems were established as shown in materials and methods. In the stroma-containing culture, tfhMSCs or untransduced hMSCs were irradiated and cocultured with CD34<sup>+</sup> cells from UCB, and in the stroma-free culture only cytokines were used for expansion. The total number of nucleated cells, CD34<sup>+</sup> cells, CFU-C

**Figure 2** Effects of several culture systems on ex vivo expansion of hematopoietic progenitors. UCB CD34<sup>+</sup> cells were cultured in serum-containing medium using four culture systems. **A:** Total nucleated cells; **B:** CD34<sup>+</sup> cells; **C:** Total colony-forming units in culture (CFU-C); **D:** Mixed colonies containing erythroid and myeloid cells and megakaryocytes (CFU-GEMM). The results represent the mean fold increase  $\pm$  SD of three different experiments on d 7, 14, and 21 of culture. 'No significant differences between different culture systems. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$  as compared with other three groups.  $\blacklozenge$  = tfhMSCs coculture system;  $\blacksquare$  = hMSCs coculture system;  $\blacktriangle$  = cytokines culture system;  $\bullet$  = hMSCs (TPO/FL-free) culture system. A = tfhMSCs coculture system; B = hMSCs coculture system; C = cytokines culture system; D = hMSCs (TPO/FL-free) culture system.

and CFU-GEMM was evaluated on d 7, 14 and 21. CD34 and CD38 expression among hematopoietic cells in four culture conditions were also determined on d 14.

We first assessed the effect of tfhMSCs on ex vivo expansion of UCB-PPC in the serum-containing culture. As a result, tfhMSCs alone could not effectively support proliferation of UCB hematopoietic progenitors (data not shown). The effects of four culture systems on ex vivo expansion of total nucleated cells and CD34<sup>+</sup> cells were then studied in serum-containing medium. During culture, there were no significant differences in the number of total nucleated cells among different culture systems (Figure 2A). The expansion magnitude of CD34<sup>+</sup> cells by tfhMSCs coculture system ( $11.52 \pm 1.51$  fold) and cytokines culture system ( $12.32 \pm 2.69$  fold) was lower than that by hMSCs coculture system ( $15.40 \pm 1.89$  fold) on d 7 ( $P < 0.05$ ), and hMSCs (TPO/FL-free) culture system ( $6.59 \pm 1.26$  fold) manifested the lowest expansion capacity ( $P < 0.01$ ) among the four groups (Figure 2B). However, on d 14, CD34<sup>+</sup> cells were generated more by the tfhMSCs coculture system ( $35.42 \pm 2.25$  fold) than by hMSCs coculture system ( $25.24 \pm 3.32$  fold), cytokines culture system ( $19.75 \pm 2.56$  fold) and hMSCs (TPO/FL-free) culture

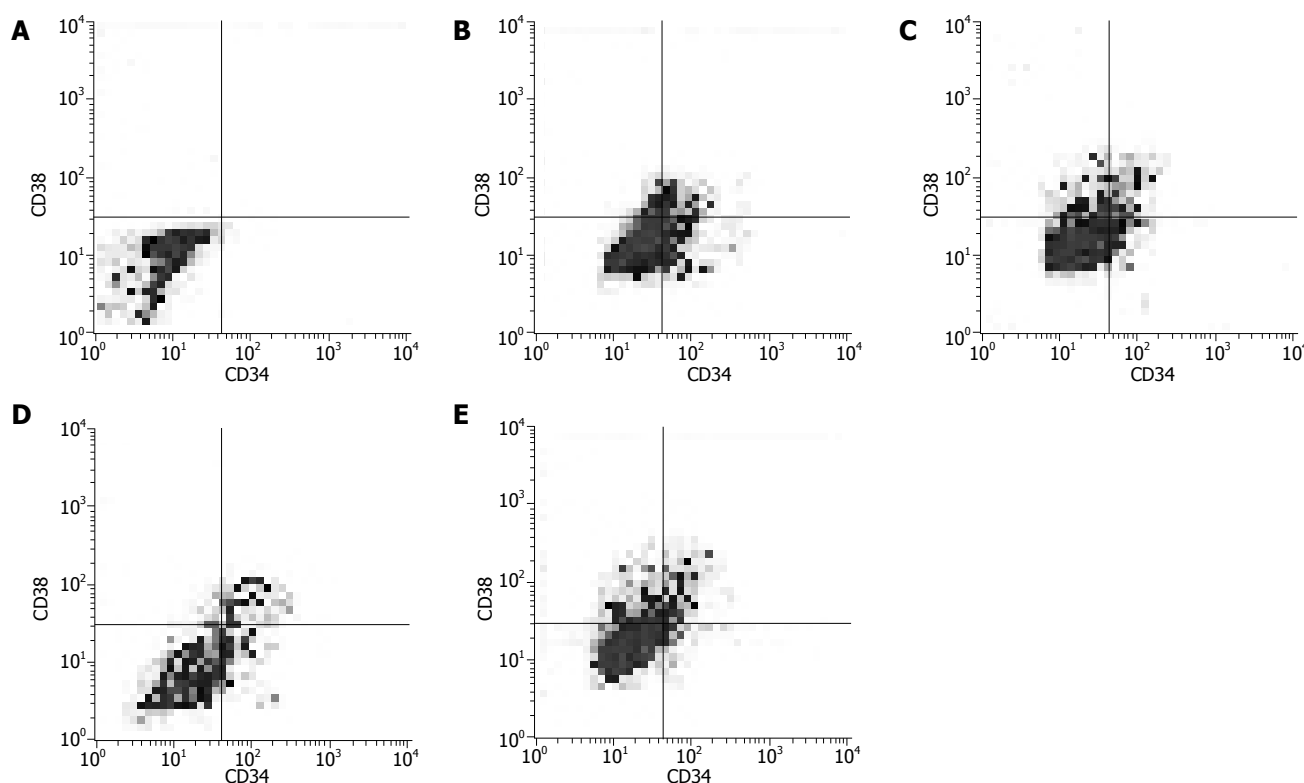

system ( $11.32 \pm 2.48$  fold) ( $P < 0.01$ ) (Figure 2B). Although fold increase of CD34<sup>+</sup> cells was largely decreased among all the four systems on d 21, the expansion magnitude of CD34<sup>+</sup> cells by tfhMSCs coculture system ( $20.15 \pm 3.16$  fold,  $P < 0.01$ ) was higher than that by the three systems (Figure 2B).

Next, we determined the outputs of CFU-C and CFU-GEMM. The expansion magnitude of CFU-C in tfhMSCs coculture system ( $126.54 \pm 15.42$  fold), although lower than cytokines culture system on d 7 ( $P < 0.05$ ), was much higher than other three culture systems on d 14 ( $P < 0.01$ ). Interestingly, tfhMSCs coculture system significantly stimulated production of CFU-C on d 21 ( $101.12 \pm 7.23$  fold,  $P < 0.01$ ) (Figure 2C). The output of CFU-GEMM in tfhMSCs coculture system on d 7, 14 and 21 was also enhanced ( $12.65 \pm 1.36$  fold,  $25.16 \pm 2.53$  fold and  $10.93 \pm 4.12$  fold, respectively) ( $P < 0.01$ ) (Figure 2D). Analysis for expression of CD34 and CD38 by flow cytometry among the four culture systems on d 14 was shown in Figure 3.

#### Ex vivo expansion of UCB CD34<sup>+</sup> cells in a short-term (7 d) serum-free tfhMSCs coculture system

The synergistic effects of tfhMSCs and additive cytokines

**Figure 3** Comparison of CD34 and CD38 expression among hematopoietic cells in different culture systems. CD34<sup>+</sup> cells derived from a single delivery were cultured using different culture systems in serum-containing medium. On d 14 of culture, aliquots of harvested cells were subjected to flow cytometric analysis. **A**=Negative control; **B**=tfhMSCs coculture system; **C**=hMSCs coculture system; **D**=cytokines culture system; **E**=hMSCs (TPO/FL-free) culture system.

on ex vivo expansion of UCB hematopoietic progenitors was also studied in serum-free culture for a short duration. After 7 d of culture, the number of total nucleated cells in tfhMSCs coculture system was remarkably increased ( $P < 0.01$ ) (Table 1). As a result, the mean number of total nucleated cells was approximately 50 to 90 times the initial input number. CD34<sup>+</sup> cells were generated more by tfhMSCs coculture system than by other three groups ( $P < 0.01$ ); the number of CD34<sup>+</sup> cells was over 12 times the initial input number. The outputs of CFU-C and CFU-GEMM in tfhMSCs coculture system were also increased approximately 40-fold ( $P < 0.05$ ) and 15-fold ( $P < 0.01$ ), respectively.

#### **LTC-IC assay using the CD34<sup>+</sup> population isolated from cells cultured in four culture systems**

To determine whether cells generated in four culture systems could preserve the ability to sustain long-term hematopoiesis, the LTC-IC frequency in cells cultured by these systems was quantified. Initially, isolated UCB CD34<sup>+</sup> cells were cultured for 14 d using four culture systems in the serum-containing culture. Cultured cells were harvested and subjected to a second CD34<sup>+</sup> cell purification by sorting. LTC-IC assay was performed using sorted CD34<sup>+</sup> cell populations, as well as those initially prepared from UCB (control samples). The LTC-IC frequency was determined as previously described<sup>[28]</sup>. As shown in Table 2, Although the yields of LTC-IC expansion in hMSCs coculture system ( $5.32 \pm 1.73$  fold) was higher than cytokines culture system ( $3.58 \pm 1.48$  fold) and hMSCs (TPO/FL-free) culture system ( $2.79 \pm 0.56$

fold), the tfhMSCs coculture system demonstrated the most powerful activity ( $10.23 \pm 2.89$  fold,  $P < 0.01$ ). The findings suggest that the tfhMSCs coculture system might be a novel as well as efficient culture system for UCB-derived hematopoietic progenitor cells.

#### **Effects of coculture system using tfhMSCs as feeder layer on human reconstituting hematopoietic progenitors**

Accordingly, we studied the SRC assay to determine whether cells cultured in the tfhMSCs coculture system were capable of long-term multilineage reconstitution *in vivo*. Purified  $1 \times 10^5$  UCB CD34<sup>+</sup> cells were initially cultured for 14 d using the tfhMSCs coculture system; harvested cells were then transplanted into NOD/SCID mice. As controls, uncultured 100 000 UCB CD34<sup>+</sup> cells obtained from the same sources were also transplanted into other mice. Seven weeks after transplantation, human CD45<sup>+</sup> cells were found in the bone marrow, and peripheral blood cells of mice transplanted with the cultured cells (Figure 4A, and data not shown). There were marked differences in the percentage of chimerism between bone marrow cells in mice transplanted with cultured cells and those transplanted with control samples. Human CD45<sup>+</sup> cells in the murine bone marrow were further subjected to flow cytometric analysis to determine multilineage reconstitution. As a result, human CD45<sup>+</sup> cells were positive for CD34, CD33, CD14, CD41, glycophorin A, or CD19 (Figure 4B). Furthermore, PCR analysis demonstrated the presence of human hematopoietic cells in the bone marrow and peripheral blood cells of NOD/SCID mice (Figure 5).

## DISCUSSION

In this study we demonstrated that TPO/FL-transduced human marrow-derived mesenchymal stem cells (tfhMSCs) could effectively support ex vivo expansion of UCB-PPC in synergy with human cytokines. We assessed the supportive effects of four culture systems on proliferation of PPC in serum-containing liquid medium. Although there were no significant differences in the number of total nucleated cells among the different culture systems during culture, tfhMSCs coculture system could dramatically enhance generation of CFU-C, CFU-GEMM and CD34<sup>+</sup> cells, and more importantly was capable of expanding LTC-IC.

In ex vivo expansion of human UCB-PPC, there are several benefits to using the tfhMSCs as the feeder: (1) tfhMSCs can be maintained easily; (2) consistent hematopoietic-supportive effects are repeatedly obtained; (3) additive TPO and FL are not needed in culture system. The effects of tfhMSCs coculture system were comparable to those obtained by classical culture, including cytokines culture and contact culture. Although contamination of tfhMSCs into cultured cells is a problem, and it is difficult to harvest cultured hematopoietic cells completely, since a number of cultured cells migrate under feeder layers, the tfhMSCs coculture system was considered to be a suitable system for ex vivo manipulation of PPC under stroma-contact culture conditions. Moreover, the tfhMSCs, unlike the primary stromal cells<sup>[17,18]</sup>, could be expanded and cryopreserved without transformation. Thus, we can prepare a large quantity of these human tfhMSCs at any time. Taking advantage of this culture system, clinical research on ex vivo expansion could be facilitated. For example, progenitor cells such as CD34<sup>+</sup> cells and CFU-C were extensively expanded more than 125-fold in this system in 2 wk, and it may be possible to use these

expanded cells as a new source of blood transfusion after differentiation of the expanded cells into megakaryocytes or erythroblast progenitor cells<sup>[31]</sup>.

Although the present study and others<sup>[5,8,32]</sup> have demonstrated that addition of TPO and FL in culture systems could lead to significant expansion of HSC populations, including LTC-IC, the tfhMSCs coculture system, which have no addition of TPO and FL, manifested higher expansion of LTC-IC. The mechanism of supportive effect of tfhMSCs remains unknown. Previous investigations have shown that the very hematopoietic cell types whose maximum proliferation in vitro depends on stimulation by the highest concentrations of cytokines<sup>[32]</sup>. The ability that tfhMSCs expressing TPO and FL can maintain a higher concentrations of TPO and FL in medium may be a reason.

Serum-free culture could prevent UCB primitive-cell differentiation<sup>[14]</sup>, and when a serum-free medium is used, the risks of contamination of heterogenic antigen and infectious danger were small<sup>[33]</sup>. We then assessed the supportive effects of four culture systems on proliferation of PPC in serum-free liquid medium. We attempted ex vivo manipulation for a short duration. As a result, adequate expansion of UCB-PPC was obtained in tfhMSCs coculture system. Furthermore, compared with serum-containing culture the number of CD34<sup>+</sup> cells was not increased and the total nucleated cells were not significantly decreased during culture; However, the output of CFU-C and CFU-GEMM was enhanced, suggesting that serum-free conditions prevent primitive-cell differentiation.

Previous findings showed that UCB LTC-IC were present among the CD34<sup>+</sup> cell fraction<sup>[34,35]</sup>. Furthermore, Bhatia *et al.* identified the SRC that were capable of multilineage reconstitution of human hematopoiesis in the bone marrow of NOD/SCID mice<sup>[29]</sup>. Therefore, the

**Figure 4** Determination of human hematopoietic reconstitution in NOD/SCID mice 7 wk after transplantation. **A:** Expression of human CD45 on bone marrow cells (BMC) collected from NOD/SCID mice 7 wk after transplantation; (**A<sub>1</sub>**): Cells in the gated area were analyzed by flow cytometry; (**A<sub>2</sub>**): Bone marrow cells (BMC) from an untransplanted mouse (negative control); (**A<sub>3</sub>**): BMC from a mouse transplanted with  $1 \times 10^5$  human CD34<sup>+</sup> cells before culture; (**A<sub>4</sub>**): BMC from a mouse transplanted with cells obtained after 14-d cultivation of those 100 000 human CD34<sup>+</sup> cells in the tfhMSCs coculture system; **B<sub>1</sub>-B<sub>6</sub>**: Specific subsets of human CD45<sup>+</sup> cells in bone marrow cells of the NOD/SCID mouse transplanted with UCB cells after the coculture. Harvested cells were stained with PE-conjugated CD45 and various FITC-conjugated monoclonal antibodies.

expanded hematopoietic progenitors were expected to sustain long-term hematopoiesis. As a result, 10.23-fold LTC-IC amplification was observed in cells expanded by the tfhMSCs coculture system, although LTC-IC frequency was decreased during culture. The SRC assay indicated the reconstituting ability of these cultured human PPC. Although we could not perform a quantitative SRC assay, the difference in the percentage of chimerism of human CD45<sup>+</sup> cells between bone marrow cells of mice

transplanted with cultured cells and those transplanted with control samples strongly suggested the extensive ability of these ex vivo-generated PPC to sustain and reconstitute long-term human hematopoiesis in vivo. Furthermore, PCR analysis confirmed flow cytometric results.

In conclusion, the main obstacle to UCB transplantation in adult recipients is the insufficiency of hematopoietic progenitors. A novel tfhMSCs coculture

**Figure 5** PCR analysis of human Alu sequence in NOD/SCID mice 7 wk after transplantation. DNA was extracted from the bone marrow and peripheral blood cells of NOD/SCID mice 7 wk after transplantation. PCR analysis demonstrated the presence of human hematopoietic cells in the bone marrow (lane 2) and peripheral blood cells (lane 3) of NOD/SCID mice. DNA extracted from human UCB cells was used as a positive control (lane 4). Negative control is shown in lane 1 and DNA marker is shown in lane 5.

system that could efficiently expand UCB hematopoietic progenitors is successfully established. The extent of LTC-IC expansion shown herein has important practical implications in terms of clinical hematopoietic stem cell transplantation.

## Abstract

**AIM:** To investigate the role of Kupffer cells (KCs) in acute hemorrhagic necrotizing pancreatitis-associated lung injury (AHNP-LI).

**METHODS:** Forty-two rats were allocated to four groups [sham operation, AHNP model, gadolinium chloride (GdCl<sub>3</sub>) pretreatment, GdCl<sub>3</sub> control]. In GdCl<sub>3</sub> pretreatment group, GdCl<sub>3</sub> was administered by caudal vein injection 24 h before the AHNP model induction. Blood from the iliac artery, alveolar macrophages and tissues from the pancreas and lung, were collected in six animals per group 3 and 6 h after acute pancreatitis induction. TNF-α, IL-1 of serum, myeloperoxidase (MPO) of lung tissue, NF-κB activation of alveolar macrophages were detected. Serum AST and ALT in sham operation group and GdCl<sub>3</sub> control group were tested. In addition, histopathological changes of the pancreas and lung were observed under light microscope.

**RESULTS:** MPO of lung tissue and TNF-α, IL-1 levels of serum were all reduced significantly in GdCl<sub>3</sub> pretreatment group compared to those in AHNP group ( $P < 0.01$ ). NF-κB activation of alveolar macrophages was also attenuated significantly in GdCl<sub>3</sub> pretreatment group compared to that in AHNP group ( $P < 0.01$ ). The pathological injury of the lung was ameliorated obviously in GdCl<sub>3</sub> pretreatment group compared to that in AHNP group. Nevertheless, the serum amylase level did not reduce and injury of the pancreas was not prevented in GdCl<sub>3</sub> pretreatment group.

**CONCLUSION:** Pulmonary injury induced by AHNP is mediated by KC activation and AHNP-LI can be

## INTRODUCTION

Acute lung injury is a severe complication of acute hemorrhagic necrotizing pancreatitis (AHNP)<sup>[1-3]</sup>. However, its pathogenic mechanism is not well understood and its treatment remains supportive. Recent researches suggest that inflammatory cytokines derived from the liver, especially hepatic cytokine released from Kupffer cells (KCs) may cause distant organ failure and death in severe pancreatitis and that KCs are an important source of inflammatory cytokines and may be the main factor causing lung damage in AHNP<sup>[4,5]</sup>. Here we studied the KC contribution to lung injury associated with AHNP. The present study was to investigate the role of KCs in acute hemorrhagic necrotizing pancreatitis-associated lung injury.

## MATERIALS AND METHODS

### Experimental animals, agents, and ELISA kits

Male Wistar rats were provided by Experimental Animal Center of Capital Medical University (Beijing). Sodium taurocholate and gadolinium chloride (GdCl<sub>3</sub>) were purchased from Sigma-Aldrich (St. Louis, MO, USA). TNF-α, IL-1 ELISA kits were purchased from TPI Ltd. (USA). TransAM<sup>TM</sup> NF-κB P<sup>65</sup> chemi ELISA kit was provided by Active Motif (USA). Central LB 960 microplate luminometer was from Berthold Ltd.

### Induction of AHNP model

Experimental AHNP was induced as previously described<sup>[6]</sup>. Briefly, a small median laparotomy was performed, then the pancreas was exteriorized and the hepatic duct was closed at the liver hilum with a soft microvascular clamp to prevent reflux of the infused

material into the liver. The biliopancreatic duct was cannulated through the duodenum and 5% sodium taurocholate (1 mL/kg body weight, 0.1 mL/min) was retrogradely injected into the biliopancreatic duct. The clamp was removed 5 min after the injection. The abdominal wound was closed, and the animals were sent back to their cages with free access to water and food after surgery.

### Animals

Forty-two male Wistar rats (weighing 250-280 g) were randomly divided into four groups: sham operation, AHNP model, GdCl<sub>3</sub> pretreatment and GdCl<sub>3</sub> control. In the GdCl<sub>3</sub> pretreatment group, GdCl<sub>3</sub> solution (4%, 10 mg/kg) was administrated by caudal vein injection 24 h before the AHNP model was established. Blood from the iliac artery, alveolar macrophages, and tissues from the pancreas and lung, were collected in six animals per group 3 and 6 h after acute pancreatitis induction. Serum levels of TNF- $\alpha$  and IL-1 were determined by enzyme-linked immunosorbent assay. Myeloperoxidase (MPO) level in the lung and NF- $\kappa$ B activation of the alveolar macrophages were detected. Serum AST and ALT in sham operation group and GdCl<sub>3</sub> control group were tested by biochemical method. In addition, histopathological changes of the pancreas and lung were observed under light microscope.

### Alveolar macrophage isolation and nuclear protein extraction

Bronchoalveolar lavage (BAL) was performed five times in the left lung, using 5 mL of sterile normal saline per lavage given through a tracheal cannula<sup>[7]</sup>. The whole BAL fluid (BALF) was centrifuged at 280 r/min for 10 min at 4 °C. Cell pellets were resuspended ( $1 \times 10^5$  cells/mL) in RPMI 1640 medium. Cell suspension was then placed in plastic petri dishes (Nunc, Denmark) and incubated at 37 °C for 1 h in a CO<sub>2</sub> incubator (50 mL/L CO<sub>2</sub>+95% air). Non-adherent cells were removed from adherent macrophages by washing with RPMI 1640 medium. Purified alveolar macrophages were recovered by gently rubbing the dishes with a rubber policeman. Nuclear protein was extracted from purified alveolar macrophages as previously described<sup>[8]</sup>. Protein content was determined by Bradford method, stored at -70 °C for subsequent examination of NF- $\kappa$ B activity.

### Amylase estimation

Serum amylase activity was measured by iodoamylum method and expressed as U/L.

### Serum TNF- $\alpha$ , IL-1 estimation

Serum TNF- $\alpha$  and IL-1 were measured by ELISA method according to the instructions of the kits.

### Lung tissue MPO estimation

Lung tissue MPO activity was detected according to the instructions of commercial kit.

### Serum AST and ALT estimation

Serum levels of AST and ALT were determined using Toshiba VF-A5/A5P Bio-Chemical analyzer.

**Table 1 Serum amylase in all experimental groups (U/L, mean $\pm$ SD)**

Group	Serum amylase	
	3 h (n=6)	6 h (n=6)
Sham	499.4 $\pm$ 86.3	503.8 $\pm$ 91.2
AHNP	10 444.5 $\pm$ 1 863.2 <sup>b</sup>	13 316.4 $\pm$ 1 374.1 <sup>b</sup>
GdCl <sub>3</sub> pretreatment	9 107.1 $\pm$ 569.9 <sup>b</sup>	12 420.4 $\pm$ 1 779.2 <sup>b</sup>

<sup>b</sup>P<0.001 vs sham group.

**Table 2 Influence of GdCl<sub>3</sub> on hepatic functions of experimental animals (U/L, mean $\pm$ SD)**

Group	n	Serum AST	Serum ALT
Sham 3 h	6	74.2 $\pm$ 13.6	31.6 $\pm$ 9.3
Sham 6 h	6	71.3 $\pm$ 15.0	32.7 $\pm$ 11.3
GdCl <sub>3</sub> control	6	82.5 $\pm$ 14.6	28.9 $\pm$ 8.7

### NF- $\kappa$ B of alveolar macrophage estimation

NF- $\kappa$ B activation of alveolar macrophages was determined using TransAM<sup>TM</sup> NF- $\kappa$ B P<sup>65</sup> chemi ELISA kit by Central LB 960 microplate luminometer and expressed as relative light units (RLU).

### Histology

Pancreas and lung tissues were collected and evaluated by a pathologist blinded to the experimental assignment of the animals. After embedded with paraffin, the tissue was stained with hematoxylin-eosin (H&E). Pulmonary lesion was scored following Lei's criteria<sup>[9]</sup>.

### Statistical analysis

All data were expressed as mean $\pm$ SD. Comparisons among multiple experimental groups and between each time point were made using ANOVA. P<0.05 was considered statistically significant.

## RESULTS

Table 1 illustrates the levels of serum amylase in all the three groups. Three and six hours after AHNP induction, serum amylase increased significantly in AHNP group compared to that in sham operation group. But there was no significant difference between GdCl<sub>3</sub> pretreatment group and AHNP group 3 and 6 h after AHNP induction.

Table 2 shows the influence of GdCl<sub>3</sub> on hepatic functions of experimental animals. No changes were found in GdCl<sub>3</sub>-treated animals and the values of ALT and AST in GdCl<sub>3</sub> control group were similar to those in sham group measured at all time points.

Serum TNF- $\alpha$  and IL-1 in AHNP group were significantly increased compared to those measured in sham group at all time points (P<0.01). In GdCl<sub>3</sub> pretreatment group, 3 and 6 h after AHNP induction, serum TNF- $\alpha$  and IL-1 were significantly decreased (P<0.01, Table 3).

Table 4 shows the MPO activity of lung injury in

Group	MPO	
	3 h (n = 6)	6 h (n = 6)
Sham	0.51 $\pm$ 0.13	0.50 $\pm$ 0.17
AHNP	1.59 $\pm$ 0.26	1.79 $\pm$ 0.23
GdCl <sub>3</sub> pretreatment	0.94 $\pm$ 0.15 <sup>b</sup>	1.02 $\pm$ 0.19 <sup>b</sup>

<sup>b</sup>*P*<0.01 vs AHNP group.**Figure 1** NF- $\kappa$ B activity of alveolar macrophages in BALF of all groups. <sup>b</sup>*P*<0.01 vs AHNP group, <sup>d</sup>*P*<0.01 vs sham operation group.**Figure 2** Histopathological changes in different groups. **A:** Extensive necrosis, intense edema and inflammatory infiltrate in AHNP group (100 $\times$ ); **B:** extensive necrosis and intense edema in GdCl<sub>3</sub> pretreatment group (100 $\times$ ); **C:** diffuse alveolar blood stasis and heavy infiltration of inflammatory cells (100 $\times$ ) in AHNP group; **D:** mild edema of the alveolar walls and mild alveolar blood stasis with slight infiltration of neutrophils in GdCl<sub>3</sub> pretreatment group (100 $\times$ ).

all the groups. The MPO levels in AHNP group were significantly higher than those in sham operation group (*P*<0.01). In GdCl<sub>3</sub> pretreatment group, 3 and 6 h after AHNP induction, the lung MPO levels were significantly decreased (*P*<0.01).

Figure 1 shows that the NF- $\kappa$ B activity of alveolar macrophages in AHNP group was significantly higher than that in sham operation group (*P*<0.01) and was significantly decreased in GdCl<sub>3</sub> pretreatment group (*P*<0.01).

Histopathological study of the pancreas, 3 and 6 h after AHNP induction (Figure 2A) revealed extensive necrosis of pancreatic tissue, intense edema, and inflammatory infiltrate. The necrosis of pancreatic tissue and edema in GdCl<sub>3</sub> pretreatment group were similar to those in AHNP group (Figure 2B). The sham operation group was normal.

Diffuse alveolar blood stasis, intense alveolar septum

swelling and heavy infiltration of inflammatory cells mostly neutrophils were found in the lung tissue of AHNP group (Figure 2C). The mean histopathologic scores of AHNP group were significantly higher than those in sham operation group (*P*<0.01, Table 5). In GdCl<sub>3</sub> pretreatment group, the major histopathological findings were mild edema of the alveolar walls and mild alveolar blood stasis with slight infiltration of neutrophils (Figure 2D). The mean histopathologic scores of GdCl<sub>3</sub> pretreatment group decreased significantly compared to those of AHNP group (*P*<0.05).

## DISCUSSION

Acute hemorrhagic necrotizing pancreatitis (AHNP) is a potentially fatal disease with a morbidity and mortality rate of approximately 30%. Acute lung injury (ALI)

is a common complication of AHNP, but the events that link AHNP and pulmonary damage are not fully understood. Many factors, such as oxygen free radicals, platelet activating factor, phospholipase A<sub>2</sub> (PLA<sub>2</sub>), cyclooxygenase-2 (COX-2), cytokines and arachidonic acid metabolites are related to AHNP and ALI<sup>[10-13]</sup>. Pancreatic proteolytic enzymes or activated PLA<sub>2</sub> released into the circulatory system determines the development of lung injury<sup>[14]</sup>. Furthermore, other mediators in lung tissue such as platelet activating factor, arachidonic acid metabolites can stimulate inflammatory cell activation<sup>[15,16]</sup>. Also, interaction of polymorphonuclear granulocytes, endothelium, and endothelium-derived mediators seems to be important to amplify lung damage<sup>[17]</sup>. Recently, Cheng *et al*<sup>[18,19]</sup> noted that activation of alveolar macrophages may play an important role in lung injury associated with AHNP, and that TNF- $\alpha$  and nitric oxide (NO) secreted by alveolar macrophages are increased significantly in rats with AHNP. Bhatia *et al*<sup>[20]</sup> reported that inhibition of the production of hydrogen sulfide (H<sub>2</sub>S) can significantly reduce the severity of cerulein-induced pancreatitis and associated-lung injury, suggesting an important proinflammatory role in regulating the severity of pancreatitis and associated-lung injury.

In recent years, some researchers found that the liver, especially KCs, might play a vital role in ALI caused by other different factors. Okutan *et al*<sup>[21]</sup> reported that KCs blocked by GdCl<sub>3</sub> can attenuate lung damage caused by aortic ischemia reperfusion and malondialdehyde (MDA) level, an indicator of free radical generation and MPO activity, an indirect evidence of neutrophil infiltration in lung injury are decreased significantly<sup>[21]</sup>. Although there is no evidence that GdCl<sub>3</sub> can suppress the function of neutrophils, it was reported that GdCl<sub>3</sub> can suppress the accumulation of neutrophils and alveolar macrophages<sup>[22]</sup>. Feng *et al*<sup>[23]</sup> investigated the role of KCs in the pathogenesis of ALI during acute obstructive cholangitis (AOC) and found that the phagocytic function of KCs is damaged in ALI induced by AOC.

KCs, the resident macrophages in the liver, are the major component of mononuclear phagocytic system (MPS). These macrophages make up 90% of the MPS and have abundant cytoplasm where abundant ribosome and phagosomes are located. These typical structures are associated with their functions. It was reported that KCs are responsible for the increased levels of TNF, IL-1, IL-6 in trauma, hemorrhagic shock and resuscitation. Decreasing the number or functional ability of KCs can lead to decreased levels of inflammatory cytokines as seen in the models of liver resection and sepsis<sup>[24,25]</sup>.

Also, KCs are regarded as the predominant source of inflammatory cytokines in AHNP at present<sup>[26,27]</sup>. Closa *et al*<sup>[4,5]</sup> performed an end-to-side portacaval shunt before AHNP induction in rats and found that portacaval shunting appears to exert a profound effect on ameliorating the inflammatory infiltrate. It is suggested that almost all the pancreatic enzymes and mediators released from the pancreas into the plasma during AHNP pass through the liver before their dilution in the systemic circulation, indicating that this step is a determinant in the development of the lung injury response. These

observations point to the key role of liver as a triggering mechanism for inflammatory processes in the lung as a consequence of AHNP. Moreover, activation of hepatic inflammatory cells, especially KCs, plays a key role in the development of lung injury<sup>[4,5]</sup>.

To improve our understanding of the role of KCs in AHNP-ALI, GdCl<sub>3</sub> was given 24 h prior to AHNP model induction to eliminate KCs in the present study. Moreover, the dose of GdCl<sub>3</sub> used in our study was 10 mg/Kg because administration of GdCl<sub>3</sub> at a dose 10 mg/kg can block the phagocytic activity of KCs completely<sup>[28]</sup>. In GdCl<sub>3</sub> pretreatment group, the levels of MPO in lung tissue and the levels of TNF- $\alpha$ , IL-1 in serum all decreased significantly compared to those in AHNP group. NF- $\kappa$ B activation of alveolar macrophages was also attenuated significantly in GdCl<sub>3</sub> pretreatment group compared to that in AHNP group. All these data suggest that GdCl<sub>3</sub> can ameliorate AHNP-ALI significantly and these results are in accordance with those reported by Folch *et al*<sup>[29]</sup>. It was reported that lung injury associated with acute necrotic pancreatitis (ANP) is ameliorated by GdCl<sub>3</sub> through inducing apoptosis of alveolar macrophages of ANP<sup>[30]</sup>.

In our study, the serum amylase level did not decrease and the injury of pancreas was not prevented in GdCl<sub>3</sub> pretreatment group, suggesting that GdCl<sub>3</sub> cannot prevent lung injury by ameliorating pancreatic injury.

Using GdCl<sub>3</sub> as a tool to investigate the role of KCs is more reasonable than portacaval shunting operation which appears to exert a profound effect on animal's systemic circulation. Serum AST and ALT estimation suggests that GdCl<sub>3</sub> has no harmful effects on hepatic functions.

In conclusion, KCs play a vital role in AHNP and ALI.

## Abstract

**AIM:** To evaluate the effectiveness and safety of different portal vein branch embolization agents in inducing compensatory hypertrophy of the remnant liver and to offer a theoretic basis for clinical portal vein branch embolization.

**METHODS:** Forty-one adult dogs were included in the experiment and divided into four groups. Five dogs served as a control group, 12 as a gelfoam group, 12 as a coil-gelfoam group and 12 as an absolute ethanol group. Left portal vein embolization was performed in each group. The results from the embolization in each group using different embolic agents were compared. The safety of portal vein embolization (PVE) was evaluated by liver function test, computed tomography (CT) and digital subtraction angiography (DSA) of liver and portal veins. Statistical test of variance was performed to analyze the results.

**RESULTS:** Gelfoam used for PVE was inefficient in recanalization of portal vein branch 4 wk after the procedure. The liver volume in groups of coil-gelfoam and absolute ethanol increased 25.1% and 33.18%, respectively. There was no evidence of recanalization of embolized portal vein, hepatic dysfunction, and portal hypertension in coil-gelfoam group and absolute ethanol group.

**CONCLUSION:** Portal vein branch embolization using absolute ethanol and coil-gelfoam could induce atrophy of the embolized lobes and compensatory hypertrophy of the remnant liver. Gelfoam is an inefficient agent.

## INTRODUCTION

Primary carcinoma of the liver is one of the common malignant tumors in our country. Hepatectomy remains one of the most important therapies. However, only 15-30% of diagnosed patients are suitable for hepatectomy. Although extended hepatic resection is an effective therapy, partial excision of normal and functional liver is unavoidable in this surgery. If partial excision resects a certain amount of liver, patients especially those with liver cirrhosis, would suffer from postoperative liver failure. Although limiting resection area can reduce the possibility of complications, it increases the incidence of postoperative recurrence and metastasis. These problems can be effectively solved by artificially inducing hyperplasia of normal liver tissue preoperatively. Therefore, preoperative portal vein embolization (PPVE) is an effective procedure to settle this contradiction<sup>[1-5]</sup>.

In 1920, Roust Larimore discovered that ligation of rabbits' portal vein branch could contribute to the atrophy of pathological lobe and hyperplasia of non-pathological one. In 1975, Honjo *et al*<sup>[6]</sup> tried portal vein ligation in liver cancer patients not fit for hepatic resection, which resulted in atrophy of the ligated lobe of portal vein and its tumor and hyperplasia of non ligated lobe. In 1980s, Makuuchi *et al*<sup>[7]</sup> found that if the portal vein of one lobe is embolized by tumor thrombi, hyperplasia usually occurs in the other lobe of the liver, and meanwhile, patients enjoy better recovery after hepatectomy because unexpected rising of portal vein pressure could be avoided. These findings have led to the exploration of preoperative PVE prior to extensive liver hepatic resection. PVE in clinical practice<sup>[1,2,8,9]</sup> and experimental studies<sup>[10-13]</sup> has achieved success. Since foreign emboli materials are expensive and difficult to obtain, it is essential to screen for easily-obtained, convenient, cheap, and safe embolic agents to effectively induce compensatory hyperplasia. The purpose of our study was to evaluate the effectiveness and safety of three convenient and cheap agents in inducing compensatory hypertrophy of liver.

## MATERIALS AND METHODS

### Experimental animals

Forty-one healthy adult dogs weighing 16.2±4.2 kg (range, 12.0-20.0 kg) without obvious growth (to avoid sudden changes of weight during the process of experiment, which would affect liver volume and influence experimental results), were included in the study. All dogs were provided by Experimental Animal Center of Union Hospital attached to Fujian Medical University. Before and after the experiment, they were fed with same standard forage. Five served as the control group and the remaining 36 were divided into 3 groups at random, 12 in each group. Gelfoam, coil-gelfoam and absolute ethanol were applied to these 3 experimental groups for portal vein embolization.

### Methods

A dog with jejunitis on operative day was given an intravenous injection of 10% pentobarbital sodium into the hind legs to induce general anesthesia. Then, the dog underwent helical CT scanning to conduct pre and post contrast-enhanced CT study of its liver. The liver volume was measured automatically by a computer with the help of SOMATOM PLUS4 spiral CT scanner (Siemens Co.). The dog was transferred into the interventional operating room and cut open for catheter placement of portal vein under general anesthesia. After a 5F Cobra catheter was inserted into the trunk of portal vein, 76% angiografin was injected at the speed of 8-10 mL/s through the catheter to study the branch pattern of portal vein. Because the right lobe was relatively fixed, left portal vein was chosen as a target vessel for embolization. Then, the catheter was inserted into the left portal vein and saline or an embolic agent was injected into the appropriate position in different experimental groups. Control group: 30-50 mL saline was injected through the catheter. Gelfoam group: gelfoam was cut into strips of 10 mm×1.0 mm, which were inserted into the embolized portal vein through the catheter with saline until complete embolization was achieved. Embolization procedure was stopped when the embolized portal vein was completely embolized and the distal portal vein branch was not opacified. The number of gelfoams used ranged between 40-60 strips. Coil-gelfoam group: gelfoam was used to embolize smaller branches of the left portal vein, then coils were used to embolize the trunk of the left portal vein until satisfactory results were achieved. The number of coils ranged between 3-5. Absolute ethanol group: Five milliliters of absolute ethanol was slowly injected through the catheter. After several minutes, an additional amount of absolute ethanol was provided based on the embolization situation of portal vein in order to achieve the result of complete embolization. The amount of absolute ethanol was generally 0.5-1.0 mL/kg. After embolization, 9-12 mL angiografin was injected through the catheter at a speed of 6-8 mL/s to carry out angiography of the portal vein, which would allow us to understand its iconography expression after embolization. At the same time, we measured the pressure of main portal vein, and the radial lines of the nonembolized portal veins including the right portal vein and main portal vein.

Table 1 Changes of the right lobe volume in gelfoam group (cm<sup>3</sup>)

No	Pre-embolization	4W	6W	8W

Mean±SD	318±18.2	347.6±21.4	321.7±17.7	331.9±19.4

After embolization, all dogs were regularly fed. Angiography was performed 4 and 8 wk after embolization, transcatheter portal vein angiography was undertaken to understand the iconography expression of portal vein branches, and then diameter of the nonembolized portal vein was measured. Changes of portal vein pressure were monitored 4 and 8 wk after embolization, transcatheter portal vein angiography was performed to measure the portal vein pressure. Changes of liver function were detected before and after embolization, alanine aminotransferase (ALT) was assayed every 2 d until liver function became normal. Changes of liver volume were determined 4, 6, and 8 wk after embolization, liver CT scanning was performed to measure the volume of the nonembolized lobe. Dogs were killed 8 wk after embolization, pathology observation was implemented of liver tissues of the embolized and nonembolized lobes.

### Statistical analysis

SPSS11.0 software package was adopted to carry out statistical analysis of experimental results.

## RESULTS

### Control group

During the period of embolization, all the five dogs survived. Iconography expression was the same as before, suggesting that no blood vessel was embolized. Meanwhile, there were no changes of portal vein pressure, volume of the right lobe, liver function, and pathology before and after saline injection.

### Gelfoam group

One dog died of respiratory failure, another dog died of acute liver failure due to gelfoam back-flow which led to extensive embolization of portal vein branches in liver, and 10 dogs survived. Post embolization angiography showed that the left branch of portal vein was completely embolized, while the right branch was not obstructed, the right portal vein and main portal vein were dilated compared to pre-embolization. Four weeks after embolization the embolized left portal vein had blood flow (Figure 1). The portal vein pressure was 94.1±1.8 mm H<sub>2</sub>O, 123.2±2.8 mm H<sub>2</sub>O before embolization, and 94.7±2.0 mm H<sub>2</sub>O, 95.8±6.6 mm H<sub>2</sub>O after embolization, respectively ( $P>0.05$ ). ALT value obviously increased 2 d after embolization ( $P<0.01$ ), but decreased subsequently

Figure 1 Portal vein angiography before (A) and after (B) embolization as well as 4 wk (C) after embolization with gelfoam.

Figure 2 No obvious changes in volume of the right lobe before (A) and after (B) embolization.

Figure 3 Portal vein angiography before (A) and after (B) embolization as well as 8 wk (C) after embolization with coil-gelfoam.

and then became normal in the following 3 d. No obvious changes were found in the volume of the right lobe before and after embolization (Table 1). Contrast-enhanced CT scanning revealed that the left branch of portal vein was recanalized (Figure 2). Ten dogs were killed 8 wk after embolization, no obvious differences were found between the embolized and nonembolized lobes.

#### Coil-gelfoam group

One dog died of respiratory failure due to narcosis, the rest had successful surgery (91.7%). After embolization, the left branch was completely embolized while the

right branch was patent. Compared to pre-embolization situations, the main portal vein and right portal vein were expanded to a certain extent (Figure 3). The portal vein pressure was  $96.5 \pm 5.1$  mm H<sub>2</sub>O,  $133.9 \pm 10.4$  mm H<sub>2</sub>O before embolization and  $97.0 \pm 6.3$  mm H<sub>2</sub>O,  $97.6 \pm 4.7$  mm H<sub>2</sub>O after embolization. ALT in experimental dogs increased 2 d after embolization ( $P < 0.01$ ), and returned to the pre-embolization level in the following 3 d ( $P > 0.05$ ). The right lobes of all the survived dogs after embolization were expanded to varying extent. The liver volume was  $344.9 \pm 38.3$ ,  $374.8 \pm 43.0$  before embolization and  $431.5 \pm 50.9$ ,  $434.0 \pm 50.4$  after embolization (Table

2). No further hyperplasia was found (Figure 4). The embolized lobe was dark red with a sharp edge, while the nonembolized lobe was slightly bright red and comparatively plump. Coils were surrounded by fibrin and

combined forming the tight emboli. Under microscope, the embolized lobe showed structural changes of hepatic lobules, atrophy and degeneration of liver cells, and congestion of blood vessel, while the nonembolized lobe

revealed cell hypertrophy and obvious hyperplasia.

### Absolute ethanol group

One dog died during surgery and 1 dog died in 24 h after surgery due to respiratory failure and acute liver failure caused by the back-flow of absolute ethanol. The rest 10 dogs had successful surgery. The left branch of portal vein was completely embolized, while the right branch was patent. Meanwhile, the main portal vein and right portal vein compared to pre-embolization, were dilated to a certain degree. The left branch of portal vein was occluded without recanalization 8 wk after embolization, while blood flow was seen in the right portal vein and further dilatation was seen in the main portal vein and right portal vein (Figure 5). The portal vein pressure was  $95.2 \pm 5.2$  mm H<sub>2</sub>O,  $125.2 \pm 6.4$  mm H<sub>2</sub>O before embolization and  $96.2 \pm 5.2$  mm H<sub>2</sub>O,  $95.8 \pm 6.6$  mm H<sub>2</sub>O after embolization. ALT was  $25.2 \pm 1.2$ ,  $62.2 \pm 3.2$ ,  $28.8 \pm 1.6$ , and  $26.1 \pm 1.3$  IU/L after 1, 3, 5, and 7 d of embolization, respectively. ALT values increased by different degrees according to the different injection amount of absolute ethanol, decreased dramatically 3-5 d after embolization and then returned to the pre-embolization level after 1 wk. The volume of right lobe was  $328.2 \pm 37.1$ ,  $353.2 \pm 37.9$  before embolization and  $436.7 \pm 42.5$ ,  $438.9 \pm 45.6$  after embolization. No further liver hypertrophy was found (Figure 6). Experimental dogs were killed 8 wk after embolization for pathological observation. The embolized lobe was dark red with a sharp edge, while the nonembolized lobe was slightly bright red and comparatively plump. Under microscope, the embolized lobe showed structural changes of hepatic lobules, liver atrophy, degeneration of liver cells and congestion of fiber tissue, while the nonembolized lobe revealed cell hypertrophy and obvious hyperplasia (Table 3).

## DISCUSSION

All our experimental groups with coil-gelfoam and absolute ethanol as embolic agents for left portal vein had right lobe hypertrophy, but the control group and gelfoam group failed to embolize the left portal vein, suggesting that there was no compensatory hypertrophy in the right lobe. The increasing blood flow to the nonembolized portal vein is one of the important factors for liver regeneration. After PVE, dilatation of the nonembolized portal vein branch with obviously increased blood flow could lead to hyperplasia of the nonembolized lobe. These changes were found in our study. Nutritious substances can stimulate regeneration of liver cells. As we know, portal vein blood contains nutritious substances which stimulate regeneration of liver cells. In clinical practice, patients with liver cirrhosis or portal hypertension after shunt operation would suffer from liver atrophy due to decreased blood flow of portal vein. Lindroos *et al*<sup>[14]</sup> reported that hepatocyte growth factor (HGF) could increase 17 times after two-thirds of rat liver were resected and 13 times after being treated with carbon tetrachloride. Kinoshita *et al*<sup>[15]</sup> reported that the amount of HGF mRNA in rat liver interstitial cells increased obviously after being treated with carbon tetrachloride, indicating that the increase of HGF can lead to the regeneration of liver cells.

The increase of portal vein pressure and abnormal liver function after PVE, were transient and returned to normal after 4 wk and 1 wk, respectively<sup>[16]</sup>, indicating that transient ischemia of liver portal vein branch has a limited impact on liver function. In our study, five dogs died of accidental extensive embolization of liver portal vein or respiratory failure related to narcosis overdose or absolute ethanol. If PVE is applied in clinical practice, overdose of narcosis can be avoided. The levels of ALT and total bilirubin increased after PVE and returned to normal in 1-2 wk<sup>[17,18]</sup>, demonstrating that the abnormal liver function secondary to PVE is transient and reversible, and does not result in permanent damage to liver function. The portal vein pressure of the three experimental groups was measured at different time points after embolization. We found that the portal vein pressure after embolization was usually higher after embolization, and then returned to normal within 4 wk. Our result is consistent with the study of Baere *et al*<sup>[2]</sup>. Portal hypertension has not been found in long-term follow-up<sup>[19]</sup>.

All kinds of materials such as absolute ethanol, polydocanol, and gelfoam can be used for portal vein embolization<sup>[20-22]</sup>. Park *et al*<sup>[23]</sup> used percutaneous puncture of portal vein to inject Embol into the left branches of pigs' portal vein, and then killed these pigs at different time points to show the safety and effect of Embol. Ko *et al*<sup>[24]</sup> employed Embol-78 to embolize portal vein of patients with hepatocellular carcinoma or with nonhepatocellular carcinoma to evaluate its effect and safety. Wu *et al*<sup>[25]</sup> carried out selective embolization experiment of portal vein branches in SD rats with  $\alpha$ -cyanoacrylate (DTH) and found compensatory hyperplasia of the nonembolized lobe, suggesting that DTH can effectively induce compensatory hypertrophy of nonembolized lobes. Brown *et al*<sup>[26]</sup> adopted transcatheter portal vein operation to embolize portal vein branches of liver-cancer patients with polyvinyl alcohol particles (PVA). The above PVA embolization materials have many disadvantages, such as high price, deficient specifications and lack of supply. Gelfoam, coils and absolute ethanol with different characteristics have been used as embolic agents in our clinical practice. Gelfoam can last for a moderate length of time and is safe, non-poisonous and cheap. However, during the process of portal vein embolization, a large amount of gelfoam should be used to completely embolize distal branches of the portal vein, because it easily results in back-flow of gelfoam and accidental embolization of non-target portal vein. We also found that recanalization occurred in gelfoam-embolic portal vein, which failed to effectively induce compensatory hypertrophy of the nonembolized lobe. Therefore, it is not suitable and safe to use gelfoam as an embolic agent for PVE. On the other hand, after being inserted into the target blood vessel, coils lead to mechanical embolization and neointimal hyperplasia, forming permanent embolization. However, coils cannot embolize small blood vessels and easily result in collateral vessels, limiting its use as a PVE embolic agent for inducing hypertrophy of liver. Therefore, combination of gelfoam and coils is a kind of safe and effective mode to achieve complete embolization and to avoid displacement and accidental embolization. In addition, absolute ethanol

can instantly produce permanent embolization in target blood vessels without collateral vessel formation after embolization, thus preventing recanalization of blood vessels and achieving better embolized results. The above results show that absolute ethanol is better than coil-gelfoam for PVE. However, when absolute ethanol is used as an embolic agent, back-flow easily occurs. Once back-flow occurs, it results in serious consequences. It is safe and effective to settle back-flow of absolute ethanol using a balloon catheter<sup>[27,28]</sup>. In absolute ethanol group, two dogs died of injection of large absolute ethanol doses, while the rest of the dogs which received an injection of small absolute ethanol doses survived. A larger amount of absolute ethanol can achieve good embolic effect, but death rate of experimental animals increases. A smaller amount of absolute ethanol cannot achieve satisfactory results. Thus, further research is needed to determine the safe amount of absolute ethanol injected. Absolute ethanol is a peripheral embolic agent. Compared to coil-gelfoam, it can reach distal branches of portal vein. After embolization, collateral vessels are difficult to form. At the same time, absolute ethanol exerts stronger influence on embolized portal vein branches and even smaller distal branches. Absolute ethanol causes certain damage to neointimal cells inside small branches of hepatic arteries and hepatic cells. The event enhances embolic effect, prevents recanalization of blood vessel, thus stimulating and inducing compensatory hypertrophy of nonembolized lobes more significantly.

In conclusion, gelfoam alone cannot effectively induce compensatory hypertrophy. Coil-gelfoam and absolute ethanol can be used as selective embolic agents to induce compensatory hypertrophy of liver, but absolute ethanol is better than coil-gelfoam for inducing compensatory hypertrophy. However, the safety of absolute ethanol is inferior to that of coil-gelfoam.

## Abstract

**AIM:** To examine the expression of p53 and vascular endothelial growth factor (VEGF) as well as microvessel count (MVC) and to investigate the role of VEGF as an angiogenic marker and the possible role of p53 in the regulation of angiogenesis in human gallbladder carcinoma.

**METHODS:** Surgically resected specimens of 49 gallbladder carcinomas were studied by immunohistochemical staining for p53 protein, VEGF, and factor VIII-related antigen. VEGF expression and mutant p53 expression were then correlated with Nevin stage, differentiation grade, MVC, and lymph node metastasis.

**RESULTS:** Positive p53 protein and VEGF expressions were found in 61.2% and 63.3% of tumors, respectively. p53 and VEGF staining status was identical in 55.1% of tumors. The Nevin staging of p53- or VEGF-positive tumors was significantly later than that of negative tumors. The MVC in p53- or VEGF-positive tumors was significantly higher than that in negative tumors, and MVC in both p53- and VEGF-negative tumors was significantly lower than that in the other subgroups.

**CONCLUSION:** Our findings suggest that p53-VEGF pathway can regulate tumor angiogenesis in human gallbladder carcinoma. Combined analysis of p53 and VEGF expression might be useful for predicting the tumor vascularity of gallbladder cancer.

## INTRODUCTION

Angiogenesis refers to the formation of new blood vessels from a pre-existing vascular network. Adequate vascularization is critically required for the growth and metastasis of human solid tumors<sup>[1-5]</sup>. Angiogenesis is influenced by multiple factors such as growth factors, extracellular matrix proteins, and cell adhesion molecules, as well as by the imbalance between angiogenesis-stimulating factors and inhibiting factors<sup>[6-10]</sup>. One of the most important angiogenesis-stimulating factors is VEGF, a diffusible endothelial cell-specific mitogen that induces endothelial-cell proliferation and increases vascular permeability. There is evidence that it may promote a degradative environment that facilitates migration of endothelial cells by the conduction of plasminogen activators and collagenase<sup>[11]</sup>. VEGF plays a major role in regulating angiogenesis. Most tumors produce high levels of VEGF. Neutralization of VEGF leads to a marked inhibition of angiogenesis and tumor growth<sup>[12-15]</sup>.

However, there is little information about the genetic changes associated with angiogenesis. So far, most studies have stressed the role of oncogene activation and tumor suppressor gene (TSG) inactivation in promoting aberrant tumor-cell proliferation. Although it remains unclear whether any of these genetic alterations can trigger the disruption of control of angiogenesis, some *in vitro* studies have demonstrated the important role played by the p53 tumor suppressor gene in controlling tumor angiogenesis<sup>[16,17]</sup>. In the present study, we have examined p53 and VEGF expressions as well as microvessel count (MVC) in human gallbladder carcinoma tissues to investigate the involvement of the p53 gene in regulation of tumor angiogenesis and its clinical significance.

**Table 1** Nevin staging system for gallbladder cancer<sup>[18]</sup>

Stage	Definitions
1	Tumor invades mucosa only
2	Tumor invades muscularis and mucosa
3	Tumor invades subserosa, muscularis, and mucosa
4	Tumor invades all layers of gallbladder wall plus cystic lymph node
5	Tumor extension into liver bed or distant spread

Six cases had papillary adenocarcinoma (12.2%), 43 cases had tubular adenocarcinoma (87.8%), 22 cases had well-differentiated tumor (44.9%), 17 cases had moderately differentiated tumor (34.7%), 10 cases had poorly differentiated tumor (20.4%). Nevin stage (Table 1) was determined based on clinical materials: 19 cases of S1, S2, and S3, and 30 cases of S4 and S5. Twenty-seven cases (55.1%) had lymph node metastasis (+), 22 cases (44.9%) had no lymph node metastasis (-). In each case, all available sections stained with hematoxylin and eosin were reviewed.

### Immunohistochemical study of p53 and VEGF

Four micrometer thick sections from the formalin-fixed and paraffin-embedded tissues were placed on the poly-L-lysine-coated slides for immunohistochemistry.

Immunohistochemical staining was performed by the streptavidin-biotin method. In brief, sections were de-paraffinized and incubated with 3% hydrogen peroxide for 20 min to block endogenous peroxidase activity. The sections were treated twice with microwave at 500 W for 5 min each time in 10 mmol/L sodium citrate (pH 6.0). After washing with PBS, the sections were incubated in 10% normal rabbit or goat serum for 20 min to reduce non-specific antibody binding. The antibodies used were mouse monoclonal antibody (MAb) against human p53 protein (Maxin-Bio Co., Fuzhou, China) in 1:100 dilution at 4 °C overnight, and a rabbit polyclonal antibody against human VEGF (A-20; Santa Cruz Biotechnology, Santa Cruz, CA, USA) in 1:50 dilution at 4 °C overnight. After washing thrice with PBS, the sections were incubated with biotinylated rabbit anti-mouse or goat anti-rabbit immunoglobulin G (Maxin-Bio Co., Fuzhou, China) for 30 min, washed thrice again with PBS, treated with streptavidin-peroxidase reagent for 30 min and then washed thrice with PBS again. Finally, the specimens were incubated in PBS containing diaminobenzidine and 1% hydrogen peroxide for 5 min and counterstained with hematoxylin. PBS was substituted for each primary antibody as negative control. Slides were examined by two investigators without the knowledge of the corresponding clinicopathologic data. p53 immunoreactivity was assessed as being positive only when tumors exhibited intense nuclear staining, and reactivity was categorized into negative expression (less than 10% positive tumor cells) and positive expression (at least 10% positive tumor cells). Immunostaining for VEGF was considered positive when unequivocal staining of cell membrane or cytoplasm was observed in more than 10% of tumor cells.

### Microvessel staining and counting

Microvessel staining and counting were performed as described previously<sup>[19]</sup>. Briefly, intratumoral microvessels were highlighted by immunostaining with a mouse MAb against factor VIII-related antigen (F-VIII RAg) (Maxin-Bio Co., Fuzhou, China) in 1:100 dilution and incubated at 4 °C overnight, after pre-digestion with 0.1% (v/v) trypsin at 37 °C for 20 min. Any single brown-stained cell or cluster of endothelial cells that was clearly separated from adjacent vessels, tumor cells and other connective tissues was considered as a microvessel. The stained sections were screened at ×40 fields to identify the regions of the high-

**Figure 1** Microvessel distribution (A) and expression of VEGF (B) and p53 (C) in gallbladder carcinoma tissue.

## MATERIALS AND METHODS

### Clinical materials

Forty-nine histologically proven gallbladder carcinomas were selected. All patients were surgically treated at the Department of General Surgery of the First and Second Hospitals affiliated to China Medical University, Shenyang, China, but did not receive chemotherapy or anti-angiogenesis therapy before surgery. The cases included 24 males and 25 females. The average age of the males and females was 62 years and 55 years, respectively.

est vascular density within the tumor. Vessels were counted in the five regions of the highest vascular density at  $\times 200$  fields (Olympus BH-2 microscope, 0.74 mm<sup>2</sup> per field). MVC was the mean number of vessels in these areas.

### Statistical analysis

The relationship between p53 or VEGF expression and MVC was evaluated by *t*-test, and the relationship between p53 and VEGF expression and various clinicopathologic factors was examined by the  $\chi^2$  test. *P*<0.05 was considered statistically significant.

## RESULTS

### Expression of VEGF, p53, and MVC

The microvessels in malignant tissues were heterogeneously distributed. These neovascular areas occurred anywhere within the tumor but most frequently at the tumor margins (Figure 1A). The immunoreactive regions of VEGF were located in cytoplasm or membranes of the gallbladder carcinoma cells (Figure 1B). The immunoreactive regions of mutant p53 were located in the nuclei of the gallbladder carcinoma cells (Figure 1C).

### Clinicopathologic characteristics of MVC, VEGF, and p53 expressions

The average MVC in 49 cases of gallbladder carcinoma was (35 $\pm$ 12)/HP. MVC was markedly higher in cases of Nevin stage S4-S5 than in those of S1-S3 (*P*<0.01). MVC in moderate-poor differentiation group was higher than that in good differentiation group (*P*<0.05). MVC

in patients with lymph node metastasis was significantly higher than that in those without lymph node metastasis (*P*<0.01, Table 2).

The positive rate of VEGF expression was 63.3% in these 49 cases and was higher in cases of Nevin stage S4-S5 (76.7%) than in those of S1-S2 (42.1%) (*P*<0.05). The positive rate of VEGF expression was not correlated with tumor differentiation (*P*>0.05). With regard to the association with lymph node metastases, the positive rate of VEGF expression was significantly higher in patients with metastasis than in those without metastasis (*P*<0.05, Table 3).

The positive rate of mutant p53 expression was 61.2% in these 49 cases and was lower in cases of Nevin stage S1-S3 (47.4%) than in those of S4-S5 (70.0%), the difference was statistically significant (*P*<0.05). The positive rate of mutant p53 expression was not correlated with tumor differentiation (*P*>0.05). With regard to the association with lymph node metastases, the positive rate of p53 expression was significantly higher in patients with metastasis than in those without metastasis (*P*<0.05, Table 4).

### Correlation between p53, VEGF, and MVC

Table 5 shows the relationships between MVC and the presence of p53 and VEGF. Staining status was identical in 27 of 49 tumors (55.1%), and a significant (*P*<0.05) association between p53 and VEGF expression was demonstrated. The MVC in tumors that were p53 or VEGF positive was significantly (*P*<0.05) higher than that in p53- or VEGF-negative tumors. Moreover, the

mean MVC in tumors of all the subgroups that were both p53 and VEGF positive was the highest, while the mean MVC was significantly lower in patients with tumors that were both p53 and VEGF negative than in all the other subgroups.

## DISCUSSION

In 1971, Folkman proposed that tumor growth depends on angiogenesis. Now there is considerable indirect and direct evidence that tumor growth is dependent on angiogenesis. Numerous studies showed that neovascularization is closely associated with growth, invasion, metastasis, staging and prognosis of tumors<sup>[7,20-23]</sup>. Our study also indicated that angiogenesis was correlated with the Nevin staging and tumor differentiation. The higher the staging is, the poorer the differentiation and the higher the level of MVC are in gallbladder carcinoma. Since MVC is of prognostic value, we investigated whether this holds true for VEGF expression as well. Our findings demonstrate that both VEGF expression and MVC are significantly elevated in patients with disease progression and depend on each other. Tumors with established poor outcome (staging, MVC) are likely to produce higher levels of VEGF, suggesting that VEGF significantly contributes to the poor outcome in these patients.

The most common genetic alteration in various cancers is loss of the p53 tumor suppressor gene function. P53 protein has various important functions in cellular integration, including cell growth control, response to DNA damage, checkpoint mechanisms during the cell cycle, regulation of transcription and control of genomic stability. It is suggested that p53 protein may play a role in suppressing angiogenesis<sup>[24-27]</sup>. In addition, it was reported that a pathway from p53 regulating VEGF induces angiogenesis in cellular transfection models<sup>[16]</sup>. In the present study, we explored the possibility of a relationship between aberrant p53 and VEGF expression and tumor angiogenesis in gallbladder carcinoma. We observed that VEGF-positive tumors had significantly more microvessels than VEGF-negative tumors. Our findings agree with other studies<sup>[13,28,29]</sup>, suggesting that VEGF-induced tumor angiogenesis plays an important role not only in tumor progression but also in metastasis. Although little is known concerning the VEGF regulatory pathways, Kieser *et al.*<sup>[16]</sup> reported that mutant-type p53 might stimulate VEGF expression. In the present study, p53 and VEGF expression status coincided in 27 of 49 (55.1%) tumors, and a significant association was found between the two factors. Moreover, MVC was the highest in p53 and VEGF positive tumors and the lowest in p53 and VEGF negative tumors. These results suggest not only the existence of a p53-VEGF regulatory pathway in gallbladder carcinomas, but also a possible role of such a pathway in regulating tumor angiogenesis in this type of cancer. These further suggest that tumors that have lost p53 suppressor function not only permit uncontrolled cell growth, but also possibly produce a suitable environment for hematogenous metastasis by stimulating VEGF-induced angiogenesis in the primary site of carcinoma. In contrast, tumors with preserved p53 function and angiogenic inhibitory pathway

are less possible to progress, and the p53 gene may therefore contribute to better prognosis.

In conclusion, our results demonstrate that abnormal p53 accumulation is closely associated with VEGF expression and tumor vascularity in human gallbladder carcinoma. P53 plays a critical role in suppressing tumor growth by regulating tumor angiogenesis. Clinical application of combined analysis of p53 and VEGF expression may be useful for predicting the clinical staging, occurrence of metastasis in patients with this disease. More prospective studies should be made to prove our findings.

### Abstract

**AIM:** To investigate the action of genistein (GST), a broad spectrum tyrosine kinase inhibitor, on voltage-gated potassium channels in guinea pig proximal colon smooth muscle cells.

**METHODS:** Smooth muscle cells in guinea pig proximal colon were enzymatically isolated. Nystatin-perforated whole cell patch clamp technique was used to record potassium currents including fast transient outward current ( $I_{Kto}$ ) and delayed rectifier current ( $I_{Kdr}$ ), two of which were isolated pharmacologically with 10 mmol/L tetraethylammonium or 5 mmol/L 4-aminopyridine. Contamination of calcium-dependent potassium currents was minimized with no calcium and 0.2 mmol/L  $CdCl_2$  in an external solution.

**RESULTS:** GST (10-100  $\mu$ mol/L) reversibly and dose-dependently reduced the peak amplitude of  $I_{Kto}$  with an  $IC_{50}$  value of  $22.0 \pm 6.9$   $\mu$ mol/L. To a lesser extent,  $I_{Kdr}$  was also inhibited in both peak current and sustained current. GST could not totally block the outward potassium current as a fraction of the outward potassium current, which was insensitive to GST. GST had no effect on the steady-state activation ( $n=6$ ) and inactivation kinetics ( $n=6$ ) of  $I_{Kto}$ . Sodium orthovanadate (1 mmol/L), a potent inhibitor of tyrosine phosphatase, significantly inhibited GST-induced inhibition ( $P < 0.05$ ).

**CONCLUSION:** GST can dose-dependently and reversibly block voltage-gated potassium channels in guinea pig proximal colon smooth muscle cells.

Li SY, Huang BB, Ouyang S. Effect of genistein on voltage-gated potassium channels in guinea pig proximal colon

### INTRODUCTION

Ion channels are targets of many intracellular signaling pathways, including protein phosphorylation and dephosphorylation. These processes can modify channel activity and dramatically alter the electrophysiological properties of both excitable and nonexcitable cells<sup>[1]</sup>. In addition to the extensive information available about the regulation of ion channels by serine-threonine kinases, an emerging body of evidence suggests that channels are also regulated by phosphorylation on tyrosine residues, such as ligand-gated channels AChR<sup>[2]</sup>, NMDA receptor<sup>[3]</sup>, potassium channels<sup>[4,5]</sup> as well as calcium channels<sup>[6,7]</sup>. GST, a specific inhibitor of tyrosine kinases, inhibits visceral smooth muscle contraction induced by tyrosine phosphatase inhibitor vanadate<sup>[8]</sup>, angiotensin II<sup>[9]</sup> and carbachol<sup>[10]</sup> via tyrosine kinase-mediated process. Potassium channels, which are substrates for protein phosphorylation and dephosphorylation, control the contraction of gastrointestinal smooth muscles by setting resting potential and influencing slow waves and action potential configuration<sup>[11]</sup>. However, little is known of the modulation of potassium channels in gastrointestinal smooth muscle cells via tyrosine kinase pathway. This study was to investigate the effects and mechanisms of GST on voltage-gated potassium channels (Kv) in smooth muscle cells of guinea pig proximal colon.

### MATERIALS AND METHODS

#### Cell dissociation

Smooth muscle cells were enzymatically isolated using modified procedures as previously described<sup>[12]</sup>. Briefly, male guinea pigs (200-350 g) were killed by cervical dislocation and proximal colon about 2 cm aboral to cecum was rapidly excised. Under anatomical microscope, smooth muscle strips were dissected out, cut into small pieces and incubated for 30 min in low calcium solution containing 10 mmol/L HEPES, 135 mmol/L NaCl, 6 mmol/L KCl, 0.05 mmol/L  $CaCl_2$ , 1.2 mmol/L  $MgCl_2$ , 10 mmol/L Glucose, pH 7.4. The pieces of muscles were then transferred to low calcium solution containing

**Figure 1** Two components of voltage-gated potassium currents in guinea pig colon smooth muscle cells and effect of GST. **A<sub>1</sub>-A<sub>3</sub>**: Currents recorded every 10 s between -80 and +50 mV then back to -40 mV with holding potential -80 mV in the control (**A<sub>1</sub>**), in the presence of 10 mmol/L TEA (**A<sub>2</sub>**) and TEA and 30 μmol/L GST (**A<sub>3</sub>**). **B<sub>1</sub>**: Currents recorded every 10 s between -80 and +50 mV with holding potential -80 mV in the control; **B<sub>2</sub>**: current in the presence of 5 mmol/L 4-AP developed slowly and showed slower inactivation over 400 ms; **B<sub>3</sub>**: effect of 50 μmol/L GST in the presence of 5 mmol/L 4-AP.

3 g/L papain, 2 g/L DTT, 2 g/L bovine serum albumin. Tissues were incubated at 36 °C in enzyme solution for 15 min and then suspended in enzyme-free low calcium solution. Tissue pieces were gently agitated to create a cell suspension. Dispersed cells were stored at 4 °C for later use. Experiments were performed at 20-22 °C within 10 h.

#### Perforated whole cell voltage clamp recording

Relaxed single colon smooth muscle cells with smooth appearance and spindle shape observed under an inverted microscope (IX70, Olympus) were used. Myocytes were perfused with  $\text{Ca}^{2+}$ -free cell bath solution in a self-made small volume chamber in which solution could be exchanged in 30 s. The composition of bath solution was the same as that of low calcium solution except for exclusion of calcium and inclusion of 0.2 mmol/L  $\text{CdCl}_2$  to minimize the contamination of calcium-dependent potassium currents.

Patch clamp micropipettes were pulled with a programmable puller (P-97, Sutter Instruments) and their tips were fire polished (CPM-2, ALA Co.). The pipette resistance was 3-5 MΩ. Currents were amplified with Axopatch 200B (Axon Instruments). Data were filtered at 1 kHz and analyzed with pClamp software (version 8.2).

Nystatin-perforated whole cell patch clamp technique was used to record voltage-gated potassium currents. Nystatin was dissolved in DMSO at a concentration of 25 g/L, and then added to the internal pipette solution to yield a final nystatin concentration of 100 mg/L. The internal solution contained 10 mmol/L HEPES, 110 mmol/L gluconate (potassium salt), 30 mmol/L KCl, 10 mmol/L NaCl, 2 mmol/L  $\text{MgCl}_2$ , pH 7.2. After giga seals were obtained, access resistance was monitored for 10 min to allow the drop of access resistance (average  $17.7 \pm 5.7 \text{ M}\Omega$ ,  $n=28$ ) and then compensated at 70%. Macroscopic current values were normalized for cell capacitance as whole cell current densities ( $\text{pA/pF}$ ). The average cell capacitance was  $41.3 \pm 7.5 \text{ pF}$  ( $n=28$  cells).

#### Drugs and chemicals

Papain, 4-aminopyridine (4-AP), nystatin, tetraethylammonium (TEA), sodium orthovanadate (VAN), genistein (GST) were purchased from Sigma. GST was prepared as a 50 mmol/L stock solution in DMSO and stored at -20 °C. DTT (BBI), HEPES, DMSO, bovine serum albumin were from Shanghai Sangon Biological Engineering Technology and Services Company.

#### Statistical analysis

Data were expressed as mean  $\pm$  SD. Differences in the data were evaluated by paired or independent *t*-test when appropriate.  $P < 0.05$  was considered statistically significant. Software Microcal Origin 5.0 was used for statistical analysis and graph plotting.

## RESULTS

#### Potassium currents in single smooth muscle cells

Outward potassium currents are mainly composed of voltage-gated potassium current and calcium-dependent potassium current. Under the conditions of our recordings (no added  $\text{Ca}^{2+}$  and 0.2 mmol/L  $\text{CdCl}_2$  in the bath solution), contamination of currents through calcium-dependent potassium currents was minimized.

Currents were evoked using standard stimulus protocol, i.e., the membrane potential was stepped for 400 ms from a holding potential of -80 mV to test potentials between -80 and +50 mV in 10 mV increments. Depolarization to potentials positive to -40 mV activated non-linear, time-dependent outward currents which could be divided into transient outward potassium current ( $I_{\text{kto}}$ ) and delayed rectifier potassium current ( $I_{\text{kdr}}$ ) as shown in Figure 1.  $I_{\text{kto}}$  was sensitive to millimolar concentration of 4-AP and insensitive to TEA.  $I_{\text{kdr}}$  was on the contrary. When 10 mmol/L TEA was externally applied, early peak current of transient outward current (peak current among the first 50 ms of test pulse,  $I_{\text{peak}}$ ) was only slightly decreased, but the quasi steady state current (average current from 350 to 400 ms after test pulse onset,  $I_{\text{ss}}$ ) was blocked -60% (Figure 1A). When 5 mmol/L 4-AP was externally applied,  $I_{\text{peak}}$  was much reduced (Figure 1B) and the time to half-maximum current at test potential was significantly increased (data not shown),  $I_{\text{ss}}$  was little affected. Detailed description of voltage-dependent potassium current of guinea pig proximal colon smooth muscle cells could

**Figure 2** Concentration-dependent inhibition of transient outward potassium currents by genistein in guinea pig colon smooth muscle cells. Currents were elicited by depolarization to +50 mV for 400 ms then back to -40 mV from holding potential of -80 mV. Washout was performed for about 2 min.

**Figure 3** Average concentration-dependent transient outward potassium currents inhibited by genistein. Peak currents were measured and normalized by control current amplitude. The smooth line represents the best fitting with Hill equation. Data are expressed as mean  $\pm$  SE. The number of cells used in each concentration is indicated besides the error bars.

be seen elsewhere<sup>[13]</sup>, which agrees well with our study. According to the different sensitivity to TEA and 4-AP, we isolated these two kinds of current pharmacologically to study the effect of GST independently.

#### Concentration-dependent inhibition of GST on $I_{Kto}$

Currents recorded were mainly  $I_{Kto}$  when 10 mmol/L TEA was externally applied to bath solution. Repetitive single current traces were elicited for 400 ms from a holding potential of -80 mV to test potentials +50 mV in every 20 s until stable currents were recorded.  $I_{peak}$  of  $K_{to}$  decreased progressively and reached a stable state in about 1-2 min after the external perfusion of GST. GST (10-100  $\mu$ mol/L) induced a reduction in  $I_{peak}$ , with little effect on the steady state potassium current. The inhibitory effects of GST were reversible (Figure 2). Perfusion of calcium-free saline including TEA could restore the amplitude of currents to about 80% of control in 2 min (data not shown).

GST could not totally block the outward potassium currents even when 100  $\mu$ mol/L GST was applied. Since no significant difference in the inhibitory effect was

**Figure 4** Effect of genistein (30  $\mu$ mol/L) on current-voltage relationship of transient outward potassium current ( $I_{Kto}$ ) in guinea pig proximal colon smooth muscle cells in the presence of TEA (10 mmol/L) and  $Cd^{2+}$  (0.2 mmol/L). **A:**  $I$ - $V$  curves of peak current density of voltage-gated potassium channels under control condition (solid square), in the presence of 10 mmol/L TEA (solid circle) as well as 10 mmol/L TEA and 30  $\mu$ mol/L genistein (solid triangle); **B:**  $I$ - $V$  curves of steady state current density of voltage-gated potassium channels under control condition, in the presence of 10 mmol/L TEA as well as 10 mmol/L TEA and genistein (30  $\mu$ mol/L).  $n=6$  cells.

found between 50 ( $n=10$ ) and 100 ( $n=5$ )  $\mu$ mol/L GST, a fraction of the outward potassium current was insensitive to GST.

Early peak transient outward potassium current of  $K_{to}$  measured at +50 mV test pulse from a holding potential of -80 mV was used as an index of inhibition, which was plotted as a function of GST concentration (10-100  $\mu$ mol/L). The data were fitted with  $I_{GST}/I_{control} = 1 / \{1 + (IC_{50}/[D])^n\}$ , where  $[D]$  is the concentration of GST used,  $IC_{50}$  is the concentration at half maximal inhibition, and  $n$  is the Hill coefficient. Figure 3 shows that the effect of GST on  $I_{peak}$  of  $K_{to}$  was concentration-dependent, with an  $IC_{50}$  of  $22.0 \pm 6.9$   $\mu$ mol/L.

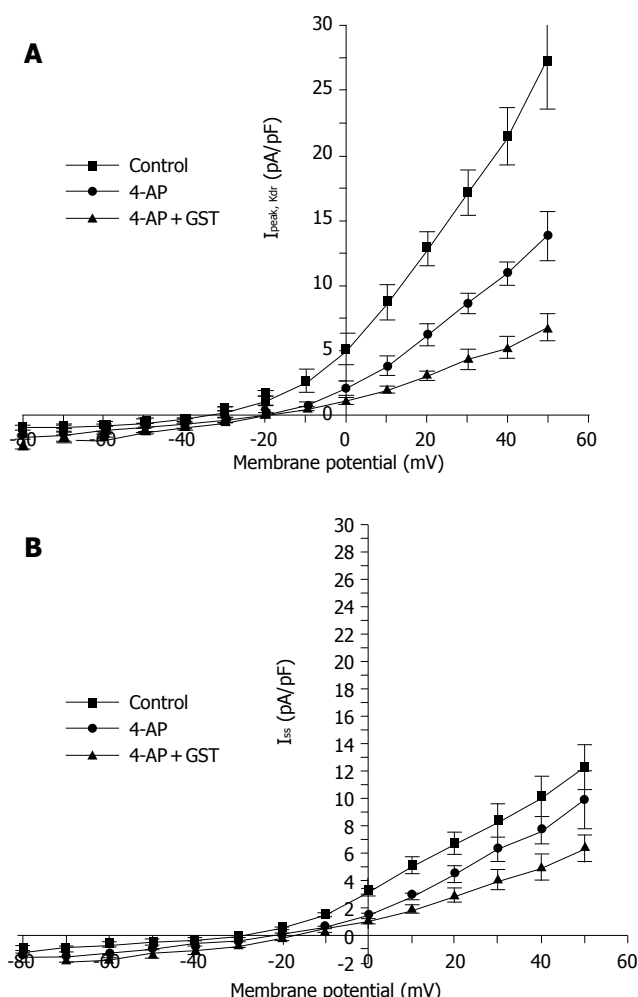

#### Effect of GST on current-voltage relationship ( $I$ - $V$ curves) of $I_{Kto}$

Currents were evoked using standard stimulus protocol. The membrane potential was stepped for 400 ms from a holding potential of -80 mV to test potentials between -80

**Figure 5** Effect of genistein on delayed rectifier potassium currents in the presence of 4-AP in guinea pig colon smooth muscle cells. Currents were elicited by depolarization to +50 mV for 400 ms then back to -40 mV from holding potential of -80 mV. Washout was performed for about 2 min.

**Figure 6** Effect of genistein (50  $\mu\text{mol/L}$ ) on current-voltage relationship of delayed rectifier potassium current ( $I_{Kdr}$ ) in guinea pig proximal colon smooth muscle cells in the presence of 4-AP (5 mmol/L) and  $\text{Cd}^{2+}$  (0.2 mmol/L). **A:**  $I$ - $V$  curves of peak current density of voltage-gated potassium channels under control condition, in the presence of 5 mmol/L 4-AP as well as 5 mmol/L 4-AP and 50  $\mu\text{mol/L}$  genistein; **B:**  $I$ - $V$  curves of steady state current density of voltage-gated potassium channels under control condition, in the presence of 5 mmol/L 4-AP as well as 5 mmol/L 4-AP and 50  $\mu\text{mol/L}$  genistein.  $n=4$  cells.

and +50 mV in 10 mV increments. The interval between two pulses was set at 10 s to allow inactivated conductance to recover.  $I_{\text{peak}}$  and  $I_{\text{ss}}$  were measured at test pulses from -80 to +50 mV and converted into current densities, which were plotted as a function of test pulse.

Figure 1 shows that in the presence of 10 mmol/L TEA, 30  $\mu\text{mol/L}$  GST significantly blocked  $I_{\text{peak}}$  ( $P<0.05$ ,  $n=6$  cells) and only slightly reduced  $I_{\text{ss}}$ . Figure 4 shows the averaged  $I$ - $V$  curves of  $I_{Kto}$  inhibited by GST. The inhibition showed no voltage dependence.

#### Effect of GST on $I_{Kdr}$

Currents recorded in the presence of external 5 mmol/L 4-AP were mainly delayed rectifier potassium currents. Repetitive single current traces were elicited for 400 ms from a holding potential of -80 mV to test potentials +50 mV in every 20 s until stable currents were recorded. In the presence of 5 mmol/L 4-AP, 50  $\mu\text{mol/L}$  GST reduced peak current and steady state current with a fractional inhibition of current  $f$  [ $f=(1-I_{\text{GST}}/I_{\text{drug}})\times 100\%$ ] of  $52\pm 8\%$  ( $P<0.05$ ,  $n=4$ ) and  $33\pm 2\%$  ( $P<0.05$ ,  $n=4$ ), respectively. The inhibitory effects of GST were reversible. Perfusion of calcium-free saline could restore the amplitude of currents in 2 min (data not shown). Details are shown in Figure 5.

#### Effect of GST on $I$ - $V$ curves of $I_{Kdr}$

The same experimental protocol as that of the study on the effect of GST on  $I_{Kto}$  was used. Figure 1B shows that in the presence of 5 mmol/L 4-AP, 50  $\mu\text{mol/L}$  GST significantly blocked  $I_{\text{peak}}$  as well as  $I_{\text{ss}}$  ( $P<0.05$ ,  $n=4$  cells). Figure 6 shows the averaged  $I$ - $V$  curves of  $I_{Kdr}$  inhibited by GST. The inhibition showed no voltage dependence, and 50  $\mu\text{mol/L}$  GST had a greater effect on  $I_{Kto}$  than on  $I_{Kdr}$  ( $P<0.05$ ).

#### Effect of GST on steady state activation kinetics of $I_{Kto}$

The activation curves of  $I_{Kto}$  were derived from  $I$ - $V$  curves of  $I_{Kto}$ .  $G_{Kto}$  was calculated by dividing the initial peak current value by their driving force and plotted as a function of membrane potential. The activation curves were fitted with a Boltzmann function  $G/G_{\text{max}}=1/\{1+\exp[(V-V_h)/\epsilon]\}$ , where  $V$  is membrane potential,  $V_h$  is the half-maximal activation voltage, and  $\epsilon$  is the slope constant (mV). GST had no significant effect on steady state activation kinetics of  $I_{Kto}$ . The value of half-maximal activation voltage  $V_h$  was  $3.3\pm 1.3$  and  $3.5\pm 1.4$  mV, respectively in the absence and presence of 30  $\mu\text{mol/L}$  LGST, the slope constant  $\epsilon$  was  $12.9\pm 1.0$  and  $13.3\pm 1.1$  mV, respectively ( $n=6$ , Figure 7).

#### Effect of GST on steady state inactivation kinetics of $I_{Kto}$

Classic double pulse protocol was used to determine the voltage dependence of inactivation of  $I_{Kto}$ . Currents were elicited by a depolarizing pulse of +50 mV with 1 s preconditioning pulses from -80 to 20 mV by increment of 10 mV. The interval between two sweeps was set at 20s. A plot of normalized peak current ( $I/I_{\text{max}}$ ) as a function of preconditioning potential was fitted with a Boltzmann function:  $I/I_{\text{max}}=1/\{1+\exp[(V_h-V)/\epsilon]\}$ , where  $V$  is the

**Figure 7** Effect of GST on steady state activation and inactivation of transient outward potassium currents. Inactivation is shown as a plot of normalized peak current as a function of conditional potential from -80 to +20 mV. For voltage dependence of activation, normalized currents were calculated by dividing peak outward currents by their driving force and plotted against potential. Smooth curves were fitted with Boltzmann equation which yields values of half-maximally activated or inactivated voltage ( $V_h$ ) and slope constant ( $K$ ).

membrane potential,  $V_h$  is the half-maximal inactivation voltage, and  $k$  is the slope constant (mV). GST had no significant effect on steady state inactivation kinetics of  $I_{Kto}$ . The values of half-maximal inactivation voltage  $V_h$  were  $-43.4 \pm 0.7$  and  $-39.2 \pm 0.8$  mV, respectively in the absence and presence of 30  $\mu\text{mol/L}$  GST, the slope constant  $k$  was  $5.8 \pm 0.6$  and  $6.5 \pm 0.7$  mV, respectively ( $n=6$ , Figure 7).

#### VAN blocked inhibition of GST on $I_{Kto}$

Inhibition of phosphatase-mediated tyrosine dephosphorylation would be expected to block current inhibition by GST, since dephosphorylation in the presence of GST would require ongoing phosphatase activity<sup>[14]</sup>. At commonly used bath concentrations of 0.1-10 mmol/L, inhibitor of tyrosine phosphatase orthovanadate could antagonize various GST-induced cellular responses such as blocking the inhibition of  $I_{Ca,L}$  by PTK inhibitors<sup>[15]</sup>. Solely applied VAN had minor stimulating but no significant effect on  $I_{Kto}$  ( $n=7$ ). In the presence of 1 mmol/L VAN, the fractional inhibition of current  $f$  of 30  $\mu\text{mol/L}$  GST significantly decreased to  $28 \pm 6\%$  (Figure 1) compared with  $49 \pm 6\%$  of solely applied GST ( $n=10$ ). The rapid onset and offset responses to GST did not change (Figure 8).

## DISCUSSION

At least four types of potassium channel have been identified in excitable gastrointestinal smooth muscle cells, such as voltage-dependent outward potassium channel, calcium-dependent potassium channel, ATP-sensitive potassium channel, and inward rectifier potassium channel. A given smooth muscle cell can express several families of potassium channels and several members of a single family of channels. This complexity is necessary for the control of smooth muscle function<sup>[11]</sup>. Kv channels are of particular importance in the regulation of colonic smooth muscle electrical activity because they provide

**Figure 8** Orthovanadate antagonizes the inhibition of transient outward potassium currents by genistein.

outward currents over the voltage range in which these tissues operate<sup>[11]</sup>. Kv shapes the action potential (AP) by controlling its repolarization phase and determines the membrane potential and duration of the interspike interval. Delayed rectifier potassium channels keep single AP short and permit high-frequency trains of APs. Transient outward potassium channels help a cell fire at low frequency and promote broadening of APs during repetitive activity<sup>[16]</sup>. In murine colon, application of 4-AP to intact preparations can abolish the quiescent periods between slow waves and induce a slight depolarization<sup>[11]</sup>.  $I_{Kto}$  is fully inactivated during the upstroke depolarization<sup>[17]</sup>. In this study, GST could block transient outward potassium currents to depolarize membrane potential as well as delayed rectifier potassium currents to induce slight depolarization<sup>[11]</sup>, thus modulating the contraction of smooth muscle.

Protein tyrosine kinase activity is a major signaling mechanism in regulating long-term processes such as cell growth, division, and metabolism<sup>[18]</sup>. PTK signaling is also important in regulating ion channel conductance. GST, a natural isoflavone which is abundant in soybean, is a specific inhibitor of tyrosine specific kinases by competing with ATP to form the nonproductive enzyme-substrate complexes<sup>[19]</sup>. In this study, GST concentration - dependently and reversibly blocked voltage-gated potassium currents. Though it was reported that GST has no specific effects such as direct interaction with potassium channels<sup>[14,20,21]</sup>, orthovanadate could antagonize the blockage of GST on  $I_{Kto}$ , suggesting that although direct blockage of potassium channels by a mechanism unrelated to PTK inhibition could not be entirely excluded in this study, GST blocks the transient outward potassium channels partly via PTK pathway.

There are some differences in GST action on ion channel currents and contraction of different types of smooth muscle. GST can inhibit visceral smooth muscle contraction induced by vanadate<sup>[8]</sup>, angiotensin II<sup>[9]</sup> and carbachol<sup>[10]</sup> as well as nifedipine-sensitive calcium currents in rabbit colon myocytes<sup>[22]</sup>. GST also can inhibit apamin-sensitive relaxation of the longitudinal muscle in rat distal colon induced by pituitary adenylate cyclase activating peptide<sup>[23]</sup> as well as potassium channels<sup>[4,5]</sup>. Besides species and tissue differences, it is possible that multiple receptor

and nonreceptor PTKs are involved in the regulation of smooth muscle contraction. Further studies are required to identify the physiological role of PTKs in gastrointestinal motility.

To check whether GST could affect the biophysical kinetics of voltage-dependent potassium channels, we examined the steady state activation and inactivation kinetics in the absence and presence of 30  $\mu\text{mol/L}$  GST. Peretz *et al.*<sup>[4]</sup> found that GST affects potassium gating properties of Schwann cells such as a positive shift in voltage dependence of activation (by +30 mV) and a decrease in steepness of activation gating. In our experiment, no significant effect of GST on gating properties of potassium channels was observed. Whether species or cell type difference contributes to the variation needs further investigation.

In conclusion, GST concentration dependently and reversibly inhibits transient outward potassium currents.

### Abstract

**AIM:** Endoscopic metal stenting (EMS) offers good results in short to medium term follow-up for bile duct stenosis associated with chronic pancreatitis (CP); however, longer follow-up is needed to determine if EMS has the potential to become the treatment of first choice.

**METHODS:** EMS was performed in eight patients with severe common bile duct stenosis due to CP. After the resolution of cholestasis by endoscopic naso-biliary drainage three patients were subjected to EMS while, the other five underwent EMS following plastic tube stenting. The patients were followed up for more than 5 years through periodical laboratory tests and imaging techniques.

**RESULTS:** EMS was successfully performed in all the patients. Two patients died due to causes unrelated to the procedure: one with an acute myocardial infarction and the other with maxillary carcinoma at 2.8 and 5.5 years after EMS, respectively. One patient died with cholangitis because of EMS clogging 3.6 years after EMS. None of these three patients had showed symptoms of cholestasis during the follow-up period. Two patients developed choledocholithiasis and two suffered from duodenal ulcers due to dislodgement of the stent between 4.8 and 7.3 years after stenting; however, they were successfully treated endoscopically. Thus, five of eight patients are alive at present after a mean follow-up period of 7.4 years.

**CONCLUSION:** EMS is evidently one of the very

### INTRODUCTION

Chronic pancreatitis (CP) is reported to become complicated with bile duct stenosis in about 5-40% of the patients<sup>[1,2]</sup>. The severity of the stenosis varies; however, radical treatment is needed for serious cases presenting persistent cholestasis, jaundice or cholangitis. Moreover, it has been shown that long-standing biliary stenosis, even if mild or moderate, often causes liver damage<sup>[3,4]</sup>. Half of these patients will present liver fibrosis by the time of decompression<sup>[5]</sup>.

Non-surgical treatment has been reported to be comparable with surgery, with lower morbidity and mortality. Especially, endoscopic biliary drainage (ERBD) using a plastic tube stent has been adopted as the first-line treatment, and there are many reports concerning the usefulness of ERBD<sup>[5,6]</sup>. Although plastic stents offer satisfactory short-term drainage, medium to long-term results have been disappointing because of stent clogging or migration<sup>[6,7]</sup>, and surgical treatment is chosen for a permanent palliation. However, surgical treatment is associated with important morbidity<sup>[8]</sup>.

ERBD using a metallic stent (EMS) is useful for malignant biliary stricture since a relatively long-term non-surgical palliation can be attained<sup>[9]</sup>. In contrast, EMS for a benign biliary stricture is still controversial<sup>[10,11]</sup>. Furthermore, there have been few reports on EMS for biliary stenosis due to CP. Deviere *et al* reported favorable

results with the self-expandable metal mesh stent for biliary obstruction due to CP, but the long-term results have not been reported<sup>[12]</sup>. In this study, we intended to clarify the outcome of patients with biliary stenosis due to CP who underwent EMS and have been followed up for more than 5 years.

## MATERIALS AND METHODS

Between July 1996 and August 1998, EMS was performed in eight patients with severe common bile duct stenosis associated with CP in our institution. We had experienced 64 patients with CP during that period in the endoscopic retrograde cholangiopancreatography (ERCP) division. The indication for EMS was intractable bile duct stenosis uncontrollable by plastic tube biliary drainage. Ten patients gave their informed consent and the procedure was approved by the Ethical Committee of our institute; however, one patient underwent surgical treatment and another was lost to follow-up. They were all males with a median age of 65.7 years (range: 42-78 years). The etiology of CP was alcohol abuse in seven and idiopathic in one. Underlying diseases were diabetes mellitus in five patients, angina pectoris in one and early colon cancer in one. Mean duration of the illness before manifesting the first symptoms of bile duct stenosis was 3.7 years.

On their first admission, five patients presented with

**Figure 2** No bile duct stone was observed immediately after EMS in patient number 7 (A), however, stones were noted 6.1 years later (arrow), and they were successfully removed using a basket wire (B). Peroral cholangioscopy revealed the common bile duct distal to the stone (arrow) was patent and the hyperplastic change was not conspicuous (C). Arrow head indicates the pancreatic duct stent.

abdominal pain, six had symptomatic jaundice, and six had cholangitis (Table 1). Serum alkaline phosphatase concentration (ALP) was three times or more the upper limit of normal (mean 1 815 U/L; range 984-3 358) in all the patients. Similarly, serum conjugated bilirubin (D-Bil) was elevated above the upper limit of normal (mean 3.45 mg/dL; range 1.2-7.4) in seven patients. Abdominal ultrasonography and CT scan demonstrated marked dilatation of the common bile duct and slight to moderate dilatation of the intra-hepatic bile duct.

Endoscopic naso-biliary drainage (ENBD) using a 7-Fr. Plastic tube was performed in all the patients as the initial treatment. At that time, cholangiography showed almost complete obstruction or severe stenosis of the lower part of common bile duct. After the resolution of symptoms and laboratory findings of cholestasis by ENBD, three patients were subjected to EMS, while the other five underwent EMS after stenting using a 10 Fr. tube. The mean duration of tube stenting was 1.4 mo (range, 2-7 mo). Three patients developed clogging of the tube stent and subsequently the stent was changed by an EMS. In the other two patients, the tube stents were withdrawn; however, symptoms of re-obstruction were detected within 3 mo and thus EMS was performed.

For EMS, a non-covered, non-self-expandable stent (Strecker stent) was used in two patients and a self-expandable stent (Wallstent, Boston Scientific Corporation, Natick, MA, USA) was used in the other six patients, the length and internal diameter of the stents were 4 and 5 cm, 7 and 10 cm after full expansion, respectively.

In four patients, plastic tube stents were inserted to resolve the main pancreatic duct stenosis, and they were

**Table 2** Clinical course of the patients after EMS

Patient number	Cholestasis	Cholangitis	Stone formation	Dislodgement	Alcohol intake	Outcome	Duration of stent patency(yr)
1	+ 1 mo	+ 1 mo	-	-	-	Dead	2.8
2	+ 4.6 yr	-	-	-	-	Alive	8.3
3	+	-	+ 7.3 yr	+ 5.9 yr	+	Alive	7.3
4	-	-	-	-	-	Alive	7.1

7	+	-	+ 6.1 yr	-	+	Alive	6.1
8	+ 3.6 yr	+ 3.6 yr	-	-	+	Dead	3.6

occasionally inserted depending on the patient's symptoms: abdominal and/or back pain.

After EMS, periodical examination of hemogram, blood biochemistry, urinalysis, and abdominal ultrasonography were conducted every 3-4 mo. Examination by cholangiography was occasionally performed, when a patient presented symptoms of biliary obstruction.

## RESULTS

### **Short and medium-term (up to 3 years) follow-up after EMS (Table 2)**

EMS was successfully performed in all the patients; however, in one patient (no. 1) clogging was observed within 1 mo and another EMS was inserted inside the first EMS. The patient showed no symptoms of bile duct obstruction thereafter.

The serum concentration of ALP and D-bil markedly decreased after the initial treatment including EMS (Figure 1), and 1 year after EMS, five of eight patients showed normal values, two patients showed slightly higher than the upper limit of normal, and one patient had a high serum concentration of ALP. Two years after EMS, none of the patients showed symptoms of bile duct obstruction and abdominal US demonstrated no dilatation of the intra-hepatic bile duct with the stent located at the original position.

One patient (no. 1) died of acute myocardial infarction 2.8 years after EMS without symptoms of cholestasis during the follow-up period. The course of the other seven patients was uneventful for 3 years.

### **Long-term follow-up after EMS (Table 2)**

One patient (no. 8) died of cholangitis (acute obstructive suppurative cholangitis, AOSC) caused by EMS clogging 3.6 years after EMS. The patient had presented no symptoms up to 1 wk before the last admission, when he felt acute pain in the right upper abdomen and experienced a sudden rise of his body temperature. He was brought to the hospital in a state of shock and was admitted to the ICU, but intensive care including ENBD was not effective and he died 17 d after the last admission. The patient's periodical check up with US and laboratory tests showed no signs of marked cholestasis except slight elevation of serum ALP concentration during the 3.5 years of follow-up as well as 1 mo before. It was suggested from

**Figure 3** Endoscopic view showing a duodenal ulcer on the side opposite to the duodenal papilla (A) 5.9 years after the EMS in patient number 3. The stent had become dislodged and the steel wires protruded from the papilla (B). They were efficiently cut using the end-cutter (arrow) (C).

the medical chart that the patient had suffered from cholangitis caused by stent clogging 1 wk before his admission, but he did not take it seriously; he thought that the symptoms were those of common cold, and delayed his visit to the hospital. Another patient (no. 2) presented

**Figure 4** Plotting of the serum alkaline phosphatase concentration (●) and conjugated bilirubin (○) of each patient 3 yr after EMS. The broken line indicates the upper limit of normal.

with signs of cholestasis caused by acute exacerbation of pancreatitis 4.6 years after EMS; however, his condition improved soon after the treatment for pancreatitis without any endoscopic treatment, and he showed no symptoms thereafter. Two other patients (nos. 3 and 7) presented with cholestasis caused by choledocholithiasis in the upper part of the CBD proximal to the stent 7.3 and 6.1 years after EMS, respectively. In one patient (no. 7) the stones were successfully removed with a basket wire and he presented no symptoms thereafter (Figures 2A and 2B). In the other patient (no. 3) the stone could not be removed with a basket wire and two sessions of endoscopic hydraulic lithotripsy were necessary to eliminate it. Cholangioscopic examination of these patients showed that the metallic mesh was embedded into the bile duct wall allowing sufficient inner space without epithelial hyperplasia within the stent (Figure 2C).

Two patients (nos. 3 and 5) suffered from duodenal ulcers at 5.9 and 4.8 years after EMS, respectively, because the EMS wire dislodged and protruded from the papillary orifice, contacting the duodenal wall on the opposite side. The wire of the protruding part was cut under endoscopy with the end-cutter (Olympus, Tokyo, Japan), and the ulcer healed later (Figure 3).

Patient (no. 6) died of maxillary carcinoma 5.5 years after EMS although he presented no symptoms of cholestasis during the follow-up period.

Thus, five of the eight patients are alive at present and their mean follow-up period is already 7.4 (range: 6.5–8.3 years) years. The value of ALP is over the upper limit of normal in three patients now (Figure 4), and mild dilatation of the intra-hepatic bile duct is observed in three of them.

Patients (nos. 3, 6, 7, and 8) continued drinking alcohol after EMS; two of them developed choledocholithiasis and one suffered from AOSC. The other four patients did not drink alcohol after EMS and only one showed mild, transient signs of cholestasis.

## DISCUSSION

EMS for benign bile duct stenosis as a complication of CP has been attempted in some institutes and patency of the stent is likely to be better<sup>[12–16]</sup>. Kahl *et al* used metal stents

as the permanent treatment option and their patients remained free of obstructive jaundice or cholangitis for 1 year<sup>[16]</sup>. Deviere *et al* conducted a prospective study with a mean follow-up of 33 mo, and the stent lumen remained patent and functional throughout the follow-up period<sup>[12]</sup>. The reported results agree with our study concerning short to medium-term follow-up after EMS. In fact within 3 years after the treatment, all the patients except one who died of a heart attack showed almost uneventful clinical courses regarding biliary stenosis; judging from symptoms, laboratory findings including ALP, D-Bil, and imaging findings. One elderly patient died of causes other than CP with no signs of bile duct re-obstruction for 2.8 years. Such a good outcome was not achieved with the plastic tube stent<sup>[5,6,8,9,17]</sup>, and long-term outcome of treatment with multiple tube stents was also disappointing<sup>[18]</sup>.

Based on these results, EMS is obviously better than tube stenting regarding patency and not requiring scheduled changing of the stent. These advantages are thought to come from the characteristics of EMS: large caliber and expanding effect. However, the main problem of EMS is the development of epithelial hyperplasia in the stent resulting in obstruction<sup>[18]</sup>. Deviere *et al* reported that only two of 20 patients developed epithelial hyperplasia leading to cholestasis and jaundice within six months after stenting<sup>[12]</sup>. One of our patients also developed early obstruction of EMS, but an additional stent resolved this difficult problem. The metallic mesh is thought to become embedded in the bile duct wall early after stenting, so that a continuous membrane covers the inner stent<sup>[12]</sup>. Based on this hypothesis, ingrowth within the stent and subsequent obstruction may be related to the tumor rather than to CP, and in fact, the majority of our patients did not develop an early obstruction.

Although good results have been reported after a short- to medium-term follow-up, long-term results are unknown. Hastier *et al* reported the outcome of a patient treated with a metallic stent, who presented with no evidence of recurrence of cholestasis or episodes of cholangitis for a relatively long period of 3 years<sup>[14]</sup>. Van Berkel *et al* recently reported that they treated 13 patients with biliary stricture due to CP by self-expanding metal stent (SEMS) with the mean follow-up for 50 mo and that SEMS was found to be safe and provides successful as well as prolonged drainage in selected patients<sup>[19]</sup>. Nevertheless, the opinions in our institute were controversial regarding uncertainty of safety and outcome of EMS in patients with CP after a long-term follow-up, and we voluntarily decided to stop the application of EMS treatment from August 1998 until December 2003, when we could assess the long-term outcome and re-started EMS. Since then, two patients have been subjected to EMS up to now.

The outcome of EMS after more than 3 years was fairly good. But we experienced a very serious complication caused by re-obstruction of the bile duct. Emergency treatment was delayed leading to disappointing results in this case. If adequate intensive treatment had been started much earlier, the patient would have been saved. Another patient showed mild cholestatic symptom due to acute exacerbation of pancreatitis, but recovered soon after pancreatitis resolved without any intervention,

suggesting cholestasis was not caused by clogging of the stent but by another factor such as papillary edema. In two other patients with stone formation, cholangioscopic findings showed the patency of the stent lumen, according to the assumption of Deviere *et al*<sup>[12]</sup>. However, stones were thought to develop as a consequence of stagnation of bile, accordingly complete bile flow may be difficult to obtain even with EMS. Another complication of dislodgement was duodenal ulcers which were well controlled by endoscopic treatment.

One of our patients died of maxillary cancer long after EMS. Hastier *et al* decided to insert a metallic stent in their patient in view of his poor prognosis associated with the pulmonary malignancy<sup>[14]</sup>. CP is shown to frequently associate with various malignancies and a significantly lower survival rate compared with non-CP<sup>[20-22]</sup>. Therefore, in choosing EMS, this is one of the decision-making facts as well as the patients' general conditions and the lack of response to stenting using a plastic tube<sup>[2,13]</sup>.

It is difficult to determine the optimal indications for EMS from our results because of the limited number of patients and the absence of a control group. However, since five of the eight patients are alive and leaving ordinary lives 7.4 years after EMS, this procedure is evidently one of the very promising options of treatment for bile duct stenosis in patients with CP, provided they are closely followed up through periodical check-ups. Thus setting a system for prompt management in case of an emergency is desirable. In addition, our results indicate that alcohol intake may be related to the poorer prognosis of patients subjected to EMS; thus prohibition of alcohol consumption is essential.

### Abstract

**AIM:** To evaluate the efficacy of hilar duct oriented hepatectomy for intractable hepatolithiasis, the ventral hilum exposure (VHE) method that has been applied by the authors.

**METHODS:** From June 1994 to June 2004 for a period of 10 years, 153 patients who had Tsunoda type III or IV hepatolithiasis, received hepatectomy at our institution. Among these patients, 128 who underwent hepatectomy by the VHE method were the subjects for the study. We analyzed the risk of this procedure, residual rate of intra-hepatic stones, and stone recurrent rates.

**RESULTS:** The average age was 54.2 years, and the male to female ratio was 1:1.7. The average follow-up period was 25.6 mo (6-114 mo). There was no post-operative severe complication or mortality after the operation. The rate of residual stones was 5.4% and the rate of recurrent stones was 4.2%.

**CONCLUSION:** VHE is a safe surgical procedure and provides favorable treatment results of intractable hepatolithiasis. Especially, this procedure has advantage in that intra-hepatic bile duct stricture may be confirmed and corrected directly during surgery.

### INTRODUCTION

Although hepatolithiasis is a benign condition, the clinical progression of this disease not only often limits a patient's social activities, sometimes to an extreme degree, but also may lead to liver parenchymal destruction due to recurrent cholangitis or even septic death if adequate treatment is not provided. Moreover, cholangiocarcinoma is found in approximately 5-10% of patients with hepatolithiasis<sup>[1,2]</sup>. The incidence of hepatolithiasis in the Korean population has been reported as 15% of all biliary tract stones, which is relatively higher than the data reported in Western populations<sup>[3]</sup>.

In clinical practice, however, the treatment results are less favorable when compared to those of extrahepatic bile duct stones. The reason for this is the stricture of the intra-hepatic duct as a major cause of hepatolithiasis<sup>[4,5]</sup>, which is commonly intractable because of the anatomical characteristics. It has been known that the most important aspects in the treatment of hepatolithiasis is the complete removal of all intra-hepatic stones and resolution of accompanied intra-hepatic duct stricture, in order to reduce the incidence of post-operative cholangitis and stone recurrence<sup>[6]</sup>.

Recent developments in endoscopic techniques have also been shown to result in favorable outcomes<sup>[7]</sup>. Such advances have led to the shifting of surgical practice from uniform surgery to a combination of surgery and endoscopy for the treatment of hepatolithiasis<sup>[8,9]</sup>. But the endoscopic approach for hepatolithiasis is not always successful due to various intra-hepatic duct anatomies and cannot solve concomitant liver atrophy or latent cholangiocarcinoma.

The authors of this study implemented a surgical approach for hepatolithiasis according to the Tsunoda classification of hepatolithiasis, which describes the intra-hepatic duct in terms of dilatation and strictures, and is as follows: type I, no marked dilatation or strictures of intra-hepatic bile ducts; type II, diffuse dilatation of the intra-hepatic biliary tree without intra-hepatic duct strictures and frequently a stricture of the distal common bile duct; type III, unilateral solitary or multiple cystic intra-hepatic dilatation, frequently accompanied by stenosis of the left or right intra-hepatic bile ducts; and type IV, the same attributes as type III but with bilateral involvement of hepatic lobes<sup>[10]</sup>. The authors' policy of treatments in hepatolithiasis is according to Tsunoda type, that is, the type I or II is treated with endoscopic approach and the type III or IV is with surgical approach.

**Figure 1** Schematic drawing of VHE procedure during left lobectomy. **A:** Hepatotomy commences vertically from the Cantlie's line to the direction of the hilar bile duct (thick arrow); **B:** after reaching the hilum, the hepatotomy is continued along the pre-caudate plane (angled thick arrow); **C:** the ventral portion of the hilar hepatic duct is opened along its direction; **D:** after completion of the necessary ductal procedure.

## MATERIALS AND METHODS

From June 1994 to June 2004, a retrospective review was undertaken of 153 patients who received partial hepatectomy for hepatolithiasis at our institution, among whom, 128 patients underwent hilar duct oriented hepatectomy (ventral hilum exposure method, VHE). We analyzed the surgical risk of VHE method, residual rate of intra-hepatic stones, stone recurrent rates, and those patients with concomitant cholangiocarcinoma were also investigated.

The definition of hepatolithiasis was according to the description by Couinaud in which a gallstone is present in the proximal portion of the confluence of the common hepatic duct. The presence of residual or recurrent hepatolithiasis after surgery were assessed by ultrasonography (US), computerized tomography (CT) scans, cholangiograms by endoscopic retrograde cholangiopancreatography (ERCP) and/or percutaneous transhepatic cholangiography (PTC). The postoperative follow-up comprised of US every 3 mo and CT scan every 6 mo for the first three years, and then once a year thereafter, or when abnormal symptoms suspicious of cholangitis or residual or recurrent hepatolithiasis were present. If the residual or recurrent stones were suspected by US or CT scan, the PTC and/or ERCP were introduced.

Recurrent hepatolithiasis was defined as stones recurring after 2 years of initial therapy. Operative mortality and hospital mortality was defined as death of a patient within 30 d of surgery, and death before discharge from the hospital after surgery, respectively.

### Operative techniques

The goal of VHE is total exposure of the hilar bile duct. In case of left lobectomy, first the course of middle hepatic vein

and the distribution of intra-hepatic stones are confirmed by intra-operative US, then the gallbladder is removed. A sagittal liver parenchyma dissection (hepatotomy) along the Cantlie's line or midline of the GB bed is done until reaching the right hilar Glisson's sheath. Then the sagittal dissection plane is rotated 90° to the left along the coronal plane or pre-caudate plane<sup>[11]</sup>. The preservation of the middle hepatic vein during sagittal hepatotomy is optional. Managed thus, long segment of the ventral portion of hilar Glisson's sheath can be separated from dorsal part of the segment IVb liver parenchyma (Figures 1A and 1B). Without exception in our experience, the hepatic hilar bile duct is situated at the extreme antero-superior aspect in the hilar Glisson's pedicle that can be confirmed by needle puncture aspiration of bile, and then the anterior wall of the hilar bile duct can be opened safely along its direction without the need of dissection of hilar Glisson's sheath (Figures 1C and 1D).

In this way, direct visualization of the openings of the second order branches of the intra-hepatic bile duct allows pronounced accuracy of intra-operative cholangioscopy in each of the intra-hepatic duct branches, and precise evaluation of the distribution of intra-hepatic stones and hilar stricture, and plastic reconstruction of the strictured hilar hepatic duct. Plastic reconstruction of intra-hepatic duct results in avoidance of a hepatico-jejunostomy in almost every patient, and also primary closure of the bile duct incision site maintains the physiologic anatomy of the intra-hepatic bile duct. The VHE procedure also resulted in easier confirmation of the common bile duct status, and none of the patients who received this therapy required a T-tube choledochostomy (Figures 2 and 3).

We did not perform VHE in cases where the hepatolithiasis was situated in the third branch or the more periphery of the intra-hepatic bile duct, when parenchymal destruction of the liver was observed in the periphery, and when no stricture was present up to the second

**Figure 2** **A:** Dissecting along the pre-caudate plane allows the ventral portion of the hilar duct to be exposed during left lobectomy; **B:** the hilar duct was opened along its direction; RHD: right hepatic duct opening.

**Figure 3** During central lobectomy, the hilar duct was exposed and opened. **A:** Extraction of the IHD stones; **B** and **C:** application of intra-operative choledochoscope to the left and right IHD; **D:** after the removal of all intra-hepatic stones.

order branches of the hilar bile duct. These patients were managed with conventional liver parenchyma resection (Table 1).

## RESULTS

The average age of patients who received VHE surgery was 54.2 years, and the male to female ratio was 1:1.7. All 128 patients who underwent VHE surgery were Tsunoda type III or IV (98 patients were Tsunoda type III, and 30 were type IV). The type of stone in all the 153 patients who received surgery was pigment stone, and hilar duct stricture was confirmed in 90 of 128 patients who had VHE surgery (70%). In the remaining 38 patients without hilar ductal stricture, strictures were observed in the

second order branches.

The average follow-up period of 128 patients after VHE for hepatolithiasis was 25.6 months (range; 6-114 mo). The number of patients with residual stones after VHE hepatectomy was 7/128 (5.4%), and residual stones were found in 4/98 patients with Tsunoda type III (4.1%) and in 3/30 with type IV (10%). Among them, there were six patients in whom residual stone removal by PTCS was performed who had symptoms such as cholangitis. And the remaining four asymptomatic patients were being followed up only with observation to date.

We could follow-up 48 patients with CT scan and US for more than two years after complete stone removal by the VHE method. The range of the follow-up period of these 48 patients was 26-116 mo, with an average of

Table 1 Type of hepatic resection

<sup>1</sup>Explo-laparotomy only due to carcinomatosis of cholangiocarcinoma. <sup>2</sup>Left lateral segmentectomy. <sup>3</sup>Right posterior segmentectomy. <sup>4</sup>Central lobectomy. <sup>5</sup>Left lobectomy. <sup>6</sup>Right lobectomy+subsegmentectomy IVb.

Table 2 Rate of residual and recurrent stones after VHE procedure (n = 128) according to Tsunoda type

Tsunoda type	Number of residual stone (%)	Number of recurrent stone (%)
III	4/98 (4.1)	2/39 (5.1)
IV	3/30 (10)	0/9 (0)
Total	7/128 (5.4)	2/48 (4.2)

60.4 mo. Among them, only two patients had recurrent stones, showing a recurrence rate of 4.2% (2/48). Both of these patients were Tsunoda type III at the time of surgery (Table 2). And these two recurrent patients developed cholangitis, and one died of sepsis as a result of the cholangitis. Among the 46 patients who were followed up for more than 2 years without recurrent stones, 2 developed acalculous cholangitis as the complication and were managed by conservative treatment. One patient was diagnosed with cholangiocarcinoma 3 years after surgery without evidence of stone recurrence (Table 3).

Among the total of 153 patients who received hepatectomy for hepatolithiasis, there were 17 cases of cholangiocarcinoma (11%), and six of these patients were of advanced state of unresectable disease during laparotomy. There were also three patients with *in situ* cholangiocarcinoma after confirmation of pathology. And only three patients were pre-operatively determined to be with cholangio-carcinoma among the total of 17 cases of concomitant cholangiocarcinoma.

There was no case of operative mortality or hospital mortality in all patients who were studied. Post-VHE complications occurred in 33/128 patients (25.7%), and consisted of wound infections (20 patients, the most common complication), pulmonary complications such as pleural effusion or pneumonia (nine patients), bile leakage (four patients), and one case each of post-operative minor intra-abdominal hemorrhage, intraperitoneal abscess, and gastrointestinal bleeding. All of the complicated cases were successfully managed conservatively.

## DISCUSSION

Recent therapy by the combination of endoscopy and

Table 3 Long-term results in patients (n = 48) who underwent complete stone removal by VHE

Long-term results	Number of cases (%)
Free of symptoms and no recurrent stones	43 (89.6)
Recurrent stones with cholangitis	2 (4.2)
Cholangitis without recurrent stones	2 (4.2)
Cholangiocarcinoma	1 (2.1)

surgery for the treatment of hepatolithiasis has allowed overcoming the limitations of each modality and therefore has led to marked enhancement of treatment results. Another reason for the increased treatment success may be due to the more accurate pre-operative evaluation of intra-hepatic bile duct strictures and distribution of intra-hepatic stones.

Many favorable results have been reported in the literature with regard to endoscopy in the management of hepatolithiasis<sup>[7,12]</sup>. In our institutional experience, analysis of endoscopic treatment results of 106 patients with hepatolithiasis has shown that the overall residual stone rate was 16%, but this rate was higher in patients with Tsunoda types III and IV (24% and 30%, respectively). We thought that this result was from the intra-hepatic stricture and the sharp angled branches of the intra-hepatic bile duct anatomy<sup>[13,14]</sup>. And it is well known that there are major limitations of endoscopic hepatolithiasis, such as parenchymal destruction of the liver, liver abscess formation, and a 5-10% incidence of cholangiocarcinoma that occurs in patients with hepatolithiasis<sup>[1,2,15,16]</sup>. Our study revealed a slightly higher rate (11%) of patients found with cholangiocarcinoma, compared to previous reports from other institutions, and the reason for this is thought to be due to the fact that patients who received surgery in our institution were those with parenchymal destruction and intra-hepatic bile duct stricture, and also because a larger number of patients were with long-standing, advanced hepatolithiasis. Another serious problem in patients with hepatolithiasis accompanied by the presence of cholangiocarcinoma is that the latter disease is not easily detected in the pre-operative evaluation, and thus may be missed during endoscopic treatment of hepatolithiasis<sup>[2,17]</sup>. This was also our finding in this study.

Endoscopic treatment of hepatolithiasis is considered to be relatively safe<sup>[18]</sup>. However, to endoscopically remove all stones completely and to resolve stricture of the intra-hepatic bile duct, the procedure is conducted on an average of 3 to 4 times at 1-2 wk intervals, restricting the patients' activities over a long period of time, even though the procedure entails less physical and psychological burden for the patient than surgical operation.

In Korea as well as in most Asian populations, pigment stones are the most common, while cholesterol stones are predominant in Western populations. This was also the case in our study in which all patients who received surgery were with pigment stones. In contrast to cholesterol stones, pigment stones demonstrate different clinicopathologic features of the intra-hepatic bile duct. Most cholesterol hepatolithiasis are usually located in the

**Figure 4** A and B: Pre-operative imaging of hepatolithiasis with hilar duct stricture; C: opened hilar IHD shows narrow entry of right IHD (arrow); D: after stricture-plasty both entries of the right anterior and posterior ducts are seen.

peripheral intra-hepatic ducts, accompanied by a lesser incidence of cholangitis, there is less wall thickening of the stone-containing duct, and the presenting symptoms are usually mild. However, pigment stones are frequently accompanied by hilar duct stricture and hilar duct stones, show severe wall thickening of the stone-bearing duct, and the symptoms are more severe due to a higher incidence of cholangitis<sup>[19]</sup>. According to our knowledge of previously reported literature, we have not been able to find any reports with regard to the rate of hilar duct stricture in hepatolithiasis patients due to pigment stone. We, however, were able to observe in our study that hilar stricture was present in 90 of 153 (59%) patients. Therefore, it is the opinion of the authors that during surgery for pigment stone hepatolithiasis, resection of the stone bearing liver parenchyma and removal of stones only is inadequate because the possibly accompanied hilar strictures will make recurrent diseases, and which must be appropriately corrected during surgery.

The VHE procedure adopted and analyzed by the authors of this study has been established as a safe method in a previous report of the pre-caudate plane of the para-caval portion of the caudate lobe<sup>[11]</sup>. Anatomically, the pre-caudate plane may be described as a plane bounded inferiorly by the hilar Glisson's pedicle, superiorly by the dorsal portion of origin of the middle hepatic vein, the left side by the ligamentum venosum, and the right side by the imaginary line of the second order branching point of the right Glisson's pedicle and the dorsal portion of origin of the right hepatic vein<sup>[11,20]</sup>.

According to the experience of the authors of this study, we did not observe any postoperative incidence

of severe hemorrhage of the resection plane or hypoxic damage of the caudate lobe during hepatotomy along the pre-caudate plane for left lobectomy or extended right lobectomy of the liver.

This VHE method also permitted facilitated understanding of individual hilar bile duct anatomy, the openings of second order branches from the hilar bile duct by completely exposing the ventral hilar Glisson's pedicle and then incising along the hilar bile duct. It also allowed increased accuracy of the intra-operative choledochoscopy, complete removal of intra-hepatic stones without difficulty under direct visualization, and easier stricture-plasty of the constricted hilar bile duct.

Our experience showed that the opening of hilar bile duct along its direction will allow visualization of 3 or 4 openings of the second order branches of the intra-hepatic bile duct, which emerge beginning from the right side in the following order; the anterior segmental branch, the posterior segmental branch (or common duct opening of right anterior and posterior hepatic duct), and 2 caudate branches. In many instances, the order and the number of caudate branches varied from patient to patient, and the order frequently presented as anterior segmental branch, caudate branch, posterior branch, and then the caudate branch. When hilar bile duct stricture is present, the stricture site may exist anywhere in the openings of the second order branches, thus necessitating adequate exposure of the hilar bile duct for direct visualization of the inside of the hilar bile duct for preservation of each second order branches during stricture-plasty (Figure 4).

Whenever possible, the authors did not perform a bilioenterostomy after hepatectomy but attempted to

conserve the anatomy of the bile duct physiologically. This was because according to two studies by Kusano *et al*<sup>[21]</sup> and Jan *et al*<sup>[22]</sup>, incidence of cholangitis was high after bilioenterostomy.

In this study, the 5.4% rate of residual stones and 4.2% of recurrent stones after VHE surgery for hepatolithiasis were much better results than historical control datas of conventional hepatectomy that showed residual stone rate about 10% and recurrent stone rate about 12-29.6%<sup>[22-25]</sup>, and this may be attributed to the high efficacy of the VHE procedure in correcting the bile duct stricture. Moreover, as the patients who underwent VHE for hepatolithiasis in this study were all high grade Tsunoda type which is difficult to remove by endoscopic methods, the effectiveness of the proposed VHE method is further stressed. We also emphasize the complication rate of VHE which was comparable with that of conventional hepatectomy.

In conclusion, we present in this study the VHE method that allows accurate assessment of the pathologic anatomy of the intra-hepatic bile duct during hepatectomy for hepatolithiasis. We also suggest from our observed data that this procedure will decrease the residual stone rate and long term recurrent stone rate after surgery without serious complications. We recommend this procedure for surgical treatment of intractable hepatolithiasis.

### Abstract

**AIM:** We examined quantitative mRNA expression of growth factor receptors (c-erbB-1, c-erbB-2) and the anti-apoptosis gene survivin known to be regulated in pancreatic adenocarcinomas and compared the expression pattern with that in carcinomas of the papilla of Vater.

**METHODS:** Quantitative real-time reverse transcriptase-PCR (QRT-PCR, Taqman™) was performed to analyze mRNA expression levels of c-erbB-1, c-erbB-2 and survivin in normal and corresponding tumor samples of 31 pancreatic adenocarcinomas and 8 cancers of the papilla of Vater.

**RESULTS:** The overall median mRNA expression of survivin was significantly increased in both adenocarcinoma of the pancreas ( $P < 0.01$ ) and papilla of Vater ( $P < 0.008$ ) compared with uninvolved normal control tissue. In pancreatic cancer, expression of c-erbB-1 was significantly decreased compared with the normal pancreatic tissue ( $P < 0.03$ ), whereas in the cancer of the papilla of Vater expression of c-erbB-2 was significantly downregulated ( $P < 0.05$ ) compared with the paired normal samples. Gene expression was not associated with tumor stage, differentiation or prognosis.

**CONCLUSION:** The common anti-apoptosis gene survivin is overexpressed both in the cancer of the papilla of Vater and pancreas. In contrast, the growth factor receptor genes c-erbB-1 and c-erbB-2 are differentially regulated in both tumor entities adding further evidence that pancreatic cancer is biologically different from the cancer of papilla of Vater.

### INTRODUCTION

Adenocarcinoma of the pancreas has the worst prognosis of all cancers, with a 5-year survival rate less than 3%, accounting for the fifth highest number of cancer related deaths in North America and Europe with a rising incidence<sup>[1-3]</sup>. The only curative treatment for pancreatic cancer (PC) is complete resection which is possible in only 10-20% of patients<sup>[4]</sup> and associated with relatively constant 5-year survival rates of approximately 20% for the last 30 years<sup>[5,6,7]</sup>. The dismal prognosis and the lack of effective therapeutic regimens for this disease are attributed to several causes: (a) PC shows an aggressive biological phenotype, which is characterized by the early invasion of surrounding structures and rapid metastatic spread<sup>[8,9]</sup>; (b) radiation therapy and chemotherapy are reported to be effective only in selected patients after tumor resection<sup>[9-11]</sup>; (c) although various genetic alterations were identified, which have improved our understanding of the carcinogenesis of this disease, the responsible molecular mechanisms are largely unknown. New treatment regimens based on molecular classifications of the individual tumor may improve the outcome for patients with PC.

In contrast, cancer of the papilla of Vater (CPV) has a better prognosis with a 5-year survival rate of over 40% after curative resection<sup>[12,13]</sup>. CPV is a rare disease representing 6-12% of all periampullary malignancies<sup>[14]</sup> with an estimated incidence of 2.9 per million<sup>[15]</sup>. Because of its anatomical location, CPV becomes symptomatic at an earlier stage than PC. Therefore, the majority of the patients with CPV are candidates for surgical therapy. Evidence is increasing that differences in the tumor

biology of these two entities contribute to the different prognosis<sup>[16]</sup>.

Survivin is a member of the inhibitor of apoptosis gene family, which is unique for its expression in a wide range of embryonic and fetal tissues, whereas almost no transcripts are detected in terminally differentiated normal adult tissues. In human pancreatic islets survivin expression is also developmentally regulated<sup>[17]</sup>. Survivin expression in human fetal islets was identified immunohistochemically in alpha and beta islet cells whereas adult pancreases showed a staining only in the alpha cells. However, it is re-expressed in several human cancers<sup>[18]</sup> and has an additional function in the regulation of cellular proliferation<sup>[19]</sup> and angiogenesis<sup>[20]</sup> of cancers. Survivin expression has been reported to be associated with poor survival in patients with colorectal cancer<sup>[21,22]</sup> and several other human cancers<sup>[23]</sup>. In a recent immunohistochemical study on 52 PC patients, increased survivin expression was strongly correlated to a higher proliferative index, nevertheless no correlation between survivin expression and survival of the patients was shown<sup>[24]</sup>.

The epidermal growth factor receptor (EGF-R) family contains four structurally homologous transmembrane proteins with intracellular tyrosine kinase activity. The best-described growth factor receptors of this family are EGF-R also known as c-erbB-1<sup>[25]</sup> and the c-erbBs-2, 3, and 4<sup>[26]</sup>. They share a significant sequence homology and are frequently overexpressed in PC. Activation of the receptors leads to increased DNA synthesis, and changes in cell motility and cell metabolism<sup>[27]</sup>. EGF-R is activated by a family of peptide ligands that includes EGF, TGF- $\alpha$ , heparin binding EGF-like growth factor, betacellulin, and amphiregulin<sup>[28]</sup>. The EGF-R is encoded by the c-erbB-1 proto-oncogene and is a transmembrane growth factor with tyrosin kinase activity. In normal pancreas, c-erbB-1 is expressed only in the islets of Langerhans. Nevertheless the c-erbB-1 gene is overexpressed in human pancreatic cell lines and in 95% of ductal adenocarcinomas, due to an increase in gene transcription<sup>[29]</sup>. Overexpression of c-erbB-1 detected by immunohistochemistry is correlated with reduced survival rates in several studies<sup>[30,31]</sup>.

The c-erbB-2 (also called HER2/neu) gene encodes a 185-ku transmembrane glycoprotein with tyrosine kinase activity, and acts as a receptor for a class of ligands that includes the heregulins, gp30, and NEU-differentiation factor. C-erbB-2 is overexpressed in the bladder, breast, esophageal, and gastric cancer, where it appears to have a role in lymphatic tumor spread<sup>[32,33]</sup>. In ductal adenocarcinomas of the pancreas and in ampullary tumors, c-erbB-2 is overexpressed in 20%, which is usually caused by gene amplification<sup>[34]</sup>. Reports about the prognostic significance of c-erbB-2 are not uniform throughout the literature. One study showed a survival advantage for patients without the overexpression of c-erbB-2 in their tumors<sup>[35]</sup>, while another study showed a correlation of c-erbB-2 serum levels and survival of the patients<sup>[36]</sup>. In the majority of studies no prognostic significance for the expression of c-erbB-2 in PC was revealed<sup>[37,38]</sup>.

In the present study we have determined gene expression levels of survivin, c-erbB-1 and c-erbB-2 in PC and CPV applying quantitative real-time RT-PCR (TaqMan

™) in order to look for gene profiles that might account for the different biological behavior.

## MATERIALS AND METHODS

### *Patients and specimens*

Between July 1997 and December 2003 fresh frozen tumor and corresponding normal tissue from 63 patients, who underwent curative resection of suspected or proven pancreatic or ampullary tumors were collected. Informed consent was obtained from all the patients. Data and tissue collection were in accordance with the regulation of the local ethic committee. Tissues were frozen immediately in liquid nitrogen and stored at -80 °C until further analysis.

The definitive histology of the tissue used for RNA isolation was confirmed in serial sections by a staff pathologist. Only tumor specimens with at least 75% malignant cells were used for RNA isolation.

Finally, 31 specimens from ductal adenocarcinomas of the pancreas and 8 from adenocarcinomas of the papilla of Vater with paired normal control tissues were available for gene expression analysis. This study population consisted of 24 (62%) men and 15 (38%) women with a median age of 59.4 years (range, 33-81 years). Tumor staging was performed according to the International Union Against Cancer (UICC) tumor-node-metastasis classification. In patients with PC, 1 (3.2%) patient had a stage I tumor, 3 (9.6%) patients had a stage II tumor, 24 (77.4%) patients had a stage III, and 3 (9.6%) had a stage IVa tumor. In patients with CVP, 5 patients presented with a stage II tumor, 2 patients had stage III, and 1 patient a stage IV tumor.

Twenty four patients underwent a Kausch-Whipple procedure, and in 10 patients the pylorus was preserved. In four patients a left-sided pancreatic resection and in one patient a pancreatectomy was performed. In patients with cancer of the papilla ( $n=8$ ) of Vater, five received a pylorus preserving partial pancreaticoduodenectomy, whereas three patients underwent a Kausch-Whipple procedure. The median follow-up for surviving patients was 9.5 mo and no patient was lost to follow-up.

### *RNA isolation*

Total cellular RNA was isolated using RNeasy Mini Kit (Qiagen, Hilden) adding proteinase K (0.2 mg/mL) and quantified at  $A_{260/280\text{ nm}}$  (SmartSpec; Bio-Rad, Hercules, CA, USA).

### *Quantitative RT-PCR*

Total cellular RNA (0.5  $\mu\text{g}$ ) was reverse-transcribed as described previously<sup>[39]</sup>. An amount of 25 ng of cDNA was taken for real-time PCR using the TaqMan ABI PRISM 7900HT Sequence Detection System (Applied Biosystems, Darmstadt, Germany). To normalize the amount of total RNA present in each reaction, the housekeeping gene  $\beta$ -actin was amplified.

Primers and probes were designed to encompass intron between exon sequences using the Primer Express Software (Applied Biosystems, Darmstadt, Germany). The  $\beta$ -actin probe was labeled with 5'-VIC and 3'-Minor Groove Binder/Non-Fluorescent Quencher (Applied

**Figure 1** Expression of survivin in PC ( $n=31$ ) and CPV ( $n=8$ ).

Biosystems, Darmstadt, Germany). The survivin, c-erbB-1 and c-erbB-2 probes were labeled at the 5' end with FAM and at the 3' end with the quencher TAMRA (Eurogentec, Seraing, Belgium). The sequences for the primers and probes were as follows: survivin described by Warnecke-Eberz *et al* 2005. C-erbB-2 sense 5' CCA GGA CCT GCT GAA CTG GT 3', anti-sense 5' TGT ACG AGC CGC ACA TCC 3', probe 5' CAG TTG CCA AGG GGA TGA GCT ACC TG 3'. C-erbB-1 sense 5' CGC AAG TGT AAG AGT GCG AA 3', anti-sense 5' CGT AGC ATT TAT GGA GAG TGA GTC T 3', probe 5' CCT TGC CGC AAA GTG TGT AAC GGA AT 3'. The reliability of PCR amplification and detection was verified on serial dilutions of standard cDNAs prior to analyses of patient samples. To ensure that no genomic DNA was amplified the assays were checked with RNA samples minus reverse transcription control as well as with genomic DNA as template.

The PCR reaction was performed as described previously<sup>[39]</sup>. All analyses were done in triplicates. Gene expression levels were calculated using standard curves generated by serial dilutions of placenta cDNA (Clontech Laboratories, Palo Alto, CA, USA).

### Statistical analysis

The gene expression analyses yielded values, which were expressed as ratios between two absolute measurements: the gene of interest and the internal reference gene  $\beta$ -actin. Gene expression levels were described using the median as point estimator and the range of values. Cut-off values for discrimination of dichotomized mRNA expression levels and clinicopathologic parameters were derived from receiver operating curve data (area under the curve and the 95% confidence interval) according to Metz *et al*<sup>[40]</sup>. Associations between gene expression levels and clinicopathological parameters were evaluated using the  $\chi^2$  test for dichotomized variables, Wilcoxon's rank test for paired variables and the Mann-Whitney test for independent variables applying Fisher's exact testing for significance.

Partitioning of gene expression levels to construct prognostic groups was performed according to LeBlanc *et al*<sup>[41]</sup>. Briefly, the best cut-off value for a supposed

**Table 1** Results of non-parametric paired samples Wilcoxon's test. mRNA expression of c-erbB-1 and c-erbB-2 are compared between tumor (T) and normal (N) samples

Tumor		c-erbB-1	P	c-erbB-2	P
Pancreatic cancer	T<N	21	0.03	14	0.99
	T>N	9		17	
Cancer of the papilla of Vater	T<N	5	0.38	6	<0.05
	T>N	3		2	

prognostic variable is determined by simulating the log-rank test for all observed covariate values within the entire data set. The minimal log-rank  $P$ -value determines the best cut-off value for dichotomization of the covariate. Kaplan-Meier<sup>[42]</sup> plots were used to describe the survival distribution and the log-rank test was used to evaluate survival differences<sup>[43]</sup>.

The level of significance was set at  $P<0.05$  in all statistical testing. Unless otherwise specified,  $P$ -values were given for two-sided testing.

## RESULTS

### Survivin mRNA expression

Survivin mRNA expression was detected in 30 of 31 (97%) PC in all tumor specimens of the papilla of Vater and in all paired non-malignant control specimens. In 26/31 (83%) PC expression of survivin mRNA was higher in tumor compared to normal control tissue and this difference was statistically significant (Wilcoxon's test:  $P<0.001$ ). In CPV, all tumor specimens ( $n=8$ ) had a higher expression than the normal tissue (Wilcoxon's test:  $P<0.01$ ). Expression of survivin mRNA was not significantly different between PC and CPV (Mann-Whitney test:  $P=0.195$ ). Representative box-plots are shown in Figure 1.

### C-erbB-1 mRNA expression

C-erbB-1 mRNA expression could be detected in 30 of 31 (97%) pancreatic tumors, all tumors of the papilla and all normal tissues. Expression of c-erbB-1 was lower in the malignant than in the normal pancreatic tissue in 21 out of 31 (68%) individual cases. This difference was statistically significant (Wilcoxon's test:  $P=0.028$ ), whereas in CPV no statistically significant difference ( $P=0.38$ ) in c-erbB-1 expression between tumor and corresponding normal tissue was revealed (Table 1).

### C-erbB-2 mRNA expression

The expression of c-erbB-2 was detectable in all tumor and non-malignant specimens. In PC paired non-parametric testing revealed no statistically significant difference in c-erbB-2 expression between tumor and normal tissue. In contrast, c-erbB-2 expression was significantly (Wilcoxon's test:  $P<0.05$ ) downregulated in 6/8 cases of CPV (Table 1).

No significant association between gene expression levels and clinical parameters such as sex ( $\chi^2$  test), tumor stage, lymph node stage, and grade of differentiation (Mann-Whitney test) was observed.

**Figure 2** Kaplan-Meier analysis of survival of patients with pancreatic cancer ( $n=31$ ) and CPV ( $n=8$ ) after resection.

### **mRNA expression and survival of patients with pancreatic cancer and cancer of the ampulla of Vater**

At a median follow-up of 56 months (range 7-89 mo) for surviving patients, median survival was 14 mo (range 2-60 mo) for patients with pancreatic carcinoma and 39.5 months (range 4-66 mo) for patients with carcinoma of the papilla of Vater (log-rank:  $P<0.016$ ). Kaplan-Meier survival curves are shown in Figure 2.

Partitioning of gene expression levels to construct prognostic groups according to LeBlanc *et al*<sup>[41]</sup> did not reveal any correlation between gene expression (c-erbB-1, c-erbB-2, and survivin) and survival of patients with pancreatic or papillary cancer.

## **DISCUSSION**

The surgical therapy of carcinoma of the papilla of Vater and adenocarcinoma of the pancreas consists of a pylorus preserving or a classical pancreaticoduodenectomy (Whipple procedure). Despite this identical surgical approach, the long-term prognosis is different. Five-year survival rates from 0% to 25% for PC and from 15% to 56% for CPV have been reported<sup>[1,12]</sup>. It was shown that different tumor biology, represented by higher expression of members of the EGF-R family (c-erbB-1, c-erbB-2, and c-erbB-3) contributes to the different behavior<sup>[16,44]</sup>. C-erbB-1 and c-erbB-2 were also differentially expressed in our study. In contrast to Friess *et al*<sup>[16]</sup>, our results showed a significant downregulation of c-erbB-1 expression in PC tissue and of c-erbB-2 expression in the malignant tissue of the papilla of Vater compared with the adjacent normal tissues. These results were based on a smaller number of patients, but were obtained by quantitative real time RT-PCR. Whereas the above mentioned study<sup>[16]</sup> applied immunohistochemical staining and Northern blot analysis, quantitative real time RT-PCR provides more accurate and reproducible quantitation of gene expression and has a large range of results<sup>[45,46]</sup>.

The downregulation of c-erbB-1 in malignant pancreatic tissues compared with the adjacent normal tissue is in contrast to the existing literature that shows

an overexpression of c-erbB-1 in pancreatic ductal adenocarcinoma and a worse prognosis for patients with high expression of c-erbB-1 in their tumors<sup>[29,30,47,48]</sup>. As mentioned above, these studies, which were mainly published about 10 years ago, were based on immunohistochemical techniques showing c-erbB-1 expression in only 30-70% of the investigated PC cases. Importantly, the results were not compared with the matching normal pancreatic tissue from the same patients. In our investigation using real time RT-PCR, c-erbB-1 expression was detected in 97% of PCs and in all matching normal pancreatic samples.

The reported expression of c-erbB-2 in PC has varied widely (7-82%) in different studies due to the differences in methodology and/or patient selection<sup>[35-38]</sup>. Our study, which is the first in using quantitative real-time RT-PCR to assess the expression of c-erbB-2 in pancreatic and CPV, did not show a different expression of c-erbB-2 between tumor and normal pancreatic tissue. This is in agreement with two recent studies<sup>[49,50]</sup> using immunohistochemical methods, which found no correlation between c-erbB-2 expression and stage or survival of patients with PC. However, a series of other publications<sup>[45-48,51]</sup> reported overexpression of c-erbB-2 in a subset of patients with PC and its prognostic relevance. For other malignancies such as gastric cancer<sup>[52]</sup>, breast cancer<sup>[53]</sup>, and ovarian cancer<sup>[54]</sup> an increased expression of the c-erbB-2 oncogene has been reported, applying PCR based methods. According to our results and the recent literature one must consider, that the role of c-erbB-2 in the tumorigenesis and its value as a prognostic marker in PC has not been finally elucidated.

In concordance with other authors<sup>[24,55-57]</sup>, we found an increased expression of survivin in the samples of PC and CPV compared with the adjacent non-malignant pancreas. One study<sup>[24]</sup> also found an overexpression of survivin in a series of 12 ampullary carcinomas; expression was not different from PC, which is comparable with our result. Kami *et al*<sup>[58]</sup> reported a significant correlation between poor survival and increased expression of survivin in a study with 47 patients with PC using immunohistochemistry. Whereas Sarela *et al*<sup>[24]</sup>, as well as our study revealed no association between survival and expression of survivin. The comparable results of survivin expression in our patients and other studies in the literature strengthen our data regarding the expression of c-erbB-1 and c-erbB-2 in PC and CPV. For a variety of other malignancies it was shown that survivin expression is a reliable marker for an unfavorable disease with poor overall survival<sup>[59,60]</sup>. The high number of locally advanced tumors, on which our and other studies are based, could explain the difference to PC. The significantly increased expression of survivin in PC, obtained by different methodologies, opens possibilities for new diagnostic and therapeutic strategies, such as new targets for gene therapy, differentiation between malignant and benign pancreatic lesions before surgical resection and to monitor response to neoadjuvant treatment regimens.

### Abstract

**AIM:** To examine the contribution of interleukin-10 (IL-10) gene polymorphisms to Crohn's disease (CD) phenotype, and the possible genetic epistasis between IL-10 gene polymorphisms and *CARD15/NOD2* gene mutations.

**METHODS:** A cohort of 205 Spanish unrelated patients with Crohn's disease recruited from a single center was studied. All patients were rigorously phenotyped and followed-up for at least 3 years (mean time, 12.5 years). The clinical phenotype was established prior to genotyping.

**RESULTS:** The correlation of genotype-Vienna classification groups showed that the ileocolonic location was significantly associated with the -1082G allele in the *NOD2/CARD15* mutation-positive patients ( $RR = 1.52$ , 95%CI, 1.21 to 1.91,  $P = 0.008$ ). The multivariate analysis demonstrated that the IL-10 G14 microsatellite allele in the *NOD2/CARD15* mutation positive patients was associated with two risk factors, history of appendectomy ( $RR = 2.15$ , 95%CI = 1.1-4.30,  $P = 0.001$ ) and smoking habit at diagnosis ( $RR = 1.29$ , 95%CI = 1.04-4.3,  $P = 0.04$ ).

**CONCLUSION:** In Spanish population from Madrid, in CD patients carrying at least one *NOD2/CARD15* mutation, the -1082G allele is associated with ileocolonic disease

### INTRODUCTION

Crohn's disease (CD) is a chronic inflammatory disorder of the gastrointestinal tract. The inflammation may involve any segment of the digestive tract, from the mouth to the anus, and may affect mucosa and deeper layers of the digestive wall, with or without granulomas. The etiopathogenesis of the disease remains poorly understood. Experimental and observational data suggest that intestinal inflammation arise from abnormal immune reactivity to bacterial flora in the intestine of individuals who are genetically susceptible<sup>[1]</sup>.

Epidemiologic and linkage studies suggest that genetic factors play a significant role in determining CD susceptibility. CD has no simple Mendelian pattern of inheritance. As other immune diseases, CD is thought to be a heterogeneous, complex polygenic disease, where both genetic and environmental factors play an important role in the disease and, in which multiple interactions between susceptibility and resistance alleles are involved in disease pathogenesis<sup>[2,3]</sup>.

Human genetic studies, notably the landmark identification in 2001 of *NOD2/CARD15* within the linkage region IBD1, have confirmed a genetic influence on CD<sup>[4-6]</sup>, and it is now clear that a genotype-phenotype relationship exists. In our population of Spanish CD

patients from Madrid, mutations in the *NOD2/CARD15* gene were a marker of susceptibility to disease and were associated with ileal disease<sup>[7]</sup>.

In CD, the mucosal inflammation is associated with an exaggerated and prolonged immune response because of a dysregulated production and interaction of pro-inflammatory and anti-inflammatory cytokines and their receptors<sup>[8]</sup>. A variety of genes encoding various proteins involved in the immune regulation have been postulated as possible candidates for disease susceptibility, including, among others, cytokines as interleukin-10 (IL-10). IL-10 is a regulatory cytokine that has several functions, but one important role is to act as an inhibitor of development of Th1 cells, activated macrophages and their products interleukin-12 (IL-12), tumor necrosis factor (TNF) and interferon-gamma (IFN- $\gamma$ ). Even though it is usually considered an inhibitory cytokine, it also has stimulatory effects (e.g. stimulating B cell proliferation)<sup>[9]</sup>. Recently, we have also shown that IL-10 polymorphisms contribute to susceptibility to CD in our Spanish population. IL-10G14 microsatellite allele as well as -1082G allele (guanine at position -1082) were significantly increased in Crohn's disease patients. The combined presence of both alleles in one individual notably increased the risk to develop CD<sup>[10]</sup>.

Although the pathogenetic mechanisms mediated by *NOD2/CARD15* remain elusive, it has recently been shown that one of the mutations in the *NOD2/CARD15* gene results in defective release of IL-10 from blood mononuclear cells after stimulation with Toll-like receptor (TLR) 2 ligands and this could contribute to the overwhelming inflammation seen in CD<sup>[11]</sup>.

As IL-10 polymorphisms appear to confer a risk to develop CD in the Spanish population, the present study examined genotype-phenotype correlations in the disease process. Moreover, after stratifying the patients on the basis of the presence or absence of the well-established *NOD2/CARD15* mutations, we looked for susceptibility factors being present in one specific phenotypic subpopulations.

## MATERIALS AND METHODS

### Study population

We studied a cohort of 205 Caucasian unrelated consecutive patients with CD who were recruited in a Unit of Inflammatory Bowel Disease (IBD) from a single tertiary referral center in Madrid, Spain. Diagnosis of Crohn's disease was based on standard clinical, radiologic, endoscopic, and histologic criteria<sup>[12]</sup>. Phenotypic details were obtained by review of clinical charts and personal interview with the patients. The same clinical questionnaire was completed for each patient. This questionnaire included: date of birth, sex, familial IBD, age at diagnosis, follow-up interval, smoking habits, history of surgery (tonsillectomy, appendectomy), definitions of the Vienna classification for age at diagnosis (A1, < 40 years; A2,  $\geq$  40 years), disease location (L1, terminal ileum; L2, colon; L3, ileocolon; L4, upper gastrointestinal), behavior (B1, nonstricturing nonpenetrating; B2, stricturing; B3, penetrating), perianal disease (defined as the presence of perianal abscess, fistulas and/or ulceration), extraintestinal

clinical manifestations (articular and cutaneous), and previous treatment as an indication of severity of disease (surgical intervention, corticosteroids, immunosuppressant agents, infliximab). All patient data were recorded by a gastroenterologist from the Unit of IBD (J. L. M.) who was blind to the genotype status of each patient. The protocol was approved by the Ethics Committee of the Hospital Clínico San Carlos, Madrid, and all patients were included in the study after giving informed consent.

### Genotyping

**IL-10 polymorphisms:** IL-10G and IL-10R microsatellites were amplified using primers and conditions as previously described<sup>[13]</sup>. Blood samples were subsequently denatured and run on an ABI Prism 3100 automatic sequencer (Applied Biosystems, Foster City, CA, USA). Each sample included an internal size standard (HD400 ROX, Applied Biosystems) in order to achieve a highly consistent measure. The results were analyzed using GeneMapper v3.0 (Applied Biosystems).

As previously described<sup>[14]</sup>, a combined amplification of the IL-10G microsatellite and the -1082 and -819 SNPs was performed. Our typing method allowed us to construct haplotypes directly. SNPs at positions -1082, -819 and -592 only form three different haplotypes in our population<sup>[15,16]</sup>, namely, ACC, ATA and GCC. Based on this previous finding, we only typed the samples for the two first SNPs, as the information provided by the third one is redundant.

**NOD2/CARD15 polymorphisms:** SNP13 (Leu1007fsinsC) was genotyped using a TaqMan assay (Applied Biosystems, Foster City, CA, USA). Primers and probes used were as previously described<sup>[5,17]</sup> and PCR products were analysed on an ABI 7700 Sequence Detector (Applied Biosystems). SNP8 (Arg702Trp) (sense, 5'-CAT CTG AGA AGG CCC TGC TC(C/T)-3'; antisense, 5'-CAG ACA CCA GCG GGC ACA-3') and SNP12 (Gly908Arg) (sense, 5'-TTG GCC TTT TCA GAT TCT GG (G/C)-3'; antisense, 5'-CCC CTC GTC ACC CAC TCT G-3') were typed by allele-specific PCR. Detection of wild-type/mutant variants was assessed in an ABI 7700 Sequence Detector by an SYBRGreen assay. Previously sequenced samples were used as controls. In cases of doubt, samples were sequenced to confirm the result.

### Statistical analysis

The frequencies for the IL-10 polymorphisms and *NOD2/CARD15* mutations were estimated by counting gene and calculating sample proportions. Subsequently, Hardy Weinberg equilibrium for each of the polymorphisms was tested to check for Mendelian inheritance using  $\chi^2$  test with one degree of freedom. Carrier status was considered if any subject inherited at least one copy of the mutant allele 2. The association between IL-10 polymorphisms and phenotypic characteristics of CD was estimated by the relative risk (RR) with the 95% confidence interval (CI). Logistic regression analysis was performed to assess whether IL-10 polymorphisms were correlated with a particular clinical phenotype. The multiple logistic regression analysis was

**Table 1** Distribution of IL-10G14 microsatellite allele and -1082G allele stratified by NOD2/CARD15 status

Allele frequencies	At least one CARD15/NOD2 mutation positive <i>n</i> = 76 (%)	CARD15/NOD2 mutation negative <i>n</i> = 129 (%)	<i>P</i>

<sup>1</sup> -1082G allele in NOD2/CARD15 mutation positive patients: ileocolonic location ( $P=0.008$ ,  $RR=1.52$ , 95%  $CI=1.21-1.91$ ). <sup>2</sup> -1082G allele in NOD2/CARD15 mutation positive patients: infliximab ( $P=0.03$ ,  $RR=0.54$ , 95%  $CI=0.27-1$ )

adjusted for age (years). A two-tailed  $P$  value equal to or less than 0.05 was considered statistically significant. Statistical analysis was performed using the Statistical Package for the Social Sciences (SPSS) version 10.07 for Windows (SPSS Inc., Chicago, Ill. USA).

## RESULTS

The cohort of 205 patients with Crohn's disease consisted of 109 men and 96 women. The median age at diagnosis was 27 years (mean 31.6, range 8-80) with an interquartile range of 22-26 years. The median duration of follow-up was 11 years (mean 12.57, range 3-47) with an interquartile range of 7-16 years.

No statistically significant difference in IL-10G14 and -1082G or both allele frequencies was found between NOD2/CARD15 mutation positive and negative patients (Table 1).

The genotype-phenotype correlations are shown in Tables 2 and 3. No Vienna classifications of the disease, neither risk factors, clinical manifestations, or treatment modalities were associated with either IL-10G14 or -1082G alleles. A gene-dosage effect (IL-10G14 and -1082G alleles) on phenotypic characteristics was not observed (data

not shown).

When we examined the associated IL-10G14 and -1082G alleles in the NOD2/CARD15 mutation positive and negative patients separately, three new positive associations were found. With regard to Vienna classifications of the disease, ileocolonic disease was significantly associated with -1082G allele in the NOD2/CARD15 mutation positive patients ( $P=0.008$ , Table 2). On the other hand, relative to risk factors for Crohn disease, two significant associations of the IL-10G14 allele carriership and history of appendectomy ( $P=0.002$ ) and smoking habit at diagnosis ( $P=0.02$ ) in the NOD2/CARD15 mutation positive patients as compared with the negative patients were observed (Table 3). The multivariate analysis demonstrated that IL-10G14 allele was associated with history of appendectomy ( $P=0.001$ ,  $RR=2.15$ , 95%  $CI=1.1-4.30$ ) and with smoking habit at diagnosis ( $P=0.04$ ,  $RR=1.29$ , 95%  $CI=1.04-4.3$ ).

## DISCUSSION

In this study, we performed a genotype-phenotype correlation study in a cohort of 205 Caucasian patients with Crohn's disease from the community of Madrid

(central Spain) who had been followed-up for a mean of 12.57 years. The clinical diagnosis of Crohn's disease was confirmed by the criteria of Gasche *et al*<sup>[18]</sup>. Our results showed that a relation existed between disease location (ileocolon), risk factors for CD (appendectomy and smoking habit) and genetic heterogeneity in our population. This could suggest an epistatic interaction of both genes.

CD is an extensively heterogeneous disease. Epidemiologic and genetic data suggest that heterogeneity of CD may be genetically determined. Recently, Ahmad *et al*<sup>[19]</sup> have shown the importance of the *NOD2/CARD15* gene and the HLA region in determining clinical subgroups of CD. Similarly, in our CD population, we confirmed the association between *NOD2/CARD15* mutations and ileal disease and the strong association between DRB1\*0103 allele and colonic disease<sup>[17]</sup>. These studies may provide an initial basis for the construction of a molecular classification of CD<sup>[20]</sup>.

Location of disease is the variable that remains more stable during the course of the disease<sup>[21]</sup> and it showed a stronger association with mutations of the *NOD2/CARD15* gene in genotype-phenotype studies using the Vienna classification. In our population<sup>[7]</sup>, like others<sup>[19,22,23]</sup>, possession of an *NOD2/CARD15* variant was significantly associated with ileal disease. On the contrary, mutations of the *NOD2/CARD15* gene were exceptional in patients with solely colonic involvement<sup>[7]</sup>. In contrast to findings in the Norwegian and German populations<sup>[24]</sup> and similar to findings in the British population<sup>[19,25]</sup>, we could not find an

association between ileocolonic location and mutations of the *NOD2/CARD15* gene<sup>[7]</sup>. In contrast, this association has been found between the *NOD2/CARD15* variants and IL-10 -1082G carriers. This suggests the importance of classifying the patients according to the different genes implicated in the etiopathogenesis of CD and, therefore, of performing the molecular characterization of CD patients. Tagore *et al*<sup>[26]</sup> have shown that IL-10 production is associated with three biallelic polymorphisms within the promotor region of the IL-10. The allele -1082G is associated with higher IL-10 production in peripheral blood leukocytes. This different levels of IL-10 expression could explain the diverse phenotypic clinical behaviour of CD in specific genetic susceptibility background, like *NOD2/CARD15*.

No other factor is likely to contribute in isolation to the pathogenesis of CD. The modulation of the immune system either locally or systemically has an important role to play in the etiology and pathogenesis of this disease. The IL-10 gene has special interest for a candidate gene approach in CD. The biology of IL-10 is highly complex: a potent down-regulator of CD peripheral monocyte and intestinal lamina propria mononuclear cells activator *in vitro* and *in vivo*<sup>[27]</sup>. Both human IL-10 and murine IL-10 exert immunostimulatory effects by up-regulating MHC class II expression in B lymphocytes and inducing cytotoxic T-cell differentiation<sup>[28]</sup>. Due to the dual regulatory function of IL-10 itself, its gene is indeed an interesting susceptibility candidate and it would be worthwhile to know whether environment factors could modulate the IL-10 function.

The IL-10 gene knockout mouse spontaneously develops a chronic enterocolitis<sup>[29]</sup> and gene therapy using an adenovirus IL-10 construct is successful in preventing experimental colitis in rats<sup>[30]</sup>. Moreover, there have been preliminary reports of amelioration of clinical symptoms of CD following administration of human recombinant IL-10<sup>[27,31]</sup>.

Regarding the risk factors for CD, we found two significant associations between carriage of the IL-10G14 microsatellite allele in CARD15-positive patients and previous history of appendectomy and smoking habit at diagnosis. The interaction between genetics and smoking has been demonstrated in siblings from mixed-disease families, where some individuals develop CD and others in the same family develop ulcerative colitis. There is a strong positive relationship between smoking and CD and an equally strong negative relationship between smoking and ulcerative colitis<sup>[32]</sup>. Appendectomy provides a spectrum of protection against ulcerative colitis development and progression, whereas its role in CD remains unclear. Russel *et al.*<sup>[33]</sup> have also noted a positive association of CD and previous appendectomy, suggesting that, in some cases, appendectomy is a result of still undiagnosed CD. Recently, other retrospective study concluded the risk of CD after appendectomy was associated with an increased risk of CD dependent on the patient's sex, age, and the diagnosis at operation<sup>[34]</sup>. Future work should pursue to investigate the epidemiological relationships in CD, addressing a greater number of potentially important confounders, such as smoking, hygiene, and pathology of the appendix. And parallel with these clinical observations, new target could be defined by genetic and immunologic analysis to evaluate if appendicitis could be correlated with any particular genetic modification involved for patients with CD<sup>[35]</sup>.

In conclusion, our study has shown that in the Spanish population from Madrid, in CD patients carrying at least an *NOD2/CARD15* mutant, the -1082G allele might be associated with ileocolonic disease, and the IL-10G14 microsatellite allele might be associated with previous history of appendectomy and smoking habit at diagnosis. Identification of plausible factors that may interact with genes is a promising step toward understanding how sequence variation influences disease susceptibility.

## Abstract

**AIM:** To retrospectively evaluate the clinical relevance, perioperative risk factors, outcome of different pharmacological prophylaxis, and short-term prognostic value of atrial fibrillation (AF) after surgery for esophageal carcinoma.

**METHODS:** We retrospectively studied 63 patients with AF after surgery for esophageal carcinoma in comparison with 126 patients without AF after esophagectomy during the same time. Postoperative AF incidence was related to different clinical factors possibly involved in its occurrence and short-term survival.

**RESULTS:** A strong relationship was observed between AF and postoperative hypoxia, history of chronic obstructive pulmonary disease (COPD), postoperative thoracic-gastric dilatation, age older than 65 years, male sex and history of cardiac disease. No difference was observed between the two groups with regard to short-term mortality and length of hospital stay.

**CONCLUSIONS:** AF occurs more frequently after esophagectomy in aged and male patients. Other factors contributing to postoperative AF are history of COPD and cardiac disease, postoperative hypoxia and thoracic-gastric dilatation.

## INTRODUCTION

Atrial fibrillation (AF) is a frequently occurring arrhythmia after esophageal procedures. It has been suggested that AF may be generally related to a worse prognosis and a longer postoperative hospital stay<sup>[1]</sup>. Reports on the effectiveness of alternative strategies to control AF are contradictory<sup>[2,3]</sup>. Therefore identification of all high-risk populations will allow targeted use and hence more cost-effective and successful application of these methods can be achieved.

The purpose of the present study was to retrospectively evaluate the clinical relevance, perioperative risk factors, outcome of different pharmacological interventions, and short-term prognostic value of AF after surgery for esophageal carcinoma.

## MATERIALS AND METHODS

### Patients

From 1998 to the end of 2003, a total of 63 consecutive patients had AF after surgery for esophageal carcinoma in our institution. AF was defined as a sustained or repetitive electrocardiographically documented arrhythmia requiring antiarrhythmic therapy<sup>[4]</sup>. During the same time of surgery, 126 patients without postoperative AF after esophageal carcinoma resection were randomly chosen as the control group. A retrospective chart review was performed on all the patients with and without AF. Patients were identified by search of registry database and hospital medical records. Records were reviewed by two independent researchers to confirm the diagnosis of AF.

There were 63 AF patients, 55 males and 8 females with an average age of 64.7 (range, 51-83) years. The onset of AF occurred on the first postoperative day in 22 patients (34.9%), on the second postoperative day in 30 patients (47.6%), on the third postoperative day in 7 patients (11.1%), and on the fourth postoperative day, and later in 4 patients (6.4%). The control group consisted of 126 patients, 94 males, and 32 females with an average age of 57.2 (range, 32-79) years. Patients with a known history of atrial dysrhythmias or those receiving digoxin were excluded from analysis.

### Methods

Postoperative AF incidence was related to different pre-

**Table 1 Preoperative factors associated with postoperative AF (%)**

operative, intraoperative, and postoperative clinical factors possibly involved in its occurrence and short-term survival. The demographic data that were analyzed included patients' age, sex, history of cardiac disease, chronic obstructive pulmonary disease (COPD, defined as  $FEV_1 \leq 70\%$  predicted and  $FEV_1/FVC$  ratio  $\leq 70\%$  in pulmonary function tests), diabetes mellitus, and hypertension. Intraoperative and postoperative factors examined were surgical approach (via the left or the right thorax), site of anastomosis (at the neck, above or below the aortic arch), hypotension in operation (defined as systolic blood pressure lower than 6 kPa, persisting for more than 5 min), postoperative fever (defined as body temperature higher than  $38.5^\circ\text{C}$ , persisting for more than 3 d), hypoxia (defined as aortic blood oxygen saturation lower than 93%, persisting for more than 1 h before the onset of AF), thoracic-gastric dilatation before the onset of AF confirmed by chest X-ray, 30-d mortality rate and length of hospital stay.

### Statistical analysis

Statistical analysis was performed with the SPSS software version 10.0. Intergroup difference was determined using Student's *t* test and Fisher's exact test.  $\chi^2$  test was used to analyze categorical data. To identify which factors could predict AF, univariate, and stepwise multiple logistic regression analysis was used.  $P < 0.05$  was considered statistically significant.

## RESULTS

A higher incidence of AF was found in male patients older than 65 years, with a history of cardiac diseases and COPD than that in the control group patients (Table 1). There was no significant difference in patients with a history of hypertension and diabetes mellitus between the two groups. AF patients had a higher incidence of postoperative hypoxia and thoracic-gastric dilatation than the control group (Table 2). There was no significant difference in surgical approach, anastomosis site, intraoperative hypotension and postoperative fever between the two groups.

Results from the univariate analysis for the association of each factor with AF are summarized in Table 3. The factors associated with increased risk for AF on multivariate analysis included postoperative hypoxia, history of COPD, thoracic-gastric dilatation, age older than 65 years, male sex and history of cardiac disease. The incidence of AF was not dependent on the history of hypertension and diabetes mellitus, intraoperative hypotension, surgical approach, anastomosis site, and postoperative fever.

In the AF group, 15 patients who did not receive any antiarrhythmic drug therapy in the early stage of AF were given oxygen and sedation therapy. Only one of the 15 patients (6.67%) had sinus rhythm spontaneously within 24 h. All the other 62 patients were treated with antiarrhythmic drugs such as cedilanid, isoptin, propafenone and amiodarone. It was considered successful if the heart rhythm changed to sinus rhythm in 24 h after the treatment. Otherwise, other antiarrhythmic drugs were used. The outcome of antiarrhythmic therapy is presented in Table 4.

Death within 30 d after the surgery occurred in 2 AF patients with a mortality of 3.2% (2/63), and in 2 patients of the control group with a mortality of 1.6% (2/126) ( $P > 0.05$ ). The overall mortality in our patients was 2.1% (4/189). None of these deaths were directly attributed to AF. The average length of hospital stay was  $10.65 \pm 0.87$  d for the AF group and  $9.98 \pm 0.96$  d for the control group ( $P > 0.05$ ).

## DISCUSSION

AF after esophagectomy remains one of the most frequent complications. The cause for postoperative AF is unclear. However, previous studies have shown different results, sometimes contradictory with regard to the clinical significance of various factors for AF after esophagectomy<sup>[1,3]</sup>. We found that postoperative hypoxia, history of COPD, thoracic-gastric dilatation, age older than 65 years, male sex, and history of cardiac disease were predictors of postoperative AF. We considered that only clinically significant

**Table 3** Univariate analysis of risk factors for postoperative AF

Risk factors	P
Postoperative hypoxia	<0.001
COPD	0.001
Thoracic-gastric dilatation	0.009
Age more than 65 y	0.009
Male sex	0.017
History of heart disease	0.038
Postoperative fever	0.051
History of hypertension	0.062
Surgical approach	0.143
Anastomosis site	0.189
History of diabetes mellitus	0.412
Intraoperative hypotension	0.475

AF defined by electrocardiography had an association with hemodynamic changes. A possible limitation of our study is that continuous electrocardiographic monitoring was not employed to detect asymptomatic AF, as our study was designed to evaluate clinically significant AF, which was the focus of patients' complaints and needed therapeutic interventions. Our conclusions, therefore, do not apply to the occurrence of asymptomatic AF after the surgery for esophageal carcinoma.

We did not find differences in survival rate and length of hospital stay between patients who developed AF and those who did not in the early postoperative period. We found that some pharmacological interventions were effective for AF after esophagectomy, but symptomatic management without drug treatment was not effective, suggesting that AF, if treated promptly, is fairly tolerated in all the patients. The peak incidence of AF on the second day after surgery, with more than 80% of events occurring during the first three postoperative days, is consistent with the findings of a previous study<sup>[6]</sup>. We speculate that AF after esophagectomy is precipitated by the resolution of inflammatory response following blunt or sharp surgical trauma to sympathovagal nerve fibers supplying the heart for 1-4 d postoperatively, which alter the autonomic modulation of atrial myocardial cells to endogenous catecholamines.

The identification of reliable predictors of AF after esophagectomy may help us to develop corresponding preventive strategies. The presence of postoperative hypoxia and history of COPD were associated with the development of AF in our study. It has been well established that due to diminished cardiopulmonary reserve, patients with COPD and hypoxia are more prone to perioperative complications following noncardiac thoracic surgical procedures in general<sup>[7,8]</sup>. The definition of COPD might vary between different authors and our definition was based on the pulmonary function testing, and some authors' definition is based on the presence or absence of bronchodilator treatment<sup>[4]</sup>.

The association between postoperative thoracic-gastric dilatation and AF found in our analysis has not been previously demonstrated. We speculate that it may correlate with hypoxia, physical influence on the heart from the

**Table 4** Outcome of AF after drug treatment

Prophylaxis	Cases	Successful antiarrhythmic cases (%)
Cedilanid	51	18 (35.29)
Isoptin	17	2 (11.76)
Propafenone	21	11 (52.38)
Amiodarone	20	20 (100.00)

dilated stomach, and the uncomfortable feeling of patients for the thoracic-gastric dilatation. It is not surprising that advanced age is a strong predictor of postoperative AF, because at the age of 75, only approximately 10% of normal sinus node pacemaker cells remain<sup>[9]</sup>. It is well known that age-related cardiac structural changes, such as increased fibrous and adipose tissue in the sinoatrial node, and focal interstitial deposits of amyloid in the atria, and atrial dilations may play a significant role in the genesis of arrhythmia<sup>[10]</sup>. The age is closely related with AF<sup>[11]</sup>.

The association between male sex and AF might be explained by the effect of sex on immune response. One hypothesis for the cause of postoperative AF is atrial or pulmonary vein inflammation<sup>[12]</sup>. After trauma, male patients have an increased proinflammatory immune response compared to female patients<sup>[13]</sup>, and this might lead to increased AF after surgical trauma. The association of cardiac disease with AF has been demonstrated inconsistently by other investigators<sup>[14]</sup>. The common occurrence of AF after cardiac surgery supports the association of cardiac disease with AF after thoracic surgery. The lack of association between hypertension and AF in our analysis is also noteworthy. Other investigators have shown this association, but their analysis is limited to patients with lung cancer<sup>[15]</sup>.

In conclusion, AF is associated with postoperative hypoxia, history of COPD, thoracic-gastric dilatation, age older than 65 years, male sex, and history of cardiac disease. The identification of patients with a high risk for AF will allow more direct application of pharmacological and alternative methods of prophylaxis.

## Abstract

**AIM:** To generate dendritic cells (DCs) from human peripheral blood and to detect the expression of dendritic cell-specific intercellular adhesion molecule 3 grabbing nonintegrin (DC-SIGN; CD209) for the further study of DC-SIGN in hepatitis C virus (HCV) transmission.

**METHODS:** Peripheral blood monocytes were isolated from blood of healthy individuals by Ficoll-Hypaque sedimentation and cultured in complete medium containing rhGM-CSF and rhIL-4. Cells were cultured for seven days, with cytokine addition every two days to obtain immature DCs. Characteristics of the cultured cells were observed under light and scanning microscope, and the expression of DC-SIGN was detected by immunofluorescence staining.

**RESULTS:** After seven-day culture, a large number of cells with typical characteristics of DCs appeared. Their characteristics were observed under light and scanning electron microscope. These cells had a variety of cell shapes such as those of bipolar elongate cells, elaborate stellate cells and DCs. DC-SIGN was detected by immunofluorescence staining and its expression level on cultivated dendritic cells was high.

**CONCLUSION:** DCs with a high expression of DC-SIGN can be generated from human peripheral blood monocytes in complete medium containing rhGM-CSF and rhIL-4.

## INTRODUCTION

Dendritic cells (DCs) are professional antigen presenting cells (APCs) critically involved in the initiation of T cell-dependent immune responses as a consequence of their high expression of MHC and co-stimulatory molecules. However, it is becoming increasingly clear that some pathogens subvert DC functions to escape immune surveillance<sup>[1]</sup>. Many cell-surface molecules of DCs can bind to viral envelope glycoproteins without mediating entry. Instead, they serve as capture receptors that disseminate viral particles to target organs or susceptible cells. The C type lectin of DC-SIGN, one of the cell-surface molecules of DCs, functions as a capture receptor for several viruses, such as HIV type 1 (HIV-1)<sup>[2]</sup>, hepatitis C virus (HCV)<sup>[3]</sup> and dengue virus<sup>[4]</sup>. Therefore, further investigations of the function of DCs and the interactions between DC-SIGN and pathogens are helpful in determining their importance *in vivo*. In this study, we generated dendritic cells from peripheral blood mononuclear cells (PBMC) from normal donors and high DC-SIGN expression was detected on the surface of dendritic cells by immunofluorescence staining.

## MATERIALS AND METHODS

### Medium and reagents

RPMI1640 and fetal calf serum (FCS) were purchased from Gibco Laboratories (Grand Island, NY). FCS was heat-inactivated at 56°C for 30 min. Human recombinant IL-4(rhIL-4) and rhGM-CSF were from R&D Systems (Abingdon, UK) and used at 1000U/mL, respectively. Monoclonal anti-human DC-SIGN phycoerythrin (FAB161P) was also from R&D Systems. Bovine serum albumin (BSA) was from Huamei Co. Human peripheral

**Figure 1** Dendritic cells in liquid cultures of complete RPMI 1640 supplemented with FCS, rhGM-CSF and rhIL-4. **A:** Low-power view of adherent PBMC after 3 d of culture (original magnification $\times 200$ ). Red arrows indicate the cellular aggregates and black arrows indicate veil- or sheet-like processes of dendritic cells; **B:** Veil- or sheet-like processes of most cells after 7 d of culture (original magnification $\times 400$ ).

blood was obtained from healthy adult donors.

### Culture of DCs

Human peripheral blood mononuclear cells (PBMC) were isolated from buffy coat from normal donors by Ficoll-Hypaque density gradient centrifugation according to standard procedures. Monocytes were re-suspended in RPMI-10% FCS at  $1 \times 10^6$  cells/mL, and allowed to adhere to 6-well plates (Costar Corp., Cambridge, MA). After a 2h adherence step at 37 °C in complete medium, nonadherent cells were washed with PBS and the remaining adherent cells were immediately subjected to the DC differentiation protocol. Briefly, monocytes were re-suspended and cultured in RPMI 1640 supplemented with 10% FCS, 25 mmol/L HEPES, and 2 mmol/L glutamine (complete medium) containing 1000 U/mL rhGM-CSF and 1000 U/mL rhIL-4. Cells were cultured for seven days, with cytokine addition every two days to obtain DCs (before incubation, a piece of 12mm  $\times$  12mm sterile coverslip was put into one of the plates and used for scanning electronic microscopy)

### Morphological observation of cultured cells

Cells were observed under light microscope during incubation. After seven-day culture, the coverslip was covered with DCs and prefixed with a 2% glutaraldehyde solution for 1 h at 4 °C. Post-fixation was done with a 2% osmium tetroxide solution for 30 min at 4 °C. After each fixation, the samples were washed twice in PBS containing

**Figure 2** Cells cultivated with 10% FCS-RPMI 1640 supplemented with rhGM-CSF and rhIL-4 for 7 d (original magnification $\times 1500$ ).

BSA, dehydrated in graded ethanol and dried at “critical point” in liquid CO<sub>2</sub> under 95-bar pressure. Then, the coverslip was covered with gold by cathodic spraying. Finally, the samples were examined under scanning electron microscope (S-520, HITACHI).

### Immunofluorescence staining of DC-SIGN

Cells to be used for staining with antibody were Fc-blocked cells by treatment with 1 $\mu$ g of BSA/ $10^5$  cells for 15 min at room temperature, without washing the excess blocking BSA from this reaction. Then 25  $\mu$ L of the Fc-blocked cells ( $1 \times 10^5$  cells) was transferred to a 5 mL tube, and 10  $\mu$ L of PE-conjugated anti-DC-SIGN reagent was added. After incubated for 30-45 min at 4 °C in the dark, un-reacted anti-DC-SIGN reagent was removed by washing the cells twice in 4 mL of isotonic phosphate buffer supplemented with 0.5% BSA by centrifugation at 500 r/min for 5 min. The cell pellet was re-suspended in 100  $\mu$ L of PBS buffer and allowed to adhere to poly-L-lysine-coated coverslips for 30 min at 4 °C in darkness for final immunofluorescence. The representative fields of cells were photographed through an oil immersion lens on a Leica DM 6000B microscope (Leica Microsystems, Wetzlar, Germany).

## RESULTS

### Morphology of cultivated DCs

**Phase-contrast observation:** Three cellular aggregates were attached to a layer of adherent cells (Figure 1A). Some of the profiles in the aggregates had veil- or sheet-like processes of DCs. On d 7 of culture, these adherent

**Figure 3** Cells stained with monoclonal anti-human DC-SIGN phycoerythrin (original magnification×400).

cells emigrated from the clusters, came off the surface and many typical DCs were seen floating in the culture medium (Figure 1B).

**Scanning electron microscopy:** Further morphological observations were carried out under scanning electron microscope (SEM). These cells had a variety of cell shapes such as bipolar elongated cells, elaborate stellate cells and DCs. Most pseudopods were long and uniform in width with blunt terminations, but smaller spinous processes were also evident (Figure 2). This phenomenon indicated that DCs had a variety of branching forms, and constantly extended and retracted many fine cell processes. The adjective “dendritic” might be appropriate for this particular cell type (Figure 3).

#### Determination of DC-SIGN expression

The DC-SIGN expression was detected by immunofluorescence staining with monoclonal anti-human DC-SIGN phycoerythrin. Most of the cultured cell surfaces were stained red, exhibiting a high level of expression of DC-SIGN on the surface of DCs.

## DISCUSSION

In this study, we generated DCs from human PBMC with 10% FCS-RPMI 1640 supplemented with rhGM-CSF and rhIL-4. DC-SIGN expression was found on the surface of DCs.

DCs are specialized and co-stimulatory cells which play an important role in the induction of cellular immune response to antigens. DCs interact with pathogens using conserved pattern-recognition receptors, which recognize characteristic molecular arrangements within microbial carbohydrates, lipids and nucleic acids<sup>[5]</sup>. Receptors of this type include Toll-like receptors (TLRs)<sup>[6,7]</sup> and C-type lectins<sup>[8]</sup>. TLRs can transfer information about the interacting pathogens into DCs through intracellular signaling cascades, thereby eliciting appropriate cellular processes, such as DC maturation and induction of anti-inflammatory cytokines<sup>[5,6,9]</sup>. By contrast, C-type lectins recognize pathogens through their carbohydrate structure and internalize the pathogens for antigen processing and presentation<sup>[10,11]</sup>. Pathogens survive and evade the antimicrobial defense system of the host by subverting the

function of these pattern-recognition receptors. Hence, an understanding of the interaction of pathogens with these receptors is essential for the design of approaches to combat infections.

DC-SIGN is a type II membrane protein with a C-type lectin extracellular domain<sup>[12]</sup>. DC-SIGN plays an important role in establishing the initial contact between DCs and resting T lymphocytes through its recognition of ICAM-3, and mediates DC trafficking through interactions with endothelial ICAM-2<sup>[13]</sup>. Therefore, DC-SIGN appears to be a critical mediator of the migratory cell and T cell-interacting capabilities. It has been identified that DC-SIGN helps HIV-1 to subvert DC functions and infect the host.

Recently, it was found that DC-SIGN is also an HCV envelope binding receptor and the HCV envelope glycoprotein E2 can bind to DC-SIGN through high-mannose N-glycans<sup>[14]</sup>. It is becoming increasingly clear that other pathogens including cytomegalovirus (CMV), Ebola, SARS coronavirus, *Helicobacter pylori*, mycobacterium tuberculosis, *Leishmania*, *schistosoma mansoni*, etc, can subvert DC functions to escape immune surveillance<sup>[15]</sup>. Therefore, investigation of the mechanisms of DC-mediated T lymphocyte priming, tolerance, effector cell migration and function may be helpful in restricting HCV dissemination and infection.

### Abstract

**AIM:** To investigate the expression of co-stimulatory molecule B7-H3 in gastric carcinoma and adenoma tissue as well as normal gastric tissue and to explore the relationship between B7-H3 expression and pathological features and prognosis of gastric carcinoma.

**METHODS:** B7-H3 expression was detected in 102 samples of human gastric carcinoma and 10 samples of gastric adenoma and 10 samples of normal gastric tissue by immunohistochemical assay. Correlation between the expression of B7-H3 and the patients' age, sex, gastric carcinoma locus, tumor size, tissue type, tumor infiltration depth, differentiation degree, lymph node metastasis, and survival time was analyzed.

**RESULTS:** B7-H3 was expressed in all gastric adenoma samples and in 58.8% samples of gastric carcinoma. B7-H3 expression in gastric carcinoma samples was not related with the patients' age, sex, lymph node metastasis, and tumor size ( $P > 0.05$ ), but with the survival time, infiltration depth of tumor and tissue type.

**CONCLUSION:** Detection of B7-H3 expression in gastric carcinoma tissue is beneficial to the judgment of the prognosis of gastric carcinoma patients and the choice of treatment.

### INTRODUCTION

Tumor immune response is a very complicated physiological process involving many immune cells and molecules including membranous molecules and dissolubility factors. Studies indicate that a group of cell membrane molecules (co-stimulatory molecules) play a very important role in tumor immune response in the place of adjusted expression, interaction, and signal transmission. Co-stimulatory molecules are divided into two groups: TNF-TNF receptor superfamily and immunoglobulin superfamily. B7 family can transmit signals to co-stimulatory molecules of T cells<sup>[1]</sup>. B7RP-1 (B7H, B7-H2), B7-H1 (PD-L1), B7-DC (PD-L2) and B7-H3 have been found and make it more complex to adjust the effects of this family<sup>[2,3]</sup>. B7-H3 is a new co-stimulatory member of the B7 family and shares 20-27% identical amino acids with other members of the B7 family<sup>[4]</sup>. It was reported that B7-H3 could stimulate CD4+ and CD8+T cells to increase the activity of CTL<sup>[5]</sup>. B7-H3 is regarded as a positive regulation molecule. To our knowledge, expression of B7-H3 in gastric carcinoma has not been previously demonstrated.

### MATERIALS AND METHODS

#### Materials

From 1998 to 1999, 102 samples were collected from gastric cancer patients who had undergone surgery in our hospital. The tumor was located in the mucosa in 10 cases, in shallow muscularis in 20 cases and in deep muscularis in 72 cases. The tumors were classified into well-, moderately- and poorly-differentiated adenocarcinomas. None of the patients received chemotherapy or radiotherapy before the surgery. We also investigated 10 specimens from gastric adenoma patients who had undergone surgery between 1998 and 1999.

The study was approved by the ethics committee of our hospital and all patients gave their written informed consent prior to enrolment.

**Figure 1** Staining of B7-H3 in normal gastric tissue (A), gastric adenoma tissue (B), and gastric carcinoma tissue (C).

**Figure 2** Correlation between B7-H3 expression and death of gastric carcinoma patients.

#### Immunohistochemical staining and assessment

Labeling was carried out with Elivision™ plus kit. The samples were fixed in formalin, embedded with paraffin wax and cut into 3-μm-thick sections. The sections were dewaxed and rinsed and washed thrice with PBS (pH 7.4) for 3 min. The antigen of tissue was repaired and one drop or 50 μL of 3% hydrogen peroxidase solution was added to each section and incubated at room temperature for 10 min to eliminate endogenous peroxidase activity. The sections were washed thrice with PBS for 3 min again. PBS was discarded; one drop or 50 μL of primary antibody was added to each section and incubated at room temperature for 10 min or placed overnight at 40 °C. The sections were washed thrice with PBS for 5 min. PBS was discarded, one drop or 50 μL of polymer accentuator (reagent A) was added to each section and incubated at room temperature for 20 min. After being washed thrice with PBS for 3 min each time, PBS was discarded and one drop or 50 μL of enzyme-labeled anti-mouse/rabbit polymer (reagent B) was added to each section and incubated at room temperature for 30 min. The sections were washed thrice with PBS for 3 min each time. PBS was discarded; two drops or 100 μL of freshly prepared DBA coloration fluid was added to each section and examined under microscope for 3-10 min. All the samples were fixed in formalin, embedded with paraffin wax and cut into 3-μm-thick sections. The samples were assessed blindly by calculating the average ratio of positive cells in 10 vision fields (the plasma was stained brown-yellow) under a 400× microscope. If the average positive cell ratio was more than 20%, the sample was considered positive.

#### Statistical analysis

Difference between the groups was evaluated by  $\chi^2$  test

using SPSS version 10.0 for Windows and the relationship between the prognosis and various factors was evaluated by multivariable logistic regression. All *P* values were based on two-sided testing. *P* < 0.05 was considered statistically significant.

## RESULTS

#### B7-H3 expression in gastric cancer and adenoma

B7-H3 was positively expressed in cell membrane and cytoplasm of gastric cancer and adenoma cells (Figure 1). B7-H3 was expressed in all the 10 specimens of gastric adenoma tissue and in 58.8% samples of gastric cancer tissue.

#### Relationship between B7-H3 expression and age, sex, and prognosis of patients

B7-H3 expression in gastric carcinoma tissue was not related with the patients' age and sex (*P* > 0.05, Table 1). The association of B7-H3 expression with the survival time after surgery indicated that B7-H3 expression was related to the prognosis of patients (Figure 2). The positive rate (74.5%) of B7-H3 expression was higher in gastric cancer patients who survived more than 5 years than in those who survived less than 2 years (43.1%, *P* < 0.01).

#### Relationship between B7-H3 expression and pathological features of gastric cancer

B7-H3 expression was not related with lymph node metastasis, tumor location and size (*P* > 0.05), but with survival time, infiltration depth of tumor and histology type (Table 1).

#### Related factors of gastric cancer patients' survival time

Univariate analysis suggested that the infiltration depth of tumor, survival time of patients and histology type of gastric cancer were related to B7-H3 expression. After adjustment for these factors, gastric cancer patients with high intratumor B7-H3 expression could survive 2-fold longer than those with low intratumor B7-H3 expression (risk ratio = 2.803; 95%CI = 1.051-7.477; *P* = 0.040), suggesting that B7-H3 expression might be an independent factor affecting the survival time of gastric cancer patients.

## DISCUSSION

Human B7-H3 is also known as B7 relative protein 2 (B7RP-2) and its gene map on chromosome 15 is composed of seven exons and six introns. Mature B7-H3 protein has 316 amino acids and its molecular weight is 45-66 ku. It belongs to immunoglobulin superfamily and is a type I transmembrane protein composed of

**Table 1** Correlation between tumor B7-H3 expression and pathologic features of gastric carcinoma patients

Features	Total cases (n)	Positive cases (n)	Positive rate (%)
Tumor location			
Top 1/3 layer of stomach	31	19	61.2
Middle 1/3 layer of stomach	30	17	56.7

>5 cm	47	25	53.2

extracellular, transmembrane and intracellular regions. B7-H3 has been recently identified as a new co-stimulatory member of the B7 family and shares 20-27% identical amino acids with other members of the B7 family<sup>[4]</sup>. It is extensively expressed in non-lymphoid tissues including the heart, liver, prostate, placenta, testis, pancreas, small, and large intestine and also in some tumor cell lines such as G361, HeLa S3, K562, A546, and SW480. B7-H3 was expressed in all the 10 specimens of gastric adenoma tissue and in 58.8% samples of gastric cancer tissue. We also found that B7-H3 was highly expressed in some epithelial tumor cell lines such as M435, A549, and H01299. A recent study found that B7-H3 can stimulate CD4+ and CD8+ T cells to increase the activity of CTLs<sup>[5]</sup>. In addition, B7-H3 increases the secretion of IFN- $\gamma$  and can upregulate IL-8 and TNF- $\alpha$ . When B7-H3Ig is blocked by anti-B7-H3 multi-clone antibody, secretion of IFN- $\gamma$  by DCs can be downregulated, indicating that B7-H3 is a positive regulatory molecule.

Our study suggested that B7-H3 expression in gastric carcinoma tissue was not related with the age and sex of patients, lymph node metastasis and size of tumor but with the survival time of patients, infiltration depth and histology type of tumor. The positive rate (74.5%) of B7-H3 expression was higher in gastric cancer patients who survived more than 5 years than in those who survived less than 2 years (43.1%), suggesting that B7-H3 expression is an independent factor affecting the survival time of gastric cancer patients and that B7-H3 might act as a positive regulatory factor in tumor immunology.

Sun *et al.*<sup>[6]</sup> showed that intratumor injection of a mouse B7-H3 pcDNA3 expression plasmid leads to

complete regression of 50% tumors and can significantly inhibit tumor growth. Mice with their tumors completely regressed can resist a challenge with parental tumor cells. B7-H3-mediated anti-tumor immunity is mediated by CD8(+) T and NK cells, rather than CD4(+) T cells. These results indicate that B7-H3 interactions play a role in regulating cell-mediated immune responses against cancer.

However, Suh *et al.*<sup>[7]</sup> found that B7-H3 inhibits immune response by inhibiting type 1 [T(H)1] responses and production of IFN- $\gamma$ . A recent study showed that B7-H3 induces T cell proliferation and IFN- $\gamma$  production through non co-stimulatory pathways<sup>[8]</sup>, indicating that B7-H3 may have more than one receptor on activated T cells.

Because the known receptor of B7-H3 has not been found, its function in the immune response is not clear. B7-H3 is extensively expressed in peripheral tissues, suggesting that it may play an important role in inflammation and transplantation immune response. B7-H3 is highly expressed in epithelial tumor cell lines and positively related to the prognosis of gastric cancer patients, indicating that B7-H3-deficient expression in tumor tissues may be closely associated with tumor immune escape.

In conclusion, B7-H3 is related to the development of gastric cancer and acts as an independent index for the diagnosis and prognosis of gastric cancer. Further study is needed to explore the exact relationship between B7-H3 and gastric cancer.

### Abstract

**AIM:** To analyze 67 cases of splenic abscess in a medical center of Taiwan during a period of 19 years.

**METHODS:** From January 1986 to December 2004, a total of 67 patients with splenic abscess were enrolled for the retrospective study. The clinical characteristics, underlying diseases, organism spectra, therapeutic methods, APACHE II scores, and mortality rates were analyzed.

**RESULTS:** There were 41 males and 26 females with the mean age of  $54.1 \pm 14.1$  years. Multiple splenic abscesses (MSA) account for 28.4% and solitary splenic abscess in 71.6% of the patients. Twenty-six of sixty-seven patients (35.8%) had extrasplenic abscesses, with leading site of liver (34.6%). Microbiological cultures were positive in 58 patients (86.6%), with 71.8% in blood culture and 93.5% in abscess culture. Gram negative bacillus (GNB) infection predominated (55.2%), with leading pathogen of *Klebsiella pneumoniae* (22.4%), followed by gram positive coccus (GPC) infection (31%). Splenectomy was performed in 26 patients (38.8%), percutaneous drainage or aspiration in 21 (31.3%), and antibiotic therapy alone in 20 patients (29.9%). Eventually, 12 of 67 patients expired (17.9%). By statistics, spleen infected with GNB was likely to develop multiple abscesses compared with infection with GPC ( $P=0.036$ ). Patients with GNB infection ( $P=0.009$ ) and

multiple abscesses ( $P=0.011$ ) experienced a higher mortality rate than patients with GPC infection and solitary abscess. The mean APACHE II score of 12 expired patients ( $16.3 \pm 3.2$ ) was significantly higher than that of the 55 survivals ( $7.2 \pm 3.8$ ) ( $P<0.001$ ).

**CONCLUSION:** MSA, GNB infection, and high APACHE II scores are poor prognostic factors. Early surgical intervention should be encouraged when these risk factors are present.

### INTRODUCTION

Splenic abscess is a rare entity, with a reported frequency in autopsy series between 0.14% and 0.7%<sup>[1,2,3]</sup>. It remains a subject of case reports and of small institutional series. Large case numbers reviewed in a single institute was rare and difficult. However, reviews from different series of geographic localizations and populations might be obscure on pathologic features in local area. Further, splenic abscess often occurs in the patients with underlying diseases<sup>[4-8]</sup>. Patients with multiple splenic abscesses (MSA) or immunodeficiency are considered to have a poor prognosis and high mortality<sup>[4,5,9]</sup>. Many surgeons had reported that splenectomy is a better way for treatment of splenic abscess<sup>[3,5,8-10]</sup>. Recently, medical treatment and abscess drainage are proved to be efficient methods in the treatment of splenic abscess<sup>[11-14]</sup>. However, various conditions interfere with the prognosis of splenic abscess, such as underlying diseases, abscess number and size, organism spectra, therapeutic methods and general conditions. There is no single risk factor that can predict

the prognosis exactly till now. APACHE II score is a method to evaluate the general condition and to easily get the score from the patient's general data<sup>[15]</sup>. It has not been adopted in the evaluation of splenic abscess. To further elucidate the prognostic factors in splenic abscess, we have analyzed the various risk factors (including APACHE II score) of splenic abscess in a large series of 67 cases from a single medical center during a period of 19 years.

## MATERIALS AND METHODS

From January 1985 to December 2004, a total of 67 patients with splenic abscess were enrolled. The diagnosis of splenic abscess was made if one of the following criteria was met: (1) microbiologically documented abscess (blood or splenic aspirate) with compatible splenic imaging studies of computed tomography (CT) or ultrasonography (US); (2) Pathologic microscopic examination of the spleen on autopsy, resection or aspirate that revealed abscess formation; (3) Operative findings of splenic abscess on exploratory laparotomy; (4) In the presence of typical clinical manifestations and finding of CT or US, the patients' conditions regressed after antibiotic therapy in cases without interventional therapies (only three cases in this study). Patients with diseases progressing to death and sterile culture were excluded from this study. The demographic, clinical, and laboratory characteristics, underlying diseases, organism spectra, abscess number and size, therapeutic methods, patients' APACHE II scores, and mortality rates were collected and analyzed. The size of abscess is recorded as the largest diameter in either solitary or multiple abscesses. The APACHE II score was evaluated following the criteria of Knaus' report<sup>[15]</sup>. Age, chronic health problem score, Glasgow coma score, and 12 physiologic variables (vital signs, oxygenation, laboratory values; the most severely abnormal of each in the first 24 h of admission) were used to make a sum of scores<sup>[15]</sup>. All the survival cases had been followed clinically for more than 6 mo. Comparison between groups of independent samples was assessed by the Student's *t*-test, one-way ANOVA (*post hoc* multiple comparisons by Scheffe's procedure). The associations between categorical variables were assessed using the  $\chi^2$  or Fisher's exact test. A two-tailed  $P < 0.05$  was considered statistically significant.

## RESULTS

There were 41 males and 26 females with the mean age of  $54.1 \pm 14.1$  years (range 19-79 years). The mean age of males was  $51.9 \pm 13.6$  years, and that of the females was  $57.4 \pm 14.5$  years ( $P = 0.123$ ). Sizes of abscess ranged from 1.5 to 16 cm, with a mean of  $4.02 \pm 2.56$  cm.

The symptoms were fever in 57 patients (85.1%), left upper quadrant pain in 29 patients (43.3%), diffuse abdominal pain in 10 patients (14.9%), left chest wall pain in 3 patients (9%), and dyspnea in 5 patients (7.5%). Twenty five patients (37.3%) suffered from more than two symptoms at the time of diagnosis. The physical examination revealed splenomegaly in 34 patients (50.7%), left upper quadrant tenderness in 30 patients (44.7%), generalized abdominal tenderness in 9 patients (13.4%), left chest basilar rales in 6 patients (8.9%), and left chest basilar dullness in 5 patients (7.5%), leukocytosis over  $10\,000/\text{mm}^3$  in 47 patients (70.1%), and leucopenia in 3 patients (4.5%) (Table 1).

Among the 67 patients, 54 of them (80.6%) had predisposing underlying diseases. Diabetes mellitus (DM) was the leading disease (25 patients, 46.3%). Seven of 54 patients (12.9%) had more than two underlying diseases simultaneously (Table 2). Statistical analysis revealed that the presence of underlying disease did not correlate with any clinicopathologic parameter, including size of abscess, numbers of abscess, age, gender, species of microorganism, and mortality rates of patients.

Of the images of splenic abscess, 65 patients underwent chest roentgenogram study. Forty of sixty-five patients (61.5%) had abnormalities as left lower lung infiltration (13 cases, 20%) or left pleural effusion (27 cases, 41.5%). Further, 66 of 67 patients underwent abdominal US and/or abdominal CT studies, in which 46 patients received both US and CT, 9 patients received US alone, and 11 patients received CT alone. One who had a solitary splenic abscess (SSA) had no image study because of emergent operation for peritonitis. The sensitivity of US and CT was 98.18% and 98.24%, respectively. Splenomegaly was found by images in 45 patients (67.2%). There were MSA in 19 cases (28.4%) and SSA in 48 cases (71.6%) (Table 3). Gas formation in the abscess was found in only 8 patients (11.9%), mainly in patients with gram negative bacillus (GNB) infections (7 cases). In addition

DM, diabetes mellitus; MDS, myelodysplastic syndrome; SLE, systemic lupus erythematosus; CHF, congestive heart failure; AIDS, acquired immunodeficiency syndrome; ALL, acute lymphocytic leukemia; ESRD, end stage renal disease; COPD, chronic obstructive pulmonary disease. <sup>1</sup>Liver: 3; subphrenic area: 2; pancreas: 1; anus: 1; gluteal muscle: 1; retroperitoneal cavity: 1; brain+lung: 1. <sup>2</sup>brain: 2; aortic valve: 1; lung: 1. <sup>3</sup>pancreas: 2. <sup>4</sup>gluteal muscle: 1. <sup>5</sup>liver: 2. <sup>6</sup>subphrenic area: 1. <sup>7</sup>liver: 1. <sup>8</sup>liver: 2; brain+lung: 1; retroperitoneal cavity: 1; subphrenic area: 1.

to spleen, 26 of 67 patients (35.8%) had extrasplenic abscesses, with leading site of liver (Table 4). Among them two patients showed two sites of extrasplenic abscesses in the lung and brain. By statistics, we found that MSA tended to develop in non-diabetic patients ( $P=0.053$ ), and in abscess with GNB infection ( $P=0.036$ , Tables 2 and 3). Furthermore, MSA patients experienced a higher mortality rate than SSA patients ( $P=0.011$ , Table 5). Seven of nineteen (36.8%) MSA patients, in contrast to 5 of 48 (10.4%) SSA patients expired eventually. *Klebsiella pneumoniae* (*K. pneumoniae*) (70%) and staphylococcus aureus (60%) were most common pathogens to develop extrasplenic abscess (Table 3). However, statistical analysis revealed no significant correlation between the presence of extrasplenic abscess and any clinicopathologic factor.

Bacteriologic studies revealed that positive microbiological cultures were found in 58 patients (86.6%), and sterile in the other 9 patients (Table 3). Blood culture was positive in 46 of 64 patients (71.8%), and abscess culture in 43 of 46 patients (93.5%). Twenty-eight of thirty patients who had both positive blood and abscess cultures revealed identical pathogens. The microorganisms of 58 cases of positive culture were predominantly GNB (32 cases, 55.2%), with *K. pneumoniae* as the leading pathogen

<sup>1</sup>Brain: 1; liver: 1. <sup>2</sup>lung: 1; retroperitoneum: 1; brain: 1. <sup>3</sup>retroperitoneum: 1. <sup>4</sup>liver: 1; subphrenic area: 1; gluteal muscle: 1; pancreas: 1. <sup>5</sup>liver: 4; brain+lung: 2; subphrenic area: 1. <sup>6</sup>anus: 1. <sup>7</sup>aortic valve: 1; subphrenic area: 1. <sup>8</sup>subphrenic area: 1. <sup>9</sup>gluteal muscle (1). <sup>10</sup>pancreas: 1. <sup>11</sup>liver: 1. <sup>12</sup>liver: 1. <sup>13</sup>pancreas: 1.

(22.4%, Table 3). Statistical analysis revealed that abscesses with GNB were likely to develop multiple focus compared with abscesses with gram positive coccus (GPC) ( $P=0.036$ ). There were 11 MSA in 32 patients (34.4%) with GNB. In contrast, only one of the 18 patients (5.6%) with GPC had MSA. Furthermore, patients with GNB infection also experienced a higher mortality rate than patients with GPC ( $P=0.009$ ). Ten of 32 GNB (31.2%) patients, in contrast to none of 18 (0%) GPC patients expired eventually (Table 5).

In the treatment of splenic abscess, all patients received antibiotic therapy. Splenectomy was performed in 26 patients (38.8%), percutaneous drainage or aspiration in 21 (31.3%), and antibiotic therapy alone in 20 patients (29.9%). Eventually, 12 patients expired (17.9%) at the end of follow-up. Three patients with percutaneous drainage or aspiration initially were finally referred for splenectomy, and all of them survived. Two mortality patients who underwent splenectomy died of predisposing factors as extensive pancreatitis and severe abdominal trauma rather than splenic abscess itself. The mortality rate was 7.7% in patients treated with splenectomy, 28.6% in patients with percutaneous drainage or aspiration, and 20% in patients with antibiotic therapy alone. There was no difference of

<sup>1</sup>Twenty-six patients had single, and two patients had two sites of extrasplenic abscesses (lung+brain).

mortality rate between the groups (Table 5). But marginally better outcome was found in patients with splenectomy than patients with percutaneous drainage or aspiration ( $P=0.06$ ).

For analysis of patients' outcome, we first applied the APACHE II score for further correlation study. The twelve expired patients had high APACHE II scores over 15 except one. The mean score of 12 expired patients ( $16.1 \pm 3.2$ ) was significantly higher than that of the 55 survivals ( $7.3 \pm 3.8$ ) ( $P<0.001$ ). It was also found that higher scores presented in fatal cases of each category, regardless of underlying disease, abscess number and size, organism spectrum, and different therapeutic methods (data not shown). To summarize our results, we found that patients with multiple splenic abscesses, GNB infection had a higher mortality rate than patients with solitary splenic abscess and GPC infection. Mortality patients also had a higher mean APACHE II score than survival patients (Table 5).

## DISCUSSION

Reports on splenic abscess between 1900 and 1977<sup>[16]</sup>, between 1977 and 1986<sup>[4]</sup>, and between 1987 and 1995<sup>[17]</sup> showed a great variety of causative pathogens with a wide range of demographic and clinical conditions. Reviews of large series of patients with splenic abscess are capable of shedding light on the pathogenesis and clinical characteristics of splenic abscess<sup>[4,16,17]</sup>. Reviews from different geographic localizations and populations might obscure some specific pathologic features in the local area. Therefore, our large series review in single medical center might provide a further insight of the pathogenesis of splenic abscess in Taiwan.

Our patients experienced an older age, and higher percentage of splenomegaly and more left lung change (infiltration or pleural effusion) than that reported by other studies<sup>[4,16,17]</sup> (Table 1). These might be attributed to extensive studies by images. US and CT may help to detect small amount of pleural effusion which is subtle in CXR. Further, US and CT are also more sensitive to demonstrate splenomegaly than physical examination did. With a reported sensitivity of 96%, CT was considered to be superior to US (sensitivity 75-90%) for detecting splenic

abscess<sup>[12,17]</sup>. However, we found that the sensitivity of both CT and US in this study was equal and extremely high (98%). Therefore, US is an easy diagnostic and therapeutic tool for splenic abscess<sup>[18]</sup>.

The cause of splenic infection has been most often a metastatic infection or contiguous distant infection<sup>[4,16,17]</sup>. Recently, changing lifestyles resulted in an increasing prevalence of DM, malignancies, and immunosuppression becomes advanced therapeutic methods. These conditions constitute the increasing predisposing risk for the development of splenic abscess. Underlying diseases such as DM, endocarditis, and other diseases were reported not to be a good predictor for prognosis before. However, immunodeficiency is considered to be a poor prognostic factor and caused a high mortality<sup>[7-8]</sup>. In our series, the most common predisposing factors were still metastatic or contiguous infections. But 10 patients had immunodeficiency disorders (acquired immunodeficiency disease, myelodysplastic syndrome, systemic lupus erythematosus, acute lymphocytic leukemia, malignancies after chemotherapy, and aplastic anemia), and six of ten patients suffered from MSA and expired. Based on the limited case numbers, we cannot arrive at any conclusion about the prognostic role of immunodeficiency disorder.

But actually, we have found many mortality patients with severe illness (due to immunodeficiency) during the initial patients search for this study. They were excluded from this study mostly because of progression of disease to death with uncertain microbiological information. In these patients, multiple microabscesses were hard to be differentiated from micrometastatic or infarction lesions. Therefore, the real incidence of splenic abscess and the percentages of immunodeficient risk might be underestimated.

In contrast to previous reports (*Streptococcus* and *Staphylococcus* species predominant)<sup>[3,4,7,8,10]</sup>, our series revealed GNB were the leading pathogens causing splenic abscess (55.2%). Among GNB, *K. pneumoniae* was the most frequently encountered pathogen (22.4%). It has been reported to be the most common pathogen of liver abscess in Taiwan<sup>[19]</sup>. Further, metastatic splenic infections from liver abscesses caused by *K. pneumoniae* were rare<sup>[19]</sup>. Primary splenic abscess due to *K. pneumoniae* has also been rarely addressed before. In the present study, we have found that extrasplenic abscesses existed in 26 of 67 patients (38.8%), with leading site of liver in 9 (34.6%). Among the 9 liver abscesses, *K. pneumoniae* accounted for 44% of pathogens. We wonder whether it was a sequela of metastatic infection from liver to spleen or a co-infection of both. Nevertheless, these results indicated the significant role of GNB infection in splenic abscess. By statistics, we found that patients with GNB infection were prone to develop multiple splenic abscess ( $P=0.036$ ) and had a higher mortality rate ( $P=0.009$ ) than patients with GPC did. It is a novel finding which was never reported.

In this series, the treatment was carried out by antibiotic therapy alone, percutaneous splenic aspiration and/or drainage, or surgical methods. The mortality rate in patients receiving antibiotic therapy alone or percutaneous splenic drainage was marginally higher than that undergoing splenectomy. This result came from (1) the patient number in each different treatment group was still small, and (2) surgical treatment was not performed in some patients, if patient's condition was too ill to tolerate an operation. Based on these, the prognosis of our patients cannot be predicted by treatment methods exactly. In fact, even the previous inferences were mostly derived from comparison of patients in different series because of the rarity of disease<sup>[5,16,17]</sup>. There is a lack of a prospective cohort study to demonstrate which therapy is superior to others. To overcome this, we first adopted APACHE II score to predict the patients' outcome. The fatal patients had higher APACHE II score ( $16.1 \pm 3.2$ ) than the survivals ( $7.3 \pm 3.8$ ) ( $P < 0.001$ ). It was also found that higher scores presented in fatal cases of each category, regardless of underlying disease, abscess number and size, organism spectrum, and different therapeutic methods. Among the nine expired patients, eight had a score of over 15. Therefore, we thought that a score over 15 was a risk point for splenic abscess, the sensitivity, specificity, positive

predict value, and negative predict value would be 89%, 94%, 80%, and 97%, respectively.

In conclusion, we have obtained a novel finding of GNB serving as a leading pathogen in splenic abscess and provided evidence that multiple splenic abscesses, GNB infection, and high APACHE II scores are poor prognostic factors. Aggressive and early surgical intervention of splenic abscess should be encouraged when these risk factors are present.

## Abstract

**AIM:** To study the activity of telomerase and the expression of human telomerase reverse transcriptase (hTERT) in colorectal carcinoma and its adjacent tissues, normal mucosa and adenomatoid polyp, and to evaluate their relation with carcinogenesis and progression of colorectal carcinoma.

**METHODS:** Telomerase activity and hTERT expression were determined in 30 samples of colorectal carcinoma and its adjacent tissues, normal mucosa and 20 samples of adenomatoid polyp by modified telomeric repeat amplification protocol (TRAP), enzyme-linked immunosorbent assay (ELISA) and immunohistochemical method.

**RESULTS:** Telomerase activity and hTERT expression were 83.33% (25/30) and 76.67% (23/30) respectively in colorectal carcinoma, which were obviously higher than those in paracancerous tissues (13.33%, 16.67%), normal mucosa (3.33%, 3.33%) and adenomatoid polyp (10%, 10%). There was a significant difference between colorectal carcinoma and other tissues ( $P=0.027$ ). The telomerase activity and hTERT expression were higher in colorectal carcinoma with lymphatic metastasis than in that without lymphatic metastasis ( $P=0.034$ ). When the histological classification and clinical stage were greater, the telomerase activity and hTERT expression increased, but there was no significant difference between them. In colorectal carcinoma, the telomerase activity was correlated with hTERT expression (positive vs negative

## INTRODUCTION

Colorectal carcinoma is one of the most common malignant tumors in digestive system, threatening human life and health. Recent investigations demonstrated that the telomerase activity is significantly increased in human malignant tumors, but is not expressed in normal somatic cells<sup>[1,2]</sup>, suggesting there is a close relation between telomerase activity and malignant tumors. In order to study the role of telomerase activity in the carcinogenesis and progression of colorectal carcinoma as well as the correlation between telomerase activity and hTERT expression, the telomerase activity and hTERT expression were determined in colorectal carcinoma and its adjacent tissues, normal mucosa and adenomatoid polyp in this study.

## MATERIALS AND METHODS

### Patients and specimens

Thirty specimens of colorectal carcinoma and corresponding paracancerous tissues and normal mucosa were obtained by surgical resection, 20 specimens of adenomatoid polyp were taken during endoscopic examination. All patients were diagnosed pathologically and no patient received radiotherapy or chemotherapy before the sampling. Clinical staging showed Dukes' A in none, Dukes' B in 2 cases, Dukes' C in 24 cases, and Dukes' D in 4 cases. Well-differentiated adenocarcinoma

**Table 1** Telomerase activity and hTERT expression in four different groups

Group	<i>n</i>	Telomerase <i>n</i> (%)	hTERT <i>n</i> (%)
Colorectal carcinoma	30	25 (83.33) <sup>a</sup>	23 (76.67) <sup>a</sup>
Adjacent peritumoral tissues	30	4 (13.33)	5 (16.67)
Adenomatoid polyp	20	2 (10.00)	2 (10.00)
Normal mucosa	30	1 (3.33)	1 (3.33)

<sup>a</sup> $P < 0.05$  ( $\chi^2 = 59.58$ ,  $\chi^2 = 49.23$ ) vs adjacent peritumoral tissues, adenomatoid polyp and normal mucosa.

**Table 2** Relation between telomerase activity and hTERT expression and clinical pathologic factors of colorectal carcinoma

Group	<i>n</i>	Telomerase (%)	hTERT (%)
Dukes' A	0	0	0
Dukes' B	2	1/2 <sup>a</sup>	1/2 <sup>a</sup>
Dukes' C	24	83.33 (20/24)	83.33 (20/24)
Dukes' D	4	4/4 <sup>a</sup>	2/4 <sup>a</sup>
High differentiation	5	2/5 <sup>a</sup>	3/5 <sup>a</sup>
Moderate differentiation	8	6/8 <sup>a</sup>	5/8 <sup>a</sup>
Poor differentiation	17	100.00 (17/17)	88.24 (15/17)
With lymphatic metastasis	10	80.00 (8/10) <sup>b</sup>	70.00 (7/10) <sup>b</sup>
Without lymphatic metastasis	20	0.00 (0/20)	5.00 (1/20)

<sup>a</sup>indicates cases less than 10 not included in the percentage; <sup>b</sup> $P < 0.01$  vs the group without lymphatic metastasis

was found in 5 cases, moderately-differentiated adenocarcinoma in 8 cases and poorly-differentiated adenocarcinoma in 17 cases. Ten patients had lymph node involvement and 20 had no lymph node involvement. Of the patients with adenomatoid polyp, two had accompanying moderate-severe atypical hyperplasia. Specimens were collected within 30 minutes *in vitro*. Each specimen was divided into two parts, one for pathological diagnosis and immunohistochemical staining and the other for telomerase activity assay.

#### TRAP PCR ELISA protocol for telomerase activity assay

Telomerase activity was detected with a kit (Roche, Germany). Primers TS (5' AATCCGTCGAGCAGAGTT) and CX (5' CCCTTACCCTTACCCTTACCCTAA) were designed. Thirty cycles of PCR were performed at 25 °C for 30 min, at 94 °C for 5 min, at 94 °C for 30s, at 50 °C for 30s, at 72 °C for 90s, and a final extension at 72 °C for 10 min. The PCR products were analyzed and defined positive when  $A > 0.2$  on the reading of the microplate reader.

#### hTERT expression detection by immunohistochemical staining

Expression of hTERT was detected by immunohistochemical assay with the kit provided by Beijing Zhongshan Golden Biotechnology Co. Ltd according to the manufacturer's instructions. S-P method was adopted and positive calls were calculated and compared according to the accessory tester of the product. A negative control was prepared for each sample using

**Table 3** Correlation between telomerase activity and hTERT expression

Telomerase	hTERT			
	<i>n</i>	+	-	<i>P</i>
+	25	20	5	<0.05
--	5	3	2	

PBS as the primary antibody. Microscopically, no staining was negative, karyon and perikaryon cytoplasm with brown granules were defined as positive cells.

#### Statistical analysis

Statistical analyses were carried out with PEMS statistical-software. Chi-square test or Fisher's exact test was used for data processing.  $P < 0.05$  was considered statistically significant.

## RESULTS

#### Telomerase activity and hTERT expression in colorectal carcinoma and its adjacent tissues, normal mucosa and adenomatoid polyp

The high telomerase activity and hTERT expression were found in 25 (83.33%) and 23 (76.67%) out of the 30 specimens of colorectal carcinoma, but in only 4 (13.33%) and 5 (16.67%) specimens of adjacent peritumor tissues, in 1 (3.33%) and 1 (3.33%) specimens of normal mucosa, in 2 (10.00%) and 2 (10.00%) out of the 20 specimens of adenomatoid polyp (Table 1).

#### Relation between telomerase activities and hTERT expression and clinical pathologic factors of colorectal carcinoma

The telomerase activity and hTERT expression had a close relation with lymphatic metastasis, and the positive expression rate in the patients with lymphatic metastasis was significantly higher than that in the patients without lymphatic metastasis ( $P < 0.05$ ). The telomerase activity and hTERT expression increased when the histological grade and clinical staging were greater, but the difference was of no statistical significance ( $P > 0.05$ , Table 2).

#### Relation between telomerase activity and hTERT expression

The expression coincidence rate of telomerase activity and hTERT expression in colorectal carcinoma and its adjacent tissues, normal mucosa and adenomatoid polyp was 92% (23/25), 80% (4/5), 100% (1/1), 100% (2/2) respectively. The total coincidence rate of telomerase activity and hTERT expression was 90.91% (30/33). Of the 30 cases of colorectal carcinoma, 20 cases had positive expression in telomerase activity and hTERT expression, 2 showed no telomerase activity and hTERT expression. The conformity rate was 73.33% (22/30) ( $P < 0.05$ , Table 3).

## DISCUSSION

Telomerase is a ribonucleoprotein complex (a cellular

reverse transcriptase) consisting of three components: human telomerase RNA (hTR), telomerase-associated protein 1 (TP1/TLP) and human telomerase reverse transcriptase (hTERT). The first two components are expressed constitutively in both normal and tumor tissues and their expression levels are not correlated with the telomerase activity, whereas hTERT expression is closely correlated with telomerase activity in cells and tissues. Telomerase uses its internal RNA component as a template to synthesize telomeric DNA (TTAGGG)<sub>n</sub>, participating in the maintenance of telomere length and immortalization of cells<sup>[3]</sup>. Shay *et al*<sup>[4]</sup> reported that the total positive rate of telomerase activity was 85% in more than 20 malignant tumors and merely 9% in adjacent peritumor tissues and normal tissues, suggesting that telomerase activity is closely associated with malignancies. Our study showed that the telomerase activity and hTERT expression in colorectal carcinoma (83.33% and 76.67% respectively) were much higher than those in adjacent peritumoral tissues, normal mucosa and adenomatoid polyp. The telomerase activity and hTERT expression were positive in 2 cases of adenomatoid polyp with a diameter >2 cm, suggesting that telomerase activity may be an important index of canceration. This result is consistent with the findings of Tang *et al*<sup>[5]</sup>. The telomerase activity was higher in colorectal carcinoma with lymphatic metastasis than in that without lymphatic metastasis ( $P < 0.01$ ), indicating that the level of telomerase activity is closely related with lymphatic metastasis. The increased telomerase activity was in accord with the histological grade and staging of tumor, suggesting that telomerase activity plays a key role in the occurrence and development of colorectal carcinoma, and can be used as a marker for the early diagnosis and prognostic estimation of colorectal carcinoma.

hTERT is a telomerase reverse transcriptase isoform which is highly expressed in cell lines of positive telomerase<sup>[4]</sup>. hTERT transcription translated with hTR is indicative of telomerase activity *in vitro*. The activity of telomerase decreases or even disappears if the amino acid in hTERT is changed, whereas introduction of hTERT into normal cells activates the telomerase and prolongs cell life span while the karyotype and phenotype of cells remain normal<sup>[6-9]</sup>. In our study, the expression of hTERT was closely associated with telomerase activity, the coincidence rate of telomerase activity and hTERT

expression was as high as 90.91% (30/33), suggesting that telomerase activity is related with hTERT expression. The results support the opinion that hTERT is an important rate-limiting determinant of telomerase activity and the expression level of hTERT is directly associated with the telomerase activity. Since hTERT test can be conducted in paraffin- embedded tissues, more samples are available for telomerase activity test and hTERT may be used as a new tumor marker.

In conclusion, telomerase activity and hTERT expression in colorectal carcinoma are closely related. hTERT may play an important role both in the activation of telomerase and in the formation and development of colorectal carcinoma. hTERT can be used as a new marker for the early diagnosis of colorectal carcinoma.

pharynx, which was remarkably higher ( $P=0.042$ ) than that in the patients without stomach ailment history (1 case, which was 2.9%).

**CONCLUSION:** *H. pylori* may not be detected in the pharynx of healthy people. Chronic pharyngitis may be related to *H. pylori* infection. The infection rate with *H. pylori* in the pharynx is higher in patients with stomach ailment histories than in patients without stomach ailment histories, suggesting that chronic pharyngitis may be related to stomach ailment history.

### **Abstract**

**AIM:** To detect whether there is *Helicobacter pylori* (*H. pylori*) colonization in the pharynx mucous membrane of healthy people and whether chronic pharyngitis is related to *H. pylori* infection.

**METHODS:** Fifty cases of chronic pharyngitis refractory over three months were prospectively studied from March 2004 to August 2004 in the otolaryngology outpatient department of the Second Hospital of Xi'an Jiaotong University. Template-directed dye-terminator incorporated with fluorescence polarization detection (TDI-FP) and modified Giemsa stain were used to examine pharynx mucous membrane tissue for *H. pylori* colonization in the patients with chronic pharyngitis and the healthy people as a control group.

**RESULTS:** In the control group, no people were detected to have *H. pylori* in the pharynx. In contrast, in 50 cases with chronic pharyngitis, 19 (38.0%) cases were *H. pylori* positive with a TDI-FP assay and 4 (8%) cases were TDI-FP positive with Giemsa staining in the pharynx. Sixteen of the 50 pharyngitis cases had stomach ailment history, 11 cases (68.8%) of these 16 patients were determined to be *H. pylori* positive in the pharynx with the TDI-FP assay.  $\chi^2$  test showed that this infection rate was remarkably higher ( $P=0.0007$ ) than that in the cases without stomach ailment history. Giemsa staining showed that 3 cases (18.8%) of the patients with stomach ailment history were infected with *H. pylori* in the

### **INTRODUCTION**

Chronic pharyngitis is a common disease in the otolaryngology clinic. Pharyngitis, bronchitis, and pneumonia represent the most common respiratory tract infections. Upper respiratory tract infections are common and important. These include sinusitis, otitis media, and pharyngitis/tonsillitis. Many patients visiting an office-based physician report "sore throat, foreign-body sensation in the throat" as their primary reason for the visit<sup>[1]</sup>. Acute pharyngitis may be caused by a wide variety of microbial agents, but some of the most common and potentially dangerous microorganisms are group A beta-hemolytic streptococci (GABHS). For example, streptococcal pharyngitis is responsible for about 5% to 17% of sore throats in adults. However, the causative microorganisms in many cases remain unclear<sup>[2]</sup>. An important risk factor for chronic pharyngitis is gastroesophageal reflux disease (GERD). GERD is a common disorder in the Western population and is also common in Xi'an's adult population. The etiology and pathogenesis of GERD are probably associated with other conditions that are also risk factors

for chronic pharyngitis, including functional dyspepsia (FD), irritable bowel syndrome (IBS), and some respiratory and laryngopharyngeal diseases<sup>[3]</sup>.

The Gram-negative bacterium *Helicobacter pylori* (*H. pylori*) is associated with severe gastric pathologies, including peptic ulcers, chronic active gastritis and gastric cancer. This microorganism is able to invade and colonize in the human stomach, gastric juice, saliva, and faeces of patients<sup>[4-6]</sup>. Moreover, as relates to the current study, investigations using the CLO (Campylobacter-like organism) test and PCR showed that there was a high rate of *H. pylori* colonization in tonsil and adenoid tissues<sup>[7,8]</sup>, however, another investigation indicated the opposite result<sup>[9]</sup>. Therefore, we sought to detect whether there was *H. pylori* colonization in the pharynx in healthy people, as compared to patients suffering from chronic pharyngitis. We used two methods to detect *H. pylori* infection in the pharynx: template-directed dye-terminator incorporated with fluorescence polarization detection (TDI-FP) and modified Giemsa stain. From this study, it can be determined more definitively whether there is a relationship between *H. pylori* infection of the pharynx and chronic pharyngitis; moreover, it can be determined if a history of certain gastric diseases may contribute to this infection.

## MATERIALS AND METHODS

### Patients

Two groups were studied, a group with chronic pharyngitis and a control group without chronic pharyngitis. The group with chronic pharyngitis consisted of 50 cases of chronic pharyngitis refractory over three months that were studied from March, 2004 to August, 2004 in the otolaryngology outpatient department. Among them, 32 cases were females and 18 cases were males, with ages ranging from 23 to 52 years old. The shortest disease history was 3 mo and the longest was 8 years. Major symptoms included foreign body sensation, dry sensation, angina in the pharynx, nausea, cough and belching. Clinical examination showed congestion in the pharynx mucosa, lymph follicle hyperplasia, and slightly swollen tonsils. Of these 50 cases, there were 34 cases with no specific stomach ailment history and 16 cases with gastric ulcers or chronic active gastritis. There were 20 cases in the control group. Of these, 12 cases were females and 8 cases were males. Ages ranged from 20-51 years old. The people in the control group had no specific pharyngitis or stomach ailment history, such as gastric ulcer or chronic active gastritis. In addition, all the people in the above two groups (1) had no other system diseases; (2) had no antibiotics treatment 10 d before examination; and (3) had no clear history of metronidazole, amoxicillin or tetracycline treatment. To collect tissue from the pharynx of each patient, the surface of the pharynx mucous membrane was sprayed with 20 g/L amethocaine for anaesthesia. Epithelial tissue in the pharynx was then collected with a sterilized curette. The protocol was approved by the Institutional Human Subject Committee at Xi'an Jiaotong University.

### Methods

The biopsied epithelial tissue from the pharynx of each patient was routinely fixed in 4 g/L formaldehyde and embedded in paraffin wax. Histological sections were stained with routine modified Giemsa.

Fluorescence Polarization-Capable Instrument-Victor, AmpliTaq DNA Polymerase, shrimp alkaline phosphatase, *E. coli* exonuclease I, mixtures of TAMRA-ddTTP and RP110-ddGTP were purchased from PerkinElmer. The pGEM-T-Easy Vector System TA Cloning Kit was purchased from Promega. The ABI 377 and BigDye Terminator Cycle Sequencing Kit were purchased from Applied Biosystem(s). All reactions were run and read in 96-well black-skirted plates purchased from MJ Research. The specific probes and terminators of *H. pylori* were designed by DNA Star based on a specific target sequence. All probes were synthesized by Sbsbio (Beijing, China).

Scrapes or biopsies were collected and washed into 5 mL PBS (pH 7.2). In each case, the cell suspension was centrifuged for 5 min at 10 000 r/min. The cell pellet was re-suspended and mixed in 1.5 mL TE buffer (200 mg/L proteinase K, 10 mmol/L Tris, 0.1 mmol/L EDTA, 1 g/L SDS, 3 g/L Triton X-100) at 37°C for 12 h. The suspension was incubated at 95°C for 10 min to inactivate proteinase K, and then it was centrifuged for 5 min at 10 000 r/min. The supernatant DNA was used as a template for PCR.

### Amplification of *H. pylori* DNA by using a conservative primer pair

For extensive detection of *H. pylori* DNA, each sample DNA was first amplified in a 25 µL reaction mixture containing 1 µL of DNA extract, 2 µL of 6.25 pmol/L common conservative primer pair (P1, 5' tgccccgttc-cactaacccca 3'; P2, 5' gtcagccactttgccacttctacag 3', *H. pylori* urease B (*ureB*) gene (gene bank accession number AY295085), 10×PCR reaction buffer (10 mmol/L Tris-HCl, 50 mmol/L KCl), 2.5 µL of 2.5 mmol/L dNTP, 1.5 µL of 25 mmol/L MgCl<sub>2</sub>, and 2.5 µL of 0.25 U AmpliTaq DNA Polymerase. The mixture was denatured initially for 5 min at 94°C, followed by 30 cycles of amplification in a PCR processor. Each cycle included a denaturing step of 94°C for 1 min, an annealing step of 45°C for 1 min and a chain elongation step of 72°C for 1.5 min. The final elongation step was then prolonged for another 5 min. The size of all *H. pylori* genotyping PCR products was predicted to be 413bp according to gene bank accession number AY295085. Sample containing other plasmid DNA was the negative control.

All PCR products were analyzed using a template directed dye-terminator incorporation assay (TDI) with fluorescence polarization (FP). In order to degrade excess dNTP and common conservative primers in the PCR product, 1µL of PCR product, 16.67 nkat of shrimp alkaline phosphatase, 1U of *E. coli* exonuclease I in 1 µL of shrimp alkaline phosphatase buffer (0.5 mol/L Tris-HCl, pH8.5, 50 mmol/L MgCl<sub>2</sub>), and 8 µL of distilled water were mixed and incubated at 37°C for 60 min before enzymes were heat-inactivated at 80°C for 15 min. Thirteen microliters of TDI-FP mixture containing 10× reaction

**Table 1** *H pylori* infection in the pharynx of patients with chronic pharyngitis

Group	Case	TDI-FP(%)	Giemsa(%)
Chronic pharyngitis	50	19 (38.0) <sup>a</sup>	4 (8.0)
With stomach ailment history	16	11 (68.8) <sup>b</sup>	3 (18.8) <sup>b</sup>
Without stomach ailment history	34	8 (23.5)	1 (2.9)
Normal (Control)	20	0	0

<sup>a</sup> $P \leq 0.05$  vs Control; <sup>b</sup> $P \leq 0.01$  vs group without stomach ailment history.

buffer, TAMRA-ddTTP, RP110-ddGTP, *H pylori* probes and 7  $\mu$ L of the enzymatically treated PCR product were mixed and denatured at 95°C for 2 min, followed by 25 cycles of 95°C for 15 s and 50°C for 30 s. At the end of the cycles, the mixture was held at room temperature. *H pylori* genes were acquired by reading FP (mp) at wavelengths of 535 nm and 595 nm, and analyzed by Fluorescence Polarization-Capable Instrument-Victor.

### Statistical analysis

All the data were analyzed by the  $\chi^2$  test.

## RESULTS

*H pylori* infections in the pharynx of the people in the control group and the patients suffering from chronic pharyngitis were examined with TDI-FP and modified Giemsa stain. In the control group, analysis with TDI-FP showed that none of the 20 cases was infected with *H pylori* in the pharynx. The examination using modified Giemsa stain revealed that no cases were infected with *H pylori* in the pharynx.

Regarding the 50 cases of the patients who were suffering from chronic pharyngitis, 19 cases (38%) were determined using TDI-FP to be infected with *H pylori* in the pharynx. When the modified Giemsa stain procedure was used, 4 cases (8.0%) of patients were determined to be infected with *H pylori* in the pharynx. In the 16 pharyngitis cases with stomach ailment history, 11 cases (68.8%) were determined using TDI-FP to be infected with *H pylori* in the pharynx, which was remarkably higher ( $P \leq 0.01$ ) than that in the cases without stomach ailment history (8 cases, 23.5%) as determined by the Statistical  $\chi^2$  test. From using the modified Giemsa stain method, 3 cases (18.8%) of patients with a stomach ailment history were determined to be infected with *H pylori* in the pharynx, which was remarkably higher ( $P \leq 0.01$ ) than that in patients without a stomach ailment history (1 case, 2.9%), as determined by the statistical  $\chi^2$  test (Table 1). This showed the following: (1) that *H pylori* is not detected in the pharynx of healthy people; (2) that chronic pharyngitis is often related to *H pylori* infection; and (3) that a stomach ailment history is associated with a higher rate of *H pylori* infection of the pharynx.

## DISCUSSION

We used two methods to detect *H pylori* infection,

template-directed dye-terminator incorporation with fluorescence polarization (TDI-FP), and modified Giemsa stain. TDI-FP is a single base extension technique in which an oligonucleotide probe anneals to a polymerase chain reaction (PCR)-amplified product adjacent to a single nucleotide polymorphism (SNP) of interest<sup>[3,10]</sup>. In the presence of DNA polymerase and fluorescently labeled dideoxynucleoside triphosphates (ddNTPs), the probe is extended by a single base dictated by the polymorphic site in the target sequence. Fluorescence polarization, the property that fluorescent molecules emit polarized fluorescent light when excited by plane polarized light, is used to identify incorporated ddNTP, and to assign a genotype<sup>[10]</sup>. With this design, the PCR primers will not interfere with the primer extension step of the assay. This method is simple, rapid, sensitive, specific and could also be used for detecting pathogen DNA in the clinic<sup>[11,12]</sup>. The modified Giemsa stain is very straightforward, inexpensive, and takes about five minutes to perform, excluding the time in solution, and rarely requires repeat stains<sup>[13]</sup>.

In the current study, we examined for *H pylori* infection in the pharynx with TDI-FP and the modified Giemsa stain methods. These two methods are rapid, sensitive, specific, easily reproducible and easy to perform technically. The secretion in the pharynx in our study was washed out by water from the epithelial tissue in the checked pharynx before examination so that the results were not affected by gastric juice and saliva.

Sore throat is one of the most common reasons for visits to family physicians. While most patients with sore throat have an infectious cause (such as pharyngitis), fewer than 20 percent have a clear indication for antibiotic therapy (i.e., group A beta-hemolytic streptococcal infection). Useful, well-validated clinical decision rules are available to help family physicians care for patients who present with pharyngitis<sup>[14]</sup>. Because of recent improvements in rapid streptococcal antigen tests, throat culture can be reserved for patients whose symptoms do not improve over time or who do not respond to antibiotics. Pharyngitis and the common cold are among the most frequent diseases. Two thirds of the patients consulting for respiratory infection received antibiotic treatment, and antibiotics confer relative benefits in the treatment of sore throat<sup>[16]</sup>. Pharyngitis may be caused by a wide variety of microbial agents. *Burkholderia cepacia* is a Gram-negative bacillus that is widely distributed in nature; pharyngitis due to *Burkholderia cepacia* was reported for person-to-person transmission<sup>[17]</sup>. The main aetiological agents reportedly causing acute pharyngitis were adenovirus, respiratory syncytial virus (RSV), *Mycoplasma pneumoniae*, *Streptococcus pyogenes* and *Chlamydia pneumoniae*. *M. pneumoniae* was the agent found most frequently as a single pathogen. A history of recurrent pharyngitis, having older siblings and a negative outcome were significantly more common among patients with acute *M. pneumoniae* infection than among those with infections due to other pathogens, or healthy controls. That study demonstrates that: (1) adenovirus and RSV have a prominent role in acute pharyngitis; (2) *S. pyogenes* is found frequently, but it is not possible to distinguish simple carriers from patients with a true infection; and (3) *M. pneumoniae* appears to be

able to cause acute pharyngitis<sup>[18]</sup>. In our daily work, we use antibiotics to treat pharyngitis and sore throat and find antibiotics are effective, although we are not clear about the mechanism of the treatment.

*H pylori* is one of the world's most widespread microorganisms. The abrupt increase of *H pylori* during high school may result from a marked increase of interpersonal social activities<sup>[19]</sup>. Its acquisition in humans remains poorly understood, however, epidemiological studies have identified drinking water as a reservoir for the bacterium<sup>[20]</sup>. *H pylori* has been associated with the development of gastritis, peptic ulcers and gastric cancer. Although *H pylori* infects up to more than half of the world's population, to date the precise modes of transmission have not been fully understood<sup>[13]</sup>. *H pylori* has been investigated in several other organ systems and localizations besides the gastrointestinal cavity, such as the oral cavity. For example, in one study, it was found that the majority of patients with oral diseases have possible *H pylori* colonization in dental plaque; while about two-thirds have *H pylori* associated chronic active gastritis. The oral cavity may be the first place for colonization by *H pylori*, and then the infection involves the gastric mucosa<sup>[21]</sup>. Oral hygiene (the frequency of dental visits and teeth cleaning) did not have a significant influence on the presence of *H pylori* in dental plaque. Other investigators supported the hypothesis that *H pylori* infection begins in the oral cavity by concluding that dental plaque is the reservoir of *H pylori* with no relationship to gastric infection<sup>[22]</sup>. In our study, the pharynx may be a place for *H pylori* colonization, but the number of *H pylori* was so few that the modified Giemsa stain was not very useful. Therefore, we made an amplification of *H pylori* DNA by using a conservative primer pair, then detected the *H pylori* colonization using TDI-FP and acquired a good result.

Other investigators have studied the localization of *H pylori* as well. Akbayir *et al*<sup>[23]</sup> demonstrated that *H pylori* was not present in laryngeal squamous cell carcinoma tissue or in benign lesions. They could not find any evidence indicating that *H pylori* played a role at the tissue level in the pathogenesis of laryngeal carcinoma. Their results may indicate that *H pylori* does not colonize in either adenoid or tonsils and that these tissues do not constitute a reservoir for *H pylori* infection. On the contrary, Cirak *et al*<sup>[7]</sup> detected *H pylori* and its *CagA* gene in tonsil and adenoid tissues by PCR. These authors found: 7 of 23 (30%) patients to be positive for *H pylori* DNA, 5 (71%) of whom also possessed the *CagA* gene. In another study, specimens from 208 dyspeptic patients were collected from saliva, supra- and subgingival dental plaque, tongue scrapings, and oropharyngeal swabs. *H pylori* was detected from multiple sites (dental plaque, gastric juice, gastric biopsy, duodenal aspirate, and the oropharynx<sup>[26]</sup>). As in our study, the authors used more than one method for detecting *H pylori*. When PCR was used, 15 of 208 patients (7%) tested positively for *H pylori* by PCR in dental plaque. In contrast, only 2 samples were positive by culture. This demonstrates the importance of using more than one method for detecting *H pylori* infection. We also found this to be true in our own study, where we used two methods, TDI-FP and modified Giemsa stain,

to detect *H pylori* infection. As shown in Table 1, TDI-FP consistently detected *H pylori* infections that were missed by the modified Giemsa stain method. These authors also found that four of the dental plaque strains had restriction patterns similar to those of the stomach and duodenal sites, providing evidence that these sites were infected with the same strain of *H pylori*. The detection in dental plaque could indicate that the oral cavity may act as a reservoir or sanctuary for the organism. Likewise, this finding also relates to our data. We found that *H pylori* infection in the pharynx was significantly more likely in patients with a history of stomach ailments than in patients without a history of stomach ailments. That is, just as there is a relationship between the occurrence of *H pylori* in dental plaque and its occurrence in the stomach and duodenum, there may be a relationship between infection of the pharynx with *H pylori* and a history of stomach ailments. However, whether *H pylori* is a resident or transient oral microorganism is still unclear, although it is more likely to be transient in nature<sup>[27]</sup>.

In our study, the goal was to determine if there was a relationship between *H pylori* infection in the pharynx and chronic pharyngitis, and, in addition, to determine if such infections correlated with a history of stomach ailments. We determined both of these relationships to be true. In addition, we utilized two methods for detecting *H pylori*, TDI-FP and modified Giemsa stain, and found the TDI-FP method to be the most sensitive. These findings can be applied to the clinical setting: doctors will be able to use the appropriate method to test if a patient with chronic pharyngitis is infected in the pharynx with *H pylori*, aiding in prescribing the appropriate antibiotic. These findings also should cause doctors to examine a patient with chronic pharyngitis for ailments in the digestive system. But on the other hand, the TDI-FP test can yield false positive results.

To determine whether *H pylori* infection is related to other upper respiratory tract infections, such as sinusitis, or with otitis media, further investigations will need to be performed.

### Abstract

**AIM:** To study whether heat-shocked tumor cells could enhance the effect of tumor cell lysate-pulsed dendritic cells (DCs) in evoking anti-tumor immune response *in vivo*.

**METHODS:** Mouse undifferentiated colon cancer cells (CT-26) were heated at 42°C for 1 h and then frozen-thawed. The bone marrow-derived DCs pulsed with heat-shocked CT-26 cell lysate (HSCT-26 DCs) were recruited to immunize syngeneic naïve BALB/c mice. The cytotoxic activity of tumor specific cytotoxic T lymphocytes (CTLs) in mouse spleen was evaluated by IFN-enzyme-linked immunospot (ELISpot) and LDH release assay. The immunoprophylactic effects induced by HSCT-26 DCs in mouse colon cancer model were compared to those induced by single CT-26 cell lysate-pulsed DCs (CT-26 DCs) on tumor volume, peritoneal metastasis and survival time of the mice.

**RESULTS:** Heat-treated CT-26 cells showed a higher hsp70 protein expression. Heat-shocked CT-26 cell lysate pulsing elevated the co-stimulatory and MHC-II molecule expression of bone marrow-derived DCs as well as interleukin-12 p70 secretion. The IFN- $\gamma$  secreting CTLs induced by HSCT-26 DCs were significantly more than those induced by CT-26 DCs ( $P=0.002$ ). The former CTLs' specific cytotoxic activity was higher than the latter CTLs' at a serial E/T ratio of 10:1, 20:1, and 40:1. Mouse colon cancer model showed that the tumor volume of HSCT-26 DC vaccination group was smaller than that of CT-26 DC vaccination group on tumor volume though there was no statistical difference between them

### INTRODUCTION

Dendritic cells (DCs) are the most potent antigen-presenting cells (APCs) mediating effective immune effects *in vitro* and *in vivo*<sup>[1,2]</sup>. DCs-based tumor vaccines have been recruited to prevent postoperative recurrence and metastasis of malignant tumors<sup>[3,4]</sup>. During the development of this approach, distinct methods have been attempted to enhance the effect of DC tumor vaccine in evoking tumor rejection response.

Heat shock protein (HSP), the molecule chaperon in cells, binds to the antigenic peptides and guides them to accurate folding, transporting, and conjugating to major histocompatibility complex (MHC) molecules<sup>[5]</sup>. Referring to the current knowledge of HSPs, it acts as chaperone peptides including antigenic peptides, interacts with antigen presenting cells through a receptor, stimulates antigen presenting cells to secrete inflammatory cytokines and mediates maturation of DCs. It was reported that heating could enhance the immunogenicity of tumor cells, which is ascribed to HSPs<sup>[6]</sup>. Furthermore, vaccination with the lysate of heated tumor cells can result in effective tumor rejection *in vivo*<sup>[7]</sup>. In the present study, we used heat-shocked tumor cells to elicit HSP expression. We assumed that pulsing with these HSP-rich tumor cell lysate might enhance the effect of DCs to stimulate stronger anti-tumor response than pulsing with tumor cell lysates. Because hyperthermal treatment is a standardized manipulation in

clinical practice of oncologic surgery, such a DC tumor vaccine is convenient to be prepared. We examined the specific CTL response induced by heat-shocked tumor cell lysate-pulsed DCs in naïve mice and further evaluated its immunoprophylactic effects in mouse colon cancer model.

## MATERIALS AND METHODS

### *Mice and cell line*

Six to eight-week-old female BALB/c mice were purchased from Laboratory Animal Research Center (LARC) of the Fourth Military Medical University (FMMU, Xi'an) and housed under pathogen-free conditions. All experiments involving the use of mice were performed in accordance with the protocols approved by LARC. CT26 is a carcinogen-induced undifferentiated colon adenocarcinoma cell line of BALB/c mice. Cells were maintained in Dulbecco's modified Eagle's medium (DMEM, Gibco) containing 10% heat-inactivated fetal bovine serum (FBS; Sijiqin Biotech, Hangzhou), 100 IU/mL penicillin and 100 µg/mL streptomycin at 37 °C in an atmosphere containing 50 mL/L CO<sub>2</sub> and passaged every 2 d.

### *Heating and lysing CT-26 cells*

CT-26 cells at 90% confluence were heated in 42 °C water bath for 1 h followed by recovering for 2 h at 37 °C in an atmosphere containing 50 mL/L CO<sub>2</sub>. Cells were then digested by 0.02% trypsin and washed twice with PBS. After being enumerated and re-suspended in PBS at 1×10<sup>6</sup> cells/mL, CT-26 cells were frozen in liquid nitrogen for 10 min and then thawed thrice at 4 °C. The frozen-thawed resultants were centrifuged at 12 000 *g* for 15 min and the supernatant was preserved as tumor cell lysate at -80 °C.

### *Western blot assay*

Equivalent protein samples were subjected to 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). Then, the separated proteins were transferred onto nitrocellulose (NC) membranes. Membranes were blocked with 5% non-fat milk in TBST (20 mmol/L Tris-HCl, pH 7.4, 150 mmol/L NaCl, and 0.05% Tween 20) for 2 h and incubated for 1 h at room temperature with hsp70 mAb (H5147, Sigma) diluted in TBST. After washing, membranes were incubated with horseradish peroxidase conjugated goat-anti-rabbit IgG (Boxtex) diluted 1:400 in TBST at room temperature for 1 h. Detection was performed using the DAB detection system.

### *Generation and pulse of bone marrow-derived DCs*

Bone marrow-derived DCs were generated as described by Lutz *et al*<sup>[8]</sup> with minor modifications. Briefly, 1×10<sup>6</sup> cells/mL erythrocyte-depleted mouse bone marrow cells from flushed marrow cavities were cultured in complete medium (CM) with 20 ng/mL recombinant mouse GM-CSF (PeproTech, Rocky Hill, NJ, USA) in 10-cm tissue culture dishes at 37 °C in an atmosphere containing 50 mL/L CO<sub>2</sub>. On d 3, 5, and 7, respectively, half media were removed and centrifuged for 5 min at 1 500 r/min, the collected cells were resuspended in the same volume of fresh CM and replenished to original plates. The frozen-

thawed tumor lysate was added to the DC culture systems on d 7 at a ratio of five DC equivalents to one tumor cell (i.e., 5:1) and incubated at 37 °C in an atmosphere containing 50 mL/L CO<sub>2</sub>. After 48 h of incubation, non-adherent cells including DCs were harvested by gentle pipetting. DCs were enumerated by FACS (FACScan, Becton Dickinson) analysis through staining with PE anti-mouse CD11c Ab (N418, hamster IgG, Biolegend). The co-stimulatory and MHC-II molecules were analyzed by staining with FITC anti-mouse I-A/I-E (m5/114.15.2, ratIgG2b, Biolegend) and FITC anti-mouse CD86 (B7-2, PO3, ratIgG2b, Biolegend). The corresponding labeled isotypes served as the controls. For further vaccination, DCs were washed twice, enumerated and resuspended in PBS at 5×10<sup>6</sup>/mL.

### *ELISA*

Following the protocol of mIL-12 p70 ELISA Ready-SET-Go kit (Ebioscience, San Diego, CA, USA), plates (NUNC Maxisorp) were pre-coated with capture antibody (clone C18.2) overnight at 4 °C and blocked at room temperature for 1 h. After being washed, 100 µL/well of mIL-12 p70 standard (8 pg-1 024 pg/mL at twofold serial dilutions) or 100 µL/well of samples was added to the appropriate wells and incubated at room temperature for 2 h. Wells were aspirated and washed, then 100 µL/well detection antibody (clone C17.8) was added and incubated at room temperature for 1 h. After being washed, 100 µL avidin-HRP was added and incubated at room temperature for 30 min. Plates were washed thoroughly and 100 µL/well of substrate solution was added. After being incubated at room temperature for 15 min, 50 µL of stop solution was added to each well. The plates were read. Data represented the value of 450 nm subtracted the value of 570 nm. All assays were performed in triplicate.

### *Immunization assay and colonic cancer inoculation*

BALB/c mice were immunized with DC vaccine through tail-vein on d 0 and 7 respectively at the same dose of 5×10<sup>5</sup> DCs (100 µL). Each treatment group contained not less than 15 mice. Seven days after the second immunization, three mice of each group were killed and the spleens were taken to perform the ELISpot and cytotoxic assays. The remaining mice were anesthetized with 0.75 mg of sodium pentobarbital. Colonic cancer inoculation was performed as follows. In brief, a vertical midline incision was made and the cecum was exposed. Upon visualization, 1×10<sup>5</sup> CT-26 cells (50 µL) were injected into subserosa using a 30-gauge needle (Becton Dickinson) and 1 mL syringe. The midline incision was closed with a running suture. Fourteen days later, not less than five mice of each group were killed, the weight of the colon tumors was measured and the peritoneal metastases were checked. The remaining mice were fed to observe the tumor-bearing survival time. The end point of observation was selected when all the mice of any of the two teams were dead.

### *ELISpot analysis*

The murine interferon-gamma ELISpot kit (Diaclone, France) was used to determine tumor-specific IFN-γ

**Figure 1** Western blot detection of HSP70 expression of CT-26 cells heating at 42 °C. 1: No heating. 2: heat-shocked for 30 min. 3: heat-shocked for 1 h. 4: heat-shocked for 2 h.

**Figure 2** The surface molecule expressions of mouse bone marrow derived DCs were measured by staining with PE anti-mouse CD11c (N418, hamster IgG), FITC anti-mouse I-A/I-E (m5/114.15.2, ratIgG2b), FITC anti-mouse CD86 (B7.1, PO3, ratIgG2b) and analyzed by FACS. 1: DC culture system at d 7. 2: DC culture system at d 9. 3: DC culture system stimulating with LPS (1 µg/mL). 4: DC culture system pulsed with CT-26 lysates. 5: DC culture system pulsed with HSCT-26 lysates. The data are representative for 3 independent experiments.

secreting T cells<sup>[9]</sup>. The 96-well filtration plates (Nunc) were coated with 100 µL capture antibody (clone DB1). After an overnight incubation at 4 °C, the wells were washed and blocked with 2% dry skimmed milk in PBS. Splenocytes ( $1 \times 10^6$ /well) isolated from the mice were added to the wells and incubated at 37 °C in an atmosphere containing 50 mL/L CO<sub>2</sub> for 20 h with target cells ( $5 \times 10^4$ /well). Plates were washed and then incubated with 100 µL biotinylated detection antibody (polyclonal) at 37 °C for 90 min. After the removal of unbound antibodies, 100 µL avidin-alkaline phosphatase was added and plates were incubated for 1 h at 37 °C. After washing, spots were developed by adding 100 µL of ready-to-use BCIP/NBT buffer and incubated at room temperature for spot formation. The spots were scanned and counted.

#### Lactate dehydrogenase release assay

Specific cytolytic activities of murine spleen cells were determined by LDH assay. The CT-26 cells were used as target cells. Effector and target cells were mixed at the E/T ratio of 20:1 at 0.2 mL/well in 96-well round-bottomed plates (Nunc). After incubation for 4 h, cells were centrifuged at 250 r/min for 5 min and the cell-free supernatant was collected for LDH assay using CytoTox96 (Promega, Madison, WI, USA). The percentage of specific LDH release was calculated by the following formula: % cytotoxicity = [(experimental LDH release) - (spontaneous LDH release by effector and target cells) / (maximum LDH release) × (spontaneous LDH release)] × 100. For the controls, the target cells were incubated either in culture

**Figure 3** The concentration of mIL-12 p70 in supernatant of different DC culture system were measured by ELISA assay. 1: DC culture system at d 7. 2: DC culture system at d 9. 3: DC culture system pulsed with CT-26 lysates. 4: DC culture system pulsed with HSCT-26 lysates. 5: DC culture system stimulating with LPS (1 µg/mL). The data were representative for three independent experiments.

medium alone to determine spontaneous release or in a mixture of 2% Triton X-100 to define the maximum LDH release. The spontaneous release was always <10% of the maximum release. All assays were performed in triplicate.

#### Statistical analysis

Each group included at least five mice. All experiments were carried out thrice. Data were expressed as mean ± SD. Tumor volume and immune cell yield data were analyzed by two-way analysis of variance (ANOVA). All analyses were conducted with SPSS8.0 software.  $P < 0.05$  was considered statistically significant.

## RESULTS

### Phenotype and cytokine production in heat-shocked CT-26 cell lysate-pulsed DCs

To evaluate the hsp70 protein expression in CT-26 cells, we performed Western blot analysis using an anti-hsp70 mAb. hsp70 protein in CT-26 cells increased after being heated for 30 min and peaked at 1 h (Figure 1). Therefore, heating at 42 °C for 1 h was selected as a standard treatment for heat shocking in the following experiment. To determine the quantity of DCs in culture system, we analyzed the surface molecules of harvested cells by flow cytometry. About 65% of the harvest cells in culture system on d 7 were CD11c positive and increased to 75% or more on d 9. DCs pulsed with HSCT-26 lysate manifested higher CD86 and I-A/I-E expression than pulsed with CT-26 lysate (Figure 2). We also measured the mIL-12 p70 concentration in the supernatant of different DC culture systems by ELISA. HSCT-26 lysate-pulsed DCs showed a higher level of mIL-12 p70 than either CT-26 lysate-pulsed or unpulsed DCs on d 9 (Figure 3).

### Immunization with HSCT-26 lysate-pulsed DCs elicited tumor specific CTLs in naïve BALB/c mice

To investigate the ability of HSCT-26 lysate-pulsed DCs to induce CT-26 specific CTLs in naïve syngeneic BALB/c mice, we examined the CT-26 specific IFN-γ-producing T

**Figure 4** Tumor-specific IFN- $\gamma$  secreting Splenic T cells induced by different cell lysates pulsed DC. 1: positive control (no target, 1mg/L PHA stimulated). 2: negative control (no target). 3: single DC immunized. 4: CT-26 lysates pulsed DC immunized. 5: HSCT-26 lysates pulsed DC immunized. Results are representative of three experiments.

**Figure 5** Bone marrow-derived DC pulsed with HSCT-26 lysate can generate tumor-specific CTLs *in vivo*. Splenic T cells obtained from immunized mice were evaluated for cytolytic activity against Mitomycin C treated CT-26 cells at the effector: target (E:T) ratios indicated. Values are the mean  $\pm$  SE of triplicate wells.

cells in splenocytes derived from immunized and control mice by ELISpot assay. As shown in Figure 4, after being restimulated with mitomycin C-treated CT-26 cells at an E: T ratio of 20:1, the CT-26 specific IFN- $\gamma$  secreting T cells in HSCT-26 DCs-immunized mice were significantly more than those in CT-26 DCs-immunized mice ( $P=0.002$ ). Then we evaluated the CT-26 specific cytolytic activity of splenocytes stimulated with different DC tumor vaccines. As shown in Figure 5, splenocytes from mice that received HSCT-26 DC vaccination displayed significantly stronger cytolytic activity against CT-26 cells at ratios 10:1, 20:1, and 40:1 of effector cells to target cells.

#### **Immunization of HSCT-26 lysate-pulsed DCs protected mice with colonic cancer inoculation**

We examined whether heat-shocked CT-26 cells lysate-pulsed DCs could display enhanced immunoprophylactic potential in mouse colon cancer model. After being vaccinated twice at an interval of 7 d, BALB/c mice were inoculated with CT-26 cells into cecum through open surgery. Fourteen days after the inoculation, autopsies were performed to check the growth and metastasis of colon

**Figure 6** Survival curves of mice immunized with different dendritic cells tumor vaccine.

tumor. The mice that received CT-26 DC vaccination or single DC vaccination had colon tumor formation, whereas one of the six mice that received HSCT-26 DC vaccination was tumor free. The tumor volumes in single DC vaccination group, CT-26 DC vaccination group and HSCT-26 DC vaccination group were  $107 \pm 69$ ,  $24 \pm 8$ , and  $8 \pm 7$  mm<sup>3</sup>, respectively. ANOVA analysis showed significant differences in tumor volume among the three groups ( $P=0.000$ ), but there was no difference between HSCT-26 DC vaccination group and CT-26 DC vaccination group ( $P=0.480$ ). Neither HSCT-26 DC vaccination group nor CT-26 DC vaccination group had peritoneal metastasis. In contrast, 50% mice in single DC vaccination group (3/6) had tumor planting to adjacent peritoneum and intestine surface accompanied with a small quantity of bloody ascites. No hepatic metastasis was found in the mice of the three groups macroscopically during autopsy.

To investigate the tumor-bearing survival time, we observed immunized mice for at least 60 d. The median survival time of mice in the single DC vaccination group, CT-26 DC vaccination group and HSCT-26 DC vaccination group was 27.0, 43.0, and 57.0 d, respectively. Log-rank test showed that the median survival time was significantly different in the three groups of mice ( $P=0.0001$ ). Most importantly, the mice vaccinated with HSCT-26 DCs had a much longer survival time than those vaccinated with CT-26 DCs ( $P=0.0384$ ). The survival curves are shown in Figure 6.

## **DISCUSSION**

Radical surgery is the standard treatment for most patients with advanced cancer. After resection of primary tumor and local drainage lymph nodes, the tumor burden of patients is released and the immune system may have a good chance for recovery. It is the critical time to commence adjuvant immunotherapy for preventing postoperative recurrence and metastasis. The prophylactic effects of this therapy last for a long time and can be augmented by revaccination.

The anti-tumor effect of tumor cell lysate-pulsed DCs was first reported in 1998<sup>[10]</sup> and has been utilized to treat

malignant diseases including renal cancer, lymphoma, and colorectal cancer, *etc.*<sup>[11-13]</sup>. However, a misgiving of rising autoimmunity still exists as shown in animal models<sup>[14]</sup>. Current pilot clinical studies have not found clinical signs of autoimmune disease except for vitiligo and occurrence of auto antibodies. Reinhard *et al.*<sup>[15]</sup> reported that vaccination with tumor lysate-pulsed DCs does not show a higher incidence of autoimmunity than vaccination with peptide-pulsed DCs. Tumor lysate is superior to other ways of DC pulsing and can elicit immunity for the entire array of TAAs of source tumors, circumventing the need of prior identification of TAAs from individual cancers. Enhancing the anti-tumor effect of whole tumor cell lysate-pulsed DCs promotes the use of this kind of tumor vaccine.

In our present study, tumor cells heated at 42 °C increased the expression of HSPs such as HSP70. Pulsed with such lysates of heat-shocked tumor cells, DCs showed higher expression of MHC-II and co-stimulatory molecules on their surface and secreted more mIL-12 P70. As we know, DC priming T lymphocytes require signals I and II. Signal I presents the antigenic epitopes introduced by MHC molecules. Signal II as the co-stimulatory molecules on DC surface, can improve epitopes of DCs by interacting with their respective ligands on T lymphocytes. Upregulated expression of MHC-II and co-stimulatory molecules on DC surface facilitates activation of T lymphocytes effectively. IL-12 is a cytokine leading to cell-mediated immune response (Th1 response) and is preferable for successful tumor immunotherapy<sup>[16]</sup>. Heat-induced HSPs may also serve as endogenous danger signals to drive DC maturation. Mature DCs obtain high viability and present antigenic epitopes to T lymphocytes through migrating to local drainage lymph nodes. Our result is in agreement with related reports<sup>[17]</sup>. DC activating process may be involved in NF- $\kappa$ B pathway<sup>[18]</sup>.

It is believed that HSP-chaperoned TAAs represent the specific fingerprint of tumor cells. A gp96 receptor, CD91 on APC surface has been recently identified<sup>[19,20]</sup>. HSP-chaperoned antigen might target to APCs with the assistance of HSP receptors on these cells. HSP-peptide complexes can be internalized by APCs through receptor-mediated endocytosis<sup>[21]</sup>. HSP-mediated epitopes could go through endogenous antigen-processing pathways in the context of MHC-I molecules<sup>[22]</sup>. DCs have an impressive ability to "cross-present" MHC class I-restricted peptide epitopes derived from exogenous proteins to CD8 T lymphocytes. In our study, compared to tumor cell lysate-pulsed DCs, immunization with heat-shocked tumor cell lysate-pulsed DCs might induce a large amount of specific CTLs in naïve mice *in vivo*. Furthermore, the induced CTLs exhibited a higher tumor specific cytotoxic activity. Immunized and challenged mouse model proved that vaccination of HSCT-26 DCs could prolong the survival time of tumor-bearing animals. All the results suggest that heating tumor cells can enhance the effect of whole tumor cell lysate-pulsed DCs to elicit specific anti-tumor response. We suppose that after taking up the HSP-chaperoned antigens, epitopes coming from HSCT-26 might be complexed with MHC class I molecules in endoplasmic reticulum and transported to the cell surface

to priming CD8 T lymphocytes. Increased HSPs in tumor cells may serve as epitope chaperons and natural adjuvants in the process of DC antigen presentation, enhancing anti-tumor effects of DC vaccine.

In conclusion, heat-shocked tumor cell lysate-pulsed DCs can elicit effective anti-tumor effects *in vivo*, suppress the growth of colon cancer and eliminate occurrence of peritoneal metastasis. Using this tumor vaccine postoperatively may decrease the local recurrence and peritoneal metastasis of colon cancer and prolong the tumor-free survival time of the patients. The prophylactic effects of this DC vaccine on preventing liver metastasis of colon cancer should be further evaluated.

## Abstract

**AIM:** To investigate the intestinal barrier changes in rats with CCl<sub>4</sub>-induced portal hypertension.

**METHODS:** The permeability of intestinal barrier detected by Lanthanum as a tracer was evaluated in rats. Bacterial translocation and plasma endotoxin were also determined.

**RESULTS:** The incidence of bacterial translocation was 85% in rats with CCl<sub>4</sub>-induced portal hypertension, which was significantly higher than that in control rats (20%,  $P < 0.01$ ). Plasma endotoxin level was significantly higher in experimental group than in control group. Permeability of the epithelial mucosa and pathological alteration were increased in the ileum and the microvilli became shorter and thinner in rats with portal hypertension.

**CONCLUSION:** Bacterial translocation occurs in rats with CCl<sub>4</sub>-induced portal hypertension and increased permeability between epithelial cells contributes to the translocation.

## INTRODUCTION

The incidence of bacterial infection in patients with portal

hypertension is higher than that in the general population<sup>[1]</sup>. Most of these infections are caused by bacteria normally present in the intestine. Portal hypertension may play an important role in the pathogenesis of infections in cirrhotic patients<sup>[2]</sup>. On the other hand, endotoxemia present in patients with portal hypertension is correlated with the severity of the disease. Recently, bacterial translocation from the gut to extraintestinal organs and systemic circulation has been proved in patients with other diseases<sup>[3]</sup> and is considered as the cause of endotoxemia in patients due to the disruption of the gut barrier function. However, the exact route of bacterial translocation and endotoxemia in patients with portal hypertension is not clear. In the present study, bacterial translocation, permeability of the enterocyte membrane and intestinal morphological alterations in rats with CCl<sub>4</sub>-induced portal hypertension were evaluated by transmission electrosocopy.

## MATERIALS AND METHODS

Adult male Sprague-Dawley rats ( $n = 40$ ) weighing 250-300 g were used. The animals were allowed to acclimate to laboratory condition for 4-6 d with free access to water and rat chow before the experiment.

Twenty rats entered the experimental group and received intragastric CCl<sub>4</sub> via a Hamilton syringe with an attached stainless steel animal feeding tube after light ether anesthesia. The first dose of CCl<sub>4</sub> was 20  $\mu$ L and subsequent doses were adjusted based on the body weight 48 h after the last dose. After the appearance of ascites, the dose was reduced to 40  $\mu$ L and increased according to the schedule if ascites resolved. The other 20 rats were gavaged with water and served as control group.

Studies on intestinal permeability and bacterial translocation from the gut were carried out on d 14. The abdominal cavity was opened by a midline incision and blood samples were immediately inoculated into 3 mL blood culture medium and 0.5 mL plasma was used to detect endotoxin. Limulus-amoebocyte-lysate (LAL) test was used to determine plasma endotoxin levels as previously described<sup>[4]</sup>. *Escherichia coli* 055 was used as endotoxin standard. The results were expressed as endotoxin units per milliliter (EU/mL). The mesenteric lymph nodes (MLNs) near the distal ileum, liver, and spleen were harvested and weighed, tissues were then homogenized in a test tube containing 3 mL brain heart infusion broth, 0.2 mL supernatant was taken for bacterial culture. All media for aerobic culture were incubated at 37 °C for

**Figure 1** Normal microvilli of enterocytes in control rats (A) and shortened and thinned microvilli of enterocytes in rats with portal hypertension (B).

**Figure 2** Lanthanum tracer in the ileum of control rats (A) and rats with CCl<sub>4</sub>-induced portal hypertension (B and C).

3-5 d and isolated bacteria were identified by standard procedures. At the end of the experiment, a segment of the distal ileum was removed and placed into 2.5% glutaraldehyde fixative with 4% lanthanum hydroxide for 1 h, then washed thrice to assay the permeability of the intestinal barrier. Sections were made from each sample and the presence of the tracer was observed under transmission electron microscope.

Positive MLN culture was considered indicative of bacterial translocation from the gut. Positive blood, spleen or liver cultures were considered indicative of passage bacteria to the systemic circulation.

### Statistical analysis

Translocation incidence was analyzed by the Fisher's exact test. Weights and other data were expressed as mean  $\pm$  SD

and compared with Student's *t* test.

## RESULTS

The mean spleen weight in rats with CCl<sub>4</sub>-induced portal hypertension ( $5.32 \pm 0.38$  mg/g body wt) was significantly greater than that in control rats ( $2.31 \pm 0.28$  mg/g body wt). The weight of MLN was also greater in rats with CCl<sub>4</sub>-induced portal hypertension ( $1.85 \pm 0.42$  mg/g body wt) than that in control rats ( $0.86 \pm 0.25$  mg/g body wt). Ascites occurred in all rats.

Bacterial translocation to MLN occurred in 17 of 20 (85%) CCl<sub>4</sub>-PH rats and in 4 of 20 (20%) control rats. Bacteria were found in ascites in the experimental group (7/20, 35%) while no bacteria were found in the control group. All bacteria isolated from MLNs and ascites were Gram-negative. No bacteria were isolated from blood, spleen or liver.

Plasma levels of endotoxin ( $0.083 \pm 0.012$  EU/mL) and ascites ( $0.062 \pm 0.012$  EU/mL) were significantly higher in the experimental group than in the control group ( $0.046 \pm 0.009$  EU/mL,  $P < 0.01$ ).

The distal ileum of rats with CCl<sub>4</sub>-induced portal hypertension did not differ grossly from that of the control rats. Clear and intact microvilli were seen in ileal enterocytes in the control rats. Shortened and thinned microvilli appeared in rats with CCl<sub>4</sub>-induced portal hypertension (Figure 1).

The tracer did not penetrate into the cells or intercellular juncture in the control rats. The tracer appeared between enterocytes and cellular junctions in rats with CCl<sub>4</sub>-induced portal hypertension. The penetrated tracer aggregated along the cellular junctions (tight or gap) or within the mucosal propria lamina without entering enterocytes or winding lines (Figure 2).

## DISCUSSION

The mechanism underlying bacterial penetration into the intestinal barrier and entry into the systemic circulation in cirrhotic patients remains unclear<sup>[5-7]</sup>. Recent studies in animal model demonstrated that bacteria from the gastrointestinal tract can cross over the intestinal barrier to infect extraintestinal sites and/or the systemic circulation, a process known as bacterial translocation<sup>[8-10]</sup>. Various pathological changes such as damage of the intestinal barrier can increase the incidence of bacterial translocation<sup>[11]</sup>. Cirrhotic patients usually develop portal hypertension that causes intestinal congestion, thus inducing intestinal mucosal abnormalities<sup>[12]</sup>, suggesting that portal hypertension may play a prominent role in the pathogenesis of spontaneous bacteremia and peritonitis in cirrhotic patients. Our results indicated that bacterial translocation occurred in 85% portal hypertensive rats, which was significantly higher (20%) than that in the control rats. Surgical manipulation and stress may be responsible for the translocation of bacteria<sup>[13-15]</sup>.

The reason why permeability of the intestinal mucosa is increased remains unclear. In the present study, the tracer (Lanthanum) with a mean diameter of 4 nm is normally located outside the cell membrane, but may

enter the cells through cellular pores, while their diameter exceeds 2 nm. Our results showed that the permeability of intestinal barrier was greatly increased in rats with portal hypertension. The tracer appeared between enterocytes and lamina propria cells, indicating that translocation occurs between enterocytes and lamina propria cells. This finding is consistent with the observation of Cole *et al.*<sup>[17]</sup>. The damaged microvilli in rats with CCl<sub>4</sub>-induced portal hypertension demonstrated that permeability changes might occur before the development of pathological abnormality<sup>[15-17]</sup>.

In conclusion, bacterial translocation occurs in rats with CCl<sub>4</sub>-induced portal hypertension and the increased permeability between epithelial cells contributes to the translocation.

### Abstract

**AIM:** To investigate the relationship between serum soluble interleukin-2 receptor (sIL-2R) level and anti-HBc in patients with chronic hepatitis B virus (HBV) infection.

**METHODS:** Sera from 100 patients with chronic HBV infection and 30 healthy controls were included in this study. The patients were divided into group A [HBsAg (+), HBeAg (+) and anti-HBc (+),  $n=50$ ] and group B [HBsAg (+), HBeAg (+) and anti-HBc (-),  $n=50$ ]. sIL-2R levels were determined using ELISA. HBV DNA and alanine aminotransferase (ALT) were also detected.

**RESULTS:** Serum sIL-2R levels were significantly higher in patients with chronic HBV infection than in healthy controls. Moreover, serum sIL-2R levels were significantly higher in patients with HBsAg (+), HBeAg (+) and anti-HBc (+) ( $976.56 \pm 213.51 \times 10^3$  U/L) than in patients with HBsAg (+), HBeAg (+) and anti-HBc (-) ( $393.41 \pm 189.54 \times 10^3$  U/L,  $P < 0.01$ ). A significant relationship was found between serum sIL-2R and ALT levels ( $P < 0.01$ ) in patients with chronic HBV infection, but there was no correlation between sIL-2R and HBV DNA levels. The anti-HBc status was significantly related to the age of patients ( $P < 0.01$ ).

**CONCLUSION:** The high sIL-2R level is related to positive anti-HBc in chronic hepatitis B patients. Positive anti-HBc may be related to T-lymphocyte activation and negative anti-HBc may imply immune tolerance in these patients.

### INTRODUCTION

About 350 million persons are chronically infected with hepatitis B virus (HBV) in the world<sup>[1]</sup>. Carriers of HBV are at an increased risk of developing cirrhosis, hepatic decompensation and hepatocellular carcinoma (HCC)<sup>[2]</sup>. China has the greatest burden of hepatitis B and liver cancer in the world. A third of all chronic HBV carriers live in China. Each year, about half a million Chinese die of liver cancer or liver failure due to hepatitis B. However, HBV has no cytopathic effect on hepatocytes. Some liver damages caused by HBV are attributed to immune clearance of virus-infected cells and associated immune reactions. While antibody response in patients with HBV infection plays a critical role in viral clearance through the formation of complexes with viral particles and their removal from the circulation<sup>[3]</sup>, specific cellular immune response plays a main role in hepatic necrosis due to HBV infection and in the persistence of viral infection<sup>[4]</sup>.

IL-2R system plays an important role in the activation and proliferation of lymphocytes<sup>[5]</sup>. IL-2R is expressed on the cell membrane of lymphocytes and contains at least three different chains. Serum sIL-2R is predominantly released from activated T lymphocytes and can serve as an index of activation of T lymphocytes<sup>[6]</sup>. Serum sIL-2R levels are significantly higher in patients with chronic HBV infection than in healthy controls<sup>[7]</sup>. The serum sIL-2R level one year after interferon administration may be a useful marker of interferon's therapeutic effectiveness<sup>[8]</sup>.

In the present study, we determined the serum levels of sIL-2R in chronic hepatitis B patients with positive or negative anti-HBc to analyze the elevated patterns of sIL-2R in patients with different anti-HBc status.

### MATERIALS AND METHODS

#### Patients

Serum samples were obtained from 100 Chinese patients

**Table 1** Levels of sIL-2R, ALT, and HBV DNA in sera of patients with chronic HBV infection (mean  $\pm$  SD)

Group	Number	sIL-2R ( $\times 10^3$ U/L)	ALT (IU/L)	HBV DNA (copies/mL, IgC)
A	50	967.56 $\pm$ 213.51 <sup>b</sup>	79 $\pm$ 21.2 <sup>d</sup>	7.954 $\pm$ 1.754
B	50	393.41 $\pm$ 189.54 <sup>a</sup>	24 $\pm$ 12.3	7.875 $\pm$ 1.011
Control	30	243.59 $\pm$ 121.34	13 $\pm$ 6.5	0

<sup>b</sup> $P < 0.01$  vs group B and control group; <sup>a</sup> $P < 0.05$  vs control group; <sup>d</sup> $P < 0.01$  vs group B and control.

positive for HBsAg and HBeAg. All the patients were followed up from 2001 to 2004. The patients were divided into two groups. Group A consisted of 50 patients positive for HBsAg, HBeAg, and anti-HBc (age range, 3–71 years; mean age, 37 years). Group B consisted of 50 patients positive for HBsAg and HBeAg but negative for anti-HBc (age range, 12–33 years; mean age, 22.5 years). Another 30 healthy persons negative for all HBV markers served as the control group.

#### Blood sampling

Venous blood samples were taken to detect sIL-2R, alanine aminotransferase (ALT), HBV DNA and HBV markers (HBsAg, HBeAg, and anti-HBc). All serum samples were separated and stored at  $-20^\circ\text{C}$  until testing.

#### Determination of sIL-2R

Serum sIL-2R levels were determined by sandwich ELISA using commercially available sIL-2R assay kits (Department of Immunology, Dr Bethune Medical University, Changchun, China). An anti-sIL2R monoclonal antibody was adsorbed onto the substrate of polystyrene microtiter wells. The sIL-2R present in the samples or in the standard solutions was bound to the antibody-coated wells. The unbound sample components were removed by washing thrice. A peroxidase-linked anti-sIL-2R monoclonal antibody against another epitope on the sIL-2R molecule was then added to complete the sandwich. After being washed, the unbound materials were removed and a substrate solution was added into the wells. A stopping solution was added to stop the reaction and then light absorbance at 492 nm was measured. A standard curve was prepared from four IL-2R standards. The values were expressed as unit (U) per L.

#### Assay of HBV markers and HBV DNA

HBsAg, HBeAg, and anti-HBc were detected using commercially available EIA or ELISA kits (Reagents Development Center, Shanghai Hospital for Infectious Diseases, Shanghai, China). HBV DNA levels were tested using real-time PCR on ABI 7000 real-time detection system (Applied Biosystems, Foster City, CA, USA).

#### Measurement of ALT

ALT was tested on a CX4 chemistry analyzer (Beckman Coulter, Fullerton, CA, USA) using commercially available kits.

**Table 2** Age difference between anti-HBc (+) and anti-HBc (–) patients with chronic HBV infection

Group	Number	Median (yr)	Rank sum
A	50	37 <sup>b</sup>	66.88
B	50	22.5	40.12

<sup>b</sup> $P < 0.0001$  vs group B.

#### Statistical analysis

The significance of difference between the two groups was determined with Student's *t* test and Wilcoxon's rank-sum test.  $P < 0.05$  was considered significant.

## RESULTS

Serum sIL-2R levels were significantly higher in patients with chronic HBV infection than in healthy controls. Moreover, serum sIL-2R levels were significantly higher in patients with HBsAg (+), HBeAg (+) and anti-HBc (+) (group A,  $967.56 \pm 213.51 \times 10^3$  U/L) than in patients with HBsAg (+), HBeAg (+) and anti-HBc (–) (group B,  $393.41 \pm 189.54 \times 10^3$  U/L,  $P < 0.01$ ). ALT levels were significantly higher in group A ( $79 \pm 21.2 \times 10^3$  U/L) than in group B ( $24 \pm 12.3 \times 10^3$  U/L,  $P < 0.01$ ). Serum sIL-2R levels were significantly related to ALT levels. There was no significant difference in HBV DNA levels between the two groups (Table 1). Anti-HBc status was related to the age of the patients. Positive anti-HBc was detected in older patients ( $P < 0.01$ , Table 2).

## DISCUSSION

HBV infection is a major health problem. About 350 million persons are chronically infected with HBV in the world. HBV itself is non-cytopathic and it is widely accepted that the mechanism of hepatocellular injury is the host anti-viral immune response<sup>[9]</sup>. A human leukocyte antigen (HLA) class I-restricted cytotoxic T-lymphocyte (CTL) response to one or more HBV-encoded antigens on the hepatocyte membrane is a major mechanism of hepatocellular injury and clearance of infected cells<sup>[10]</sup>. Serum sIL-2R is predominantly released from activated T lymphocytes<sup>[11]</sup>. It was reported that serum sIL-2R levels reflect cellular IL-2 receptor expression<sup>[6]</sup>. Hence, levels of serum sIL-2R are useful in monitoring T-lymphocyte activity and serial measurement aids in assessing the progression of the disease<sup>[12]</sup>.

High levels of serum sIL-2R have been observed in patients with chronic HBV infection<sup>[7,8,12–14]</sup> and hepatitis C virus (HCV) infection<sup>[15]</sup>. Serum sIL-2R levels indicate the degree of liver damage in patients with chronic HBV infection<sup>[8]</sup>. Our results showed that serum sIL-2R levels were significantly higher in patients with chronic HBV infection than in healthy controls. The serum sIL-2R levels were significantly related to the serum ALT levels, but did not correlate with serum HBV DNA levels in patients with chronic HBV infection. These results are consistent with previous findings of Sawayama *et al*<sup>[8]</sup>.

Anti-HBc is detected in virtually all patients exposed

to HBV<sup>[16]</sup> and typically persists for life<sup>[17]</sup>. However, many patients with chronic HBV infection are negative for anti-HBc in China probably due to the fact that Chinese people acquire the infection at birth or during the early postnatal period<sup>[18,19]</sup>. These patients may have an immune tolerance to the virus for several decades of life<sup>[20,21]</sup>. We found that serum sIL-2R levels were significantly higher in patients with HBsAg (+), HBeAg (+) and anti-HBc (+) than in patients with HBsAg (+), HBeAg (+) and anti-HBc (-). Furthermore, patients with anti-HBc (+) were older than those with anti-HBc (-). Transfer of hepatitis B core antigen-reactive T cells is associated with the resolution of chronic HBV infection<sup>[22]</sup>. Based on these results, it seems that patients with chronic HBV infection who are negative for anti-HBc may be in a status of immune tolerance to the virus. Serum sIL-2R levels and anti-HBc may be useful indicators of immune status in patients with chronic HBV infection. Serum sIL-2R levels reflect the activation of T lymphocytes<sup>[5]</sup>. Hence, positive anti-HBc may be related to the activation of T lymphocytes.

Though interferon alpha to some extent hastens the loss of HBeAg in Chinese patients, the treatment is generally less effective than in white patients. This is probably due to the fact that the majority of Chinese people have a long period of immune tolerance to the virus<sup>[23]</sup>. Several studies have revealed that serum sIL-2R levels can serve as an index of the activation of T lymphocytes<sup>[5,6]</sup>. The serum sIL-2R level one year after interferon administration may be a useful marker of its therapeutic effectiveness<sup>[8]</sup>. Our results showed that elevated serum sIL-2R and positive anti-HBc were related to the high levels of serum ALT in patients with chronic HBV infection. Low serum ALT levels are associated with the poor response to interferon alpha treatment in patients with chronic HBV infection<sup>[23]</sup>. Hence, we can deduce that elevated serum sIL-2R levels, positive anti-HBc and high ALT concentrations may serve as indicators for interferon alpha treatment in Chinese patients with chronic HBV infection. However, further exploration is needed.

In conclusion, serum sIL-2R levels are related to anti-HBc and serum ALT concentrations, but not related to HBV DNA levels in patients with chronic HBV infection. Positive anti-HBc may be related to T-lymphocyte activation and negative anti-HBc may imply immune tolerance in these patients.

### Abstract

**AIM:** To investigate the role of nitric oxide (NO) in Toll-like receptor 2 (TLR2)/4mRNA expression in livers of acute hemorrhagic necrotizing pancreatitis (AHNP) rats.

**METHODS:** One hundred and ten SD male rats were randomly divided into sham-operated group ( $n=10$ ), AHNP group ( $n=30$ ), chloroquine (CQ)-treated group ( $n=30$ ) and L-Arg-treated group ( $n=40$ ). TLR2/4mRNA expression in the liver of AHNP rats was measured by RT-PCR.

**RESULTS:** Expression of TLR2/4mRNA could be detected in the liver of AHNP rats in sham-operated group ( $0.155\text{E-}5 \pm 0.230\text{E-}6$  and  $0.115\text{E-}2 \pm 0.545\text{E-}4$ ), but was markedly increased at 3 h in AHNP group ( $0.197\text{E-}2 \pm 0.114\text{E-}3$  and  $0.175 \pm 0.349\text{E-}2$ ) peaking at 12 h ( $0.294\text{E-}2 \pm 0.998\text{E-}4$  and  $2.673 \pm 2.795\text{E-}2$ ,  $P < 0.01$ ). Hepatic injuries were aggravated, TNF- $\alpha$  concentration in the liver was increased and NO concentration was decreased ( $P < 0.05$  or  $P < 0.01$ ). When TLR2/4mRNA expression was inhibited by CQ (3 h:  $1.037\text{E-}4 \pm 3.299\text{E-}6$  and  $0.026 \pm 3.462\text{E-}3$ ; 6 h:  $1.884\text{E-}4 \pm 4.679\text{E-}6$  and  $0.108 \pm 6.115\text{E-}3$ ; 12 h:  $2.443\text{E-}4 \pm 7.714\text{E-}6$  and  $0.348 \pm 6.807\text{E-}3$ ;  $P < 0.01$ ), hepatic injuries were relieved, NO concentration in the liver was increased and TNF- $\alpha$  concentration was decreased ( $P < 0.05$  or  $P < 0.01$ ). When rats with AHNP

were treated with L-Arg, TLR2/4mRNA expression in the liver could be effectively inhibited ( $50\text{ mg-T: } 0.232\text{E-}2 \pm 0.532\text{E-}4$  and  $0.230 \pm 6.883\text{E-}3$ ;  $100\text{ mg-T: } 0.210\text{E-}2 \pm 1.691\text{E-}4$  and  $0.187 \pm 0.849\text{E-}2$ ;  $200\text{ mg-T: } 0.163\text{E-}2 \pm 0.404\text{E-}4$  and  $0.107 \pm 0.195\text{E-}2$ ;  $400\text{ mg-T: } 0.100\text{E-}2 \pm 0.317\text{E-}4$  and  $0.084 \pm 0.552\text{E-}2$ ;  $P < 0.01$ ) and hepatic injuries were relieved. At the same time, NO concentration in the liver was markedly increased and TNF- $\alpha$  concentration was decreased ( $P < 0.05$  or  $P < 0.01$ ).

**CONCLUSION:** The expression of TLR2/4mRNA is increased and hepatic injuries are aggravated in the liver of AHNP rats. TLR2/4mRNA gene expression in the liver of AHNP rats can be markedly inhibited by NO, leading to the relief of hepatic injuries.

### INTRODUCTION

Acute hemorrhagic necrotizing pancreatitis (AHNP) is a serious disease of human beings with a high mortality and morbidity. AHNP could cause multiple organ dysfunction syndrome (MODS). Unfortunately, the pathogenesis and mechanism of AHNP are still unclear. Many researches indicate that diverse inflammatory factors such as tumor necrosis factor (TNF- $\alpha$ ), interleukin-1 (IL-1), IL-6 and reactive oxygen species result in systemic inflammatory response syndrome (SIRS) which might play an important role in the pathogenesis and development of AHNP<sup>[1-3]</sup>. It was reported that Toll-like receptor 2 (TLR2)/4 activated by stimulations can result in excessive production and release of cytokines<sup>[4]</sup>. In the present study, we have investigated the changes of TLR2/4 gene expression and the effect of NO on TLR2/4 gene expression in livers of AHNP rats.

## MATERIALS AND METHODS

Chloroquine (CQ) and sodium taurocholate (TAC) were purchased from Sigma (St. Louis, MO, USA). L-Arg was purchased from Cayman Chemical Company, USA. Trizol was purchased from Promega Co., Hong Kong, China. Reverse transcriptase RNase and DNA polymerase were purchased from TOYOBO CO., LTD, Japan. Serum-amylase and NO detection kits were provided by Jiancheng Biological Engineering Research Institute, Nanjing, China.

### Groups and models

One hundred and ten SD male rats (weighing 180-200 g) were purchased from Experimental Animal Center of Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China. Rats were randomized into sham-operated group (*n*=10), AHNP group (3, 6, and 12 h, units B-D, *n*=10), CQ-treated group (3, 6, and 12 h, units E-G, *n*=10), L-Arg-treated group (50, 100, 200, and 400 mg; units H-K; *n*=10).

AHNP was induced by infusion of 5% TAC (1 mL/kg) into biliopancreatic duct. After models of AHNP were made, L-Arg (100 mg/kg) was immediately injected via inferior vena to make L-Arg-treated models. Sham-operated models were made by flipping ceca. Samples of liver and blood were taken for analysis.

### Alanine aminotransferase, aspartate aminotransferase, AST, serum amylase, and NO concentrations in the liver

Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were detected to assess the degrees of hepatic injuries. ALT and AST concentrations were measured using an automatic biochemistry analyzer. Concentrations of serum amylase and NO in the liver were measured spectrophotometrically.

### TLR2/4 mRNA and TNF-α mRNA gene expression in the liver

The expression of TLR2/4mRNA and TNF-αmRNA in the liver was assayed by RT-PCR. The sequence of TLR2 primer was 5'-CGCTTCCTGA ACTTGTC-3' (sense), 5'-GGTTGTCACCTGCTTCCA-3' (anti-

sense) and 5'-ACTAAGAGGCGGAGCGGA-3' (fluorescent probe). The sequence of TLR4 primer was 5'-ATCATGGCATTTGTTCTTTCCT-3' (sense), 5'-CTGAGATTCTG ATCCATGCATTG-3' (anti-sense) and 5'-TCGGTAACG ACGGTTGTAG-3' (fluorescent probe). The sequence of TNF-α primer was 5'-CCCGTCG GAACAGGGAACCTT-3' (sense), 5'-GGGTGTCCTTAGGGCAAG-3' (anti-sense) and 5'-CGAGGAGGCGAACCACCAA-3' (fluorescent probe). The sequence of β-actin primer 5'-GAACGGTGAAGGTGACAG-3' (sense), 5'-TAGA GAGAGTGGGGTGG-3' (anti-sense) and 5'-ACCACAGCACCTGCGG GAT-3' (fluorescent probe). Results were obtained using FTC-2000 real-time instrument (Fengling Biotechnology Limited Company, Shanghai, China).

### Statistical analysis

The data were expressed as mean±SD. The differences between the two groups were assessed by Student's *t*-test. *P*<0.05 was considered statistically significant.

## RESULTS

### Serum amylase, ALT and AST concentrations

Serum amylase concentration was lower in CQ-treated and L-Arg-treated groups than in AHNP group (*t*: 2.087-2.195, *P*<0.05). ALT and AST concentrations were low in sham-operated group but significantly increased in AHNP group (*t*: 4.58-9.740, *P*<0.01). Administration of CQ or L-Arg significantly reduced ALT and AST concentrations in the liver (*t*: 1.074-8.765, *P*<0.05, Table 1).

### NO, TNF-α concentrations and TLR2/4mRNA expression

TNF-α was low in sham-operated group but significantly increased in AHNP group (*t*: 6.848-9.959, *P*<0.01). Administration of CQ or L-Arg significantly reduced TNF-α concentration in liver (*t*: 3.946-8.997, *P*<0.01). NO concentration was markedly lower in AHNP group than in sham-operated group (*t*: 2.403-8.521, *P*<0.05, CQ-treated group and L-Arg-treated group (*t*: 2.138-9.597, *P*<0.05). TLR2/4mRNA expression was low in sham-operated group but markedly increased at 3 h in AHNP group and peaked at 12 h (*t*: 2.193-9.623, *P*<0.01). TLR2/4mRNA expression was inhibited by CQ (*t*: 2.294-8.382, *P*<0.01), and L-Arg (*t*: 3.880-8.995, *P*<0.05; Table 2).

## DISCUSSION

Ten members have been identified from the mammalian TLR family<sup>[5,6]</sup>. TLRs belong to a wider superfamily, called IL-1 receptors/TLR superfamily, including receptors for the pro-inflammatory cytokines IL-1 and IL-18. All members possess cytoplasmic Toll/IL-1 receptor (TIR) domains. The TIR domain consisting of 160 amino acids is essential for signaling. TLRs are the key front-line sensors of invading microbes, responding to a wide range of microbial products through recognizing a different pathogen-associated molecular pattern (PAMP). At the same time, when TLRs are combined with PAMP, antigen presenting cells (APCs) are activated and produce co-

stimulatory molecules and cytokines, activating specific immune responses. TLR2/4 plays the most important role in responding to bacterial infections. TLR2 is the major receptor for PAMPs of Gram-positive bacteria, such as peptidoglycan and lipoteichoic acids. TLR4, the major receptor for LPS, are highly susceptible to infections with Gram-negative bacteria and fungal pathogens, such as lipopolysaccharide (LPS) and heat shock protein (HSP)<sup>[7]</sup>. Mechanisms responsible for TLR-mediated protection, potentiation of cytokine release, mediation of neutrophil recruitment to the site of infection and release of oxygen and nitrogen radicals, and contribute to TLR activation<sup>[8]</sup>. Researches showed that TLR2<sup>-/-</sup> or TLR4<sup>-/-</sup> mice have an increased susceptibility to infections<sup>[9-12]</sup>. NO produced from L-Arg by catalysis of nitric oxide synthase (NOS) is the only resource of NO in body<sup>[13]</sup>. In our experiment, rats were injected with L-Arg so that NO concentration in the bodies of rats was elevated. At the same time, it was reported that TLR2/4mRNA expression can be inhibited by CQ<sup>[14]</sup>. In the present study, we investigated the changes of TLR2/4 gene expression and NO concentration in the liver when TLR2/4mRNA expression was inhibited by CQ and the effect of NO on TLR2/4 gene expression in the liver of AHNP rats.

Enteric bacteria and endotoxin can result in aggravation of AHNP. In the course, enteric bacteria and endotoxin enter the liver through portal vein and are deactivated. But when the function of the liver is damaged or the quantity of enteric bacteria and endotoxin exceeds the endurance of liver, bacteria and endotoxin enter the blood and result in sepsis. At the same time, AHNP can lead to the dysfunction of the liver and even the failure of liver, suggesting that liver may play an important role in the pathogenesis and development of AHNP.

Our study showed that TLR2/4mRNA expression could be detected in sham-operated group (0.155E-5 $\pm$ 0.230E-6 and 0.115E-2 $\pm$ 0.545E-4), but markedly increased at 3 h in AHNP group (0.197E-2 $\pm$ 0.114E-3 and 0.175 $\pm$ 0.349E-2) and peaked at 12 h (0.294E-2 $\pm$ 0.998E-4 and 2.673 $\pm$ 2.795E-2,  $P$ <0.01). Hepatic injuries were aggravated, while TNF- $\alpha$  concentration increased and NO concentration decreased ( $P$ <0.05). When TLR2/4mRNA expression was inhibited

by CQ (3 h: 1.037E-4 $\pm$ 3.299E-6 and 0.026 $\pm$ 3.462E-3; 6 h: 1.884E-4 $\pm$ 4.679E-6 and 0.108 $\pm$ 6.115E-3; 12 h: 2.443E-4 $\pm$ 7.714E-6 and 0.348 $\pm$ 6.807E-3;  $P$ <0.01), hepatic injuries were relieved while NO concentration increased and TNF- $\alpha$  concentration decreased ( $P$ <0.05). When AHNP rats were treated with L-Arg, TLR2/4 mRNA expression was effectively inhibited (50 mg-T: 0.232E-2 $\pm$ 0.532E-4 and 0.230 $\pm$ 6.883E-3; 100 mg-T: 0.210E-2 $\pm$ 1.691E-4 and 0.187 $\pm$ 0.849E-2; 200 mg-T: 0.163E-2 $\pm$ 0.404E-4 and 0.107 $\pm$ 0.195E-2; 400 mg-T: 0.100E-2 $\pm$ 0.317E-4 and 0.084 $\pm$ 0.552E-2;  $P$ <0.01) and hepatic injuries were relieved. At the same time, NO concentration markedly increased and TNF- $\alpha$  concentration decreased ( $P$ <0.05).

When TLR2/4mRNA expression inhibited, synthesis and release of inflammatory factors decreased and hepatic injuries were relieved, suggesting that lower concentration of NO has the anti-inflammatory effect<sup>[15,16]</sup>. In our study, NO concentration in AHNP rats was decreased. When TLR2/4mRNA expression was inhibited by CQ, NO concentration increased, suggesting that TLR2/4mRNA expressions can be inhibited by NO. Our results suggest that synthesis and release of anti-inflammatory factors might be inhibited by TLR2/4mRNA expression and TLR2/4mRNA gene expression might play an important role in the pathogenesis and development of hepatic injury in AHNP.

Lower concentration of NO may exert its anti-inflammatory effect by reducing neutrophilic leukocytes, platelet and adhesion molecules, concentration of inflammatory factors in bronchoalveolar lavage, improving the pancreatic blood flow and pancreatic microcirculation, inhibiting the production of oxyradicals and cytokines, interaction of leukocytes and endotheliocytes.

NO may decrease TLR2/4mRNA expression by directly inhibiting production of cytokines, reducing differentiation of phagocytes and interaction between leukocytes and endotheliocytes. The results of our experiment provide evidence for the role of NO in TLR2/4mRNA expression in the liver of AHNP rats.

## Abstract

A 67-year old man was presented with a 6-mo history of recurrent right lower quadrant abdominal pain. On physical examination, a vague mass was palpable in the right lumbar region. His routine laboratory tests were normal. Ultrasonography showed a hypoechoic lesion in the right lumbar region anterior to the right kidney with internal echoes and fluid components. Abdominal contrast-enhanced computed tomography (CECT) showed a well-defined hypodense cystic mass lesion lateral to the ascending colon/caecum, not communicating with the lumen of colon/caecum. After complete open excision of the cystic mass lesion, gross pathologic examination revealed a turgid cystic dilatation of appendiceal remnant filled with the mucinous material. On histopathological examination, mucinous cyst adenoma of appendix was confirmed. We report this rare unusual late complication of mucocele formation in the distal viable appendiceal remnant, which was leftover following incomplete retrograde appendectomy. This unusual complication is not described in the literature and we report it in order to highlight the fact that a high index of clinical and radiological suspicion is essential for the diagnosis of mucocele arising from a distal viable appendiceal remnant in a patient who has already undergone appendectomy presenting with recurrent abdominal pain.

## INTRODUCTION

Appendiceal mucocele was first described by Rokitanski in 1842<sup>[1]</sup> and an unusual variant of appendiceal mucocele -myxoglobulosis was first described by Latham in 1897<sup>[1-3]</sup>. The term "mucocele of appendix"<sup>[4,5]</sup> is an inherently imprecise descriptive term that refers to any macroscopic (localised or diffuse) globular cystic dilatation of appendix (unilocular or multilocular) filled with thick tenacious mucoid/mucinous material regardless of underlying cause and is not a pathologic entity.

The majority of mucoceles of appendix arise secondary to proximal obstruction of appendiceal lumen in which the appendiceal lumen is usually in communication with caecum<sup>[6]</sup>. The potential causes of proximal appendiceal obstruction include faecolith, epithelial/mucosal hyperplasia, post inflammatory-fibrosis, cystadenoma, cystadenocarcinoma, carcinoid tumor, endometriosis and developmental anomalies such as occlusive membrane or obstructive diaphragm at the level of appendiceal orifice<sup>[7]</sup>. But the origin of mucocele of appendix from a distal viable leftover remnant tip of appendix not communicating with the caecum following incomplete retrograde open appendectomy has not been described.

We report such an extremely rare case of retention mucocele arising from a distal vascularized remnant of appendix tip, which is a leftover following incomplete open appendectomy.

## CASE REPORT

We report a 67-year old man who was presented with a 6-mo history of recurrent right lower quadrant abdominal pain not associated with vomiting. He had normal appetite and bowel habits. He was not a hypertensive and diabetic, neither an alcoholic nor a smoker. He underwent open appendectomy 15 years ago. At presentation his vital

**Figure 1** Ultrasonography shows a hypoechoic space occupying lesion measuring 6.5 cm × 3 cm × 6 cm in the right lumbar region anterior to right kidney (arrows). Internal echoes and fluid components are seen within the cystic mass (arrowheads) (A-C).

**Figure 2** CECT shows a well defined hypodense blind ending tubular lesion (arrows) measuring 6.8 cm × 3.1 cm × 3.0 cm (CT value +32 HU) in the right lumbar region lateral to ascending colon along the antimesenteric border not communicating with the lumen of colon (A-C). C=Caecum, AC=Ascending colon, M=Mucocoele, A=Distal appendiceal remnant not communicating with caecal lumen.

**Figure 3** Macroscopic/gross pathology. **A:** Perioperative photograph shows a turgid cystic mass measuring 6 cm × 5 cm × 3 cm in the distal appendicular remnant with a separate mesentery located adjacent to the pulled up caecum and not communicating with lumen of caecum (arrows); **B:** Resected specimen shows cystic dilatation of turgid distal appendicular remnant with surrounding fibrofatty, mesenteric, and omental tissues (arrow); **C:** Cut open resected specimen shows protruding mucinous material from the lumen of cystically dilated turgid distal appendicular remnant (arrow).

parameters and systemic examination were normal. On examination of abdomen, a vague mass was palpable in the right lumbar region suspicious of a retroperitoneal tumor. Rectal examination was normal.

Hemoglobin value was 13.8 gm/dL (reference range: 13.5-17.0 gm/dL) and other biochemical investigations, chest X-ray and electro-cardiogram were normal. Upper gastrointestinal (GI) endoscopy and colonoscopy study was normal. Ultrasonography revealed a 6.5 cm × 3 cm × 3.5 cm hypoechoic space-occupying lesion in the right lumbar

region anterior to the right kidney with internal echoes and fluid components which suggested retroperitoneal cyst (Figure 1). Abdominal CECT showed a well defined blind ending tubular hypodense lesion with CT value +32 Hounsfield unit (HU) in the right lumbar region lateral to the ascending colon along the antimesenteric border (Figure 2). The lesion was not communicating with lumen of the colon, which suggested colonic duplication cyst.

At laparotomy, a 6 cm × 3 cm mucus-filled turgid mass was found in the distal appendiceal remnant having a

**Figure 4** Histopathological microphotographs of mucinous cystadenoma of appendix. **A:** Low power microscopic view. Appendicular lumen shows mucinous secretions (1) with no epithelial elements. Mucosa lined by a single layer of mucinous columnar epithelium with basally situated nuclei (2) does not show any atypia with underlying lymphoid aggregates (3). **B,C:** High power microscopic view. Appendiceal lumen shows lakes of mucin (1) with no epithelial elements. Mucosa lined by a single layer of mucinous columnar epithelium with basally situated nuclei (2) does not show any atypia with underlying lymphoid aggregates (3).

separate mesentery with no communication with the cecum (Figure 3A). Complete surgical excision was performed with an uneventful recovery. Gross pathological examination showed a distended turgid appendiceal remnant filled with characteristic mucinous material (Figures 3B, 3C). Histopathological examination showed that the appendix was lined by a single layer of mucinous epithelium with basally situated nuclei which did not show any atypia with underlying lymphoid aggregates. The appendiceal lumen showed mucinous secretions (lakes of mucin) with no epithelial elements suggestive of mucinous cyst adenoma-appendix with no evidence of malignancy or dysplasia. (Figures 4A,4B,4C). The patient was symptom-free during a 6-mo follow-up period.

## DISCUSSION

Primary appendiceal mucocoele, a relatively uncommon clinical entity, is most frequently an incidental finding at the time of surgery and is occasionally discovered only at pathological examination<sup>[8]</sup>. The majority of these patients are not diagnosed preoperatively and in fact 60%<sup>[8]</sup> of them are diagnosed incidentally during surgery for some other disease. The incidence of appendiceal mucocoele is estimated to be 0.2-0.3% of appendicectomy specimens with myxoglobulosis constituting 0.35-0.8% of mucocoeles<sup>[7]</sup>.

Mucocoeles are histologically subdivided into four types on the basis of World Health Organization classification<sup>[4,8]</sup>.

Simple/non neoplastic mucocoele or retention mucocoele or obstructive form of mucocoele<sup>[5]</sup> is defined as cystic dilatation of the distal appendix with accumulation of abnormal mucoid material in the appendiceal lumen secondary to appendiceal outflow obstruction.

Benign neoplastic mucocoele-mucinous cystadenoma<sup>[5]</sup> is defined as dilated mucus /mucin filled appendix containing adenomatous mucosa lined by atypical mucinous epithelium containing basal nuclei and showing only minimal dysplastic features. Secondary changes<sup>[9]</sup> in mucinous cyst adenoma include thinning of the wall, extensive ulceration, calcification and ossification ("porcelain appendix")<sup>[5]</sup>. There is also a high association

between appendiceal mucinous cystadenoma with ovarian mucinous cyst adenoma and synchronous or metachronous neoplasms elsewhere in the colon<sup>[10]</sup>.

Malignant mucocoele<sup>[5]</sup>-mucinous cystadenocarcinoma is defined as adenocarcinoma associated with mucus-filled cystic dilatation of the appendix presenting as mucocoele. A malignancy is suspected at surgery in about 30%<sup>[4-5]</sup>. In the others the diagnosis is made during pathologic examination.

Cystadenocarcinoma<sup>[4]</sup> is grossly indistinguishable from a cystadenoma. But histologically<sup>[5]</sup> the former is distinguished from mucinous cystadenoma by three criteria: presence of invasive neoplasm below the level of muscularis mucosa, when the muscularis mucosa cannot be distinguished because of distortion or fibrosis, the diagnosis is made by the finding of infiltrative tongues of tumor or single tumor cells in the wall (infiltrative appearance of border of epithelial elements) as opposed to the broad pushing edge appearance of the borders of epithelial elements that characterize mucinous tumor of uncertain/undetermined malignant potential (UMP)<sup>[5,11]</sup>, presence of malignant epithelial cells in the lakes of mucin either in the wall of the appendix or outside the appendix.

Myxoglobulosis or Caviar appendix<sup>[5,7]</sup> is an extremely rare variant of appendiceal mucocoele caused by proximal obstruction of appendiceal lumen in which pieces of mucinous/mucoid material can become broken off the appendiceal wall into the appendiceal lumen resulting in the formation of characteristic pearl-like translucent "mucinous globules" or pearly luminal spheroids<sup>[7]</sup> or a "cluster of frog eggs"<sup>[12]</sup> 1-10 mm in diameter with surface calcification.

Mucocoele of appendix is most common in the sixth or seventh decade of life with a female preponderance<sup>[7]</sup>. The common presenting symptoms of appendiceal mucocoele are episodic right lower quadrant abdominal pain (27%)<sup>[8]</sup>, abdominal mass (16%)<sup>[8]</sup>, weight loss (10%)<sup>[8]</sup> and change in bowel habits (5%)<sup>[8]</sup>. Complications<sup>[12-13]</sup> of mucocoele include intussusception, bleeding, perforation, peritonitis, rupture and pseudomyxoma peritonei.

Colonoscopy may show a smooth glassy submucosal

or extra-mucosal caecal mass moving in and out with respiratory movement. This endoscopic sign has been described as the “trapped balloon sign”<sup>[14]</sup>. The classical CT scan findings<sup>[7, 15]</sup> of a mucocoele in a patient who has not undergone appendectomy are a cystic low attenuation well encapsulated round or ovoid mass with smooth regular walls in the right lower quadrant adherent to caecum, mural calcification in the wall of the mucocoele, and absence of peri-appendiceal inflammation or abscess which is the key differentiating point in excluding acute appendicitis. The presence of thickened wall and enhanced nodules favors the diagnosis of mucinous cystadenocarcinoma.

The clinical and radiological differential diagnosis<sup>[7, 13]</sup> of mucocoele of appendix includes mesenteric cyst, colonic duplication cyst, colonic lymphoma and lipoma, intussusception, right ovarian cyst and hydrosalpinx.

The treatment of mucocoele of appendix is essentially by simple appendectomy but in cases of rupture or suspected malignancy a standard right hemicolectomy is indicated<sup>[8]</sup>. At the time of surgery, a spontaneous appendiceal perforation or any extravasation from appendicular lumen is strongly suggestive of malignancy in such situations, a right hemicolectomy<sup>[8, 16]</sup> should always be performed with a curative intent. Laparoscopic appendectomy for mucocoele removal has been described, but caution has also been suggested because of the risk of port site recurrences<sup>[17]</sup>.

In a patient who has undergone open appendectomy, with the CT finding of a cystic well encapsulated mass in the right lumbar region adherent to the pulled up caecum/ascending colon not communicating with the lumen of colon/caecum, one should consider the possibility of mucocoele of distal appendiceal remnant. Therefore, a high index of clinical and radiological suspicion is essential for the preoperative diagnosis of mucocoele of distal appendiceal remnant in a patient who has undergone appendectomy. Incomplete surgical removal of appendix must be avoided in order to prevent the late complication of mucocoele formation in the distal leftover vascularized remnant tip of appendix. All appendiceal mucocoeles measuring at least 2 cm must be completely excised to eliminate the chance of progression to malignancy. The association between appendiceal mucocoele and colonic neoplasm is more clear and logical to recommend

surveillance colonoscopy in patients with diagnosis of appendiceal mucocoele, at least in those with appendiceal mucinous cystadenoma.

## Abstract

The introduction of transjugular intrahepatic portal-systemic stent-shunt (TIPSS) has been a major breakthrough in the treatment of portal hypertension, which has evolved to a large extent, into a routine procedure. A 21-year-old male patient with progressive graft fibrosis/cirrhosis requiring TIPSS for variceal hemorrhage in the esophagus due to portal hypertension was unresponsive to conventional measures two years after living related liver transplantation (LDLT). Subsequently, variceal hemorrhage was controlled, however, liver function decreased dramatically with consecutive multi organ failure. CT scan revealed substantial necrosis in the liver. The patient underwent successful "high urgent" cadaveric liver transplantation and was discharged on postoperative d 20 in a stable condition.

## INTRODUCTION

Transjugular intrahepatic portal-systemic stent-shunt

(TIPSS) is defined as artificial shunts between branches of the portal vein and the systemic circulation within the liver parenchyma, and is comparable to a surgical H-shunt with partial decompression of portal hypertension. The first TIPSS has been performed by Rösch *et al*<sup>[1]</sup> in 1969 in dogs. After the stage had been set for the implantation of stent-shunts into human beings, the first TIPSS was performed on a 49-year-old male patient with liver cirrhosis and bleeding from esophageal varices due to portal hypertension<sup>[2]</sup>. Since then this procedure has rapidly progressed to a well defined and established standard procedure for a wide variety of liver disorders, i.e., TIPSS is preferred for acute or recurrent variceal hemorrhage refractory to medical treatment, endoscopic sclerotherapy or banding<sup>[3]</sup>. Since TIPSS enables pre-transplant patients to recover from bleeding episodes and improves their general status before a graft becomes available, this procedure forms a bridge to liver transplantation<sup>[4]</sup>. The first 30-d mortality after TIPSS (up to 11%) is usually due to liver failure, acute respiratory distress syndrome, sepsis, recurrent hemorrhage, or right heart or multi organ failure<sup>[4]</sup>. Here we report a case of liver necrosis with subsequent organ failure making it necessary for high urgency (HU) cadaveric liver transplantation following TIPSS for conventionally uncontrolled variceal hemorrhage after living related liver transplantation (LDLT).

## CASE REPORT

A 21-year-old male patient underwent LDLT with biliodigestive anastomosis because of liver cirrhosis due to hereditary tyrosinemia type I and hepatocellular carcinoma (T<sub>3</sub>N<sub>0</sub>M<sub>0</sub>). After an uneventful transplantation, the postoperative course was further complicated by a bilioma followed by both a bilio-cutaneous fistula and chronic cholangitis. Two years after LDLT, the patient was referred to our institution and presented with progressive cholestasis, all signs of portal hypertension (i.e., varicose veins of the esophagus and hypersplenism) while graft function was still adequate, classified as Child-Pugh A. Post-contrast sequences of MRI originally performed to identify the total extent of the bilio-cutaneous fistula, showed perfusion of the liver was inhomogeneous with regular appearance of the intra- and extrahepatic portal venous branches, inferior vena cava (IVC) and hepatic artery (Figure 1A). For a complete

**Figure 1** Pre-TIPSS MRI/angiography and post-TIPSS macroscopy of the liver. Pictures illustrating pre-TIPSS inhomogeneous intrahepatic parenchyma texture (A); clinically irrelevant stenosis of the hepatic artery (B) and macroscopic aspect of the liver after TIPSS and organ failure due to substantial necrosis in areas where circulation was compromised before TIPSS (C).

**Figure 2** TIPSS-placement. Picture illustrating correctly placed TIPSS.

**Figure 3** Spiral-CT scan after TIPSS was established. Spiral-CT after TIPSS revealed substantial necrosis at the time of liver failure.

examination of the patient's preoperative status, a celiac-mesenteric angiography was performed which identified a stenosis of the arterial anastomosis, considered as hemodynamically irrelevant (Figure 1B). Revision of the biliodigestive anastomosis was performed and a y-Roux hepatojejunostomy after adhesiolysis was established to close the biliocutaneous fistula, which maintained cholangitis. Histology of the intraoperative biopsy revealed severe fibrosis associated with secondary biliary cirrhosis of the transplant. After surgery the patient recovered quickly; however, on postoperative d 10 recurrent variceal hemorrhage unresponsive to conventional measures, including endoscopic therapy, required TIPSS since surgery was not feasible at that time. TIPSS was performed in a standard procedure with an uncoated 8/39 Corinthian-Stent, which decreased the portacaval pressure gradient from 23 mmHg (measured after a 8 mm tract was established) to 8 mmHg at the end of the procedure (Figure 2). Subsequently, variceal hemorrhage in the esophagus stopped, however, serum transaminases, bilirubin and ammonia increased, while liver function decreased dramatically with fulminant consecutive multi organ failure within 3 postoperative days. At that time, a spiral-CT scan revealed both substantial disturbances of intrahepatic perfusion and necrosis, while TIPSS, extrahepatic portal vein, hepatic artery and IVC displayed normal (Figures 2 and 3). One day later, the patient underwent successful (HU) orthotopic cadaveric re-transplantation of the liver and was discharged in a stable condition thereafter on postoperative d 20.

## DISCUSSION

Biliary complications after LDLT are observed in 15-40% of patients, which can increase the risk of developing secondary biliary cirrhosis and all signs of portal hypertension (i.e. variceal bleeding)<sup>[5]</sup>. The significant decrease of portal flow to the liver after TIPSS, due to portal decompression, may result in decreased liver function. An increase in hepatic arterial flow, however, maintains sufficient liver function in most patients<sup>[9]</sup>. The latter is inadequate in a small number of patients and TIPSS results in liver failure<sup>[4]</sup>. Further, cirrhotic patients have a cirrhotic cardiomyopathy. This is important since TIPSS shunts a large blood volume back to the right heart and may impair cardiac function.

Till date most information of both arterial and portal venous hemodynamic in the liver are based on indirect scintigraphic or invasive electromagnetic measurement of blood flow during portosystemic shunt surgery. Burchell *et al*<sup>[6]</sup> demonstrated in their early work an increased blood flow in the hepatic artery after porto-caval shunting. Since no flow measurements were performed intravascularly, precise information on complex flow changes over time (i.e., detection of mechanisms of arterio-portal compensation) were impossible<sup>[6]</sup>. In the late sixties Hanson<sup>[7]</sup> and Lutz<sup>[8]</sup> hypothesized that both dilatation and contraction of the intrahepatic arterioles, which occur immediately after liver- or shunt-operations, can be defined as regulatory reflex-mediated responses to changes of pressure in the hepatic sinusoids. Richter *et al*<sup>[9]</sup> later demonstrated

online the dynamic changes of arterial and portal blood flow during partial porto-systemic decompression with TIPSS. Real-time monitoring of the arterial flow with endoluminal catheters revealed that arterial blood flow increased significantly and momentarily while portal venous flow decreased; however, total liver perfusion after TIPSS maintained steady in their studies. Since the fraction of arterial perfusion was increased after TIPSS, both pressure of portal venous perfusion and portal flow in hepatic sinusoids decreased. Reduced portal venous inflow in hepatic capillaries was compensated by an increased arterial perfusion. Since these changes in hepatic flow were immediately present in all the patients after TIPSS, underlying regulatory mechanisms that maintain a constant sinusoidal liver perfusion are most likely based on reflexes.

How can it be explained that major disturbances in hepatic circulation with subsequent liver necrosis and deterioration of liver function occurred after TIPSS in the case described above? Several factors most likely contributed to pathology: One major factor was the initially compensated stenosis of the hepatic artery, diagnosed with a celiac-mesenteric angiography (Figure 1B), which most likely prevented an increase in the arterial flow reserve to compensate for a decreased portal flow after TIPSS. Moreover, chronic inflammation (cholangitis) and liver cirrhosis may have also factored into the reduction of possible regulatory mechanisms stated above that compensated for reduced portal flow<sup>[10,11]</sup>. Therefore, severe dysfunction of the liver due to disturbances in hepatic perfusion, with subsequent necrosis of liver tissue, complicated treatment after TIPSS (Figures 1C and 3). In such cases, TIPSS should be indicated with great caution in centers where the salvage therapy, high urgent liver transplantation, can be performed.

## Abstract

As a disease commonly encountered in daily practice, acute appendicitis is usually diagnosed and managed easily with a low mortality and morbidity rate. However, acute appendicitis may occasionally become extraordinarily complicated and life threatening. A 56-year-old man, healthy prior to this admission, was brought to the hospital due to spiking high fever, poor appetite, dysuria, progressive right flank and painful swelling of the thigh for 3 d. Significant inflammatory change of soft tissue was noted, involving the entire right trunk from the subcostal margin to the knee joint. Painful disability of the right lower extremity and apparent signs of peritonitis at the right lower abdomen were disclosed. Laboratory results revealed leukocytosis and an elevated C-reactive protein level. Abdominal CT revealed several communicated gas-containing abscesses at the right retroperitoneal region with mass effect, pushing the duodenum and the pancreatic head upward, compressing and encasing inferior vena cava, destroying psoas muscle and dissecting downward into the right thigh. Laparotomy and right thigh exploration were performed immediately and about 500 mL of frank pus was drained. A ruptured retrocecal appendix was the cause of the abscess. The patient fully recovered at the end of the third post-operation week. This case reminds us that acute appendicitis should be treated carefully on an emergency basis to avoid serious complications. CT scan is the diagnostic tool of choice, with rapid evaluation followed by adequate drainage as the key to the survival of the patient.

**Key words:** Acute appendicitis; Retrocecal appendicitis; Complication; Retroperitoneal abscess; Thigh abscess

## INTRODUCTION

Acute appendicitis is a disease commonly encountered in daily practice, and a very low morbidity and mortality rate can be achieved with proper diagnosis and management at present<sup>[1,2]</sup>. Generally, a non-perforated acute appendicitis can be managed by urgent appendectomy, while perforated appendicitis which may be associated with the formation of localized abscess in the right iliac fossa or in the pelvic cavity, can be managed depending on their symptoms either by early appendectomy or by interval appendectomy following percutaneous drainage<sup>[3]</sup>. Even with a more severe form of ruptured appendicitis such as those complicated with diffuse peritonitis as commonly encountered in patients of pre-school age, the post-operative recovery is usually smooth<sup>[4]</sup>. However, acute appendicitis such as those forming appendiceal masses and extensive abscesses or resulting in intestinal obstruction may sometimes become more complicated and require a prolonged treatment period<sup>[3,4]</sup>. These complications should not be overlooked in order to avoid further sequelae. Hence, we present here a rare and critical case of ruptured retrocecal acute appendicitis with extensive formation of retroperitoneal and thigh abscess, re-emphasizing the importance of early diagnosis and prompt management for this common disease.

## CASE REPORT

A 56-year-old man was generally in good health when he first experienced right flank and right thigh pain with daily spiking fever of up to 39°C for 3 d. He also experienced progressive loss of appetite, epigastric fullness and painful disability of the right thigh. There was minimal abdominal pain initially, but this became more prominent over the right lower quadrant a few days later. He was brought to our hospital 3 d after the onset of the symptoms.

Physical examination on admission revealed an acute ill-

**Figure 1** Retroperitoneal and right thigh abscess in a patient with ruptured retrocecal appendicitis. **A:** Retroperitoneal abscess with mass effect, demonstrating the upward-pushed duodenum and pancreatic head as well as compressed and encased inferior vena cava (white arrowheads); **B:** suspicious septic thrombus inside inferior vena cava (white arrow); **C:** reconstructed coronal image demonstrating extensive involvement of the abscess (short black arrows); **D:** dissection of the abscess in the right thigh via the femoral canal just beneath the femoral vessels (long black arrow).

looking man with a body temperature of 39.6°C. He was slightly anemic in appearance and breathed both shallowly and rapidly at a rate of 28/min. He was lying in supine position with his right knee joint mildly flexed and hip joint externally rotated, being reluctant to move his right leg because of severe tenderness. A positive psoas stretch test was performed and the results indicated that there were significant inflammatory signs such as local heat, swelling, edema, and tenderness disclosed at areas involving the entire right trunk from right subcostal region to right knee joint, but no subcutaneous emphysema or crepitation was noted. Palpation of the abdomen revealed tenderness at right lower quadrant without muscle rigidity and no mass-like lesion was palpable. Laboratory data indicated leukocytosis with a WBC count of  $16.4 \times 10^6/\text{mL}$ , of which 80% were mature neutrophils and 3% were immature neutrophils. The hemoglobin level was slightly decreased to the level of 12.8 g/dL and his platelet count was also decreased to  $617 \times 10^6/\text{mL}$ . The C-reactive protein level was 26.1 mg/dL. All the other blood chemistry data were within the normal range. X-ray of the abdomen revealed an indistinct shadow of right psoas muscle. CT scan of the abdomen revealed formation of multiple gas-containing abscesses involving the entire right retroperitoneum with mass effect. At the upper abdominal region, the duodenum and pancreatic head were pushed upward by the abscess, the right perinephric space was filled with the abscess and the inferior vena cava at the same level was encased and compressed. There was also a suspicious septic thrombus inside the inferior vena cava. In addition to destroying the right psoas muscle, the abscess also dissected downward to the right thigh through the femoral canal, forming an abscess between muscle groups (Figure 1).

The patient underwent a laparotomy immediately for retroperitoneal exploration, which revealed more than 500 mL of feculent fluid collection in the above-mentioned locations. However, the intra-abdominal cavity

was clear without any contamination. A gangrenous ruptured appendix was identified with its entire length embedded in the retroperitoneum, draining fecal content into it and forming an abscess. Appendectomy was done cautiously making sure that no necrotic residual appendix remained in the retroperitoneal cavity. The abscess was communicated with those at the thigh as expected, through the femoral canal just behind the inguinal ligament, even though a separate incision was made at the right thigh to ensure complete drainage of the abscess. Fortunately, the muscle groups of the right thigh were still viable and therefore no debridement of the muscle was performed. Multiple sump drainages were inserted at the end of the operation. The bacterial culture revealed an *Escherichia coli* infection.

The patient recovered smoothly with his fever subsiding 2 d after surgery and oral intake resumed in 4 d. Painful disability of his right thigh improved immediately after surgery and he was able to walk 12 d later. The patient was discharged uneventfully 3 wk after the surgery.

## DISCUSSION

Acute appendicitis is the most common abdominal emergency worldwide and can usually be managed smoothly even if it is perforated. However, formation of retroperitoneal abscesses remains one of the most serious but rare complications of acute appendicitis and is always associated with perforation of a retrocecal appendix due to delayed diagnosis and treatment<sup>[5-7]</sup>. Knowing that the anatomical position of the appendix is variable and 65% of the appendix has been reported to be at the retrocecal<sup>[8]</sup>, the importance of early management for acute appendicitis cannot be over-emphasized.

There are quite a few case reports discussing related problems similar to the present case, such as psoas and thigh abscesses<sup>[9,10]</sup>, lower extremity subcutaneous

emphysema of abdominal origin<sup>[11-15]</sup> and rare complications of acute appendicitis<sup>[16,17]</sup>. Among these reports, descriptions are similar regarding patients' presentation and their management. In short, the onset of symptoms is usually insidious and atypical, initial medical treatment is usually unsuccessful. The causes of abscess formation are usually unclear before surgery and patients are usually critical on presentation. Surgical management is mandatory but may or may not be effective and mortality is not an uncommon result. In addition to the above-mentioned experiences, there are still some important issues that can be addressed based on our present case and a literature review.

First of all, it is still difficult to distinguish primary from secondary psoas abscesses. While the primary psoas abscess is defined as an abscess of unknown origin, its diagnostic symptoms and signs are almost identical to those of the secondary psoas abscess<sup>[9,10]</sup>. For example, the insidious onset of abscess formation is not responsive to medical treatment, the classical triads of psoas abscess such as fever, flank pain, and limitation of hip movement, can all present in both primary and secondary psoas abscesses<sup>[6-8,11]</sup>. After reviewing the information from the literature, we found that only the results of bacterial culture, if could be obtained before surgery, could indicate the nature of the abscess being primary or secondary. The most common causative pathogen of primary psoas abscess is *Staphylococcus aureus*, while that of secondary psoas abscess is usually mixed intestinal floras<sup>[9,10,12,18]</sup>.

Second, as CT scan is used as a modality in addition to the physical signs for definite diagnosis in most of the reported cases, there is no doubt that CT scan of the abdomen with contrast is the most widely-used imaging study with the highest accuracy and efficiency<sup>[5-10,19]</sup>. CT scan of the abdomen not only helps in the establishment of the diagnosis, but also in the evaluation of the extension of involvement and in its treatment. For example, application of advanced high speed helical CT (which was the case in this report and has never been demonstrated before) can demonstrate a reconstructed coronal image that is of great help for surgical planning because it simulates the operation field. In addition, the drainage of abscess can be achieved by percutaneous and retroperitoneal approach or by laparotomy based on CT findings.

Third, whether the abscess is managed surgically or non-surgically should be carefully evaluated. With the improving technique and the accumulating experiences of interventional radiology, there are several reports demonstrating substantial results by percutaneous drainage of the abscess and then by surgery only if percutaneous drainage fails or is contraindicated. For example, Benoist *et al*<sup>[20]</sup> demonstrated that percutaneous drainage can drain 81% postoperative abdominal abscesses in patients without sepsis at presentation. Cantasdemir *et al*<sup>[21]</sup> showed that primary and secondary iliopsoas abscesses can be successfully treated with percutaneous drainage in patients without secondary abdominal pathology. Percutaneous drainage of the abscesses is less invasive. Gerzof *et al*<sup>[22]</sup> have recommended that percutaneous drainage should be done for most complex abscesses, but we are still

uncertain if the percutaneous approach is adequate for our patient, because our patient was in a critical condition requiring prompt drainage of the abscess which cannot be achieved by percutaneous method and the infection could not be controlled if there was a persistent existing focus as previously reported by Ushiyama *et al*<sup>[15]</sup>. In addition, according to the results reported by Benoist *et al*<sup>[20]</sup> and Cantasdemir *et al*<sup>[21]</sup>, a combined therapy (that is drainage in combination with surgery) might be contraindicated in our patient because he was septic and had a persistent existing intra-abdominal focus. Hence, it is our experience that surgery is advantageous over percutaneous drainage in patients under critical conditions such as perforated appendicitis, diverticulitis or malignancy<sup>[14]</sup>.

Fourth, though abscesses inside the thigh is due to direct extension from retroperitoneum, it might be wise to create a separate incision at the thigh to drain the abscess rather than from the trunk. Draining thigh abscess by an incision at the thigh has two advantages. First, the abscess can be more easily and directly approached. Second, the viability of muscle and fascia of the thigh as well as the need for further debridement can be adequately evaluated. This is supported by the fact that some of thigh abscesses can be cured by drainage alone<sup>[6,7]</sup>, while others with extensive myonecrosis require debridement or amputation<sup>[5,13]</sup>.

In conclusion, formation of huge retroperitoneal abscesses with thigh involvement is a serious complication of perforated acute appendicitis. To improve the treatment outcome, patients with retroperitoneal infection should undergo CT scan in order to find the origin of the infection and to choose the best way to drain the abscess.

### Abstract

To our knowledge, stercoral perforation of the colon is rarely seen with fewer than 90 cases reported in the literature till date. We explored the principles of management to prevent impending mortality in five patients with this condition. Five patients, two males and three females, whose median age was 64 years, had sustained stercoral perforation of the sigmoid colon. Chronic constipation was the common symptom among these patients. Three patients underwent a Hartmann's procedure and another two were treated with segmental colectomy with anastomosis and diverting colostomy. There was one surgical mortality and the other patients had an uneventful hospital stay. Timely intervention to prevent and/or treat any associated sepsis along with extensive peritoneal lavage and surgical intervention to remove diseased colonic tissue at the primary stercoral ulceration site coupled with aggressive therapy for peritonitis are key treatment modalities in salvaging patients presenting with stercoral perforation of the colon.

### INTRODUCTION

Berry<sup>[1]</sup> presented the first case of stercoral perforation of the colon to the Pathological Society of London in 1894, and it is a rare event with fewer than 90 cases reported in the literature through 2002<sup>[2]</sup>. Stercoral perforation of the colon is an aggravating condition following successive bowel wall ischemic necrosis by fecal mass<sup>[3]</sup>, and dictates a rather poor clinical outcome in patients with a compromised general condition<sup>[4,5]</sup>. We reviewed the history of five patients of stercoral perforation of colon at our hospital, in order to elucidate the appropriate intraoperative procedures and obtain clinical results which will enhance the percentage of accurate preoperative diagnosis and clarify the most feasible perioperative management.

### CASE REPORTS

During the years 2001-2005, 22 patients with free perforation of the colon were hospitalized at Chang Gung Memorial Hospital in Chiayi. The etiology of perforation was cancer in nine patients, ruptured diverticulitis in five, iatrogenic colon perforation related to colonoscopy procedure in two, one patient with traumatic colon perforation, and the other five patients were diagnosed as stercoral perforation which fit the diagnostic criterion proposed by Maurer *et al*<sup>[3]</sup>.

These five patients formed the basis for this brief report (Tables 1 and 2). There were two men and three women aged between 4-84 years. All gave a long history of serious and chronic constipation except for a little girl. Four patients also had concomitant diseases that might have enhanced the development of chronic constipation such as diabetic enteropathy, hypothyroidism, and hemiparesis sequelae of stroke.

These five patients presented with sudden and severe abdominal pain. On physical examination, diffuse peritonitis was present in all the patients along with high fever and leukocytosis. Four patients were found to have sub-diaphragmatic free air on a standing chest roentgenogram, but only one showed localized extraluminal air on abdominal CT scanning. All patients underwent emergency laparotomy by a general surgeon with a preoperative diagnosis of hollow organ perforation. The colorectal surgeon was summoned during surgery to verify an intraoperative finding of colonic perforation. All perforation sites were found to be located at the

Table 1 Perioperative data on patients with stercoral perforation of the colon

Patient Number	Gender	Age	Interval (day) <sup>1</sup>	Case history	X-ray finding	Peritonitis	Localization	Perforation size (cm) and site	Fecaloma
A	F	4	1	Chronic constipation	Subdiaphragmatic free air	Generalized	Mid-sigmoid Colon	1 × 0.8 Anti-mesocolic	Within abdominal cavity
B	M	70	3	Chronic constipation, Cushing's syndrome	Subdiaphragmatic free air	Generalized	Rectosigmoid colon junction	5 × 3 Anti-mesocolic	Within the colon
C	F	84	2	Chronic constipation, D.M.	Subdiaphragmatic free air	Generalized	Sigmoid Colon	3 × 2, Anti-mesocolic	Protruding through perforation
D	F	79	1	Chronic constipation, stroke	Subdiaphragmatic free air	Lower abdomen	Mid-sigmoid Colon	2.5 × 1.5, Anti-mesocolic	Within the colon

E	Purulent ascites	<i>E. coli</i> , <i>Enterococcus faecium</i> , <i>Bacteroides sp.</i>	Yes (80, A-colon)	No ulceration	Hartmann's operation+rectal mucus fistula	Massive	Fascial dehiscence

<sup>1</sup>Heavy flora cultured as. <sup>2</sup>(cm) distance at the most proximal to perforation and location. <sup>3</sup>Massive: >10 000 mL; moderate: <6 000 mL; plenty: 1 500 mL.

antimesenteric part of the sigmoid colon with perforations ranging in size from 2 to 5 cm. The perforation margins were well circumscribed with no local inflammation or any other chronic process. Three patients underwent a Hartmann's operative procedure with colostomy and rectal mucous fistula, another two patients were treated with segmental resection of the diseased colon with anastomosis and diverting enterostomy.

During the operation four patients, with the exception of the little girl, underwent colonoscopy to clarify the extent of the lesion of severe stercoral ulceration with impending colon perforation. Colon lavage was also performed as permitted by the proximity of the lesion.

Hemodynamic improvement and reversal of hypotensive status was noted immediately after colectomy was performed.

Intraperitoneal irrigation with massive amounts of warm normal saline solution and adequate placement of drainage tubes preceded the closure of the celiotomy incision.

All patients received broad-spectrum intravenous antibiotics and nutritional support for the duration of their hospital stay. Diverting enterostomy was closed in two patients 3 mo later. Hartmann's procedure was reversed in two patients after a minimum time of one and a half years. There were one surgical mortality due to overwhelming sepsis, morbidities due to superficial wound infection in two patients and fascial dehiscence in one patient, respectively.

## DISCUSSION

Colon perforation is a rather uncommon event usually caused by malignancy, amoebic colitis, diverticular disease, spontaneous perforation, stercoral ulceration, steroid therapy, trauma, and ulcerative colitis<sup>[4]</sup>. The usual definition of stercoral perforation is "Perforation of the large bowel due to pressure necrosis from a fecal mass"<sup>[6]</sup>, and represents a cause of colon perforation. Stercoral perforation of the colon was very rare for it was

first described in 1894 and less than 90 cases have been reported in the literature till date. We had five patients (22%) with this condition presenting as colonic perforation (22 patients) at our hospital, and it was said to be the largest series involving stercoral perforation of the colon in a single medical institute within a short-term interval.

Severe chronic constipation is considered to be the main causative factor in the development of stercoral perforation of the colon<sup>[4,6-8]</sup>. In our series, each patient had a long history of chronic constipation requiring medication for relief; the youngest female patient did not have congenital Hirschsprung's disease based on the pathologic examination of the colectomy specimen.

Long-standing constipation may enhance the formation of stone-hard fecalomas and maintain a persistent pressure over the bowel wall leading to pressure necrosis of the mucosa. Nevertheless, stercoral ulceration of colonic mucosa does not always occur among constipation cases, and not every stercoral ulceration results in colon perforation.

Multiple fecalomas can result in multiple stercoral ulcerations<sup>[6]</sup>. One of our five patients and 28% of the cases found in the literature showed this characteristic feature. There are several reasons why the perforation sites are located in the antimesenteric aspect and in the sigmoid colon: (1) Hypoperfusive status existing in the antimesenteric aspect other than the mesenteric border; (2) due to its more distal location and more solid consistency, fecalomas tend to form in more distal aspects of the large intestine such as the sigmoid colon; (3) being the most narrow region of the entire large intestine stool has difficulty passing through the sigmoid colon which increases the intraluminal pressure to the point where it can compress submucosal capillary vessels and reduce perfusion of the colonic wall; (4) prolonged localized pressure on the colon wall causing pressure ulcerations to appear<sup>[3,5,9]</sup>. In this series of patients perforation was only found in the anti-mesenteric margin of the sigmoid colon and not in other colonic site.

Treatment of intra-abdominal sepsis was achieved by massive saline irrigation and perforation control with the intention of decreasing the bacterial load in the abdominal cavity and deterring the development of overwhelming sepsis<sup>[10]</sup>.

The single mortality in this series differed from the other four cases in the reduced amount of peritoneal lavage received due to intraoperative hypothermia.

Broad spectrum antibiotics were initiated in all the patients after hospital admission for polymicrobial peritoneal cavity contamination resulting from intestinal perforation<sup>[11]</sup>.

In reviewing the literature, it was noted that intraoperative colonoscopy to inspect the remainder of the colon for stercoral ulceration was not undertaken in cases of stercoral perforation of the colon. To our knowledge, we are the first group to perform intraoperative colonoscopic examination.

The purpose of intraoperative colonoscopic examination was to ensure the adequacy of the colonic resection and rule out the presence of additional stercoral ulcerations that might lead to delayed colonic perforation.

Intraoperative colonoscopy was performed within 10 min after the colon was cleared of impacted stools.

Only one patient was found to have more than one stercoral ulceration of the entire colon. Colectomy was performed to remove all stercoral ulcerated lesions in this patient, unfortunately, due to an immuno-compromised state the patient expired after developing overwhelming sepsis.

Maurer *et al*<sup>[3]</sup> postulated that colonic dilation and the presence of multiple fecalomas may indicate such additional stercoral ulceration and carried the risk of a second perforation. We concur with this point of view based on the findings during intraoperative colonoscopy in our series and recommend removing pathologically altered or dilated colon segments to prevent another episode of colon stercoral perforation.

Mortality related to colon stercoral perforation was reported to be high<sup>[4,6,9]</sup>. Analysis of the reports in the literature revealed additionally that 28% of patients with stercoral perforation of the colon have multiple stercoral ulcers in the colon and that substantial mortality is encountered if only minor surgical procedures are employed as treatment such as simple exteriorization of the perforation site or closure of perforation hole with the addition of a diverting enterostomy<sup>[6,9]</sup>.

Two review articles<sup>[6,9]</sup> and one series<sup>[3]</sup> with optimal clinical outcome in relation to the treatment of colonic stercoral perforation recommended that resection of the colon segment with an end colostomy and either mucous fistula or Hartmann's closure of the rectum would encounter comparatively low mortality. In our series, we took surgery of resection of colon with anastomosis and loop diverting colostomy in two patients (case 1 and case 4) with limited intraperitoneal septic condition and acceptable general condition. There were some advantages doing this procedure such as simple closure of colostomy someday. The other three patients were performed Hartmann's procedure with rectal mucous fistula.

In our series, we undertook surgical colonic resection with anastomosis and loop diverting colostomy in two patients (case 1 and case 4) with limited intraperitoneal sepsis and an acceptable general medical condition. The advantage of performing this procedure resides in the possibility of performing a simple closure of the colostomy in the future. The other three patients underwent Hartmann's procedure with rectal mucous fistula.

Stercoral perforation of the colon is not purely a surgical condition as it is usually complicated by a medical illness such as a superimposed immuno-compromised state which imparts a poor prognosis. Despite efforts to correct Cushing's syndrome, sufficient nutritional support and aggressive antibiotics therapy, it was not possible to prevent the systemic sepsis in case 2.

In conclusion, a favorable outcome in the treatment of stercoral perforation depends upon: (1) immediate treatment of any underlying sepsis; (2) removal of all stercoral ulcerated diseased colonic tissue; (3) extensive peritoneal lavage; (4) aggressive therapy to counteract colonic perforation peritonitis and (5) appropriate treatment of any co-morbid medical conditions. Prompt

institution of these measures will enhance survival of the patient and contribute to achieving a low mortality rate in stercoral perforation of the colon.

## Meetings

### MAJOR MEETINGS COMING UP

Digestive Disease Week  
107th Annual Meeting of AGA, The American  
Gastroenterology Association  
May 20-25, 2006  
Loas Angeles Convernion Center, California  
www.ddw.org

### EVENTS AND MEETINGS IN THE UPCOMING 6 MONTHS

10 th World Congress of the International Society  
for Diseases of the Esophagus (ISDE 2006)  
February 22-25, 2006  
Adelaide  
isde@sapmea.asn.au  
www.isde.net

EASL 2006 - The 41<sup>st</sup> Annual Meeting  
April 26-30, 2006  
Vienna, Austria

International Gastrointestinal Fellows Initiative  
February 22-24, 2006  
Banff, Alberta  
CAGOffice@cag-acg.org  
www.cag-acg.org

Canadian Digestive Disease Week  
February 24-27, 2006  
Banff, Alberta  
CAGOffice@cag-acg.org  
www.cag-acg.org

European Multidisciplinary Colorectal Cancer  
Congress 2006  
February 12-14, 2006  
Berlin  
info@congresscare.com  
www.colorectal2006.org

ILTS 12th Annual International Congress  
May 3-6, 2006  
Milan  
www.ils.org

World Congress on Gastrointestinal Cancer  
June 14-17, 2006  
Barcelona, Spain  
c.chase@imedex.com

5<sup>th</sup> International Congress of The African Middle  
East Association of Gastroenterology  
February 24-26, 2006  
Sharjah  
infoevent@infomedweb.com

October 20-25, 2006  
Venetian Hotel, Las Vegas, Nevada

AASLD 57<sup>th</sup> Annual Meeting - The Liver Meeting™  
October 27-31, 2006  
Boston, MA

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7<sup>th</sup>, 14<sup>th</sup>, 21<sup>st</sup> and 28<sup>th</sup> of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc.*, from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

**Published by**  
The WJG Press

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297mm×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

#### Online submission

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to [wjg@wjgnet.com](mailto:wjg@wjgnet.com) for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

#### Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4(297 mm×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or \*.rtf format to:

#### Editorial Office

*World Journal of Gastroenterology*  
Editorial Department: Apartment 1066, Yishou Garden,  
58 North Langxinzhuang Road,  
PO Box 2345, Beijing 100023, China  
E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)  
<http://www.wjgnet.com>

### MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

#### Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full

address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

#### Abstract

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

#### Key words

Please list 3-10 key words that could reflect content of the study mainly from *Index Medicus*.

#### Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

#### Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm×76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

#### Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

#### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P*<0.05, <sup>b</sup>*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P*<0.05 and <sup>d</sup>*P*<0.01 are used. Third series of *P* values can be expressed as <sup>e</sup>*P*<0.05 and <sup>f</sup>*P*<0.01. Other notes in tables or under illustrations should be expressed as <sup>1</sup>*F*, <sup>2</sup>*F*, <sup>3</sup>*F*; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

#### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

### PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

### Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>)

### Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

### Format

Standard journal article (list all authors and include the PubMed ID [PMID] where applicable)

- 1 **Das KM**, Farag SA. Current medical therapy of inflammatory bowel disease. *World J Gastroenterol* 2000; 6: 483-489 [PMID: 11819634]
- 2 **Pan BR**, Hodgson HJF, Kalsi J. Hyperglobulinemia in chronic liver disease: Relationships between *in vitro* immunoglobulin synthesis, short lived suppressor cell activity and serum immunoglobulin levels. *Clin Exp Immunol* 1984; 55: 546-551 [PMID: 6231144]
- 3 **Lin GZ**, Wang XZ, Wang P, Lin J, Yang FD. Immunologic effect of Jianpi Yishen decoction in treatment of Pixu-diarrhoea. *Shijie Huaren Xiaobua Zazhi* 1999; 7: 285-287

Books and other monographs (list all authors)

- 4 **Sherlock S**, Dooley J. Diseases of the liver and biliary system. 9th ed. Oxford: Blackwell Sci Pub, 1993: 258-296

Chapter in a book (list all authors)

- 5 **Lam SK**. Academic investigator's perspectives of medical treatment for peptic ulcer. In: Swabb EA, Azabo S. Ulcer disease: investigation and basis for therapy. New York: Marcel Dekker, 1991: 431-450

Electronic journal (list all authors)

- 6 **Morse SS**. Factors in the emergence of infectious diseases. *Emerg Infect Dis* serial online, 1995-01-03, cited 1996-06-05; 1(1):24 screens. Available from: URL: <http://www.cdc.gov/ncidod/EID/eid.htm>

### Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

### Statistical data

Present as mean  $\pm$  SD and mean  $\pm$  SE.

### Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as *r* (in italics), degree of freedom as  $\gamma$  (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

### Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4  $\pm$  2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5  $\mu$ g/L; CO<sub>2</sub> volume fraction, 50 mL/L CO<sub>2</sub> not 5% CO<sub>2</sub>; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

### Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

### Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindII*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *Helicobacter pylori*, *H pylori*, *E coli*, etc.

## SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

### Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

### Copyright assignment form

It is the policy of *WJG* to acquire copyright in all contributions. Papers accepted for publication become the copyright of *WJG* and authors will be asked to sign a transfer of copyright form. All authors must read and agree to the conditions outlined in the Copyright Assignment Form (which can be downloaded from <http://www.wjgnet.com/wjg/help/9.doc>).

### Final check list for authors

The format is at: <http://www.wjgnet.com/wjg/help/13.doc>

### Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: <http://www.wjgnet.com/wjg/help/10.doc>

### Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

### Publication fee

Authors of accepted articles must pay publication fee.

EDITORIAL and LETTERS TO THE EDITOR are free of charge.

## World Journal of Gastroenterology standard of quantities and units

Number	Nonstandard	Standard	Notice
1	4 days	4 d	In figures, tables and numerical narration
2	4 days	four days	In text narration
3	day	d	After Arabic numerals
4	Four d	Four days	At the beginning of a sentence
5	2 hours	2 h	After Arabic numerals
6	2 hs	2 h	After Arabic numerals
7	hr, hrs,	h	After Arabic numerals
8	10 seconds	10 s	After Arabic numerals
9	10 year	10 years	In text narration
10	Ten yr	Ten years	At the beginning of a sentence
11	0,1,2 years	0,1,2 yr	In figures and tables
12	0,1,2 year	0,1,2 yr	In figures and tables
13	4 weeks	4 wk	
14	Four wk	Four weeks	At the beginning of a sentence
15	2 months	2 mo	In figures and tables
16	Two mo	Two months	At the beginning of a sentence
17	10 minutes	10 min	
18	Ten min	Ten minutes	At the beginning of a sentence
19	50% (V/V)	500 mL/L	
20	50% (m/V)	500 g/L	
21	1 M	1 mol/L	
22	10 μM	10 μmol/L	
23	1N HCl	1 mol/L HCl	
24	1N H <sub>2</sub> SO <sub>4</sub>	0.5 mol/L H <sub>2</sub> SO <sub>4</sub>	
25	4rd edition	4 <sup>th</sup> edition	
26	15 year experience	15- year experience	
27	18.5 kDa	18.5 ku, 18 500u or M:18 500	
28	25 g.kg <sup>-1</sup> /d <sup>-1</sup>	25 g/(kg·d) or 25 g/kg per day	
29	6900	6 900	
30	1000 rpm	1 000 r/min	
31	sec	s	After Arabic numerals
32	1 pg L <sup>-1</sup>	1 pg/L	
33	10 kilograms	10 kg	
34	13 000 rpm	13 000 g	High speed; g should be in italic and suitable conversion.
35	1000 g	1 000 r/min	Low speed. g cannot be used.
36	Gene bank	GenBank	International classified genetic materials collection bank
37	Ten L	Ten liters	At the beginning of a sentence
38	Ten mL	Ten milliliters	At the beginning of a sentence
39	umol	μmol	
40	30 sec	30 s	
41	1 g/dl	10 g/L	10-fold conversion
42	OD <sub>260</sub>	A <sub>260</sub>	"OD" has been abandoned.
43	One g/L	One microgram per liter	At the beginning of a sentence
44	A260 nm <sup>b</sup> P<0.05	A <sub>260</sub> nm <sup>a</sup> P<0.05	A should be in italic. In Table, no note is needed if there is no significance instatistics: <sup>a</sup> P<0.05, <sup>b</sup> P<0.01 (no note if P>0.05). If ther is a second set of P value in the same table, <sup>c</sup> P<0.05 and <sup>d</sup> P<0.01 are used for a third set: <sup>a</sup> P<0.05, <sup>b</sup> P<0.01.
45	<sup>*</sup> F=9.87, <sup>§</sup> F=25.9, <sup>#</sup> F=67.4	<sup>1</sup> F=9.87, <sup>2</sup> F=25.9, <sup>3</sup> F=67.4	Notices in or under a table
46	KM	km	kilometer
47	CM	cm	centimeter
48	MM	mm	millimeter
49	Kg, KG	kg	kilogram
50	Gm, gr	g	gram
51	nt	N	newton
52	l	L	liter
53	db	dB	decibel
54	rpm	r/min	rotation per minute
55	bq	Bq	becquerel, a unit symbol
56	amp	A	ampere
57	coul	C	coulomb
58	HZ	Hz	
59	w	W	watt
60	KPa	kPa	kilo-pascal
61	p	Pa	pascal
62	ev	EV	volt (electronic unit)
63	Jonle	J	joule
64	J/mm <sup>3</sup>	kJ/mol	kilojoule per mole
65	10×10×10cm <sup>3</sup>	10 cm×10 cm×10 cm	
66	N·km	KN·m	moment
67	x±s	mean±SD	In figures, tables or text narration
68	Mean±SEM	mean±SE	In figures, tables or text narration
69	im	im	intramuscular injection
70	iv	iv	intravenous injection
71	Wang et al	Wang <i>et al.</i>	
72	EcoRI	EcoRI	<i>Eco</i> in italic and RI in positive. Restriction endonuclease has its prescript form of writing.
73	Ecoli	<i>E.coli</i>	Bacteria and other biologic terms have their specific expression.
74	Hp	<i>H pylori</i>	
75	Iga	<i>Iga</i>	writing form of genes
76	igA	IgA	writing form of proteins
77	~70 kDa	~70 ku

## Abstract

Hepatic fibrosis is a wound healing response, involving pathways of inflammation and fibrogenesis. In response to various insults, such as alcohol, ischemia, viral agents, and medications or hepatotoxins, hepatocyte damage will cause the release of cytokines and other soluble factors by Kupffer cells and other cell types in the liver. These factors lead to activation of hepatic stellate cells, which synthesize large amounts of extracellular matrix components. With chronic injury and fibrosis, liver architecture and metabolism are disrupted, eventually manifesting as cirrhosis and its complications. In addition to eliminating etiology, such as antiviral therapy and pharmacological intervention, it is encouraging that novel strategies are being developed to directly address hepatic injury and fibrosis at the subcellular and molecular levels. With improvement in understanding these mechanisms and pathways, key steps in injury, signaling, activation, and gene expression are being targeted by molecular modalities and other molecular or gene therapy approaches. This article intends to provide an update in terms of the current status of molecular therapy for hepatic injury and fibrosis and how far we are from clinical utilization of these new therapeutic modalities.

## INTRODUCTION

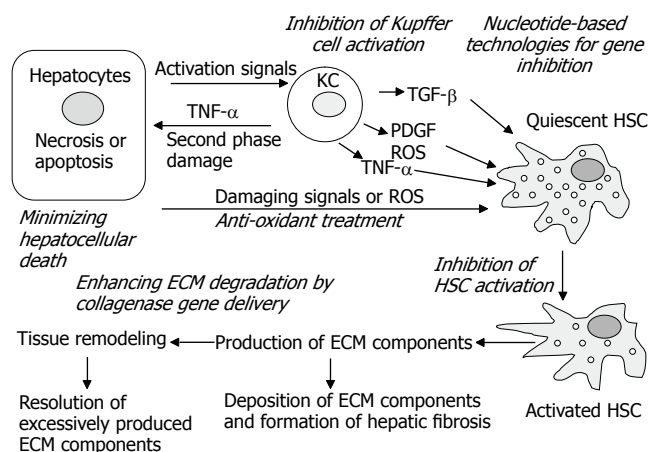

Hepatic fibrosis is a wound-healing process after chronic liver injury, and is characterized by the activation of hepatic stellate cells (HSC) and excess production of extracellular matrix (ECM) components. The activation of HSC involves the transdifferentiation from a quiescent state into myofibroblast-like cells with the appearance of smooth muscle  $\alpha$ -actin (SMA) and loss of cellular vitamin A storage<sup>[1]</sup>. The activated HSC are distinguished by accelerated proliferation and enhanced production of ECM components. Cross-talks between parenchymal and non-parenchymal cells constitute the major interactions in the development of hepatic injury and fibrosis. Soluble factors, such as cytokines, chemokines or reactive oxygen species (ROS) are the intermediates in these cross-talks, and are possible targets for therapeutic consideration. A schematic illustration shown in Figure 1 represents the major cascades of the injury process, including the interactions between damaged hepatocytes and Kupffer cell activation, proliferation and activation of HSC, and the excess production of ECM components during hepatic fibrosis. Along with these cascades, possible molecular therapeutic targets are provided in *italics*. From our improved understanding of the mechanisms underlying liver injury and fibrosis, key steps, such as signaling, activation, and gene expression in specific cell types of the liver, have been targeted by molecular modalities<sup>[2,3]</sup>. However, various molecular therapeutic approaches carry advantages and disadvantages and patient safety is the primary concern in considering the use of novel modalities<sup>[4]</sup>. Thus, people may ask: "What is the current status of molecular therapy for hepatic injury and fibrosis?" "How far from now these novel modalities will be possibly utilized in patients?" This concise review intends to answer these questions.

## TARGETING SPECIFIC MOLECULES OR PATHWAYS

### *Inhibition of hepatocellular apoptosis*

Chronic hepatocellular death via necrosis and/or apoptosis initiates inflammatory responses and hepatic fibrogenesis. Ideally, hepatocytes regenerate and replace dying cells; however, hepatocellular regeneration in chronic liver injury is often inhibited due to the imbalance of growth factors and distortion of liver architecture and circulation. Cellular debris and apoptotic bodies accumulate and initiate inflammatory responses, which may form a self-amplifying loop that further compromises recovery from injury, and facilitates the fibrogenic process<sup>[5]</sup>. HSC may

**Figure 1** Strategies for the prevention and treatment of hepatic fibrosis. A simplified version of the pathogenesis of hepatic fibrosis is illustrated schematically. At various stages, possible therapeutic strategies are provided in *italics*. See the text for details. KC = Kupffer cells; ECM = extracellular matrix; HSC = hepatic stellate cells; PDGF = platelet-derived growth factor; ROS = reactive oxygen species; TNF- $\alpha$  = tumor necrosis factor- $\alpha$ ; TGF- $\beta$  = transforming growth factor- $\beta$ .

engulf the apoptotic bodies, which has been demonstrated *in vitro*, and phagocytosis of apoptotic bodies by quiescent HSC facilitates the phenotypic transdifferentiation to myofibroblasts<sup>[6]</sup>. Activated HSC with engulfed apoptotic bodies were identified in a rat model of bile-duct ligation and liver biopsy specimens from HCV infection<sup>[7]</sup>.

Tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) (via TNF-receptor-1) can initiate apoptosis<sup>[8,9]</sup>. This extrinsic pathway is signaled through cell surface death receptors<sup>[9]</sup>, including Fas (also known as CD95), TNF- $\alpha$ -receptor-1, and TNF- $\alpha$ -related-apoptosis-inducing-ligand receptors 1 & 2 (TRAIL-R1 and R2). Examples of this extrinsic pathway of programmed cell death include autoimmune hepatitis, viral hepatitis<sup>[10,11]</sup>, chronic alcohol consumption, D-galactosamine (GalN) plus lipopolysaccharide (LPS)-induced acute liver injury, and ischemia/reperfusion-associated liver injury. In these forms of injury, cytotoxic cytokines or chemokines play a crucial role in the mediation of the injury process<sup>[12-18]</sup>. In contrast to the extrinsic apoptotic pathway, the intrinsic pathway is based on damage or dysfunction of intracellular organelles, such as lysosomes, endoplasmic reticulum, nucleus and mitochondria<sup>[19]</sup>. This mechanism involves changes in membrane permeability and integrity of the subcellular organelles. Examples are that damage to nuclear or mitochondrial DNA can initiate apoptosis, and that the release of cytochrome C from mitochondria triggers apoptotic cascades. This intrinsic pathway of programmed cell death is often seen in drug toxicity or hepatotoxin-induced liver injury, such as acetaminophen overdose, alcohol toxicity, *etc*<sup>[18,20]</sup>.

Inhibiting apoptosis will alleviate liver injury, and in turn, delay or stop the progression of hepatic fibrosis. Molecular therapy has specifically targeted various steps in the apoptosis pathway including inhibition of cell death receptors, mediators of the apoptosis cascade, and regulation of the apoptosis cascade. One target is to inhibit Fas receptor expression, which signals the initiation of the apoptosis cascade. Another possible target includes inhibition of caspase expression. Caspases are proteolytic

enzymes classified according to their function into ICE-like caspases (caspase 1, 4, 5, 13), death signaling or initiator caspases (caspase 2, 8, 9, 10), and death effector or executioner caspases (caspase 3, 6, 7).

Zhang *et al*<sup>[21]</sup> employed antisense oligodeoxynucleotide (ODN) ISIS 22023, specific for mouse Fas to prevent Fas ligand (Jo2 or CD95)-induced fulminant liver failure and mortality. Antisense ODN treatment reduced Fas mRNA and protein expression in the liver by 90%, and completely prevented mortality which was 100% in the control group with extensive hepatocyte apoptosis and liver hemorrhage. In a separate study, Song *et al*<sup>[22]</sup> evaluated small interfering RNA (siRNA) against Fas for its ability to inhibit apoptosis and protect the liver in the same animal model. siRNA against the Fas receptor was administered via tail vein injection, which led to 88% of uptake by hepatocytes. The injection decreased Fas mRNA expression by 8 to 10-fold when compared to controls, and the decline in Fas mRNA and Fas protein was sustained for up to 10 d. Control mice displayed bridging fibrosis, whereas mice receiving anti-Fas siRNA injections had no evidence of necrosis or fibrosis. Mice treated with Fas-specific siRNA also had an improved mortality. Eighty-two percent of mice survived over 10 d of observation, whereas all control mice died within 3 d of lethal challenge with Jo2. Thus, both studies demonstrate that the inhibition of Fas receptor synthesis by either specific antisense ODN or siRNA protects animals from Jo2-induced fulminant liver failure and mortality<sup>[21-22]</sup>.

Regulators of apoptosis in the Bcl-2 family have also been targeted with molecular approaches. Bcl-2 is a member of the proto-oncogene family, which blocks cytochrome C release during apoptosis signaling. Several gene products in the Bcl-2 family inhibit apoptosis, including Bcl-xL, Bcl-w, A1, Mcl-1 and Boo, whereas others, such as Bax, Bak, Bok, Bik, Bad and Bid, promote apoptosis<sup>[23]</sup>. Zhang *et al*<sup>[24]</sup> evaluated effects of the antisense against Bcl-xL (ISIS16009) and Bid on Jo2-induced fulminant liver failure in mice. Pre-administration of ISIS16009 reduced liver Bcl-xL expression, potentiated liver apoptosis and increased lethality in this mouse model of Fas-mediated fulminant hepatitis. Antisense ODN against Bid caused an 80% decrease in Bid expression. The reduction of Bid expression by the antisense treatment protected mice from Fas-mediated fulminant hepatitis and death with 100% survival in treated mice<sup>[24]</sup>. Therefore, Bid seems to be a reasonable target for reducing liver injury in which apoptosis is a predominant pathway of cell death, such as Fas ligand-induced acute liver injury.

Caspase 8 is a downstream target of death receptors and is important in the mediation of apoptosis by Fas and TNF- $\alpha$ . Zender *et al*<sup>[25]</sup> evaluated the effects of siRNA against caspase 8 in acute liver damage induced by Jo2 and adenovirus expressing Fas ligand (AdFasL). siRNA against specific caspase 8 target sequences was transfected into Hep G2 cells, and the transfected cells were further infected with AdFasL. Their results confirmed that the inhibition of caspase 8 by siRNA prevented Fas-mediated apoptosis in Hep G2 cells. The animal experiments involved siRNA delivery and administration of Fas antibody or AdFasL. The siRNA delivery resulted in a greater than 3-fold reduction in caspase 8 mRNA

expression. Improved survival was significant even when caspase 8 siRNA was administered during ongoing acute liver failure. In addition, the study is of particular interest in that caspase 8 siRNA treatment was successful not only in acute liver failure mediated by specific Fas agonistic agents (Jo2 and AdFasL), but also in acute liver failure caused by an injection of a large amount of wild-type adenoviruses.

### **Transforming growth factor- $\beta$ (TGF- $\beta$ )**

TGF- $\beta$  is the most potent cytokine for enhancing hepatic fibrogenesis. It suppresses hepatocyte proliferation, stimulates the activation of HSC, promotes ECM production, and mediates hepatocyte apoptosis<sup>[26]</sup>. Smad3 (a transcriptional factor in TGF- $\beta$  receptor downstream signal transduction) knock-out mice did not develop hepatic fibrosis<sup>[27]</sup>; while, transgenic mice overexpressing TGF- $\beta$ 1 developed hepatic fibrosis faster than wild type mice, and the fibrosis regressed slower after the withdrawal of the fibrogenic agent<sup>[28-30]</sup>. Many different strategies of molecular therapy have focused on the inhibition of TGF- $\beta$  effects by blocking its synthesis, using TGF- $\beta$  binding proteins, soluble receptors, or targeting its downstream signal transduction pathways.

Qi *et al.*<sup>[31]</sup> evaluated adenoviral expression of truncated TGF- $\beta$  receptor type II to abolish TGF- $\beta$  signaling in liver fibrosis mediated by dimethylnitrosamine (DMN). DMN induces fatty degeneration of hepatocytes, activation of HSC, macrophage infiltration and secretion of TGF- $\beta$ . Sprague-Dawley rats were given a single infusion of adenoviral vectors (AdCAT $\beta$ -TR) encoding the TGF- $\beta$  receptor II gene (TGF- $\beta$ RII) via portal vein injection. A greater than 20-fold increase in truncated receptor mRNA expression with the adenoviral gene delivery was detected in animals after the TGF- $\beta$  receptor type II gene delivery with adenoviral vectors. The gene delivery improved the animal mortality, decreased liver hydroxyproline content by 3.4-fold, hyaluronate levels by nearly 20-fold, AST by 100-fold, and ALT by 63-fold. Less hepatocyte injury and fibrosis with a decreased infiltration of monocytes/macrophages and reduced semiquantitative score of fibrosis in histopathology were reported, which was consistent with decreased gene expression of collagen type I, fibronectin, smooth muscle  $\alpha$ -actin (SMA), and TGF- $\beta$ 1 in the treated animals. Yata *et al.*<sup>[32]</sup> administered a soluble TGF- $\beta$  type II receptor (STR) protein in CCl<sub>4</sub>-induced liver fibrogenesis in BALB/c mice. Elevated STR levels were associated with a reduction in procollagen type I mRNA expression in the mouse liver. In the 8-wk study, lower concentrations of STR had the greatest effect on procollagen type I mRNA expression. Quantitative morphometrics showed that lower concentrations of STR were the most anti-fibrogenic. These findings verified the antifibrotic effect of inhibiting TGF- $\beta$  in chronic hepatic injury.

### **Tumor necrosis factor- $\alpha$ (TNF- $\alpha$ )**

TNF- $\alpha$  is a key cytokine involved in many forms of liver injury, and may play a crucial role in HSC activation and hepatocyte regeneration<sup>[33-34]</sup>. The major cell type for TNF- $\alpha$  production in the liver is Kupffer cells which release TNF- $\alpha$  when activated by factors released by

damaged hepatocytes, and by ROS occurrence. TNF- $\alpha$  participates in the second phase of hepatocellular damage via apoptosis and TRAIL receptor activation in alcoholic or other hepatotoxin-induced liver injury<sup>[35]</sup>. It acts on HSC, and may contribute to the activation process<sup>[36]</sup>. Accordingly, reducing TNF- $\alpha$  production, or blocking its action will significantly minimize liver injury caused by alcohol toxicity, acetaminophen overdose, or ischemia/reperfusion-associated liver injury in animal models<sup>[35, 37]</sup>.

Ponnappa *et al.*<sup>[38]</sup> has developed a pH-sensitive liposomal formulation consisting of phosphatidyl ethanolamine, cholesteryl hemisuccinate, and cholesterol in a specific ratio (7:4:2), to deliver antisense ODN against TNF- $\alpha$ . This liposomal formulation, which is characterized by its feature of lysosomal resistance, helps release encapsulated-antisense ODN (TJU-2755) into the cytoplasm of Kupffer cells. Rats that received pretreatment with liposome-encapsulated TJU-2755 had a decreased expression of TNF- $\alpha$  mRNA and TNF- $\alpha$  secretion in response to LPS challenge. In subsequent studies, the *in vivo* efficacy of TJU-2755 was assessed against LPS-induced liver damage in ethanol-fed rats<sup>[39]</sup>. Liver damage was induced in male Lewis rats fed an ethanol-containing liquid diet for 8-10 wk followed by an intravenous injection of LPS. Pretreatment of the animals with TJU-2755 encapsulated in pH-sensitive anionic liposomes prevented liver damage by 60-70%, as assessed by the release of liver enzymes and histology. These results indicate that pH-sensitive, anionic liposomes can be used to effectively deliver TNF- $\alpha$  antisense ODN against TNF- $\alpha$ -mediated liver injury<sup>[39]</sup>.

### **Platelet-derived growth factor (PDGF)**

PDGF is the most potent mitogen for HSC with effects in growth stimulation, chemotaxis, and intracellular signaling. PDGF expression is upregulated in hepatic injury, as are PDGF receptors in activated HSC. The tyrosine kinase activity of PDGF receptors signals through PI-3K, Ras, Raf-1, and ERK, leading to nuclear translocation and activation of nuclear transcription factors<sup>[40]</sup>. Interrupting PDGF signal effects with specific agents inhibiting tyrosine phosphorylation, or interrupting down-stream signal transduction pathways attenuates hepatic fibrosis by preventing proliferation and chemotaxis of HSC *in vitro* and *in vivo*<sup>[40]</sup>. Selectively targeting the PDGF receptor by specific antibodies or agents has been considered to be a valuable strategy to block the progression of hepatic fibrogenesis<sup>[41-42]</sup>.

Borkham-Kamphorst *et al.*<sup>[43]</sup> cloned a chimera of PDGF receptor type  $\beta$  gene, fused to the IgG-Fc domain of human immunoglobulin, into an adenoviral vector. The gene product, soluble PDGF receptor, has a high ligand binding capacity, 100 to 1000-fold higher than that of extracellular monomeric PDGF receptors. The effects of soluble PDGF receptor gene therapy on PDGF-induced DNA synthesis, tyrosine autophosphorylation, and activation of ERK, P13K, and protein kinase B in HSC were evaluated *in vitro*. The *in vitro* studies with rat HSC transfected with AdsPDGFR showed decreased levels of PDGF-BB mRNA and thrombospondin-1 with lowered expression of collagen type I mRNA. The receptor gene

delivery, however, did not affect levels of SMA or desmin levels in HSC, indicating that it did not significantly affect the HSC activation<sup>[43]</sup>. In their subsequent study, antisense against PDGF  $\beta$ -chain incorporated into adenoviral vector serotype 5 (Ad5-CMV-PDGF) was transduced in cultured rat HSC<sup>[44]</sup>. The antisense clearly exhibited the ability to down-regulate endogenous PDGF  $\beta$ -chain and PDGF R- $\beta$  mRNA as well as procollagen type I gene expression in culture-activated HSC and rat livers<sup>[44]</sup>.

### Kupffer cells

Due to the critical role of Kupffer cells in the mediation of liver injury and fibrogenesis, inhibiting Kupffer cell activity has been proposed as a means to reduce liver injury. Ogushi *et al*<sup>[45]</sup> modulated Kupffer cell function by administering double stranded antisense ODN targeting NF- $\kappa$ B, the p65 subunit. The mice were first sensitized with intraperitoneal injection of heat killed *Propionibacterium acnes*. Phosphorothioate modified antisense ODN was delivered with hemagglutinating virus of Japan (HVJ)-liposomal complexes via portal vein injection on d 4 and 7 after *P. acnes* priming challenge. The treated mice also had decreased levels of activated NF- $\kappa$ B translocation as shown by p65 staining. Then, the mice were injected with LPS and sacrificed later. The HVJ-liposome-mediated antisense ODN against NF- $\kappa$ B significantly improved animal survival, and the mortality was decreased to 15% in mice treated with NF- $\kappa$ B decoy ODN as compared to 90% in control mice that died within 24 hours. The treatment with decoy antisense ODN against NF- $\kappa$ B also suppressed the production of proinflammatory cytokines (IL-1 $\beta$ , TNF- $\alpha$ , IL-18, and IL-12) by Kupffer cells and decreased mRNA expression of IFN- $\gamma$  and Fas-L. Less infiltration of inflammatory cells and destruction of sinusoidal architecture were documented by histopathology in the animals treated with antisense ODN against NF- $\kappa$ B<sup>[45]</sup>.

## REACTIVE OXYGEN SPECIES AND FREE RADICAL SCAVENGERS

Oxidative stress is an important mechanism in liver injury. ROS include superoxide anions, hydroxyl radicals, hydrogen peroxide, and hydroxyethyl radicals (HER), and are generated from a variety of insults such as drug/toxin metabolites, ischemia/reperfusion, and alcohol metabolism. ROS are involved in necrosis and apoptosis of hepatocytes, and contribute to HSC activation<sup>[2,46]</sup>. Several major classes of free radical scavengers, such as superoxide dismutase (SOD), catalase, and glutathione peroxidase (GSH-P), as well as SOD mimics, were investigated in various forms of liver injury, and they afforded effective protection against the oxidative insults to the tissue<sup>[47-48]</sup>.

Three isoforms of SOD exist. Copper/Zinc (Cu/Zn) SOD is localized to the cytosol and nucleus, manganese (Mn) SOD is localized to the mitochondria and, extracellular (EC) SOD is primarily localized to the interstitial matrix. We employed polycationic liposomes previously formulated by our group with polycationic lipids (PCL)<sup>[49]</sup> to deliver the EC-SOD gene for the prevention of acute liver injury<sup>[50]</sup>. Our *in vitro* experiments showed that transfection of the EC-SOD plasmid in

Hep G2 and Hep3B cells led to an increase in SOD activity in cell culture medium. Transfected cells were more resistant to the exposure of superoxide anions generated by hypoxanthine and xanthine oxidase, and to HER by an HER-generating system. We employed polycationic liposomes to deliver the human EC-SOD gene via portal vein injection in mice<sup>[50]</sup>. Two days after the gene delivery, a 55-fold increase in human EC-SOD gene expression was detected. When mice receiving the EC-SOD gene delivery were challenged with GalN and LPS, their serum ALT levels were much lower than those receiving control vector delivery, whereas their serum SOD levels were higher. Moreover, liver levels of the reduced form of glutathione (GSH) were preserved, and lipid peroxidation products, malondialdehyde (MDA) and 4-hydroxyalkenal (HAE) were reduced. Liver histology confirmed the effectiveness of the gene delivery. Thus, the overexpression of the human EC-SOD gene protected the mice from hepatotoxin-induced liver injury<sup>[50]</sup>. Laukkaen *et al*<sup>[51]</sup> achieved similar results when adenovirus-derived EC-SOD was delivered to prevent acetaminophen-induced acute liver injury in mice. Delivery of the Cu/Zn-SOD gene by adenoviral vector was also shown to protect rats from alcohol-induced liver injury<sup>[52]</sup>. Cu/Zn-SOD was expressed in approximately 60% of liver cells with 3-5 fold higher levels of SOD compared to controls. The treatment of alcohol-fed rats with Cu/Zn-SOD gene delivery attenuated alcohol-induced elevation of serum aminotransferase levels with a 60% decrease of ALT levels and a 39% decrease in AST levels. Liver histopathology demonstrated less inflammation, reduced steatosis and no detectable necrosis. Free radical adduct formation measured by electron spin resonance (ESR) spectroscopy was reduced in mice treated with Ad.Cu/Zn-SOD. Nuclear extracts examined by electrophoretic mobility shift assays demonstrated a decrease in activation and translocation of NF- $\kappa$ B. Thus, these studies provide substantial evidence that the delivery of SOD isoforms will protect the liver from acute and chronic liver injury in which the generation of ROS is a major component in the pathogenesis of the injury process.

Zhong *et al*<sup>[53]</sup> evaluated adenoviral delivery of either Mn-SOD or Cu/Zn-SOD in a cholestatic model of liver injury. Rats were treated with AdMnSOD or AdCu/ZnSOD 3 d prior to bile duct ligation (BDL). Over 90% of hepatocytes were infected by virus. Mn-SOD and Cu/Zn-SOD activity increased 4-fold at d 3 and remained elevated up to 2-fold for 3 wk after the injection of adenoviruses. Elevated serum aminotransferase levels in rats with BDL were abrogated by 70% with AdMnSOD and 40% with AdCu/ZnSOD. Alkaline phosphatase (ALP) release was reduced by 50% with AdMnSOD and by 25% with AdCu/ZnSOD. AdMnSOD was also able to abrogate the increase in 4-hydroxynonenal (lipid peroxidation product). Enhanced NF- $\kappa$ B activation, TGF- $\beta$  and TNF- $\alpha$  expression in the cholestatic liver were reversed by AdMnSOD delivery. Furthermore, BDL caused enhanced fibrosis and a 20-fold increased level of procollagen type I ( $\alpha$ 1) mRNA in the liver. These changes were reversed significantly by prior Ad-Mn-SOD gene delivery. Thus, it appears that antioxidant gene delivery is a promising

approach to prevent a variety of forms of liver injury, including drug-induced toxicity, ethanol consumption, and cholestasis or ischemia/reperfusion-associated liver injury<sup>[54]</sup>, as well as hepatic fibrogenesis<sup>[53]</sup>.

## EXTRACELLULAR MATRIX REMODELING

ECM is composed of collagens, glycoproteins, proteoglycans, glycosaminoglycans, and other proteins<sup>[55-56]</sup>. In the normal liver, collagens types I, III, V and XI are principally found in the capsule, around large vessels, and in the portal triad. Of note, the ECM components of the subendothelial space are typically low in collagen type I. Changes in the proportion of ECM components also contribute to the activation of HSC. Matrix metalloproteinases (MMPs) are important in the modeling and degradation of ECM, and they are classified according to their target substrates as interstitial collagenases, gelatinases, stromelysins, and metalloelastases<sup>[57-58]</sup>. Stromelysin-1 degrades proteoglycans and glycoproteins. MMP-1 degrades collagen type I, while MMP-2 and MMP-9 degrade collagen type IV. These MMPs require activation by proteolytic cleavage and are inactivated by tissue inhibitors of metalloproteinases (TIMPs). The balance of production and degradation of ECM components maintains normal liver structure. The increased and disordered deposition of ECM components that occurs in fibrotic liver disease, especially fibrillar collagen types I and III, is due to unbalanced excessive production and reduced degradation. Enhancing the production of collagenase by gene delivery is a possible strategy to promote tissue remodeling and minimize the net accumulation of ECM components in chronic liver injury. Various collagenase genes have been delivered in attempts to decrease ECM deposition in animal models of hepatic fibrosis. Iimuro *et al.*<sup>[59]</sup> evaluated the effectiveness of adenovirus-mediated gene delivery of matrix metalloproteinase-1 on the attenuation of liver fibrosis induced by thioacetamide or BDL in rats. The administration of Ad5MMP-1 significantly attenuated hepatic fibrosis with resolution within 2 wk, a decrease in cross-linked collagen type I, hydroxyproline content, and SMA-positive HSC, which corresponded to a decreased number of activated HSC in the liver sections. The treatment with Ad5MMP1 induced a transient increase in serum ALT levels that resolved by wk 4. This may reflect hepatocyte damage induced by adenoviral gene delivery. Subsequently, enhanced hepatocyte proliferation was found in the animals treated with MMP-1 gene therapy.

Siller-López *et al.*<sup>[60]</sup> evaluated the efficacy of adenoviral delivery of MMP8 in ameliorating liver cirrhosis induced by either BDL or CCl<sub>4</sub> intoxication in rats. Marked expression of MMP-8 was found to reach a level of 550 pg/mL in AdMMP8-treated cirrhotic animals. This was accompanied with a significant decrease of a fibrotic score by 45% in BDL rats, as indicated by decreased liver hydroxyproline content. Moreover, TIMP-1, MMP-9, and HGF were found to be increased, whereas, TGF- $\beta$  was decreased in animals receiving the MMP-8 gene delivery. The gene delivery also improved ascites, hepatic function tests, and gastric varices in these cirrhotic rats.

Thus, MMP-8 gene delivery seems to be highly effective in accelerating the resolution of the deposited ECM components in experimental animal models of hepatic fibrosis. However, immunoreaction to the adenoviral vectors or a high viral titer used, caused marked hepatocyte damage in those animals receiving adenoviral gene delivery<sup>[60]</sup>.

Urokinase-type plasminogen activator (uPA) is known to be an initiator of matrix proteolysis and promotes degradation of the extracellular matrix. Salgado *et al.*<sup>[61]</sup> employed adenoviral vector to deliver human uPA in a rat model of hepatic fibrosis induced by chronic CCl<sub>4</sub> intoxication. At the end of 6 wk of repeated CCl<sub>4</sub> injections, rats were given Ad- $\Delta$ huPA via iliac vein injection. Animals were sacrificed 2 d after Ad- $\Delta$ huPA treatment for evaluating the gene delivery efficacy. Human uPA gene expression was detected in 46-80% of hepatocytes with marked elevation of human uPA in serum. The successful human uPA gene delivery resulted in an almost complete resolution of periportal and centrilobular fibrosis when compared to the animals with a control vector injection (Ad-GFP) as evidenced by histochemical staining for ECM components. The gene delivery also led to an elevated MMP-2 activity, and induced hepatocyte proliferation with increased levels of HGF. Thus, the study indicated that enhanced uPA expression by a gene delivery approach may activate MMP activity and accelerate ECM degradation, as well as facilitate a resolution of hepatic fibrosis. The same group performed another experiment in BDL rats and found that combination of adenoviral delivery of human uPA gene with biliodigestive anastomosis achieved a synergistic effect in reducing hepatic fibrosis<sup>[62]</sup>. These studies provide substantial evidence that hepatic fibrosis is reversible in animal models when the underlying injury process is attenuated or stopped and an accelerated tissue remodeling occurs.

## CONCLUSIONS AND PROSPECTS

New understanding and insights into the pathogenesis of hepatocellular damage and hepatic fibrogenesis, and the development of molecular techniques, such as new viral or non-viral vector systems, RNAi, ribozyme and antisense technologies have made it possible to modulate the expression of specific genes involved in the key pathways of liver injury and fibrosis. The fact that blocking Fas-ligand activity by siRNA or antisense against Fas receptor almost completely prevented Fas ligand-induced fulminant liver failure and animal mortality is noteworthy. It is also striking that silencing of a key enzyme, caspase 3 or 7, in an apoptotic cascade by siRNA blocks the cell damage. The transfer of anti-oxidant genes, such as isoforms of SOD, by viral or non-viral vectors prevents a variety of forms of liver injury in which ROS generation is involved in the pathogenic pathways. Alternatively, when the overexpression of fibrogenic cytokines, such as TGF- $\beta$  and PDGF and their receptors are inhibited at the mRNA level with antisense, ribozymes or siRNA, or interrupted by specific antibodies or protein molecules, the interventions result in marked amelioration of hepatic

fibrosis. Moreover, delivery of collagenase genes by adenoviral vectors promotes the resolution of excessive deposition of ECM components and reverses hepatic fibrosis. Although these progresses in treatment of liver injury and fibrogenesis are encouraging, one issue that requires additional attention remains that targeting these molecular therapeutics to specific cell types (hepatocytes, Kupffer cells or HSC) is critical in avoiding undesired effects on other organs or cell types<sup>[39,41,63]</sup>.

Gene therapy itself is still in its infancy, and ideal gene delivery systems for selective gene transfer with high and prolonged gene expression, as well as less cytotoxicity or immunogenicity remain to be developed. Nevertheless, molecular therapeutics has already proven to be powerful research tools and explorative experimental medicine. They have demonstrated some promise as novel modalities in reducing liver injury, inhibiting HSC activation, and promoting the resolution of fibrotic deposition. However, the transition of promising molecular therapeutics from animal models to clinical trials for the validation of their clinical efficacy, adverse effects, target patient population will usually take a quite long period of time. One may anticipate that in combination with other more standard therapeutic modalities, these molecular approaches may yield effective treatments for hepatic injury and fibrogenesis in man in the foreseeable future.

### Abstract

Massive ascites and hepatorenal syndrome (HRS) are frequent complications of liver cirrhosis. Thus, effective therapy is of great clinical importance. This concise review provides an update of recent advances and new developments. Therapeutic paracentesis can be safely performed even in patients with severe coagulopathy. Selected patients with a refractory or recurrent ascites are good candidates for non-surgical portosystemic shunts (TIPS) and may have a survival benefit and improvement of quality of life. Novel pharmaceutical agents mobilizing free water (aquaretics) are currently under test for the therapeutic potential in patients with ascites. Prophylaxis of hepatorenal syndrome in patients with spontaneous bacterial peritonitis is recommended and should be considered in patients with alcoholic hepatitis. Liver transplantation is the best therapeutic option with long-term survival benefit for patients with HRS. To bridge the time until transplantation, TIPS or Terlipressin and albumin are good options. Albumin dialysis can not be recommended outside prospective trials.

### INTRODUCTION

Haemodynamic alterations and activation of neurohumoral systems are essential in the pathophysiology of ascites

formation<sup>[1,2]</sup>. The most common circulatory alterations in patients with cirrhosis of the liver are portal hypertension and peripheral arterial vasodilatation which results in a decrease of centrally effective blood volume. As a consequence, neurohumoral systems are activated in an attempt to maintain intravascular volume (Figure 1). Among those, activation of the renin-angiotensin-aldosterone system, the sympathetic nervous system and the non-osmotic release of arginin-vasopressin play the major role. These neurohumoral systems induce renal sodium and water retention leading to the formation of ascites. The most severe form with renal vasoconstriction and a decrease of renal blood flow leads to hepatorenal syndrome. Recently, it has been suggested that a decrease in cardiac output may contribute to HRS<sup>[3]</sup>.

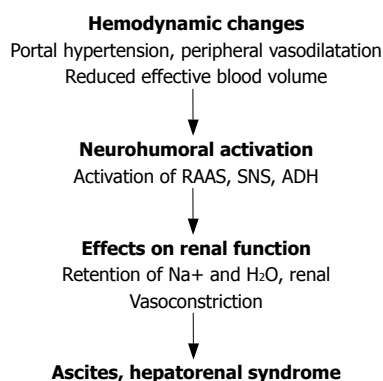

Novel therapeutic strategies for ascites and hepatorenal syndrome thus focus to counteract the initial changes of this pathophysiological cascade: controlled reduction of portal hypertension and/or peripheral vasoconstriction combined with plasma expanders.

### TREATMENT OF MASSIVE ASCITES

In order to achieve fast relief, patients with massive ascites undergo therapeutic paracentesis<sup>[4]</sup>. Apart from the risk of infection which can easily be prevented, major concerns have been raised regarding the risk of bleeding and haemodynamic instability. It has been shown that large volume paracentesis can be safely performed even in patients with severely impaired coagulation parameters<sup>[5,6]</sup>. In a study investigating more than 500 patients with cirrhosis of the liver, an average paracentesis of 9 g/L was performed<sup>[5]</sup>. Although the majority of patients exhibited less than  $50 \times 10^9$ /L platelets and more than a quarter had severely prolonged prothrombin time, no case had severe complication or bleeding.

Following large volume paracentesis rapid re-formation of ascites may effectively reduce central blood volume and compromise systemic haemodynamic and renal function. To prevent intravenous administration of plasma expanders, a paracentesis has been established<sup>[2,7]</sup>. For large volume paracentesis (more than 6 L) 20% human albumin in a concentration of at least 6 g per liter ascites seems to be the safest strategy. Recent work demonstrated that the incidence of paracentesis-induced circulatory dysfunction following paracentesis of less than 6 L is only 7% with albumin or saline as plasma expanders with almost no clinical complications<sup>[8]</sup>. Thus, it may be safe and cost-effective to perform paracentesis of up to 6 L without albumin.

**Figure 1** Pathogenesis of ascites formation and hepatorenal syndrome in patients with cirrhosis.

**Table 1** Definition of refractory and recurrent ascites according to the consensus of the International Ascites Club<sup>[9]</sup>

Refractory ascites	cannot be mobilized by diuretics because of a lack of response (mean weight loss less than 200g/d during the last 4 d) or the development of diuretic-induced complications such as hyponatremia, hypokalemia, renal impairment, hepatic encephalopathy, precluding an effective diuretic dosage
Recidivant ascites	recurs at least on 3 occasions within 1 year despite prescription of dietary sodium restriction and adequate diuretic dosage

## REFRACTORY AND RECURRENT ASCITES

Refractory and recurrent ascites have been defined according to a consensus conference of the International Ascites Club<sup>[9]</sup> (Table 1). Repeated large volume paracentesis in addition to diuretic treatment is the standard treatment for these patients. Reduction of portal hypertension with non-surgical shunts (transjugular intrahepatic portosystemic shunt = TIPS) has the potential to markedly increase renal sodium excretion<sup>[10]</sup>. This has prompted several prospective randomized controlled trials comparing repeated paracentesis with insertion of a TIPS (Table 2). The unequivocal result of all four trials<sup>[11-14]</sup> has a highly significant advantage in the control of ascites by TIPS. Regarding survival, two trials have shown a significant advantage. Possibly, inclusion of patients with more severely impaired liver function and a bilirubin above 5mg/100mL at inclusion may be responsible for the lack of survival benefit following TIPS<sup>[15]</sup> (Table 3). Encephalopathy following TIPS should be avoided as the major obstacle for improvement of quality of life as compared to paracentesis patients<sup>[13]</sup>. Thus, careful selection of patients and management in experienced centers are the prerequisite for a TIPS benefit. Patients with ascites resolution following TIPS insertion enjoy a markedly improved quality of life<sup>[16]</sup>.

## AQUARETICS

Vasopressin-V2-receptor antagonists mobilize free water and thus might be an excellent alternative or adjunct to

**Table 2** Important features of large prospective trials<sup>[11-14]</sup> comparing TIPS with paracentesis for massive ascites

**Table 4** Definition of hepatorenal syndrome according to the consensus of the International Ascites Club<sup>[9]</sup>

<b>HRS Type 1:</b> Rapidly progressing renal failure (<2 wk) ≥2-fold increase of serum creatinine to >221μmol/L or 50% decrease of creatinine clearance to <20mL/min
<b>HRS Type 2:</b> Not rapidly progressing renal failure
Serum creatinine >132.6 μmol/L or
Creatinine clearance <40mL/min
Absence of shock, ongoing bacterial infection, current or recent treatment with nephrotoxic drugs, gastrointestinal or renal fluid loss
No sustained improvement upon withdrawal of diuretics and plasma volume expansion
Proteinuria <0.5g/d, no abnormalities of renal ultrasound

diuretic treatment. The efficacy and safety of these new compounds in patients with cirrhosis have recently been demonstrated<sup>[17,18]</sup>. In these patients, urine volume increased and urine osmolality dose-dependently decreased, thus demonstrating an increase of free water clearance. Moreover, while patients in the placebo group gained weight, body weight was stable with a lower dose and clearly decreased with a higher dose of the V2-receptor antagonist. This promising new pharmaceutical concept is currently under investigation in international phase II/III trials.

## HEPATORENAL SYNDROME

According to established criteria, hepatorenal syndrome can be classified into type 1 and type 2<sup>[9]</sup> (Table 4). Rapid progressive type 1 exhibits a very poor prognosis with a 3-month mortality rate of above 90%<sup>[19]</sup>. Thus, prophylaxis of HRS is an important task and effective treatment is a highly desirable goal.

## PROPHYLAXIS OF HRS

In patients with severe alcoholic hepatitis, the TNF-α inhibitor pentoxifyllin significantly reduces the incidence of

HRS, HRS-related and over-all mortality<sup>[20]</sup>. Spontaneous bacterial peritonitis is often followed by deterioration of renal function and even hepatorenal syndrome. Interestingly, a randomized prospective trial<sup>[21]</sup> showed that intravenous albumin administration (1.5g/kg per day on day one and 1g/kg per day on day three) together with antibiotic treatment with cefotaxim is clearly superior to antibiotic treatment alone because renal failure and moreover mortality were significantly reduced in hospital and during a 3-month follow-up period.

## TREATMENT OF HEPATORENAL SYNDROME TYPE 1

Following liver transplantation, patients with HRS may reach 5-year survival probability of 60%<sup>[22]</sup>. While this is a tremendous improvement compared to the spontaneous prognosis, survival rates are significantly lower than those in patients undergoing liver transplantation with normal renal function. Moreover, in many Western countries, waiting lists for liver transplantation are steadily growing, thus increasing the need to bridge severely sick patients to transplantation. Therapeutic concepts are needed to normalize renal function in patients with hepatorenal syndrome type 1. As stated in the introduction, very early interventions in the pathomechanistic cascade would seem more promising.

Indeed, controlled reduction of portal hypertension with TIPS seems to be rather effective. In an uncontrolled trial, the average mean survival time was around 4 mo in 14 out of 23 patients with HRS type 1 who received TIPS<sup>[23]</sup>. Nine of the 23 patients, however, were at high risk for liver failure and therefore did not receive TIPS. For these severely ill patients, strategies should be used to counteract peripheral vasodilatation combined with volume expansion.

Several studies suggest that vasopressin analogues combined with albumin may be suitable to reverse hepatorenal syndrome<sup>[24-26]</sup>. Terlipressin (average daily dose of 3 mg) could be a valuable option for patients with HRS type 1 and very poor liver function to bridge the time to transplantation if combined with plasma expanders<sup>[27]</sup>. In this retrospective analysis best results with terlipressin were seen in patients with Child-Pugh score below 12 points, receiving at least 3 mg per day. However, only one randomized controlled trial on terlipressin has shown improvement of renal function in patients with HRS type 1 compared to no response in the placebo group<sup>[28]</sup>. No survival data are provided.

In numerous uncontrolled observations extracorporeal albumin dialysis (MARS) has been suggested as a beneficial therapy for patients with acute-on-chronic liver failure. There are only two randomized trials investigating the effects of MARS, comprising a total of 23 patients with hepatorenal syndrome<sup>[29,30]</sup>. No 30-d survival benefit has been demonstrated, disqualifying this procedure for the use outside of controlled trials<sup>[30]</sup>.

### Abstract

Active ulcerative colitis (UC) is frequently associated with infiltration of a large number of leukocytes into the bowel mucosa. Therefore, removal of activated circulating leukocytes by apheresis has the potential for improving UC. In Japan, since April 2000, leukocytapheresis using Adacolumn has been approved as the treatment for active UC by the Ministry of Health and Welfare. The Adacolumn is an extracorporeal leukocyte apheresis device filled with cellulose acetate beads, and selectively adsorbs granulocytes and monocytes/macrophages. To assess the safety and clinical efficacy of granulocyte and monocyte adsorptive apheresis (GMCAP) for UC, we reviewed 10 open trials of the use of GMCAP to treat UC. One apheresis session (session time, 60 min) per week for five consecutive weeks (a total of five apheresis sessions) has been a standard protocol. Several studies used modified protocols with two sessions per week, with 90-min session, or with a total of 10 apheresis sessions. Typical adverse reactions were dizziness, nausea, headache, flushing, and fever. No serious adverse effects were reported during and after GMCAP therapy, and almost all the patients could complete the treatment course. GMCAP is safe and well-tolerated. In the majority of patients, GMCAP therapy achieved clinical remission or improvement. GMCAP is a useful alternative therapy for patients with steroid-refractory or -dependent UC. GMCAP should have the potential to allow tapering the dose of steroids, and is useful for shortening the time to remission and avoiding re-administration of steroids at the time of relapse. Furthermore, GMCAP may have efficacy as the first-line therapy for steroid-naïve patients or patients who have the first attack of UC. However, most of the previous studies were uncontrolled trials. To assess a definite efficacy of GMCAP, randomized, double-blind, sham-controlled trials are necessary. A serious problem with GMCAP is cost; a single session costs ¥145 000 (\$1 300). However, if this treatment prevents hospital admission, re-administration of steroids and

surgery, and improves a quality of life of the patients, GMCAP may prove to be cost-effective.

### INTRODUCTION

Ulcerative colitis (UC) is an inflammatory bowel disease of unknown etiology that involves colon and rectum. Active UC is frequently associated with infiltration of large number of leukocytes into the bowel mucosa<sup>[1,2]</sup>. The infiltrated leukocytes can cause extensive mucosal tissue injury by releasing a large number of inflammatory mediators such as prostaglandins, leukotrienes, platelet activating factor, thromboxanes, oxygen radicals, proteases, and cytokines<sup>[3]</sup>. Therefore, removal of activated circulating leukocytes by apheresis has the potential for improving the bowel inflammation and patient status in UC. Recently, leukocytapheresis has been tried as a novel approach for UC<sup>[4,5]</sup>.

Clinical efficacy and safety of leukocytapheresis for UC were initially investigated in a multicenter study in Japan, and the results were published in 1999<sup>[5]</sup>. In that study, 120 patients were randomly divided into two groups; one group received leukocytapheresis and the other group conventional drugs (corticosteroids and/or sulfasalazine/mesalazine). Clinical efficacy was observed in 58% of patients in the leukocytapheresis group compared with 44% in the drug group. Adverse effects were noted in 8% of patients in the leukocytapheresis group compared with 43% in the drug group. From these data, leukocytapheresis seemed to be superior to conventional drugs, and this was more striking in patients with severe and intractable diseases<sup>[5]</sup>. In Japan, since April 2000, leukocytapheresis using Adacolumn (Japan Immunoresearch Laboratories, Takasaki, Japan)<sup>[6]</sup> has been approved as the treatment of patients with active UC by the Ministry of Health and

GMCAP, granulocyte and monocyte/macrophage adsorptive apheresis; UC, ulcerative colitis.

<sup>1</sup>Five apheresis sessions for five consecutive weeks; session time, 60 min; blood flow rate, 30 mL/min.

<sup>2</sup>This study was a randomized controlled trial comparing efficacy of GMCAP and prednisolone.

<sup>3</sup>This study also included 12 patients with Crohn's disease.

<sup>4</sup>One or two sessions per week; session time, 60 or 90 min.

Welfare. Hence, currently the Adacolumn is available in the market throughout Japan and is being used for treating UC. The Adacolumn is an extracorporeal leukocyte apheresis device filled with cellulose acetate beads, and selectively adsorbs granulocytes and monocytes/macrophages; lymphocytes are not significantly adsorbed<sup>[7]</sup>. Thus, the Adacolumn is for selective granulocyte and monocyte/macrophage adsorptive apheresis (GMCAP). As leukocytapheresis therapy, Cellsorba (Asahi Kasei Medical Co., Ltd, Tokyo, Japan)<sup>[8]</sup> is also available in Japan. The Cellsorba is filled with very fine polyester fiber as adsorptive carriers, and removes lymphocytes in addition to granulocytes and monocytes.

In this paper, we have discussed safety and efficacy of GMCAP using the Adacolumn, which has been used as leukocytapheresis therapy in our institution. Since 2000, there have been 10 open trials of the use of GMCAP to treat UC (Table 1)<sup>[9-18]</sup>. Eight of the ten trials were performed in Japan. We mainly reviewed these trials to assess clinical efficacy and safety of GMCAP for UC. Finally, we discussed possible future role of GMCAP in the management of UC.

### GMCAP procedures

The Adacolumn<sup>[6]</sup> is a single use adsorptive type apheresis column, with a volume of 335 mL, filled with 220 g of cellulose acetate beads of 2 mm diameter as the column adsorptive carriers. An outline of GMCAP procedures using the Adacolumn is shown in Figure 1. GMCAP was

**Figure 1** An outline of GMCAP procedures using the Adacolumn. Blood is drawn into the column from the antecubital vein of one hand, and returned to the patient via antecubital vein of the contralateral hand. GMCAP, granulocyte and monocyte/macrophage adsorptive apheresis.

performed in out-patient clinic for patients with mild symptoms, and patients with severe symptoms were hospitalized for GMCAP. The process of performing GMCAP is relatively simple. Prior to apheresis, the system is primed by saline-containing anticoagulant, nafamostat mesilate or heparin, and during apheresis saline containing those anticoagulants is continuously administered into the column. Blood is drawn into the column from the antecubital vein of one hand, and returned to the patient via antecubital vein of the contralateral hand, without using a shunt. The commonly used apheresis time and blood flow rate are 60 min and 30 mL/min, respectively. During these procedures, the carriers adsorb about 65% of granulocytes, 55% of monocytes and 2% of lymphocytes from the blood in the column<sup>[7]</sup>. After completion of each apheresis session, the residual blood in the column and circuit lines is returned to the patient by infusing physiological saline at the blood inflow line. Vital signs are continuously monitored during the apheresis by dialysis staff. One apheresis session (session time, 60 min; blood flow rate, 30 mL/min) per week for five consecutive weeks (a total of five apheresis sessions) has been a standard protocol. Recently, other protocols with two sessions per week or a total of 10 apheresis sessions have been used for patients with severe UC. Furthermore, apheresis sessions longer than 60 min and apheresis with a higher blood flow rate have been tried for severe diseases. In several institutions, the efficacy of the protocol with a longer session time and higher blood flow rate is being compared with that of the standard protocol<sup>[17]</sup>.

### Indications for GMCAP

According to the Guidelines of the Investigation and Research Committee of Inflammatory Bowel Disease of the Ministry of Health and Welfare of Japan, GMCAP has been mainly used for patients with steroid-refractory (no or little improvement after high dose steroid therapy) and steroid-dependent (inability to decrease the steroid dosage) moderate-to-severe UC. For the majority of patients, corticosteroids were given during GMCAP therapy as concomitant medications. In contrast, steroid-naïve patients with milder UC were also treated with GMCAP<sup>[11,12,15]</sup>.

### Adverse effects

No serious adverse effects were reported during and after GMCAP therapy, and almost all patients could complete the treatment course. From the data in the previous trials<sup>[9-18]</sup>, adverse effects were observed in 5%-27% of patients (Table 1). Typical adverse reactions were dizziness, nausea, headache, flushing, and fever. These symptoms lasted from only a couple of minutes to a couple of hours. Fever could be treated with antifebrile, and headache could be prevented with painkillers before the apheresis. Infectious problems due to GMCAP were rarely reported<sup>[16]</sup>. In our study, one patient developed a mild liver dysfunction probably due to an anticoagulant, nafamostat mesilate<sup>[15]</sup>. Thereafter, heparin was used instead. The liver dysfunction normalized without any special treatment.

### Clinical efficacy

Patients were followed up regularly during and after GMCAP therapy, and the final efficacy assessment was performed at one or two weeks after the last apheresis session<sup>[9-18]</sup>. The efficacy of GMCAP was evaluated using clinical activity index or disease activity index scores<sup>[19-21]</sup>. In a prospective multicenter trial in Japan<sup>[9]</sup>, 53 patients refractory to conventional drug therapy were treated with the standard GMCAP protocol (five apheresis sessions for five consecutive weeks; session time, 60 min; blood flow rate, 30 mL/min) in combination with prednisolone. After the treatment, 21% and 37% of patients achieved remission and improvement (without remission), respectively, and the mean daily dose of prednisolone per patient was reduced from 24.4 mg at enrollment to 14.2 mg after GMCAP therapy. In another prospective multicenter study in Korea<sup>[18]</sup>, 27 patients with moderate-to-severe active UC refractory to conventional drugs were treated with the standard GMCAP protocol. Clinical improvement was observed in 70% of patients (44% markedly improved), and tapering down or discontinuation of steroids was possible in 56% of concomitant steroid users. Naganuma *et al*<sup>[13]</sup> treated 44 steroid-refractory or -dependent patients with the standard GMCAP protocol. Twenty-four patients (55%) obtained remission, 9 (20%) showed a clinical response (without remission), and 11 (25%) remained unchanged. Only 20% of patients with severe steroid-refractory UC achieved remission, whereas 70% of patients with moderate steroid-refractory UC achieved remission. In 90% of patients with steroid-dependent UC, the daily dose of corticosteroids could be tapered during GMCAP therapy. In the long-term, 61% of patients who achieved clinical improvement or remission maintained remission, whereas 39% had relapsed. Approximately half of the relapsed patients were successfully treated with repeat GMCAP therapy. The Spanish Group for the Study of Crohn's Disease and Ulcerative Colitis (GETECCU)<sup>[16]</sup> conducted a prospective, open, pilot study including 26 patients with steroid-dependent inflammatory bowel disease (UC, 14; Crohn's disease, 12). Patients were started on 60 mg/d of prednisone; after one week, GMCAP therapy with the standard protocol was started. The steroid dose was tapered weekly if there was clinical improvement. Remission was achieved in 62% and 70% of patients with UC and Crohn's disease, respectively. During a median follow-up of 12.6 mo, 6 of 8 UC patients maintained their clinical remission; however, only one Crohn's disease patient remained in remission after the first 6 mo of follow-up.

Higher remission or improvement rates have been reported using the modified GMCAP protocols. Hanai *et al*<sup>[11]</sup> examined 31 patients with steroid-refractory UC and eight steroid-naïve patients who were treated with a total of 10 or 11 GMCAP sessions (session time, 60 min; blood flow rate, 30 mL/min); for patients with severe diseases, two sessions per week for the first three weeks and then weekly session for five weeks; for the other patients, weekly session for the first five weeks and after an interval of one week, weekly session for another five weeks. After the treatment, 81% of steroid-refractory and 88% of

steroid-naïve patients achieved remission, and 79% of patients maintained their remission during 12 mo. The same research group<sup>[14]</sup> conducted a randomized controlled trial comparing the efficacy of GMCAP and prednisolone. Sixty-nine steroid-dependent patients were randomly assigned to two groups; 46 patients were given 11 GMCAP sessions (session time, 60 min; flow rate, 30 mL/min) over 10 wk in combination with prednisolone (GMCAP group), and the other 23 patients were treated with 30 mg/d of prednisolone (prednisolone group). Prednisolone was tapered or discontinued with improvement of disease in both the groups. At 12 wk after the treatment, 83% of patients in the GMCAP group and 65% in the prednisolone group achieved remission and the difference was not statistically significant. During the 12 wk of the treatment, the cumulative amount of prednisolone received per patient was 1 157 mg in the GMCAP group, which was significantly lower than 1 938 mg in the prednisolone group. Kanke *et al*<sup>[17]</sup> treated 60 patients with active UC with 10 GMCAP sessions with different duration (60 or 90 min) and frequency (one or two sessions per week) of apheresis. There was an association between the final disease activity and the duration of apheresis, and twice a week was superior to one session per week for the improvement of disease activity. Furthermore, twice a week or 90 min was superior to one session per week or 60 min for improvement of clinical symptoms such as diarrhea, abdominal pain, and bloody stools.

GMCAP has been also used for steroid-naïve patients or patients with milder UC<sup>[12,15]</sup>. Suzuki *et al*<sup>[12]</sup> treated 20 steroid-naïve patients with active UC with 6-10 GMCAP sessions (two sessions per week; session time, 60 min; blood flow rate, 30 mL/min). Seventeen patients (85%) achieved remission, and 60% had maintained their remission during eight months. In our study<sup>[15]</sup>, GMCAP therapy with the standard protocol (no concomitant steroid medications) was performed for 30 patients with mild-to-moderately active distal UC. Clinical symptoms significantly improved after the third apheresis session. Clinical remission was achieved in 21 patients (70%), and clinical improvement (without remission) was recognized in 5 patients (17%). In 4 patients (13%), clinical response was not recognized. GMCAP was not effective for patients with long disease duration and those who had been treated with high-dose steroids. All of the 21 patients who achieved clinical remission were able to maintain remission during the 12-wk follow-up after GMCAP. The efficacy of GMCAP for pediatric UC has been reported. Tomomasa *et al*<sup>[10]</sup> retrospectively reviewed 12 steroid-refractory children who were treated with weekly GMCAP for 5-10 consecutive weeks. In eight patients, clinical symptoms improved after two apheresis sessions. The dose of steroid was tapered during GMCAP therapy by 50%. Four of the eight patients relapsed 3.5 mo after the last apheresis session, the other four patients remained in remission up to 22.8 mo.

## DISCUSSION

A lot of research is going on to clarify the detailed mechanism of GMCAP on UC<sup>[7,22-29]</sup>. Although during GMCAP,

the carriers adsorb 65% of granulocytes, 55% of monocytes and 2% of lymphocytes from the blood in the column, the number of these leukocytes in the systemic circulation did not fall immediately after the apheresis<sup>[7]</sup>. This can be explained by an influx of new leukocytes into the systemic circulation from the marginal pools, principally the bone marrow during apheresis. Thus, the efficacy of GMCAP cannot be fully explained on the basis of reducing leukocytes. Rembacken *et al*<sup>[4]</sup> found that the markedly increased expression of  $\alpha(m)$  integrin/Mac-1 and low L-selectin expression alter the capability of granulocytes to migrate to inflammatory sites. Kashiwagi *et al*<sup>[23]</sup> found a significant suppression of proinflammatory cytokines (interleukin [IL]-1 $\beta$ , IL-6, IL-8 and tumor necrosis factor [TNF]- $\alpha$  production) by leukocytes, neutrophils chemotaxis, down-regulation of leukocyte adhesion molecule (L-selectin) and neutrophil adhesion to IL-1 $\beta$ -activated endothelial cells after GMCAP for UC. Furthermore, the number of CD10-negative premature granulocytes increased, indicating increased turnover of these cells in the systemic circulation. Takeda *et al*<sup>[27]</sup> found that granulocyte adsorption to cellulose acetate beads required plasma IgG, the complement C3 and was inhibited by an antibody to leukocytes CD18. Furthermore, hepatocyte growth factor and IL-1 receptor antagonist (IL-1ra) which have strong anti-inflammatory actions were released by granulocytes that adhered to cellulose acetate beads. Hanai *et al*<sup>[28]</sup> found that TNF- $\alpha$  receptors I and II were significantly increased in the peripheral blood after apheresis. These observations suggest that selective granulocyte and monocyte adsorption is associated with modified peripheral blood leukocyte function favorable to patients with UC which reflect leukocyte hyperactivity. Further investigations are necessary to explain the precise mechanism of GMCAP.

No serious adverse effects were reported during and after GMCAP therapy, and almost all patients could complete the treatment course<sup>[9-18]</sup>. GMCAP is fairly safe and well tolerated. The clinical remission and improvement rates were different among the studies because many factors such as the indications of GMCAP, disease activity before GMCAP, protocol of GMCAP (frequency, duration and a total number of apheresis), concomitant medications, and the method of efficacy assessment were different. However, the data from the previous trials suggest that GMCAP is a useful alternative therapy for patients with steroid-refractory or -dependent UC. GMCAP should have the potential to allow tapering the dose of steroids, and is useful for shortening the time to remission and avoiding re-administration of steroids at the time of relapse. Furthermore, GMCAP may have efficacy as the first-line therapy for steroid-naïve patients or patients who have the first attack of UC.

The modified apheresis protocols with two sessions per week, with 90-min session, or a total of 10 apheresis sessions seem to be more effective than the standard protocol (weekly, 60-min apheresis and a total of five sessions). The modified protocol should be used for patients with more severe diseases, and patients with milder diseases can be treated with the standard protocol. However, the most appropriate frequency and duration of apheresis, and number of apheresis sessions still remain

unknown. Although several patients maintained their remission after GMCAP therapy, the long-term efficacy of GMCAP should be assessed in future. Furthermore, whether GMCAP is useful as maintenance therapy during remission needs to be assessed. Most of the previous studies were uncontrolled trials; only one study was a randomized, open-labeled, controlled trial comparing GMCAP and prednisolone<sup>[14]</sup>. To assess a definite efficacy of GMCAP, well-designed randomized controlled trials are necessary. In the United States and Canada, a randomized, prospective, double-blinded, placebo-controlled (sham-controlled) study to evaluate the safety and effectiveness of the Adacolumn apheresis system for the treatment of moderate-to-severe UC is being conducted<sup>[30]</sup>.

There have been few studies which examined the efficacy of GMCAP for Crohn's disease<sup>[16,31-34]</sup>. One study reported that a five-session protocol of GMCAP seemed to be efficient in the treatment of steroid-dependent UC, but not in Crohn's disease<sup>[16]</sup>. In contrast, several studies reported that GMCAP was useful to decrease the disease activity in patients with Crohn's disease<sup>[31-34]</sup>. Kusaka *et al*<sup>[33]</sup> treated six patients with active Crohn's disease unresponsive to conventional medications with GMCAP (five apheresis sessions for five consecutive weeks). The Crohn's disease activity index (CDAI) significantly decreased after GMCAP therapy. Three of the six patients responded to the therapy, and one patient could be induced to remission. Fukuda *et al*<sup>[34]</sup> treated 21 patients with a CDAI of >200 and unresponsive to standard medication with GMCAP (five apheresis sessions for five consecutive weeks). After GMCAP therapy, significant improvements in CDAI scores were observed. GMCAP could be effective for inducing remission and improving the quality of life in patients with active Crohn's disease that is refractory to conventional therapy. However, further clinical studies are necessary to assess the efficacy of leukocytapheresis for Crohn's disease because the number of patients included in the previous studies was quite small.

A serious problem with GMCAP is cost; a single session of GMCAP costs ¥145 000 (\$1 300). Because of high cost, GMCAP therapy may not be favorable as a first-line alternative to steroids in patients with active UC. Up to now, the most common medication for UC has been steroids<sup>[35,36]</sup>. When the patient does not respond to steroids and the disease is progressing, surgery is implemented as the last option. Most patients experience adverse effects associated with high dose and long-term administration of steroids and hence, they could have a poor quality of life<sup>[35,36]</sup>. Patients with active UC can be successfully treated with leukocytapheresis, without the usage of corticosteroids, which is good news for both patients and physicians because the prolonged use of steroids may be limited and patient compliance diminished by potential adverse effects. If GMCAP prevents hospital admission, re-administration of steroids and surgery, and it improves and maintains a quality of life of the patients, GMCAP may prove to be cost-effective. The future of GMCAP in the treatment of UC requires further evaluation.

### Abstract

Patients with cirrhosis and portal hypertension exhibit characteristic cardiovascular and pulmonary hemodynamic changes. A vasodilatory state and a hyperdynamic circulation affecting the cardiac and pulmonary functions dominate the circulation. The recently defined cirrhotic cardiomyopathy may affect systolic and diastolic functions, and imply electromechanical abnormalities. In addition, the baroreceptor function and regulation of the circulatory homeostasis is impaired. Pulmonary dysfunction involves diffusing abnormalities with the development of the hepatopulmonary syndrome and portopulmonary hypertension in some patients. Recent research has focused on the assertion that the hemodynamic and neurohumoral dysregulation are of major importance for the development of the cardiovascular and pulmonary complications in cirrhosis. This aspect is important to take into account in the management of these patients.

### INTRODUCTION

The clinical picture of patients with cirrhosis is dominated by the classical complications to portal hypertension, such as ascites, bleeding from esophageal varices, and encephalopathy. In addition, a considerable number of patients show signs of peripheral vasodilatation with

palmar erythema and reddish skin, raised and bounding pulse, and a low systemic blood pressure indicating a hyperdynamic circulation<sup>[1]</sup>. The hyperdynamic syndrome comprises an increased heart rate, cardiac output, and plasma volume, and a reduced systemic vascular resistance and arterial blood pressure<sup>[2-6]</sup>. The typical circulatory changes in patients with cirrhosis are summarized in Table 1. Increased cardiac output in cirrhosis was described more than 50 years ago<sup>[7]</sup> and a hyperdynamic, hyporeactive circulation is today a well-characterized element in the clinical appearance of these patients<sup>[8]</sup>. In addition, patients with cirrhosis develop complications from a variety of organs including the heart, lungs, and kidneys, and other organ systems. Besides the hepatorenal syndrome, this has led to the introduction of new clinical entities, such as cirrhotic cardiomyopathy and the hepatopulmonary syndrome.

Among the mechanisms involved in the peripheral arterial vasodilatation in cirrhosis, intensive research has focused on the presence of arteriovenous communications, increased blood volume, and potent vasodilating systems such as the NO and endothelin (ET) systems<sup>[9-14]</sup>. Activation of a number of neurohumoral homeostatic system, like the renin-angiotensin-aldosterone systems (RAAS), the sympathetic nervous system (SNS), and the hypothalamic/neuropituitary release of vasopressin also seem to play a pivotal role in the circulatory dysfunction in cirrhosis<sup>[15-18]</sup>.

This review will focus on the pathophysiological aspects of the systemic circulatory abnormalities in cirrhosis with emphasis on cardiac and pulmonary dysfunctions.

### SYSTEMIC CIRCULATION IN CIRRHOSIS

The cardiac output is primarily determined by the venous return, heart rate, and myocardial contractility, all of which are controlled by the autonomic nervous system. Among the mechanisms that may raise the cardiac output are increased sympathetic nervous activity, vasodilatation (low systemic vascular resistance), increased blood volume, and the presence of arterio-venous communications. It is noteworthy that the majority of these physiological changes are present in cirrhosis and may more or less contribute to raise cardiac output<sup>[1,19]</sup>. In the early stages of compensated cirrhosis, the presence of a hyperdynamic circulation is often not apparent. But with the progression of the liver disease, there is an overall association between the severity of cirrhosis and the degree of hyperdynamic circulation. Investigations on circulatory changes and reactivity from the upright to the supine position, and vice versa, suggest that the patients are mostly hyperdynamic in the supine position<sup>[20,21]</sup>. On the other hand, the pressor systems are relatively deactivated in the supine position and

it is well documented that sodium-water excretion is higher in the supine position than in the upright position<sup>[22]</sup>.

**Pathophysiology of arterial vasodilatation**

Peripheral vasodilatation in cirrhosis may be brought about either by overproduction of circulating vasodilators, or by vasodilators of intestinal or systemic origin, or by vasodilators that escape degradation in the diseased liver or bypass the liver through portosystemic collaterals<sup>[19]</sup>. A predominantly splanchnic vasodilatation precedes renal sodium and water retention and plasma volume expansion, which correlates with activated counter regulatory vasoconstrictor systems<sup>[6,19]</sup>. In 1988, Schrier *et al* proposed the “*peripheral arterial vasodilation hypothesis*”<sup>[23]</sup>. According to this theory, primary splanchnic arteriolar vasodilatation leads to the reduction of the overall systemic vascular resistance, to avoid arterial underfilling with low arterial blood pressure. A reduced effective blood volume, which is that part of the blood volume where baroreceptors are located, leads to the activation of vasoconstrictor systems and secondary sodium-water retention<sup>[6,23-25]</sup>. Thus, most of the hemodynamic changes seen in cirrhosis can be explained by this theory, as shown in Figure 1.

**Circulating vasodilators**

In recent years, research has focused especially on vasodilating substances, such as NO, calcitonin gene-related peptide (CGRP), and adrenomedullin, but other vasodilators substances, like natriuretic peptides, tumor necrosis factor alpha, interleukins, substance P, ETs, and endocannabinoids,

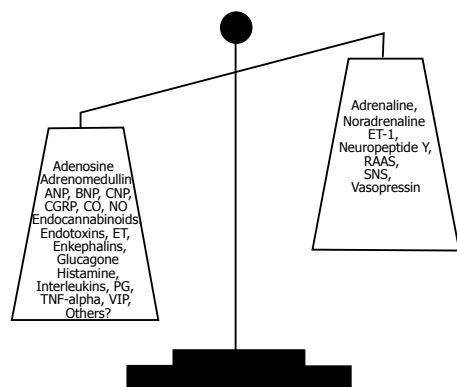

**Figure 1** Pathophysiology of the splanchnic and peripheral arteriolar vasodilation and systemic hemodynamic changes in cirrhosis. Endogenous vasodilators may escape hepatic degradation, owing to portosystemic shunting and/or hepatocellular damage, and induce vasodilatation preferentially in the splanchnic vascular area. Reduced systemic and splanchnic vascular resistance leads to a reduced effective arterial blood volume, and hence to activation of vasoconstrictor systems. The hemodynamic and clinical consequences are increases in cardiac output, heart rate, and plasma volume and decreased renal blood flow, low arterial blood pressure, and fluid and water retention. The development of the hyperdynamic circulation may increase portal inflow and further aggravate the portal pressure in a vicious cycle. SNS, sympathetic nervous system; RAAS, renin-angiotensin-aldosterone system; ET-1, endothelin-1.

have also been implicated<sup>[12,26-32]</sup>.

NO is synthesized in the vascular endothelium from L-arginine by NO synthase (NOS)<sup>[33]</sup>, of which three isoforms have been identified: inducible NOS (iNOS), constitutive endothelial NOS (ecNOS), and neuronal NOS (ncNOS)<sup>[12,34]</sup>. In portal hypertension, there seems to be a diminished release of NO from sinusoidal endothelial cells in the cirrhotic liver<sup>[34,35]</sup> whereas, in the systemic circulation, there is evidence of increased eNOS upregulation, which is probably related to shear stress<sup>[26,33,36]</sup>. Exhaled air from cirrhotic patients contains higher NO levels than that of controls and correlates with the severity of disease and degree of hyperdynamic circulation; in animal models and cirrhotic patients, blockade of NO formation significantly increases arterial blood pressure and decreases plasma volume and sodium retention<sup>[37-40]</sup>. Taken together, there is a growing body of evidence that the systemic NO production is increased and precedes the development of the hyperdynamic circulation in cirrhosis, thereby playing a major role in the arteriolar and splanchnic vasodilatation and vascular hyporeactivity<sup>[12,41]</sup>. In addition, vascular endothelial growth factor (VEGF) seems to stimulate angiogenesis and the development of portosystemic collaterals, and recently blockade of the VEGF receptor-2 has been shown to inhibit this process<sup>[42]</sup>. In spite of the experimental nature of the study, this principle may have some therapeutic implications in the treatment of portal hypertension.

CGRP, a 37-amino-acid neuropeptide with a neurotransmitter function, is on a molar basis the most powerful vasodilating peptide known<sup>[43]</sup>. It is elevated in cirrhosis, especially in those patients with ascites and the hepatorenal syndrome<sup>[43,44]</sup> and correlates to hemodynamic markers of vasodilatation and central hypovolaemia, such as cardiac output, systemic vascular resistance, arterial compliance, and central blood volume<sup>[27,45-47]</sup>. Adrenomedullin is a vasodilating peptide with a sequence

**Figure 2** Imbalance between vasoconstricting and vasodilating forces. ANP, atrial natriuretic peptide; BNP and CNP: B- and C-type natriuretic peptides; CGRP, calcitonin gene-related peptide; ET, endothelin; TNF- $\alpha$ , tumor necrosis factor  $\alpha$ ; VIP, vasoactive intestinal polypeptide; RAAS, The renin-angiotensin-aldosterone system; SNS, The sympathetic nervous system.

similarity to CGRP, it is primarily released from the adrenal medulla and induces relaxation of smooth muscle cells<sup>[48]</sup>. The circulating levels of adrenomedullin seem to be higher in decompensated patients with cirrhosis and correlate with pressor substances, such as endothelin, renin, vasopressin, and catecholamines<sup>[29,49,50]</sup>.

In addition to a surplus of vasodilators, resistance to pressor hormones may play a role in the pathogenesis of vasodilatation, as patients with cirrhosis are hyporesponsive to the pressor effects of such potent vasopressors as noradrenaline, angiotensin II, and vasopressin<sup>[51-53]</sup>. This may be brought about by a change in receptor affinity, a decrease in the numbers of receptors, and a variety of post-receptor defects<sup>[54,55]</sup>. Helmy *et al* have reported hyporesponsiveness to angiotensin II and endothelin-1, chiefly because of enhanced NO generation<sup>[41,56]</sup>. Thus, the excess of vasodilators combined with an inadequate hemodynamic response to vasoconstrictors may explain the vasodilatory state and vascular hyporeactivity in cirrhosis.

### Vascular territories with vasoconstriction

Although cardiac output is increased, thus reflecting substantial vasodilatation, it may cover perfusions from vascular beds that are hyperperfused, normoperfused, and hypoperfused. The kidney in cirrhosis is a vascular region where vasoconstriction prevails and plays a pivotal role in the development of hepatic nephropathy with a decreased renal blood flow and glomerular filtration rate, increased sodium reabsorption, and decreased free water excretion<sup>[6,57]</sup>. Liver dysfunction, central hypovolaemia, arterial hypotension, and neurohumoral activation with renal vasoconstriction seem to be of major importance. Recent results suggest that a decrease in the cardiac output in the face of severe vasodilatation and activation of the RAAS is an important determinant of the hepatorenal syndrome<sup>[58]</sup>. Splanchnic vasodilatation and central hypovolaemia activate the SNS, the RAAS, the endothelin system, and increased release of vasopressin<sup>[17,18]</sup>. The imbalance between vasoconstricting and vasodilating forces is illustrated in Figure 2. Secondary hyperaldosteronism and increased tubular sensitivity to aldosterone increase sodium reabsorption in the distal nephron, whereas SNS

stimulates sodium reabsorption in proximal tubules, the loop of Henle, and distal tubules<sup>[59]</sup>. Angiotensin II mainly acts on the efferent arteriole and a low dose of an ACE-inhibitor may induce a significant reduction in glomerular filtration and a further reduction in sodium excretion, even in the absence of a change in arterial blood pressure. This suggests that the integrity of the RAAS is important for the maintenance of renal function in cirrhotic patients, and that RAAS overactivity does not solely contribute to the adverse renal vasoconstriction. Because of the arterial vasodilatation, the renal perfusion pressure is low and critically dependent on counter regulatory systems. For these reasons, blockers of these systems by ACE-inhibitors (captopril), angiotensin II antagonists (Losartan),  $\beta$ -adrenergic blockers, and V1 vasopressin antagonist may decrease further the renal blood flow<sup>[60,61]</sup>. The hepatorenal syndrome denotes a functional and reversible impairment of renal function with a poor prognosis in patients with severe cirrhosis. Treatment is directed towards improving liver function, arterial hypotension, and central hypovolaemia, and reducing renal vasoconstriction for instance with the combined use of splanchnic vasoconstrictors such as terlipressin and plasma expanders like human albumin<sup>[62]</sup>.

### Distribution of volumes and flow

Blood and plasma volumes are increased in patients with advanced cirrhosis<sup>[25,63]</sup>, and the distribution of blood in the different vascular beds is abnormal and relates to the severity of the disease<sup>[64]</sup>. By different techniques it has been established that the central and arterial blood volume is most often decreased, whereas the non-central blood volume, in particular the splanchnic blood volume is increased in animals and patients with cirrhosis<sup>[65-67]</sup>. The effective arterial blood volume is decreased with relation to the systemic circulatory derangement. Moreover, the central circulation time (i.e. central blood volume relative to CO) is substantially reduced and has a significant relation to poorer survival in advanced cirrhosis<sup>[68,69]</sup>.

During volume expansion, most cirrhotic patients respond with a further reduction in systemic vascular resistance rather than an increase in arterial blood pressure<sup>[70,71]</sup>. Volume expansion by head-out water immersion provides, in principle, the same volume changes by central relocation as in healthy subjects<sup>[70]</sup>. However, especially in decompensated cirrhosis, there may be a further decrease in the arterial blood pressure, owing to the unloading of baroreceptors, and renal salt-water excretion is prolonged and incomplete. The infusion of hyperosmotic solutions or albumin in cirrhosis results initially in a shift of fluid from the interstitial space into the plasma volume, with an expansion of the latter<sup>[63,71]</sup>. Albumin infusion is important in the prevention of postparacentesis circulating dysfunction<sup>[72]</sup>. When considering volume expansion in terms of the severity of the disease, certain differences become clear. Irrespective of severity, volume expansion produces a rise in stroke volume and cardiac output. Whereas in early cirrhosis there is a proportional expansion of the central and non-central parts of the blood volume, in late cirrhosis expansion is mainly confined to the non-central part, with a proportionally smaller increase in cardiac output, probably because of cardiac dysfunction (cirrhotic

cardiomyopathy) and abnormal vascular compliance<sup>[71,73]</sup>.

The increased plasma volume in cirrhosis should be considered secondary to the activation of neurohumoral mechanisms consequent on arterial vasodilatation, low arterial blood pressure, and reduced central and arterial blood volume. However, a non-volume-dependent activation of the SNS through hepatic reflexes, owing to portal hypertension, may occur. This has been documented in animal experiments and there are indications of such a reflex in men<sup>[74]</sup>. Although the relative importance of non-volume-dependent sympathetic activation and volume/arterial pressure-dependent activation of SNS and other neurohumoral systems has not been finally established, the latter is probably far the most important.

## CARDIAC DYSFUNCTION IN CIRRHOSIS

The hyperdynamic circulation in cirrhosis comprises increased cardiac output and work<sup>[5,75]</sup>. In other circumstances, this would cause cardiac failure, but because of the decreased afterload as reflected by reduced systemic vascular resistance and increased arterial compliance, a left ventricular failure may be latent in cirrhosis<sup>[75,76]</sup>. Cardiac failure may become manifest under strain or treatment with vasoconstrictors. This type of cardiac dysfunction has been termed as cirrhotic cardiomyopathy and includes impaired cardiac contractility with a systolic dysfunction, diastolic dysfunction, and electromechanical abnormalities with a prolonged *Q-T* interval<sup>[77]</sup>. Various electrophysiological mechanisms for the conductance abnormalities and impaired cardiac contractility have been put forward, including reduced beta-adrenoceptor density, post-receptor signal defects, abnormal excitation-contraction coupling, and molecular abnormalities<sup>[73]</sup>.

### Systolic dysfunction

At rest, when the systemic vascular resistance (afterload) against which the heart works is reduced, cardiac pressures are almost normal and may thereby mask an underlying ventricular dysfunction. Cardiac failure, therefore, becomes manifest only under conditions of hemodynamic stress. Thus, after the exercise, the left ventricular end-diastolic pressure increases, but the expected increase in cardiac stroke index and left ventricular ejection fraction (LVEF) are absent or subnormal, which indicates inadequate ventricular reserve response to a rise in ventricular filling pressure<sup>[78,79]</sup>. A vasoconstrictor-induced increase in left ventricular afterload by 30% results in an increase in pulmonary capillary wedged pressure about double, without any change in the cardiac output<sup>[80]</sup>. A similar pattern is seen after the insertion of transjugular intrahepatic portosystemic shunt (TIPS), but the increased cardiac pressures tend to normalize with time<sup>[81-83]</sup>. A failure to increase cardiac output, despite an increased ventricular filling pressure, indicates that normalization of the afterload impairs cardiac performance and unmasks left ventricular dysfunction<sup>[80]</sup>. Similar effects are seen after infusion of plasma expanders. Infusion of a plasma protein solution, however, increases cardiac output, as well as the right atrial pressure, pulmonary arterial pressure, and pulmonary capillary wedged pressure, whereas infusion of

packed red blood cells may not change these variables<sup>[84]</sup>.

The LVEF, i.e. the stroke volume relative to the left ventricular end-diastolic volume, is an often used measure of systolic function even though it is still very much influenced by preload and afterload. It has been reported to be normal at rest in some studies<sup>[78,85-90]</sup> and reduced in one study in a subgroup of patients with ascites<sup>[91]</sup>. The maximum aerobic exercise capacity and maximum heart rate are lower in the majority of patients with cirrhosis<sup>[79,85,92]</sup>. After exercise, LVEF increases significantly less in cirrhotic patients than in controls<sup>[79,92,93]</sup>. The reduced functional capacity may be attributed to a combination of blunted heart rate response to exercise, reduced myocardial reserve, and profound skeletal muscle wasting with impaired oxygen extraction<sup>[85,94]</sup>. Normalization of the low systemic vascular resistance by vasoconstrictors results in an increase in the left atrial and left ventricular filling pressures<sup>[75,80]</sup>. Therefore, attempts to normalize the reduced cardiac afterload seem to unmask a latent ventricular dysfunction which appears to be resistant to inotropic drugs<sup>[77,80]</sup>. The expanded blood volume in advanced cirrhosis contributes to a persistent increase in cardiac output, which may overload the heart, with impaired cardiac contractility as the outcome<sup>[20,86,95]</sup>. In patients with advanced cirrhosis and severe vasodilatation, activation of the RAAS, and impaired renal function, a reduced systolic function (a decrease in cardiac output) seems to be a major determinant for the development of the hepatorenal syndrome<sup>[58]</sup>.

### Diastolic dysfunction

A diastolic dysfunction implies changes in myocardial properties that affect left ventricle acceptance of a sufficient volume during the diastole, despite normal filling pressures; the increased stiffness of the myocardial wall will thus result in impaired filling of the left ventricle<sup>[96]</sup>. This increases the transmitral pressure gradient and the atrial contribution to ventricular filling in order to normalize the left ventricular diastolic volume. Determinants of a diastolic dysfunction include impaired left ventricular diastolic filling, in spite of high stroke volume. In the Doppler-echocardiogram, the E-wave reflects the early rapid transmitral flow and the A-wave the late atrial contribution to filling. Indications of diastolic dysfunction are a decreased E/A ratio and delayed early diastolic transmitral filling with prolonged deceleration and isovolumetric relaxation times<sup>[97]</sup>, as shown in Figure 3. In cirrhosis, the morphological basis of cirrhotic cardiomyopathy seems to be cardiac hypertrophy, patchy fibrosis, and subendothelial edema<sup>[77,93]</sup>. In a number of studies, A-wave and E-wave velocities and deceleration times are much increased and the E/A-ratio is decreased in cirrhotic patients, especially in those with ascites<sup>[91,97]</sup>. Recent studies of ventricular diastolic filling in cirrhosis support the presence of a subclinical myocardial disease with diastolic dysfunction, which, in ascitic patients, is improved after paracentesis and aggravated after TIPS<sup>[82,88,91,97]</sup>. In these decompensated patients, paracentesis seems to ameliorate diastolic, but not systolic, function<sup>[91]</sup>. Liver transplantation has recently been shown to revert cardiac alterations, including diastolic

dysfunction<sup>[93]</sup>. It has been proposed that a diastolic dysfunction precedes systolic dysfunction in early heart disease and that antialdosterone treatment improves cardiac function. Pozzi *et al* recently demonstrated that antialdosterone treatment with K-canrenoate in cirrhosis ameliorated cardiac structure and function, but had almost no effects on systolic and diastolic functions<sup>[98]</sup>. It is also possible that antialdosterone treatment may have beneficial effects on catecholamine-induced cardiac fibrosis, as described in heart failure<sup>[99]</sup>.

The clinical significance of diastolic dysfunction and the importance in cirrhotic cardiomyopathy have been questioned, as overt cardiac failure is not prominent in cirrhosis. However, there are several reports of unexpected death from heart failure following liver transplantation<sup>[100]</sup>, surgical portocaval shunts and TIPS<sup>[81]</sup>. These procedures involve a rapid increase in cardiac preload. In a less compliant heart, the diastolic dysfunction could be enough to cause pulmonary edema and heart failure. This is consistent with the findings of Huonker *et al*<sup>[82]</sup>, who reported an increase in pulmonary artery pressure, pre-load, and diastolic dysfunction after TIPS. Diastolic dysfunction could thus account for part of the cardiac dysfunction in cirrhotic cardiomyopathy.

### Electromechanical abnormalities

The sympathetic nervous activity influences the heart rate and electromechanical coupling by several mechanisms: noradrenaline binding to beta-receptors, receptor-mediated G protein interaction, and consequently stimulation of adenylcyclase, activation of cAMP-dependent phosphokinase A, and channel phosphorylation. Several receptor and post-receptor defects have been described in cirrhosis with reduced beta-receptor density and sensitivity<sup>[101]</sup>, and altered G protein and calcium channel functions<sup>[102]</sup>. All these defects may explain both impaired chronotropic responses and electromechanical uncoupling. This coupling between the cardiac contractions and the arterial system is of major importance to the amount of work performed by the left ventricular myocardium, and thereby, of the strain on the heart<sup>[85]</sup>. The ascending aorta and aortic arc are the most compliant systemic arteries in the body. The ability to contain the entire stroke volume without excessive deflection in the arterial systolic pressure profile is of crucial importance, especially in patients with a large CO and stroke volume. On the other hand, too compliant a central arterial system will be unable to perform a timely and prompt delivery of blood to the different parts of the body, but may delay the flow to important areas of the vascular bed. Thus, the heart and central arterial tree work together in an essential coordination of the oscillating blood flow. This is especially important when vascular beds with highly different hemodynamic resistances are connected to the central arterial system, as in chronic liver disease.

In addition to the abnormal function of the calcium channels, Ward *et al*<sup>[103]</sup> have shown a decrease in K<sup>+</sup> currents in ventricular cardiomyocytes from cirrhotic rats, which prolong the *Q-T* interval. A prolonged *Q-T* interval is often present in chronic liver disease, potentially leading to ventricular arrhythmias and sudden cardiac

death<sup>[75,77,104]</sup>. Bernardi *et al* have reported a prolonged *Q-T* interval, which is significantly related to the severity of the liver disease, plasma noradrenaline, and survival<sup>[105]</sup>. A reversal of the *Q-T* interval seems to occur with improved liver function, for instance, after orthotopic liver transplantation<sup>[106]</sup>. Results from our group indicate that the frequency adjusted *Q-Tc* becomes partly normalized after oral  $\beta$ -blocker treatment<sup>[107]</sup>. The prolonged *Q-T* interval in cirrhosis should be considered as an element in the cirrhotic cardiomyopathy and may be of potential use in identifying patients at risk<sup>[77]</sup>. Pathophysiological and clinical research is needed to assess the prognostic and therapeutic significance of the prolonged *Q-Tc* interval in chronic liver disease.

It can be concluded that there is evidence of a cirrhotic cardiomyopathy in cirrhosis that appears to be unmasked by procedures that stress the heart, such as pharmacological vasoconstriction, exercise, and by such portosystemic shunt procedures as insertion of TIPS. Future studies should be directed against an operable definition of cirrhotic cardiomyopathy, a delineation of the clinical importance, and potential treatment regimens. Until then, we still do not know how or if cirrhotic cardiomyopathy should be treated specifically.

## CARDIOVASCULAR REGULATION IN CIRRHOSIS

### Autonomic dysfunction

Evidence of autonomic defects in patients with cirrhosis has emerged from hemodynamic responses to standard cardiovascular reflex tests, such as Valsalva ratio, heart rate variability, and isometric exercise<sup>[87,108-111]</sup>. Most studies of these issues have found a high prevalence of autonomic dysfunction in cirrhosis with associations to liver dysfunction and survival<sup>[111,112]</sup>. The results of Mohamed *et al* suggest that the autonomic dysfunction is temporary, arises as a consequence of liver dysfunction, and may be reversible after liver transplantation<sup>[106]</sup>. Whereas most studies have focused on the defects in the SNS, recent papers have emphasized the importance of a vagal impairment for sodium and fluid retention<sup>[108,110,112]</sup>. Sympathetic responses to dynamic exercise seem to be normal in patients with cirrhosis, but those to isometric exercise are clearly impaired<sup>[113,114]</sup>. Similarly, blood pressure responses to orthostasis are impaired, probably because of a blunted baroreflex function<sup>[87,115,116]</sup>. Abnormal cardiovascular responses to pharmacological stimulations with angiotensin II, noradrenaline, and vasopressin in terms of impaired responses in blood flow and blood pressure have also been reported in cirrhosis<sup>[117-119]</sup>. Dillon *et al*<sup>[112]</sup> have described the correction of autonomic dysfunction in cirrhosis by captopril, which indicates that vagal dysfunction in cirrhosis is partly caused by neuromodulation by angiotensin II. Involvement of the RAAS is also supported by the data from La Villa *et al*, who recently reported that canrenone, an aldosterone antagonist, normalized cardiac responses to postural changes in compensated cirrhotic patients<sup>[116]</sup>.

At present the pathophysiological basis of the autonomic dysfunction is unknown, but it could be within the central nervous system through damage to

**Figure 3** Diagram of the transmitral Doppler flow signal in the healthy state and in a patient with cirrhosis. The Doppler flow profile reflects the early filling of the ventricle (Peak E) and the late atrial contribution to its filling (Peak A). A decrease in the E/A ratio and prolonged acceleration time (AT) and deceleration time (DT) indicate diastolic dysfunction, as illustrated in the right panel. The broken lines are the time-related electrocardiogram.

the peripheral nerves or changes in neurotransmission in terms of a post-receptor defect which could explain the vascular hyporeactivity (Figure 4). From the amount of data available, a multifactorial etiology to the hyporesponsiveness in cirrhosis seems most likely.

### Vascular hyporeactivity and arterial compliance in cirrhosis

The hyporeactivity of the vascular system in chronic liver disease is probably a result of a differential balance between vasoconstricting and vasodilating forces in different vascular areas (Figure 2). Generally, however, the vascular system in cirrhosis is very flexible as reflected by an overall increased vascular and arterial compliance<sup>[120-122]</sup>. The systemic arterial compliance, defined as an increase in intra-arterial volume relative to an increase in transmural arterial blood pressure, is especially increased in patients with decompensated cirrhosis<sup>[46]</sup>. This is because of the changes in the arterial wall, as well as dynamic changes, and is closely associated with the circulatory and homeostatic derangement<sup>[47,122]</sup>. Therefore, the changes in arterial mechanics are partly reversible. The arteriolar tone adjusts the level of blood pressure and may thereby also affect large artery compliance. In fact, arterial compliance depends on the properties of arterial intrinsic elastic and smooth muscle, whereas arteriolar tone should result more from the balance between vasoconstrictors and vasodilators. The increased arterial compliance is directly related to the severity of liver disease and to the circulating vasodilator, CGRP, but is inversely related to circulating adrenaline, and unrelated to indicators of potent vasoconstrictor systems (SNS and ET-1)<sup>[47,123]</sup>. In addition, other operative elements in the abnormal arterial compliance are blood volume abnormalities, hypoxia, and abnormalities in the C-type natriuretic peptide (CNP), but not to arterial natriuretic peptide. Arterial compliance is not affected by  $\beta$ -adrenergic blockade, but terlipressin almost normalizes it<sup>[124]</sup>. Arterial compliance is an important determinant of the coupling between the heart and the arterial system, and of the dynamics

**Figure 4** Vascular hyporeactivity in cirrhosis may originate in the central nervous system, the autonomic nervous system, from local mediators, or within the smooth muscle cell/heart muscle cell. An autonomic dysfunction may act at cardiac, arterial, and arteriolar levels. Vasodilators and vasoconstrictors may act variably at cardiac, arterial, and arteriolar levels. At the smooth cellular (arteriolar) level, hyporeactivity may be caused by increased concentrations of vasodilators (NO, nitric oxide; CGRP, calcitonin gene-related peptide; ANP, atrial natriuretic peptide; TNF- $\alpha$ , tumor necrosis factor- $\alpha$ ; endocannabinoids; CO: carbon monoxide) and/or decreased sensitivity to vasoconstrictors (ET-1: endothelin-1).

of intravascular volume relocation<sup>[125]</sup>. An element in the elevated arterial compliance in advanced cirrhosis is the reduced arterial blood volume and blood pressure<sup>[47]</sup>.

Recent data suggest that the hyperdynamic circulation is mainly caused by circulatory alterations in the splanchnic area<sup>[67]</sup>. Thus, arteriolar vasodilatation is a more localized event, whereas the increased arterial compliance is more general<sup>[47]</sup>. Arterial compliance may therefore be an integral variable for vascular responsiveness, together with the systemic vascular resistance. Changed dynamic and static function of the arterial tree may contribute to the abnormal reactions of volume and baroreceptors, and have implications for the abnormal circulatory regulation, and potentially for therapy with vasoactive drugs. These aspects are, however, a topic for further research. In conclusion, arterial compliance is elevated in advanced cirrhosis. Besides a relation to age, body size, gender, and the level of the arterial blood pressure, arterial compliance is directly related to the severity of cirrhosis and the hyperdynamic circulatory derangement.

### Baroreceptor function and homeostasis of arterial blood pressure in cirrhosis

The arterial vasodilatation contributes to the displacement of the central blood volume towards peripheral and splanchnic vascular regions, resulting in central and arterial hypovolaemia and activated counter regulatory mechanisms<sup>[65,71,126]</sup>. The pronounced vasodilatation and the fall in arterial blood pressure elicit reduced baroreflex activity and diminished central signaling from the cardioinhibitory center and results primarily in SNS-mediated vasoconstriction of resistance vessels<sup>[127]</sup>. The normal response to upright posture is a fall in arterial, central venous, and pulse pressures and there is a close relation between the decline in pulse pressure on the one hand and the rising heart rate and declining splanchnic blood flow on the other, which suggests that arterial baroreceptors initiate an increase in heart rate and

splanchnic vasoconstriction<sup>[127]</sup>. Whether this pattern is disturbed in cirrhosis is unclear at present. Some studies have shown that a reduction in thoracic blood volume increases the sensitivity of the arterial baroreflex<sup>[127,128]</sup>. A resetting of the baroreceptors is still discussed in human conditions in relation to wall tension of the fibroelastic tissues in the vessels and stretch-induced activation of the sodium-potassium channels<sup>[127]</sup>. As mentioned above, autonomic dysfunction is well-established in cirrhosis<sup>[112,114,129]</sup>, and impaired baroreceptor reflex sensitivity has been suggested<sup>[121,115,130]</sup>. The baroreceptor function is influenced by hypoxia<sup>[131,132]</sup> which is often seen in cirrhosis and in particular in those patients with the hepatopulmonary syndrome<sup>[133,134]</sup>.

Baroreceptor sensitivity in the small subset of cirrhotic patients with arterial hypertension has not been investigated, but it is very likely that the co-existence of two different conditions of baroreceptor function involved may affect the cardiovascular regulation<sup>[135]</sup>. Future studies should seek to reveal the direction of this possible baroreceptor dysfunction in this specific group of patients.

### Blood pressure regulation

Potent vasodilators such as NO, CGRP, histamine, bradykinin, and serotonin have been implicated in the regulation of the blood pressure in chronic liver disease<sup>[1]</sup>. A significant inverse relation of the potent vasodilator, adrenomedullin, to arterial blood pressure and ET suggests that these two vasoactive systems play a role in blood pressure regulation in cirrhosis. NOS blockade causes higher arterial blood pressure in cirrhotic rats. Inhibition of the endocannabinoid CB1 receptor raises arterial blood pressure in experimental cirrhosis, and anandamide from the monocytes of cirrhotic rats may contribute to the arterial hypotension observed<sup>[132,136]</sup>. However, the significance of blood pressure dysregulation in human cirrhosis awaits further studies.

The arterial blood pressure is kept low below normal, depending on the state of the disease, as a circulatory compromise between the vasodilating and counter regulatory vasoconstricting forces affecting both vascular resistance and compliance. The arterial blood pressure possesses a circadian variation. Twenty-four-hour determinations in cirrhotic patients show that during the day, the systolic, diastolic, and mean arterial blood pressures are substantially reduced, whereas at night, the values are unexpectedly normal<sup>[14]</sup>. In cirrhosis, the drop from day time to night-time and the rise from night-time to daytime show lower values than in controls. It is known from several diseases, such as uraemia and different types of heart failure, that the circulation of patients classified as "nondippers" is abnormally regulated. The combination of normal blood pressure and increased heart rate at night suggests abnormal regulation of the circulation in cirrhosis. Prolonged rest in the supine position (as during sleep) may lessen the abnormal distribution of the blood volume and improve the ability to maintain a normal "sleeping" arterial blood pressure, only at the cost of an increased heart rate and CO. The upright position further aggravates central hypovolaemia, and normal arterial blood pressure cannot be maintained, even when the heart rate and CO

are increased<sup>[20,21,137]</sup>. The negative correlation of the arterial blood pressure to the Child score during the day and at night confirms that the hemodynamic derangement is related to the severity of the liver disease<sup>[69]</sup>. The low arterial blood pressure, the abnormal distribution of the circulating medium and diurnal variation in arterial blood pressure, and the marked activation of neurohumoral systems contribute to the abnormal homeostatic regulation in patients with cirrhosis.

Previous reports of findings that arterial hypertension does not occur together with cirrhosis of the liver are not true in an absolute sense. However, the prevalence of arterial hypertension in cirrhotic patients is substantially reduced, especially in advanced cirrhosis<sup>[135]</sup>. As hypertensive patients are often effectively treated with diuretics, calcium channel antagonists, beta-blockers, ACE-inhibitors, etc., and some of these drugs are also applied in the treatment of cirrhosis and portal hypertension, the natural history and prevalence of cirrhosis in patients with arterial hypertension, arterial hypertension in patients with cirrhosis, and the interrelationship of these two diseases may be difficult to study today in prospective and untreated cases. Nevertheless, such studies are relevant, since there are many unsolved questions.

### PULMONARY DYSFUNCTION IN CIRRHOSIS

Patients with cirrhosis often complain of dyspnea and platypnea, and arterial oxygenation is often impaired with orthodeoxia<sup>[138,139]</sup>. The etiology of abnormal lung function and ventilation in cirrhosis may be multifarious and is often a combination of the presence of cardiac dysfunction, heavy smoking, and chronic obstructive lung disease which is common in patients with alcoholic cirrhosis<sup>[140]</sup>. In addition, lung function and oxygenation can be affected by edema and tense ascites, which are ameliorated after diuretic treatment and paracentesis<sup>[141]</sup>. But independent of smoking status, patients with cirrhosis have a compromised lung function with a reduced transfer factor and ventilation/perfusion abnormalities<sup>[45,134,140,142]</sup> and arterial hypoxemia is seen in 30%-70% of patients with chronic liver disease, depending on the severity<sup>[143,144]</sup>. Various pathophysiological factors may be involved in the reduced diffusing capacity, including an abnormal ventilation/perfusion ratio ( $V_A/Q$ ), the presence of arterial venous shunts, and changes in the alveolar-arterial membrane (Figure 5).

### Hepatopulmonary syndrome

The reduced diffusion capacity (transfer factor) has been related to the increased amount of blood in the lung capillaries<sup>[145]</sup>, but this does not seem to be the case, as there is a direct correlation between the amount of circulating red blood cells and flow in the lung capillaries and the diffusing capacity in normal physiology<sup>[146]</sup>. To support this concept, we have earlier described direct relations between the diffusing capacity and the cardiac output and central blood volume in cirrhosis (Figure 5)<sup>[45]</sup>.

Pulmonary vascular resistance is most often decreased in cirrhosis<sup>[147]</sup> and in a substantial number of patients there seem to be areas with a high perfusion rate in relation to alveolar ventilation<sup>[45,140]</sup>. Besides the abnormal ventilation/

**Figure 5 Panel A.** Lung diffusion and blood oxygenation depend on the diffusion properties of the alveolar-arterial membrane, the degree of arterial-venous shunting through pulmonary shunts, and the degree of ventilation-perfusion inequality ( $V_A/Q$ ). **Panel B.** The alveolar-arterial oxygen gradient increases with the severity of liver disease e.g. graduated according to the Child-Turcotte classification with the highest values in patients with hepatic coma. <sup>1</sup>denotes significant difference from Child class A patients (from Ref. [143]). **Panel C.** In cirrhosis, the diffusing capacity bears a direct relation to the increased cardiac output and to the central blood volume (not shown). Data from Ref. [45].

perfusion ratio and the presence of regular pulmonary arteriovenous shunts, intrapulmonary vascular dilatations have also been described<sup>[134,140,147,148]</sup>. The condition with reduced transfer factor, abnormal ventilation/perfusion ratio or shunts, low arterial oxygen saturation, and pulmonary vasodilatation and hyperdynamics is termed as the hepatopulmonary syndrome<sup>[134,149,150]</sup>. Pulmonary angiography of these patients has revealed two types of patterns with a spongiform appearance of the vessels and small arteriovenous communications<sup>[134]</sup>. Fallon *et al.*<sup>[151-153]</sup> have recently reported increased pulmonary vascular endothelial NOS and increased production of cholangiocyte endothelin-1 and increased expression of endothelin-B receptors. Experimental NO-dependent vasodilatation is supported by clinical studies showing increased NO in the exhaled air of cirrhotic patients<sup>[154,155]</sup>. A recent paper has shown increased carboxyhemoglobin levels that correlate with arterial oxygen tension and alveolar-arterial oxygen gradient in patients with the hepatopulmonary syndrome<sup>[156]</sup>.

The frequency of the hepatopulmonary syndrome in patients with cirrhosis is not yet established. Different reports have given different frequencies of reduced arterial oxygen saturation in cirrhotic patients varying from about 10% to as high as 70%<sup>[143,157,158]</sup>.

The degree of gas exchange abnormalities, such as the oxygen tension and the alveolar-arterial oxygen gradient, correlates with the severity of liver disease (Figure 5). The diagnosis of the hepatopulmonary syndrome relies on the demonstration of arterial hypoxemia ( $PaO_2 < 9.31$  kPa), an age-adjusted increased alveolar-arterial oxygen gradient ( $> 2.66$  kPa) and intrapulmonary vasodilatation<sup>[159,160]</sup>. According to the severity of deoxygenation, four stages have been proposed<sup>[160]</sup>. A 100% oxygen shunt study with the

patient breathing 100% oxygen may discriminate between functional and anatomic shunts<sup>[134]</sup>. Contrast-enhanced echocardiography is considered as the method of choice in the diagnosis of the hepatopulmonary syndrome<sup>[161]</sup>. Agitated saline (microbubbles) is injected into a brachial vein and the bolus is shortly seen in the right heart chambers. A positive test for intrapulmonary vasodilatation occurs with delayed visualization of the microbubbles in the left heart chambers after more than three heart beats<sup>[162]</sup>. Finally, a lung perfusion scan with the injection of macroaggregated albumin and estimation of the extra-pulmonary shunt fraction can be used<sup>[148]</sup>. From counts over lungs and brain, the shunt fraction can be calculated and a value  $> 6\%$  is considered positive with a sensitivity of 85%<sup>[148,160]</sup>.

No specific treatment, apart from long-term oxygen therapy, is available for the hepatopulmonary syndrome. It has been reversed by successful orthotopic liver transplantation in some patients<sup>[144,163]</sup> and by insertion of a TIPS in others<sup>[164]</sup>. TIPS insertion increases pulmonary artery pressure but cardiorespiratory complications are common and TIPS cannot be recommended for this indication at present<sup>[165,166]</sup>.

### Portopulmonary hypertension

The association between portal hypertension and pulmonary artery hypertension is termed portopulmonary hypertension and is defined as a mean pulmonary artery pressure  $> 3.325$  kPa and pulmonary vascular resistance  $> 120$  dyn·s/cm<sup>5</sup>, and normal left atrial pressure ( $< 1.995$  kPa)<sup>[147]</sup>. It is seen infrequently in cirrhosis with an average prevalence from 1% to 4%<sup>[167]</sup>. Symptoms are typically progressive and include fatigue, dyspnea, and edema<sup>[134]</sup>. Systemic vascular resistance and cardiac output are not different from that of cirrhotic patients

without portopulmonary hypertension, whereas their arterial oxygenation is impaired<sup>[168]</sup>. The histological appearance of pulmonary vessels is similar to that seen in primary pulmonary artery hypertension, and includes smooth muscle proliferation and hypertrophy<sup>[160]</sup>. Local vasoconstrictor systems, like the endothelin system, may play a role and recently the administration of a mixed ET-antagonist has showed beneficial effects in portopulmonary hypertension<sup>[169,170]</sup>. Treatment of portopulmonary hypertension is in general non-specific and palliative, and includes vasodilators, such as calcium channel blockers, nitrates, and prostacyclin<sup>[160]</sup>.

## CONCLUSION

So far, a huge body of research has revealed that, in addition to portal and splanchnic complications to chronic liver disease, complications relating to the systemic and pulmonary circulation affect the prognosis of the patient as part of a multi-organ syndrome. Splanchnic vasodilatation in relation to portal hypertension is responsible for the hyperdynamic circulation and abnormal distribution of blood volume with a reduced "effective arterial blood volume" and activation of baroreceptor and volume-receptor reflexes as the outcome. The enhanced vasodilatation and counter regulatory over-activity of vasoconstrictor systems play major roles in the development of the multi-organ failure in cirrhosis with impaired function and perfusion of kidneys, lungs, brain, skin, and muscles. The function of the heart in cirrhosis is disturbed, with an increased cardiac output and heart rate. Left atrial and ventricular volumes tend to be slightly dilated, whereas the cardiac pressures are normal at rest. Cardiac performance and the systolic and diastolic functions are clearly impaired, in relation to the degree of liver dysfunction. The impaired cardiac contractility, termed cirrhotic cardiomyopathy, is different from that seen in alcoholic heart muscle disease. Reduced  $\beta$ -adrenergic receptor signal transduction and a defective cardiac excitation-contraction coupling are among the significant pathophysiological mechanisms. The cirrhotic heart is overloaded with a high-output failure and at the same time hyperdynamic and dysfunctional, and strain may unmask latent heart failure. In addition, the circulation and the function of a variety of organs are disturbed, including the lungs, kidneys, brain, and peripheral tissues. No specific treatment can be recommended and the only radical treatment option is liver transplantation. A considerable number of patients present with reduced pulmonary vascular resistance, impaired ventilation, and hypoxemia as part of a hepatopulmonary syndrome. A few patients develop portopulmonary hypertension with increased pulmonary vascular resistance.

Although there are still major unsolved questions that remain to be answered, the circulatory and neuroendocrine derangements play important roles in the clinical aggravation, hepatopulmonary dysfunction, and circulatory reactivity. This aspect is important to take into account in the clinical handling of the patient and the assessment of the prognosis.

## Abstract

Platelet-activating factor (PAF) is a potent proinflammatory phospholipid mediator that belongs to a family of biologically active, structurally related alkyl phosphoglycerides with diverse pathological and physiological effects. This bioactive phospholipid mediates processes as diverse as wound healing, physiological inflammation, angiogenesis, apoptosis, reproduction and long-term potentiation. PAF acts by binding to a specific G protein-coupled receptor to activate multiple intracellular signaling pathways. Since most cells both synthesize and release PAF and express PAF receptors, PAF has potent biological actions in a broad range of cell types and tissues. Inappropriate activation of this signaling pathway is associated with many diseases in which inflammation is thought to be one of the underlying features. Acute pancreatitis (AP) is a common inflammatory disease. The onset of AP is pancreatic autodigestion mediated by abnormal activation of pancreatic enzyme caused by multiple agents, which subsequently induce pancreatic and systemic inflammatory reactions. A number of experimental pancreatitis and clinical trials indicate that PAF does play a critical role in the pathogenesis of AP. Administration of PAF receptor antagonist can significantly reduce local and systemic events that occur in AP. This review focuses on the aspects that are more relevant to the pathogenesis of AP.

## INTRODUCTION

Inflammatory reaction is a common pathophysiological process. Appropriate inflammatory reaction has protective effects, but excessive reaction often induces injury. The underlying pathological changes of inflammation include exudation, alteration, and proliferation, which are the outcomes mediated by inflammatory mediators such as platelet-activating factor (PAF), leukotriene, tumor necrosis factor alpha (TNF- $\alpha$ ), and interleukin-1 (IL-1). Numerous researches have shown that PAF is one of the most potent mediators in many inflammatory processes, and not only induces inflammatory reaction but also mediates synthesis and release of other mediators to aggravate the degree of inflammation.

Acute pancreatitis (AP) is a common clinical inflammatory disease. A single injection of PAF into the superior pancreaticoduodenal artery of rabbits induces dose-dependent morphologic alterations of pancreatic tissue and increases serum amylase levels<sup>[1]</sup>. Murine pancreatic acini synthesizes PAF<sup>[2]</sup> and pancreatic vascular endothelium expresses PAF receptor<sup>[3]</sup>. These findings suggest that this mediator may have a role in AP. AP is usually classified into mild and severe type. Severe acute pancreatitis (SAP) still has a high mortality rate, while the pathogenesis of AP is not well-defined. There is growing evidence that pathogenetic factors deciding the severity of AP are complicated. PAF has been strongly implicated in the development of AP.

Here we have reviewed the role of PAFs such as excessive leukocyte stimulation, microcirculatory disorder, gut endothelial barrier dysfunction, bacterial translocation, acinar cell necrosis and apoptosis in the pathogenesis of AP.

## BIOLOGICAL CHARACTERISTICS OF PAF

Phospholipids are the major components of cellular membrane and are also known to be the source of arachidonic acid, which is metabolized into bioactive eicosanoids. Some phospholipids, including lysophosphatidic acid, sphingosine-1-phosphate, and PAF, exert bioactive effects. The term PAF is used because it

was first described as the substance responsible for the aggregation of platelets released from rabbit basophils after IgE stimulation<sup>[4]</sup>. Although PAF is still commonly used, it has diverse and potent physiological effects<sup>[5,6]</sup>. The chemical structure of PAF is 1-O-alkyl-2-acetyl-sn-glycero-3-phosphocholine determined in 1979 by three independent laboratories<sup>[7-9]</sup>.

Two distinct pathways for the synthesis of PAF have been demonstrated: the remodeling pathway and *de novo* pathway<sup>[10]</sup>. The remodeling pathway is mainly involved in the synthesis of PAF by stimulated inflammatory cells. The activities of lyso-PAF acetyltransferase (lyso-PAF AcT) and PAF-synthesizing phosphocholine transferase (PAF-PCT) are directly responsible for PAF synthesis. Lyso-PAF AcT catalyzes the transfer of acetyl moiety from acetyl CoA to free hydroxyl at sn-2 position of 1-alkyl-sn-glycero-3-phosphorylcholine. PAF-PCT catalyzes the conversion of 1-alkyl-2-acetyl-sn-glycerols to PAF<sup>[11]</sup>. The synthesis and catabolism of PAF are highly regulated. The final molecular composition of PAF in tissues and the expression of its biological activities depend on the activation of catabolic pathways. The most important enzyme in limiting the PAF bioactivity is a PAF-specific acetylhydrolase (PAF-AH), which cleaves the short acyl chain at sn-2 position and forms biologically inactive lyso-PAF<sup>[12]</sup>.

A diverse array of cells has been shown to synthesize PAF upon appropriate stimulation. In particular, PAF is produced by a variety of cells such as monocytes/macrophages, polymorphonuclear leukocytes (PMN), eosinophils, basophils, platelets, mast cells, vascular endothelial cells, and lymphocytes, which may participate in the inflammatory reaction<sup>[5,13]</sup>. Murine pancreatic acini can also synthesize PAF induced by cerulein<sup>[2]</sup>.

PAF is a phospholipid mediator possessing a wide spectrum of potent proinflammatory action. *In vitro*, PAF promotes chemotaxis, aggregation, granule secretion, and oxygen radical generation of leukocytes and adherence of leukocytes to the endothelium. Moreover, PAF is involved in allergy, wound healing, atherosclerosis, angiogenesis, apoptosis, reproduction, and long-term potentiation<sup>[5,6,13]</sup>. Recent findings have revealed some novel effects of PAF. Through inflammatory cytokines, estrogen depletion enhances PAF production as a unique autocrine factor for osteoclast functions. Inhibition of PAF function might pave the way for a new strategy to prevent postmenopausal bone loss without disturbing osteoblast functions<sup>[14]</sup>. The study investigating the functional PAF receptor on cell and nuclear surfaces of leukemic B cells in chronic lymphocytic leukemic patients showed that the potent immunoregulatory role of PAF in B cell physiology and the presence or absence of PAF receptor on leukemic B cells may profoundly affect their *in vivo* behavior<sup>[15]</sup>. In jet fuel-induced immune suppression, PAF receptor binding can modulate immune function and is an early event in the induction of immune suppression by immunotoxic environmental agents targeting the skin<sup>[16]</sup>. PAF can amplify the heterogeneity between ischemic and normal cardiac myocytes during ischemia/reperfusion which might play a vital role in the pathogenesis of arrhythmia induced by ischemia/reperfusion<sup>[17]</sup>, increase the expression of nerve

growth factor mRNA and protein in human astrocytes under hypoxia which may protect the nervous tissue by promoting neuronal survival<sup>[18]</sup>. PAF is also involved in the etiopathogenesis of type 1 diabetes<sup>[19]</sup> and the pathogenesis of acute liver failure as well as in augmented compensatory liver tissue repair post-acetaminophen treatment<sup>[20]</sup>.

PAF acts by binding to a specific receptor, subsequently activates multiple intracellular signaling pathways in various cell types. PAF receptor belongs to G protein-coupled receptor subfamily<sup>[21,22]</sup>. Most cells that produce PAF possess PAF receptors and are targets for PAF action. The pancreatic vascular endothelium also expresses PAF receptor<sup>[3]</sup>. It has been demonstrated that PAF binds to the receptor and activates the associated G protein. In turn, G protein activates a phosphatidylinositol-specific PLC which hydrolyzes a membrane phospholipid, phosphatidylinositol 4, 5-bisphosphate (PIP<sub>2</sub>), to generate two second messengers: diacylglycerol and inositol 1,4,5-trisphosphate (IP<sub>3</sub>). These compounds mediate the release of Ca<sup>2+</sup> from intracellular store (ER) and activation of protein kinase C (PKC), respectively. Moreover, it has been shown that PAF can activate mitogen-activated protein kinases (MAPKs), including extracellular signal-regulated kinase (ERK)<sup>[23-27]</sup>, p38 MAPK<sup>[25-27]</sup>, and c-Jun N-terminal kinase (JNK)<sup>[28]</sup>. Using human umbilical vein endothelial cells (HUVECs) as a model system, Deo *et al.*<sup>[29]</sup> suggested for the first time that PAF activates pertussis toxin-insensitive Gα<sub>q</sub> protein upon binding to its seven transmembrane receptors and adenylate cyclase, as well as elevates cAMP levels, which activate protein kinase A (PKA). PAF exposure induces the expression of TIMP2 and MT1-MMP and binding of p<sup>130</sup>Cas, Src, SHC, and paxillin to FAK. It was found that PAF is capable of stimulating nuclear factor kappa B (NF-κB) activation and transcription of c-fos and c-jun genes in inflammatory cells<sup>[30,31]</sup>.

## INVOLVEMENT OF PAF IN THE PATHOGENESIS OF AP

AP is a common clinical condition and is usually classified into mild and severe type. SAP is characterized by acute morbidity, rapid progression, multiple complications, and high mortality rate. While the pathogenesis of AP is not well-defined, considerable advances have been made in this research field. At present, it is considered that severity of pancreatitis is associated with excessive leukocyte stimulation, microcirculatory disorder, gut endothelial barrier dysfunction, bacterial translocation, and acinar cell necrosis and apoptosis. In the pathogenesis of AP, PAF has been strongly implicated (Table 1).

### Role of PAF in excessive leukocyte stimulation

In the course of AP, abnormal intra-acinar cell activation of digestive enzymes induced by diverse stimuli triggers morphopathological changes in pancreatic and adjacent tissues, such as inflammation, edema, hemorrhage, necrosis, and even systemic manifestations. In 1988, Rinderknecht<sup>[32]</sup> proposed the hypothesis of excessive leukocyte stimulation. Consequently, a great number of studies have demonstrated that the initial injury results in the expression of inflammatory mediators such as PAF.

**Table 1** Important roles of PAF in pathogenesis of AP

Main pathogenesis of AP	Important roles of PAF
Excessive leukocyte stimulation	To facilitate adhesion, chemotaxis and degranulation and to mediate the production of inflammatory mediators of leukocytes, and to delay PMN apoptosis
Microcirculatory disorder	To modulate indirectly/directly microvascular permeability
Gut endothelial barrier dysfunction	To upregulate adhesion molecules, intercellular signals and leukocyte-endothelial cell interactions
Bacterial translocation	To depend on its ability to induce gut endothelial barrier dysfunction
Acinar cell necrosis and apoptosis	To mediate neutrophil chemotaxis and delay neutrophil apoptosis in the pancreas, but neutrophils convert acinar cells undergoing apoptosis into necrotic cells

These mediators mediate activation and infiltration of leukocytes, a subsequent systemic inflammatory response, and multiple organ injury.

*In vivo* and *in vitro* studies suggest that proteolytic enzyme trypsin stimulates cytokine production from macrophages<sup>[33]</sup>. In an idealized *in vitro* experiment mimicking cerulein-induced AP, cerulein induces amylase release, increases  $[Ca^{2+}]_i$  and PAF synthesis of cultured pancreatic acini<sup>[2]</sup>. PAF plays a role in inflammatory reaction and induces expression of adhesion molecules that mediate neutrophil accumulation. However, PAF antagonists reduce expression of adhesion molecules and the severity of inflammation when given immediately after the induction of mild AP in mice<sup>[34]</sup>. Another research showed that PAF mediates macrophages to release thermolabile neutrophil chemotactic protein that induces neutrophil migration<sup>[35]</sup>. Moreover, activation of neutrophils with zymosan leads to the activation of PAF receptors followed by activation of CD11/CD18, phagocytosis of zymosan particles and subsequent IL-8 release. The production of IL-8 by neutrophils in response to particulate stimuli may play a role in the recruitment and activation of neutrophils in inflammatory reaction<sup>[36]</sup>. In addition, PAF is able to enhance superoxide production of PMN, expression of CD11b, and release of elastase, which are essential factors in the pathophysiology of multiple-organ failure<sup>[37]</sup>. PAF can delay apoptosis of PMN and amplify the inflammatory response by activating ERK signaling pathway<sup>[38,39]</sup>. Furthermore, PAF induces NF- $\kappa$ B activation and regulates gene expression through G protein-coupled transcription factor activation pathway<sup>[40]</sup>. NF- $\kappa$ B is a key element in inflammatory responses based on its ability to regulate the expression of inflammatory mediators. Activation of NF- $\kappa$ B within the pancreas is sufficient to initiate an inflammatory response<sup>[41]</sup>.

The above findings indicate that PAF is involved in adhesion, chemotaxis, degranulation and, the whole procedure of activation of leukocytes. Besides, it can amplify inflammatory response via delaying apoptosis of PMN. PAF receptor is almost ubiquitous in diverse type cells and acts not only on local pancreas but also on distant organs to induce systemic inflammatory response and multiple organ injury.

### Role of PAF in microcirculatory disorders

A number of experimental studies suggest that pathogenesis of AP correlates with microcirculatory disorders. Many complications of SAP are due to the amplifying effects of microcirculatory disruption. Constriction of interlobular pancreatic arteries 2 min after intraductal infusion of sodium taurocholate has been observed, indicating that microcirculatory changes may occur in early AP<sup>[42]</sup>. There is evidence that pancreatic microcirculatory changes are closely related to the process of AP. Ligating duodenum over half its circumference at 2 cm on either side of the duodenal entry of the biliopancreatic duct induces histopathologic alterations of the pancreas such as edema, parenchymal necrosis, thrombosis and hemorrhage, indicating that tissue ischemia plays a role in increasing the severity of pancreatitis<sup>[43]</sup>.

Many vasoactive mediators activated during the inflammatory response to pancreatic injury can cause microcirculatory disorders in AP. PAF is one of the most important mediator. Increased microvessel permeability caused by PAF may be related to direct endothelial cell activation, adhesion molecule expression, and leukocyte activation. Synthesis of PAF by endothelial cells at the site of plasmin generation may render the endothelial cell surface pro-adhesive for neutrophils and favor a local increase in vascular permeability<sup>[44]</sup>. Recent data suggest that PAF is able to directly modulate microvascular permeability and increase venular permeability<sup>[45]</sup>. Increased capillary permeability permits sequestration of macromolecules and fluid, which causes a deficiency of circulating blood volume and microcirculatory disorders. Predominant microcirculatory disorders are nutritive capillary perfusion failure, with the consequence of prolonged focal hypoxia or anoxia, and inflammation-associated microvascular leukocyte recruitment, CD11b and intercellular adhesion molecule (ICAM)-1-mediated leukocyte-endothelial cell interaction and loss of endothelial integrity, which may result in both edema formation and necrosis. Moreover, vasospasm and microthrombi formation due to hypercoagulability can also lead to the deterioration of pancreatic microcirculation and pancreatic necrosis.

It has been shown that the treatment of AP with PAF antagonists can significantly improve capillary blood flow in the pancreas and colon, renal, and respiratory function as well as survival rate, stabilize capillary permeability, decrease fluid loss into the third space<sup>[46,47]</sup>. The partial protective effect of PAF antagonists further supports the role of PAF in microcirculatory disorders.

### Role of PAF in gut endothelial barrier dysfunction

Gut endothelial barrier dysfunction is a critical factor for the development of tissue injury and organ dysfunction in AP. The study on dogs colonized with a strain of *Escherichia coli* (*E. coli* 6938K) bearing plasmid pUC4K showed that most dogs with severe pancreatitis have ischemic changes in the small bowel mucosa and *E. coli* translocation to the pancreas and mesenteric lymph nodes (MLNs), suggesting that the gut is a primary source of infection in pancreatitis<sup>[48]</sup>.

PAF plays a key role in the development of pancreatitis-associated gut endothelial barrier dysfunction and acts via the upregulation of adhesion molecules, intercellular signals and leukocyte-endothelial cell interactions. Leukocyte  $\beta 2$ -integrins play an important role in PAF-induced intestinal necrosis, and CD11b/CD18 are the main adhesion molecules involved in the pathogenesis of injury<sup>[49]</sup>. Moreover, PAF can activate rapidly intestinal xanthine oxidase (XO) by converting proteolytic xanthine dehydrogenase (XD) to XO in the ileal epithelium. This effect is mediated by neutrophils. XO is an important source of reactive oxygen species in the small intestine and its activation promotes PAF-induced PMN sequestration in the intestine, thus causing gut endothelial injury<sup>[50]</sup>. PAF can alter the cytoskeletal structure of intestinal epithelium and cause the influx of FD-4 (an index of intestinal permeability) from intestinal lumen to systemic circulation, and induce tyrosine phosphorylation of E-cadherin and cadherin-associated proteins. These findings reveal the possible mechanism of PAF in modulating intestinal mucosal permeability, PAF modulates macromolecular movement across the intestinal mucosal barrier probably via tyrosine phosphorylation of E-cadherin and cytoskeletal alteration of enterocytes<sup>[51]</sup>. In addition, gut microcirculatory disorder plays a pivotal role in endothelial barrier dysfunction.

Further support for the role of PAF in gut endothelial barrier dysfunction is provided by the fact that the administration of PAF antagonists improves pancreatitis-associated gut barrier dysfunction characterized by increased endothelial permeability, albumin leakage from blood to the mucosal interstitium and intestinal lumen, and bacterial translocation<sup>[52-54]</sup>.

#### **Role of PAF in bacterial translocation**

Bacterial translocation is an important source of pancreas infection in AP and is responsible for the high incidence of pancreas and distant infections occurring after AP. Support for the role of PAF in bacterial translocation is provided by the fact that PAF antagonists reduce bacterial translocation. Pretreatment with PAF antagonists, WEB-2170, lexipafant and BN52021, reduces bacterial translocation to distant organs other than the pancreas<sup>[55]</sup>. Similar findings showed that AP induced by supramaximal cerulein stimulation significantly increases bacterial translocation in MLNs, pancreas, liver, spleen and blood<sup>[56]</sup>. Both recombinant PAF-acetylhydrolase (rPAF-AH) and PAF receptor antagonist, BN52021, can decrease bacterial translocation in the pancreas and blood. In addition, rPAF-AH decreases bacterial translocation in MLNs. The action of PAF involved in bacterial translocation may be due to its ability to induce gut endothelial barrier dysfunction in AP.

#### **Role of PAF in acinar cell necrosis and apoptosis**

Pancreatitis is characterized by inflammation and death of acinar cells. Death can occur due to either necrosis or apoptosis. Kaiser *et al.*<sup>[57]</sup> have observed marked necrosis but very little apoptosis in severe pancreatitis models. In contrast to the findings in severe pancreatitis, mild

pancreatitis is characterized by very little necrosis but a high degree of apoptosis, suggesting that apoptosis may be a teleologically beneficial response to acinar cell injury in general, especially in AP. Deficiency of pancreatic connexin converts reversible AP into severe disease and decreases the sensitivity of acinar cells to apoptotic stimuli, demonstrating that apoptosis determines the severity of AP<sup>[58]</sup>.

It has been reported that PAF is involved in acinar cell damage<sup>[59]</sup>. Treatment with antineutrophil serum (ANS) and BN52021 can prevent inflammatory responses caused by cerulein and decreases cell damage. Treatment with ANS increases apoptosis in cerulein-infused animals, indicating that cerulein stimulates pancreatic production of PAF. PAF mediates both apoptosis and neutrophil chemotaxis in the pancreas. Neutrophils in turn may convert acinar cells undergoing apoptosis to necrotic cells.

### **THERAPEUTIC EFFECTS OF PAF ANTAGONISTS ON AP**

Recent studies have established the critical role of inflammatory mediators such as TNF- $\alpha$ , IL-1 $\beta$ , IL-6, IL-8, IL-10, PAF, C5a, ICAM-1 and substance P, in the progression of AP from local pancreatic inflammation to a systemic inflammatory disease. Elucidation of the key mediators in AP coupled with the discovery of specific inhibitors makes it possible to develop clinically effective anti-inflammatory therapy. At present, a number of inflammatory mediator antagonists are tested. PAF antagonists, including ginkgolide B (BN52021), lexipafant (BB-882), CV-6209, TCV309, and WEB-2170, *etc.*, have shown beneficial effects on the manifestations of AP. In experimental pancreatitis and clinical trials, administration of several PAF antagonists significantly reduces the level of serum amylase, leukocyte infiltration, and improves capillary blood flow in the pancreas and distant organs, renal and respiratory function, and survival rate.

In animal pancreatitis model, ginkgolide B could significantly reduce vascular permeability, pancreatic edema, hyperamylasemia, diminute superoxide dismutase (SOD) activity, and inhibit lipid peroxidation in pancreatic tissue. These changes are accompanied with significant reduction of acinar cell vacuolization and remarkable inhibition of inflammatory cell infiltration in the interacinar space<sup>[60,61]</sup>. In addition, treatment with ginkgolide B has shown protective effects on slow mesenterio-angial small arteriolar and venular blood flow velocity and dilated mesenterio-angial small venular diameter at the early phase of AP<sup>[62]</sup>. Moreover, ginkgolide B reduces bacterial translocation to distant sites, has a significant effect on serum pancreatic enzymes and histologic score of pancreatitis, and suppresses elevation in IL-6 levels. Preventing bacterial dissemination in early AP may have beneficial effects on the evolution of this disease<sup>[55,56]</sup>. Furthermore, ginkgolide B reduces malondialdehyde accumulation in pancreatic tissue, prevents sulfhydryl depletion in lung tissue, necrotic and inflammatory changes in the pancreatic tissue, and improves survival rate<sup>[63]</sup>. Activation of pulmonary alveolar macrophages (PAMs) might play an important role in

severe complications of AP. Ginkgolide B reduces total and free activity of lysosomal hydrolases of PAMs and partly prevents labilization of their lysosomal membranes. Therefore, an important mechanism of ginkgolide B underlying pulmonary complications of AP is to stabilize PAM lysosomes<sup>[64]</sup>. Moreover, BN50739 can reduce intestinal injury, levels of endotoxin and bacterial counts in the portal blood, MLNs and pancreas and increase intestinal mucosal blood flow<sup>[54]</sup>. In pigs with SAP, pre- and post-treatment with BN50739 can effectively reduce PAF levels in lung and tracheal mucosa and the severity of acute lung injury following SAP by reducing PMN sequestration and the amount of elastase, or by inhibiting PLA<sub>2</sub> activities in lung and tracheal mucosa<sup>[65]</sup>.

In rats with AP induced by intraductal infusion of 5 g/L sodium taurodeoxycholate, pretreatment with lexipafant could reduce pancreatic endothelial barrier dysfunction and severity of pancreatitis-associated intestinal dysfunction as well as systemic concentrations of IL-1 and local leukocyte recruitment<sup>[53,66,67]</sup>. AP lexipafant reduces the activity of serum cytokines (TNF- $\alpha$ , IL-1 $\beta$ ), lung myeloperoxidase (MPO) and serum amylase<sup>[68]</sup>. Lexipafant treatment can decrease bacterial spread to distant sites in AP induced by pressure injection of 3% taurocholate and trypsin into the common biliopancreatic duct<sup>[69]</sup>.

In rats, TCV-309 administered prior to cerulein and/or PAF reduces cerulein-induced pancreatitis and prevents PAF-induced pancreatitis<sup>[70]</sup>. It was reported that treatment with TCV-309 before septic challenge effectively prevents hyperactivity of bronchoalveolar macrophages and pancreatitis-associated lung injury by reducing serum concentrations of cytokine-induced neutrophil chemoattractant (CINC) and CINC messenger RNA (mRNA) in the lung, as well as pulmonary infiltrates immunoreactive for CINC or Mac-1 (CD11b/CD18)<sup>[71]</sup>.

## CONCLUSION

In the pathogenesis of AP, PAF exhibits pleiotropic function and is involved in both local pancreatic injury and systemic multiple organ damage. The effectiveness of PAF antagonists depends not only on their ability to block the effects of inflammatory mediators but also on their administration early enough in the course of pancreatitis before pancreatic necrosis or organ dysfunction occur. PAF antagonist therapy for systemic inflammatory response syndrome and multi-organ dysfunction syndrome in the management of patients with SAP has been considered as an important advance in the treatment of these patients.

### Abstract

**AIM:** To determine which treatment modality - hepatectomy or percutaneous ablation - is more beneficial for patients with small hepatocellular carcinoma (HCC) ( $\leq 4$  cm) in terms of long-term outcomes.

**METHODS:** A retrospective analysis of 149 patients with HCC  $\leq 4$  cm was conducted. Eighty-five patients underwent partial hepatectomy (anatomic in 47 and non-anatomic in 38) and 64 underwent percutaneous ablation (percutaneous ethanol injection in 37, radiofrequency ablation in 21, and microwave coagulation in 6). The median follow-up period was 69 mo.

**RESULTS:** Hepatectomy was associated with larger tumor size ( $P < 0.001$ ), whereas percutaneous ablation was significantly associated with impaired hepatic functional reserve. Local recurrence was less frequent following hepatectomy ( $P < 0.0001$ ). Survival was better following hepatectomy (median survival time: 122 mo) than following percutaneous ablation (median survival time: 66 mo;  $P = 0.0123$ ). When tumor size was divided into  $\leq 2$  cm vs  $> 2$  cm, the favorable effects of hepatectomy on long-term survival was seen only in patients with tumors  $> 2$  cm ( $P = 0.0001$ ). The Cox proportional hazards regression model revealed that hepatectomy ( $P = 0.006$ ) and tumors  $\leq 2$  cm ( $P = 0.017$ ) were independently associated with better survival.

**CONCLUSION:** Hepatectomy provides both better local control and better long-term survival for patients with HCC  $\leq 4$  cm compared with percutaneous ablation. Of the patients with HCC  $\leq 4$  cm, those with tumors  $> 2$  cm

### INTRODUCTION

Hepatectomy and percutaneous ablation are the treatments of choice for small hepatocellular carcinoma (HCC)<sup>[1,2]</sup>. Hepatectomy is recommended by surgeons, as this procedure removes portal venous thrombi in the adjacent liver<sup>[3]</sup>, allows for better local control<sup>[4]</sup>, and has better survival outcomes compared with percutaneous ablation<sup>[5,6]</sup>. In contrast, gastroenterologists and interventional radiologists advocate percutaneous ablation techniques including ethanol injection<sup>[7-9]</sup>, microwave coagulation<sup>[10-12]</sup>, and radiofrequency ablation<sup>[13-15]</sup>, as these methods are not as invasive as hepatectomy<sup>[7-15]</sup>, have a lower incidence of morbidity and mortality<sup>[7-13,15]</sup>, are more feasible in patients with impaired hepatic functional reserve<sup>[7-15]</sup>, and have similar survival outcomes compared with hepatectomy<sup>[7-9,15]</sup>.

The aim of this study was to determine which treatment modality - hepatectomy or percutaneous ablation - is more beneficial for patients with small ( $\leq 4$  cm) HCC in terms of long-term outcomes.

### MATERIALS AND METHODS

#### Patients

From January 1990 to December 2002, 224 consecutive patients with HCC underwent either partial hepatectomy or percutaneous ablation therapy as an initial treatment at the Niigata University Medical and Dental Hospital. Of

these patients, 149 with HCC measuring  $\leq 4$  cm formed the basis of this retrospective study; they included 104 men and 45 women with a median age of 64 years (range: 29–83 years). Only HCCs measuring  $\leq 4$  cm were included in the current study, because percutaneous ablation therapy was the treatment modality mainly recommended for such tumors in our hospital. All patients were Japanese.

### **Treatment modalities**

Of the 149 patients, 85 underwent a hepatectomy for HCC in the Division of Digestive and General Surgery. Hepatectomy. Procedures included non-anatomic hepatectomy in 38 patients, monosegmentectomy in 14, bisegmentectomy in 15, right hepatectomy in 14, and left hepatectomy in 4. In our department, the type of hepatectomy procedure selected was primarily based on the disappearance rate of indocyanine green ( $K_{ICG}$ )<sup>[16,17]</sup>, which is an indicator of hepatic functional reserve. The selection criteria were  $K_{ICG} \geq 0.12$  for hemihepatectomy,  $K_{ICG} \geq 0.10$  for bisegmentectomy,  $K_{ICG} \geq 0.08$  for monosegmentectomy, and  $K_{ICG} \geq 0.06$  for non-anatomic hepatectomy (including the enucleation of hepatic tumors).

The remaining 64 patients underwent a percutaneous ablation procedure for HCC in the Division of Gastroenterology and Hepatology. Hepatectomy was considered as a feasible option for 51 of these 64 patients and was offered as an alternative. However, all these patients preferred to undergo percutaneous ablation treatment. Hepatectomy was not considered feasible in the remaining 13 patients due to impaired hepatic functional reserve ( $K_{ICG} < 0.06$ ); therefore, these patients were only offered percutaneous ablation treatment. Percutaneous ablation procedures included percutaneous ethanol injection (PEI) in 37 patients, radiofrequency ablation (RFA) in 21, and microwave coagulation therapy (MCT) in 6. In these patients, adequacy of the ablation was assured with dual-phase dynamic computed tomography (section thickness of 5 mm) within a month of the procedure. A microwave tissue coagulator (Microtaze<sup>®</sup> OT-110M; Alfresa-Pharma Co., Inc., Osaka, Japan) and an RF generator (Cool-tip<sup>®</sup> RF System, CMI Century Medical Co., Inc., Tokyo, Japan) were introduced in our hospital in 1995 and 2000, respectively.

### **Post-treatment follow-up**

There were no mortalities 30 d post-treatment in the current study. Serum concentrations of alpha-fetoprotein were measured and abdominal ultrasonography and/or contrast-enhanced computed tomography was performed on all the patients approximately 1 mo after the treatment. Thereafter, patients were regularly monitored for recurrences in outpatient clinics every 3 mo by physical examination, laboratory tests, and imaging studies. When intrahepatic recurrences were detected, they were treated with either interventional radiological techniques, such as PEI, RFA, MCT, transarterial chemoembolization and hepatic arterial infusion, or repeat hepatectomy when indicated. Patients with disseminated recurrences and those in a debilitated state were treated with supportive care.

The follow-up period after the treatment was defined as the interval between the date of the initial treatment

and that of the last follow-up, and ranged from 11 to 178 (median: 69) mo in the current study. The median follow-up period was 73 mo in patients who had undergone hepatectomy, and 61 mo in those who had undergone percutaneous ablation.

### **Definition of local recurrence after treatment**

Local recurrence was defined as recurrences contiguous to resection margins in patients who had undergone hepatectomy, whereas in patients treated with percutaneous ablation, local recurrence was defined as recurrences contiguous to or within the ablated areas.

### **Laboratory examination**

The following laboratory tests were performed before treatment: hepatitis B surface antigen; hepatitis C antibody; serum aspartate aminotransferase; serum alanine aminotransferase; the indocyanine green clearance test; and serum alpha-fetoprotein. Hepatitis B surface antigen and hepatitis C antibody in serum were detected by radioimmunoassay (Lumipulse II HBsAg; Fujirebio Co., Inc., Tokyo, Japan) and a second-generation enzyme-linked immunosorbent assay (Lumipulse II Ortho HCV; Ortho-Clinical Diagnostics Co., Inc., Tokyo, Japan), respectively. Indocyanine green (Diagnogreen; Daiichi Pharmaceutical Co., Inc., Tokyo, Japan) retention rate at 15 min after the injection of the dye (0.5 mg/kg) was used as an indicator of hepatic functional reserve, with a reference range of 10% or less<sup>[16–18]</sup>. Serum concentrations of alpha-fetoprotein were determined by enzyme immunoassay (Luminomaster AFP; Sankyo Yell Yakuhin Co., Ltd., Tokyo, Japan).

### **Pathologic examination**

Resected specimens from all the patients who had undergone hepatectomy were submitted to the Department of Surgical Pathology in our hospital. Each specimen was examined to determine the number of hepatic tumors, tumor size, vascular invasion (gross or microscopic), and cirrhosis. Vascular invasion included both portal and hepatic venous invasion in the current study. Cirrhosis in the adjacent (non-tumorous) liver was diagnosed microscopically based on the presence of regenerative nodules surrounded by fibrous septa. The pathology of the liver was confirmed by fine-needle biopsy in all the patients undergoing percutaneous ablation. Among this group of patients, 41 patients had a fine-needle biopsy of the tumor.

### **Factors influencing outcomes after treatment**

To determine the factors that may influence outcomes after the treatment, 13 conventional variables<sup>[19–22]</sup> were identified for univariate and multivariate analyses (Table 1). Vascular invasion and histologic grade were not chosen because they were often missed in patients undergoing percutaneous ablation.

### **Statistical analyses**

Medical records and survival data were obtained for all the patients. The causes of death were determined from the medical records. Deaths from other causes were treated as uncensored cases. The Kaplan-Meier method was

used to estimate the cumulative incidences of events, and differences in these incidences were evaluated using the log rank test. The Cox proportional hazards regression model was performed to identify the factors that were independently associated with local recurrence and survival. In this model, a stepwise selection was used for variable selection with entry and removal limits of  $P < 0.1$  and  $P > 0.15$ , respectively. The stability of each model was confirmed using a step-backward and step-forward fitting procedure, and variables identified as having an independent influence on local recurrence and survival were identical in both the procedures. Clinical features and pathologic tumor-related factors were compared between the two groups using Fisher's exact test. All statistical evaluations were performed using the SPSS 11.5J software package (SPSS Japan Inc., Tokyo, Japan). All tests were two-sided and  $P$  values of  $< 0.05$  were considered statistically significant.

## RESULTS

### Clinicopathologic characteristics according to treatment modality

A total of 125 hepatic tumors (median: one per patient; range: 1-14 tumors) were resected in patients undergoing hepatectomy, and a total of 100 tumors (median: one per patient; range: 1-5 tumors) were treated in patients undergoing percutaneous ablation.

Patients treated with hepatectomy had larger tumors than those treated with percutaneous ablation. Patients who had undergone percutaneous ablation were characterized by hepatitis C virus infection, cirrhosis, Child-Pugh classification B or C, an impaired indocyanine green retention rate at 15 min, and increased serum concentrations of aspartate aminotransferase and alanine aminotransferase, suggesting impaired hepatic functional reserve with active hepatitis in these patients (Table 1).

### Factors influencing local recurrence

During the follow-up period, local recurrences developed in two patients who had undergone hepatectomy and 17 patients who had been treated with percutaneous ablation (10 treated with PEI and 7 treated with RFA). Univariate analysis revealed that treatment modality ( $P < 0.0001$ ), indocyanine green retention rate at 15 min ( $P = 0.0005$ ), Child-Pugh classification ( $P = 0.0012$ ), serum alpha-fetoprotein level ( $P = 0.0072$ ), hepatitis C virus infection ( $P = 0.0374$ ), and number of hepatic tumors ( $P = 0.0419$ ) were risk factors for local recurrence. Of these six variables, multivariate analyses revealed that treatment modality and serum alpha-fetoprotein level were the only independently significant variables (Table 2).

### Factors influencing long-term survival

At the time of disease status assessment, 53 patients who had undergone hepatectomy were alive, and 32 had died. Thirty-four patients treated with percutaneous ablation were alive, and 30 had died. Univariate analysis revealed that Child-Pugh classification ( $P = 0.0010$ ), serum alpha-fetoprotein level ( $P = 0.0052$ ), treatment modality ( $P = 0.0123$ ), serum aspartate aminotransferase ( $P = 0.0278$ ), tumor size

( $P = 0.0454$ ), and number of hepatic tumors ( $P = 0.0464$ ) were significant prognostic factors of long-term survival. Of these six variables, multivariate analyses revealed that treatment modality and tumor size were the only independent significant variables (Table 3).

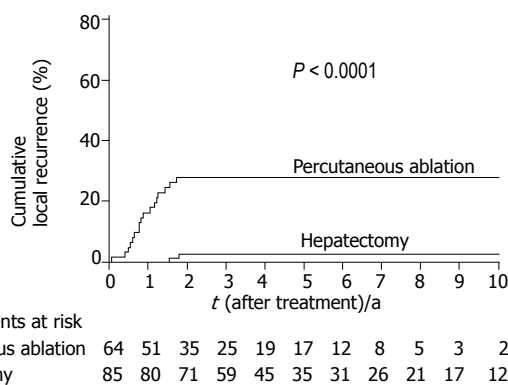

### Outcomes after treatment according to tumor size

Local recurrence was significantly less frequent in patients who had undergone hepatectomy than in those who had undergone percutaneous ablation ( $P < 0.0001$ ) (Figure 1). When the patients were divided into two groups according

**Figure 1** Kaplan-Meier estimates of local recurrence. The incidence of local recurrence reached a plateau of 28% at 20 mo after percutaneous ablation, and a plateau of 3% at 22 mo after hepatectomy.

to tumor size ( $\leq 2$  cm vs  $> 2$  cm), hepatectomy was found to be the more effective treatment for controlling local recurrence, but only in patients with HCC  $> 2$  cm ( $P < 0.0001$ ) (Figure 2). Survival after the treatment was significantly better in patients who had undergone hepatectomy than in those treated with percutaneous ablation ( $P = 0.0123$ , Figure 3). Again, hepatectomy was the more effective treatment in terms of long-term survival, but only in patients with HCC  $> 2$  cm ( $P = 0.0001$ , Figure 4).

#### Incidence of vascular invasion according to tumor size

Vascular invasion was more frequent in patients with tumors  $> 2$  cm (16/62, 26%) than in those with tumors  $\leq 2$  cm (1/23, 4%;  $P = 0.033$ , Table 4).

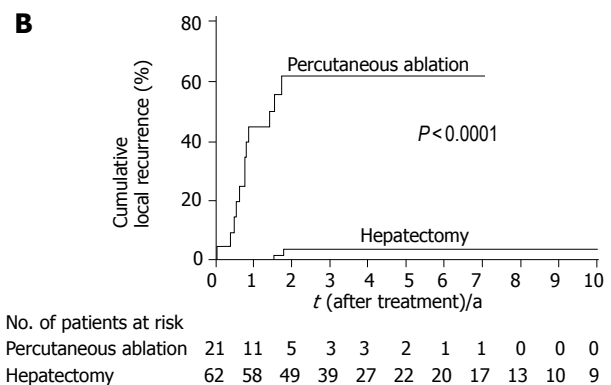

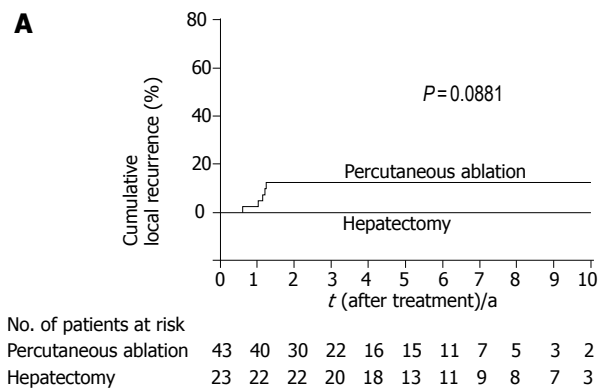

## DISCUSSION

Selecting the correct treatment modality to suit individual patients with HCC remains a matter of debate<sup>[1,4,5]</sup>. This prompted us to conduct the current study, which has revealed that hepatectomy provided better outcomes for patients with HCC  $\leq 4$  cm than percutaneous ablation. This may partly be due to the fact that hepatic functional reserve was better in patients who had undergone hepatectomy. Despite this, we found that the incidence of local recurrence decreased and long-term survival increased independently after hepatectomy, indicating that

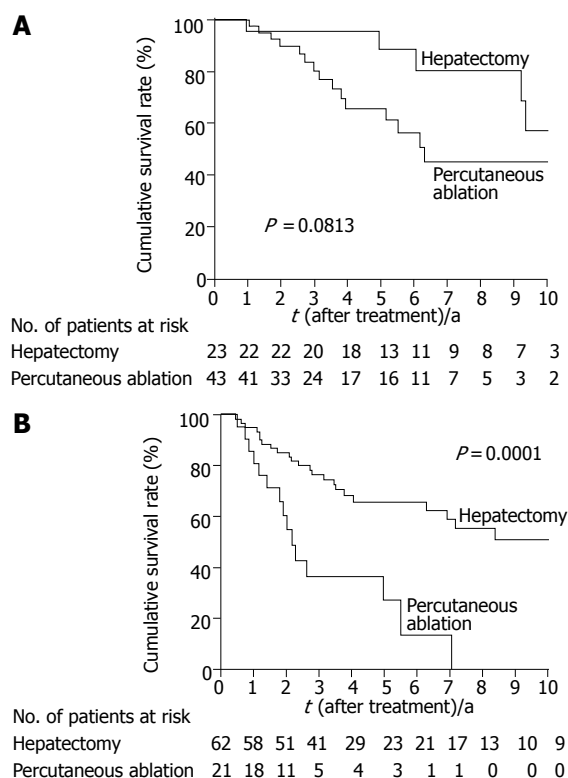

**Table 4** Incidence of vascular invasion according to tumor size

Tumor size (cm)	Vascular invasion		P value
	(-)	(+)	
≤ 2	22	1 <sup>1</sup>	0.033
> 2	46	16 <sup>2</sup>	

<sup>1</sup>Portal venous invasion was noted. <sup>2</sup>Portal venous invasion in 10 patients, hepatic venous invasion in 3, and both portal and hepatic venous invasion in 3.

**Figure 2** Kaplan-Meier estimates of local recurrence by tumor size. **A:** Among tumors  $\leq 2$  cm, the incidence of local recurrence reached a plateau of 12% at 15 mo after percutaneous ablation, whereas no recurrences had occurred after hepatectomy; **B:** among tumors  $> 2$  cm, the incidence of local recurrence reached a plateau of 61% at 21 mo after percutaneous ablation, whereas it reached a plateau of 4% at 22 mo after hepatectomy.**Figure 3** Kaplan-Meier estimates of survival. The median survival time was 122 mo with a 10-year survival rate of 53% in patients who had undergone hepatectomy. The median survival time was 66 mo with a 10-year survival rate of 31% in patients who had undergone percutaneous ablation.

**Figure 4** Kaplan-Meier estimates of survival by tumor size. **A:** Among patients with tumors  $\leq 2$  cm, survival was better following hepatectomy (median survival time of 122 mo; 10-year survival rate of 58%) than following percutaneous ablation (median survival time of 76 mo; 10-year survival rate of 45%); **B:** among patients with tumors  $> 2$  cm, survival was better following hepatectomy (median survival time of 126 mo; 10-year survival rate of 51%) than following percutaneous ablation (median survival time of 26 mo; 10-year survival rate of 0%).

this is an oncologically reliable treatment modality for HCC  $\leq 4$  cm.

Local recurrence was found to be more frequent after percutaneous ablation than after hepatectomy. Prospective, randomized controlled trials for PEI treatment of HCC  $\leq 4$  cm<sup>[23-25]</sup> demonstrated that cumulative 2-year local recurrence rates ranged from 33% to 45%. These rates are comparable with the 28% incidence of local recurrence after percutaneous ablation detected in the current study. Local recurrences after percutaneous ablation may be attributable to insufficient ablation of the primary tumor and/or the presence of portal or hepatic venous tumor thrombi in the adjacent liver<sup>[26,27]</sup>. Hepatectomy removes a rim of non-neoplastic liver parenchyma (a resection margin) together with the primary tumor, and thus eradicates both the primary tumor and venous tumor thrombi within the resection margin. This may explain better the outcomes following hepatectomy. In the current study, the beneficial effect of hepatectomy was prominent in a subgroup of patients with tumors  $> 2$  cm (Figures 2B and 4B), suggesting that these patients are good candidates for hepatectomy. Tumors  $> 2$  cm had a higher incidence of vascular invasion than tumors  $\leq 2$  cm (Table 4). Taken together, these findings suggest that the beneficial effect of hepatectomy is due to the clearance of venous tumor thrombi in the adjacent liver in addition to the complete removal of the primary tumor.

HCC mainly spreads *via* the portal and hepatic veins.

Vascular invasion is an established adverse prognostic factor of HCC<sup>[19-21,28-30]</sup>, and the incidence of vascular invasion increases as the tumor enlarges<sup>[30-33]</sup>. The current study confirmed this, with vascular invasion being more frequent in tumors  $> 2$  cm. Recent authors have suggested that tumors  $> 2$  cm are independently associated with local failure after RFA<sup>[34,35]</sup>. Considering that vascular invasion was less frequent in tumors  $\leq 2$  cm in our patients, percutaneous ablation appears to be an appropriate treatment modality for HCCs  $\leq 2$  cm. Despite this, outcomes for patients with HCCs  $\leq 2$  cm were better following hepatectomy than following percutaneous ablation. Due to the small sample size of this study, however, these differences were only marginally significant. We believe that hepatectomy may also be an appropriate treatment modality for HCCs  $\leq 2$  cm, provided that the patient is robust and that the hepatic functional reserve of the patient is at a level permitted for the resection.

Recent evidence suggests that high pre-treatment serum alpha-fetoprotein levels are associated with both the presence of portal venous invasion and intrahepatic recurrences after the treatment in HCC<sup>[26,36-41]</sup>. Serum alpha-fetoprotein levels were independently associated with local recurrences in the current study. The above findings suggest that high serum alpha-fetoprotein levels predict the presence of portal venous invasion, which may lead to treatment failure, in patients with HCC.

The current study has some limitations. First, it was a retrospective analysis of a small number of patients; second, the follow-up period in 64 patients was  $< 60$  mo; and third, percutaneous ablation therapy included three different treatment modalities. However, we believe that these limitations do not significantly influence the outcome of the study, as the marked differences between each group appear to overcome these biases.

In conclusion, hepatectomy provides both better local control and better long-term survival for patients with HCC  $\leq 4$  cm than percutaneous ablation, probably because hepatectomy eradicates both the primary tumor and venous tumor thrombi within the hepatectomy margin. Among the patients with HCC  $\leq 4$  cm, those with tumors  $> 2$  cm are good candidates for hepatectomy, provided that the level of hepatic functional reserve of the patient is suitable for resection.

## Abstract

**AIM:** To determine the distance between the branching point of the left colic artery (LCA) and the inferior mesenteric artery (IMA) by computed tomography (CT) scanning, for preoperative evaluation before laparoscopic colorectal operation.

**METHODS:** From February 2004 to May 2005, 100 patients (63 men, 37 women) underwent angiography performed with a 16-scanner multi-detector row CT unit (Toshiba, Aquilion 16). All images were analyzed on a workstation (AZE Ltd, Virtual Place Advance 300). The distance from the root of the IMA to the bifurcation of the LCA was measured by curved multi-planar reconstruction on a workstation.

**RESULTS:** The IMA could be visualized in all the cases, but the LCA was missing in two patients. The mean distance from the root of the IMA to the root of the LCA was 42.0 mm (range, 23.2-75.0 mm). There were no differences in gender, arterial branching types, body weight, height, and body mass index.

**CONCLUSION:** Volume-rendered 3D-CT is helpful to assess the vascular branching anatomy for laparoscopic surgery.

## INTRODUCTION

Laparoscopy-assisted colorectal surgery is now an important surgical modality for colorectal neoplasms. For left side colon cancer, the root of the inferior mesenteric artery (IMA) is usually cut for D3 lymph node dissection. We keep the left colic artery (LCA) intact even in D3 dissection, to maintain the blood supply of the preserved proximal sigmoid colon (manuscript submitted for publication). However, it is at times difficult to locate the root of the LCA when dissecting around the IMA.

Helical computed tomography (CT) and multi-detector CT produce an image of the mesenteric vasculature with faster scanning and narrower collimation<sup>[1]</sup> than that previously obtained by conventional angiography. Recently, three-dimensional (3D) angiography was shown to help the preoperative assessment of vascular anatomy for laparoscopic lymph node dissection. In this study, we have used preoperative 3D-CT to investigate the vascular anatomy of the IMA for laparoscopic lymph node dissection around IMA with the preservation of LCA, for rectal cancer.

## MATERIALS AND METHODS

### Patients

One hundred patients (63 men, 37 women) who underwent contrast-enhanced CT from February 2004 to May 2005 were included (Table 1).

**Table 1 Medical conditions of patients examined in this study**

Medical conditions	n
Aortic aneurysm	32
Arteriosclerosis	26
Varicose veins	5
Takayasu's arteritis	3
Angina pectoris	1
Myocardial infarction	1
Cerebral infarction	1
Hypertension	1
Thrombosis	4
<b>Total cardiovascular disease</b>	<b>74</b>
Colon cancer	9
Hepatocellular carcinoma	5
Pancreatic cancer	3
Malignant lymphoma	2
Esophageal cancer	1
<b>Total neoplasm</b>	<b>20</b>
Myoma uteri	3
Pancreatic cyst	2
Cholecystolithiasis	1

**Table 2 Distance from IMA root to LCA root and branching types of IMA**

Sex	n	Age (range)/yr	Distance (range)/mm	98 patients with branching type			
				A	B	C	D
Male	63	68.7 (30-89)	41.8 (25.3-73.5)	6	28	21	7
Female	37	67.5 (20-90)	42.3 (23.2-75.0)	4	17	6	9
Total	100	68.3 (20-90)	42.0 (23.2-75.0)	10	45	27	16

LCA was missing in two patients (1 male and 1 female). D: Branching type undetermined.

**Table 3 Distance from IMA root to LCA root in different branching types**

Branching type	Mean distance (mm) (SD)
Type A	44.1 (7.36)
Type B	42.2 (10.2)
Type C	38.3 (7.41)
All (n=82)	41.3 (9.15)

### Multi-detector row CT angiography

Multi-detector row CT angiography was performed in all the patients with 16-detector row scanners (Toshiba, Aquilion 16). Patients received 2 mL/kg (not exceeding 150 mL in total) of nonionic contrast medium (300 g/L) injected at a rate of 3 mL/s through a cubital vein, using an 18-22-gauge catheter and a power injector. Scanning was initiated by an automatic bolus-tracking system. The circular region of interest was placed in the abdominal aorta. The threshold level was 100 Hounsfield units. The CT scan parameters were collimation 16 mm×1 mm, helical pitch 23. Images were reconstructed at 1-2 mm thickness. All images were analyzed on a workstation (AZE Ltd, Virtual Place Advance 300). The 3D-volume rendering and curved multi-planar reconstruction were done on a workstation by two radiologists. The length from the root of IMA to bifurcation of LCA was measured by curved multi-planar reconstruction.

### Statistical analysis

Chi-square test was applied to analyze the differences in incidence of the types of branching of LCA, sigmoidal artery (SA), and SRA. Pearson's product moment test was used to estimate correlation between the distance from the root of IMA to LCA and body weight, height, and body mass index (BMI), respectively.

## RESULTS

There was no age difference between male (mean, 68.7 years; range, 30-89 years) and female (mean 67.5 years; range, 20-90 years) patients; the mean overall age was 68.3 years (range, 20-90 years). The IMA was observed on 3D-CT in all the patients analyzed. In two patients, 3D-CT demonstrated that the LCA was missing. The mean distance from the root of IMA to the root of LCA for all cases was 42.0 (range, 23.2-75.0) mm; gender differences were not observed [41.8 (range, 25.3-73.5) mm for male

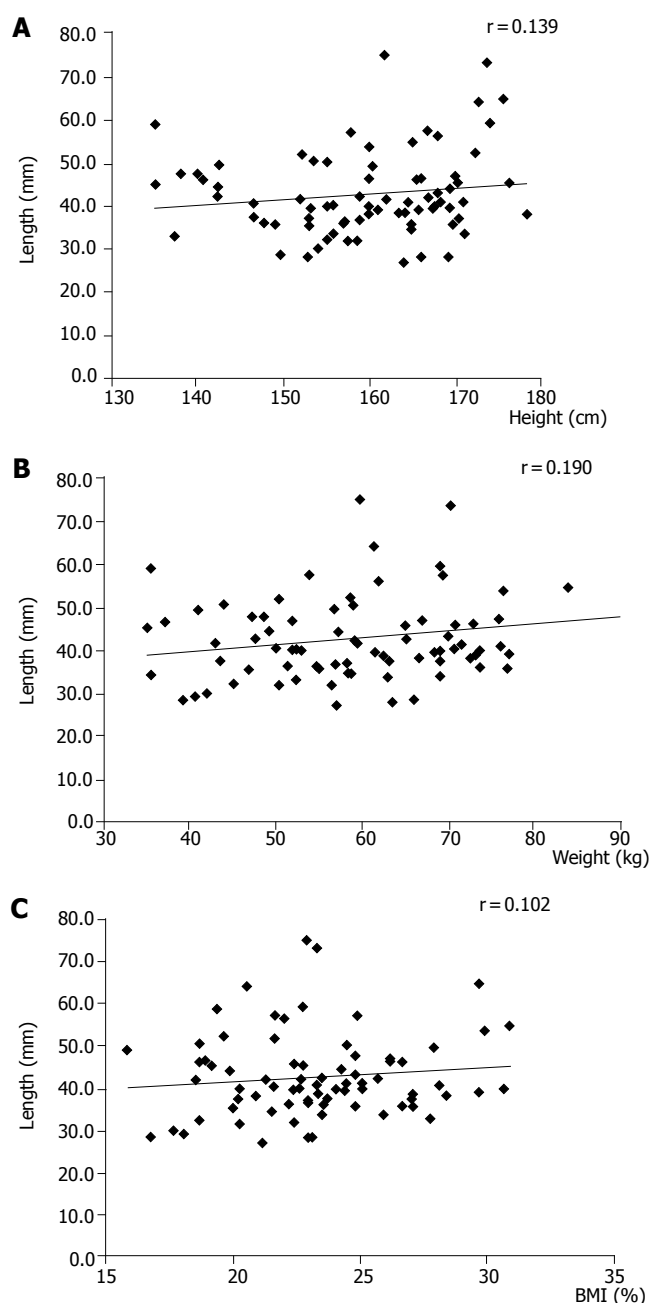

**Figure 1** The branching types of IMA, LCA and SA. Type A: the three arteries branch off from the same point; Type B: SA branches off from LCA; and Type C: SA branches off from SRA.

patients vs 42.3 (range, 23.2-75.0) mm for female patients].

The branching of LCA, SA, and SRA could be determined in 82 cases (Table 2). Three types of branching were seen (Figure 1): Type A, where the three arteries branch off from the same point (10 cases: 6 males, 4 females); Type B, where SA branches off from LCA (45 cases: 28 males, 17 females); and Type C, where SA branches off from SRA (27 cases: 21 males; 6 females). There was no significant difference in the type of branching between male and female patients ( $P=0.293$ ; Table 2). The distances from IMA root to LCA root ( $43.1 \pm 9.2$  mm,  $n=82$ ) in Types A, B, and C were  $44.1 \pm 7.4$  mm,  $42.2 \pm 10.2$  mm, and  $38.7 \pm 7.4$  mm, respectively. The distance in Type C was apparently shorter than in Type A, ( $P=0.07$ ), and there was no significant difference between the three types (Table 3).

The distance from IMA root to LCA root was examined in relation with height and body weight measured in 76 and 77 patients, respectively. There was no correlation between this distance and height ( $r=0.139$ , Figure 2A), body weight ( $r=0.190$ , Figure 2B), or BMI ( $r=0.102$ , Figure 2C).

**Figure 2** The distance from IMA root to LCA root does not correlate with patient's height (A), weight (B), or BMI (C).

## DISCUSSION

Recent advances in multi-detector row CT combined with rapid intravenous administration of contrast material have allowed excellent opacification of the mesenteric vessels. Attempts have been made to use this modality to obtain preoperative information on mesenteric vasculatures<sup>[2-4]</sup>. The blood supply and lymphatic system of the colon are simple compared with those of the stomach. Accordingly,

D3 lymph node dissection for sigmoid and rectal cancer is performed by cutting the root of the IMA. In contrast, for gastric cancer, the lymph nodes around the common hepatic artery, celiac axis, and splenic artery, most of which are group 2 lymph nodes, should be dissected while preserving these major vessels. We have reported a D3 lymph node dissection technique around IMA for lower sigmoid colon or rectal cancer cases, whereby the LCA is kept intact to maintain the blood supply of the preserved proximal sigmoid colon (manuscript submitted for publication). LCA is absent in 12% of individuals, in whom the colosigmoid artery performs its function<sup>[5,6]</sup>. In some cases, the length from the root of IMA to that of LCA is fairly long and lymph node dissection around the IMA can be a stressful procedure until the LCA is located, particularly in laparoscopic surgery. To help in locating the LCA during laparoscopic surgery, we have conducted a preoperative 3D-CT investigation to examine the branching of LCA, SA, and SRA, and evaluate the distance from the root of IMA to that of LCA.

In our study, there were no gender differences in mean distance and distance ranges. There was also no correlation between body weight, height, or BMI and the distance from IMA root to LCA root. In branching Type C, the distance from IMA root to LCA root tended to be shorter, but this was not statistically significant. Thus, the distance between IMA root and LCA root is independent of the type of branching or the patient's constitution. However, volume-rendered 3D-CT helped identify vascular branching types for laparoscopic surgery and indicated that the distance of the branching point of the LCA from the IMA root may range from as short as 20 mm to sometimes longer than 70 mm.

### Abstract

**AIM:** To determine whether body weight and/or serum leptin were independent predictors of response to antiviral treatment in patients with chronic hepatitis C.

**METHODS:** A retrospective evaluation was performed in 139 patients with chronic hepatitis C treated with interferon (IFN) from 1996 to 2000. Sustained response was defined as negative by hepatitis C virus (HCV) RNA analysis using PCR and normal transaminase at 24 wk after cessation of IFN therapy. Patients who remained positive for HCV RNA at the end of IFN treatment were defined as resistant to IFN therapy. Sex, age, body mass index (BMI) ( $\geq 25$  vs  $< 25$ ), complication of diabetes mellitus, serum leptin level ( $\geq 8.0$   $\mu\text{g/L}$  vs  $< 8.0$   $\mu\text{g/L}$ ), and the stage of liver fibrosis by needle biopsy (F1/F2 vs F3/F4) were examined.

**RESULTS:** Sustained response was achieved in 33 patients (23.7%), while others failed to show a response to IFN therapy. Overall, the factors associated with sustained antiviral effects were HCV-RNA load, HCV genotype, serum leptin level, and stage of liver fibrosis evaluated by univariate analysis. BMI was not associated with any therapeutic effect of IFN. Multivariate analysis indicated that HCV-RNA load was a significant risk factor, but among the patients with low viremia (HCV-RNA  $< 100$  MU/L), leptin level was an independent risk factor for IFN resistance. Namely, a high level of serum leptin attenuated the effect of IFN on both male and female patients with low viremia.

**CONCLUSION:** High serum leptin level is a negative

### INTRODUCTION

Hepatitis C virus (HCV) usually causes chronic infection, which can result in chronic hepatitis, liver cirrhosis, and hepatocellular carcinoma (HCC)<sup>[1]</sup>. Since interferon (IFN) therapy including pegylated interferon with ribavirin has been introduced, antiviral therapy is able to induce viral clearance and marked biochemical and histological improvements<sup>[2]</sup>. The response to IFN therapy varies among different viral (viral load and particularly genotype) and host factors, which may include race, sex, age, obesity, and presence of liver fibrosis. In Japan, around 70% of patients with chronic hepatitis C are infected with the HCV genotype 1b, and around 25% have genotype 2a. Sustained virological response to IFN monotherapy is as low as 10-20% in genotype 1b infections, whereas the response is more than 60% in genotype 2 infections until the combination therapy with pegylated interferon and ribavirin were presented<sup>[3,4]</sup>. However, it is not still possible to predict the response to IFN therapy in individual patients with each HCV genotype.

Obesity, a modifiable risk factor, may be an important cofactor in both accelerating fibrosis and increasing liver necroinflammatory activity in chronic hepatitis C<sup>[5]</sup>. Several studies have shown that obesity may also have a deleterious effect on the treatment response to both pegylated and standard IFN monotherapy<sup>[6,7]</sup>. Recent studies have indicated that food intake and body weight are regulated by leptin, of which synthesis is predominantly localized

in adipose tissue<sup>[8]</sup>. The circulating leptin concentration correlates with fat mass size and distribution<sup>[9]</sup>. In addition to regulating food intake and energy expenditure, leptin has other metabolic effects on peripheral tissue, including modulation of action of insulin and in wound healing<sup>[10]</sup>. Activated rat hepatic stellate cells express leptin, and rat sinusoidal endothelial and Kupffer cells express the signaling-component isoform of the leptin receptor. Exposure of these cells to leptin results in an increased expression of transforming growth factor- $\beta$  (TGF- $\beta$ ), which, in turn, stimulates fibrogenesis in hepatic stellate cells<sup>[11]</sup>. Recent reports have indicated that inflammatory cytokines, including TNF- $\alpha$  or IL-1, determine both leptin expression and circulation<sup>[12,13]</sup>.

Judging from these results, besides viral factors, those related to individual patients including leptin and/or obesity might have important effects on IFN therapy. In this study, we have evaluated the risk factors that were related to resistance to IFN therapy in patients with chronic hepatitis C.

## MATERIALS AND METHODS

### Materials

One hundred and thirty-nine patients with chronic hepatitis C, who had received IFN monotherapy from 1996 to 2000 at Saga Medical School Hospital, were selected according to the following inclusion criteria: persistently elevated alanine aminotransferase (ALT) levels; positive for anti-HCV (third-generation enzyme immunoassay, Chiron Corp., Emeryville, CA, USA); positive for HCV RNA qualitative analysis using PCR (nested polymerase chain reaction or Amplicor, Roche Diagnostic Systems, CA, USA); liver biopsy consistent with chronic hepatitis examined within 6 mo of enrolment; and naïve to IFN therapy. Exclusion criteria for treatment were as follows: nearly decompensated cirrhosis and/or HCC; positive for hepatitis B surface antigen (radioimmunoassay, Dainabot, Tokyo, Japan); autoimmune liver disease; hemochromatosis; Wilson's disease; primary biliary cirrhosis; ingestion of more than 40 g/d of alcohol within the previous year; history of uncontrolled depression or psychosis; and patients with uncontrolled diabetes.

The data of patients' sex, age, body mass index [BMI: weight (kg)/height (m<sup>2</sup>)], HCV genotype, HCV qualitative analysis with PCR, 75 g oral glucose tolerance test (75 g OGTT), serum leptin at initiation of treatment, and ethanol consumption were examined. Serum leptin was measured by a radioimmunoassay (RIA, Linco Research Inc., St. Louis, MO, USA). Serum was collected at the initiation of treatment following an overnight fast for 8 h.

### Liver histopathological examination

Liver biopsy specimens were obtained percutaneously or at peritoneoscopy using a modified Vim-Silverman needle. Liver biopsy specimens were reviewed by a single hepatologist, who was blinded to the clinical information of the subjects. For each liver biopsy specimen, hematoxylin-eosin and silver impregnation for collagen were available. Chronic hepatitis was diagnosed based

on histopathological assessment according to a scoring system that includes semi-quantitative assessment of liver disease grading and staging<sup>[14]</sup>. Steatosis was evaluated by Adinolfi grading system in which steatosis is graded from 0 to 4 based on the percentage of hepatocytes involved as follows: 0 = none involved; 1 = up to 10%; 2 = up to 30%; 3 = up to 60%; and 4 = more than 60%<sup>[15]</sup>.

### IFN therapy

In this protocol, 41 patients (29.5%) received IFN- $\beta$  every day for 6 or 8 wk, and 98 patients (70.5%) received IFN- $\alpha$  for 24 wk (every day for 2 wk, followed by three times per week for 22 wk). A median total dose of IFN was 27 720 MU (range: 25 200–28 800 MU) in those treated with IFN- $\beta$  and 62 500 MU (range: 46 800–78 000 MU) in those treated with IFN- $\alpha$ . Sustained response (SR) was defined as negative by HCV RNA qualitative analysis using PCR and normal ALT at 24 weeks after cessation of IFN therapy. Patients who remained positive for HCV RNA by PCR during and at the end of IFN treatment were defined as resistant to IFN therapy (non-response: NR). The study protocol was approved by the Human Ethics Review Committee of Saga Medical School Hospital and informed consent was obtained from each subject.

### Evaluation of patients

Patients were divided into two groups: SR and NR. All were classified by age, sex, HCV RNA (low: <100 MU/L; and high:  $\geq$ 100 MU/L), viral serotype, alcohol intake, complication of diabetes (evaluated by 75 g OGTT), BMI (non-obese: <25; obese:  $\geq$ 25), leptin level (high:  $\geq$ 8  $\mu$ g/L; low: <8  $\mu$ g/L), and pathological findings of biopsy samples.

### Statistical analysis

Comparisons between the two groups regarding these factors were performed using the  $\chi^2$  test. Parameters that had an influence on IFN-response were compared by the univariate Cox's proportional hazard model analysis. Variables that achieved statistical significance by univariate analysis were subsequently included in a multivariate proportional hazard model analysis. All analyses were carried out using SAS program (SAS Institute, Cary, NC, USA). Differences were considered significant if  $P < 0.05$ . Results were expressed as mean  $\pm$  SD unless otherwise stated.

## RESULTS

### Background characteristics of patients at the start of IFN monotherapy

Subjects included 87 men and 52 women. Mean BMI was 23.4 kg/m<sup>2</sup>, ranging from 16.9 to 33.6 kg/m<sup>2</sup>. Six percent of patients had an alcohol intake of more than 40 g/d. Ten subjects were complicated with diabetes mellitus. Seventy-one percent of patients were infected with HCV serotype 1, whereas 29% were infected with serotype 2. The subjects were divided into two groups using a cut-off viral load of 100 MU/L, and as a result, 50 subjects (16 women) showed a low viremia level (<100 MU/L), and 89 (36 women) a high viremia level ( $>$ 100 MU/L).

**Table 1** Demography of chronic hepatitis C patients and comparison between NR and SR to interferon

	Total (n = 139)	NR (n = 106)	SR (n = 33)	P value
Age (yr)	49.9±11.1	70:30	25:6	NS
Sex (male:female)	87:54	62:44	25:8	NS
HCV RNA load (<100 U/L; ≥ 100 U/L)	50:89	23:83	27:6	<0.0001
Serotype (1:2)	99:40	81:25	18:15	0.026
Alcohol intake (yes:no)	8:131	6:100	2:31	NS
Complication of diabetes mellitus (yes:no)	10:129	6:100	4:29	NS
Body mass index (<25; ≥ 25)	108:31	80:26	28:5	NS
Leptin (< 8 µg/L; ≥ 8 µg/L)	91:48	63:43	25:3	0.017
Pathological findings				
Grading (A0, A1:A2, A3)	28:111	18:87	9:23	NS
Staging (F0, F1:F2, F3)	52:87	34:71	1:17	15
Steatosis (grade 1, 2:3, 4)	93:46	69:36	23:9	NS

NR: Non-responder; SR: Sustained responder.

Liver histopathological examination revealed: 28 subjects with mild activity (A<sub>0</sub> plus A<sub>1</sub>) and 111 with severe activity (A<sub>2</sub> plus A<sub>3</sub>); 52 with mild fibrosis (F<sub>0</sub> plus F<sub>1</sub>) and 87 with advanced fibrosis (F<sub>2</sub> plus F<sub>3</sub>); 93 with mild steatosis (steatosis grade 1 plus 2) and 46 with severe steatosis (grade 3 plus 4). Mean serum leptin concentrations in all the subjects was 6.8±5.5 µg/L, while high serum leptin concentrations beyond 8 µg/L were detected in 48 (34.5%) patients (Table 1).

### Univariate analysis between SR and NR groups

SR was achieved by 33 patients (23.7%), while the remaining 106 patients (76.3%) failed to show a response. Comparison between the two groups evaluated by  $\chi^2$  is shown in Table 1. Low viremia level was more frequent in patients with SR than in those with NR ( $P<0.0001$ ). In addition, HCV serotype was related to the response to IFN ( $P=0.026$ ). Subjects with low serum leptin levels (< 8 µg/L) were significantly associated with a good IFN-response ( $P=0.017$ ), whereas the low viremia group with a high serum leptin level (≥ 8 µg/L) achieved SR only in 12.5% of the subjects.

When subjects were classified into mild fibrosis (F<sub>0</sub>+F<sub>1</sub>) and advanced fibrosis (F<sub>2</sub>+F<sub>3</sub>), subjects with mild fibrosis were more likely to have a good response to IFN ( $P=0.038$ ). There was no significant difference of BMI or hepatic steatosis grade or leptin/BMI ratio (data not shown) between NR and SR. These factors were evaluated by univariate analysis and four possible risk factors that influenced the effect of IFN therapy on HCV virus were selected: serotype, HCV-RNA, liver fibrosis, and serum leptin level (data not shown).

### Multivariate analysis between SR and NR groups

Multivariate analysis indicated that viremia level was the most significant factor among the four selected ones (Table 2). As a next step, we evaluated the data limited to the factors in the low viremia patients ( $n=50$ ). In patients with low viremia, only leptin level was an independent risk factor for IFN resistance (Table 2). This result regarding leptin level was supported by analysis using another

**Table 2** Multivariate analysis of parameters

		P	Odds ratio	RR (95%CI)
independently	Serotype	0.93	1.05	(0.34-3.32)
influenced SR (n = 33)	HCV RNA	<0.0001	12.74	(4.15-39.08)
	Fibrosis	0.18	0.49	(0.18-1.39)
	Leptin level	0.14	2.87	(0.18-11.63)
50 subjects with low viremia level	Serotype	0.95	0.25	(0.25-3.63)
	Fibrosis	0.14	0.37	(0.1-1.4)
	Leptin level	<0.05	9.38	(0.99-88.85)

**Figure 1** Effectiveness of IFN and serum leptin level in subjects with a low viremia level. NR: Non-responder group for IFN therapy; SR: Sustained responder group. <sup>a</sup> $P<0.05$ , NR vs SR. Mann-Whitney U-test.

statistical method (Figure 1), that is, evaluated by U-test. In patients with low viremia, leptin levels were significantly higher in the NR group compared to the SR group ( $P<0.05$ ).

Although histopathological findings were not independent risk factors in multivariate analysis for IFN therapy, there were significant relations between the leptin level and activity grading + steatosis evaluated by Kruskal-Wallis test (Figures 2A and 2B). Evaluations using Kruskal-Wallis did not indicate a relationship between liver fibrosis and serum leptin level (Figure 2C).

## DISCUSSION

This study demonstrated the possibility that among the host factors, serum leptin level can be a significant negative predictor for IFN-response in chronic hepatitis C. We evaluated 139 naïve patients with chronic hepatitis C who had received IFN monotherapy at our hospital. In this protocol, IFN- $\alpha$  or IFN- $\beta$  was administered because intramuscular IFN- $\alpha$  and once-a-day intravenous IFN- $\beta$  resulted in a similar sustained HCV RNA clearance in patients with chronic hepatitis C in Japan<sup>[16]</sup>. We showed the response rate and pretreatment predictive factors associated with IFN response in these patients. It was suggested that serum leptin level was an important factor for IFN response, although viral load was most critical for IFN therapy.

Overall, the SR rate in our study was 23.7% in patients receiving IFN monotherapy. Subjects with a low serum leptin level (< 8 µg/L) were significantly associated with

**Figure 2** Histopathological parameters and serum leptin level. **A:** Hepatic steatosis and serum leptin level. Steatosis was evaluated by the Adinolfi grading system in which steatosis is graded from 0 to 4 based on the percentage of hepatocytes involved. There were significant relationships between leptin level and hepatic steatosis evaluated by Kruskal-Wallis test ( $^bP < 0.01$ , steatosis 1 vs 2 vs 3 vs 4); **B:** Necroinflammatory activity and serum leptin level. There were significant relationships between leptin level and activity grading evaluated by Kruskal-Wallis test ( $P < 0.05$ ). The scoring system includes the semi-quantitative assessment of liver disease grading of histopathological inflammatory activity (1: mild, 2: moderate, 3: severe activity;  $^aP < 0.05$ , activity 1 vs 2 vs 3); **C:** Fibrosis and serum leptin level. F1: Fibrosis is located to the portal tract; F2: fibrosis is located septally with distinct widening of portal fields; F3: fibrosis extended portally to the portal; F4: liver cirrhosis. There was no relationship between leptin level and liver fibrotic staging evaluated by Kruskal-Wallis test. NS: not significant.

a good IFN response. Multivariate analysis of all factors could not identify serum leptin level as an independent predictive factor associated with SR, because the high viral load markedly influenced on IFN therapy as has been indicated in several previous studies<sup>[17,18]</sup>. When evaluation was limited in the 50 patients with low viral load (<100 MU/L), multivariate analysis revealed a significantly independent association between high serum leptin level and low IFN-response (OR = 9.38,  $P < 0.05$ ). In this study, the relationship between BMI and serum leptin level was clearly seen, but not BMI alone, as an independent risk factor for IFN therapy. The reason for this discrepancy between leptin level and BMI was not ascertained in this study, but most Japanese obese subjects have a moderate BMI of around 25<sup>[19]</sup>.

A histopathological approach indicated that serum leptin level was significantly associated with worsening steatosis and inflammatory activity, although these two factors in liver samples were not independent risk factors for IFN therapy in this study. Piche *et al.*<sup>[20]</sup> reported that leptin is an independent metabolic factor associated with the severity of liver fibrosis in patients with chronic hepatitis C and higher BMI. Previous study demonstrated that overweight patients with chronic hepatitis C had significantly more steatosis and increased serum insulin and leptin levels<sup>[21]</sup>. On the other hand, Giannini *et al.*<sup>[22]</sup> demonstrated that there was no relationship between serum leptin levels and the severity of steatosis, but their study design was different from this study. Namely, they excluded patients who had complicated diabetes mellitus, hyperlipidemia, obesity, and alcohol ingestion. The relationship between serum leptin levels and the severity of steatosis in patients with chronic hepatitis C remains controversial, because serum leptin levels can be affected by the progression of chronic hepatitis and host factors, such as visceral adiposity, insulin resistance and other adipokines. In this study, we could not demonstrate the relationship between liver fibrosis and serum leptin; the reason for this result might be explained by the fact that we enrolled naïve

patients for IFN therapy in this study.

The mechanism of leptin in the antiviral response to IFN treatment was not determined in this study, but several studies might support the possibility of a relationship between the two factors. Serum leptin concentration increased in liver steatosis and cirrhosis in addition to obesity<sup>[23]</sup>. Another study also has shown that liver fibrosis correlates with steatosis and obesity<sup>[24]</sup>. From these studies, it could be judged that lipid deposits within the hepatocytes might cause functional disturbances by increasing the architectural distortion of the hepatic lobule caused by fibrosis, and decrease the contact area between drugs (e.g., IFN) and hepatocytes. While the expression of leptin in adipose tissue increased in response to feeding and energy repletion, leptin had a proinflammatory and/or profibrogenic role that might regulate cytokine-influenced repair and fibrogenesis of liver<sup>[11]</sup>.

Our data suggests that low serum leptin might be a predictor for sustained viral response following a course of IFN therapy for chronic hepatitis C with low viremia. In this study, we did not assess the difference of serum leptin levels in males and females because it was difficult to define normal ranges of serum leptin level in various stages of hepatic fibrosis and also the activity of leptin in each male and female patients are unclear. However, high serum leptin level is a remarkable risk factor for antiviral therapy in chronic hepatitis C, because this study showed that serum leptin levels over 8 μg/L or less than 8 μg/L were able to be the threshold line for both males and females about the efficacy of antiviral therapy. This study does not address the issue if pretreatment intervention to decrease serum leptin level before IFN therapy would compensate for the low response rate in patients with a high serum leptin level. Prospective studies are needed to investigate the effectiveness of decreasing leptin level by interventions, such as weight reduction before IFN-therapy for enhancing antiviral responsiveness, and to investigate using combination therapy by peg-interferon and ribavirin.

breakthrough was defined as the reappearance of a serum HBV DNA level to more than 10-fold the minimum during treatment.

**RESULTS:** Lamivudine produced virological response in 86.8% of the 318 patients at 6 mo, in 80.2% of 252 patients at 12 mo, in 69.2% of 133 patients at 24 mo, and in 53.6% of 28 patients at 36 mo. Forward stepwise logistic regression analysis showed an HBV DNA level less than 6.8 log copies/mL ( $P < 0.0001$ ), HBeAg negativity ( $P < 0.0001$ ), a platelet count of  $100 \times 10^9/L$  or more ( $P = 0.0162$ ) at baseline, and a decline of the HBV DNA level of more than 3.2 log copies/mL as compared with the baseline level at 3 mo after the start of treatment ( $P = 0.0003$ ) to be significantly associated with virological response. Among patients with a virological response, virological breakthrough was seen in 5.3% of 19 patients who responded virologically at 1 mo, in 20.7% of 203 patients at 3 mo, in 27.5% of 51 patients at 6 mo, in 33.3% of 12 patients at 9 mo, and in 100% of 3 patients at  $\geq 15$  mo. A virological breakthrough was found significantly more often in patients with delayed virological response.

**CONCLUSION:** Lamivudine treatment could suppress serum HBV DNA in most of the tested Japanese patients. Long-term efficacy might be seen in patients without HBeAg at baseline, in the absence of cirrhosis, and in patients with a decline in HBV DNA level soon after the start of treatment.

### Abstract

**AIM:** To determine the efficacy of long-term lamivudine treatment of a large number of Japanese patients with chronic hepatitis B.

**METHODS:** In this retrospective, multi-center trial, 318 Japanese patients with chronic hepatitis B received 100 mg of lamivudine daily for up to 36 (median 21) mo. Virological response was a decline to a serum HBV DNA level less than 3.7 log copies/mL. Virological

## INTRODUCTION

Chronic hepatitis B virus (HBV) infection affects 400 million people worldwide, three-quarters of whom reside in Asia<sup>[1]</sup>. The morbidity and mortality of chronic HBV infection are a major public health concern. Vertical transmission of HBV is the main cause of chronic HBV infection in the endemic areas of Asia. In Japan which is endemic for HBV infection, transmission can be easily prevented by vaccination of at risk-infants. The prevalence of hepatitis B surface antigen (HBsAg) carriage in the general population was reported to be less than 2%<sup>[2]</sup>. However, in areas of high HBV endemicity, persons with HBV-related cirrhosis have an approximately threefold higher risk of hepatocellular carcinoma (HCC) than those with chronic hepatitis but without cirrhosis and a 16-fold higher risk of HCC than the carriers in whom the virus is inactive<sup>[3]</sup>. Interferon-alpha (IFN- $\alpha$ ) has been approved for the treatment of chronic hepatitis B<sup>[4]</sup>, but it is poorly tolerated and effective in only 20%-30% of patients. Since the late 1990s, several studies have demonstrated the effectiveness of the initially available antiviral medicine, lamivudine, for patients with chronic hepatitis B: HBV DNA suppression, normalization of alanine aminotransferase (ALT), loss of hepatitis B e antigen (HBeAg). Moreover, studies have demonstrated the improvement of hepatic histology by the administration of lamivudine compared to placebo<sup>[5-8]</sup>.

Lamivudine, an oral cytosine nucleoside analog, is the (-) - beta-enantiomer of 2',3'-dideoxy-3'-thiacytidine. HBV replicates through a pregenomic RNA intermediate. Lamivudine interferes with HBV reverse transcriptase (DNA polymerase) activity and causes chain termination of nascent viral DNA, leading to the inhibition of HBV replication<sup>[9]</sup>. Long-term treatment with lamivudine is not an option because it leads to drug resistance in most cases<sup>[10,11]</sup>. Lamivudine treatment, especially for chronic HBV-infected patients with cirrhosis, may also act as a bridge to more definitive treatments, such as liver transplantation. However, in several countries, including Japan, liver transplantation is not easily available because of insufficiency of donors, and even in other countries, many patients have to wait for long periods for transplantation. Although several non-Asian studies, from North America and Europe, have shown the efficacy of long-term use of lamivudine<sup>[12,13]</sup>, few studies have assessed the efficacy of long-term lamivudine treatment of a large number of Japanese patients with chronic hepatitis B.

To acquire more data on these issues, 37 Japanese liver units involved in the management of HBV-related chronic liver diseases in Kyushu, Japan cooperated in this study. The objective of the present study was to analyze the results of long-term lamivudine administration for the suppression of HBV replication and the clinical outcomes of a large number of Japanese patients with chronic hepatitis B.

## MATERIALS AND METHODS

### Patients

This retrospective analysis encompassed 318 Japanese

chronic hepatitis B patients (231 males and 87 females, mean age 47.8 years) on lamivudine monotherapy for up to 36 (median 21, range 9-36) mo. Clinical features from 403 HBsAg-positive patients with chronic liver diseases, who started lamivudine treatment between December 2000 and March 2004 in 37 Japanese liver units in Kyushu, were recorded in a centralized database. All patients were determined to be serum HBV DNA-positive via polymerase chain reaction (PCR) assay prior to treatment. The diagnosis of chronic hepatitis and cirrhosis was based on a liver biopsy in most patients, if unavailable, on clinical laboratory, and ultrasound data. Eighty five patients were excluded from the present analysis because of one or more of the following reasons: age below 18 years; positive for antibody to hepatitis C virus or human immunodeficiency virus type 1; diagnosis of HCC within 3 mo after enrolment; time of lamivudine treatment within 9 mo; or treatment with anticancer drugs or corticosteroid drugs for other malignancies, such as leukemia, lymphoma or autoimmune diseases. Because this was a retrospective analysis of treated patients, there were no predefined criteria for treatment withdrawal or combination treatments. Criteria for withdrawal and combination treatments after the start of the treatment were dependent upon the strategy used by the physician at each center. In the present study, follow-up was stopped for patients who discontinued lamivudine treatment or started receiving a combination treatment with IFN and lamivudine, or with adefovir dipivoxil and lamivudine.

### Therapeutic protocol

The patients received lamivudine (Zeffix<sup>®</sup>, Glaxo Smith Kline, UK) orally in a single daily dose of 100 mg. Data concerning age, sex, history of prior IFN treatment, Child-Turcotte-Pugh (CTP) score, series of serum laboratory testing of ALT, total bilirubin, albumin, HBeAg, and HBV DNA level were collected. Also, we analyzed virological (time of virological response and virological breakthrough) and biological events (time of ALT normalization, ALT breakthrough, and hepatitis flare) during the observation period. The clinical events recorded were hepatic decompensation (ascites, portal hypertensive bleeding, and hepatic encephalopathy) and liver-related death during the study period.

### Biochemical and virological measurement

Quantification of serum HBV DNA was performed at each center using one of the following commercial assays according to local availability: quantitative PCR assay (Amplicor HBV Monitor, Roche Diagnostics, Mannheim, Germany), over a detection range from 2.6 (corresponding to 400 copies/mL) to 7.5 log copies/mL; or transcription-mediated amplification and hybridization protect assay (TMA-HPA, Chugai Diagnostics, Tokyo, Japan), over a detection range from 3.7 log genome equivalents (LGE)/mL (corresponding to 5000 copies/mL) to 8.7 LGE/mL. A decline of the serum HBV DNA level to less than 3.7 log copies/mL during treatment was considered as a virological response. Virological breakthrough was defined as the reappearance of a serum HBV DNA level to more

than 10-fold the minimum during treatment. We analyzed whether or not an early decline of the HBV DNA level at 3 and 6 mo after the start of the treatment was related to virological response and breakthrough.

The serum ALT, bilirubin, and albumin levels were serially determined using the standard method every month before treatment and during the treatment. The upper normal limits for the ALT level were slightly different in each facility, ranging between 30 and 40 IU/mL. Normalization with an ALT level 667 or below during the treatment was considered as a biological response. A deterioration of ALT to an abnormal level after normalization during the treatment was considered as an ALT breakthrough. A deterioration of the ALT level more than 10 times the upper limit of normal (ULN) was considered as a hepatitis flare.

### Statistical analysis

Categorical variables were analyzed using  $\chi^2$  test or Fisher's exact test. The Mann-Whitney *U*-test was also used to compare responders and non-responders with regard to various characteristics, when appropriate. The Cochran-Armitage's trend test was used to determine the relationship between the increases or decreases in the virological breakthrough rates of patients with virological response. Independent factors associated with responders were studied using forward stepwise logistic regression analysis of the following variables: age at the start of treatment, sex, history of prior IFN treatment, histological staging and grading, pretreatment laboratory data, serum pretreatment HBV DNA level, and the median declines of HBV DNA level at 3 and 6 mo after the start of the treatment. Forward stepwise logistic regression analysis was performed using a commercially available software package (BMDP Statistical Software Inc., Los Angeles, CA, USA) for the IBM 3090 system computer. The BMDP program LR was used to evaluate the relationship between the clinical features and SVR. Using this method, the most significant associated variable was entered into the model. After adjusting for that variable, the next most significant variable was added to the model. Two-tailed *P* values less than 0.05 were considered statistically significant.

## RESULTS

### Baseline assessment

The mean age and percentage over 35 years were significantly higher in patients with cirrhosis than in those without cirrhosis, while the mean ALT level, albumin, and platelet counts were significantly higher in patients without cirrhosis than in those with cirrhosis. No significant differences in sex distribution, total bilirubin, positivity of HBeAg, or HBV DNA level were observed between these groups (Table 1). This study consisted of 173 HBeAg-positive and 145 HBeAg-negative patients with a mean pretreatment HBV DNA level of  $6.8 \pm 1.2$  (median 7.0) log copies/mL. Concerning the relationship between HBeAg and HBV DNA level, the mean HBV DNA level was significantly higher in HBeAg-positive patients with ( $7.3 \pm 1.1$  log copies/mL) and without cirrhosis ( $7.2 \pm 1.0$  log copies/mL) as compared with HBeAg-negative

patients with ( $6.3 \pm 1.2$  log copies/mL) and without cirrhosis ( $6.2 \pm 1.1$  log copies/mL) (both  $P < 0.0001$ ). No significant difference in HBV DNA level, even classified by HBeAg status, was observed between patients with and without cirrhosis.

### Virological and biological efficacy during lamivudine treatment period

In analyses of an early decline of HBV DNA level by lamivudine, the mean declines of all the studied patients were  $3.2 \pm 1.2$  (median 3.2) log copies/mL at 3 mo and  $3.6 \pm 1.1$  (median 3.8) log copies/mL at 6 mo after the start of treatment. During the treatment period of up to 36 (median 21) mo, a virological response was found in 90.6% (288/318) patients and ALT normalization was found in 86.2% (274/318) patients. Of the 288 with virological response, 255 (88.5%) had ALT normalization. Of the remaining 30 without virological response, 19 (63.3%), who had achieved virological suppression with a low HBV DNA level of 3.7-4.0 log copies/mL by lamivudine, had ALT normalization, but 11 (36.7%) had no ALT normalization and an HBV DNA level of more than 4.0 log copies/mL.

The mean pretreatment HBV DNA level was significantly lower in patients with virological response ( $6.6 \pm 1.2$  log copies/mL) than those without virological response ( $7.7 \pm 0.7$  log copies/mL) ( $P < 0.0001$ ). The frequency of pretreatment HBeAg positivity was significantly lower in patients with virological response (51.0%, 147/288) than those without virological response (86.7%, 26/30) ( $P = 0.0004$ ). No significant differences in sex distribution, age, ALT level, platelet count, presence of cirrhosis, or CTP score were found between the patients with and without virological response (Table 2).

Lamivudine suppressed serum HBV DNA to less than 3.7 log copies/mL in 69.2% patients at 3 mo, in 86.8% patients at 6 mo, in 80.2% patients at 12 mo, in 69.2% patients at 24 mo, and in 53.6% patients at 36 mo. The efficacy rate of virological response decreased with the length of the treatment period of patients who received lamivudine for over 6 mo (Figure 1).

Of the 288 patients with virological response, 224

**Table 2** Virological response of 318 patients with chronic HBV infection treated with lamivudine (mean  $\pm$  SD)

Characteristics	Virological response		P
	No n = 288	Yes n = 30	
Number of men (%)	207 (71.9)	24 (80.0)	0.4624
Age (yr)	47.9 $\pm$ 11.4	46.9 (22-73)	0.6453
Number of cirrhosis (%)	90 (31.2)	12 (40.0)	0.4403

Number of HBeAg positivity (%)	147 (51.0)	26 (86.7)	0.0004
HBV-DNA <sup>1</sup>	6.6 $\pm$ 1.2	7.7 $\pm$ 0.7	<0.0001

ALT, alanine aminotransferase; HBeAg, hepatitis B e antigen; SD, standard deviation <sup>1</sup>Logarithmic transformed copies/mL

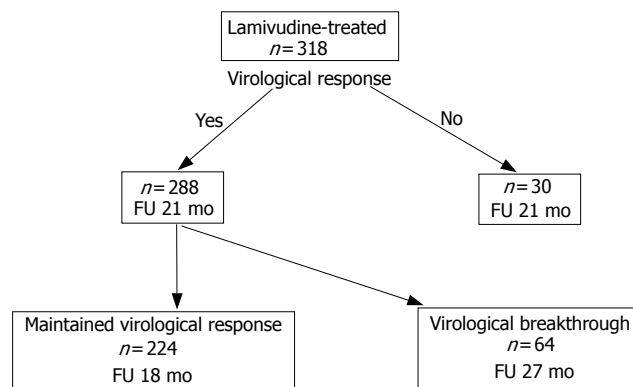

**Figure 1** Treatment period and virological response rates to lamivudine treatment of Japanese patients with chronic hepatitis B virus infection.

(77.8%) had a sustained virological response, and 64 (22.2%) had a virological breakthrough. The median follow-up time was significantly shorter for patients with sustained virological response (18 mo) than those with virological breakthrough (27 mo). The frequencies of pretreatment HBeAg positivity [65.6% (42/64) *vs* 46.8% (105/224);  $P=0.0123$ ] and cirrhosis [43.8% (28/64) *vs* 27.7% (62/224);  $P=0.0218$ ] were significantly higher for patients with virological breakthrough than those without a breakthrough (Figure 2). No significant differences in sex distribution, age, or pretreatment HBV DNA level were observed between these groups.

#### HBeAg status during lamivudine treatment

Of the 318 patients, 173 (54.4%) were detected to have HBeAg in their sera at baseline. Of the 173 HBeAg-positive patients, 82 (47.4%) had clearance of HBeAg and 91 (52.6%) continued to have HBeAg during treatment. Lamivudine led to HBeAg clearance by 6.9% of the patients at 1 mo, by 24.9% of the patients at 3 mo, by 32.9% at 6 mo, by 35.8% at 9 mo, by 37.6% at 12 mo, by 45.1% at 18 mo, and by 47.4% at 36 mo, suggesting

**Figure 2** Virological events in all patients during lamivudine treatment period. FU: Follow-up period.

**Figure 3** Relationship between treatment period and HBeAg clearance rate during lamivudine treatment of Japanese patients with chronic HBV infection.

that HBeAg clearance rates increased with the duration of lamivudine treatment (Figure 3). HBeAg clearance always occurred after virological response in all the 82 who cleared HBeAg. No significant differences in sex distribution, age, ALT level, platelet count, presence of cirrhosis, or CTP score were found between the patients with and without HBeAg clearance. Of the 145 patients with HBeAg negative at baseline, no patient reversed to HBeAg positive. We observed that the patients who cleared HBeAg (79/82, 96.3%) and the patients with HBeAg negative at baseline (141/145, 97.2%) had a significantly higher virological response rate than those without HBeAg clearance (68/91, 74.8%,  $P=0.0002$ ,  $P<0.0001$ , respectively).

#### ALT breakthrough and hepatitis flare during lamivudine treatment

Of the 274 patients with ALT normalization by lamivudine, 231 (84.3%) had sustained ALT normalization, and 43 (15.7%) had an ALT breakthrough. Of the 43 patients with an ALT breakthrough, 4 (9.3%) had a hepatitis flare: 4 males, 3 with cirrhosis and 1 without cirrhosis, and 4 with HBeAg. However, no patient with hepatic decompensation, who had marked hyperbilirubinemia, or had a liver-related death, was observed in this study. The

**Table 3** Forward stepwise logistic regression analysis for all independent factors contributing to virological response

Factors	Odds ratio	95% CI	P
(At baseline)			
HBV DNA less than 6.8 <sup>1</sup>	434.7	104.1-2000	< 0.0001
HBeAg negativity	7.142	2.136-238.0	<0.0001
Platelet count more than 100×10 <sup>9</sup> /L	4.625	1.242-17.22	0.0224
(During treatment)			
Decline of HBV-DNA more than 3.2 <sup>1</sup> within 3 mo of the start of treatment	51.13	11.21-233.0	<0.0001

HBV, hepatitis B virus; HBeAg, hepatitis B e antigen; CI, confidence interval of odds ratios <sup>1</sup>Logarithmic transformed copies/mL.

**Table 4** Forward stepwise logistic regression analysis for all independent factors contributing to virological breakthrough

Factors	Odds ratio	95% CI	P
(At baseline)			
Cirrhosis	3.527	1.687-7.371	0.0008
HBeAg positivity	2.512	1.265-4.989	0.0085
Platelet counts less than 100×10 <sup>9</sup> /L	2.386	1.003-5.676	0.0491
(During treatment)			
Decline of HBV-DNA less than 3.9 <sup>1</sup> within 6 mo of the start of treatment	2.358	1.246-4.464	0.0084

HBV, hepatitis B virus; HBeAg, hepatitis B e antigen; CI, confidence interval of odds ratios <sup>1</sup>Logarithmic transformed copies/mL.

time of ALT changes always depended on the time of virological change: ALT deterioration after normalization followed an increase in the HBV DNA level in all cases. The frequency of HBeAg positivity at baseline was significantly higher in patients with a breakthrough than those without a breakthrough [72.1% (37/43) *vs* 51.5% (119/231); *P*<0.0001]. No significant differences in sex distribution, age, pretreatment HBV DNA level, presence of cirrhosis or CTP score were observed between these groups.

### Relationship between early virological response and virological breakthrough

Among the 288 with virological response, virological breakthrough was seen in 1 (5.3%) of 19 who had virological response at one month, in 42 (20.7%) of 203 at 3 mo, in 14 (27.5%) of 51 at 6 mo, in 4 (33.3%) of 12 at 9 mo, and in 3 (100%) of 3 at ≥15 mo. Cochran-Armitage's trend test revealed that virological breakthrough was significantly more prevalent in patients with delayed virological response (*P*<0.0001) (Figure 4).

### Factors contributing to virological response and breakthrough

At baseline, an HBV DNA level less than 6.8 log copies/mL (*P*<0.0001), HBeAg negativity (*P*<0.0001), and platelets count of 100×10<sup>9</sup>/L or more (*P*=0.0224) were significantly associated with virological response in the 318 studied patients (Table 3). Of the treatment factors, an early decline of 3.2 or more log copies/mL of HBV DNA at 3 mo after the start of the treatment was significantly associated with the response (*P*<0.0001).

**Figure 4** Relationship between time of virological response and virological breakthrough rate during lamivudine treatment of Japanese patients with chronic HBV infection. VR: Virological response.

At baseline, cirrhosis (*P*=0.008), HBeAg positivity (*P*=0.0085), and platelets count less than 100×10<sup>9</sup>/L (*P*=0.0491) were significantly associated with a virological breakthrough in the 288 patients with virological response (Table 4). Of the treatment factors, an early decline of 3.8 or less log copies/mL of HBV DNA at 6 mo after the start of the treatment was significantly associated with the breakthrough (*P*=0.0084).

## DISCUSSION

To our best knowledge, no such large-scale studies as this of lamivudine have been carried out for Japanese chronic hepatitis B patients. In this retrospective study, good virological and biological efficacy for up to 36 mo of lamivudine treatment was seen in Japanese patients with chronic hepatitis B, with no relation to sex, age, or ALT level at baseline. The effect was sustained for the patients with HBeAg-negative before treatment, absence of cirrhosis, and with an early decline of the HBV DNA level after the start of the treatment. During the treatment, very few patients with a hepatitis flare were seen and none with hepatic decompensation, marked hyperbilirubinemia, or liver-related death were seen in this study. The aims of treatment for chronic hepatitis B are to achieve sustained suppression of HBV replication and remission of inflammation in the liver. The antiviral responses for chronic hepatitis B are categorized as biochemical (ALT normalization), virological (decrease of HBV DNA to less than 5 log copies/mL and loss of HBeAg), and histological, and as on-therapy or sustained off-therapy<sup>[14]</sup>. Treatment for chronic hepatitis B patients seems to be necessary when the HBV DNA level exceeds 5 log copies/mL, independent of ALT activity<sup>[11]</sup>. Lamivudine well inhibited HBV DNA replication in Japanese chronic hepatitis B patients.

HBeAg clearance usually predicts long-lasting suppression of HBV, reduced infectivity and an improved clinical prognosis<sup>[15]</sup>. In this study, 47.4% of patients with HBeAg at baseline had HBeAg eliminated from their sera. Follow-up reports of the multicenter Asian study for Chinese patients showed that HBeAg clearance rates increased with the duration of lamivudine treatment, from 17% to 22% at

12 mo, 27 to 29% at 24 mo, and 33 to 40% at 36 mo<sup>[12,16,17]</sup>. The results of our study were consistent with those of these non-Japanese patient, although the HBeAg clearance rates within 24 mo were relatively high in our study. Lamivudine was effective in terms of HBeAg clearance in Japanese chronic hepatitis B patients. Patients successfully treated for chronic hepatitis B are less likely to develop cirrhosis, liver failure, and HCC in comparison with those who do not respond to treatment<sup>[18]</sup>. A randomized controlled trial of lamivudine for chronic hepatitis B patients demonstrated that HCC incidence was reduced by lamivudine antiviral therapy, showing an incidence of 3.9% in lamivudine-treated patients and 7.4% in a placebo control group, with a hazard ratio of 0.49 (95%CI = 0.25-0.99)<sup>[19]</sup>. For chronic hepatitis B patients, antiviral therapy with lamivudine that results in sustained suppression of HBV DNA replication and hepatic necroinflammation may reduce the incidence of HCC.

It has been reported that resistance to lamivudine often develops after 6 mo of treatment<sup>[10]</sup>. The present study was limited in its value because we detected viruses resistant to lamivudine. However, in our study, the emergence of resistant viruses could be defined by the virological breakthrough (reappearance of serum HBV DNA levels more than 10-fold increase from the minimum). A serious drawback of long-term lamivudine treatment is the development of resistant HBV mutants, i.e., the mutations in a tyrosine-methionine-aspartate-aspartate (YMDD) motif of the HBV polymerase gene, associated with increase in serum HBV DNA and the ALT level<sup>[19]</sup>. The present study showed that the HBV DNA suppression rates by lamivudine decreased with the duration of treatment, but that a relapse of biochemical response, ALT breakthrough was found only in 15.7% of patients during these treatment periods. Lamivudine treatment withdrawal can cause HBV DNA to revert to pretreatment levels, with the relapse of clinical hepatitis<sup>[20]</sup>. With the excellent safety and tolerability of lamivudine, continuous therapy is suggested as beneficial<sup>[4]</sup>. After the start of phylogenetic analyses, based on inter group divergence of 8% or more over the complete HBV nucleotide sequence, seven different genotypes, arbitrarily designed A-G, have been recognized<sup>[21,22]</sup>. Several reports have shown geographical distribution of the genotypes, with genotypes A and D predominant in Western Europe, B and C in South Asia and the Far East, and F in South America<sup>[21-26]</sup>. Due to the geographical distribution pattern, HBV genotypes B and C are commonly observed in Japan<sup>[24-27]</sup>. Moreover, Japan is apparently at a geographical boundary for genotypes B and C, forming a south to north gradient in which genotype C is more frequent in the south of Kyushu, and genotype B is more frequent in the north of Tohoku. Interestingly, however, genotype B is more frequent in Okinawa, the southern-most area of Japan<sup>[27]</sup>. Our previous epidemiological study of the Japanese HBV genotype distribution showed that 95% of the patients studied had genotype C<sup>[24]</sup>. Genotype C has been reported to cause more severe liver damage and to have lower rates of HBeAg clearance, which usually indicates cessation of HBV replication and represents a later stage of chronic HBV infection, than genotype B in Japanese patients<sup>[24-26]</sup>. Accordingly, our results were equivalent in

the response to lamivudine to Japanese HBV genotype C patients, although we did not determine the genotyping of our patients.

Another noteworthy finding of our study was that predictive marker of the efficacy to lamivudine and its durability were HBeAg negativity and a low HBV DNA level at baseline. HBV DNA reappears in serum after cessation of lamivudine treatment because HBV replication within the HBV-infected hepatocytes originates primarily from the covalently closed circular DNA (cccDNA) of HBV in the liver. Lamivudine appears to have no effect on the level of cccDNA<sup>[28]</sup>. Liver injury seems to be particularly severe and rapidly progressive in HBeAg-negative patients, but clinically significant HBV replication persists in them<sup>[24]</sup>. Most HBeAg-negative chronic hepatitis B patients who are HBV DNA-positive harbor HBV variants with mutations in the precore or core promoter region, which can suppress synthesis of HBeAg<sup>[11,26]</sup>. The clearance of HBeAg is perhaps a reflection of a loss of the cccDNA pool of HBV in the liver<sup>[29]</sup>. The great concern of clinicians is that HBeAg negativity and a low HBV DNA level at baseline are significant predictive markers for lamivudine treatment in Japanese patients.

A previous report on Japanese patients showed that the emergence rate of lamivudine-resistant viruses in patients with cirrhosis was higher than those without cirrhosis<sup>[28]</sup>, suggesting that a virological breakthrough appears more frequently in patients with cirrhosis than those without cirrhosis. The present study showed that lamivudine treatment was not so effective or durable in patients with cirrhosis and low platelet counts. Clinicians should always do close monitoring or use other antiviral drugs because hepatitis flare was occasionally severe, especially in patients with cirrhosis. The present study also showed that an early virological response to lamivudine was predictive of both efficacy and durability, but a lack of an early virological response was found to predict a virological breakthrough. A high HBV DNA level reflects a greater pool of virus and a higher rate of virus replication, thereby increasing the likelihood that drug-resistant mutations will be selected. Such an early decrease of viral load after the start of lamivudine might be associated with the lack of viral resistance.

In conclusion, the present study suggests a long-term lamivudine treatment to be safe and to result in the reduction of serum HBV DNA in most Japanese patients with chronic hepatitis B. The efficacy is sustained in patients with HBeAg-negative at baseline, absence of cirrhosis, and a reduction of the HBV DNA level soon after the start of the treatment.

### Abstract

**AIM:** To determine whether a specific adenosine A<sub>2A</sub> receptor agonist (ATL-146e) can ameliorate aspirin-induced gastric mucosal lesions in rats, and reduce neutrophil accumulation and production of pro-inflammatory cytokines.

**METHODS:** Gastric lesions were produced by oral gavage of aspirin (200 mg/kg) and HCl (0.15 mol/L, 8.0 mL/kg). 4-{3-[6-Amino-9-(5-ethylcarbamoyl-3,4-dihydroxy-tetrahydro-furan-2-yl)-9H-purin-2-yl]-prop-2-ynyl}-cyclohexanecarboxylic acid methyl ester (ATL-146e, 2.5-5 µg/kg, IP) was injected 30 min before the administration of aspirin. Tissue myeloperoxidase (MPO) concentration in gastric mucosa was measured as an index of neutrophil infiltration. Gastric mucosal concentrations of tumor necrosis factor-α (TNF-α) and interleukin-1β (IL-1β) were determined by ELISA. Also, we examined the effect of ATL-146e on tissue prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) production and gastric secretion.

**RESULTS:** Intragastric administration of aspirin induced multiple hemorrhagic erosions in rat gastric mucosa. The total length of gastric erosions (ulcer index) in control rats was 29.8±7.75 mm and was reduced to 3.8±1.42 mm after pretreatment with 5.0 g/kg ATL-146e ( $P<0.01$ ). The gastric contents of MPO and pro-inflammatory cytokines were all increased after the administration of aspirin and reduced to nearly normal levels by ATL-146e. Gastric mucosal PGE<sub>2</sub> concentration was not affected by intraperitoneal injection of ATL-146e.

**CONCLUSION:** The specific adenosine A<sub>2A</sub> receptor agonist, ATL-146e, has potent anti-ulcer effects presumably mediated by its anti-inflammatory properties.

### INTRODUCTION

Nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin are widely used as anti-inflammatory, analgesic agents<sup>[1,2]</sup>. However, gastrointestinal injury is a serious adverse effect of NSAIDs, and effective strategies to protect the gastrointestinal mucosa are required. Many previous studies have investigated the mechanisms for the development of NSAIDs-induced gastric mucosal lesions<sup>[3-5]</sup>. NSAIDs may cause gastric lesions by inhibiting cyclooxygenase (COX) and reducing prostaglandin (PG) production, but the exact pathogenic mechanism remains to be elucidated<sup>[6]</sup>. Several investigators have reported that intraperitoneal injection of anti-neutrophil serum or immunoneutralization of adhesion molecules on neutrophils and endothelial cells significantly attenuates gastric mucosal injury induced by NSAIDs<sup>[7,8]</sup>. Therefore, activation and infiltration of neutrophils into the stomach appear to contribute to the gastric mucosal lesions induced by NSAIDs.

Adenosine is a primordial signaling molecule that elicits numerous physiological responses in all mammalian tissues. The receptor-mediated effects of adenosine are mediated by four G protein-coupled receptors (A<sub>1</sub>, A<sub>2A</sub>, A<sub>2B</sub>, and A<sub>3</sub>)<sup>[9,10]</sup> which are variably expressed on immune cells depending on cell type and species. A<sub>2A</sub> receptors are found on bone marrow derived cells including neutrophils, monocytes, macrophages, lymphocytes, platelets, and mast cells<sup>[11]</sup>. Activation of A<sub>2A</sub> receptors on immune cells produces a series of responses that in general can be categorized as anti-inflammatory effects<sup>[12]</sup>. It has been reported that the activation of A<sub>2A</sub> receptors attenuates ischemia/reperfusion injury in the heart, lung, liver, and

kidney by reducing neutrophil accumulation, superoxide generation, inhibition of endothelial adherence, and expression of the adhesion molecules<sup>[13-16]</sup>. Furthermore, activation of A<sub>2A</sub> receptors on human monocytes and mouse macrophages inhibits secretion of the pro-inflammatory cytokines, IL-12 and TNF- $\alpha$ <sup>[17,18]</sup>. We have reported that ATL-146e reduces gastric mucosal lesions induced by water-immersion stress<sup>[19]</sup>. On the basis of this evidence, we hypothesized that the activation of adenosine A<sub>2A</sub> receptors would reduce gastric mucosal injury induced by aspirin. In this study, we used ATL-146e, a new compound that has been shown to be more potent and selective than the older A<sub>2A</sub> agonist, CGS21680. In binding assays, ATL-146e was found to bind with more than 100 times higher affinity to recombinant human A<sub>2A</sub> receptors ( $K_i = 0.2$  nmol/L) than to the other three adenosine receptor subtypes, A<sub>1</sub>, A<sub>3</sub> and A<sub>2B</sub><sup>[20]</sup>. We have reported that a single intraperitoneal injection of ATL-146e into the rats could inhibit TNF- $\alpha$  and IL-1 $\beta$  production, neutrophil accumulation in gastric injury induced by aspirin without affecting mucosal prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) concentration.

## MATERIALS AND METHODS

### Animals

Male Sprague-Dawley rats weighing 250-300 g were fed on a standard laboratory diet and water *ad libitum*, and kept in cages in a temperature and humidity controlled room with a 12-h dark-light cycle before and during the experiment. Prior to the administration of aspirin, animals were deprived of food for 24 h but had free access to water. This experimental protocol was approved by the Akita University Animal Care Committee.

### Chemicals

4-{3-[6-Amino-9-(5-ethylcarbamoyl-3,4-dihydroxy-tetrahydro-furan-2-yl)-9H-purin-2-yl]-prop-2-ynyl}-cyclohexanecarboxylic acid methyl ester (ATL-146e) with its purity >99% was provided as a gift from Jayson Rieger, PhD Adenosine Therapeutics, Charlottesville, VA, USA<sup>[21]</sup>. ATL-146e was dissolved in a small volume of dimethylsulfoxide and then diluted >100-fold with physiological saline just before the injection.

### Effect of ATL-146e on aspirin-induced gastric mucosal injury

Aspirin-induced gastric injury was produced by intragastric administration of aspirin (200 mg/kg) and HCl (0.15 mol/L, 8 mL/kg). ATL-146e (2.5 or 5  $\mu$ g/kg,  $n=5$  each group) or vehicle was injected intraperitoneally 30 min prior to the administration of aspirin. The animals were killed by stunning and cervical dislocation 3 h after the administration of aspirin and the stomach was removed. Gastric mucosal lesions were measured by two independent observers who were blinded to the treatment. The ulcer index was calculated as the sum of the lengths of all lesions<sup>[22]</sup>.

### Effect of ATL-146e on myeloperoxidase in gastric mucosa

Gastric mucosal myeloperoxidase (MPO) concentration

was assayed to quantify the degree of neutrophil infiltration. Three hundred milligrams of scraped mucosa was homogenized for 30 s with a polytron homogenizer (PT 1200, Kinematica AG, Littau, Switzerland) in 1.0 mL of ice-cold 5g/L hexadecyltrimethylammonium bromide in 50 mmol/L phosphate buffer (pH 6.0). Hexadecyltrimethylammonium bromide was used to negate the pseudoperoxidase activity of hemoglobin and to solubilize membrane-bound MPO. The homogenate was sonicated (U50 IKA Werke GmbH and Co. KG, Staufen, Germany) for 10 s, freeze-thawed thrice and centrifuged at 18000  $g$  for 20 min. The supernatant was taken for the determination of the enzyme activity utilizing an ELISA kit (Bioxytech, Oxis International, Inc., Portland, OR, USA). The change in absorbance at 405 nm was measured with a spectrophotometer (Microplate reader model 3550, Bio-Rad, Hercules, CA, USA). The concentration of MPO was expressed as nanogram per milligram protein measured using Bradford's method<sup>[23]</sup>.

### Effect of ATL-146e on gastric of TNF- $\alpha$ and IL-1 $\beta$

One hundred milligrams of scraped mucosa was homogenized for 30 s with a polytron homogenizer (PT 1200, Kinematica AG, Littau, Switzerland) in 1.0 mL of ice-cold potassium phosphate buffer (pH 7.4). Aliquots of homogenate supernatants in PBS were obtained by centrifugation at 10000  $g$  for 10 min. Total protein was measured by Bradford's method. Concentration of TNF- $\alpha$  and IL-1 $\beta$  in the supernatant of mucosal homogenates was determined by ELISA (R&D Systems Inc., Minneapolis, MN, USA) according to the manufacturer's instructions. After color development, optimal density was measured with a microplate reader. The concentration of TNF- $\alpha$  and IL-1 $\beta$  was expressed as pictogram per milligram protein.

### Effect of ATL-146e on gastric secretion

Gastric juice was collected using the pylorus ligation method<sup>[24]</sup>. Briefly, rats were fasted for 24 h, placed in restraint cages, and injected intraperitoneally with 5  $\mu$ g/kg of ATL-146e. Thirty minutes after the injection, pylorus ligation was performed. The stomach of the rats were removed 3 h after pylorus ligation, and the gastric contents were collected. Following centrifugation, acid content in the supernatant determined by titration with 0.01 mol NaOH to pH 7.0 using a pH meter ( $\Phi$ 50 pH Meter; Beckman, Tokyo, Japan), was used to calculate gastric acid secretion in mmol/3 h.

### Effect of ATL-146e on mucosal PGE<sub>2</sub>

To evaluate the effect of ATL-146e on mucosal content of PGE<sub>2</sub>, rats were divided into four groups. In group A, rats were treated with vehicle. In group B, rats were treated with 5  $\mu$ g/kg of ATL-146e. Thirty minutes later, the animals were killed. In group C, vehicle was injected intraperitoneally 30 min prior to the administration of aspirin and were killed 3 h later. In group D, ATL-146e (5  $\mu$ g/kg) was injected intraperitoneally 30 min prior to the administration of aspirin and killed 3 h later. A part of fundic mucosa (about 100 mg) was excised for the

**Figure 1** Ulcer length of rats 3 h after the administration of aspirin with or without pretreatment with ATL-146e (2.5 or 5 µg/kg, ip) ( $n=5$  each group). <sup>b</sup> $P<0.01$  vs aspirin alone treated group.

**Figure 2** Effect of ATL-146e on myeloperoxidase concentration in gastric mucosa ( $n=5$  each group). <sup>b</sup> $P<0.001$  vs aspirin alone treated group.

determination of PGE<sub>2</sub> synthesis. The samples were weighed, finely minced with scissors for 15 s, and then suspended in 1.0 mL of 10 mmol/L sodium phosphate buffer (pH 7.4). The samples were then incubated in a shaking bath (37 °C) for 29 min followed by centrifugation at 9 000 *g* for 30 s. The supernatant was frozen and subsequent determination of PGE<sub>2</sub> was performed by radioimmunoassay using PGE<sub>2</sub> [125I] RIA kit (Dupont/NEN, Boston, MA, USA).

### Statistical analysis

All data were expressed as mean±SE. Statistical significance was determined by ANOVA using Statview-J 4.11 statistical program (Abacus Concepts, Berkeley, CA, USA).  $P<0.05$  was considered statistically significant.

## RESULTS

### Effect of ATL-146e on aspirin-induced gastric lesions

Administration of aspirin resulted in the appearance of linear and dotted erosions in the gastric mucosa of vehicle-treated rats. In contrast, pre-treatment with ATL-146e resulted in smaller erosions. The total length of gastric erosions (ulcer index) in control rats was  $29.8 \pm 7.7$  mm. The ulcer index in rats pretreated with ATL-146e was significantly suppressed to  $7.0 \pm 2.34$  mm (2.5 µg/kg,  $P<0.05$ ), or  $3.1 \pm 1.42$  mm (5.0 µg/kg,  $P<0.01$ ) (Figure 1).

**Figure 3** Effect of ATL-146e on increased TNF-α (A) and IL-1β (B) concentration in gastric mucosa induced by aspirin administration ( $n=5$  each group). <sup>b</sup> $P<0.01$ , vs aspirin alone treated group.

### Effect of ATL-146e on MPO in gastric mucosa

Tissue MPO concentration in the gastric mucosa increased 3 h after the initiation of administration of aspirin. The MPO concentration in normal control animals ( $2.8 \pm 0.2$  µg/g protein) increased to  $13.8 \pm 1.2$  µg/g protein in vehicle-treated rats. The increment of MPO concentration in the gastric mucosa by aspirin was suppressed by pretreatment with ATL-146e to  $2.9 \pm 0.35$  µg/g protein (2.5 µg/kg,  $P<0.001$ ) or  $2.7 \pm 0.14$  µg/g protein (5 µg/kg,  $P<0.001$ ) compared to that in vehicle-treated rats (Figure 2). The increase in MPO above control levels caused by aspirin was reduced to nearly normal levels after the administration of 2.5 and 5 µg/kg ATL-146e.

### Effect of ATL-146e on gastric of TNF-α and IL-1β

The gastric concentrations of TNF-α and IL-1β were significantly increased 3 h after the administration of aspirin. ATL-146e at the doses of 2.5 and 5.0 µg/kg significantly suppressed the increment of tissue TNF-α and IL-1β in the gastric mucosa by the administration of aspirin (Figure 3). The increase in TNF-α above the control levels caused by aspirin was reduced by the administration of 2.5 and 5 µg/kg ATL-146e by 90.3% and 99.7%, respectively. The increase in IL-1β above the control levels caused by aspirin was reduced by the administration of 2.5 and 5 µg/kg ATL-146e by 64.0% and 97.2%, respectively.

### Effect of ATL-146e on gastric secretion

ATL-146e caused a three-fold increase in gastric acid output from 114 to 326 mmol/3h ( $P<0.05$ , Figure 4).

**Figure 4** Effect of 5 µg/kg ATL-146e on gastric acid secretion. Rats were treated with or without 5.0 µg/kg of ATL-146e and killed 3 h later ( $n=5$  each group). <sup>a</sup> $P<0.05$  vs vehicle treated group.

### Effect of ATL-146e on mucosal of PGE2

The concentration of PGE2 was  $255.3 \pm 64.7$  ng/g in vehicle-treated rats (group A) and  $47.4 \pm 5.6$  ng/g in aspirin-treated animals (group C) (82.3% reduction,  $P<0.05$ ). ATL-146e (5 µg/kg) administration did not interfere with the reduction of gastric PGE2 concentration induced by aspirin ( $P>0.05$  vs aspirin alone) (Figure 5).

## DISCUSSION

The results of this study clearly showed that a single bolus injection of the adenosine A<sub>2A</sub> agonist, ATL-146e 30 min prior to the administration of aspirin, could effectively reduce the extent of gastric mucosal lesions. This protection is correlated with the inhibition of neutrophil infiltration into the gastric mucosal tissue and production of pro-inflammatory cytokines in gastric mucosal tissue. Previous studies have shown that gastric mucosal MPO concentration, a biochemical indicator of neutrophils, increases with the development of gastric mucosal lesions<sup>[25]</sup>. These findings suggest that most of the stimuli for aspirin-induced gastric injury that is susceptible to the inhibition by ATL-146e may occur early after the administration of aspirin.

Recent studies reported that gastric mucosal lesions can be reduced by the administration of antibodies against TNF- $\alpha$ <sup>[26]</sup>. Therefore, we may postulate that infiltration of neutrophils in rat gastric mucosa after the administration of aspirin could occur in response to the gastric production of pro-inflammatory cytokines, resulting in the development of gastric mucosal lesions secondary to neutrophil accumulation. Anti-inflammatory and tissue protective effects of ATL-146e in the models of ischemia-reperfusion injury have been reported<sup>[13,14,27-29]</sup>.

Adenosine has been identified as an endogenous anti-inflammatory agent because the activation of the A<sub>2A</sub> receptor is known to increase intracellular cAMP levels and to reduce diverse leukocyte functions<sup>[30]</sup>. Ross *et al.*<sup>[14]</sup> demonstrated that ATL-146e protects lung from reperfusion injury by reducing neutrophil sequestration<sup>[14]</sup>. Our recent study reported that ATL-146e inhibits water-immersion stress-induced gastric injury due to the inhibition of neutrophil accumulation and reduction of

**Figure 5** Gastric mucosal concentrations of prostaglandin E2 in control group (vehicle group) and in rats treated with 200 mg/kg aspirin alone or pretreated with 5 µg/kg ATL-146e ( $n=5$  each group). <sup>b</sup> $P<0.01$  vs vehicle treated group. NS: no significant difference between each group.

pro-inflammatory cytokine production<sup>[19]</sup>. These findings led us to examine the effect of ATL-146e on aspirin-induced gastric mucosal lesion. In the present study, we have demonstrated that MPO concentration, an index of tissue-associated neutrophil accumulation, increased in the gastric mucosa 3 h after the administration of aspirin. The increased MPO concentration was significantly inhibited by treatment with ATL-146e.

TNF- $\alpha$  is a pro-inflammatory cytokine and has recently been shown to be a crucial mediator of NSAIDs-induced gastric mucosal injury<sup>[31]</sup>. Also, TNF- $\alpha$  is a cytokine that strongly stimulates neutrophil adherence by inducing synthesis and expression of adhesion molecules on endothelial cells and neutrophils<sup>[32,33]</sup>. TNF- $\alpha$  augments neutrophil-derived superoxide generation and upregulates the expression of adhesion molecules on neutrophil and endothelium, and stimulates production of IL-1 $\beta$ , leading to neutrophil accumulation<sup>[32,33]</sup>. Furthermore, studies on experimental models have shown that intravenous administration of TNF- $\alpha$  produces extensive neutrophil infiltration within the microvasculature of the digestive tract. In addition, portal infusion of TNF- $\alpha$  causes gastric and small intestinal damage in rats<sup>[34]</sup>. The present study demonstrated that ATL-146e treatment could inhibit increase of TNF- $\alpha$  and IL-1 $\beta$  concentration in the gastric mucosa after the administration of aspirin. These findings strongly support the hypothesis that ATL-146e attenuates aspirin-induced neutrophil accumulation by inhibiting production of pro-inflammatory cytokines.

Okusa *et al.*<sup>[13]</sup> reported that ATL-146e inhibits ischemic reperfusion injury of kidney not only by reducing neutrophil accumulation, but also by reducing the expression of the adhesion molecules, P-selectin, and ICAM-1 on the reperfused vascular endothelium. Andrews *et al.*<sup>[6]</sup> also reported that the expression of ICAM-1 on endothelial cells is increased by NSAIDs. Therefore, the anti-ulcer effect of ATL-146e might be due to the inhibition of neutrophil adhesion.

In addition, it is well established that various anti-secretory agents, such as H<sub>2</sub>-receptor antagonists and proton pump inhibitors prevent gastric lesions<sup>[35]</sup>. However, we found that ATL-146e could significantly increase gastric acid secretion. These data indicate that

the protective effect of ATL-146e is not due to reduced gastric acid secretion. Also, it has been reported that PGE2 prevents gastric mucosal damage by aspirin in human beings and animals<sup>[36]</sup>. The protective effect of ATL-146e is not dependent on gastric mucosal prostaglandin synthesis, since pretreatment with ATL-146e, which reduces gastric damage, has no effect on the gastric mucosal prostaglandin concentration. Therefore, inhibition of mucosal lesions by ATL-146e cannot be attributed to gastric acid inhibition and prostaglandin synthesis.

In conclusion, the potent and selective adenosine A<sub>2A</sub> receptor agonist, ATL-146e, significantly inhibits acute gastric mucosal injury induced by aspirin in rats. This effect may be due in part to a reduction in neutrophil infiltration into the gastric mucosa and inhibition of pro-inflammatory cytokines production. Also, modulation of adenosine A<sub>2A</sub> receptor activity by specific agonists may be clinically useful for the therapy of NSAIDs-induced gastric mucosal damage.

## ACKNOWLEDGMENTS

### Abstract

**AIM:** To investigate the role of gastric oxidative stress and nitric oxide (NO) in the formation of gastric hemorrhagic erosion and their protection by drugs in rats with ischemic brain.

**METHODS:** Male Wistar rats were deprived of food for 24 h. Under chloral hydrate (300 mg/kg) anesthesia, bilateral carotid artery ligation was performed. The pylorus and carotid esophagus of the rats were also ligated. The stomachs were then irrigated for 3 h with either normal saline or simulated gastric juice containing 100 mmol/L HCl plus 17.4 mmol/L pepsin and 54 mmol/L NaCl. Rats were killed and stomachs were dissected. Gastric mucosa and gastric contents were harvested. The rat brain was dissected for the examination of ischemia by triphenyltetrazolium chloride staining method. Changes in gastric ulcerogenic parameters, such as decreased mucosal glutathione level as well as enhanced gastric acid back-diffusion, mucosal lipid peroxide generation, histamine concentration, luminal hemoglobin content and mucosal erosion in gastric samples, were measured.

**RESULTS:** Bilateral carotid artery ligation produced severe brain ischemia (BI) in rats. An exacerbation of various ulcerogenic parameters and mucosal hemorrhagic erosions were observed in these rats. The exacerbated ulcerogenic parameters were significantly ( $P < 0.05$ ) attenuated by antioxidants, such as exogenous glutathione and allopurinol. These gastric parameters were also improved by intraperitoneal aminoguanidine (100 mg/kg) but were aggravated by *N*<sup>ε</sup>-nitro-L-arginine-methyl ester (L-NAME: 25 mg/kg). Intraperitoneal L-arginine (0-500 mg/kg) dose-dependently attenuated BI-induced aggravation of ulcerogenic parameters and hemorrhagic erosions that were reversed by L-NAME.

**CONCLUSION:** BI could produce hemorrhagic erosions

through gastric oxidative stress and activation of arginine-nitric oxide pathway.

### INTRODUCTION

Brain ischemia (BI) resulting from cardiovascular stenosis, hypercholesterolemia or intracranial hemorrhage is frequently found in the clinic. The development of this disease may lead to cerebral hypoxia, brain tissue damage, and stroke. The peripheral manifestations of BI may include seizures<sup>[12]</sup>, neurological deficiency<sup>[15]</sup> and hemostatic disturbance<sup>[8]</sup>. However, whether gastric mucosal integrity is also impaired during the occurrence of BI is still unknown till now. In general, the disruption and/or degeneration of gastric mucosal cells may result in the decrease in gastric defensive factors, including mucosal reduced glutathione (GSH), and/or in increase of offensive factors, such as gastric acid back-diffusion and generation of oxyradicals. Our previous papers indicated that acid back-diffusion was a critical factor of acid-induced exacerbation of gastric hemorrhagic ulcer in diabetic or starved rats<sup>[19,20]</sup>. The back-diffused free acid may damage gastric mucosal cells by increasing oxyradicals and the release of histamine<sup>[15]</sup>. In fact, oxyradicals produced during oxidative stress play a pivotal role in the etiology of many diseases<sup>[26]</sup>, including cancer<sup>[1]</sup> and sepsis<sup>[14,15]</sup>. However, effects of gastric oxidative stress and oxyradical scavengers, such as exogenous reduced GSH or allopurinol on the formation of gastric hemorrhage and mucosal erosion in gastric juice-irrigated stomachs of rats with ischemic brain, remain obscure.

Ample documents demonstrate that nitric oxide (NO) plays an important role in physiological vasodilatation, cytotoxicity and vascular diseases. NO and prostacyclin released from the endothelium may act synergistically to inhibit platelet aggregation and adhesion<sup>[36]</sup> that are

associated with pathophysiological mechanisms of many diseases<sup>[10]</sup>. L-arginine, an NO donor, is an important amino acid nutrient in living organs. Whether this amino acid can protect gastric mucosa against gastric hemorrhage and stomach erosion through the production of NO in rats with ischemic brain is also unknown. In the present study, the non-selective NO synthase inhibitor, N<sup>G</sup>-nitro-L-arginine-methyl ester (L-NAME) or relatively selective inducible NO synthase (iNOS) inhibitor, aminoguanidine (AMG), were used to clarify the role of NO in the protection of gastric mucosa against damage in rats with ischemic brain. Taken together, the aim of the present study was to investigate whether or not oxidative stress-induced changes in acid back-diffusion, histamine release and mucosal oxyradical generation as well as in GSH level and NO liberation are important to modulate gastric hemorrhagic erosion in stomachs of rats with ischemic brain.

## MATERIALS AND METHODS

### Animals

Male Wistar rats, weighing 200-250 g, were obtained from and housed in the Laboratory Animal Center, National Cheng Kung University, Tainan, Taiwan. Rats were housed individually in a room with 12-h dark-light cycle and central air conditioning (25 °C temperature, 70% humidity). Rats were allowed free access to water and pellet diets (the Richmond standard, PMI Feeds, Inc., St. Louis, MO, USA). The animal care and experimental protocols were in accordance with the guidelines of the National Science Council of Taiwan (NSC 1994). Before the experiment, rats were deprived of food for 24 h. BI induced by bilateral carotid artery ligation (BCAL) for 3 h was carried out under potent anesthesia of intraperitoneal chloral hydrate (300 mg/kg). Adequate amount of chloral hydrate was injected to rats for the maintenance of anesthesia. To maintain spontaneous respiration, a polypropylene tube (3.0 mm in diameter and 50 mm in length) was intubated in the rat trachea. Control rats received sham BCAL. At the end of the experiment, rat brains were dissected and sliced for 2-mm thick at a distance of 4, 6, and 8 mm from the forebrain. Brain slices were soaked in triphenyltetrazolium chloride solution for 30 min at 37 °C as described by Isayama *et al*<sup>[18]</sup>

### Chemicals

The following reagent-grade chemicals were used. Acivicin, allopurinol, AMG, L-arginine, chloral hydrate, *n*-butanol, 2,2'-dinitro-5,5'-dithio-dibenzoic acid, pyridine, L-NAME, *o*-phthaldialdehyde (OPT), rat hemoglobin, reduced GSH, sodium lauryl sulfate, 1,1,3,3-tetramethoxypropane, trichloroacetic acid and 2-thiobarbiturate were purchased from Sigma, St. Louis, MO, USA. The purity of all drugs was over 98%. All chemical solutions were freshly prepared before use.

### Drug administration

Intraperitoneal L-arginine (0-500 mg/kg), AMG (100 mg/kg), L-NAME (25 mg/kg, i.p.), GSH (800 mg/kg) or allopurinol (100 mg/kg) were administered to rats 30 min before gastric juice irrigation.

### Gastric surgical procedures

Rat stomachs were surgically exposed for the ligation of pylorus and carotid esophagus. A small incision was made in the forestomach of rats. The stomach contents were gently expelled from the incision. A polypropylene tube (1.0 mm internal diameter×20 mm long) was inserted through the same incision and secured with a ligature. Subsequently, the stomach was rinsed meticulously with warm saline (37 °C). Care was taken to avoid gastric distension. The residues were gently removed.

### Measurement of gastric acid back-diffusion

Gastric acid back-diffusion (luminal H<sup>+</sup> loss) was quantified by the method as previously described<sup>[14]</sup>. Briefly, 7-mL of either normal saline or simulated gastric juice containing 100 mmol/L HCl, 17.4 mmol/L pepsin and 54 mmol/L NaCl<sup>[25]</sup> were instilled into the cleansed stomach with a syringe. The luminal contents were mixed with the same syringe by three repeated aspirations and injection, and 3 mL of the fluid was taken as an initial sample. The forestomach was tightly closed. The abdominal wound was sutured. After 3 h, rats were killed with an overdose of ether. The gastric sample (final sample) was collected and centrifuged for 20 min at 3 000 r/min

### Quantitation of gastric sample

The volumes of the initial and final samples were measured. Gastric acidity of the samples was assessed by titrating 1.0 mL of sample gastric contents with 0.1 mol/L NaOH to pH 7.0 on an autoburette titrator (Radiometer, Copenhagen, Denmark). The net flux of ions through gastric mucosa was calculated as follows: Net flux =  $F_v \times F_c - (7 - I_v) \times I_c$ , where  $F_v$  and  $I_v$  are the volumes (mL) of final sample and initial sample, respectively, while  $F_c$  and  $I_c$  are the ionic concentrations (mmol/L) in the final sample and initial sample, respectively. The negative value means the luminal electrolyte loss and the positive value indicates the luminal electrolyte gain.

### Morphological and histological studies of gastric mucosa

As soon as the final sample was collected, the stomach was filled with 10 mL/L formalin for 10 min. The mucosa was exposed by opening the stomach along the greater curvature. The length (mm) and the width (mm) of erosion on the gastric mucosa were measured with planimeter (1 mm×1 mm) under a dissecting microscope (×0.7-×3.0; American Optical Scientific Instrument 569, Buffalo, NY, USA). The erosion areas were determined as previously described<sup>[14]</sup>: Erosion area = length × width ×  $\pi/4$ . The total erosion area (mm<sup>2</sup>) of each stomach was recorded. Histological studies of the stomach were also conducted by methods as previously described<sup>[6]</sup>. Briefly, after gross examination, the specimens taken from the stomachs were blocked and immersed into 100 mL/L neutral formalin for 2 d. Blocks were then dehydrated in series of alcohol, cleared in xylene and embedded in paraffin. Sections (7  $\mu$ m thickness) were cut and stained with hematoxylin and eosin as routine histological procedures. Each section was examined under a microscope (Nikon HF, X-IIA, Tokyo, Japan), and the tissue damage was quantified. Sections were scored as 0-5, in which 0 indicated a normal

appearance, 1 indicated mild injury in the epithelial cells, 2 indicated mild injury in the upper part of mucosal cells, 3 indicated hemorrhage or edema in the mid or lower part of mucosal cells, 4 indicated degranulation or necrosis of the epithelial cells and 5 indicated serious cell disruption of lower part of the mucosa. The index score of each section was evaluated on a cumulated basis to give a maximal score of 15.

#### **Determination of hemoglobin**

The cleansed rat stomachs were irrigated for 3 h with either saline or simulated gastric juice. Initial and final gastric samples were collected by aforementioned methods. The blood attached on the gastric mucosa was carefully scraped and added into the final sample. Subsequently, both initial and final samples were adjusted to pH 1.5 with 0.1 mol/L HCl. The concentrations of hemoglobin in samples were measured spectrophotometrically<sup>[15]</sup>. The absorption maximum of Hb was measured at 376 nm. The appropriate irrigated solutions adjusted to pH 1.5 were used as blank. Absorbances of samples were measured against a standard curve ( $r > 0.90$ ) contrasted with freshly prepared rat Hb (0.05-1.00 g/L) treated in the same manner as gastric samples. The luminal Hb content was calculated as  $F_v \times F_{Hb} - (7 - I_v) \times I_{Hb}$ , where  $F_v$  and  $I_v$  are the volumes (mL) of the final sample and initial sample, respectively, while  $F_{Hb}$  and  $I_{Hb}$  are the luminal Hb concentrations (g/L) in the final sample and initial sample, respectively. The results obtained from gastric samples were expressed as milligram Hb per stomach.

#### **Assay of mucosal GSH**

The quantitation of gastric mucosal GSH was performed by methods as previously demonstrated<sup>[19]</sup>. After the final sample was collected, the rat stomach was dissected. The corpus mucosa was scraped using two glass slides on ice, weighed and homogenized immediately in 2 mL of phosphate buffer (0.1 mol/L  $\text{NaH}_2\text{PO}_4$  plus 0.25 mol/L sucrose, pH 7.4). Acivicin (250  $\mu\text{mol/L}$ ), an irreversible inhibitor of  $\gamma$ -glutamyltransferase, was added to the homogenate to inhibit the catabolism of GSH. The samples were then centrifuged at 4000 r/min for 15 min at 4 °C. To determine the recovery of reduced thiol, the supernatant was added with or without GSH (200  $\mu\text{mol}$  of reduced GSH contained in phosphate buffer solution, pH 7.0). Subsequently, 0.5 mL of 0.25 mol/L trichloroacetic acid was added to 1.0 mL of the supernatant of each sample and kept for 30 min at 4 °C. After centrifugation for 15 min at 3 000 r/min, the supernatant was used to determine GSH using 2,2'-dinitro-5,5'-dithio-dibenzoic acid. The optical density was measured at 412 nm on a Hitachi spectrophotometer (model U-3210, Tokyo, Japan). All samples were measured in duplicate. Recovery of added internal standard was greater than 90% in all experiments. Absorbances of the samples were measured against a standard curve constructed with freshly prepared GSH solutions (0.05-0.5 mmol/L), which were treated in the same manner as the tissue samples. The results obtained from tissue samples were expressed as micromole per gram wet tissue.

#### **Determination of mucosal lipid peroxides**

The concentrations of gastric mucosal lipid peroxides (LPO) were determined by estimating malondialdehyde (MDA) using thiobarbituric acid test<sup>[32]</sup>. Briefly, the stomachs of rats were promptly excised and rinsed with cold saline. To minimize the possibility of interference of Hb with free radicals, any blood adhering to the mucosa was carefully removed. The corpus mucosa was scraped, weighed and homogenized in 10 mL of 100 g/L KCl. The homogenate (0.5 mL) was added with a solution containing 0.2 mL of 80 g/L sodium laurylsulfate, 1.5 mL of 200 g/L acetic acid, 1.5 mL of 8 g/L 2-thiobarbiturate and 0.3 mL of distilled water. The mixture was incubated at 98 °C for 1 h. Upon cooling, 5 mL of n-butanol:pyridine (15:1) was added. The mixture was vortexed for 1 min and centrifuged for 10 min at 4000 r/min. The supernatant was measured at 532 nm. The standard curve was obtained by using 1,1,3,3-tetramethoxypropane. The recovery was over 90%. All samples were measured in duplicate. The results were expressed as nanomole MDA per gram wet tissue.

#### **Measurement of mucosal histamine**

Gastric mucosal histamine concentration was determined by the methods as described previously<sup>[33]</sup>. Briefly, gastric mucosa was scraped and homogenized with trichloroacetic acid (90 mmol/L) in a final concentration of 100 g tissue/L. The homogenate was further centrifuged at 54000 r/min for 10 min. The OPT-NaOH solution was prepared by dissolving 10 mg of OPT in 1.0 mL methanol (10 g/L) and 4 mL of NaOH (0.06 mol/L). This mixed solution was then gassed with nitrogen for 10 min. Then, 2.2 mL of a 20 g/L OPT-NaOH solution was added to 100  $\mu\text{L}$  of a 1/10-fold diluted sample of supernatant or histamine test solution. The mixture was placed at -20 °C for 10 h. Then 200  $\mu\text{L}$  of 0.35 mol/L  $\text{H}_2\text{SO}_4$  (final pH 1.6-2.4) was added to this frozen mixture. After thawing, the sample was vortexed for 1 min. The fluorescence of the sample was read at room temperature (25 °C) at 350 and 450 nm on a fluorescent spectrophotometer (Model 251-0030, Tokyo, Japan) using 1  $\text{cm}^2$  quartz cells. All samples were measured in duplicate. The fluorescence of the sample was calculated against a standard curve constructed with freshly prepared histamine solutions (0.78-25 mg/L) that were treated in the same manner as the tissue samples. The results obtained from tissue samples were expressed as microgram histamine per gram wet tissue.

#### **Statistical analysis**

The data obtained from the experiments were expressed as mean  $\pm$  SE. Differences in the data of experiments were analyzed statistically using ANOVA<sup>[28]</sup>. A simple regression analysis was used to determine the correlation between two different variances.  $P < 0.05$  was considered statistically significant.

## **RESULTS**

#### **Morphological changes of gastric mucosa of rats with ischemic brain**

Gastric mucosa was morphologically intact in sham

**Table 1** Influences of gastric juice on various gastric biomedical parameters in sham operation and BCAL rats

	Acid back-diffusion ( $\mu\text{Eq}/\text{stomach}$ )	Glutathione ( $\mu\text{mol}/\text{g}$ tissue)	Lipid peroxide (nmol MDA/g tissue)	Hemoglobin (mg/ stomach)	Erosion (area $\text{mm}^2$ )	Histological score
Sham operation						
Saline	$56.0 \pm 6.0$	$3.0 \pm 0.4$	$36.1 \pm 4.5$	$0.1 \pm 0.1$	$0.3 \pm 0.2$	$0.3 \pm 0.1$
Gastric juice	$-135.6 \pm 4.4$	$2.6 \pm 0.3$	$50.1 \pm 6.4$	$0.3 \pm 0.1$	$0.4 \pm 0.8$	$0.7 \pm 0.3$
BCAL						
Saline	$30.2 \pm 4.1^a$	$2.1 \pm 0.3^a$	$88.1 \pm 3.4^a$	$0.8 \pm 0.2^a$	$8.2 \pm 0.9^a$	$1.8 \pm 0.3^a$
Gastric juice	$-250.2 \pm 10.4^c$	$1.4 \pm 0.2^c$	$137.6 \pm 10.4^c$	$2.0 \pm 0.4^c$	$40.2 \pm 7.1^c$	$4.5 \pm 0.7^c$

Data are means $\pm$ SE (N=8). Significant differences are analyzed by using ANOVA. <sup>a</sup> $P < 0.05$  vs saline treated sham operation group; <sup>c</sup> $P < 0.05$  vs gastric juice treated sham operation group, BCAL= bilateral carotid artery ligation, MDA = malonedialdehyde.

**Figure 1** Histological study of gastric mucosa in sham operative rats and rats with ischemic brain. **A:** In sham operative rat stomachs irrigated with gastric juice, gastric mucosal cells appear intact; **B:** Disruption of the upper mucosal cells and lamina propria (indicated by arrows) in rats with ischemic brain, the injured cells are characterized by karyorrhexis and dense homogenous acidophilic cytoplasm (HE $\times$ 150)

operative rats. Nevertheless, gastric hemorrhagic erosions were observed in the stomachs of rats with ischemic brain (photo not shown). Histological studies showed that gastric mucosal cells appeared intact in sham operative rat stomachs irrigated with gastric juice (Figure 1A). However, necrotic cell-injury was found in both epithelial layers and lamina propria when gastric juice was present in the stomachs of rats with ischemic brain (Figure 1B). In sham operative rat stomachs irrigated with normal saline, no damage of gastric mucosal cells was observed. In gastric juice-irrigated stomachs of sham operative rats, gastric mucosal cells also appeared undamaged. In rats with ischemic brain, normal saline-irrigated stomachs produced a little gastric mucosal cell damage than did

those treatments in sham operative rats. Furthermore, a pronounced aggravation of mucosal cell damage was observed when gastric juice was used instead of normal saline in these rats. Apparently, intra-luminal gastric juice could enhance mucosal cell damage in rats with ischemic brain (Table 1).

We observed that back-diffused  $\text{H}^+$  concentrations, luminal Hb contents and mucosal erosion in normal saline-irrigated stomachs of sham operative rats were negligible (Table 1). Gastric mucosal GSH concentrations and LPO generations in these rats were also at normal levels. Similar results were observed in gastric juice-irrigated stomachs of sham operative rats. In rats with ischemic brain, normal saline-irrigated stomachs produced significant increases in these gastric parameters compared with those found in sham operative rat stomachs irrigated with normal saline ( $P < 0.05$ ). When gastric juice was used instead of normal saline in rats with ischemic brain, remarkable exacerbations of gastric hemorrhagic erosions accompanied with great enhancement in acid back-diffusion and mucosal LPO as well as a lowering of mucosal GSH levels were observed. High correlations between exacerbated gastric mucosal damage and decreased GSH levels as well as between mucosal erosions and increased LPO were observed in those gastric juice-irrigated stomachs of rats with ischemic brain (Figure 2). Apparently, BI could produce gastric oxidative stress in rats. Furthermore, gastric juice was able to aggravate various ulcerogenic parameters in rats with ischemic brain.

#### Effect of allopurinol or exogenous GSH

Intraperitoneal allopurinol (100 mg/kg) or reduced GSH (800 mg/kg) caused a significant decrease in acid back-diffusion and LPO generation as well as histamine concentration and hemorrhagic erosion in sham operative rats ( $P < 0.05$ , Table 2). Gastric mucosal GSH levels were elevated in exogenous GSH-treated rats. In rats with ischemic brain, these two chemicals produced a pronounced inhibition in acid back-diffusion, LPO generation, histamine release and hemorrhagic erosions while GSH levels were greatly elevated.

#### Effect of L-arginine

We observed that L-arginine (500 mg/kg) significantly increased gastric mucosal GSH levels but decreased acid back-diffusion, LPO and histamine concentrations in gastric juice-irrigated stomachs of sham operative rats

Table 2 Effects of allopurinol or exogenous glutathione on various gastric parameters in sham operation and BCAL rats

Data are means $\pm$ SE (N=6). <sup>a</sup> $P$ <0.05 vs corresponding vehicle. <sup>c</sup> $P$ <0.05 vs corresponding arginine treatment (500 mg/kg) of BCAL group. MDA= malonedialdehyde, BCAL= bilateral carotid artery ligation, L-NAME= NG-nitro-L-arginine-methyl ester.

( $P$ <0.05, Table 3). In stomachs of rats with ischemic brain, the ulcerogenic parameters, such as increased acid back-diffusion, LPO generation, hemorrhage and mucosal erosions, were dose-dependently attenuated by pretreatment with L-arginine, whereas the decreased mucosal GSH levels found in these rats with ischemic brain were effectively inhibited. These cytoprotective effects of L-arginine on gastric mucosa were reversed by concomitant administration of L-NAME (25 mg/kg).

### Effects of L-NAME or AMG

Intraperitoneal L-NAME caused significant aggravation of acid back-diffusion, LPO generation, histamine release and hemorrhagic erosions in rats with ischemic brain ( $P$ <0.05). Gastric mucosal GSH levels were attenuated (Figure 3). In AMG-treated rats with ischemic brain, a remarkable inhibition of acid back-diffusion, LPO generation and hemorrhagic erosion was achieved. Gastric mucosal GSH levels and histamine concentrations were significantly augmented ( $P$ <0.05).

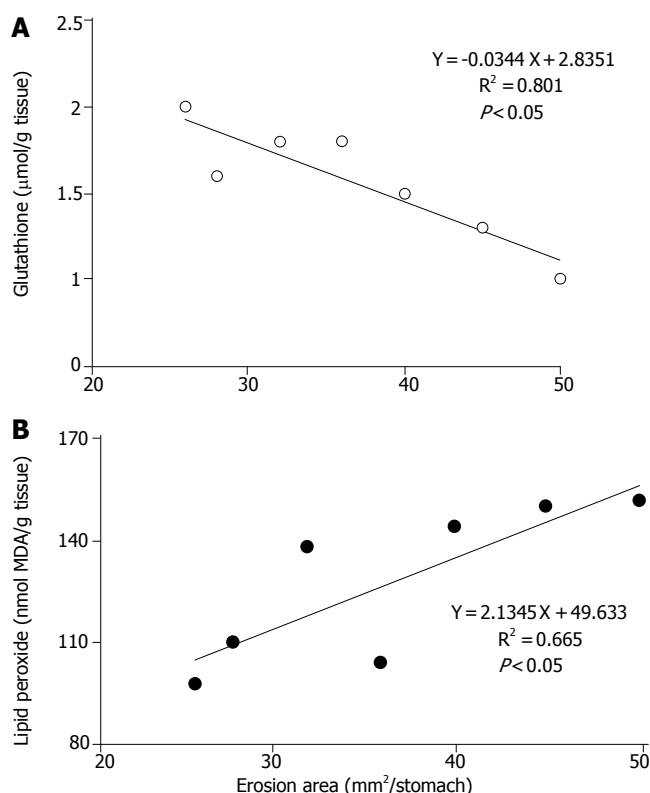

## DISCUSSION

The pathological mechanisms underlying the aggravation of gastric hemorrhagic erosion in gastric juice-irrigated stomachs of rats with ischemic brain are complex. The

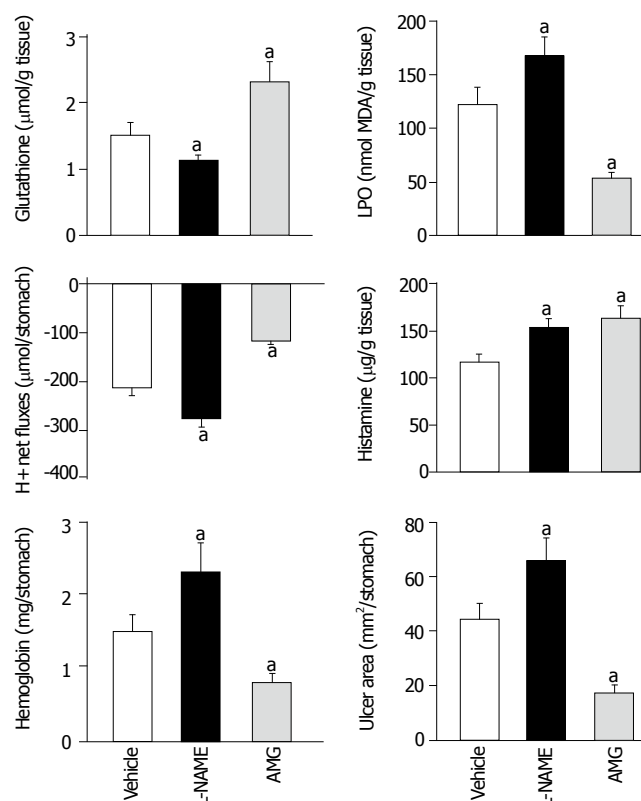

present study demonstrated that the decreased GSH levels as well as increased mucosal LPO generation, histamine concentration and acid back-diffusion were exacerbated in rats with ischemic brain. We also observed the occurrence of gastric hemorrhage and erosion. Apparently, gastric oxidative stress was produced in rats with ischemic brain. During oxidative stress, gastric mucosal barriers were degenerated and disrupted. When gastric juice was irrigated in the stomachs of rats with ischemic brain, the intraluminal free  $\text{H}^+$  back diffused through disrupted barriers to the gastric mucosa and thereby damaged the gastric cells. Consequently, aggravation of gastric hemorrhagic erosion and various ulcerogenic parameters occurred. The back-diffused gastric acid may also stimulate oxyradical release. The elimination of gastric mucosal GSH levels in gastric juice-irrigated stomachs of rats with ischemic brain might be resulted from an increase in its consumption for scavenging oxyradicals, and from a decrease in its cellular biosynthesis. It is proposed that depletion of neuronal GSH can result in increase of neuronal NO synthase activity and cell death<sup>[11]</sup>. In clinics, patients with peptic ulcer show a decreased gastric GSH<sup>[13]</sup>. The cytoprotection of GSH on gastric mucosal injury induced by ethanol in rats has also been documented<sup>[37]</sup>.

Our previous report demonstrated that increase in oxyradical generation as indicated by augmentation of

**Figure 2** Relationship between gastric mucosal ulceration and mucosal GSH levels as well as between gastric mucosal ulceration and lipid peroxide generation in gastric juice-irrigated stomachs of rats with ischemic brain. Rat stomachs were irrigated for 3 h with simulated gastric juice.

**Figure 3** Effects of L-NAME and AMG on various gastric parameters in gastric juice-irrigated stomachs of rats with ischemic brain. Data are expressed as mean  $\pm$  SE ( $n=8$ ). <sup>a</sup> $P < 0.05$  vs vehicle.

concentration of mucosal LPO, the oxyradical metabolite, was parallel to the elevation of histamine concentration in endotoxemic rats<sup>[14]</sup>. In the present *in vivo* study, increased mucosal histamine release may not only be derived from gastric mast cell *per se*, but also may be from those of other organs, including liver, lung, kidney or peritoneal tissues via circulation. Oxyradicals can directly attack mast cells, the predominant storage site for histamine, and cause cell degranulation. In turn, gastric mucosal histamine concentration is elevated. Since inflammation is greatly associated with oxyradical formation<sup>[23]</sup>, and increase in mucosal histamine concentrations may exacerbate tissue inflammation, it is likely that the aggravation of mucosal inflammation by increased histamine concentrations can produce more oxyradicals. The increased histamine found in rats with ischemic brain could be attenuated by allopurinol or exogenous GSH, implying that enzymology of oxyradical formation was involved in the metabolism of histamine. Taken together, increased histamine release and oxyradical generation in the gastric mucosa might result in hemorrhage and erosion in rats with ischemic brain. We have previously reported that activation of histamine H<sub>1</sub> and H<sub>2</sub> receptors is important in the formation of gastric hemorrhage and ulcer in septic rats<sup>[15]</sup>.

In the present study, L-arginine produced a dose-dependent increase in mucosal GSH levels and an attenuation of mucosal histamine and LPO concentrations in rats with ischemic brain. Gastric hemorrhage and stomach erosions were also remarkably ameliorated. Apart from its roles in protein biosynthesis and as an

intermediate in the urea cycle, L-arginine is a substrate for NO production and phosphocreatine synthesis as well as a precursor to proline, glutamate and putrescine via ornithine. NO is formed from L-arginine by NO synthases (NOS). Three isoforms of this enzyme have been identified; two are constitutively expressed and one is iNOS<sup>[7]</sup>. NO has dual effects on living cells. One is defensive and the other is injuring. Over-expression of NO may cause cell damage and dysfunction that plays a pivotal role in many diseases, including intestinal ischemia-reperfusion<sup>[20]</sup>, hypertension<sup>[30]</sup>, inflammation<sup>[6]</sup>, cell death<sup>[2]</sup>. On the other hand, physiological NO can protect cells against oxidative damage<sup>[38]</sup>. It also mediates many of the manifestations of septic shock, including hemodynamic instability<sup>[9]</sup>. L-arginine has been successfully used to increase vascular dilation and basal NO synthesis, and thereby reducing ischemia/reperfusion-induced injury<sup>[31]</sup>. Oral supplementation of L-arginine in hypercholesterolemic patients with endothelial dysfunction increased endothelial-dependent dilation of the bronchial artery during increased cardiac output<sup>[4]</sup>. L-arginine also promotes mucosal repair after intestinal ischemia/reperfusion<sup>[35]</sup> and relieves mucosal damage during endothelin-induced ulceration<sup>[21]</sup>. These protective effects of L-arginine are abrogated by L-NAME, a non-selective inhibitor of NO synthase. It has been reported that L-arginine can enhance mucosal growth and repair by supporting polyamine synthesis<sup>[27]</sup>. Also, it can accelerate healing of gastric erosions in rats and this effect could be attributed to the stimulation of gastric mucosal blood

flow through increased NO synthesis and stimulation of mucosal growth<sup>[3]</sup>. Altogether, these beneficial effects of L-arginine may account for the protective effects of L-arginine on gastric hemorrhagic erosions in rats with ischemic brain. In the present study, the attenuation of hemorrhage and stomach erosion in rats with ischemic brain by parental challenge of L-arginine may be associated with NO formation via arginine-NO-pathway.

The present study also showed that AMG significantly reduced gastric hemorrhagic ulcer in rats with ischemic brain. We also observed inhibition of lipid peroxide generation and augmented GSH level. However, it augmented mucosal histamine concentration. AMG is a relatively selective inhibitor of iNOS, but also is a specific inhibitor of histaminase, an enzyme that breaks down histamine. The elevated histamine by AMG might be a net result of its inhibition on histaminase and iNOS. In fact, specific inhibition of iNOS that is up-regulated in many tissues during diseases has been explored as a therapy for diseases. AMG has been shown to prevent the endotoxin-induced impairment of vascular reactivity when administered *in vivo*<sup>[19]</sup>. It has also been reported to reduce streptozotocin-induced hyperglycemia<sup>[34]</sup> and brain damage produced by occlusion of the middle cerebral artery in rats<sup>[29]</sup>. Taken together, iNOS may play an important role in the formation of hemorrhagic erosion in rats with ischemic brain.

In the present study, L-NAME failed to protect gastric mucosal damage in rats with ischemic brain. On the contrary, it reversed mucosal protective effect of L-arginine. The result might be due to the inhibition of constitute NOS by L-NAME. In fact, NO synthesis may provide protection to tissues after ischemia/reperfusion-induced injury of the tissue<sup>[22]</sup>. Document indicates that inhibition of NO synthesis by L-NAME increases ischemia/reperfusion-induced injury, which can be reversed by perfusion with NO or its donors that can decrease injury and neutrophil accumulation<sup>[27]</sup>.

In conclusion, gastric oxidative stress and excess iNOS production may play a pivotal role in modulation of hemorrhagic erosion through increased acid back-diffusion, histamine release and oxyradical generation as well as decreased GSH levels in rats with ischemic brain.

Lipid absorption data was available for seven patients on d 1 and four patients on d 3 post surgery. In patients, absorption on d 1 post-surgery was half that of healthy control subjects (AUC  $^{13}\text{CO}_2$   $1323 \pm 244$  vs  $2646 \pm 365$ ;  $P < 0.05$ , respectively), and was reduced to the one-fifth that of healthy controls by d 3 (AUC  $^{13}\text{CO}_2$   $470 \pm 832$  vs  $2646 \pm 365$ ;  $P < 0.05$ , respectively).

**CONCLUSION:** Both proximal and distal small intestinal motor activity are transiently disrupted in critically ill patients immediately after major surgery, with abnormal motility patterns extending as far as the ileum. These motor disturbances may contribute to impaired absorption of enteral nutrition, especially when intraluminal processing is necessary for efficient digestion.

### Abstract

**AIM:** To investigate distal small bowel motility and lipid absorption in patients following elective abdominal aortic aneurysm (AAA) repair surgery.

**METHODS:** Nine patients (aged 35-78 years; body mass index (BMI) range: 23-36 kg/m<sup>2</sup>) post-surgery for AAA repair, and seven healthy control subjects (20-50 years; BMI range: 21-29 kg/m<sup>2</sup>) were studied. Continuous distal small bowel manometry was performed for up to 72 h, during periods of fasting and enteral feeding (Nutrison®). Recordings were analyzed for the frequency, origin, length of migration, and direction of small intestinal burst activity. Lipid absorption was assessed on the first day and the third day post surgery in a subset of patients using the  $^{13}\text{C}$ -triolein-breath test, and compared with healthy controls. Subjects received a 20-min intraduodenal infusion of 50 mL liquid feed mixed with 200  $\mu\text{L}$   $^{13}\text{C}$ -triolein. End-expiratory breath samples were collected for 6 h and analyzed for  $^{13}\text{CO}_2$  concentration.

**RESULTS:** The frequency of burst activity in the proximal and distal small intestine was higher in patients than in healthy subjects, under both fasting and fed conditions ( $P < 0.005$ ). In patients there was a higher proportion of abnormally propagated bursts (71% abnormal), which began to normalize by d 3 (25% abnormal) post-surgery.

### INTRODUCTION

Enteral feeding reduces both morbidity and mortality in critically ill patients<sup>[1]</sup>. A number of factors, including high gastric aspirate volumes<sup>[1,2]</sup>, reduce the effectiveness of enteral feeding in critically ill patients by delaying its commencement or continuation. Slow gastric emptying is a major cause of difficulties with intragastric delivery of feeds, and occurs in 30-50% of mechanically ventilated patients<sup>[3]</sup>. Prokinetic stimulation of gastric motility or bypassing the stomach with jejunal feeding tubes overcomes some of these difficulties<sup>[4]</sup>. However, gastrointestinal symptoms such as diarrhea, abdominal distention, vomiting, and regurgitation remain common in enterally fed, critically ill patients<sup>[2]</sup>. The motor mechanisms responsible for these symptoms are poorly understood, largely because data on small intestinal motility in critically

ill patients are very limited.

Previous studies have shown that the patterning of interdigestive motor activity in the proximal small intestine is frequently disturbed in the critically ill. Bursts of abnormally propagated pressure waves that resemble phase III of the migrating motor complex are present, and persist during enteral feeding<sup>[5-7]</sup>. The potential impact of this motor disturbance on nutrient absorption in the critically ill has not been assessed. We have previously shown in healthy human beings that lipid absorption is reduced when phase III activity is stimulated during enteral feeding<sup>[8]</sup>. Previous manometric studies in critically ill patients have been limited to the proximal and mid small intestine<sup>[5-7]</sup>. It is unknown whether the motor changes observed proximally are present further down the gut. If such abnormalities prevail along the full length of the intestine, they are likely to have a greater negative impact on the success of enteral feeding.

In this study, we have recorded intraluminal pressure patterns along the distal small intestine in a group of patients immediately after abdominal aortic aneurysm (AAA) repair surgery, and for the following 3 d. In a subset of patients, these findings were correlated with the measurements of lipid absorption using the <sup>13</sup>C-triolein breath test<sup>[9]</sup>.

## MATERIALS AND METHODS

### Subjects

Nine patients (35-78 years: body mass index (BMI) range 23-36 kg/m<sup>2</sup>; APACHE II score<sup>[10]</sup> range 6-33) participated in the study following elective AAA repair surgery at Saint Andrew's Hospital, Adelaide during their post-surgical admission to the intensive care unit (ICU). All patients gave written informed consent before their surgery. Patients who had previously undergone upper gastrointestinal tract surgery or who were on medication known to affect gastrointestinal motility (other than the usual post-surgical drugs e.g. opiate analgesics) were excluded from the study.

Seven healthy control subjects (20-50 years: BMI range 21-29 kg/m<sup>2</sup>) were studied. Individuals with a history of cardiovascular, respiratory or gastrointestinal disease including severe anemia, eating disorders, diabetes mellitus or other serious past medical history were excluded. Subjects were not permitted to use medication (apart from paracetamol) in the two weeks before the study. Subjects gave written informed consent prior to entering the study.

The protocol was approved by the human research ethics committees of Saint Andrew's Hospital and the Repatriation General Hospital South Australia.

### Manometric recordings

In all the subjects, small intestinal pressure waves were measured using a 200-cm-long, purpose-built silicone rubber multilumen assembly (outer diameter 4 mm) (Dentsleeve, Adelaide, South Australia), incorporating 16 pressure recording channels (inner diameter 0.4 mm). The two most proximal side-holes were spaced 5 cm apart and the following 14 at 12.5-cm intervals. A single larger channel of the assembly (inner diameter 0.9 mm, located 142 cm from the distal tip) was used to deliver enteral

**Table 1** Time periods for manometry data analysis in patients following admission to the ICU

Description	t(post surgery)/h	Feeding condition	Ventilation condition	n
Early ventilation	1-5	No enteral feeding	Ventilation	9
Early post-operative	20-24	No enteral feeding	No ventilation	7
Early feeding	29-33	Enteral feeding	No ventilation	8
Late feeding	53-57	Enteral feeding	No ventilation	8
Late post-operative	68-72	No enteral feeding	No ventilation	9

feeds into the distal duodenum. Correct positioning of the assembly was facilitated by small weights and a balloon (7 mL) located at the tip of the assembly.

All manometric lumina were perfused with degassed distilled water at a constant rate of 0.05 mL/min. This resulted in a total daily infusion volume of 1150 mL/d of water, which was accounted for in the patients' daily fluid, electrolyte, and nutrient requirements. Pressures were measured via external transducers (Abbott Critical Care Systems, North Chicago, IL, USA) and recorded onto a Power Macintosh G3 computer using MPS 100 software (Biopac System Inc., Santa Barbara, CA, USA).

### Protocol

Patients were studied continuously over 3 d immediately following surgical repair of AAA. The manometric assembly was passed transnasally and its tip positioned in the stomach prior to surgery. The assembly incorporated a silicone rubber balloon at its distal tip that when inflated allowed the surgeon to palpate the tip of the catheter in the stomach. At the time of surgery, the assembly was passed through the pylorus, along the duodenum, jejunum, and ileum by manipulation of the inflated balloon by the surgeon, and by intrinsic motor activity. The final position of the assembly was determined by routine abdominal X-ray.

Measurement of intraluminal pressures commenced immediately after the arrival of patients in the ICU and continued for approximately 72 h. Patients were fasted for the first 24 h post surgery (d 1), during which low-pressure suction was used to aspirate gastric contents. On d 2, enteral feeding (Nutrison®, Nutricia, Zoetermeer, Holland; 40-80 mL/h) was commenced via the infusion channel incorporated into the manometric assembly. The effects of enteral feeding on small intestinal motility were assessed in two time windows: (1) immediately after commencing enteral feeding (d 2; early feeding period, *n*=8) and (2) over the following 24 h (d 3; late feeding period, *n*=8). These data were averaged to obtain final feeding data (Table 1).

Healthy subjects arrived at the Repatriation General Hospital Gastrointestinal Ward after an overnight fast from 2000 h (except for water). The manometric assembly was introduced into the stomach *via* an anesthetized nostril (Lignocaine 50 g/L, PaedPharm, Australia). The subject was then positioned in the right lateral position until the tip of the assembly had passed beyond the pylorus. Progression of the assembly along the small intestine was assisted by inflation of the catheter balloon. Correct positioning of the assembly occurred when only the two most proximal side-holes remained in the gastric antrum,

**Figure 1** Schematic representation of manometry recording periods in two patients: ventilated and fasting (gray), non-ventilated and fasting (white), non-ventilated and feeding (black); and analysis periods: early ventilation (EV) (1-5 h), early post-operative (EP) (20-24 h), early feeding (EF) (29-33 h), late feeding (LF) (53-57 h) and late post-operative (LP) (68-72 h).

which was verified by the analysis of pressure wave frequencies<sup>[13]</sup>. Side holes located within the first 25 cm of the small intestine were considered to be in the duodenum, side holes in the next 120 cm were defined to be in the jejunum, and the remaining side holes were considered to be in the ileum.

Manometric recordings commenced immediately following the correct placement of the assembly and continued for 72 h. Pressures were measured during fasting (0-24 h) and enteral feeding (Nutrison<sup>®</sup>, Nutrica, Zoetermeer, Holland; 80 mL/h) (24-72 h).

### Lipid absorption test

Lipid absorption was assessed using the <sup>13</sup>C-triolein breath test<sup>[9]</sup>. In patients, absorption was evaluated on d 1 (*n*=7) and d 3 (*n*=4) post surgery. Absorption data from both days were compared to healthy subjects (*n*=7). After a minimum of 4 h fasting, 50 mL of a mixed nutrient liquid (Nutrison<sup>®</sup>, Nutrica, Zoetermeer, Holland) was mixed with 200 µL of [1,1,1-<sup>13</sup>C<sub>3</sub>] triolein (99%, 200 mg) (Cambridge Isotope Laboratories, Andover, MA, USA) and infused intraduodenally over 20 min. End-expiratory breath samples were collected at baseline (5 min prior to label administration) and every 30 min thereafter for 6 h<sup>[9]</sup>. For patients, a purpose-built connector on the ventilator tube was used to collect the breath samples directly into 10 mL glass tubes (Exetainer<sup>®</sup>, Buckinghamshire, UK). Healthy subjects were asked to exhale through a straw into the collection tubes. Breath samples were analyzed for <sup>13</sup>CO<sub>2</sub> concentration using an isotope ratio mass spectrometer (Europa Scientific, ABCA model 20/20, Crewe, UK). The values obtained were converted to percent dose recovery per hour, and used to calculate the area under the CO<sub>2</sub> recovery curve (AUC <sup>13</sup>CO<sub>2</sub>).

### Analysis of manometry

Manometric data obtained from patients were analyzed during five 4-h periods that corresponded to different stages within the 72 h post surgery: early ventilation (0-5 h), early post-operative (20-24 h), early feeding (29-33 h), late feeding (53-57 h), and late post-operative (68-72 h) (Table 1 and Figure 1). For healthy subjects, recordings were analyzed during fasting (d 1; 0-24 h) and enteral feeding (d 3; 48-72 h).

### Small intestinal burst activity

Motility recordings were analyzed manually to determine the frequency, site of origin (proximal/not proximal), distance of propagation and direction of travel of small intestinal burst activity. A burst was defined as the presence of  $\geq 10$  pressure waves per minute for at least 2 min, which migrated sequentially over four or more side-holes<sup>[11]</sup>. A threshold pressure wave amplitude  $>1.33$  kPa measured from the end inspiratory pressure level to peak pressure was set to avoid confusion with respiratory pressure oscillations. Changes in pressure due to physical strains, which were recognized by having the same timing and amplitude in all channels, were excluded from the analysis. The spatial patterning of propagation of each burst sequence was classified as normal (antegrade, sequential) or abnormal (retrograde, bi-directional, simultaneous or multi-origin onset).

### Statistical analyses

Analyses were performed using Statview Version 4.5 (Abacus Concepts Inc., CA, USA) software. The following parameters were analyzed: burst frequency (number of bursts per hour), percentage of normal bursts, percentage of bursts to start proximally, and the percentage of bursts to reach the ileum. Data were assessed using analysis of variance (ANOVA) to compare the data from different fasting periods. The Mann-Whitney *U* test was used to compare fasting and fed data, as well as patient and healthy data. Data for triolein absorption was compared using the Mann-Whitney *U* test. Data were expressed as mean $\pm$ SE. A *P*<0.05 was considered statistically significant.

## RESULTS

The study protocol was well tolerated by all the subjects. Four patients reported minor local discomfort in the throat due to intubation of the manometry extrusion. The median APACHE II score<sup>[10]</sup> in patients was 11 (range 6-33). Major concomitant diseases were coronary artery disease (*n*=7), hypertension (*n*=2), chronic pulmonary disease (*n*=3) and diabetes mellitus (*n*=1). Manometric recordings were performed continuously for 72 h after surgery (range 66-121 h). Patients received mid-thoracic

**Table 2** Site of origin and distance of propagation of small intestinal burst activity during fasting and enteral feeding (mean±SE)

Time period	% Bursts to start in the antrum	% Bursts propagated to the ileum
<b>Fasting</b>		
Patient: Early ventilation (1-5 h)	70.0±5.6 <sup>b</sup>	62.7±9.3
Early post-operative (20-24 h)	70.1±6.2 <sup>b</sup>	35.2±8.6
Late post-operative (68-72 h)	75.5±8.2 <sup>b</sup>	33.8±8 <sup>c</sup>
Healthy	76.6±14.3	43.7±17.6
<b>Enteral feeding</b>		
Patient	65.3±7.6 <sup>a</sup>	53.9±12.4
Healthy	75.0±11	29.2±12.0

<sup>a</sup> $P < 0.05$  vs healthy fed, <sup>b</sup> $P < 0.01$  vs healthy fast, <sup>c</sup> $P < 0.05$  vs patient early ventilation.

epidural anesthesia with 1.25 g/L marcain and 15 mg/L fentanyl for a median time of 66 h (range 21-75 h) after the operation.

### Frequency of burst sequences

The frequency of small intestinal bursts was higher in patients under both fasting and feeding conditions, compared to healthy control subjects (Figure 2). During fasting, the frequency of bursts was six times greater in patients during the early ventilation period (0-5 h), compared to healthy controls ( $P < 0.0001$ , Figure 2). By day 3 (68-72 h), the burst frequency in patients had reduced, but was still three times greater than healthy subjects ( $P < 0.0001$ ). Feeding suppressed the frequency of bursts by 23% in patients, compared to 50% in healthy subjects (Figure 2).

### Site of origin

The percentage of bursts originating in the antrum was less in patients during fasting ( $P < 0.01$ ) and enteral feeding ( $P < 0.05$ ), compared to healthy control subjects (Table 2). Feeding had no effect on the number of bursts originating in the antrum in patients ( $70.0\% \pm 6.0\%$  vs  $65.0\% \pm 8.0\%$ , early post-operative vs feeding) or healthy subjects ( $76.6\% \pm 14.3\%$  vs  $75.0\% \pm 11\%$ , fasting vs feeding).

### Distance of propagation

A greater proportion of bursts reached the ileum in patients under both fasting and fed conditions, compared to healthy subjects (Table 2). In patients, the percentage of bursts reaching the ileum was higher during early ventilation (1-5 h) compared to the late post-operative (68-72 h) period ( $P < 0.05$ , Table 2).

### Patterning of burst migration

Bursts migrated normally in healthy subjects during both fasting and feeding conditions. In patients, the majority of bursts (71%) were abnormally propagated during the early ventilation period (1-5 h) (Figure 3); this proportion decreased over time so that by d 3 only 25% of bursts migrated abnormally ( $P < 0.01$ ; early ventilation vs late post-operative) (Figures 3 and 4).

### Lipid absorption

Absorption data were available for seven patients on d 1

**Figure 2** Bursts recorded during fasting (early ventilation (EV) (1-5 h), early post-operative (EP) (20-24 h) and late post-operative (LP) (68-72 h)) and enteral feeding, in patients (gray shading) and healthy controls (black shading) ( $n = 7$ ). Data are mean±SE.  $P < 0.0001$  vs healthy fasting,  $P < 0.0001$  vs healthy fed, early ventilation ( $n = 9$ ), early post-operative ( $n = 7$ ), enteral feeding ( $n = 8$ ), late post-operative ( $n = 9$ ).

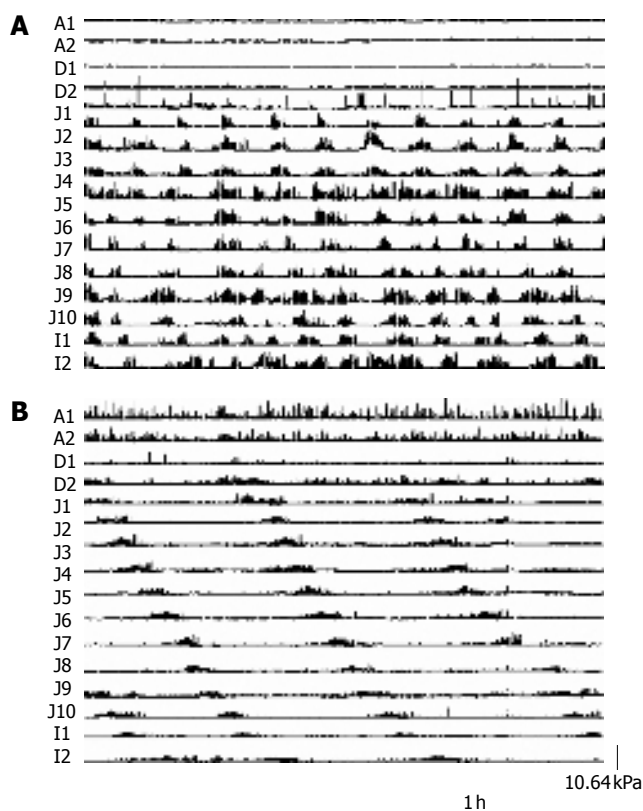

**Figure 3** Normal burst activity (% of total burst activity) recorded during fasting (early ventilation (EV) (1-5 h), early post-operative (EP) (20-24 h) and late post-operative (LP) (68-72 h)) and enteral feeding in patients (gray shading) and healthy control subjects (black shading) ( $n = 7$ ). Data are mean±SE.  $P < 0.01$  vs late post-operative, early ventilation ( $n = 9$ ), early post-operative ( $n = 7$ ), enteral feeding ( $n = 8$ ), late post-operative ( $n = 9$ ).

post surgery, and four patients on d 3 due to minor tube displacement. Recovery of  $^{13}\text{CO}_2$  was slower in patients on d 1 post surgery than healthy control subjects ( $\text{AUC } ^{13}\text{CO}_2$   $1323 \pm 244$  vs  $2646 \pm 365$ ;  $P < 0.05$ ; respectively). In the four patients for whom data were available,  $^{13}\text{CO}_2$  recovery on day 3 post-surgery was one-fifth of the healthy controls ( $470 \pm 832$  vs  $2646 \pm 365$ ;  $P < 0.05$ ; respectively). In patients, there was no difference in the recovery of  $^{13}\text{CO}_2$  between d 1 and 3 post surgery (Figure 5).

## DISCUSSION

This is the first study to examine distal small intestinal motor activity in critically ill post-operative patients. The results show a transient disruption in the patterning of small intestinal motility extending as far as the ileum, in the immediate post-operative period. Ileal motor activity was present early after surgery, but was characterized by frequent bursts of abnormally propagated pressure waves,

**Figure 4** Sample patient small intestinal manometric tracing during fasting. **A:** d 1 showing characteristic disordered burst activity with simultaneous onset and retrograde propagation; **B:** d 3 bursting activity is less frequent and predominantly antegrade.

as seen in the proximal small intestine. These bursts of activity were not abolished by duodenal nutrient infusion. Previous studies in critically ill patients have demonstrated a disruption in small intestinal motor activity, with frequent and irregular bursts of activity in the duodenum and proximal jejunum<sup>[5,6]</sup>. The distance that these motor events migrated along the intestine was previously unknown. The recording sites in earlier studies were limited by lack of access to the distal intestine. In addition, the number of pressure sensors was restricted by the volume of perfusate necessary to undertake the recordings. The novel silicone rubber catheter extrusion used in the present study allowed very low rates of manometric perfusion so that recordings from the distal small bowel could be made from 16 sites simultaneously, with a total delivery of perfusate per 24 h of approximately 1 L. This is within the allowable tolerance for fluids in critically ill patients and minimizes the risk of fluid overload. Our data thus extends previous findings by demonstrating that the motor disruption in critically ill patients is generalized at least as far as the proximal ileum. In health, phase III activity has a maximum incidence in the proximal jejunum, with only a minority of MMCs reaching the ileum<sup>[12]</sup>.

As previously reported, motor activity in critically ill patients is frequently abnormal<sup>[5,6]</sup>. In the present study, bursts of phase 3-like activity were seen extending to the ileum within the first 24 h post-surgery. The spatial organization of these bursts, however, were markedly abnormal, with both simultaneous onset and progression in a ret-

**Figure 5** Area under the curve for percentage dose recovery of <sup>13</sup>CO<sub>2</sub> until 6 h after the start of the intraduodenal infusion on d 1 (*n*=7) and d 3 (*n*=4) post surgery in AAA repair patients and in healthy subjects (*n*=8). *P*<0.05 vs healthy. Data are mean±SE.

rograde fashion, rather than a sequential migration down the gut that is typical of the fasting motor pattern. Over the subsequent 48 h, the organization of the bursts began to normalize and their frequency was reduced. However, the occurrence of bursts did not diminish during nutrient infusion, in contrast to the motor activity recorded from healthy subjects.

Enteral feeding remains as the preferred route of nutrition for critically ill patients<sup>[1]</sup>; however, effective delivery of feeds is often hampered by delayed gastric emptying<sup>[3,5]</sup>. Gastric dysmotility and stasis are likely to impair emptying both directly by the prevention of nutrient transit, and indirectly by the stimulation of feedback mechanisms that retard gastric motility. Some of these problems may be overcome by the use of post-pyloric feeding tubes; however, symptoms such as bloating, distension, and diarrhea remain common in patients receiving enteral nutrition. The effect of disordered small intestinal motility on the well-being of the patient is unclear.

There are limited data on the efficiency of the absorptive process in the critically ill. Singh *et al*<sup>[13]</sup> have previously demonstrated a severe depression in gut absorptive capacity for D-xylose in patients suffering from sepsis or trauma<sup>[13]</sup>, particularly during the first 3-4 d of admission. Although the number of patients is limited in the present study, the results provide some insights into lipid absorption during critical illness. Our data suggest that lipid absorption may be impaired for at least 3 d following major surgery. The mechanisms responsible for these findings are unclear. It is likely that mucosal ischemia contributes to the disruption of the absorption process. However, the demonstration that small intestinal dysmotility extends to the ileum may also have consequences for absorption in these patients. The failure of conversion from a fasting to a fed motor pattern may disrupt the mixing of substrate with digestive enzymes that is normally seen with postprandial motility. We have previously shown a reduction in lipid but not glucose absorption when erythromycin is used to stimulate small intestinal burst activity in healthy human beings<sup>[8]</sup>. The motor patterns recorded at 72 h in the present study are likely to increase the rate of nutrient transit through the gut. Accelerated transit has been associated

with reduced absorption in patients with ileostomies<sup>[14]</sup>. Changes in small intestinal motor function may therefore have important implications for the absorption of enteral nutrition in these patients. Further studies are necessary to examine the relative contributions of mucosal and motor dysfunction in the critically ill.

The mechanisms underlying the motor patterns recorded in the present study are unknown. Although all patients had manipulation of the bowel during the placement of the catheter, this is unlikely to explain the findings, as similar motor patterns have been reported in the proximal intestine of critically ill patients who have not undergone surgery<sup>[5,6]</sup>. It is also possible that drugs administered during routine clinical care may contribute to the observed motor dysfunctions. Opiates such as morphine are well recognized to produce burst activity. However, the majority of patients in our study received analgesia via an epidural catheter and required minimal or no systemic opiates during their ICU admission. Patients who required additional sedation for tolerance of mechanical ventilation usually received propofol. The effects of epidural anesthesia on motility are unclear. Although more rapid small intestinal transit has been reported when patients received epidural anesthesia instead of systemic opiates<sup>[15]</sup>, spinal or epidural anesthesia had no effect on orocecal transit times in healthy volunteers<sup>[16]</sup>. It has been proposed that the fasting small intestine is under tonic inhibition by predominantly nitrergic mechanisms. It is thus possible that acute metabolic insults associated with critical illness disrupts these inhibitory pathways resulting in the release of motor activity, until control mechanisms recover.

In conclusion, we have shown that abnormal small intestinal motor activity in critically ill patients extends as far as the ileum. The disruption to the organization of fasting motor patterns has improved by d 3 post surgery, but the motor response to intestinal nutrients, and in particular, the conversion to postprandial motor activity remains impaired. The effects of these motor abnormalities on nutrient transit and absorption, together with their contribution to symptoms requires further study, as do the mechanisms underlying these dysfunctions.

is also increased. Whether this serves as a defense mechanism against further cirrhosis or is a consequence of cirrhosis, is yet unknown. The elevated expression of HO-1 and HO-2 suggest that CO may compensate in its role as a vasodilator albeit weakly. It is possible that CO and NO have parallel or coordinated functions within the liver and may work antagonistically in the pathophysiology of portal hypertension.

### Abstract

**AIM:** Portal hypertension is a common complication of liver cirrhosis. Intrahepatic pressure can be elevated in several ways. Abnormal architecture affecting the vasculature, an increase in vasoconstrictors and increased circulation from the splanchnic viscera into the portal system may all contribute. It follows that endogenous vasodilators may be able to alleviate the hypertension. We therefore aimed to investigate the levels of endogenous vasodilators, nitric oxide (NO) and carbon monoxide (CO) through the expression of nitric oxide synthase (NOS) and heme oxygenase (HO).

**METHOD:** Cirrhotic ( $n = 20$ ) and non-cirrhotic ( $n = 20$ ) livers were obtained from patients who had undergone surgery. The mRNA and protein expressions of the various isoforms of NOS and HO were examined using competitive PCR, Western Blot and immunohistochemistry.

**RESULTS:** There was no significant change in either inducible NOS (iNOS) or neuronal NOS (nNOS) expressions while endothelial NOS (eNOS) was up-regulated in cirrhotic livers. Concomitantly, caveolin-1, an established down-regulator of eNOS, was up-regulated. Inducible HO-1 and constitutive HO-2 were found to show increased expression in cirrhotic livers albeit in different localizations.

**CONCLUSION:** The differences of NOS expression might be due to their differing roles in maintaining liver homeostasis and/or involvement in the pathology of cirrhosis. Shear stress within the hypertensive liver may induce increased expression of eNOS. In turn, caveolin-1

### INTRODUCTION

Liver cirrhosis is invariably associated with the incidence of hemodynamic disturbances manifested as portal hypertension and concomitant splanchnic vasodilation. Portal hypertension can be seen as a function of Ohm's law<sup>[1]</sup>:  $\Delta Pa = Q \times R$ , where  $\Delta Pa$  is the intrahepatic pressure,  $Q$  is the blood flow from systemic circulation and  $R$  is the intrahepatic vascular resistance. Increasing either or both  $Q$  and  $R$  results in an elevation of portal pressure.

Increased hepatic vascular resistance is thought to be a consequence of architectural abnormalities comprising of vascularized connective tissue which interrupt the normal organization of liver parenchyma. This establishes vascular shunts between afferent (portal and hepatic artery) and efferent (hepatic vein) vessels<sup>[2]</sup> leading to shunting. This condition is aggravated by the accommodation of the portal system to whatever is provided by the vasodilated splanchnic viscera.

Endogenous vasoconstrictors, such as endothelin and angiotensin II, mobilized by the onset or progression of cirrhosis may contribute to the increased hepatic vascular tone by the activation of hepatic stellate cells to a more contractile state<sup>[1]</sup>. It follows that mitigation of the vascular dysfunction may be promoted by endogenous vasodilators, including nitric oxide (NO) and carbon monoxide (CO).

NO has an amazing repertoire of physiological functions for a molecule with a half-life <5 s, including

homeostasis and immunological defense mechanisms, within the liver. NO is synthesized from L-arginine by three known isoforms of nitric oxide synthase (NOS), namely neuronal NOS (nNOS), endothelial NOS (eNOS) and inducible NOS (iNOS)<sup>[1-4]</sup>. Under normal physiological conditions, only constitutively expressed eNOS is believed to be active in the liver and its low level of NO production suffices for regulating hepatic perfusion, preventing platelet adhesion, thrombosis and polymononuclear cell accumulation. In pathological conditions, such as sepsis, hepatitis and endotoxaemia, iNOS is activated and induced to produce sustained amounts of NO<sup>[3]</sup>.

Zakhary *et al*<sup>[5]</sup> has suggested that CO and NO share contiguous, if not overlapping, areas of influence on vascular tone. Analogous to NOS, haem oxygenase (HO) exists in 3 isoforms: inducible HO (HO-1) and the 2 constitutively expressed HO (HO-2 and HO-3). CO, arising from the metabolism of haem by HO, has been found to attenuate sinusoidal tone and is responsible for the perfusion maintenance in normal liver<sup>[5]</sup>.

Current understanding of the contributions to the onset and/or progression of cirrhosis by NOS is not clear. Accordingly, this study aims to investigate the levels of NO and CO indirectly through the expression and distribution of NOS and HO in cirrhotic and non-cirrhotic human livers.

## MATERIALS AND METHODS

### Patients

Liver specimens were collected from 20 patients, including 10 males and 10 females (mean age  $32.5 \pm 25.5$  years), who received orthotopic liver transplantation for end-stage liver diseases. Postoperative pathology reports confirmed the presence of cirrhosis. Samples with cirrhosis due to biliary obstruction or hepatic venous obstruction and not viral or alcoholic origin were studied. Twenty control liver tissues from 14 male and 6 female patients (mean age  $57.2 \pm 11.9$  years) were obtained from partial hepatectomy surgery for malignant or other liver diseases (hepatocellular carcinoma, adenocarcinoma, leiomyosarcoma, gall bladder cancer infiltrating the liver, colonic carcinoma, Klaskin tumor). These controls were obtained from the outermost region of the tumor-free periphery from the excised lobe. The samples in our control group were ascertained to be cirrhosis-free.

Each patient provided a written informed consent before recruitment into the study. The protocol conformed to the ethical guidelines of the 1987 Declaration of Helsinki and those of the NMEC (National Medical Ethics Committee) - MOH (Ministry of Health) Ethical Guidelines on Research involving Human Subjects (1997).

All liver tissue samples were obtained intra-operatively and were snap frozen in liquid nitrogen not more than 20 min after excision and stored at  $-80^\circ\text{C}$  until processed. Venous blood of patients was collected in EDTA-tubes and centrifuged at  $3000\text{ g}$  for 10 min at  $4^\circ\text{C}$ . Plasma samples were aliquoted and stored at  $-20^\circ\text{C}$  until use.

### NO metabolites: Nitrite and nitrate (NOx -)

Plasma was analyzed for total NO metabolites using Total

NO kit (R & D Systems, Germany). Briefly, plasma was deproteinized by ultra-filtration. Enzymatic conversion of nitrate to nitrite by nitrate reductase preceded a colorimetric detection of nitrite as an azo dye product of the Griess reaction. Absorbance was read at 570 nm.

### RT-PCR

Total RNA was extracted using TriZol Reagent (Invitrogen, Grand Island NY), according to the manufacturer's protocol. Reverse transcription (RT) was performed with oligo(dT) using Superscript II RNase H-reverse transcriptase (Invitrogen, Maryland). First strand cDNA synthesis was performed at  $42^\circ\text{C}$  for 1 h. RNA-cDNA hybrids were denatured at  $72^\circ\text{C}$  for 15 min. RT-products were stored at  $-20^\circ\text{C}$  until use. PCR was performed using a DNA amplification kit (Qiagen, Germany) with Hybaid PCR express thermal cycler (UK).

Primer sequences were as follows:  $\beta$ -actin, 5'-GTGGGGCGCCCCAGGCACCA-3' (sense) and 5'-CTCCTTAATGTCACGCACGATTC-3' (antisense); iNOS, 5'-GTGGTCCAACCTGCAGGTCT-3' (sense) and 5'-CATAGCGGATGAGCTGAGCATT-3' (antisense); eNOS, 5'-GACATTGAGAGCAAAGGGCTGC-3' (sense) and 5'-CGGCTTGTCACCTCCTGG-3' (antisense); nNOS, 5'-GCAACAGCGGCAATTTTG-3' (sense) and 5'-GGTTGTCATCCCTCATCCGGCTG-3' (antisense); HO-1, 5'-CAGGCAGAGAATGCTGAGTTC-3' (sense) and 5'-GCTTCACATAGCGCTGCA-3' (antisense); HO-2, 5'-GCAATGTCAGCGGAAGTGGAA-3' (sense) and 5'-AAGTCACCTGAGGTGGTAGTT-3' (antisense); caveolin-1, 5'-CATCCCGATGGCACTCATCTG-3' (sense) and 5'-CACGGCTGATGCACTGAATCT-3' (antisense).

Predicted sizes for PCR products were 560 bp for  $\beta$ -actin, 187 bp for iNOS, 510 bp for eNOS, 387 bp for nNOS, 270 bp for HO-1, 1135 bp for HO-2 and 116 bp for caveolin-1. Each 25  $\mu\text{L}$  of PCR reaction contained 0.4  $\mu\text{mol/L}$  of sense- and antisense primers, 2.5  $\mu\text{mol/L}$  of each dNTP, 0.5 units of Taq polymerase and 2.5  $\mu\text{L}$  of cDNA, except for iNOS in which 5  $\mu\text{L}$  was used. Annealing temperatures for  $\beta$ -actin, iNOS, eNOS, nNOS, HO-1, HO-2 and caveolin-1 were  $55^\circ\text{C}$  (25 cycles),  $62^\circ\text{C}$  (40 cycles),  $60^\circ\text{C}$  (30 cycles),  $60^\circ\text{C}$  (40 cycles),  $62^\circ\text{C}$  (30 cycles),  $65^\circ\text{C}$  (25 cycles) and  $62^\circ\text{C}$  (40 cycles), respectively.  $\beta$ -actin was used as a housekeeping gene.

### Competitive PCR

Relative levels of mRNA expression can be semi-quantified by co-amplifying the cDNA with a known concentration of an internal competitor DNA. The competitor DNA, Mimic, is a non-homologous DNA fragment derived from the v-erb b gene to which a pair of gene-specific primers template had been added. The Mimic was constructed according to manufacturer's protocol (Clontech Laboratories, USA). A constant amount of cDNA was first amplified with a series of 10-fold dilution of its Mimic. This titration provided a fine-tuned 2-fold dilution series of Mimic. The amount of Mimic that obtained an optical density of 1:1 was then chosen to co-amplify with all the samples. After PCR, the products were resolved on a 18 g/L agarose gel and visualized by ethidium bromide. The ratio of optical density of target

against Mimic was then determined via the KODAK 1D Image Analysis Software (United States).

### Western immunoblot

The expressions of NOS and HO isoforms in liver samples were measured by densitometry quantitation of immunoblots. Liver tissues were homogenized in a lysis buffer (0.5 g/L SDS in 0.1 mol/L Tris-HCl, pH 7.4) containing Complete Mini-tab EDTA proteinase inhibitor (Roche Biochemicals) and centrifuged at 13 000 *g* for 15 min at 4 °C. Then 100 µg of total protein was resolved on 80 g/L SDS-PAGE and transferred onto a PVDF-membrane using Mini Trans-Blot cell (BioRad Laboratories, California). Membranes were then blocked in 5% skim milk in phosphate buffered saline for 1 h at room temperature. After an overnight incubation at 4 °C using diluted monoclonal antibodies from Transduction Lab, (200x anti-iNOS, 1000x anti-eNOS, 2000x anti-nNOS, 1000x anti-HO-1 and anti-HO-2 and 500x anti-caveolin-1), the membranes were incubated with 1000x dilution of horseradish peroxidase-conjugated secondary antibody (Amersham Pharmacia Biotech). The blots were then visualized using ECL Plus Kit (Amersham) according to the manufacturer's instructions. Relative densities of the bands were analyzed using Kodak 1D Imaging System.

### Immunohistochemistry (IHC)

Formalin-fixed and paraffin-embedded 4-µm thick sections of liver specimens were de-paraffinized in xylene (Merck, Germany) and rehydrated in decreasing concentration of ethanol. Antigen retrieval was carried out by heating the sections in 0.01 mol/L sodium citrate (pH 6.0). The sections were allowed to cool to room temperature before proceeding. Peroxidase Block (Amersham Pharmacia Biotech) was applied to inhibit endogenous peroxidase activity. Primary antibodies (same as those used in Western Immunoblot) were diluted (iNOS, eNOS, nNOS: 600x; HO-1, HO-2: 200x; caveolin-1: 400x) and incubated with the samples for 45 min at room temperature, followed by incubation with secondary antibody for 1 h at room temperature. Sections were then visualized with 3,3'-diaminobenzidine (DAB) and counter-stained with Harris' hematoxylin. The slides were dehydrated, cleared and mounted for viewing.

### Statistical analysis

Graphpad Prism 4.0 was used in all statistical analysis. Student's *t* test for unpaired samples was used to compare data between cirrhotic and non-cirrhotic groups. Differences were considered statistically significant at values of  $P < 0.05$ .

## RESULTS

Histopathology revealed micro- or macro-nodular cirrhotic morphology. Biliary cirrhosis secondary to biliary atresia or extrahepatic biliary obstruction resulting in cholestasis were the main causes of cirrhosis in our study group. The control group did not present cirrhotic morphology. All samples studied were found to be negative for hepatitis B antigen.

**Figure 1** Total NO metabolites in plasma were measured from 20 cirrhotic patients and 20 non-cirrhotic controls. Cirrhotic patients NO<sub>x</sub><sup>-</sup> levels were markedly higher at  $69.72 \pm 6.31 \mu\text{mol/L}$  serum; while non-cirrhotic patients NO<sub>x</sub><sup>-</sup> levels were lower at  $50.83 \pm 5.67 \mu\text{mol/L}$  serum.  $^{\alpha}P < 0.05$ .

### NO metabolites: Nitrite and nitrate (NO<sub>x</sub><sup>-</sup>)

Comparison of total NO<sub>x</sub><sup>-</sup> in systemic plasma is shown in Figure 1. The data showed that cirrhotic patients had significantly higher NO<sub>x</sub><sup>-</sup> levels ( $69.72 \pm 6.31 \mu\text{mol/L}$ ) as compared to the controls ( $50.83 \pm 5.67 \mu\text{mol/L}$ ) ( $P < 0.05$ ).

### Competitive RT-PCR

The mRNA levels of the various isoforms of NOS and HO were differentially expressed in cirrhotic and control groups (Figure 2). mRNA levels of nNOS and iNOS were not significantly different between the study and control groups (Figures 2A and 2B). Conversely, eNOS (Figure 2,  $P < 0.05$ ) and both isoforms of HO (Figure 2D, HO-1:  $P < 0.01$ ; Figure 2E, HO-2:  $P < 0.01$ ) were significantly elevated in the cirrhotic group. Caveolin-1 mRNA expression was also significantly elevated ( $P < 0.05$ ) in cirrhotic tissue (Figure 2F).

### Western immunoblot

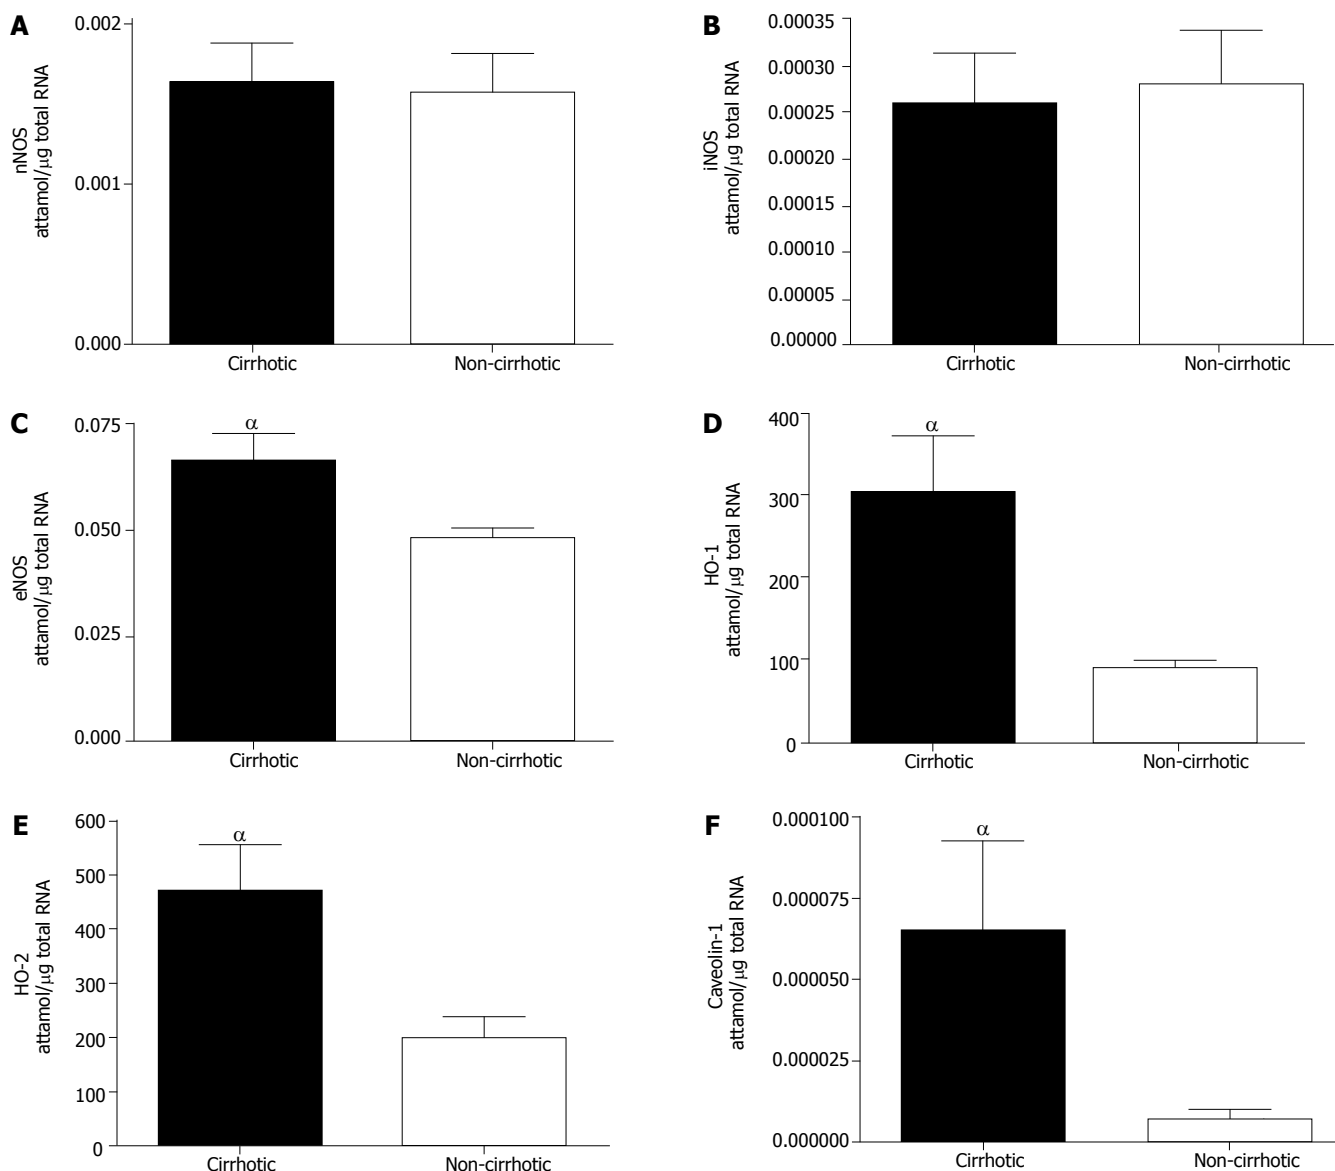

Protein levels, as semi-quantitated via densitometry of Western blot, agreed with our mRNA expression data. As shown in Figure 3A, nNOS was similar for both. Although iNOS seemed down-regulated in cirrhotic livers, it was not statistically significant (Figure 3B). We found significantly increased levels of eNOS (Figure 3C,  $P < 0.05$ ), HO-1 (Figure 3D,  $P < 0.05$ ) and HO-2 (Figure 3E,  $P < 0.001$ ) in cirrhotic groups as compared to the control group. Likewise, caveolin-1 protein level was markedly increased ( $P < 0.05$ ) in cirrhotic livers (Figure 3F).

### IHC

Figure 4 shows liver sections of the cirrhotic study group (left panel) and the control group (right panel). nNOS (Figures 4A and 4B) was seen to have little or no variance in intensity and localization as compared to liver sections of the cirrhotic (Figure 4A) and non-cirrhotic (Figure 4B) groups. Generally, a uniform cytoplasmic stain was found in hepatocytes, while the Kupffer and sinusoidal cells remained unstained.

Similarly, iNOS (Figures 4C and 4D) was found in cytoplasmic regions of the hepatocytes. Kupffer cells, resident macrophages of the liver, were surprisingly not

**Figure 2** Differential mRNA expression in cirrhotic and non-cirrhotic patient livers were measured via competitive PCR. **A, B:** nNOS and iNOS showed no significant change; **C, D, E, F:** eNOS, HO-1, HO-2 and Caveolin-1 respectively showed significant increase when compared to non-cirrhotic mRNA.  $^{\alpha}P < 0.05$ .

stained. Overall, the cirrhotic group (Figure 4C) was ascertained to be comparable to the non-cirrhotic (Figure 4D) samples.

Conversely, eNOS (Figures 4E and 4F) displayed a distinct difference in localization in cirrhotic tissues. In the non-cirrhotic group (Figure 4F), eNOS was localized typically in endothelial cells as well as the cytoplasm of hepatocytes. Interestingly, translocation of eNOS from the cytoplasm to nuclei was evident in cirrhotic liver sections (Figure 4E). Also, noteworthy was the apparent attenuation of eNOS expression in endothelial cells, and at the same time enhanced staining was noted in hepatocytes in cirrhotic sections. Kupffer cells exhibited strong immunoreactivity to HO-1 in cirrhotic liver sections (Figure 4G), while control groups (Figure 4H) showed less intense immunoreactivity. HO-1 staining in Kupffer cells was noted to have a higher intensity in cirrhotic liver specimens compared to non-cirrhotic specimens. In contrast, HO-2 (Figures 4I and 4J) was found in the cytoplasm

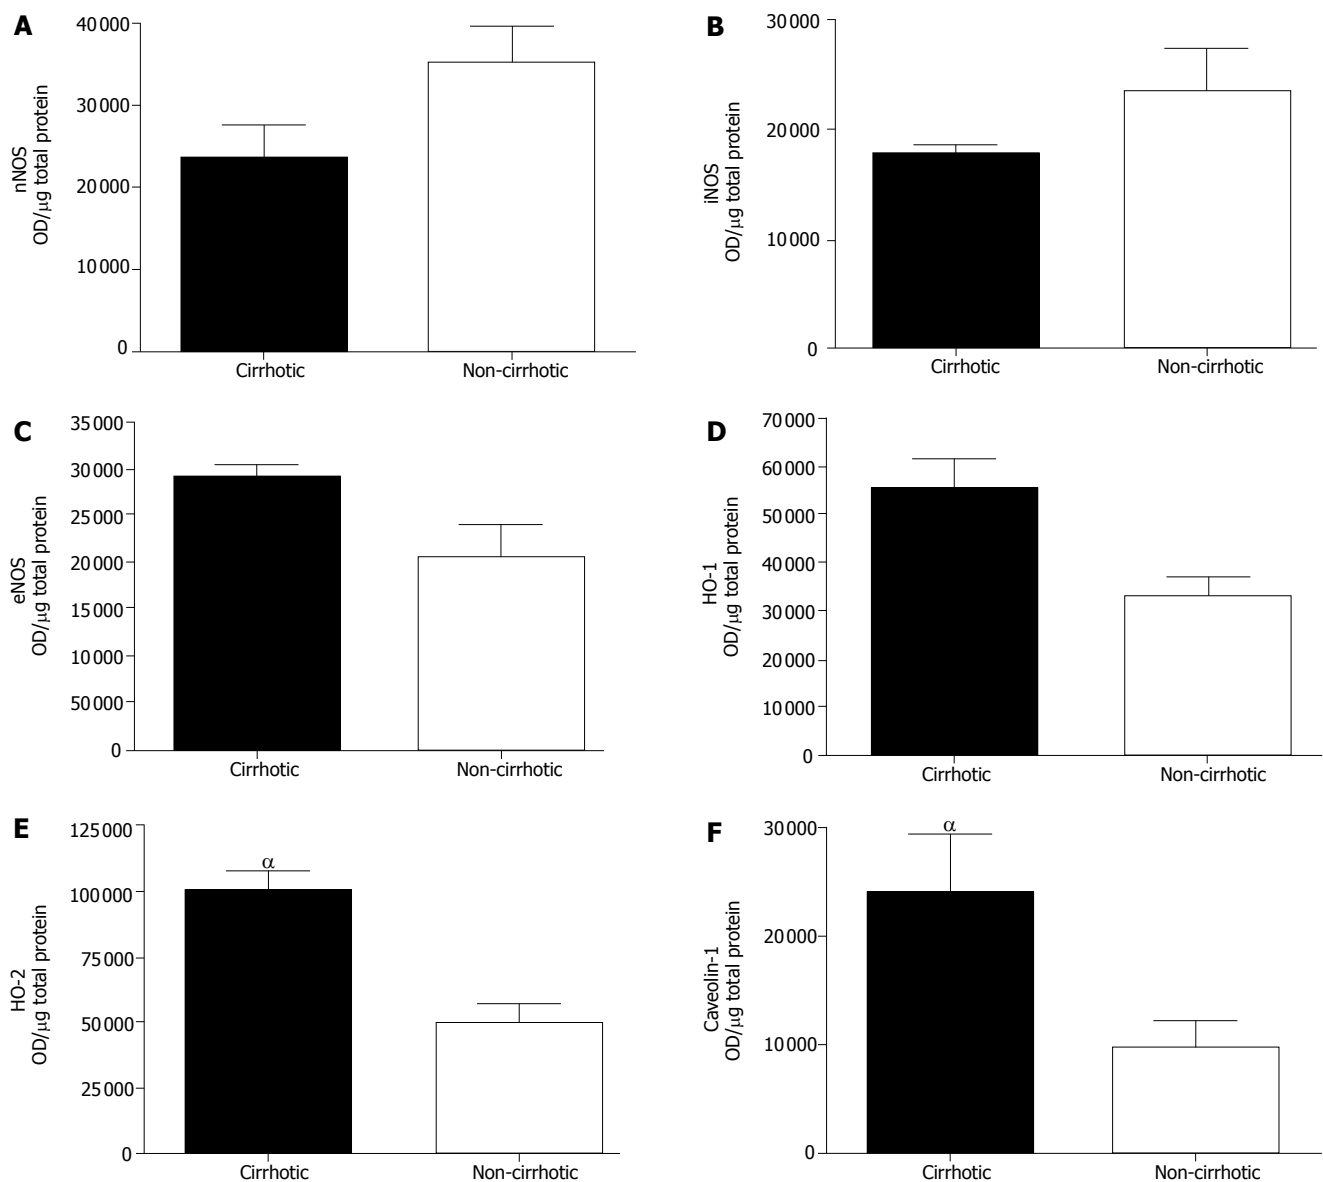

of hepatocytes. Akin to HO-1, HO-2 was expressed at a higher level in cirrhotic liver as compared to the controls.

Moreover, we observed that caveolin-1 was more vividly stained in the study group (Figure 4K). They shared the same localization as that in the non-cirrhotic group (Figure 4L), namely the endothelial cells.

## DISCUSSION

Several studies on diverse cirrhotic animal models have not reached agreement as to which isoform of NOS is the progressive/causative agent in portal hypertension<sup>[6-8]</sup>. Studies on rat models have found a marked increase in iNOS mRNA and protein expression<sup>[6-8]</sup>, but upon treatment with specific eNOS inhibitors, injury exacerbation can be observed in spite of increased levels of iNOS<sup>[9]</sup>. Ineffective selective inhibition of iNOS in ameliorating portal pressure underlined the importance of eNOS in intrahepatic haemodynamics<sup>[6-9]</sup>.

**Figure 3** Protein expression in cirrhotic and non-cirrhotic patient livers were semi-quantitated via Western Blot. Results were tabulated and presented. Both nNOS (A) and iNOS (B) were unchanged. eNOS (C), HO-1(D), HO-2(E) and Caveolin-1(F) protein expression were significantly increased in cirrhotic tissue. OD represents optical density.  $^{\alpha}P < 0.05$ .

Similar to our results, McNaughton *et al*<sup>[10]</sup> found no change in iNOS expression. Mohammed *et al*<sup>[11]</sup> found that both eNOS and iNOS levels were elevated in cirrhosis, and systemic plasma  $\text{NO}_x^-$  increase in cirrhosis was mainly attributed to iNOS induction. Our data showed a similar increase in venous plasma  $\text{NO}_x^-$ . We hesitate to attribute this to increased NOS in the liver, although it remains a plausible source of NO.

In our patient group, eNOS and caveolin-1 were found to have greater expression, while no substantial changes in iNOS or nNOS were found. This induction of eNOS can be attributed to the shear stresses resulting from hypertension<sup>[1,3]</sup>. Previously, we demonstrated that eNOS mRNA and protein levels in bile duct-ligated (BDL) rats were increased, yet activity declined by more than half<sup>[12]</sup>. In support of this, Sarela *et al*<sup>[13]</sup> showed that constitutive NOS activity was substantially lower in cirrhotic liver. In addition to the  $\text{Ca}^{2+}$ /calmodulin-dependent regulation,

caveolin-1 has been found to bind and inactivate NO production by eNOS<sup>[14,15]</sup>. Caveolin-1 is known to be stimulated by cholesterol receptors<sup>[14,15]</sup>. It is possible that the abnormal structure of the cirrhotic liver causes an induction of caveolin-1 or that the increasing fatty depositions common in cirrhosis contributes to this.

At rest, eNOS is bound to caveolin-1 and inactive. Upon stimulation, for example by shear stress, eNOS uncouples from caveolin-1 and translocates to the plasma membrane where it releases  $\text{NO}^{[14]}$ . Shear stress within the sinusoids of the cirrhotic liver presents unremitting stimuli for eNOS activation; which in turn is inhibited by increased caveolin-1 expression, reducing NO production intrahepatically. Our findings corroborate those of Yokomori *et al*<sup>[15]</sup> that eNOS and caveolin-1 expressions increase in cirrhotic patients.

Not exclusive to endothelial cells, eNOS has been found in a variety of cell types, including mesangial cells,

**Figure 4** Immunohistochemistry of cirrhotic livers sections (left panel) and non-cirrhotic sections(right panel). **A** and **B**, show no difference in nNOS localization; likewise with iNOS as shown in **C** and **D**. eNOS was found to have translocated mainly to the nuclei in cirrhotic sections as evidenced in **E**, but found in hepatocyte cytoplasm and endothelial cells in non-cirrhotic as in **F**. In **G** and **H**, HO-1 is clearly found in macrophages with marked increase in cirrhotic sections (**G**). HO-2 was more highly expressed in the cytoplasm of hepatocytes in cirrhotic (**I**) than non-cirrhotic (**J**) tissues. Cirrhotic liver in **K** shows higher immunoreactivity to caveolin-1 than that of non-cirrhotic liver in **L**. In all IHC, monoclonal antibodies were used.

neurons<sup>[8]</sup> and hepatocytes<sup>[10]</sup>. We obviously showed that hepatocellular cytoplasmic localization of eNOS was not unique to cirrhotic livers, albeit the endothelial cells stained more intensely in non-cirrhotic livers (Figures 4E and 4F). This was also pointed out by McNaughton *et al.*<sup>[10]</sup> where a similar translocation of eNOS to the nuclear periphery in cirrhotic sections was highlighted. The apparent attenuation of eNOS in cirrhotic endothelial cells may be due to the increased caveolin-1 expression in the same site. In normal liver, HO is accountable for the perfusion maintenance and sinusoidal tone<sup>[5]</sup>. Our study showed that HO-1 and HO-2 had increased expression in cirrhotic livers. HO-1 seems to be exclusively expressed in Kupffer cells while HO-2 can be visualized in the hepatocyte cytoplasm. This was also evident in BDL rat, where HO-1 showed increased mRNA and protein levels<sup>[16]</sup>. This corroborates results from Makino *et al.*<sup>[17]</sup> as they found that HO-1 activity was markedly elevated in cirrhotic livers and inferred that the cirrhotic liver up-regulated HO activity mainly through the inducible isoform, HO-1. Induction of HO has also been attributed to shear stress<sup>[17]</sup> and in the context of portal hypertension, up-regulation of HO-1 in Kupffer cells may serve as a local sensor of hemodynamics. In a study conducted by Sacerdoti *et al.*<sup>[18]</sup> using CCl<sub>4</sub>-induced cirrhosis in rats, HO-2 but not HO-1 was responsible for the splanchnic vascular hyporeactivity to vasoconstrictors. In our study, HO-2 was moderately increased in cirrhotic livers. However, the role of HO-2 in the pathophysiology of cirrhosis has not been well understood as yet. Our data suggest that it may have a

complementary function to that of HO-1 within the cirrhotic liver. Yet its obviously different locale from HO-1 implies that while it may have overlapping roles as HO-1, it may have distinctive functions that are as yet unknown or unassociated with cirrhosis.

NO has been found to stabilize HO-1 mRNA as well induce HO-1 in a cGMP-independent fashion<sup>[19]</sup>. The increase of HO may be in part due to NO from splanchnic circulation or from the shear stress faced within the liver. These serve to provide CO, a vasodilator, in the absence of adequate amounts of NO from eNOS or iNOS. Increased production of vasodilator CO in Kupffer cells possibly aids the alleviation of shear stress. CO, unlike NO, is not a radical and is known to be a thousand-fold less potent than NO with respect to vasodilation and activation of cGMP<sup>[16]</sup>. CO signaling may be particularly pertinent in conditions of oxidative stress<sup>[17-20]</sup>. Exhaled CO has been found to be significantly increased in cirrhotic patients in comparison to healthy individuals<sup>[20]</sup>. At low NO levels, such as in cirrhotic livers, CO can act a vasodilator through stimulation of soluble guanylate cyclase<sup>[20]</sup>. Taken together, HO and its product CO may act to counteract portal hypertension in cirrhosis.

In summary, we demonstrated major differences between the expression and localization of eNOS and iNOS. Possibly these differences allude to their differing roles in maintaining liver homeostasis or involvement in the pathology of cirrhosis. The lack of difference in iNOS expression between cirrhotic and non-cirrhotic tissue suggests iNOS involvement in the pathology of other liver

diseases as truly normal liver tissues were not available. The increased expression of caveolin-1 within the cirrhotic liver is also suggestive of some form of regulation imposed upon eNOS. Whether this serves as a defense mechanism against further cirrhosis or as a result of cirrhosis with escalating portal hypertension as a consequence, is yet unknown. HO-1 and HO-2 are differentially expressed. It is possible that CO and NO have parallel or coordinated functions within the liver and may work together in the pathophysiology of portal hypertension.

### Abstract

**AIM:** To elucidate the prognostic role and relationship of three molecular markers such as tumor suppressor gene p53, proliferating cell nuclear antigen (PCNA) and Ki-67 in gastric stromal tumor.

**METHODS:** A total of 108 surgically resected gastric smooth muscle tumor specimens were collected from January 1987 to December 1999. Immunohistochemical studies were performed on the paraffin sections of 99 of 108 CD117-positive tumors with antibodies of p53, PCNA, and Ki-67. Immunoreactivity of three molecular markers was recorded by labeling index (LI, %) and was analyzed for clinicopathologic and survival correlation.

**RESULTS:** Of the 99 cases, immunostaining revealed that 52 patients (52.5%) had p53, and 37 patients (37.3%) had Ki-67 immunoreactivity (defined as >10% of LI). All patients (100%) had PCNA immunoreactivity ranging from 12% to 93% of LI, divided into high or low by median. Statistics revealed that LI of three markers positively correlate to each other ( $P<0.01$ ) and to microscopic tumor mitotic counts ( $P<0.001$ ). By combination, patients with  $\geq 2$  markers (positive or high) in tumors had early tumor recurrence ( $P<0.001$ ) and unfavorable outcome ( $P<0.001$ ). Univariate analysis indicated that patients with tumor size >5 cm ( $P=0.003$ ), tumor mitosis >5/50 HPF ( $P<0.001$ ), p53 immunoreactivity ( $P=0.001$ ), Ki-67

immunoreactivity ( $P=0.026$ ), high PCNA LI ( $P=0.015$ ) and male gender ( $P=0.036$ ) were six predictors for early disease recurrence. Subsequent multivariate analysis revealed that mitotic counts, tumor size, and p53 immunoreactivity were three independent prognostic factors for both disease free and overall survival of patients. By combination of three independent prognostic factors for grouping, we found higher tumor recurrence rate ( $P<0.001$ ) and shorter survival ( $P<0.001$ ) existed in groups with increasing factors.

**CONCLUSION:** We first provide the prognostic value and linkage of three molecular markers in GISTs. The combination of three factors (p53, tumor size, and tumor mitosis) provides a more powerful prediction of prognosis than any single factor does.

### INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are interstitial tumors arising in the wall of the gastrointestinal tract. The term, GIST was first introduced in the 1980s to include a group of non-lymphomatous, non-epithelial tumors of the gut<sup>[1]</sup>. GISTs have strong morphological similarities in their pathological features, but have heterogeneous immunophenotype and biological behavior<sup>[2]</sup>. In the past, spindle cell tumors of the gastrointestinal (GI) tract were usually classified as smooth muscle tumors (leiomyomas, or leiomyosarcomas). Over the past two decades, advances in pathology and molecular genetics have provided further evidences regarding the interstitial cells of Cajal as the progenitor cells for GIST<sup>[3,4]</sup>. The use of c-kit receptor tyrosine kinase antibodies of KIT with a panel of other antibodies may distinguish true GIST from smooth muscle

tumors, neural tumors, and other spindle cell neoplasms<sup>[5,7]</sup>. Thereafter, the gastric and intestinal smooth muscle tumors in the earlier data largely would be classified as GISTs by immunohistochemical methods<sup>[5,7]</sup>.

Concerning prognosis, many studies have established clinicopathologic correlations, yet the criteria claimed to predict the prognosis remains vague. Although the proliferating activity in terms of the mitotic count is generally accepted as a prognostic indicator<sup>[1,8,10]</sup>, other gross and histologic parameters have been reported to influence the course of disease, such as tumor size<sup>[9-11]</sup>, cellular density<sup>[11,12]</sup>, predominant cell type<sup>[13,14]</sup>, neural or muscular component<sup>[13,15]</sup>, necrosis<sup>[10,12]</sup> and histological grades<sup>[10,14,16]</sup>. It has been suggested that in addition to the use of KIT expression in the diagnosis of GIST, c-kit mutation may also correlate with the malignant potential of GIST<sup>[17-19]</sup>. Molecular markers by immunohistochemical studies dealing with proliferating index like Ki-67<sup>[20-23]</sup>, proliferating cell nuclear antigen (PCNA)<sup>[8,24,25]</sup>, and tumor suppressor gene p53<sup>[20,22,26]</sup>, have been applied with encouraging results. However, the reports reflect a considerable controversy in considering the different conclusions of prognostic role in these molecular markers. Further, there were less linkage and elucidation of correlation between these genes in the previous literatures. Besides, there was a lack of documentation of KIT positive stromal tumor in the early reports that the conclusion might be misleading.

In our previous study of 81 gastric stromal tumors in the Taiwanese<sup>[9]</sup>, we have found that mitotic numbers and tumor sizes were two independent prognostic factors for disease free survival of patients. The conclusion was comparative to other studies. With the current investigation, we first elucidate the prognostic role of 99-CD117 (+) gastric stromal tumors by combination of three molecular markers such as tumor suppressor gene p53, PCNA and Ki-67. Their expression and correlation in GIST will be further verified in this original article.

## MATERIALS AND METHODS

### Subjects

A total of 108 surgically resected gastric smooth muscle tumor specimens were collected at Kaohsiung Chang-gung Memorial Hospital from January 1986 to December 1999. Patients with tumors which could not be completely

resected or patients with evident metastasis on diagnosis were excluded. All the tumors were obtained from curative resection and were diagnosed as leiomyoma or leiomyosarcoma by pathological studies. The diagnosis of malignant tumor was based on the index of mitosis as follows: benign < 5 and malignant  $\geq 5/50$  high-power fields (HPF, single field area of 0.20 mm<sup>2</sup>). The closing date of follow-up was December 31, 2004. Patients who died due to post-surgical complications were excluded from the study. Data on age, gender, and follow up duration were collected. In each case, all slides were reviewed, and the following histological parameters were regarded and recorded by two pathologists: 1) cellularity (low, medium or high); 2) predominant cell type (spindle, epithelioid or mixed); 3) nuclear pleomorphism (mild, moderate or severe). Cell type was categorized as being predominantly spindle (>75% of the tumor), epithelioid (>75% of the tumor), or mixed if both the spindle and epithelioid components occupied >25% of the tumor. Nuclear pleomorphism, defined as variation in nuclear size and shape, was judged to be mild, moderate or severe, with the highest level of nuclear pleomorphism recorded in each tumor. The tumor locations were classified into three groups as antrum, body and fundi-cardiac areas.

### Immunohistochemistry

Tissue specimens were maintained in formaldehyde-fixed, paraffin-embedded blocks. Sections stained with hematoxylin and eosin (HE) were also reviewed. The paraffin sections from the specimens were deparaffinized, blocked with 30 mL/L hydrogen peroxide for 10 min, and subjected to antigen retrieval with microwave in 0.01 mol/L citrate buffer for 15 min. The slides were then washed twice with PBS, incubated with primary antibodies of CD117, CD34, smooth muscle actin (SMA), S-100, desmin, Ki-67, p53 and PCNA for 30 min each, then examined with a peroxidase conjugate using polymer detection system (Zymed Cat. No. 87-89431) for 30 min. Specific details of the immunohistochemical condition used for each are shown in Table 1. The antibody staining was visualized with 3,3-diaminobenzidine tetrahydrochloride (DAB; Sigma, St. Louis, MO, USA) in 0.1 mol/L Tris pH 7.2, containing 0.1 mL/L H<sub>2</sub>O<sub>2</sub>. The section slides were counterstained with Gill's hematoxylin, dehydrated, and mounted. Control tissues included mastocytoma of skin for positive control, and gastric carcinoma tissues and CD117 spared GIST for negative controls.

The markers (CD117, CD34, SMA, desmin, and S100) in the tumor cells on each slide were expressed as negative or as positive stain by estimating the number of positive tumor cells in the staining intensity. Negative was defined as no staining, or less than 10% of area with positive staining. Positive staining was defined as full or numerous staining. The labeling index (LI) of Ki-67, p53 and PCNA was calculated by two pathologists for each case. The percentage of Ki-67, p53, and PCNA-labeled tumor cells (from counting 1 000 cells) was calculated thrice for each tumor and an average of the three counts used for subsequent analyses. There was disagreement between proportion scores given by the two assessors in less than 5% of the cases for each immunostain. Any cases with

CC: correlation coefficient. <sup>1</sup>Correlation is significant at the 0.05 level (two-tailed).

discrepant scores were reassessed to produce final scores for further analyses. The LI of Ki-67 and p53 more than 10% was defined as “positive” staining *vs* “negative” as less than 10%. Immunostaining of PCNA was recorded by percentage and was divided into two groups (by median) as high or low expression for further comparison.

### Statistical analysis

The ages and tumor sizes were expressed as mean±SD. Comparisons between groups of independent samples were assessed by the Student's *t* test. Associations between categorical variables were assessed using  $\chi^2$  test. The correlation between continuous variables was determined by Spearman's rank correlation test. Survival rates were calculated by the Kaplan-Meier method and the difference in survival was compared with the log rank test. The influence of various clinicopathological features on survival was assessed by the Cox's proportional hazard model. A *P* value less than 0.05 was considered statistically significant.

## RESULTS

Of these 108 patients, nine had tumors lacking immunoreactivity for c-kit. These c-kit negative tumors were more likely to show positivity for smooth muscle markers or for S100 than the 99 c-kit positive tumors. Only one of the patients with c-kit negative tumors had tumor recurrence and died. The other eight patients had no disease recurrence at the end of follow-up. Finally, these nine patients were excluded for the study population of molecular markers. A total 99 cases of GISTs were included comprising 40 males and 59 females, with age ranging from 31 to 80 (mean: 58±9.7) years and tumor size ranging from 1 to 26 (mean 6.8±4.2) cm. There were 61 benign and 38 malignant tumors based on the microscopic mitotic activities. Tumors were located in the fundi-cardiac region in 52 cases, body area in 37 cases and antral area in 10 cases.

The median follow-up period was 60 (range 3-160) mo. At the end of follow-up, 24 of 99 patients (24.2%) had disease recurrence, and 23 patients died of tumors. Subsequent survival analyses revealed that patients with smaller tumor size, less mitotic activity, and female gender had lower recurrence rates ( $P<0.05$ ) and longer survival

( $P<0.05$ ) than patients with larger tumor size, more mitotic activity, and male gender (Figures 1A-1C; Tables 3 and 4). The 1-, 3-, and 5-year disease free survival rates were 100%, 93%, 93% (tumor <5 cm); 93%, 86%, 80% (5 ≤ tumor <10 cm); and 55%, 30%, 30% (tumor ≥10 cm), respectively. In addition, The 1-, 3-, and 5-year disease free survival rates were 98%, 89%, 89% (mitosis <5/50 HPF); 84%, 84%, 84% (5 ≤ mitosis <10/50 HPF); and 68%, 42%, 33% (mitosis ≥10/50 HPF), respectively. Moreover, there was strong positive correlation between tumor sizes and tumor mitotic counts ( $P=0.001$ ) (Table 2).

Subsequently, the results of immunostaining for p53, Ki-67 and PCNA were analyzed. The immunoreactivity of these markers was calculated by labeling index (LI, %). The results revealed that 52 patients (52.5%) had positive p53, and 37 patients (37.3%) had positive Ki-67 immunoreactivity (defined as more than 10%, Figure 2). All patients had positive PCNA immunoreactivity, ranging from 12% to 93%, with a median of 70% and mean of 66% (Figure 2). Statistical analyses revealed that the LI of three markers strongly correlate to each other. The *P* value was less than 0.001 for p53 *vs* PCNA; less than 0.001 for p53 *vs* Ki-67; and 0.003 for Ki-67 *vs* PCNA, respectively (Table 2). Furthermore, we also found that LI of all three markers strongly correlate to microscopic tumor mitotic counts (all  $P<0.001$ ). But only LI of p53 ( $P<0.001$ ) and PCNA ( $P=0.04$ ) correlate to tumor sizes (Table 2). Besides that, p53 positivity also positively correlates to CD34 positivity ( $P=0.001$ ), and high PCNA positively correlates to nuclear pleomorphism ( $P=0.008$ ).

Univariate survival analysis revealed that patients with larger tumor size (≥5 cm,  $P=0.003$ ), more tumor mitosis (≥5/50 HPF,  $P<0.001$ ), positive p53 immunoreactivity ( $P=0.001$ ), positive Ki-67 immunoreactivity ( $P=0.026$ ), high PCNA LI (above median,  $P=0.015$ ) and male gender ( $P=0.036$ ) were six predictors for earlier disease recurrence (Figure 1, Table 3). In addition, these six factors also predict overall survival of patient, as tumor size ( $P=0.004$ ), tumor mitosis ( $P<0.001$ ), p53 immunoreactivity ( $P=0.001$ ), Ki-67 immunoreactivity ( $P=0.048$ ), PCNA LI ( $P=0.025$ ), and male gender ( $P=0.021$ ) (Table 4).

Further multivariate analysis by Cox's proportional hazard model revealed that only mitotic number, tumor size, and p53 immunoreactivity were independent prog-

**Figure 1** Kaplan-Meier analyses for patients survival (log rank test).

nostic factors for disease free and overall survival of GIST patients (Tables 3, 4). If we combine three molecular markers (p53 and Ki-67 positivity and high PCNA LI) for comparison, patients with more than two positive/high markers in their tumors had early tumor recurrence and unfavorable outcome (Figure 3A). Subsequently, we further combined three independent prognostic factors (p53 positivity; tumor size  $\geq 5$  cm; and tumor mitosis  $\geq 5/50$  HPF) and divided the patients into four subgroups as 1) none of the event present; 2) one of the three events

present; 3) two of three events present and 4) all three events present. Statistical analysis revealed earlier tumor recurrence ( $P < 0.001$ ) and shorter survival ( $P < 0.001$ ) were found in the groups with increasing events. The 1-, 3-, 5-year recurrence rates were 0%, 0%, 0% (Group 1); 3.2%, 9.7%, 9.7% (Group 2); 4.5%, 15%, 15% (Group 3); and 42%, 67%, 77% (Group 4), respectively (Figure 3B). Further, 1-, 3-, 5-year overall survival rates were 100%, 100%, 100% (Group 1); 100%, 96%, 93% (Group 2); 95%, 90%, 83% (Group 3); and 62%, 37%, 22% (Group 4),

respectively. The combination of three factors provides a more powerful prediction of prognosis than any single factor does.

## DISCUSSION

Several recent studies have suggested that tumor size and mitotic count, alone or in combination<sup>[27,28]</sup>, as well as Ki-67<sup>[20,23-28]</sup> or PCNA<sup>[8,24,25]</sup> proliferative index, and tumor suppressor gene p53<sup>[20,22,26]</sup> are useful in predicting the clinical behavior of GIST. However, the varying conclusions drawn from previous studies are matched by varying deficiencies of these studies. First, relatively small case numbers were studied. Second, prognostic studies should not pool GISTs from different locations into a single heterogeneous group, but evaluate prognostic factors relating to each homogeneous tumor site. Moreover, previously published series<sup>[11,28,29]</sup> indicated that distally located GISTs (small intestine, colon) seem to behave in more aggressive patterns than gastric tumors. Third, many studies were done before KIT detection was available. The distinction between GIST and pure neural or smooth muscle tumors is important as the latter may portend a better prognosis<sup>[27,30]</sup>. Fourth, the reports reflect a considerable controversy in considering the different conclusions of prognostic role in these molecular markers.

**Figure 3** Combination of molecular markers and prognostic factors **A**: p53 and Ki-67 positivity and high PCNA LI for survival analysis (log rank test) prognostic factors **B**: p53 positivity; tumor size  $\geq 5$  cm; and tumor mitosis  $\geq 5/50$  HPF.

In addition, there was also less linkage and elucidation of correlation between these genes in the previous literatures.

To overcome these deficiencies, we conducted a large

cases review of 99 KIT-positive GISTs which were limited at the gastric area. By combination of these molecular markers and other clinicopathological factors, these results might shed a light to elucidate the clinical behavior of GIST. In the present study, we provided prognostic evidence of three molecular markers Ki-67, PCNA and p53 in GISTs. The expression of single gene closely correlates to each other. Further, each single gene had diagnostic value of malignant potential (correlation to tumor mitosis) of GIST. These findings suggested that high proliferative states as well as p53 positivity occur in a portion of GISTs and may constitute poor prognosis. The expression of tumor suppressor gene p53 correlated the proliferative states (PCNA, Ki-67, tumor mitosis), tumor sizes, and CD 34 positivity. Among these factors, p53 positivity, tumor mitosis, and tumor sizes were three independent prognostic factors. By combination of three independent prognostic factors, it provided the more powerful prediction for disease recurrence and survival of GIST patients than any individual factor did.

PCNA is a nuclear protein, which is closely related to the cell cycle regulation being an auxiliary molecule for DNA polymerase- $\delta$ <sup>[31]</sup>. It is also an auxiliary protein present during G<sub>1</sub>-late phase and S phase. p53, a tumor suppressor gene, has an important function in DNA repair and in regulation of apoptosis. Mutations of p53 were described in malignant tumors and can be the cause of the alterations of this balance. The correlation between p53 and PCNA expression in other malignancies has been reported<sup>[32,33]</sup>. Progression of neoplasia is often associated with the loss of cell cycle control. PCNA overexpression might predict more aggressive tumor behavior. In general, p53 positivity correlated with increased PCNA labeling index in neoplasia and represented advanced disease states and poor outcome. However, their correlation in GIST was not reported. In the present study, we first found that there was strong correlation between p53 and PCNA index in GIST, which was comparative with previous reports of other malignancies. It might be explained that the cyclin-

dependent kinase inhibitor p21/WAF1 is regulated by p53-dependent and p53-independent pathways. In addition, p21/WAF1 binds with PCNA and inhibits the action of PCNA<sup>[34]</sup>. Overexpression of p53 on immunostaining (mostly p53 mutation) might disturb this pathway and trigger PCNA activity, thereby promoting cancer cells proliferation.

Of the three supplementary immunohistochemical markers tested, Ki-67 was most widely studied<sup>[20-23,28]</sup> and it was also demonstrated in other malignancies<sup>[35]</sup>. Ki-67 protein was considered to be more specific and reliable than PCNA as a marker of cell proliferation<sup>[28]</sup>. However, two other studies reached significant conclusion by using PCNA instead of Ki-67 in GISTs<sup>[24,36]</sup>. But they were all studied before KIT protein was available to detect GIST. In addition, whether Ki-67 or PCNA index is more practical and reliable than mitotic counting is still a matter of ongoing controversy. It has been suggested that there was less interobserver variation for Ki-67 index than for mitotic counting<sup>[37]</sup>. But there was no comprehensive report dealing with the comparisons with PCNA. In the present study, the mitotic counting and immunostaining reading were performed by two pathologists to avoid interobserver bias. Based on the large case number of KIT-positive GISTs, our finding suggested that mitotic counting was still superior to Ki-67 or PCNA to predict prognosis in gastric GIST, even though they are closely related to each other. Although both Ki-67 and PCNA predict disease recurrence and overall survival of patients after the operation, they are not independent prognostic factors. Therefore, we are unable to demonstrate the priority of clinical application between Ki-67 and PCNA.

In studies of gastrointestinal smooth muscle tumors/GISTs, p53 positivity was a negative prognostic marker<sup>[38,39]</sup>. However, p53 expression was prognostic in other studies<sup>[20,40]</sup>. In our series, we found that p53 labeling index strongly related to three mitotic indices (Ki-67, PCNA, and tumor mitotic count) and represented a independent prognostic role in GIST patients. There

were several possible reasons for the discrepancy between these studies. First, different definition of positivity of p53 expression and different intensity of immunostaining read. Second, different dilutions and antigen retrieval methods were used. Third, whether disease related deaths were used as endpoints for survival analysis. To overcome this, we adopted a multifactorial method to evaluate the patients' prognosis. By combination of three molecular markers or three independent factors, the prediction of prognosis is more powerful than any single factor did. It might provide a further insight to deal with the clinical behavior of GIST in future. In conclusion, we demonstrated the first evidence of linkage between two proliferating markers and one tumor suppressor gene p53 in GISTs and the relationship between these markers and pathological mitotic counts and tumor size. By combination of these factors, it provided a more exact and powerful prediction of the prognosis of GIST patients after surgery.

### Abstract

**AIM:** To evaluate the efficacy and toxicity of postoperative chemoradiation using FP chemotherapy and oral capecitabine during radiation for advanced gastric cancer following curative resection.

**METHODS:** Thirty-one patients who had underwent a potentially curative resection for Stage III and IV (M0) gastric cancer were enrolled. Therapy consists of one cycle of FP (continuous infusion of 5-FU 1000 mg/m<sup>2</sup> on d 1 to 5 and cisplatin 60 mg/m<sup>2</sup> on d 1) followed by 4500 cGy (180 cGy/d) with capecitabine (1650 mg/m<sup>2</sup> daily throughout radiotherapy). Four wk after completion of the radiotherapy, patients received three additional cycles of FP every three wk. The median follow-up duration was 22.2 mo.

**RESULTS:** The 3-year disease free and overall survival in this study were 82.7% and 83.4%, respectively. Four patients (12.9%) showed relapse during follow-up. Eight patients did not complete all planned adjuvant therapy. Grade 3/4 toxicities included neutropenia in 50.2%, anemia in 12.9%, thrombocytopenia in 3.2% and nausea/vomiting in 3.2%. Neither grade 3/4 hand foot syndrome nor treatment related febrile neutropenia or death were observed.

**CONCLUSION:** These preliminary results suggest that this postoperative adjuvant chemoradiation regimen of FP before and after capecitabine and concurrent radiotherapy appears well tolerated and offers a comparable

### INTRODUCTION

Numerous trials of postoperative chemotherapy or immunotherapy for advanced gastric cancer have shown no conclusive benefits<sup>[1,2]</sup>. The use of adjuvant radiation therapy in the treatment of gastric cancer has been investigated owing to the substantial incidence of local and regional failure after primary surgical resection. Following a potentially curative resection of the gastric cancer, a United States Intergroup study (INT-0116) demonstrated superior survival for patients who received a chemoradiotherapy<sup>[3]</sup>. These results established a new standard care for patients following curative resection of gastric cancer. However, the principal benefit associated with postoperative 5-FU/leucovorin (LV), and radiotherapy was reduction of the loco-regional failure; differences in the rate of distant failure were less pronounced.

We conducted a pilot study to examine the efficacy of chemotherapeutic regimens FP (Cisplatin and continuous infusion of 5-FU) that replaced 5-FU/LV and capecitabine for the radiosensitizer during external radiotherapy in patients with advanced gastric cancer.

### MATERIALS AND METHODS

#### *Patients and evaluation*

The study population was composed of 31 patients with

**Figure 1** Schema for postoperative chemoradiation study. <sup>1</sup>FP Chemotherapy: 5-FU 1000 mg/m<sup>2</sup> continuous infusion on d 1-5, cisplatin 60 mg/m<sup>2</sup> on d 1. <sup>2</sup>Chemoradiation: 4500 cGy at 180 cGy/d with capecitabine 1650 mg/m<sup>2</sup> daily during the entire radiotherapy course.

advanced gastric cancer who underwent a potentially curative gastrectomy with D2 lymph node dissection at Dong-A University Medical Center between March 2002 and September 2004. Eligibility criteria included histologically confirmed gastric adenocarcinoma, defined as resection performed with curative intent with negative pathologic margin, no gross or microscopic residual disease; disease stage IIIA to IV (M0) by the staging criteria of the American Joint Commission on Cancer (AJCC, 6<sup>th</sup> edition)<sup>[4]</sup>. All patients had undergone extensive (D2) lymph node dissection. Other requirements were as follows; hemoglobin level  $\geq 100$  g/L, normal white blood cell and platelet count, normal kidney/liver function, Eastern Cooperative Oncology Group (ECOG) performance status of  $\leq 1$ <sup>[5]</sup>, a caloric intake  $> 1500$  kcal per day by oral route and beginning of treatment within 4 wk of surgery. This study protocol was reviewed and approved by the Dong-A University Medical Center Institutional Review Board.

### Chemoradiotherapy

Three wk after surgery, all patients received one cycle of FP chemotherapy (5-FU 1000 mg/m<sup>2</sup> continuous infusion on day 1-5, cisplatin 60 mg/m<sup>2</sup> on d 1) followed by regional radiotherapy with capecitabine (1650 mg/m<sup>2</sup> daily during the entire radiotherapy course) in three wk. Four wk after completion of radiotherapy, patients received three additional cycles of FP regimen every three wk (Figure 1). According to phase I trial evaluating the concurrent combination of radiotherapy and capecitabine in rectal cancer<sup>[6]</sup>, oral capecitabine was given at a dose of 1650 mg/m<sup>2</sup> daily, which was divided into two doses given 12 h apart. A total dose of 4500 cGy in 25 fractions over five wk was delivered to the target volume that included the gastric bed, anastomosis, stump, and regional lymph nodes areas. We used the definition of the Japanese Research Society for Gastric Cancer for the delineation of the regional node areas<sup>[7]</sup>. The tumor bed was defined by preoperative computed tomographic (CT) imaging, and in some instances, surgical clips<sup>[8]</sup>. Radiation was delivered with 15 MV photons. Typical anterior-posterior/posterior-anterior (AP-PA)

portals extended from the hemidiaphragm to the L3 body, and laterally, from the external border of the postoperative gastric remnant to include the whole gastric area, duodenum, and porta hepatis. Doses were limited so that less than 3000 cGy of radiation of the hepatic volume. The equivalent of at least two thirds of one kidney was spared from the field of radiation.

### Outcome analysis

All patients were followed up every 3 mo for the first year and then every 4-6 mo for at least 3 years. The regular follow-up program entailed a physical examination, chest radiography, complete blood count, liver function tests, abdominopelvic computed tomography and gastroscopy as clinically indicated. Toxicities were recorded according to the National Cancer Institute Common Toxicity Criteria<sup>[9]</sup>. Disease relapse or progression was documented by biopsy or cytology reports or by clinical evidence of radiographic studies. Survival, as well as loco-regional and distant relapse, was analyzed with the Kaplan-Meier product limited

method. The site and date of first relapse, and the cause and date of death were recorded. The sites of relapse were classified as follows: the relapse was coded as loco-regional if tumor was detected within the radiation fields (including gastric bed, remnant stomach, and surgical anastomosis); as peritoneal if tumor was detected in the peritoneal cavity; and as distant if the metastases were diagnosed outside the peritoneal cavity or there was liver metastasis.

## RESULTS

### Patients characteristics

This study included 31 patients (21 males and 10 females) with ages ranging from 24 to 70 years (median: 51 years). Follow-up of patients ranged from 8 to 36 mo (median: 22.2 mo). Sixteen patients (51.5%) underwent subtotal gastrectomy and most tumors were located in antrum or corpus. In all patients, a D2 lymphadenectomy was performed. The patients were at high risk for relapse; all patients had pathologically involved nodes; 9(29%) N1 nodes, 17(54.8%) N2 nodes and 5(16.2%) N3 nodes, and 93.5% had stage T3 or T4 (Table 1).

### Treatment

Of the 31 patients assigned to this study, 23(74.2%) completed treatment as planned. Treatment was interrupted in 6 patients (19.3%) because of toxic effects. Two patients (6.4%) declined further treatment. All patients, including those who stopped treatment, were reviewed (Table 2).

### Toxicity

Toxicities of grade 3/4 are summarized in Table 3. The most common toxicity was neutropenia (50.2%). Anemia (12.9%), thrombocytopenia, nausea and vomiting, diarrhea and abdominal pain were also detected, and symptomatic

**Table 4** Sites of relapse (*n* = 8)<sup>1</sup>

Site	Number of patients with relapse (%)
Locoregional <sup>2</sup>	3 (9.7)

Distant <sup>4</sup>	3 (9.7)

<sup>1</sup>Patients relapsed at multiple sites, the total number of relapsed sites was greater than the number of relapsed patients (*n*=4).

<sup>2</sup> Tumor detected within the radiation fields.

<sup>3</sup> Tumor detected in the peritoneal cavity.

<sup>4</sup> Metastases were outside the peritoneal cavity (including liver).

**Figure 2** Overall survival and disease free survival for 31 patients with advanced gastric cancer treated with surgery followed by chemoradiotherapy.

treatments were performed as appropriate. There was no grade 3/4 hand foot syndrome, and there have been no treatment related febrile neutropenia. Most patients with grade 1/2 hand-foot syndrome were managed with vitamin B<sub>6</sub> administration and supportive care. Two patients (6.4%) underwent re-laparotomy for intestinal obstruction unrelated to tumor recurrence but of intestinal adhesion. No toxic death was observed.

### Survival and relapse

During a median follow-up period of 22.2 mo, 3(9.7%) patients died of recurrence. The 3-year disease free and overall survivals in this study were 82.7% and 83.4%, respectively (Figure 2). Four patients (12.9%) were relapsed during follow-up. Loco-regional recurrence occurred in 3(9.7%) of the relapsed patients. Peritoneal relapse was reported in 2(6.4%) patients and 3(9.7%) had distant metastases. Patients had relapses at multiple sites, and the total number of relapse was greater than the numbers of relapsed patients (Table 4).

## DISCUSSION

The major change in adjuvant therapy for gastric cancer comes from the results of the INT-0116 trial<sup>[3]</sup>, which used two cycles of 5-FU and leucovorin followed by concurrent chemoradiotherapy with 4500 cGy radiation given

using fields that encompassed the entire gastric bed. This study demonstrated a major advantage in overall survival, disease-free survival, and loco-regional control with the use of adjuvant chemoradiotherapy. These data suggest that the primary effect of postoperative chemoradiotherapy was a reduction in local and regional recurrence rates without apparent differences in distant relapse rates. However, questions have been raised about the adequacy of the chemotherapy and surgery of the study. The essential weakness of the INT-0116 study is that they performed D2 lymph node dissection in only 10% of patients. Hence, comparable local control might be achievable with optimal surgery that includes D2 lymph node dissection and the addition of more active chemotherapy.

The majority of trials using older systemic regimens for postoperative adjuvant chemotherapy for advanced gastric cancer failed to demonstrate a consistent reduction in the risk of recurrence<sup>[1,2,10]</sup>. A modest but statistically significant survival benefit appeared to be confined to the Asian studies only in the postoperative chemotherapy group<sup>[11-13]</sup>. The combination of cisplatin and 5-FU has also been extensively studied in gastric cancer. Phase II studies have indicated substantial activity with acceptable toxicity. Prospective randomized studies in patients with stage IV disease have not consistently demonstrated a significant improvement in survival for patients receiving cisplatin-containing regimens when compared to other combination or single agent<sup>[10,14]</sup>. However, response rates have been in general higher when cisplatin was included. Therefore, there has been substantial interest in the use of cisplatin-containing regimens in the adjuvant setting.

Capecitabine is oral prodrug of 5-FU and it would be a reasonable alternative when 5-FU or biomodulated 5-FU alone is being considered. Interest has also been shown in the use of oral agents instead of continuous-infusion 5-FU. Capecitabine has generated a great deal of interest as a simpler method of drug delivery. It is absorbed intact through the gut and then activated by a series of enzymatic alterations<sup>[15]</sup>. Phase II studies demonstrated that capecitabine had substantial activity in colorectal cancer, with an acceptable toxicity profile<sup>[16]</sup>. Phase III randomized clinical trials performed both in the United States and Europe have now shown that this oral agent is at least as effective as intravenous 5-FU/leucovorin, and the toxicity profile of capecitabine is more favorable than that of the Mayo Clinic schedule of 5-FU<sup>[17-19]</sup>.

Compared with the results from postoperative chemoradiotherapy with D2 lymph node dissection study for gastric cancer<sup>[20]</sup>, if adjusted for stage, this study showed superior 3-year survival in patients with advanced gastric cancer. This treatment modality allowed chemoradiotherapy with minor toxicities. Although it is inconclusive regarding long-term influence of chemoradiotherapy using FP or capecitabine regimens as adjuvant setting in patients with advanced gastric cancer following curative resection, results of loco-regional control rate and 3-year survivals in this study are promising. This study adds to the limited data on the promising results of chemoradiotherapy in patients with advanced gastric cancer. Randomized clinical trials need to be mounted to critically evaluated adjuvant therapy strategies in advanced gastric cancer.

### Abstract

**AIM:** To determine the feasibility of performing computed tomography (CT)-guided transpulmonary radiofrequency ablation (RFA) for hepatocellular carcinoma (HCC) located in the hepatic dome.

**METHODS:** A total of seven patients with HCC comprising seven nodules located in the hepatic dome were treated from April 2004 to December 2004. CT-guided transpulmonary RFA was performed using a cool-tip type electrode (Radionics Company) based on a standardized energy protocol. All tumors located in the hepatic dome were not detectable by the usual ultrasound (US) methods. The lesion diameters ranged from 15 to 27 mm.

**RESULTS:** RFA was technically feasible in all the patients. The puncture procedure was performed twice or less and the total average performance time was 40.6 min. Local tumor control was achieved in all the patients. The necrosis diameter ranged from 25 to 35 mm. The mean follow-up period was 9.6 (7-14 mo) mo. There was no local recurrence at the follow-up points. Pneumothorax requiring pleural drainage was the main complication, which was observed in two of the seven patients (28.6%). However, it improved with chest drainage tube, and the tube could be removed within 2-3 d. No other major complications were observed.

**CONCLUSION:** CT-guided puncture is useful for the treatment of tumors located in the hepatic dome which are hardly detectable by US, even though pneumothorax sometimes may occur as a complication. In the cases with adhesion in the pleura for which artificial pleural effusion methods are not appropriate, CT-guided RFA is thus considered to be an alternative treatment for HCC located in the hepatic dome.

### INTRODUCTION

Percutaneous radiofrequency ablation (RFA) is a standard therapy for hepatocellular carcinoma (HCC)<sup>[1-4]</sup>. Ultrasound (US)-guided puncture is the simplest and most popular method for performing RFA treatment of HCC<sup>[1-4]</sup>. However, depending on the location of tumors, it is often difficult to detect them by US<sup>[5-7]</sup>. Especially, the subphrenic area is one of the most difficult places because the lung obstructs the ultrasound<sup>[6,7]</sup>. As a result, some approaches using artificial pleural effusion method<sup>[6-8]</sup>, thoracoscopy<sup>[9,10]</sup> or open surgery have been performed for HCC located in the hepatic dome. However, each approach has its advantages and disadvantages. The artificial pleural effusion method is sometimes complicated and requires a high level of skill for the performer. Furthermore, patients with adhesion of the pleura are not indicated for this procedure. A thoracoscopic approach or open surgery needs general anesthesia. Recently, RFA has been performed for the treatment of various neoplasms including lung cancer<sup>[11,12]</sup>. Although pneumothorax is a major complication observed in 16% of all cases, lung RFA has shown itself to be a safe and feasible option for

the treatment of lung neoplasms<sup>[11]</sup>. Shibata *et al.*<sup>[13]</sup> have previously reported that CT-guided transpulmonary RFA is effective for eight patients with liver tumors in the hepatic dome. We have herein determined the utility of CT-guided transpulmonary RFA for the treatment of HCC located in the subphrenic area. The aim of this study was to assess the feasibility and efficacy of CT-guided transpulmonary RFA for HCC.

## MATERIALS AND METHODS

### Patients

A total of seven patients (five males, two females, mean age  $67.9 \pm 5.9$  years) with HCC comprising seven nodules not indicative of undergoing usual US-guided RFA were included in this study and treated from April 2004 to December 2004. In four of these patients, transcatheter arterial embolization (TAE) for HCC was performed previously. In two patients, US-guided RFA was initially attempted but proved to be impossible to perform. The patients' characteristics are given in Table 1. RFA was performed after an interdisciplinary consensus conference, with the participation of hepatologists, radiologists, and surgeons. After detailed patient information was given, written consent was obtained. The inclusion criteria for RFA were a rejection of surgical therapy by the surgeon or the patient. The exclusion criteria were tumor size of 3 cm or more than three liver lesions, a prothrombin time  $< 50\%$ , and thrombocytes  $< 50\,000/\mu\text{L}$ . Tumors detectable with usual US methods were excluded. Within 2 wk prior to RFA, all patients underwent preinterventional CT imaging.

### Radiofrequency ablation

After local anesthesia, a 17-gauge cooled-tip electrode with a 2- or 3 cm exposed tip (Radionics, Burlington, MA, USA) was attached to a radiofrequency generator and then inserted under CT guidance. The patient was placed in a supine position and two neutral electrodes were placed at the proximal thigh. For the localization of lesions, the skin entrance point was validated with a grid made from sealed plastic tubes. Thereafter, the cool-tip needle was inserted into the lesion. The punctures were controlled with CT imaging, which was acquired using the breath-hold technique. Finally, the position was checked

by CT imaging. After successful placement of the RFA needle, RFA was started. Both the temperature and tissue impedance were monitored during ablation. Cooled water was infused to maintain the tip temperature at  $< 20^\circ\text{C}$ . The radiofrequency energy was delivered for 6-12 min each time. For large lesions, the electrode was inserted into additional sites of the tumor nodule. After the ablation procedure was finished, CT was acquired with the RFA needle still in place to evaluate the size of necrosis and to rule out any remaining viable tumor parts in the region of ablation. Dynamic CT was then used to determine whether or not the tumor nodule was completely ablated and necrotized just after the procedure and a few days after RFA. For further follow-up, dynamic CT was performed after 1 mo and then every 3 mo after the procedure. Technical success was defined as complete tumor necrosis without any remaining contrast-enhanced tumor tissue a few days and 1 mo after the ablation procedure.

## RESULTS

The cool-tip needle was successfully placed and RFA was successfully performed in all the patients. All the patients presented with interventional pain and were treated with a single dose of intravenous anesthesia. No further complications occurred during the intervention. The duration of the entire RFA procedure ranged 34-55 min (mean 40.6 min). The puncture procedure was performed twice or less and the average puncture time was  $1.57 \pm 0.53$  times. The 1-mo follow-up examination showed a complete local tumor ablation in all the patients. The mean follow-up period was 9.6 (range 7-14 mo) mo. There was no local tumor recurrence in any patient. Two patients had intrahepatic recurrences and their treated lesions remained tumor-free. All patients survived 6 mo after the ablation. Five patients remained completely tumor-free during the follow-up period. The results are given in detail in Table 1 and a representative case is shown in Figure 1. Pneumothorax was noted in five cases (71.4%), including two cases (28.6%) of major pneumothorax requiring a chest tube. However, both of these patients improved due to chest drainage and the tube could be removed within 2-3 d. In addition, none of the patients demonstrated any clinical complications with problematic pleural effusion. Trans-pulmonary RFA showed itself to be a safe and

**Figure 1** A 68-year-old female patient with hepatocellular carcinoma arising from hepatitis C-related liver cirrhosis. **A:** A hypervascular tumor measuring 15 mm in diameter in the subphrenic region by CT angiography; **B:** partially but insufficiently deposited lipiodol during post-transcatheter arterial embolization (TAE); **C:** location of the lipiodol deposition identified by CT-guided transpulmonary RFA; **D:** no local recurrence after 7 mo of RFA.

feasible option in the treatment of HCC located in the hepatic dome.

## DISCUSSION

CT-guided transpulmonary RFA was successfully performed with a good local control for HCC by means of this relatively easy method in the present study. Percutaneous RFA is a standard therapy for HCC<sup>[1-4]</sup>. One advantage of such percutaneous techniques is its repeatability in cases of local or distant tumor recurrence and its minimal invasive characteristics in comparison to surgery<sup>[1-4]</sup>. Furthermore, RFA has been proved to be superior regarding the extent of tumor necrosis in comparison to percutaneous ethanol injection (PEI) for the treatment of small HCC<sup>[14]</sup>. However, depending on the location of tumors, it is often difficult to detect them by US, especially in the subphrenic area. Minami *et al*<sup>[6]</sup> have reported percutaneous US-guided RFA with the concurrent use of artificial pleural effusion for HCC located in the right subphrenic region. After 200-1 100 mL of 50 g/L glucose solution was infused intrathoracically to separate the lung and the liver, it became possible to obtain an image of the whole tumor, suggesting that US-guided RFA with artificial pleural effusion for HCC is safe and has no major complications. Although US-guided RFA with artificial pleural effusion is a good approach with minimal invasion<sup>[6-8]</sup>, its procedure is sometimes complicated and requires the performer with a high degree of experience. The success of US-guided RFA with artificial pleural effusion thus depends on the skill of the performer. In addition, some patients with adhesion of the pleura may not be indicated for artificial pleural effusion. CT-guided transpulmonary RFA does not require any infusion of the artificial pleural effusion and is thus easier to detect the tumor and to insert the needle. Although US allows for real-time surveillance of the puncture procedure, the lesion is sometimes insufficiently visualized and artifacts may hamper precise needle placement. Especially in the case of liver cirrhosis, CT imaging may sometimes be helpful in distinguishing malignant liver nodules from benign regenerative nodules<sup>[14,15]</sup>. In addition, the CT-guided technique enables us to determine whether the tumor

nodule is completely ablated and necrotized just after the procedure by dynamic CT. We avoided any reintervention due to the remaining vital tumor tissue at the site of ablation.

The transpulmonary approach has been proven to be a safe and feasible option in the treatment of lung neoplasms although pneumothorax is a major complication<sup>[11,12]</sup>. Pneumothorax requiring pleural drainage is the main complication of RFA for lung cancer<sup>[11]</sup>. Lung RFA has shown itself to be a safe and feasible option for the treatment of lung cancer<sup>[11]</sup>. In our study, the diaphragm was also punctured with RFA needle when the patient underwent CT-guided trans-pulmonary RFA for HCC. Fortunately, there was no major complication concerning diaphragm injury or massive pleural effusion. Shibata *et al*<sup>[13]</sup> also reported that percutaneous transthoracic RFA can be used in the treatment of liver tumors in the hepatic dome. They experienced a case of moderate pleural effusion<sup>[13]</sup>, suggesting that all the patients undergoing this procedure should thus be carefully watched for pleural effusion. In our study, two of seven patients required a chest tube. Fortunately, we did not experience cases complicated by uncontrollable pneumothorax. When the patients have lung emphysema, pneumothorax may be more complicated and uncontrollable. The indication for trans-pulmonary RFA should be restricted for such cases complicated by lung emphysema.

In conclusion, CT-guided trans-pulmonary RFA for patients with HCC in the hepatic dome may be a safe and potentially effective therapy. In the cases for which artificial pleural effusion methods are not appropriate, CT guidance may therefore be a useful modality.

## Abstract

**AIM:** To examine the involvement of the pancreatic and bile ducts in patients with autoimmune pancreatitis.

**METHODS:** Clinical and cholangiopancreatographic findings of 28 patients with autoimmune pancreatitis were evaluated. For the purposes of this study, the pancreatic duct system was divided into three portions: the ventral pancreatic duct; the head portion of the dorsal pancreatic duct; and the body and tail of the dorsal pancreatic duct.

**RESULTS:** Both the ventral and dorsal pancreatic ducts were involved in 24 patients, while in 4 patients only the dorsal pancreatic duct was involved. Marked stricture of the bile duct was detected in 20 patients and their initial symptom was obstructive jaundice. Six patients showed moderate stenosis to 30%-40% of the normal diameter, and the other two patients showed no stenosis of the bile duct. Although marked stricture of the bile duct was detected in 83% (20/24) of patients who showed narrowing of both the ventral and dorsal pancreatic ducts, it was not observed in the 4 patients who showed involvement of the dorsal pancreatic duct alone ( $P=0.0034$ ).

**CONCLUSION:** Both the ventral and dorsal pancreatic and bile ducts are involved in patients with autoimmune pancreatitis.

## INTRODUCTION

Autoimmune pancreatitis is a recently described clinical entity in which autoimmune mechanisms are involved in the pathogenesis<sup>[1-3]</sup>. It is characterized by the following clinical features: elderly male preponderance, the frequent initial symptom of jaundice, laboratory findings of serum elevation of gammaglobulin or IgG, especially IgG4, presence of autoantibodies, and a favorable response to steroid therapy. Histological findings are dense lymphoplasmacytic infiltration and fibrosis of the pancreas.

Frequently observed radiological imaging features are the enlargement of the pancreas and irregular narrowing of the main pancreatic duct. Most of the cases with autoimmune pancreatitis reveal a diffusely enlarged pancreas with a sausage-like appearance. Typical cases also show diffuse irregular narrowing of the entire main pancreatic duct. A focal type of autoimmune pancreatitis, showing focal swelling with a localized narrowing of the main pancreatic duct and upstream dilatation, is regarded as a variant of autoimmune pancreatitis<sup>[4]</sup>.

Stenosis of the bile duct frequently occurs with autoimmune pancreatitis. The stenotic portion of the bile duct is usually the lower bile duct; however, the middle and upper extrahepatic bile duct and intrahepatic bile duct are sometimes involved. There are few precise reports of cholangiopancreatographic findings in autoimmune pancreatitis<sup>[5-7]</sup>. In the present study, we have aimed to examine the involvement of the pancreatic and bile ducts in patients with autoimmune pancreatitis.

## MATERIALS AND METHODS

### Patients

Between 1975 and 2003, a total of 28 patients (22 men and 6 women, average age 68.4 years) were diagnosed with autoimmune pancreatitis by the following

clinicopathological criteria: irregular narrowing of the main pancreatic duct on endoscopic retrograde pancreatography ( $n=28$ ); pancreatic enlargement on ultrasound or computed tomography ( $n=27$ ); hypergammaglobulinemia in excess of 2.0 g/dL ( $n=15$ ); elevated serum IgG4 in excess of 135 mg/dL ( $n=15$ ); presence of autoantibodies ( $n=15$ ); characteristic histological findings in the pancreas ( $n=11$ ); and responsiveness to steroid therapy ( $n=15$ ).

### Methods

All patients underwent endoscopic retrograde cholangiopancreatography, and 10 patients also underwent magnetic resonance cholangiopancreatography. In all the patients treated with steroids, cholangiopancreatography was performed before and after the treatment. For the purposes of this study, we divided the pancreatic duct system into three portions: the ventral pancreatic duct; the head portion of the dorsal pancreatic duct including the accessory pancreatic duct; and the body and tail of the dorsal pancreatic duct. Clinical and cholangiopancreatographic findings were evaluated.

## RESULTS

Both the ventral and dorsal pancreatic ducts were involved in 24 patients, 6 of whom showed segmental narrowing of the head portion of the dorsal pancreatic duct. In four patients, only the dorsal pancreatic duct was involved, two of whom showed segmental narrowing of the body and tail of the dorsal pancreatic duct.

Stenosis of the bile duct was detected in 26 patients, including 23 patients in the lower portion of the duct, 1 patient in the middle portion, 1 patient in the lower and intrahepatic portions, and 1 patient in the middle and intrahepatic portions. A marked stricture of the bile duct was detected in 20 patients and their initial symptom was obstructive jaundice. The other 6 patients showed moderate stenosis to 30%–40% of the normal diameter.

Although marked stricture of the bile duct was detected in 83% (20/24) patients who showed narrowing of both the ventral and dorsal pancreatic ducts, it was not observed in the four patients who showed only the involvement of the dorsal pancreatic duct ( $P=0.0034$ ).

## DISCUSSION

The typical pancreatographic appearance of autoimmune pancreatitis is diffuse irregular narrowing of the main pancreatic duct involving both the ventral and dorsal pancreatic ducts<sup>[1–3]</sup>. Some cases of autoimmune pancreatitis show segmental irregular narrowing of the main pancreatic duct<sup>[4,7]</sup>. The segmental and diffuse types of autoimmune pancreatitis appear to represent a spectrum of the same disease rather than separate entities, as some studies<sup>[5,8]</sup> have reported the progression of segmental narrowing to diffuse narrowing on serial endoscopic retrograde pancreatography without steroid treatment. The pancreas develops by the fusion of the dorsal and ventral pancreatic primordial buds. The main pancreatic duct is formed by the fusion of the ventral and dorsal pancreatic ducts, while the accessory pancreatic

duct is formed from the proximal portion of the dorsal pancreatic duct<sup>[9,10]</sup>. In the present study, we have divided the pancreatic duct system embryologically into three parts: the ventral pancreatic duct, the head portion of the dorsal pancreatic duct including the accessory pancreatic duct, and the body and tail of the dorsal pancreatic duct. Both the ventral and dorsal pancreatic ducts were involved in 24 patients, while 4 patients exhibited pathologic changes only in the dorsal pancreatic duct. Although the pathogenesis of autoimmune pancreatitis is unclear, autoimmune mechanisms might have occurred only in the dorsal pancreas in these 4 patients.

Stenosis of the bile duct frequently occurs with autoimmune pancreatitis. While the stenotic portion of the bile duct is usually the lower bile duct, the upper extrahepatic and intrahepatic bile ducts are sometimes involved. In the present study, a marked stricture of the bile duct was observed in 83% (20/24) patients with narrowing of both the ventral and dorsal pancreatic ducts, while 4 patients without the involvement of the ventral pancreatic duct showed no stenosis or moderate stenosis of the bile duct and no clinical manifestation of obstructive jaundice. Diffuse infiltrations by numerous lymphocytes and plasma cells with marked fibrosis in the pancreas and bile duct characterize the histological findings of autoimmune pancreatitis<sup>[7,11]</sup>. Periductal inflammation and marked fibrosis are the main causes of the bile duct stricture in autoimmune pancreatitis; however, fibrosis of the ventral pancreas around the lower bile duct may also be a contributing factor. In terms of the anatomical relationship between the dorsal pancreas and the common bile duct, obstructive jaundice rarely occurs without the involvement of the ventral pancreas.

In conclusion, both the ventral and dorsal pancreatic ducts are involved in a majority of the patients with autoimmune pancreatitis, while some patients show the involvement of only the dorsal pancreatic duct. Although obstructive jaundice due to stenosis of the bile duct commonly occurs with autoimmune pancreatitis, it rarely occurs in patients without the involvement of the ventral pancreas.

### Abstract

**AIM:** To analyse the role of two common polymorphisms in genes coding for histamine metabolising enzymes as it relates to the risk to develop ulcerative colitis (UC) and the clinical course of these patients.

**METHODS:** A cohort of 229 unrelated patients with UC recruited from a single centre and 261 healthy volunteers were analysed for the presence of Thr105Ile and His645Asp amino acid substitutions at histamine N-methyltransferase (HNMT) and diamine oxidase (ABP1) enzymes, respectively, by amplification-restriction procedures. All patients were phenotyped and followed up for at least 2 years (mean time 11 years).

**RESULTS:** There were no significant differences in the distribution of ABP1 alleles between ulcerative colitis patients and healthy individuals [OR (95% CI) for variant alleles = 1.22 (0.91-1.61)]. However, mutated ABP1 alleles were present with higher frequency among the 58 patients that required immunosuppressive drugs [OR (95% CI) for carriers of mutated alleles 2.41 (1.21-4.83;  $P=0.006$ )], with a significant gene-dose effect ( $P=0.0038$ ). In agreement with the predominant role of ABP1 versus HNMT on local histamine metabolism in human bowel, the frequencies for carriers of HNMT genotypes or mutated alleles were similar among patients,

### INTRODUCTION

Mast cells have been recognized as a key cell type involved in type I hypersensitivity. Several studies support a role of mast cells in the development of IBD. These studies indicate that among patients with IBD there is an increase in the number of mast cells and high levels of their degranulation products, such as histamine and tryptase, in the mucosa of colon and ileum.<sup>[1,2]</sup> In addition, it has been shown that the extent of N-methylhistamine urinary excretion is nearly twice in patients with IBD than in healthy subjects, thus indicating that histamine is involved in IBD.<sup>[3]</sup> Increased fecal levels of N-methylhistamine in patients with inflammatory bowel disease (IBD), as compared to control subjects, has also been reported.<sup>[4,5]</sup> Further evidences support that the use of mast cell stabilizers, such as ketotifen, attenuates the severity of IBD.<sup>[5,6]</sup>

Histamine is degraded through two enzymes, histamine N-methyltransferase (HNMT, EC. 2.1.1.8) and diamine oxidase (amiloride binding protein 1, ABP1; EC 1.4.3.6). The expression of ABP1 and HNMT in human bowel has been reported.<sup>[7-9]</sup> The genes coding for these enzymes are polymorphic and diverse nonsynonymous single nucleotide polymorphisms (SPNs) have been described

on these genes. The *HNMT* gene, located in chromosome 1p32, shows eight SNPs, but only one of these, located in exon 4 C314T, causes amino acid substitution Thr105Ile.<sup>[10]</sup> The variant allele is unambiguously related to decreased enzyme activity and immunoreactive protein<sup>[11]</sup> and among Caucasian individuals corresponds to nearly 10% of alleles.<sup>[10]</sup> Four nonsynonymous SNPs have been mapped to the *ABP1* gene, located in chromosome 7q34-36. Among these, the SNP located in exon3 C2029G codes for an altered protein with the amino acid substitution His645Asp and preliminary reports indicate that these occur with a high allele frequency, corresponding to roughly 50% alleles.<sup>[12]</sup>

The role of histamine in IBD is sufficiently documented to allow the examination of the contribution of genetic polymorphisms in IBD. We hypothesize that individuals carrying variant alleles leading to a decreased inactivation of histamine may show altered susceptibility or a different evolution of IBD. A preliminary study involving 17 patients with ulcerative colitis (UC) and 34 patients with Crohn's disease indicated a similar frequency of *HNMT* C314T variant alleles among patients with IBD as compared to control subjects.<sup>[13]</sup> In contrast, the same study reported an increased frequency of individuals carrying variant *ABP1* alleles among patients with IBD. However, none of the *ABP1* gene variations analyzed in such study is located within the coding region of the gene, and no evidences on a relevant effect of these mutations in *ABP1* enzyme activity or expression have been published. The present study was undertaken to investigate whether common SNPs causing amino acid substitutions on *HNMT* and *ABP1* enzymes are related to UC. For this we selected a large group of patients and controls, numerous enough to obtain conclusive evidences even if the allele frequencies differ only by 10 % among cases and controls.

## MATERIALS AND METHODS

### Study population

We studied a cohort of 229 Caucasian unrelated consecutive patients with ulcerative colitis recruited in the Unit of Inflammatory Bowel Disease from a single tertiary referral center (Hospital Clínico San Carlos) in Madrid, Spain. Ninety-one were women (mean age  $\pm$  SD at diagnosis  $36.57 \pm 13.62$ ), and 138 men ( $38.13 \pm 15.92$ ), with a median duration of follow-up of 9 years (mean 11 years, range 2-41 years). Diagnosis of UC was based on standard clinical, radiological, endoscopic, and histologic criteria. Phenotypic details were obtained by review of clinical charts and personal interview with the patients. The same clinical questionnaire was completed for each patient. This questionnaire included: date of birth, sex, familial IBD (defined as the presence of disease in a first or second degree relative), age at diagnosis, duration of follow-up, smoking habits, history of previous surgery (tonsillectomy, appendectomy), extraintestinal clinical manifestations (articular, cutaneous, ocular, hepatic), and previous treatment as an indication of severity of disease (immunosuppressant and surgical intervention). The immunosuppressive therapy was defined by the use of azathioprine, 6-mercaptopurine and/or cyclosporine for

a minimum of 3 mo continuous treatment at standard recommended doses to control disease activity. Surgical intervention was recorded when colectomy was indicated in patients who were intractable to medical therapy and for those with massive hemorrhage, colonic perforation and unresolving toxic megacolon. Disease distribution for UC patients was simplified into two groups: extensive UC, those with total or subtotal colitis (beyond the splenic flexure), while non-extensive disease was referred to disease limited to the left colon, including patients with left side colitis, proctosigmoiditis and proctitis. Distribution was assessed macroscopically and microscopically at the time of diagnosis and at subsequent colonoscopies. The maximum extent recorded was used in the classification for this study. All patient data were recorded by a gastroenterologist from the Unit of IBD who was blind to the genotype status of each patient.

A total of 261 normal healthy unrelated controls ethnically matched with patients and from the same geographic area were recruited. All individuals were Caucasian living in Madrid and surrounding area. Control subjects were selected among the staff of the Universities and Hospitals participating in the study. One hundred and four were women (mean age  $\pm$  SD  $45.42 \pm 12.91$  years) and 157 men ( $43.51 \pm 10.62$  years). Medical examination and history was obtained from every individual to exclude pre-existing disorders. Subjects with personal or familial (up to second degree relatives) antecedents of IBD, autoimmune or allergic diseases were excluded. The protocol was approved by the Ethics Committee of the Hospital Clínico San Carlos (Madrid), and all patients and controls were included in the study after informed consent. All UC patients and over 95% of the healthy subjects requested agreed to participate in the present study.

### Genotyping

Genomic DNA was obtained from peripheral leukocytes and purified according to standard procedures. The presence of the SPNs was investigated by amplification-restriction and electrophoresis in agarose gels. The analysis of the *HNMT* C314T SNP was carried out after the amplification of a gene fragment comprising exon 4 using the following primers (based on the published human *HNMT* sequence Gene Bank Accession No. U44109): GAA AAA CGT TCT TTC TAT CTG TTT GTA TAT AA and ATT TGG GCA GAT CAT GGT CAC TTG T. After an initial step of 2 min at 94 °C, PCR amplification was carried out for 40 cycles of 25 s at 94 °C, 1 min at 52 °C, and 1 min at 72 °C, and a final extension period of 5 min at 72 °C. The 394 base pairs (bp) PCR product was incubated with the endonuclease *EcoRV* that digests the mutated allele in two fragments of 179 and 215 base pairs, leaving intact the wild-type sequence.

Regarding the C2029G SNP within the *ABP1* gene, the following primers (based on the diamine oxidase gene sequence Gene Bank Accession No. X78212) were used: GGT CAC CTG AAC CCG GTT AAC and TTG TGA CCT CTG AAC TTG CCG. After an initial step of 2 min at 94 °C, PCR amplification was carried out for 40 cycles of 25 s at 94 °C, 1 min at 61 °C, and 1 min at 72 °C, and a final extension period of 5 min at 72 °C. The amplified

476 bp fragment contains a constitutive restriction site for the endonuclease *Ava*II, and a variant-allele specific restriction site. After endonuclease digestion the wild type gene yields fragments of 369 and 107 bp whereas the mutated gene is digested to fragments of 252, 117 and 107 bp.

### Statistical analysis

The frequencies for the *HNMT* and *ABP1* SNPs were estimated by counting genes and calculating sample proportions. Case-control analyses were performed with the  $\chi^2$  statistics or Fisher exact test, each when adequate. The association between *HNMT* and *ABP1* mutations and phenotypic characteristics of UC was estimated by the odds ratio (OR) with the 95% confidence interval (CI). To assess whether *HNMT* and *ABP1* variants influence synergically upon the course of UC, subjects were classified as carriers and noncarriers of nonsynonymous SNPs. The above cited test was used for the comparison of carriers and noncarriers. Logistic regression analysis was performed to assess whether *HNMT* and *ABP1* mutations were correlated with a particular clinical phenotype. Association was expressed as OR with 95% CI. A two-tailed *P* value equal or less than 0.05 was considered as significant. Statistical analysis was performed using the Statistical Package for the Social Sciences (SPSS) version 10.07 for Windows (SPSS Inc., Chicago, Ill. USA).

## RESULTS

The frequency analyses for *HNMT* and *ABP1* polymorphisms are summarized in Tables 1 and 2. The *HNMT* genotype (Table 1) was analyzed in 195 patients and no differences with controls in genotype distribution were observed. The mutated *HNMT* allele frequencies were also similar among patients and controls, 9.2 and 11.4%, respectively. The OR (95% CI) value for the mutated allele was 0.79 (0.51-1.22).

In contrast, Table 2 shows that the distribution of *ABP1* genotypes differs between UC patients and healthy controls, and that these differences are in the limit of statistical significance for individuals heterozygous for variant alleles (OR = 1.43; 95 % CI = 0.98-2.08; *P* = 0.050). The mutated *ABP1* allele frequencies are increased at a non-significant level among patients (OR = 1.21; 95% CI = 0.92-1.60). Regarding the interaction of both

genotypes, the frequencies for individuals with both mutated genotypes were similar among UC patients (12.2%) and healthy controls (10.8%). Among UC individuals with mutated *HNMT* genotypes, the frequencies for C/C, C/G and G/G *ABP1* genotypes were 38.2%, 55.9% and 5.9%, respectively. Inversely, among UC individuals with mutated *ABP1* genotypes, the frequencies for the *HNMT* genotypes C/C C/T and T/T were 80.6%, 18.4% and 1.0%, respectively. These allele frequencies are similar to those obtained in overall patients, thus indicating that no *HNMT/ABP1* gene interaction is observed among UC patients.

In order to obtain further information on the effect of both studied polymorphisms on phenotypic and clinical characteristics of patients, these were grouped as carriers and non-carriers of the corresponding mutations, either in heterozygosity or homozygosity. *ABP1* genotypes are similarly distributed when patients are subdivided according to gender, mean age at diagnosis, mean duration of the disease, family history of IBD, smoking habits, previous appendectomy or tonsillectomy, extent of UC, and extraintestinal clinical manifestations, including cutaneous, articular, ocular and hepatic manifestations of the disease (Table 3).

However, *ABP1* genotypes were linked to parameters closely related to the severity of the disease, i.e. need of immunosuppressant therapy and/or need for surgery. Among the 58 patients that required immunosuppressive drugs, 18 of them ultimately needing colectomy due to unresponsiveness of the disease, 41 (70%) were carriers of *ABP1* mutations, 6 of them in homozygosity, the proportion of carriers of the mutated allele being significantly higher than that found in the remaining patients [OR (95 % CI) = 2.41 (1.21-4.83), *P* < 0.006] (Table 3). Moreover, the probability to need immunosuppressant therapy was higher in homo- (OR = 4.24) than in heterozygote (OR = 2.16) carriers of *ABP1* mutated alleles (Chi-square for linear trend 8.36, *P* = 0.0038).

The other clinical incidence related to severity of UC we have analyzed is the need for surgical intervention. Nineteen out of the 23 patients requiring intervention were also carriers of mutations at the *ABP1* gene (OR = 2.50; 95% CI = 1.28-4.91; *P* = 0.003). It should be noted, however, that 18 of these individuals are included in the group of patients needing immunosuppressant therapy.

**Table 3** Phenotypic characteristics among UC patients classified as carriers or non-carriers of mutations at the *ABP1* gene

Phenotypic characteristics	Carriers <i>n</i> = 128	Non-carriers <i>n</i> = 101	OR (95%CI) <i>p</i> value
Male:Female	76:52	62:39	0.79 (0.52-1.62) 0.86
Mean age at diagnosis, yr (range)	37.9 (6-83)	37.1 (17-81)	<i>P</i> = 0.64

Smokers at diagnosis, <i>n</i> (%)	28 (21.9)	22 (21.8)	1.01 (0.51-1.98) 0.99
Previous appendectomy, <i>n</i> (%)	5 (3.9)	6 (6.9)	0.64 (0.16-2.47) 0.54
Previous tonsillectomy, <i>n</i> (%)	11 (8.6)	14 (13.9)	0.58 (0.23-1.55) 0.29
Extent of UC			
Extensive, <i>n</i> (%)	53 (41.4)	42 (41.6)	1.33 (0.77-2.30) 1
Non-extensive, <i>n</i> (%)	75 (58.6)	59 (58.4)	
Extraintestinal clinical manifestations			
Cutaneous, <i>n</i> (%)	23 (17.9)	10 (9.9)	1.99 (0.85-4.76) 0.09
Articular, <i>n</i> (%)	49 (38.3)	28 (27.7)	1.64 (0.90-2.99) 0.09
Ocular, <i>n</i> (%)	3 (2.3)	4 (3.9)	0.58 (0.10-3.17) 0.7
Hepatic, <i>n</i> (%)	31 (24.2)	14 (13.9)	1.99 (0.94-4.22) 0.07
Therapy categories			
Immunosuppressants, <i>n</i> (%)	41 (70)	17 (30)	2.41 (1.21-4.83) 0.006
Surgery, <i>n</i> (%) <sup>1</sup>	19 (83)	4 (17)	2.50 (1.28-4.91) 0.003

<sup>1</sup>Eighteen of these patients are also included in the subgroup of patients receiving immunosuppressive therapy. Four of the remaining 5 patients in the surgery group were carriers of the variant *ABP1* allele.

In the remaining 5 patients colectomy was indicated by acute complications of the disease, as colonic perforation or toxic megacolon.

*HNMT* genotypes are similarly distributed when patients are subdivided according gender, mean age at diagnosis, mean duration of the disease, family history of IBD, smoking habits, previous appendectomy or tonsillectomy, extent of UC, and extraintestinal clinical manifestations, including cutaneous, articular, ocular and hepatic manifestations of the disease (Table 4). Moreover, no statistically significant differences were observed regarding *HNMT* allele frequencies among patients requiring either immunosuppressive drugs (OR = 1.03; 95 % CI = 0.44-2.42) or surgical intervention (1.94; 0.72 - 5.24), respectively. Gene interactions for these subgroups of patients were calculated as described above and no differences were found in relation to the remaining patients.

**Table 4** Phenotypic among UC patients classified as carriers or non-carriers of mutations at the *HNMT* gene

<sup>1</sup>As compared with the remaining patients.

## DISCUSSION

Nonrandom clustering of distinct diseases related to immunity supports that a common set of susceptibility genes may be involved in the etiology of immune diseases. A total of 18 clustered autoimmune loci have been reported, and among them, loci located at chromosomes 1, 3, 7, 12 and 16 have been reported to be linked to IBD.<sup>[14]</sup> Among these, chromosome 7 accumulates the highest density of autoimmune loci in man. Five loci significantly related to UC were identified in chromosome 7, where *ABP1* gene is located, with *P* values ranging from 0.003 to 0.00001.<sup>[14]</sup> Diverse gene polymorphisms have been reported to be linked to UC extension or severity, including *MDR1*, *HLA*, or *MUC3*.<sup>[15-16]</sup>

It has been shown that *ABP1* enzyme activity is decreased in patients with IBD, but the reason for such decrease remains unknown. Such alteration may be explained in part by polymorphisms on the *ABP1* gene that have been recently described. This is the first study analysing SNPs causing amino acid substitutions at *ABP1*

enzyme in patients with UC and, with the exception of a preliminary study carried out in a small group of patients,<sup>[13]</sup> this is also the first one that studies *HNMT* polymorphism in UC patients. It should be noted that the *HNMT* allele frequencies observed in this study are consistent with these described previously,<sup>[10,11]</sup> and that the frequency for the His645Asp *ABP1* polymorphism is only based on preliminary reports obtained in a limited number of individuals. In this study we have analysed a total of 456 patients and controls (912 alleles) and we have shown that in the analysed Caucasian population the mutated allele frequency observed was lower than initially expected, ranging from 25% to 30% (Table 2).

In this study we have shown that the severity of UC is influenced by a nonsynonymous *ABP1* polymorphism. Previous findings indicate that *ABP1* enzyme activity in bowel mucosa was about 50% decreased among patients with IBD, as compared to healthy individuals,<sup>[7,17,18]</sup> thus supporting the hypothesis that individuals carrying mutations at *ABP1* gene may show altered susceptibility to UC and greater activity of the disease. The lack of association of *HNMT* polymorphisms with UC may be related to the relative contribution of *HNMT* to histamine metabolism in bowel tissue, since *HNMT* activity is almost negligible in bowel tissue as compared to *ABP1* activity. It has been reported a mean *HNMT* enzyme activity in human intestine of 0.47 nmol (min/mg),<sup>[9]</sup> whereas *ABP1* enzyme activity in human intestine is nearly 150 nmol (min/mg).<sup>[18]</sup>

Histamine release into the bowel is increased in IBD patients compared with controls, and secretion of histamine is related to the disease activity. Markedly elevated mucosal histamine levels were observed in patients with UC,<sup>[1]</sup> and increased levels of N-methylhistamine, a stable metabolite of histamine, were detected in the urine of patients with UC<sup>[3]</sup>. In addition, the production of histamine and the urinary excretion of N-methylhistamine are coupled with the degree of inflammation in CD and with the extension of the mucosal surface involved in UC. N-methylhistamine urinary excretion rate was also related to the severity of mucosal inflammation, as it is higher in patients with moderate and high inflammatory mucosa than in patients with only mildly or non inflammatory mucosa.<sup>[3]</sup> On the contrary, UC is confined to the mucosa of the colon. Extracellular histamine is metabolized to imidazole acetic acid primarily by *ABP1* at the gut mucosal surface. Different polymorphisms at the *ABP1* gene might affect in different degrees the catabolic rate of histamine in the gut mucosal surface; hence, we can speculate that the association we have found between the carrier state of the His645Asp substitution and the more frequent need to use immunosuppressant therapy or surgery to control the disease depends on a slower rate of histamine metabolic inactivation. Therefore, this specific mutation could be a marker of refractivity to the standard therapies for UC (sulfasalazine, aminosalicylates and glucocorticoids).

Many symptoms of patients with IBD may be explained taking in consideration the known effects of histamine. Histamine is a key mediator responsible for diarrhea, contraction of smooth muscle, modulation of immune response, or mediation of pain in UC. Higher disease severity may result from a reduction of *ABP1* activity in

UC. In this subgroup of patients with a genetically reduced rate of *ABP1* activity, the therapeutic use of inhibitors of mast cell degranulation could result particularly useful. This family of drugs has been evaluated, with conflicting results, in patients with IBD, but without considering the genetic-induced differences in histamine metabolism.<sup>[5]</sup> The association between UC and allergic diseases could not be evaluated in the present study because the absence of personal or familial antecedents of allergy was a prerequisite to include subjects in the control group. Among UC patients, no significant differences in the frequency of allergy were identified when the *HNMT* of *ABP1* polymorphisms were considered.

The results obtained in this study provide an additional support for a key role of histamine in UC. However, it is to be noted that the *ABP1* gene is adjacent to *NOS3* gene for which there are variant alleles that seem to have differential effects on the inflammatory process.<sup>[19]</sup> Thus it cannot be ruled out that linkage disequilibrium between *ABP1* and *NOS3* variant alleles may be related to the findings obtained in the present study. In addition, it should be emphasized that polymorphisms on genes coding for histamine-metabolising enzymes may not be the only cause for increased histamine levels in patients with UC. In fact, it has been shown that intestinal mast cell secretion and release of histamine is increased in patients with IBD,<sup>[20,21]</sup> and this may be related to variations in histamine synthesis. Presently no variations affecting the histidine decarboxylase gene (*HDC*) have been reported. Once the analysis of such gene variations is completed, further studies should explore the role of variability in the *HDC* gene in IBD.

### INTRODUCTION

Inflammatory bowel disease (IBD), or ulcerative colitis (UC) and Crohn's disease (CD), is characterized by inflammation in the intestinal tract without any evident infection. The pathogenetic mechanisms underlying the disease induction and progression is still unclear, although clinical studies and animal models have offered insights into the pathogenesis of IBD<sup>[1]</sup>. It is also of prognostic value in finding analyses enabling early detection of relapses, thus being able to define medical treatment and possibly cease the disease progression at an early stage. Alternatively, if the patients are at a higher risk of relapse, a more intense clinical contact is necessary<sup>[2]</sup>. Exploring the pathogenesis of IBD and finding early markers of the disease activity are two approaches that might benefit each other. In this context, on the experimental basis, it is of great value to continuously follow animals that are born healthy, therefore displaying a disease-free interval, but pre-disposed for IBD.  $G$  protein  $\alpha i2$  deficient mice develop a chronic intestinal inflammation much resembling UC in human beings, including the development of adenocarcinomas<sup>[3]</sup>. Since the mice are born healthy and develop disease at the age of 12-25 wk, it is possible to study the pathogenesis as well as the effect of interventions initiated before the induction of the disease or during ongoing inflammation. Furthermore, the murine model of  $G\alpha i2$ -deficient mice enables studies on early markers of IBD induction/progression.

The importance of the commensal flora for the induction of experimental IBD is reported in several different models where animals under specific pathogen-free conditions develop intestinal inflammation, while they remain healthy or develop only mild inflammation in a germ-free environment<sup>[4-7]</sup>. This is true also for  $G\alpha i2$ -deficient mice (Birnbaumer, personal communication). As far as we know, the toll-like receptors (TLRs) form one of the primary sensors of the immune system in detecting bacterial structures. Interestingly, several components of the TLR intracellular (IC) signaling pathway are shared also by interleukin-1 receptor type I (IL-1RI) and the

### Abstract

**AIM:** To study the serum concentration of IL-1 $\beta$ , IL-1 receptor antagonist (IL-1Ra) and IL-18 in  $G\alpha i2$ -deficient mice at the age of 6 (healthy), 12 (pre-colitic) and 24 wk (colitic) and in healthy control mice.

**METHODS:** At the time of killing, serum samples were collected and IL-1 $\beta$ , IL-1Ra and IL-18 levels were measured using enzyme-linked immunosorbent assays.

**RESULTS:** Serum concentration of IL-1Ra was significantly increased in pre-colitic (median: 524 ng/L;  $P=0.02$ ) and colitic (450 ng/L;  $P=0.01$ ), but not in healthy (196 ng/L)  $G\alpha i2$ -deficient mice as compared with controls (217 ng/L). Serum concentrations of IL-1 $\beta$  did not differ between  $G\alpha i2$ -deficient mice and their controls, irrespective of age, IL-18 was significantly increased in colitic, but not in pre-colitic mice compared with controls (510 ng/L vs 190 ng/L;  $P=0.05$ ).

**CONCLUSION:** The increased serum concentrations of IL-18 and IL-1Ra in established diseases are suggested as markers of ongoing colitis. Interestingly, the significantly increased serum concentration of IL-1Ra in pre-colitic mice is found to be an early marker of disease progression.

interleukin-18-receptor (IL-18R). Since these IC signaling mediators, e.g. IL-1 receptor-associated kinase-1 (IRAK-1)<sup>[8]</sup> and -M (IRAK-M)<sup>[9]</sup>, are highly involved in the regulation of TLR signaling, one might expect an early and important role of IL-1RI and IL-18R in regulating inflammation induced via TLR. IL-18 is a co-stimulator for IFN- $\gamma$  production<sup>[10]</sup> and the *G $\alpha$ i2*-deficient mice is known to display an immunological dysregulation characterized by high IFN- $\gamma$  production in intestinal compartments<sup>[11]</sup>. The main sources of IL-18 in the intestinal tract are intestinal epithelial cells (IEC), macrophages and dendritic cells (DCs)<sup>[12-14]</sup>. The importance of IL-18 for the induction of colitis has previously been shown in the model of 2,4,6-trinitrobenzene sulfonic acid (TNBS) induced colitis in which IL-18-deficient mice do not develop disease, whereas a Crohn's-like disease develops in the wild-type mice<sup>[15]</sup>. The interleukin-1-receptor antagonist (IL-1Ra) binds to the IL-1RI and blocks the pro-inflammatory function of IL-1 in colitis<sup>[16]</sup> and neutralization of IL-1Ra results in the exacerbation of colitis<sup>[17]</sup>. Though the IL-1Ra production is significantly increased by IEC during inflammation in CD and UC patients<sup>[18]</sup>, an increased IL-1/IL-1Ra ratio in the intestinal mucosa is still seen in these patients<sup>[19]</sup>. The spontaneous production of IL-1 $\beta$  is highly increased (30-fold) in colons of *G $\alpha$ i2*-deficient mice with colitis as compared with wild-type mice, while the increase in TNF production is more modest (2-fold)<sup>[11]</sup>. The aim of this study was to analyze the serum concentrations of IL-1 $\beta$ , IL-1Ra, and IL-18 in pre-colitic and colitic *G $\alpha$ i2*-deficient mice in order to find early serum markers of colitis.

## MATERIALS AND METHODS

### Mice

Mice were kept and bred at the animal facility of the Department of Experimental Biomedicine, Göteborg University, Sweden. They were kept under standard conditions of temperature and light, and fed with standard laboratory chow and water *ad libitum*. The procedure of *G $\alpha$ i2* gene disruption has been described in detail elsewhere<sup>[3]</sup>. *G $\alpha$ i2*-deficient mice on a mixed C57BL/6X129SvEv background were backcrossed four generations into 129SvEv and then intercrossed. Homozygous *G $\alpha$ i2*<sup>-/-</sup> males were bred with heterozygous females and the offspring were genotyped by polymerase chain reaction (PCR) analysis. *G $\alpha$ i2*-deficient mice (*G $\alpha$ i2*<sup>-/-</sup>) on this background developed colitis between 12 and 25 wk of age, irrespective of sex, while the *G $\alpha$ i2*<sup>+/-</sup> similar to *G $\alpha$ i2*<sup>+/+</sup> mice stayed healthy. The mice were killed at the age of 6 (healthy), 12 (pre-colitic), and 24 (colitic) wk. At the time of killing, a gross examination of the intestines was performed to look for the presence of colitis. Colitis was scored: 0 = normal; 1 = mild colitis; 2 = moderate colitis and 3 = severe colitis. Blood samples were taken and spleens were weighed. Both male and female mice were included in the study. Heterozygous mice were used as controls throughout the study. The experiments were approved by the Göteborg Animal Ethics Committee.

### Cytokine analyses

Serum concentrations of IL-1 $\beta$  and IL-1Ra were estimated using Quantikine mouse immunoassays (R&D Systems, Minneapolis, MN, USA) and IL-18 was measured using a commercially available enzyme immunoassay (MBL, Nagoya, Japan). Detection limits were: IL-1 $\beta$ : 3 ng/L, IL-1Ra: 7 ng/L and IL-18: 25 ng/L. All the assays were performed in accordance with the manufacturer's instructions.

### Statistical analysis

Data were analyzed using the non-parametric Mann-Whitney *U* test. A value of  $P \leq 0.05$  was considered as statistically significant.

## RESULTS

### Serum IL-18 but not IL-1 $\beta$ is a marker of ongoing colitis

We examined the serum concentrations of IL-18 and IL-1 $\beta$  in the colitic animals as well as their littermate controls. As expected heterozygous controls displayed no or very low serum IL-1 $\beta$  concentration, but also the 24-wk-old *G $\alpha$ i2*-deficient mice had serum levels of IL-1 $\beta$  as compared to *G $\alpha$ i2*<sup>+/-</sup> controls (median: 18 ng/L *vs* 9 ng/L; ns, not shown). The levels of circulating IL-18 in heterozygous controls were clearly above the detection limit of the assay. However, in contrast to the IL-1 $\beta$  serum levels, the IL-18 concentration was significantly increased in the colitic mice as compared with control animals (Figure 1A). One of the *G $\alpha$ i2*<sup>+/-</sup> mice displayed a highly increased IL-18 level as compared with the controls. This mouse appeared healthy and was included in the statistical analysis.

### Serum IL-1-receptor antagonist is an early indicator of colitis onset

The serum concentrations of IL-1Ra were analyzed in *G $\alpha$ i2*-deficient mice and their littermate controls. In parallel with IL-18, serum IL-1Ra was also easily detected in control animals. In contrast to IL-1 $\beta$  that was not increased in colitic animals, the IL-1Ra concentrations were significantly higher than the controls (Figure 1B). Interestingly, similar to the colitic animals, pre-colitic *G $\alpha$ i2*<sup>-/-</sup> mice also had significantly higher serum IL-1Ra levels than their controls. In contrast, serum concentrations of IL-18 and IL-1 $\beta$  were not raised in the 12-wk-old pre-colitic animals as compared with their controls (median 325 ng/L *vs* 190 ng/L; and 10 ng/L *vs* 9 ng/L).

In the 12-wk-old group of pre-colitic *G $\alpha$ i2*<sup>-/-</sup> mice, 6 mice did not show any signs of colitis at gross examination, two had mild disease, one moderate and one was judged to have severe colitis. In the 24-wk-old group only one mouse had a normal colon by gross examination, two had mild disease, three moderate and three had severe disease.

The IL-18 concentrations were found higher in colitic than in pre-colitic mice, which was in parallel with a disease progression between 12 and 24 wk of age. However, this was not seen with regard to the serum IL-1Ra concentration. In our previous study *G $\alpha$ i2*-deficient cells showed exaggerated cytokine production upon

**Figure 1 A:** Serum IL-18 concentrations in 24-wk-old *Gαi2*-deficient mice ( $n=9$ ) and their heterozygous littermates (controls;  $n=7$ ). Data were analyzed using the non-parametric Mann-Whitney *U* test. A value of  $P \leq 0.05$  was regarded as statistically significant. The horizontal bars mark the median values within each group; **B:** Serum IL-1Ra concentrations in 6-wk-old (healthy;  $n=11$ ), 12-wk-old (pre-colitic;  $n=8$ ), and 24-wk-old (colitic;  $n=7$ ) *Gαi2*-deficient mice and their heterozygous controls ( $n=10$ ). Data were analyzed using the non-parametric Mann-Whitney *U* test. A value of  $P \leq 0.05$  was regarded as statistically significant. The horizontal bars mark the median values within each group.

stimulation, even if they were derived from a non-colitic genetic background<sup>[20]</sup>. To examine whether the IL-1Ra concentration was increased upon colitis onset, we also analyzed the serum IL-1Ra concentration in 6-week-old (healthy) *Gαi2*-deficient mice. The 6-wk-old *Gαi2*<sup>-/-</sup> mice had similar serum level of IL-1Ra to the *Gαi2*<sup>+/-</sup> control animals. Thus, serum IL-1Ra concentrations increased upon colitis onset which is not merely a consequence of the *Gαi2* deficiency (Figure 1B).

Spleen weight seemed to be also correlated with the stage of the disease. The median weight of 132 mg in 12-wk-old mice, was significantly higher than in *Gαi2*<sup>+/-</sup> mice (84 mg;  $P=0.03$ ). The 24-wk-old mice displayed a higher spleen weight (222 mg) than not only the controls, but also the 12-wk-old mice ( $P=0.03$ ). Interestingly, the two 12-wk-old mice with severe and moderate colitis judged by gross examination demonstrated the highest spleen weight and the highest serum IL-1Ra concentrations: 271 mg and >4000 ng/L in mouse with severe colitis and 180 mg and 1276 ng/L in mouse with moderate colitis.

## DISCUSSION

We analyzed serum concentrations of IL-18, IL-1 $\beta$  and the IL-1 receptor antagonist in *Gαi2*-deficient mice on

a colitis-prone genetic background. Since mice are born healthy and develop colitis at the age of approximately 12-25 wk, we were able to examine the mice at a “pre-colitic” (12 wk of age) and a “colitic” age (24 wk). Our results showed that the serum IL-18 concentration was significantly increased in *Gαi2*-deficient mice at 24 wk of age, a time when most of the mice displayed moderate or severe colitis, as compared with the controls. At this time-point serum IL-1Ra concentrations were also significantly increased, whereas the serum IL-1 $\beta$  levels were similar in *Gαi2*-deficient and control mice. The 12-wk-old, “pre-colitic” *Gαi2*-deficient mice did not display increased serum levels of neither IL-18 nor IL-1 $\beta$ . In contrast, the serum concentration of IL-1Ra was significantly increased in these mice. Our results suggest a potential clinical importance of measuring serum concentrations of IL-18 and IL-1Ra in IBD patients to determine the status of the inflammatory disease. The value of measuring serum IL-18 might be related to confirming ongoing colitis, additional information could be obtained by examining the serum IL-1Ra concentration. In fact, serum concentration of IL-1Ra is an early indicator for the onset of colitis.

We know from previous studies on *Gαi2*-deficient mice that the production of IL-1 $\beta$  is highly increased locally in the large intestine during ongoing colitis<sup>[11]</sup>. However, the present study clearly shows that such a dysregulation of the IL-1 $\beta$  production is not reflected in the systemic circulation. In contrast to IL-1 $\beta$ , IL-18 is easily detected in the blood in healthy individuals, of both mouse and man, which enables evaluation of fluctuations in IL-18 concentrations during the disease. The finding of significantly increased IL-18 levels in the 24-wk-old colitic mice is not very surprising, inasmuch as the intestinal inflammation of the *Gαi2*-deficient mice is characterized by high IFN- $\gamma$  production, with IL-18 being a co-stimulator for IFN- $\gamma$  production. It has been previously shown that serum IL-18 was higher in patients with CD than healthy blood donors<sup>[21]</sup>. A recent report also showed increased plasma IL-18 level in patients with moderate or severe UC, but not in patients with mild disease<sup>[22]</sup>. Our results confirm a role of IL-18 levels measurement in established colitis. However, it seems that IL-18 is not as sensitive as IL-1Ra in indicating onset of colitis, or perhaps not as useful as an early indicator of a relapse as compared with IL-1Ra. We found that although there were clearly detectable levels of IL-1Ra in young healthy *Gαi2*-deficient mice, the levels were similar to what was found in the control mice. In contrast, the 12-wk-old “pre-colitic” *Gαi2*-deficient mice displayed significantly higher serum IL-1Ra concentrations than their controls. In the healthy mucosa, IEC is capable of producing IL-1Ra<sup>[18]</sup> which might be one of the sources for the serum IL-1Ra detected in healthy *Gαi2*<sup>-/-</sup> mice and their *Gαi2*<sup>+/-</sup> littermates. During intestinal inflammation, IEC increased the production of IL-1Ra, but a decreased IL-1Ra:IL-1 ratio was nevertheless seen<sup>[23]</sup>. One reason for finding IL-1Ra but not IL-1 $\beta$  in the circulation at the onset and in established colitis might simply be that the receptor antagonist is produced excessively as compared with the cytokine and is therefore more easily detected. Another explanation could of course be that the IL-1Ra is systemically derived. Although the visceral

organs of G $\alpha$ i2-deficient mice were previously screened microscopically without finding any abnormalities, except the colon<sup>[3]</sup>, splenomegaly seems to be correlated with disease progression in G $\alpha$ i2-deficient mice. One possible tissue origin of serum IL-1Ra in healthy individuals, except IEC, is the adipose tissue<sup>[24,25]</sup>. An increased serum IL-1Ra concentration in the older G $\alpha$ i2-deficient can hardly be related to increased BMI. In contrast from previous results we found that serum leptin, also originating from white adipose tissue, is decreased upon colitis onset in G $\alpha$ i2-deficient mice<sup>[26]</sup>. Furthermore, the 12-wk-old mouse displaying severe colitis had a substantial weight reduction as compared with the other mice in the group and still highly increased serum IL-1Ra concentration.

In conclusion, our results show that while circulating IL-18 and IL-1Ra are markers of established intestinal inflammation, IL-1Ra is also an early indicator of onset of colitis in G $\alpha$ i2-deficient mice. We therefore suggest that IL-1Ra might be a useful serological marker of disease progression in IBD at an early stage as well as at a relapse.

### Abstract

**AIM:** To investigate the occurrence of chromosome 3, 7, 8, 9, and 17 aneuploidies, *TP53* gene deletion and p53 protein expression in chronic gastritis, atrophic gastritis and gastric ulcer, and their association with *H pylori* infection.

**METHODS:** Gastric biopsies from normal mucosa (NM,  $n=10$ ), chronic gastritis (CG,  $n=38$ ), atrophic gastritis (CAG,  $n=13$ ) and gastric ulcer (GU,  $n=21$ ) were studied using fluorescence *in situ* hybridization (FISH) and immunohistochemical assay. A modified Giemsa staining technique and PCR were used to detect *H pylori*. An association of the gastric pathologies and aneuploidies with *H pylori* infection was assessed.

**RESULTS:** Aneuploidies were increasingly found from CG (21%) to CAG (31%) and to GU (62%), involving mainly monosomy and trisomy 7, trisomies 7 and 8, and trisomies 7, 8 and 17, respectively. A significant association was found between *H pylori* infection and aneuploidies in CAG ( $P=0.0143$ ) and GU ( $P=0.0498$ ). No *TP53* deletion was found in these gastric lesions, but p53-positive immunoreactivity was detected in 45% (5/11) and 12% (2/17) of CG and GU cases, respectively. However, there was no significant association between p53 expression and *H pylori* infection.

**CONCLUSION:** The occurrence of aneuploidies in be-

### INTRODUCTION

Gastric carcinogenesis is considered a multi-step and multi-factorial process that proceeds from normal gastric mucosa with epithelial hyperproliferation to chronic gastritis with variable degrees of atrophy, intestinal metaplasia, dysplasia, and ultimately carcinoma<sup>[1]</sup>. In most cases, chronic gastritis, frequently associated with *H pylori* infection, precedes the formation of gastric cancer, and a great proportion of the clinical tumors occurs in connection with severe atrophic gastritis and extensive intestinal metaplasia<sup>[2]</sup>. Efforts have been made to identify changes of a precancerous nature in the gastric epithelium. The identification of such changes may help to prevent the occurrence of gastric cancer<sup>[3]</sup>.

Gastritis may also play a role in the pathogenesis of peptic ulcer disease by impairing the resistance of the gastric mucosa and consequently increasing the risk of ulcer<sup>[3]</sup>. In practice, the cancer risk in peptic ulcer disease applies exclusively to gastric ulcer. Epidemiological data on the incidence of peptic ulcer disease with gastric cancer suggest that ulcer disease may not be an important precursor of gastric cancer. However, possible links between these two are suggested by a similar relationship with chronic gastritis<sup>[2]</sup>.

*H pylori* infection is accepted as the major causal factor for the histological features leading to severe gastroduodenal disease, including chronic gastritis, peptic

ulcer disease, intestinal-type gastric cancer and gastric MALT lymphoma. Only a small proportion of the infected cases will develop clinically significant disease. About one in 5-6 individuals will develop peptic ulcer disease during their lifetime, and <1% will develop gastric cancer<sup>[4]</sup>.

It is particularly important to recognize and define the characteristics of benign and pre-malignant lesions for application to studies of carcinogenesis and cancer prevention. Hence, in this study, we aimed to verify the occurrence of aneuploidies of chromosomes 3, 7, 8, 9, and 17, and of *TP53* gene deletions using the FISH technique, besides p53 expression, in benign lesions such as chronic gastritis, atrophic gastritis and gastric ulcer. The results were associated with *H pylori* infection and other clinicopathological features, such as sex, age, smoking and alcohol consumption.

## MATERIALS AND METHODS

### Samples

Chronic gastritis (CG), atrophic gastritis (CAG) and gastric ulcer (GU) samples were obtained, respectively, from 38 (13 males and 25 females), 13 (7 males and 6 females) and 21 patients (15 males and 6 females) without gastric cancer by biopsy performed during endoscopic evaluation. The mean age of these patients was 53 years (range, 2-89 years). Biopsies of histologically confirmed normal and *H pylori*-negative mucosa (NM) were obtained from 10 healthy individuals (2 males and 8 females) with a mean age of 43 years (range, 19-75 years). All specimens were collected at the Hospital de Base of São José do Rio Preto, SP, Brazil. All biopsies of normal mucosa and gastric ulcer were collected from the antral region of the stomach, whereas those of chronic gastritis and atrophic gastritis were mainly collected from the antrum and corpus. Clinicopathological data were collected using a standard interviewer-administered questionnaire and a review of the patients' medical records. The study was approved by the National Research Ethics Committee, and written informed consent was obtained from all subjects.

### Histology

Hematoxylin-eosin (H&E) staining was used for the diagnosis and classification of gastritis<sup>[5]</sup>. A modified Giemsa staining technique was used to visualize *H pylori*.

### DNA extraction and PCR for *H pylori* diagnosis

DNA was extracted by the phenol-chloroform method after digestion with proteinase K<sup>[6]</sup>. PCR assays were performed separately with approximately 100 ng of total DNA, using three different sets of oligonucleotides. One of them amplifies a 312-bp segment of the gene *CYP1A*<sup>[7]</sup> as a DNA quality control, the other amplifies a 298-bp product of the gene encoding species-specific *H pylori* antigen<sup>[8]</sup>, and the last one amplifies a 411-bp fragment corresponding to the urease A gene<sup>[9]</sup>. Positive and negative controls were used in all experiments. PCR products were separated on 75 g/L polyacrylamide-gel electrophoresis, followed by silver nitrate staining. The assay was considered positive when at least one of the bacterial PCR products was present<sup>[10]</sup>.

### Fluorescence in situ hybridization (FISH)

Nuclear suspensions from all samples were obtained by mechanical and enzymatic disaggregation<sup>[11]</sup>. After washes in 600 mL/L acetic acid, the resulting nuclear suspension was dropped onto microscope slides and stored at -70 °C until use for FISH assay.

FISH analysis was performed on interphase nuclei using centromere probes (CEP) for chromosomes 3, 7, and 8 directly labeled with Spectrum Green, and for chromosome 9 labeled with rhodamine (Vysis, Inc., Downers Grove, IL, USA). Dual-color FISH assays were performed using *TP53* probe kits (Vysis), including the LSI *TP53* sequence labeled in Spectrum Orange, with the centromere probe for chromosome 17 labeled in Spectrum Green. The hybridization and detection protocols followed the manufacturer's instructions.

For each probe, signals of about 300 intact and non-overlapping nuclei were evaluated by two independent observers according to the criteria described by Eastmond *et al*<sup>[12]</sup>. Cutoff levels for aneuploidies were based on the upper-limit mean +4 SD of the normal gastric mucosa biopsies. By definition, for monosomy of chromosomes 3, 7, 8, 9, and 17, the cutoff values were set at 10.0%, 11.0%, 11.0%, 8.5%, and 7.5%, respectively, and, for trisomy of the same chromosomes, at 10.0%, 9.0%, 8.0%, 8.5%, and 7.0%, respectively. Tetrasomy and pentasomy were absent in the normal mucosa samples; thus, 2% was arbitrarily taken as cutoff value.

The *TP53* gene scores were taken together with those of the chromosome 17 centromere. For *TP53* gene deletion analysis, the gene-to-centromere ratio (G/C) was calculated for each case, that is, the total number of gene signals observed was divided by the total number of centromere signals.

### Immunohistochemical analysis

To assess p53 protein accumulation, the commercially available monoclonal antibody DO-7 (Novocastra, Newcastle, UK) was used in combination with the anti-Ig second-stage antibody and the ABC kit (Novocastra) on paraffin-embedded sections. This antibody recognizes both mutant and wild types of p53 protein. The slides were counterstained with Harris hematoxylin. As positive controls, sections from gastric adenocarcinoma were processed, previously shown to express high levels of p53 protein. For each sample, 500 epithelial cells were counted.

### Statistical analysis

Data were analyzed using  $\chi^2$  and Fisher's exact tests. *P* values less than 0.05 were considered statistically significant.

## RESULTS

Analysis by the FISH technique showed that 89% to 99% of the nuclei of the *H pylori*-negative normal mucosa cases were disomic for chromosomes 3, 7, 8, 9, and 17, so they were considered to have no aneuploidy. The gene-to-centromere ratio (G/C) for the *TP53* gene deletion ranged from 0.97 to 0.99 (mean of 0.98), so, in the cases of benign lesions with a G/C ratio <0.90,

gene deletion was assumed. Low-intensity nuclear p53 protein immunoreactivity was observed only in 4 of the 8 evaluated cases of normal gastric mucosa, ranging from 0.2% to 4.0% of the immunostained nuclei. The positivity index was defined as >10% of cells showing nuclear staining, according to a previous report by Gobbo-César *et al.*<sup>[11]</sup>.

Table 1 shows the results regarding aneuploidies of chromosomes 3, 7, 8, 9, and 17, *TP53* gene deletion, p53 expression, and clinicopathological data only of those cases with benign lesions (chronic gastritis, atrophic gastritis and gastric ulcer) which showed some genetic alteration.

Increasing frequencies of aneuploidies were detected in the CG, CAG and GU cases: 21% (8/38), 31% (4/13), and 62% (13/21), respectively. The samples also showed an increasing complexity of the alterations with mainly monosomy and trisomy of chromosome 7 in CG, trisomy of chromosomes 7 and 8 in CAG, and more frequent trisomy of chromosomes 7, 8 and 17 in GU. About 75% (6/8) of CG, 100% (4/4) of CAG and 69% (9/13) of GU with aneuploidies were *H. pylori*-positive. However, a significant association between the presence of

aneuploidies and *H. pylori* infection was found only in CAG ( $P=0.0143$ ) and GU ( $P=0.0498$ ), while parameters such as sex, age, smoking and alcohol consumption did not show any association with the occurrence of aneuploidies.

No *TP53* gene deletion was found in the cases evaluated, whether in CG, in CAG or in GU, but low-intensity nuclear p53-positive immunoreactivity was present in 45% (5/11) and 12% (2/17) of the CG and GU cases, respectively, ranging from 12% to 47.2% of p53-positive nuclei, as compared to over-expression of the p53 protein in positive controls from gastric adenocarcinoma (Figure 1). No significant association was found either between p53 expression and *H. pylori* infection or with the other clinicopathological features investigated.

## DISCUSSION

The development of gastric carcinoma is considered as a multistage progressive process due to alterations in oncogenes, tumor suppressor genes, cell-adhesion molecules, telomerase, as well as to a genetic instability at several microsatellite loci, possibly related to *H. pylori* infection<sup>[13,14]</sup>. The mechanisms leading to mutations, hyperproliferation

**Figure 1** p53 protein expression on paraffin-embedded sections (400X original magnification). Low-intensity nuclear p53 protein immunoreactivity in chronic gastritis (A) and gastric ulcer (B) in comparison with p53 over-expression in the positive controls from gastric adenocarcinoma of intestinal type (C) and diffuse type (D).

and apoptosis of the epithelial cells are triggered very early in the *H. pylori* gastritis cascade, resulting in atrophic gastritis, intestinal metaplasia and gastric cancer<sup>[2,13]</sup>.

The identification of genetic alterations in biopsies of the epithelium of patients with gastric dyspepsia may be helpful in early diagnosis of gastric cancer. FISH is an accurate and sensitive technique for the detection of aneuploidies in interphase nuclei from biopsies, making it possible to identify changes in early stages of benign lesions, such as gastritis and gastric ulcer. Such changes may be used as markers for estimating the risk of gastric cancer.

A few studies have evaluated aneuploidy in epithelial lesions of the stomach using DNA flow cytometry. In chronic and atrophic gastritis, Weiss *et al*<sup>[15]</sup> found DNA aneuploidy in 5.2% and in 8.5% of the cases, respectively. Teodori *et al*<sup>[16]</sup> observed aneuploidy in 45% (9/20) chronic atrophic gastritis specimens, whereas Abdel-Wahab *et al*<sup>[3]</sup> detected quantitative DNA alterations in 18.8% of atrophic gastritis cases.

To our knowledge, studies about aneuploidy in gastric ulcer are not available in the literature. Our study using the FISH technique showed increasing aneuploidy and complexity of the alterations from chronic gastritis (21%) towards atrophic gastritis (31%) and gastric ulcer (62%). The more frequent aneuploidies were monosomy and trisomy 7 in CG, trisomies 7 and 8 in CAG, and trisomies 7, 8, and 17 in GU. Moreover, in CAG and GU, these aneuploidies occurred more frequently in the *H. pylori*-positive cases, probably being responsible for the chromosomal instability observed.

Chromosomes 7, 8 and 17 carry several important genes involved in the control of cell proliferation, such as *EGFR* (7p12-13), *c-myc* (8q24), *HER-2/neu* (17q21), and *TP53* (17p13). Therefore, the presence of trisomy of these chro-

mosomes in precancerous gastric lesions leading to gene imbalance may confer proliferative advantage, increasing the risk of developing into gastric cancer.

The development of carcinoma in cases of gastric ulcer disease during long-term H2-blocker treatment is slowly increasing, and ulcers that require such treatment exhibit the characteristics of intractable conditions, including linear ulcers, simultaneous gastric and duodenal ulcers, immature intestinal metaplasia of the gastric epithelium, and atrophic gastritis accompanied by multiple ulcer cicatrices<sup>[17]</sup>. Hence, especially in these cases of gastric ulcer, it is suggested that a genetic study should be performed to allow early detection of malignant transformation.

Inactivation of the *TP53* gene by mutation or deletion occurs as an initial event in gastric tumorigenesis, possibly associated with *H. pylori* infection<sup>[14,18,19]</sup>. Using the FISH technique, Gomyo *et al*<sup>[20]</sup> detected a *TP53* deletion in 77% (10/13) cases of gastric carcinoma.

In the present study, no *TP53* deletion was found in either chronic gastritis (15 cases), atrophic gastritis (3 cases) or gastric ulcer (3 cases), although it was observed in 60% (3/5) of the intestinal metaplasia and 110% (3/3) of the adenocarcinoma cases in a previous study conducted by our group<sup>[11]</sup>, thereby corroborating the hypothesis that these pathologies share genetic alterations and progress jointly.

The p53 gene products are known to regulate cell growth and proliferation. Wild-type p53 protein suppresses cell growth by controlling the G1 checkpoint, and has several additional physiological functions, including control of the G2 cell checkpoint, as well as mediation of apoptosis<sup>[21]</sup>. The products of wild-type p53 can hardly be detected in normal cells by immunohistochemical assays because of their short half-life. However, *TP53* gene alterations induced by many missense mutations may modify the conformation and stabilize the proteins, leading to their accumulation<sup>[22]</sup>. Therefore, over-expression of a p53 protein is a useful marker for detecting a mutated *TP53* gene<sup>[23,24]</sup>.

In this study, an increase of detectable low-intensity p53 was observed in 45% (5/11) of chronic gastritis and 12% (2/17) of gastric ulcer cases. These positive immunostaining findings may be a consequence of point mutations or small deletions. However, these changes are not detected by FISH, so were not tested in the current study. Alternatively, such alterations are more likely to be due to over-expression of the wild-type protein related to a physiological response brought about by the inflammatory process of the gastric epithelium. The lack of association between p53 expression and *H. pylori* infection may be related to the reduced number of specimens from benign lesions evaluated.

Although some studies have described p53 protein accumulation in benign gastric lesions<sup>[13,25-28]</sup>, its association with *H. pylori* infection in gastric carcinogenesis is not yet clear. Whereas some authors reported over-expression of p53 protein in *H. pylori*-positive chronic gastritis and intestinal metaplasia<sup>[13,25,27,28]</sup>, Craanen *et al*<sup>[29]</sup> did not observe p53 protein accumulation in either atrophic gastritis or intestinal metaplasia and suggested that this process may be a late event in gastric carcinogenesis. On

the other hand, Lan *et al.*<sup>[13]</sup> reported that *H pylori* infection might first cause severe imbalance of proliferation and apoptosis in the precancerous lesions, leading to p53-Rb tumor suppressor system mutation and telomerase reactivation, and finally causing gastric cancer.

In conclusion, our study has clearly shown the occurrence of aneuploidies, which increases with the progression of lesions from chronic gastritis to atrophic gastritis and to gastric ulcer, is frequently associated with *H pylori* infection, evidencing chromosomal instability in benign gastric lesions that may play an important role in gastric carcinogenesis. We observed no *TP53* gene deletion in the benign gastric lesions, whereas p53 protein overexpression was detected in some cases of chronic gastritis and gastric ulcer, thus suggesting that an accumulation of wild-type p53 protein occurs, probably due to an inflammatory response.

### Abstract

**AIM:** To assess the three polymorphism regions within cytotoxic T-lymphocyte antigen 4 (CTLA-4) gene, a C/T base exchange in the promoter region -318 (CTLA-4 -318C/T), an A/G substitution in the exon 1 position 49 (CTLA-4 49A/G), a T/C substitution in 1172 (CTLA-4 -1172T/C) in patients with chronic hepatitis B.

**METHODS:** Fifty-one patients with chronic hepatitis B virus infection and 150 healthy subjects were recruited sequentially as they presented to the hepatic clinic. Classification of chronic hepatitis B virus (HBV)-infected patients was as asymptomatic carrier state (26 patients) and chronic hepatitis B (25 patients). Genomic DNA was isolated from anti-coagulated peripheral blood Buffy coat using Miller's salting-out method. The presence of the CTLA-4 gene polymorphisms was determined using polymerase chain reaction amplification refractory mutation system (ARMS).

**RESULTS:** We observed a significant association between -318 genotypes frequency (T+C-, T+C+, T-C+) and susceptibility to chronic hepatitis B ( $P=0.012$ , OR=0.49, 95%CI: 0.206-1.162). However, we did not observe a significant association for +49 genotype frequency (T+C+, T+C- T-C+) and -1172 genotype frequency (C+T+, T+C- C+T-) and state of disease.

**CONCLUSION:** Our results suggest that CTLA-4 gene polymorphisms may partially be involved in the susceptibility to chronic hepatitis B.

**Key words:** Cytotoxic T-lymphocyte antigen 4; Chronic hepatitis B; Gene polymorphism

### INTRODUCTION

The human cytotoxic T-lymphocyte antigen 4 (CTLA-4) gene was mapped to chromosome 2q33<sup>[1]</sup>. It consists of three exons; the first encodes a V-like domain of 116 amino acids. An A-to-G substitution at nucleotide 49 in exon 1 results in an amino acid substitution (Thr/Ala) in the leader peptide of the protein<sup>[2]</sup>. The Ala allele has been shown to predispose the individual carrying it to the development of various immune diseases, including Graves' disease<sup>[3]</sup>, Hashimoto's thyroiditis<sup>[4]</sup>, Addison's disease, rheumatoid arthritis<sup>[5,6]</sup>, and celiac disease<sup>[7,8]</sup>. The existence of inactive hepatitis B carriers with normal liver histology and function suggests that the virus is not directly cytopathic. The fact that patients with defects in cellular immune competence are more likely to remain chronically infected rather than to clear the virus is cited to support the role of cellular immune responses in the pathogenesis of hepatitis B-related liver injury. Differences in the robustness of cytolytic T-cell responsiveness and in the elaboration of antiviral cytokines by T cells have been invoked to explain the differences in outcomes between those who recover after acute hepatitis or between those with mild and those with severe acute hepatitis B virus infection<sup>[9]</sup>. Chronic hepatitis is an important late complication of occult hepatitis B occurring in a small proportion of patients with chronic infection without having experienced an acute illness. Certain clinical and laboratory features suggest the progression of acute hepatitis to chronic hepatitis: (1) lack of complete resolution of clinical symptoms of anorexia, weight loss, and fatigue, and the persistence of hepatomegaly; (2) the presence of bridging or multilobular hepatic necrosis on liver biopsy during protracted, severe acute viral hepatitis; (3) failure of the serum aminotransferases, bilirubin and globulin levels to return to normal within 6-12 mo after the acute illness; and (4) the persistence of HBeAg beyond 3 mo after acute hepatitis. Under ordinary circumstances, none of the hepatitis viruses are known to be directly cytopathic to hepatocytes. Evidence suggests that the

clinical manifestations and outcomes after acute liver injury associated with viral hepatitis are determined by the immunologic responses of the host<sup>[9]</sup>. It is thought that the majority of autoimmune endocrinopathies, including Graves' disease, autoimmune hypothyroidism, type 1 diabetes mellitus and autoimmune Addison's disease (sporadic as well as autoimmune polyendocrinopathy syndrome type 2), are inherited as complex genetic traits. Multiple genetic and environmental factors interact with each other to confer susceptibility to these disorders. In recent years, there have been considerable efforts towards defining susceptibility genes for complex traits. These investigations have shown, with increasing evidence, that the CTLA-4 gene is an important susceptibility locus for autoimmune endocrinopathies and other autoimmune disorders<sup>[10]</sup>. Specific immunotherapy has moved into a new era with the introduction of soluble CTLA-4 protein into clinical trials. Treatment of bone marrow with CTLA-4 protein reduces rejection of the graft in HLA-mismatched bone marrow transplantation. In addition, promising results with soluble CTLA-4 have been reported in the down-regulation of autoimmune T-cell responses in the treatment of psoriasis<sup>[9]</sup>. Treatment with a blocking antibody against the CTLA-4 gene has been shown to enhance the effect of tumor rejection in mice vaccinated with irradiated tumor cells<sup>[11]</sup>. In this study, we have investigated whether genotypes of CTLA-4 -1172, -318, +49 polymorphisms as host factors predispose subjects to chronic hepatitis B.

## MATERIALS AND METHODS

### Subjects

Fifty-one patients with chronic hepatitis B virus infection (mean age,  $36.23 \pm 12.65$  years) and 150 healthy subjects (mean age,  $32.64 \pm 7.12$  years) were recruited sequentially as they presented to the hepatic clinic. Of chronic hepatitis B patients, 68.6% were males and 31.4% were females; and of healthy subjects (control group), 56% were males and 44% were females. Chronic HBV-infected patients were positive for HBV markers and if they had chronic hepatitis B, rising in alanine aminotransferase (ALT) and aspartate aminotransferase (AST) activity was seen for about 6 mo. Control groups were matched by age and sex; none of them were positive for hepatitis B serology. We did not regard any inflammatory conditions in the groups. All studies were carried out after the approval of Local Hospital Ethical Committees.

Hepatitis B was regarded if positive for HBsAg, anti-HBe, anti-HBc by ELISA HBsAg+, HBeAg (+, -), anti-HBe (+, -), HBV DNA (+, -), IgG anti-HBc+. Classification of chronic HBV-infected patients was carried out as follows: (A) Asymptomatic carrier state (26 patients), composed of chronically HBsAg-positive patients who had anti-HBc in serum, anti-HBs either undetected or detected at low titer against the opposite subtype specificity of the antigen regarded as inactive or asymptomatic carriers, HBV DNA load  $<10^5$  copies/mL, HBeAg (+, -), liver transaminases of normal range; (B) chronic hepatitis B (25 patients) which comprised, based upon biochemical, virologic and histological activity, 17 patients who were still

on interferon or lamivudine treatment, 5 non-responders to treatment (lack of virologic and or histologic response by first treatment course in whom sustained response was unlikely) and 3 chronic hepatitis B patients. Histologic classification was measured by modified histologic activity index (HAI) by Ishak score.

### Treatment protocol

Management of chronic hepatitis B directed at suppressing the level of virus replication for patients who had HBV DNA detectable by hybridization assay and histological evidence of chronic hepatitis on liver biopsy. Interferon- $\alpha$  (IFN- $\alpha$ ) or lamivudine was used for treatment. IFN- $\alpha$  registered as a 16-wk course was given subcutaneously at a daily dose of 5 million units or thrice a week at a dose of 10 million units. Lamivudine was administered orally at a daily dose of 100 mg for 12 mo. No treatment was recommended for inactive "non-replicative" hepatitis B carriers. Control subjects had no evidence of hepatitis B infection.

### DNA isolation

Ten milliliters of venous blood was collected from each subject into tubes containing 50 mmol/L EDTA, and genomic DNA was isolated from anti-coagulated peripheral blood Buffy coat using Miller's salting-out method. All samples from cases and controls were handled in identical fashion as previously described<sup>[13]</sup>.

### Analysis of CTLA-4 gene polymorphisms

The presence of the CTLA-4 gene polymorphisms was determined by polymerase chain reaction (PCR) amplification refractory mutation system as previously described<sup>[6]</sup>.

### Statistical analysis

Allele and genotype frequencies among cases and controls were compared with values predicted by the Hardy-Weinberg equilibrium using the  $\chi^2$  test. All probability values were two-tailed. Distributions of alleles in patients and controls were compared using Fisher's exact test. The difference between susceptibility to hepatitis B was analyzed using Student's *t* test. A *P* value less than 0.05 was considered statistically significant. SPSS software version 11.05 was used for analysis.

## RESULTS

Of chronic hepatitis B group, 26 cases (12.9%) were asymptomatic carriers, 3 cases (1.5%) were chronic hepatitis B, 17 cases (8.5%) were chronic hepatitis B on first course of treatment, and 5 cases (2.5%) were non-responders to first course of treatment. In addition, 86.3% of chronic hepatitis B patients were HBeAg-negative. No significant difference was observed between the mean age of HBeAg-positive patients (34.8 years) and HBeAg-negative patients (36.4 years). Of the 44 HBeAg-negative chronic hepatitis B patients, 25 cases were inactive carriers, 12 cases had received treatment, 4 cases were non-responders and 3 patients were still on treatment ( $P < 0.0001$ ).

Distribution of genotype frequency of CTLA-4 +49,

**Table 1** Distribution of allele and genotype frequency of CTLA-4 +49, -318, -1172 polymorphisms in hepatitis B patients and controls

	Chronic hepatitis B <i>n</i> (%)	Controls <i>n</i> (%)
+49 genotype frequency ( $P=0.211$ )		
G+A-	9 (17.6)	41 (27.3)

C+	15 (29.4)	42 (28)
T+	49 (96.1)	150 (100)

-318, -1172 polymorphisms of hepatitis B patients and controls is shown in Table 1. We observed a significant association between genotype frequency of -318T<sup>+</sup>C<sup>+</sup> genotype and hepatitis B disease (19.6% *vs* 6.7%,  $P=0.012$ ). On the contrary, no obvious difference was observed between HBeAg positive or negative hepatitis B disease and frequency of either studied genotypes. Moreover, we found a significant association between -318 genotypes frequency (T+C-, T+C+, T-C+) and susceptibility to chronic hepatitis B ( $P=0.012$ , OR = 0.490, 95%CI: 0.206-1.162).

There was no other association between genotype frequency of other genotypes frequencies and hepatitis B disease. Mean AST and ALT activities were  $32.66 \pm 19.71$  and  $38.21 \pm 27.42$  IU/L (normal range, 5-30 U/L), respectively. We observed significant differences in the mean AST levels among the inactive carriers (21.34 IU/L), chronic hepatitis B on treatment (37.76 IU/L), chronic hepatitis B who had received treatment (74.4 IU/L), and non-responders to treatment (31 IU/L) ( $P<0.0001$ ). Moreover, significant differences were observed in the mean ALT levels among the inactive carriers (22.34 IU/L), chronic hepatitis B on treatment (45.7 IU/L), chronic hepatitis B who had received treatment (93 IU/L), and non-responders to treatment (42 IU/L) ( $P<0.0001$ ). The relation between frequency of genotypes of CTLA-4 49, -318, -1172 CTLA-4 polymorphisms and mean AST and ALT levels in subjects with chronic hepatitis, chronic hepatitis on first course of treatment, inactive carrier, and non-responders to first course of treatment is shown in Table 2.

Percutaneous liver needle biopsy was performed in 24 cases. Mean pathologic grade and stage were  $5.88 \pm 1.84$

**Table 2** Relation between frequencies of genotypes of CTLA-4 +49, -318, -1172 CTLA-4 polymorphisms and mean AST and ALT levels in subjects with chronic hepatitis, chronic hepatitis on first course of treatment, inactive carrier, non-responders to first course of treatment

	TC 1172 genotype	Mean	SE

	49 G-A+	35.3077	5.9497

and  $2.11 \pm 1.13$ , respectively and mean score was  $7.9 \pm 2.48$ . Mean histology score for 1172 T+C- genotype was 7.68 (95%CI: 6.4-8.9), for 1172 T+C+ genotype was 8.75 (95%CI: 4.9-12.5), for -318 T+C+ genotype was 8.25 (95%CI: 6.7-9.7), for -318 T-C+ genotype was 8.75 (95%CI: 6.5-9.11), for 49 A+G+ genotype was 8 (95%CI: 5-10.9), and for 49 A+G+ genotype was 7.7 (95%CI: 5.2-10.3).

Association between CTLA-4 +49, -318, -1172 polymorphisms, and state of disease in chronic hepatitis B patients is shown in Table 3. We observed a significant association between +49 genotypes (G+A-, G+A+, G-A+), and state of disease in chronic hepatitis B patients ( $P=0.043$ ). In contrast, no significant relation between -318 genotype frequency (T+C+, T+C-, T-C+), -1172 genotype frequency (C+T+, T+C-, C+T-) and state of disease was observed.

## DISCUSSION

In a study<sup>[14]</sup> to test the hypothesis that single-nucleotide polymorphisms (SNPs) in the gene encoding CTLA-4 may affect the vigor of the T-cell response to hepatitis B virus (HBV) infection and thus influencing viral persistence, they studied genotyped six CTLA-4 SNPs, from which all frequent haplotypes can be determined, using a large, matched panel of subjects with known HBV outcomes. Haplotypes with these SNPs were constructed for each subject using PHASE software. The haplotype distribution

**Table 3 Association between CTLA-4 +49 genotype polymorphism and state of disease in chronic hepatitis B patients**

			State of disease				Total

<sup>1</sup>*P* = 0.043.

differed between those with viral persistence and those with clearance. Two haplotypes were associated with the clearance of HBV infection, which were most likely due to the associations with the SNPs -1722C (OR = 0.60, *P* = 0.06) and +49G (OR = 0.73, *P* = 0.02). The wild-type haplotype, which contains a SNP leading to a decreased T-cell response (+6230A), was associated with viral persistence (OR = 1.32, *P* = 0.04). These data suggest that CTLA-4 influences recovery from HBV infection, which is consistent with the emerging role of T regulatory cells in the pathogenesis of disease. The results of the present study showed a difference in CTLA-4 -318 genotype distribution between subjects and controls. In this study, we have demonstrated a significant association between -318 genotypes frequency (T+C-, T+C+, T-C+) and susceptibility to chronic hepatitis B (*P* = 0.012), whereas there was no significant relation between -318 genotype frequency (T+C+, T+C-, T-C+) and -1172 genotype frequency (C+T+, T+C-, C+T-) and state of disease.

Chronic hepatitis B is either HBeAg positive or negative. In the population studies, HBeAg-negative (anti-HBe-reactive) was found more common than HBeAg-reactive chronic hepatitis B [44 (86.3%) *vs* 7 (13.7%), *P* = 0.082]. In this study population, mean levels of both AST and ALT were significantly higher in HBeAg-positive patients as compared with HBeAg-negative patients. HBeAg-negative chronic hepatitis B patients tend to have progressive liver injury, complicated more frequently by cirrhosis and hepatocellular carcinoma, episodic reactivation of liver disease and more refractory to antiviral therapy. Most such cases represent precore or core-promoter mutations. Patients with HBeAg-negative phenotype or precore mutants are unable to secrete HBeAg and tend to have severe liver disease<sup>[9]</sup>. Precore genetic mutant of HBV is associated with the more severe outcome of HBV infection; therefore, relative pathogenicity is a property of the virus, and not the host<sup>[9]</sup>. In this study, we did not regard the influence of viral effects, such as hepatitis D virus, hepatitis B virus DNA load and YMDD variants, on the susceptibility and outcome of hepatitis B. However, as most of our patients were HBeAg-negative, this predominance was seen in all states of disease composed of asymptomatic carriers, subjects still on treatment, non-responders and subjects who finished treatment.

In other studies, especially those discussing about autoimmune diseases, a greater association between polymorphisms of this gene and disease has been demonstrated<sup>[15-18]</sup>. The strong genetic associations so far in PBC are with chromosomes 6p21.3 and 2q and include HLA DRB1\*08 haplotypes, CTLA-4 G and IL1RN-IL1B haplotypes, CASP8, and nramp1. It is unlikely that only genes that influence disease susceptibility and progression in primary biliary cirrhosis (PBC) are immunoregulatory genes concerned with T-cell immunity. Recent studies have indicated a new era for immunogenetics, when genes encoding all immune active proteins may be considered as candidates. One should not concentrate solely on the immune response as recent investigations of mannose binding lectin and apolipoprotein-E have been testified. The authors stated the key issues for future investigators include defining the mechanisms whereby self tolerance is broken, defining the mechanisms that determine the rate of disease progression, and identifying genetic markers to predict progression and malignancy, and assessing the genetic basis of variability in disease progression. The significant variation in the rate of progression of PBC has led to the hypothesis that genes, in addition to contributing to disease susceptibility, may also determine the rate of disease progression. Several of the studies mentioned earlier have suggested associations between alleles at polymorphic loci and rate of progression. One problem inherent in such studies is that of definition of disease progression<sup>[15]</sup>. PBC is an autoimmune cholestatic liver disease thought to be developed through a complex interaction of genetic and environmental factors. It is characterized by T-cell-mediated non-suppurative destructive cholangitis. We have studied the polymorphic CTLA-4 gene, which encodes a molecule that is a vital negative regulator of T-cell activation, as a candidate susceptibility locus for PBC. This gene on chromosome 2q33 (designated IDDM12) is associated with susceptibility to both type 1 diabetes and autoimmune thyroid disease. The CTLA-4 exon 1 polymorphism (A/G encoding for threonine or alanine, respectively) was genotyped via PCR in 200 Caucasoid PBC patients and 200 non-related geographically matched Caucasoid controls. There was a significant over-representation of the G/A and G/G genotypes in PBC patients as compared with controls. Likewise, there was a significant difference in

allele frequencies. This association remained significant ( $P=0.00027$ ) when patients with autoimmune thyroid disease were excluded from the analysis. Thus, it was concluded that the CTLA-4 exon 1 polymorphism is the first non-major histocompatibility complex gene to be identified as a susceptibility locus for PBC. The data support the hypothesis that clinically distinct autoimmune disease may be controlled by a common set of susceptibility genes<sup>[16]</sup>.

Latent autoimmune diabetes in adults (LADA) is identified by the presence of GAD65 autoantibodies in diabetic patients who do not require insulin treatment for at least 6 mo after the diagnosis. Previous studies have shown that the risk for LADA, similarly to type 1 diabetes mellitus (T1DM), is increased in subjects carrying the HLA-DRB1\*03-DQA1\*0501-DQB1\*0201 and/or HLA-DRB1\*04-DQA1\*0301-DQB1\*0302 haplotypes. Moreover, it has been investigated the association between LADA and the CTLA-4 A/G polymorphism, another gene polymorphism associated with T1DM and other autoimmune diseases. The heterozygous A/G genotype was significantly more frequent among 80 LADA (69%) than among 85 healthy subjects of similar age and geographical provenience (47%) (OR = 2.47, corrected  $P=0.023$ ). Conversely, the homozygous A/A genotype was significantly less frequent in LADA subjects compared to healthy controls (26% *vs* 47%, OR = 0.4, corrected  $P=0.028$ ). The results of our study showed that LADA was positively associated with the CTLA-4 A/G genotype, similarly to T1DM, thus providing further supporting evidence of the autoimmune origin of this form of diabetes mellitus in adults<sup>[17]</sup>. The CTLA-4 molecule plays an important role in immune regulation by down-regulating activation of T cells by antigen-presenting cells. Polymorphisms of the CTLA-4 gene have been shown to be associated with susceptibility to a number of autoimmune diseases. Some, but not all, studies suggest the association between the CTLA-4 gene and autoimmune hypothyroidism. The aim of this study was to determine whether allelic association was present between the A-G SNP at position 49 in exon 1 of the CTLA-4 gene and autoimmune hypothyroidism. The study was performed in 158 patients with autoimmune hypothyroidism and 384 control subjects. All subjects were white Caucasians from UK. There was a significant excess of the G allele in patients with autoimmune hypothyroidism as compared with controls. The GG and the AG genotypes were found to be more frequent in patients with autoimmune hypothyroidism than controls. These results suggested that the CTLA-4 gene region on chromosome 2q33 is a susceptibility locus for autoimmune hypothyroidism<sup>[18]</sup>.

In conclusion, in the population that was studied, there is a significant difference in the frequencies of the -318 CTLA-4 gene polymorphisms (T<sup>+</sup>C<sup>-</sup>, T<sup>+</sup>C<sup>+</sup>, T<sup>-</sup>C<sup>+</sup>) and susceptibility to chronic hepatitis B between controls and patients with hepatitis B. This association supports that this gene is partially the operating mechanism for genetic susceptibility to hepatitis B disease.

However, current knowledge of the genetic basis of susceptibility to hepatitis B is incomplete. Further investigations should be considered with caution until

it is confirmed in independent large series. Elucidating predisposing genetic associations will markedly assist in understanding the susceptibility and pathophysiology of disease, the possibility of identifying the susceptibility of patients who are at elevated risk to hepatitis B infection or are in the early stages of disease or more rapid progression course of disease, would have obvious clinical benefit in terms of patient management and therapy.

### Abstract

**AIM:** To evaluate the hepatoprotective effect of garlic on liver injury induced by isoniazid (INH) and rifampicin (RIF).

**METHODS:** Wistar rats weighing 150-200 g were treated orally with 50 mg/kg of INH and RIF daily each for 28 d. For hepatoprotective studies, 0.25 g/kg per day of freshly prepared garlic homogenate was administered orally half an hour before the INH+RIF doses. Serum alanine aminotransferase (ALT), aspartate aminotransferase (AST) and bilirubin were estimated on d 0, 14, 21, and 28 in all the rats. Histological analysis was carried out to assess the injury to the liver. Lipid peroxidation (LPO) as a marker of oxidative stress and non-protein thiols (glutathione) for antioxidant levels were measured in liver homogenate.

**RESULTS:** The treatment of rats with INH+RIF (50 mg/kg per day each) induced hepatotoxicity in all the treated animals as judged by elevated serum ALT, AST, and bilirubin levels, presence of focal hepatocytic necrosis (6/8) and portal triaditis (8/8). Garlic simultaneously administered at a dose of 0.25 g/kg per day prevented the induction of histopathological injuries in INH+RIF co-treated animals, except in 4 animals, which showed only moderate portal triaditis. The histological changes correlated with oxidative stress in INH+RIF treated animals. The group which received 0.25 g/kg per day garlic homogenate along with INH+RIF showed higher levels of glutathione ( $P < 0.05$ ) and low levels of LPO ( $P < 0.05$ ) as compared to INH+RIF treated group.

**CONCLUSION:** Freshly prepared garlic homogenate protects against INH+RIF-induced liver injury in experimental animal model.

### INTRODUCTION

Tuberculosis (TB) is one of the most common infectious diseases. In India, pulmonary tuberculosis is one of the major causes for adult deaths<sup>[1]</sup>. INH and RIF, the first line drugs used for tuberculosis chemotherapy, are associated with hepatotoxicity<sup>[2]</sup>. The rate of hepatotoxicity has been reported to be much higher in developing countries like India (8%-30%) compared to that in advanced countries (2%-3%) with a similar dose schedule<sup>[3]</sup>. We have established in our laboratory oxidative stress as one of the mechanisms for INH+RIF-induced hepatic injury<sup>[4]</sup>. Majority of normally formed free radicals are removed by the action of reduced glutathione. In circumstances where there is a reduction in glutathione results in the initiation of lipid peroxidation (LPO) resulting in tissue injury<sup>[5]</sup>. Garlic, an antioxidant, has been shown to inhibit LPO<sup>[6]</sup> and dose-dependent induction of endogenous antioxidants in rat kidney and liver<sup>[7]</sup>. Hence this protocol was designed to study the protective effect of garlic on INH+RIF-induced liver injury in Wistar rats.

### MATERIALS AND METHODS

#### Materials

Wistar rats weighing 150-200 g body were used in the study. The protocol was approved by the Institute's Animal Ethical Committee. Body weights of these rats were monitored sequentially in control and experimental animals for a period of 28 d. Animals were divided into four groups as control ( $n=8$ ), INH+RIF ( $n=8$ ), garlic ( $n=8$ ), and INH+RIF+garlic ( $n=12$ ) where  $n$  was the number of animals included in the study.

For hepatotoxic model, 50 mg/kg per day of INH and RIF each was used in the study<sup>[8]</sup>. INH and RIF solutions were prepared separately in sterile distilled water. The pH of RIF solution was adjusted to 3.0 with 0.1 mol/L HCl<sup>[9]</sup>.

INH and RIF were administered orally for 28 d. Liver transaminases and bilirubin were estimated on d 0, 14, 21, and 28 in both control (saline treated) and experimental animals. The criteria for hepatotoxicity were the presence of histological changes such as hepatocytic necrosis and portal triaditis along with elevated transaminases (more than thrice the upper normal limit). For the hepatoprotective model, 0.25 g/kg per day of freshly prepared garlic homogenate along with INH+RIF solution was administered<sup>[10]</sup>.

For the preparation of fresh garlic homogenate, garlic bulbs were purchased from a local supermarket, cut into small pieces and homogenized in a motor-driven Teflon glass homogenizer on ice.

### Methods

Rats were killed after the INH+RIF and garlic treatment. Representative blocks of liver were taken and fixed in 40g/L formaldehyde. Light microscopic examination of the liver was done on sections stained with (H) and (E). Special stains like reticulin and Ziehl Nielsen for acid fast bacilli were carried out whenever necessary. Various slides of different groups (two slides per animal) containing full cross-sections of the major hepatic lobules were prepared.

Twelve hours after the last oral treatment, rats were killed by cervical dislocation. Liver was excised immediately, quickly cooled and perfused with cold normal saline. Ten percent homogenate was prepared by homogenizing the liver tissue in 100 mmol/L potassium phosphate, 150 mmol/L potassium chloride buffer containing 200g/L glycerol (pH 7.5). LPO in tissue homogenate was measured by the reaction of LPO products like malondialdehyde (MDA) with thiobarbituric acid by the method of Kornbrust and Mavis<sup>[11]</sup>.

Estimation of thiols (non-protein thiols) was carried out in tissue homogenate according to the method of Sedlak and Lindsay<sup>[12]</sup>. Protein estimation was done by the method of Lowry *et al.*<sup>[13]</sup>.

### Statistical analysis

Data were analyzed by analysis of variance (ANOVA) followed by multiple comparisons using Dunnett's procedure to compare all groups against control, Student-Newman-Keuls procedure was used to compare all the groups' pair wise.

## RESULTS

There was no mortality in any of the groups. The body weight and relative liver weights of the experimental animals calculated at the end of the study had no statistically significant difference when compared to the control animals (Table 1).

Three-fold rise above the normal upper limits in the measured serum transaminases in INH+RIF group on d 28 of the experiment was a biochemical indication of liver injury. Garlic-treated and control animals had normal values of transaminase (Table 2). However, there was a significant increase in serum bilirubin in all the animals of INH+RIF group (Table 2) and in four animals of INH+RIF+garlic group in whom histological changes

<sup>a</sup>P<0.05 vs INH + RIF; <sup>b</sup>P<0.01 vs Control and Garlic.

were present. Serum bilirubin was not significantly different in control, garlic and INH+RIF+garlic groups in whom histological changes were not present at the end of the study.

The treatment of rats with INH+RIF (50 mg/kg per day each) induced hepatotoxicity in all the treated animals as judged by elevated serum ALT, AST, and bilirubin levels, portal triaditis (8/8) and liver necrosis (Figure 1A and 1B). Simultaneously administered garlic at a dose of 0.25 g/kg per day prevented the induction of histopathological injuries in INH+RIF co-treated animals (8/12), except in four animals, who showed only moderate portal triaditis (Figure 1C).

The INH+RIF-administered animals exhibited significantly low levels of hepatic non-protein thiols ( $P<0.01$ ) as compared to control (Table 3) and co-administration of garlic and INH+RIF showed increased levels in hepatoprotected group as compared to control ( $P<0.01$ ). Fresh garlic homogenate by itself did not affect hepatic non-protein thiols significantly as compared to control. Treatment with INH+RIF depleted significantly the content of non-protein thiols as compared to control ( $P<0.001$ , Table 3). Co-administration of freshly prepared garlic homogenate maintained its levels in the liver protected group although less than that in the control group ( $P<0.05$ ).

**Figure 1** Normal morphology (A), hepatocytic necrosis (B) and portal triaditis (C) in control, INH + RIF and INH + RIF + garlic groups (H E  $\times$  55).

The treatment with INH+RIF significantly enhanced the peroxidation of lipids ( $P < 0.01$ ) and co-administration of freshly prepared garlic homogenate blocked the induction of LPO caused by INH+RIF treatment. Freshly prepared garlic homogenate-treatment alone did not reduce the LPO levels (Table 3) in rats.

## DISCUSSION

In the present study, hepatotoxicity model in Wistar rats was successfully produced by administering INH and RIF (50 mg/kg per day each) orally. The protective effect of 0.25 g/kg per day freshly prepared garlic homogenate on INH+RIF induced liver injury in rats was evaluated as previously described<sup>[8]</sup>. We did not study the metabolites of administered dose of garlic in the blood of INH+RIF-treated rats because absorption and metabolism of allicin-derived compounds are only partially understood. Allicin and allicin-derived compounds, including diallyl sulfides (DAS), ajoene and vinylthiins have never been detected in human blood, urine or stools even after the consumption of fresh garlic up to 25 g or 60 mg of pure allicin<sup>[14]</sup>.

Garlic bulb contains approximately 65% water, 28% carbohydrates (mainly fructans), 2.3% organosulfur compounds, 2% protein (mainly alliinase), 1.2% free amino acids (mainly arginine) and 1.5% fiber. Intact garlic bulbs contain a high amount of  $\gamma$ -glutamylcysteine. These reserve compounds can be hydrolyzed and oxidized to form alliin, which accumulates naturally during storage of garlic bulbs at cool temperature. After various kinds of processing, such as cutting, crushing, chewing or dehydration, the vacuolar enzyme, alliinase, rapidly lyses cytosolic cysteine sulfoxides (alliin) to form the odoriferous alkyl alkane-thiosulfinates such as allicin. Allicin and other thiosulfinates instantly decompose to other compounds, such as DAS, diallyl disulfide (DADS), and diallyltrisulfide (DATS), dithiins and ajoene. At the same time,  $\gamma$ -glutamylcysteines are converted to S-allyl cysteine (SAC) via a pathway other than the alliin/allicin pathway<sup>[15]</sup>.

Garlic has been found to have an important dietary and medicinal role for centuries. Most of its prophylactic and therapeutic effects are ascribed to specific oil and water soluble organosulfur compounds. Thiosulfinates and other secondary metabolites of garlic, including

steroids, terpenoids, flavonoids and other phenols, may be responsible for reported therapeutic effects of garlic. Reuter *et al*<sup>[16]</sup> have reviewed the therapeutic effects of garlic on cardiovascular system as well as its antibiotic, anticancer, antioxidant, immunomodulatory, anti-inflammatory, hypoglycemic and hormone-like effects. Garlic also increases anti-inflammatory monocyte IL-10 production and decreases proinflammatory cytokines such as TNF- $\alpha$ , IL-1 $\beta$ , IL-6, IL-8, T cell interferon gamma, IL-2<sup>[17]</sup>.

Garlic, a natural substance, has also been shown to inhibit LPO<sup>[18]</sup>. Phytochemicals from plant rich diets (including garlic) provide an important additional protection against oxidative damage<sup>[19]</sup>. There are a variety of antioxidants in garlic, which protect against disease-causing oxidative damage<sup>[20]</sup>. Garlic and related organosulfur compounds have antioxidant, detoxifying and other properties. These detoxifying effects are related to their ability to inhibit phase I enzymes and induce phase II enzymes or bind to exogenous toxins through sulfhydryl groups<sup>[21]</sup>. Previous studies on the mechanism of INH+RIF-induced hepatotoxicity have shown that non-protein thiols play a very important role in the detoxification of reactive toxic metabolites of INH+RIF. Liver injury has been observed when glutathione stores are markedly depleted<sup>[22]</sup>. The present study has further strengthened the protective role of garlic in INH+RIF-induced hepatic non-protein thiol depletion. These observations may be due to the inhibition of bioactivation of INH+RIF metabolites resulting in the decreased formation of INH electrophiles. A similar protective role of garlic has been documented in acetaminophen-induced hepatotoxicity<sup>[23]</sup>.

Non-protein thiol is an important defense mechanism in living cells. As a substrate for antioxidant enzymes, i.e. glutathione peroxidase and glutathione reductase, it protects cellular constituents from the damaging effects of peroxidase formed in metabolism and other reactive oxygen species reactions. Aged garlic extract increases cellular glutathione in a variety of cells including those in normal liver and mammary tissue<sup>[24]</sup>. In the present study, the oxidative injury induced by INH and RIF could be prevented by fresh garlic homogenate. Thus this study represents a novel and an attractive idea to prevent INH+RIF-induced hepatic injury by co-administration of fresh garlic homogenate.

## Abstract

**AIM:** To analyze oncological outcome of intersphincteric resection (ISR) in ultra-low rectal cancer with intent to spare colostoma.

**METHODS:** From 1995 to 1998, patients with a non-fixed rectal adenocarcinoma (tumor stage T2) preserving the lower margin at 1-3 cm above the dentate line without distant metastasis was enrolled (period I). ISR was practiced in eight patients, and their postoperative follow-up was at least 5 years. In addition, from 1999 to 2003, another 10 patients having the same tumor location as period I underwent ISR (period II). Among those, 6 patients with T3-4-staged tumor received preoperative chemoradiotherapy.

**RESULTS:** All patients received ISR with curative intention and no postoperative mortality. In these case series at period I, local recurrence rate was 12.5% and metastasis rate 25.0%; the 5-year survival rate was 87.5% and disease-free survival rate 75.0%. There was no local recurrence or distant metastases in 10 patients with a median follow-up of 30 (range, 18-47) mo at period II.

**CONCLUSION:** As to ultra-low rectal cancer, intersphincteric resection could provide acceptable local control and cancer-related survival with no permanent stoma in early-staged tumor (tumor stage T2); moreover, preoperative concurrent chemoradiotherapy would make ISR feasible with surgical curative intent in more advanced tumors (tumor stages T3-4).

intersphincteric resection for ultra-low rectal cancer. *World J Gastroenterol* 2006; 12(4): 640-643

## INTRODUCTION

In earlier ages, tumors within 7-8 cm above the anal verge were treated by abdominoperineal resection (APR), especially when the rectal tumor could be easily palpated by an examiner's finger.

Along with the recent development of circular stapling devices, it facilitates the feasibility of ultra-low anterior resection of rectal tumor. Recent studies have shown that a distal clearance margin greater than 1.5 cm is sufficient when tumor histological differentiation is not poor to achieve curative resection of low rectal tumors<sup>[1]</sup>. These have established the feasibility of ultra-low anterior resection for tumors at level as low as 3 cm from the dentate line.

For the ultra-low tumors, i.e., tumor with lower margin situated within 1-3 cm above the dentate line, the mandatory surgical procedure is still controversial. It is hardly practical to apply conventional ultra-low anterior resection with autosuture instrumentation to achieve an adequate section margin, because of the extreme difficulty in placing a stapler across the optimal distal rectal margin. While most surgeons insist in performing APR in these cases, intersphincteric resection (ISR) has drawn increasing attention as it provides anus preservation and more clear vision for resection.

Many retrospective studies have pointed out that there is a good local control after sphincter-saving resection for rectal cancer<sup>[2-11]</sup>; however, the majority of studies did not carry more than the 5-year follow-up interval and they examined all rectal tumors, many of which can be removed by low/ultra-low anterior resection. This study assessed the oncological outcome of patients with very low rectal cancer by intersphincteric resection to determine whether abdominoperineal resection could be abolished.

## MATERIALS AND METHODS

### Patients

There were two distinct periods in the present study. During period I, from January 1995 to December 1998, eight consecutive patients having a non-fixed rectal adenocarcinoma (tumor stage T2) without distant metastasis

© 2006 The WJG Press. All rights reserved.

**Key words:** Intersphincteric resection; Ultra-low rectal cancer

Chin CC, Yeh CY, Huang WS, Wang JY. Clinical outcome of

were enrolled. All tumors were smaller than 5 cm in maximal diameter and the lower margin was within 1-3 cm from the dentate line. Each patient underwent ISR. Post-operative follow-up interval was over 5 years. During period II, from January 1999 to December 2003, 10 patients with ultra-low rectal adenocarcinoma underwent ISR. Among those, six patients with T3-4 tumors received preoperative concurrent chemoradiotherapy (CCRT). The median follow-up time was 30 (range, 18-47) mo.

### Methods

ISR was performed according to the methods previously described by Schiessel *et al*<sup>[4]</sup>. This procedure was initiated by placing the patient in the Sim's position for the anal approach, mucosal incision, further exposure of the internal anal sphincter and intersphincteric space. After meticulous hemostasis was reached in the operation field, followed by closure of the rectal stump, and the patient was placed in lithotomy position to facilitate low anterior resection of the rectum with total mesorectal excision by laparotomy. A colonic J-pouch in all the patients as 6-8 cm in length was constructed from the distal descending colon and/or proximal sigmoid colon with uniform linear staplers. Mobilization of the splenic flexure colon, descending colon, sigmoid colon and ligation of the inferior mesenteric vein at the inferior margin of the pancreas are critical components of this procedure to enable the pouch to be easily drawn toward the anus. The constituted reservoir was then anastomosed to the dentate line with interrupted sutures. Under direct vision, the external anal sphincter was preserved to maintain defecation function.

During period II, ISR was performed on 10 patients with the same tumor location as period I. Among those, six patients with fixed tumors (T3-4) underwent preoperative CCRT (5 040 cGy in 28 fractions over 6 wk with continuous infusion of 5-FU and LV on the first and last 5 d during radiotherapy).

All patients in period I and period II were performed temporary diverting colostomy. Follow-up evaluations were performed on an outpatient basis. As to that whether tumor recurrence or distant metastasis existed, it was determined by digital rectal examination, clinical symptoms, measurement of serum tumor marker level and image study facilities.

## RESULTS

### Clinical and pathological data

There were eight patients enrolled in the period I from 1995 to 1998, 2 males and 6 females, median age was 61 years (range: 44-79 years). Pathologic staging as TNM categorization for these 8 patients comprised 7 T2N- and 1 T2N+. On the other hand, there were 10 patients recruited in the period II since 1999 till 2003, 5 males and 5 females, median age was 62 (range: 42-72) years. No statistic difference in age or gender between period I and period II was proved (Table 1).

Among the period II group, six patients with fixed tumors were undertaken by the protocol of preoperative CCRT (5 040 cGy in 28 fractions over 6 wk concurring

Table 1 Characteristics of cases

	Period I 1995-01/1998-12	Period II 1999-01/2003-12
Number of patients	8	10
Male	2	5
Female	6	5
Age range (yr)	44-79 (median 61)	42-72 (median 62)
Follow-up (mo)	60	18-47 (median 30)
Tumor		
Non-fixed (T2)	8	4
Fixed (T3-4)	0	6 (pre-operative CCRT)

Table 2 Pathologic results

Clinical stage	Period I (n = 8)	Period II (n = 10)	
	T2Nx (n = 8)	T2Nx (n = 4)	T3-4Nx (n = 6) CCRT
T0	0	0	2
T1N0	0	0	1
T2N0	7	3	2
T2N1	1	1	0
T3Nx	0	0	1 (T3N1)

with continuous infusion 5-FU and LV on the first and last 5 d during radiotherapy). In comparing the tumor staging between pre- and post-CCRT, there were seven patients with a significant tumor regression status, including two complete regressions. Pathologic TNM classifications for the 10 patients were 2 T0, 1 T1N-, 5 T2N-, 1 T2N+ and 1 T3N+ (Table 2).

Regardless of period I or period II, curative resection of malignancy with microscopically clear oncologic section margin was confirmed by postoperative pathologic diagnosis in all the patients. The median distal resection margin was 1.5 (range: 0.5-2) cm. There was no postoperative mortality. Postoperative morbidity was found as follows: wound infection in 4/18 (22.2%), prolonged Foley catheter indwelling in 3/18 (16.7%), and urinary tract infection in 2/18 (11.1%).

All patients underwent interval colostomy closure at a median of 7 (range, 3-14) mo, no colostomy closure-related complication was proposed.

### Postoperative local recurrence and distant metastasis

In the period I group, there were two patients who developed local recurrence/metastasis after at least a 5-year follow-up; it was comprised of local recurrence with multiple liver metastases in one patient and multiple lung metastases in another patient. Local recurrence rate was 12.5% and metastasis rate 25.0%; the 5-year survival rate was 87.5% and disease-free survival rate 75.0%. In the period II group, there was no local recurrence or distant metastasis in these 10 patients after a median follow-up of 30 (range: 18-47) mo (Table 3).

### Functional outcome

None of the patients in the period I group could be traced for functional evaluation, but we appraised bowel function in the period II group by patient themselves using self-

Table 3 Recurrence, metastasis and survival

	Period I (n = 8)	Period II (n = 10)
Follow-up (mo)	>60	18-47 (median 30)
Local recurrence	1/8 (12.5%), 12 mo after operation	-
Distant metastasis	2/8 (25%)	
Liver	1/8, 52 mo after operation	
Lung	1/8, 25 mo after operation	
Survival rate	7/8 (87.5%)	100%
Disease-free survival rate	6/8 (75.0%)	100%

confession method in one year later after the colostomy being closed. Eight patients (80%) experienced six or fewer bowel movements per day, urgency was reported in 5 patients (50%), and most of them could tolerate anal continence status well. Only two patients stated that they were incontinent to liquid stools and required pad use at night time (Table 4).

## DISCUSSION

The distal section margin of 1-2 cm would be currently considered sufficient for ultra-low rectal cancer in most instances<sup>[1,5,7,8]</sup>. Parks *et al*<sup>[12]</sup> reported that long-term survival and local recurrence rate after ISR were similar to those after APR. Several specialized studies have investigated ISR for low rectal cancer, and their local recurrence rates ranged from 0% to 12%<sup>[2-11]</sup>; however, some studies reported that the patients with the location of rectal cancer at 5 cm more proximal to anal verge and did not always carried more than a 5-year follow-up interval. In this study, the local recurrence rate was 12.5% for T2-staged ultra-low rectal tumor after at least a 5-year follow-up. However, the number of patients in this study is small because of the highly selected criteria, size of the tumors smaller than 5 cm and the lower margin of tumors within 1 to 3 cm from the dentate line.

The radial involvement of a tumor is another critical predictive factor for local recurrence after rectal cancer resection. In most instances, patients with T3-4 carcinomas of the low-third rectum require APR. Recently, by using a multimodal approach, intersphincteric resection was practical in patients with T3-4 carcinomas of the lower third of the rectum<sup>[7,10,11,13-15]</sup>.

Preoperative CCRT reducing tumor volume, causing tumor down-staging, and further facilitating surgical resection of malignancy have been proposed. Recent studies concerning preoperative chemoradiotherapy have demonstrated that it improves local control and cancer-related survival. Rullier *et al*<sup>[10]</sup> reported only 2% (1/43) local recurrence rate if combining preoperative CCRT and successive ISR for ultra-low rectal cancer were attempted (median follow-up was 30 mo)<sup>[10]</sup>. Luppi *et al*<sup>[13]</sup> reported 94% local control rate for T3-4 rectal cancer using preoperative chemoradiotherapy<sup>[13]</sup>. Saito *et al* reported similar results for local control and acceptable anal function in a series of 35 patients (median follow-up: 23 mo), these patients had T3-staged ultra-low rectal cancer and were

Table 4 Functional outcome of patients in period II

	Period II (n = 10, %)
Stool frequency: ≤3	5/10 (50)
4-6	3/10 (30)
7-9	1/10 (10)
≥10	1/10 (10)
Urgency	5/10 (50)
Continence: Perfect	3/10 (30)
Incontinence of flatus	2/10 (20)
Minor soiling to liquids	3/10 (30)
Major soiling to liquids	2/10 (20)
Incontinence to solids	0/10 (0)

treated by preoperative CCRT with consecutive ISR<sup>[7]</sup>.

In the past 4 years, 10 patients with ultra-low rectal cancer were managed in this study by multimodality treatment and no distant metastasis was disclosed during the follow-up period. Preoperative CCRT was applied to six T3-4 staged patients, and this treatment enhanced tumor shrinkage more than 25% in five patients; it is inspiring that no residual cancer was identified in 2 patients among these 5 patients. After a median follow-up of 30 mo, there was no local recurrence or distant metastasis developed.

Cluster defecation associated with tenesmus, urgency, and incontinence are not uncommon in straight coloanal anastomosis. The colonic pouch could convert the functional deficiencies associated with the loss of rectal capacity and reduced compliance resulting from straight coloanal anastomosis. Lazorthes *et al*<sup>[16]</sup> and Parc *et al*<sup>[17]</sup> conducted a colonic J pouch anastomosing at the dentate line, and they assumed superior functional outcome compared to straight anastomosis<sup>[16,17]</sup>. A number of clinical series have evidence to support that utilizing a colonic pouch anal anastomosis could enhance the functional results and postoperative quality of life of patients after rectal cancer resection<sup>[16-19,21,22]</sup>. The functional advantages of a colonic pouch anal anastomosis have been achieved within a shorter period than straight coloanal anastomosis after surgery. This superiority in J pouch groups remains evident when compared with the straight coloanal anastomosis 2 years after the surgery as reported by Joo *et al*<sup>[21]</sup> and Sailer *et al*<sup>[22]</sup>.

Optimal pouch size remains unclear. Numerous J pouch sizes have been attempted, ranged from 5 to 12 cm in length. Increasing pouch length is always associated with incomplete evacuation and requires suppositories or enemas to rescue such sufferings. Parc recommended an adequate limb length of 8-10 cm<sup>[17]</sup>. Hida *et al*<sup>[20]</sup> proposed that a 5-cm pouch could function as adequate reservoir, and it is technically easy with requiring not too long a segment of bowel for construction<sup>[20]</sup>. Clinical experience to date favors that the optimal pouch is achieved by employing two 6-7 cm limbs of the colon. In this study, a 6-8 cm pouch was constructed and harvested proper functional outcome. During the time the colonic Jpouch was constituted, the distal colon must be mobilized and adequate perfusion should be preserved to prevent complications such as mobilized colon ischemic change or

anastomotic insufficiency. We believe that these standard surgical issues have facilitated the achievement of tolerable functional results.

In conclusion, ISR could achieve acceptable local control, cancer-related survival and avoid permanent stoma in patients with early staged ultra-low rectal cancer. Preoperative CCRT facilitates intersphincteric curative resection in patients with T3-4 staged ultra-low rectal cancer. Longer follow-up of these patients should be recommended, especially for those receiving preoperative chemoradiotherapy.

## Abstract

**AIM:** To explore the role of transforming growth factor-beta1 (TGF- $\beta$ 1)-smad signal transduction pathway in patients with hepatocellular carcinoma.

**METHODS:** Thirty-six hepatocellular carcinoma specimens were obtained from Qidong Liver Cancer Institute and Department of Pathology of the Second Affiliated Hospital of Nanjing Medical University. All primary antibodies (polyclonal antibodies) to TGF- $\beta$ 1, type II Transforming growth factor-beta receptor (T $\beta$ R-II), nuclear factor-kappaB (NF- $\kappa$ B), CD34, smad4 and smad7, secondary antibodies and immunohistochemical kit were purchased from Zhongshan Biotechnology Limited Company (Beijing, China). The expressions of TGF- $\beta$ 1, T $\beta$ R-II, NF- $\kappa$ B, smad4 and smad7 proteins in 36 specimens of hepatocellular carcinoma (HCC) and its adjacent tissue were separately detected by immunohistochemistry to observe the relationship between TGF- $\beta$ 1 and T $\beta$ R-II, between NF- $\kappa$ B and TGF- $\beta$ 1, between smad4 and smad7 and between TGF- $\beta$ 1 or T $\beta$ R-II and microvessel density (MVD). MVD was determined by labelling the vessel endothelial cells with CD34.

**RESULTS:** The expression of TGF- $\beta$ 1, smad7 and MVD was higher in HCC tissue than in adjacent HCC tissue ( $P < 0.01$ ,  $P < 0.05$ ,  $P < 0.01$  respectively). The expression of T $\beta$ R-II and smad4 was lower in HCC tissue than in

its adjacent tissue ( $P < 0.01$ ,  $P < 0.05$  respectively). The expression of TGF- $\beta$ 1 protein and NF- $\kappa$ B protein was consistent in HCC tissue. The expression of TGF- $\beta$ 1 and MVD was also consistent in HCC tissue. The expression of T $\beta$ R-II was negatively correlated with that of MVD in HCC tissue.

**CONCLUSION:** The expressions of TGF- $\beta$ 1, T $\beta$ R-II, NF- $\kappa$ B, smad4 and smad7 in HCC tissue, which are major up and down stream factors of TGF- $\beta$ 1-smad signal transduction pathway, are abnormal. These factors are closely related with MVD and may play an important role in HCC angiogenesis. The inhibitory action of TGF- $\beta$ 1 is weakened in hepatic carcinoma cells because of abnormality of TGF- $\beta$ 1 receptors (such as T $\beta$ R-II) and postreceptors (such as smad4 and smad7). NF- $\kappa$ B may cause activation and production of TGF- $\beta$ 1.

## INTRODUCTION

Hepatocellular carcinoma is one of the most common malignant tumors in the world. Recent studies have demonstrated that the key factor of invasiveness and metastasis of HCC is neovascularization. There are two kinds of factors in adjusting neovascularization, one is positive adjusting factors, such as vascular endothelial cell growth factor (VEGF), hepatocellular growth factor (HGF), transforming growth factor alpha (TGF- $\alpha$ ), epidermal growth factor (EGF). The other kind includes negative adjusting factors, such as transforming growth factor beta (TGF- $\beta$ ). Synthesis of TGF is adjusted by nucleus transcription factors, such as NF- $\kappa$ B. This study was designed to investigate the significance and mechanism of TGF- $\beta$ 1-smad signal transduction pathway in hepatocellular carcinoma (HCC).

## MATERIALS AND METHODS

### Materials

Thirty-six HCC specimens were obtained from Qidong Liver Cancer Institute and Department of Pathology of the Second Affiliated Hospital of Nanjing Medical University. All primary antibodies (polyclonal antibodies) to TGF- $\beta$ 1, T $\beta$ R-II, NF- $\kappa$ B, CD34, smad4 and smad7 and secondary antibodies were purchased from Zhongshan Biotechnology Limited Company (Beijing, China).

### Methods

Each specimen was cut into 4- $\mu$ m thick sections. Tissue wax sections were unfolded on glass sheet. Immunohistochemistry (streptol-biotin-peroxidase method) was used to detect the expression of TGF- $\beta$ 1, T $\beta$ R-II, NF- $\kappa$ B, CD34, smad4 and smad7. Briefly, paraffin-embedded tissue sections were dewaxed, treated with 3% H<sub>2</sub>O<sub>2</sub> at 37 °C, washed with PBS, incubated with TGF- $\beta$ 1, T $\beta$ R-II, NF- $\kappa$ B, CD34, smad4 and smad7 antibodies separately, washed with PBS for 15 min, incubated again with streptol-biotin-peroxidase at 37 °C. Finally, the sections were washed with PBS for 15 min, visualized with DAB reagent and counterstained with hematoxylin. Negative and positive controls were used simultaneously to ensure specificity and reliability of the staining process. The negative controls were incubated with PBS instead of primary antibody and a positive section supplied by the manufacturer of the staining kit was taken as positive control. Sections were observed under microscope after being mounted. All positive sections were analyzed with RY2000 analysis system. Microvessel density (MVD) was measured as previously described [1]. High vessel density was found in 100 $\times$  sights. Microvessels in five regions were counted in 400 $\times$  sights, the average of microvessels with CD34 staining in

five regions was calculated as MVD.

### Result judgement

The buffy staining of cell membrane, plasma or nuclei was considered positive staining of TGF- $\beta$ 1, T $\beta$ R-II, NF- $\kappa$ B, smad4 and smad7 (Figures 1A and 1B). Positive staining of CD34 was considered as microvessels (Figure 1C).

### Statistical analysis

The data were expressed as mean  $\pm$  SD. Chi-square test and  $t$  test were used.  $P<0.05$  was considered statistically significant. Kappa value was regarded as consistency degree.

## RESULTS

### Expressions of TGF- $\beta$ 1 and T $\beta$ R-II in HCC and its adjacent tissue

Different expressions of TGF- $\beta$ 1, T $\beta$ R-II were observed in HCC and its adjacent tissue. There was a significant difference in the positive expressions of TGF- $\beta$ 1, T $\beta$ R-II between HCC and its adjacent tissue (Table 1).

### Relationship between expressions TGF- $\beta$ 1 and T $\beta$ R-II in HCC tissue

The positive expression rate of both TGF- $\beta$ 1 and T $\beta$ R-II was 27.78% (10/36) and their negative expression rate was 11.11% (4/36). The total rate was 38.89% (14/36). The discrepancy between expressions of TGF- $\beta$ 1 and T $\beta$ R-II was 61.11% (22/36). The consistency degree in statistical test was weak (kappa = 0.25) (Table 2).

### Comparison of MVD in HCC and its adjacent tissue

The MVD was higher in HCC tissue than in its adjacent tissue. There was a significant difference in MVD between

**Table 2 Relationship between expressions of TGF- $\beta$ 1 and T $\beta$ R-II in HCC tissue**

		TGF- $\beta$ 1		Total
		+	-	
T $\beta$ R- II	+	10	8	18
	-	14	4	18
Total		24	12	36

HCC and its adjacent tissue ( $P<0.01$ , Table 3).

#### **Relationship between MVD in HCC tissue and expression of TGF- $\beta$ 1 or T $\beta$ R- II**

The MVD in HCC tissue was higher in positive expression group of TGF- $\beta$ 1 than in negative expression group of TGF- $\beta$ 1. The difference was significant between the two groups ( $P<0.05$ ). The MVD in HCC tissue in positive expression group of T $\beta$ R- II was lower than in negative expression group of T $\beta$ R- II. The difference was significant between the two groups ( $P<0.01$ ).

#### **Relationship between expression of TGF- $\beta$ 1 and NF- $\kappa$ B in HCC tissue**

Among the 36 specimens, 19 (52.78%) had positive expression of TGF- $\beta$ 1 and NF- $\kappa$ B in HCC tissue. The negative expression rate of TGF- $\beta$ 1 and NF- $\kappa$ B was 22.22% (8/36) in HCC tissue. The consistent rate of TGF- $\beta$ 1 and NF- $\kappa$ B was 75.00% (27/36).

#### **Expressions of smad4 and smad7 in HCC and its adjacent tissue**

The positive expression rate of smad4 in HCC and its adjacent tissue was 19.44% (7/36) and 75.00% (21/28) respectively. There was a significant difference between them ( $P<0.01$ ). The positive expression rate of smad7 in HCC tissue and its adjacent tissue was 63.89% (23/36) and 35.71% (10/28) respectively. There was a significant difference between them ( $P<0.05$ ).

## **DISCUSSION**

Tumor growth, invasion, metastasis depend on angiogenesis. Through its vessels, tumor can obtain rich nutrients and secrete tumor cells, resulting in tumor growth and metastasis. MVD of tumor is a valid marker to reflect tumor angiogenesis. Chen *et al*<sup>[2]</sup> reported that HCC MVD can be reflected by dynamic enhancement of spiral CT scanning. MVD of tumor has been detected by marking vessel endothelium. Vascular endothelial growth factor (VEGF) is an important angiogenic factor regulating tumor angiogenesis. Yao *et al*<sup>[3]</sup> reported that the VEGF expression rate is 63.9% in HCC, 78.3% in non-encapsulated HCC, and 90.9% in HCC with extrahepatic metastasis, respectively. The VEGF expression is closely correlated with MVD. Moon *et al*<sup>[4]</sup> reported that overproduction of VEGF and angiopoietin 2 in HCC cells may increase vascularity and tumor growth in a paracrine manner. Poon *et al*<sup>[5]</sup> reported that the MVD in HCC tissue is higher than that in its adjacent tissue. The MVD in

**Table 3 Comparison of MVD in HCC and its adjacent tissue (mean  $\pm$  SD)**

	<i>n</i>	MVD
HCC tissue	36	32.45 $\pm$ 10.62
Adjacent tissue	36	4.62 $\pm$ 1.67

HCC tissue is associated with hepatocarcinoma prognosis. The higher the MVD is, the poorer the prognosis is. Our study revealed the same result, suggesting that tumor angiogenesis plays an important role in tumor genesis and development.

TGF- $\beta$  is an important adjusting factor and has five isoforms: TGF- $\beta$ 1-5. TGF- $\beta$ 1-3 have the same biological functions with 70-80% homology. TGF- $\beta$ 1 is a negative adjusting factor in tumor growth. There are three kinds of TGF- $\beta$  receptors: T $\beta$ R-I, T $\beta$ R-II, T $\beta$ R-III. Their relative molecules are  $65\times 10^3$ ,  $85-110\times 10^3$  and  $6\times 10^5$  respectively. T $\beta$ R-I and T $\beta$ R-II playing a part in signal transduction are serine/ threonine protein kinase receptors with a single span membrane. The section of extracellular membrane is short, while the section of cell plasma is long. The section of extracellular membrane contains rich cysteine, the section of cell plasma contains serine/ threonine protein kinase structure and possess its activity. Compared to T $\beta$ R-II, the out and inner sections of cellular membrane of T $\beta$ R-I are short. TGF- $\beta$ 1 combines with T $\beta$ R-II becoming dimer, then with T $\beta$ R-I becoming trimer. The activated T $\beta$ R-I and phosphate-acidulated smad could adjust transcription of genes. TGF- $\beta$ 1 is over-expressed in tumor tissue, but tumor cells do not respond to suppressive factor TGF- $\beta$ 1, suggesting that the signal transduction pathway is abnormal. TGF- $\beta$  plays an important role as a ligand in tumor genesis suppressing cell growth in early stage and promoting cell growth in advanced stage. TGF- $\beta$ 1 exerts its strong suppressive effect on hepatocellular proliferation. Kim *et al*<sup>[6]</sup> showed that TGF- $\beta$ 1 could induce hepatocyte apoptosis. Abou-Shady *et al*<sup>[7]</sup> detected TGF- $\beta$  mRNA in normal and HCC tissue with Northern blot method and found that TGF- $\beta$  mRNA is over-expressed in HCC and its adjacent tissue. Idobe *et al*<sup>[8]</sup> compared the intensity of TGF- $\beta$ 1 staining in HCC and its adjacent tissue and found that the former is more intense than the latter. The expression of TGF- $\beta$ 1 in HCC tissue is correlated with the histological differentiation, namely the lower the histological differentiation of HCC, the more intense the TGF- $\beta$ 1 staining in HCC tissue. Matsuzaki *et al*<sup>[9]</sup> showed that TGF- $\beta$ 1 mRNA is over-expressed in HCC cells and TGF- $\beta$ 1 accelerates their proliferation. Giannelli *et al*<sup>[10]</sup> reported that invasive HCC cells express alpha3 beta1-integrin whereas noninvasive HCC cells do not. TGF- $\beta$ 1 stimulates alpha3-integrin expression at a transcriptional level in noninvasive HCC cells, causing transformation into a motile and invasive phenotype. Invasive HCC cells secrete abundant active TGF- $\beta$ 1 in comparison to noninvasive HCC cells. Anti-TGF- $\beta$ 1 neutralizing antibody reduces alpha3-integrin expression and the ability of HCC to invade

cells, suggesting that TGF- $\beta$ 1 may play an important role in HCC invasiveness by stimulating  $\alpha$ 3-integrin expression, and may be an important target for new therapies. Cai *et al*<sup>[11]</sup> showed that TGF- $\beta$ 1 treatment can enhance the amount of  $\alpha$ 5  $\beta$ 1-integrin on HCC cell surface, the mRNA level of  $\alpha$ 5 subunit, subsequently stimulating cell adhesion to fibronectin (Fn) and laminin (Ln) matrix. TGF- $\beta$ 1 can also promote cell migration. Song *et al*<sup>[12]</sup> reported that TGF- $\beta$ 1 may be a useful serologic marker in detecting HCC at its initial stage because it shows higher sensitivity and specificity in the diagnosis of small HCC. Ueno *et al*<sup>[13]</sup> reported that expression of T $\beta$ R-II in liver tissues is significantly decreased in patients with HCC compared to that in patients with chronic hepatitis or liver cirrhosis. They transfected T beta RII cDNA to hepatoma cell line (Huh7) and compared the change of cell number and observed the induction of apoptosis after TGF-beta1 treatment using a FACScan flow cytometer. In Huh7 cells transfected with T beta RII cDNA, cell arrest and apoptosis were obviously induced. We have previously shown that expression of TGF- $\beta$ 1 mRNA and protein in HCC tissue is higher than that in its adjacent tissue<sup>[14]</sup>. Our study displayed that expression of TGF- $\beta$ 1 was enhanced, and expression of T $\beta$ R-II was weak in HCC tissue compared to that in its adjacent tissue, which may be due to the lower expression of T $\beta$ R-II in HCC cells<sup>[13]</sup> that can escape from the inhibitory effects of TGF- $\beta$ 1, thus causing genesis and development of HCC.

Smad is an essential signal transducer of TGF-beta signal pathway. At present, ten kinds of smad have been found: smad1-10. Smad4 is an action substrate of TGF- $\beta$  receptor and has been identified as a tumor suppressor gene. Mutation or lower expression of smad4 has been observed in many kinds of tumor<sup>[15-18]</sup>. In normal hepatic tissue, smad4 plays an essential role in signal transduction of TGF- $\beta$  and influences gene transcription, controls cell growth and guides the suppressive role of TGF- $\beta$  in hepatic cell growth. Tannapfel *et al*<sup>[19]</sup> reported that expression of smad4 is decreased in HCC tissue. Our study showed that expression of smad4 was lower in HCC tissue than in its adjacent tissue, suggesting that expression of smad4 is abnormal in HCC tissue, resulting in blocking signal transduction of TGF- $\beta$ 1 and taking part in hepatic carcinoma cell escaping from the suppression of TGF- $\beta$ 1. smad7 is an inhibitor of smad and can bind to T $\beta$ R-I, blocking phosphorylation of smad and signal transduction of TGF- $\beta$ 1. It is thus considered as an oncogene. Kawate *et al*<sup>[20]</sup> investigated mutation of smad7 in HCC tissue using polymerase chain reaction-single strand conformation polymorphism analysis and found that smad7 displays single nucleotide polymorphisms. Our study showed that expression of smad7 was higher in HCC tissue than in its adjacent tissue, suggesting that smad7 may take part in hepatic carcinoma cell escaping from suppression of TGF- $\beta$ 1.

Synthesis of TGF- $\beta$ 1 is controlled by nuclear transcription factors. At present, the main nuclear transcription factors are nuclear factor-kappaB (NF- $\kappa$ B) and activator protein 1. NF- $\kappa$ B could bind to enhancer  $\kappa$ B of immunoglobulin kappa light chain gene. NF- $\kappa$ B is a dimer of p65 and p50. In normal conditions, NF- $\kappa$ B exists

in cell plasma. Inhibitory factor of NF- $\kappa$ B (I- $\kappa$ B) falls off NF- $\kappa$ B complex after stimulated. Activated NF- $\kappa$ B enters into nuclei and accelerates transcription of target gene. Because tissue transglutaminase gene promotor (a TGF- $\beta$ 1 activated factor) contains binding sites of NF- $\kappa$ B, NF- $\kappa$ B can accelerate expression of TGF- $\beta$ 1. It was reported that hepatic carcinoma cells could excrete TGF- $\beta$ 1<sup>[21]</sup>. Our study showed that expression of NF- $\kappa$ B was closely related with TGF- $\beta$ 1 expression.

In conclusion, TGF- $\beta$ 1, T $\beta$ R-II, NF- $\kappa$ B, smad4 and smad7 in HCC tissue are the major factors in TGF- $\beta$ 1-smad signal transduction pathway. These factors are closely related with MVD and may play an important role in HCC angiogenesis. NF- $\kappa$ B may cause the activation and production of TGF- $\beta$ 1.

### Abstract

Duodenal Crohn's disease is rare, and patients without obstruction are treated medically. We herein report one case whose duodenal Crohn's disease was successfully managed with low-speed elemental diet infusion through a nasogastric tube. A 28-year-old female developed acute duodenal Crohn's disease. Upper GI radiologic and endoscopic examinations showed a stricture in the duodenal bulb. Using the duodenal biopsy specimens, mucosal cytokine levels were measured; interleukin (IL)-1 $\beta$ , IL-6, IL-8, and tumor necrosis factor- $\alpha$  levels were remarkably elevated. For initial 2 wk, powdered mesalazine was orally given but it was not effective. For the next 2 wk, she was treated with low-speed elemental diet therapy using a commercially available Elental™, which was infused continuously through a nasogastric tube using an infusion pump. The tip of the nasogastric tube was placed at an immediate oral side of the pylorus. The infusion speed was 10 mL/h (usual speed, 100 mL/h). After the 2-wk treatment, her symptoms were very much improved, and endoscopically, the duodenal stricture and inflammation improved. The duodenal mucosal cytokine levels remarkably decreased compared with those before the treatment. Although our experience was limited, low-speed elemental diet infusion through a nasogastric tube may be a useful treatment for acute duodenal Crohn's disease.

### INTRODUCTION

The frequency of duodenal Crohn's disease is rare, and is reported to range between 0.5% and 5.0% in Crohn's disease<sup>[1-3]</sup>. Duodenal Crohn's disease is almost invariably present in association with the disease elsewhere in the intestinal tract. Medical therapy for distal disease may mask the symptoms of duodenal disease and delay its diagnosis. The most common site of duodenal Crohn's disease is the duodenal bulb, and stricture is the most common pathology<sup>[1-3]</sup>. Medical therapy including H<sub>2</sub>-receptor antagonists, 5-aminosalicylic acid, corticosteroids, and immunosuppressive drugs is effective for patients having duodenal strictures without obstruction; however, surgery is necessary for patients with obstruction<sup>[1-3]</sup>.

Cytokines are involved in the modulation of the immune system related to the pathogenesis of inflammatory bowel disease, such as Crohn's disease and ulcerative colitis, and they are rapidly synthesized and secreted by inflammatory cells<sup>[4,5]</sup>. In our previous study, we found that elemental diet therapy markedly improved clinical symptoms, and reduced the mucosal cytokine production in patients with ileal or colonic Crohn's disease<sup>[6]</sup>. Recently, we experienced one case whose duodenal Crohn's disease was successfully managed with low-speed elemental diet infusion through a nasogastric tube.

### CASE REPORT

In June 2000, a 23-year-old female presented with abdominal pain and diarrhea, and she was diagnosed as having Crohn's disease in the terminal ileum. Thereafter, she was treated with corticosteroid (prednisolone, 5-20 mg/d) and mesalazine (Pentasa, 3.0 g/d). Despite the medical treatment, she required an operation (terminal ileal resection) in April 2002. After the initial operation, she was taking mesalazine (Pentasa, 3.0 g/d) to prevent recurrence. She started an enteral nutritional therapy using elemental diet, but could not continue the treatment. She developed abdominal pain and diarrhea due to recurrent ileal Crohn's disease, but

**Table 1 Mucosal cytokine production in the duodenal bulb before and after elemental diet therapy**

Tissue cytokine (ng/g)	Before treatment	After treatment	Normal control <sup>1</sup> median value (range)
IL-1 $\beta$	370	45	12 (0-23)
IL-6	12 000	570	220 (70-280)
IL-8	450	30	20 (0-36)
TNF- $\alpha$	310	24	14 (0-21)

<sup>1</sup>Five patients without any gastroduodenal diseases.

**Figure 1** Upper GI barium study at admission. A stricture was observed in the duodenal bulb.

she refused to receive any steroids or immunosuppressive drugs. In June 2003, she underwent reoperation (ileal resection). Thereafter, she was treated with mesalazine (Pentasa, 3.0 g/d).

In March 2005, she developed severe postprandial upper abdominal pain, nausea, and vomiting. Upper GI barium study showed a stricture of the duodenal bulb (Figure 1). Endoscopic examination revealed the stricture with mucosal edema and contact bleeding in the duodenal bulb (Figure 2A). The endoscope could be inserted into the second part of the duodenum, where the longitudinal ulcerations were observed (Figure 2B). The gastric mucosa was moderately inflamed but there were no ulcerations in the stomach. Histologically, the biopsy specimens of the duodenal bulb showed severe inflammation with the accumulation of a large amount of inflammatory cells. Granulomas were not detected. Using the duodenal biopsy specimens, mucosal cytokine levels were measured by the enzyme-linked immunosorbent assay as previously reported<sup>[6]</sup>. The cytokine measurement was performed after the clinical data has been recorded. Laboratory investigators were blind to the clinical data. Interleukin (IL)-1 $\beta$ , IL-6, IL-8, and tumor necrosis factor (TNF)- $\alpha$  levels were remarkably elevated compared with those in patients without any gastroduodenal diseases (normal control) (Table 1). She was diagnosed with acute duodenal Crohn's disease, and was hospitalized in our unit. At admission, the main results of blood examinations were: white blood cell count,  $5.6 \times 10^9$  (normal,  $3.5 \times 10^9$ - $9 \times 10^9$ )/L; hemoglobin, 99 (normal, 115-160) g/L; platelet count,  $542 \times 10^9$  (normal,  $130 \times 10^9$ - $370 \times 10^9$ )/L; erythrocyte sedimentation rate, 9 (normal,  $\leq 15$ ) mm/h; C-reactive protein, 4.5 (normal,  $\leq 4$ ) mg/L;

**Figure 2** Endoscopic examination at admission. A: A stricture with mucosal edema and contact bleeding in the duodenal bulb; B: longitudinal ulcerations in the second part of the duodenum.

**Figure 3** Endoscopic examination after the elemental diet therapy. Improvement of the duodenal stricture and inflammation was observed.

and albumin, 29 (normal,  $\geq 40$ ) g/L. Because she could not take any foods and her nutritional status was poor, she was managed with total parenteral nutrition (approximately 8368 kJ/d) after the admission. H<sub>2</sub>-receptor antagonist (famotidine; Gaster, 40 mg/d) was intravenously administered for 4 wk. For initial 2 wk after the admission, powdered mesalazine (Pentasa, 1 g) was orally given three times a day. However, her symptoms were not improved, and repeat endoscopic examination also revealed no improvement. For the next 2 wk, she was treated with low-speed elemental diet infusion therapy. The enteral formula was a commercially available Elental<sup>TM</sup> (Ajinomoto and Morishita-Russel, Tokyo, Japan), which is composed of amino acids, very little fat, vitamins, trace elements and a major energy source, dextrin. The details of Elental<sup>TM</sup> were reported in our previous paper<sup>[6]</sup>. The elemental formula was infused continuously through a silicone-elastomer nasogastric tube using an infusion pump. The tip of the nasogastric tube was placed at an immediate oral side of the pylorus, which was confirmed radiologically. The infusion speed was 10 mL/h (usual speed for this enteral formula is approximately 100 mL/h). After the 2-wk treatment, her symptoms were very much improved, and endoscopic examination also revealed improvement of the duodenal stricture and inflammation (Figure 3). The longitudinal ulcerations in the second part of the duodenum also improved but they did not normalize. The duodenal mucosal IL-1 $\beta$ , IL-6, IL-8, and TNF- $\alpha$  levels also remarkably decreased compared with those before

the elemental diet therapy (Table 1). At present, she is taking low residue and low fat foods in the daytime according to the instructions of her dietician, and in the nighttime, the elemental diet is infused through a self-intubated nasogastric tube using an infusion pump with an increased speed (100 mL/h).

## DISCUSSION

In this study, our patient refused to receive any steroids or immunosuppressive drugs in the management of Crohn's disease. Initially, powdered mesalazine (Pentasa, 3 g/d) was not effective for her duodenal Crohn's disease. We, therefore, decided to try our elemental diet therapy because there seemed to be no other useful medical treatment. The tip of the nasogastric tube was carefully placed at an immediate oral side of the pylorus. The elemental formula was infused continuously with a low speed (10 mL/h) for 2 wk because the duodenal bulb was obstructive. During the treatment, our patient did not have increased abdominal pain, nausea or vomiting. The aim of this therapy was to reduce the mucosal inflammation using the elemental diet, but not to improve the nutritional status of the patient. The enteral formula infused through the nasogastric tube continuously stayed at the site of the duodenal stricture. Eventually, this treatment remarkably reduced proinflammatory cytokine production in the duodenal mucosa. Clinical and endoscopic improvements were associated with a decline in the mucosal cytokine production. However, from our experience, the elemental diet is useful only for bowel strictures due to acute mucosal inflammation (edema). Generally, the tight fibrotic strictures require surgical treatment in patients with Crohn's disease.

In our previous prospective study<sup>[6]</sup>, 28 patients with active ileal or colonic Crohn's disease were treated with Elental<sup>TM</sup> for 4 wk. The mucosal biopsies were obtained from the terminal ileum and large bowel before and after the treatment. After the treatment, clinical remission was achieved in 71% of patients. Endoscopic healing and improvement rates were 44% and 76% in the terminal ileum and 39% and 78% in the large bowel, respectively. The mucosal concentrations of IL-1 $\beta$ , IL-6, IL-8, and TNF- $\alpha$  in the ileum and large bowel were increased before the treatment; however, these cytokine levels decreased to the levels of normal control after the treatment. Other studies also examined the relationship between the mucosal cytokine production and enteral nutrition using different formulas, and they reported similar results to that of ours<sup>[7,8]</sup>. Breese *et al*<sup>[7]</sup> investigated the proportion of lymphokine

(IL-2 and interferon- $\gamma$ )-secreting cells in the intestinal mucosa of patients with Crohn's disease treated with either enteral nutrition or cyclosporine therapy. Enteral nutrition produced a reduction in lymphokine-secreting cells equivalent to cyclosporine therapy, and it produced better clinical improvement. Fell *et al*<sup>[8]</sup> examined 29 children with active Crohn's disease treated with an oral polymeric diet. Macroscopic mucosal healing in the terminal ileum and colon was associated with a decline in ileal and colonic IL-1 $\beta$  levels. The detailed mechanism of elemental diet on immunological reactions in Crohn's disease remains unknown. The main mechanisms may be removal of food antigen and decreases of bowel secretion and motility induced by very low fat content. However, further investigations are necessary.

Our low-speed elemental diet infusion therapy through a nasogastric tube was useful to improve acute duodenal Crohn's disease without any adverse effects. Although our experience was limited, this therapy may be a preferable treatment for acute duodenal Crohn's disease because patients can be treated without steroids or immunosuppressive drugs.

## Abstract

We have reported a case of hepatic adenomatosis associated with hormone replacement therapy (estrogen and progesterone) and hemosiderosis caused by excessive blood transfusion for the treatment of chronic myeloid leukemia. A 34-year-old woman was found to have several hepatic tumors on a routine medical examination. The general condition was good. Laboratory studies showed iron overload. Abdominal computed tomography and selective hepatic angiography showed several hypervascular tumors in the right lobe of the liver (up to 20 mm in diameter). Since hepatocellular carcinoma could not be ruled out, subsegmental hepatectomy was performed. Histopathological examination of the surgical specimen showed hepatic adenomatosis with hemosiderosis. Both hormone replacement therapy and iron overload could be the cause of hepatic adenomatosis.

## INTRODUCTION

Hepatic adenoma is an uncommon benign liver tumor; however, its incidence increases in women of childbearing age because of its close relation to the usage of oral contraceptives<sup>[1]</sup>. Most patients start to develop hepatic adenoma after 5 years of usage of oral contraceptives<sup>[2]</sup>. Hepatic adenoma frequently regresses following discontinuation of oral contraceptives<sup>[3]</sup>. Hepatic adenoma also occurs in association with androgenic steroid use and with type I glycogen storage disease<sup>[4]</sup>; however, the mechanism of its occurrence is unknown. On the other hand, hepatic adenomatosis is characterized by the presence of multiple adenomas of various sizes in the liver and it has neither female predominance nor relation with estrogen/progesterone intake<sup>[5]</sup>. Thus, hepatic adenomatosis can be distinguished from hepatic adenoma. Both hepatic adenoma and adenomatosis are frequently difficult to distinguish from well-differentiated hepatocellular carcinoma (HCC). It has been reported that iron overload in the liver is occasionally associated with the development of both HCC and adenoma<sup>[6]</sup>. HCC develops in a variety of conditions associated with iron overload, particularly idiopathic hemochromatosis in which a 30% incidence has been reported<sup>[6]</sup>. Two cases of hepatic adenoma have been reported in patients with beta-thalassemia and secondary iron overload<sup>[7,8]</sup>. Furthermore, one case of hepatic adenoma has been reported in a patient with aplastic anemia treated with anabolic androgenic steroids and blood transfusions for 5 years<sup>[9]</sup>. Hepatic adenomatosis is also associated with hereditary hemochromatosis<sup>[10]</sup>. Based on these findings, iron overload seems to be involved in the hepatocarcinogenic process. While the mechanism of hepatic tumorigenesis in the presence of hemosiderosis is not understood, it is possible that the Fenton's reaction generates free oxygen radicals that in turn cause DNA damage<sup>[11]</sup>.

Here we have reported a case of hepatic adenomatosis complicated with hepatic hemosiderosis caused by excessive blood transfusion for the treatment of chronic myeloid leukemia (CML), followed by sex steroid hormone therapy for 8 years.

## CASE REPORT

A 34-year-old woman was found to have four hepatic tumors by computed tomography (CT) on a routine medical check-up. At 22 years of age, she was diagnosed

**Figure 1** Radiological features of liver tumor. **A:** T1-weighted MRI showing high-intensity masses and reduced liver parenchymal intensities, suggestive of iron deposition in the liver; **B:** Hepatic arteriogram showing several hypervascular tumors in the liver; **C:** CTHA showing these mass lesions with increased arterial supply, which reduced portal supply on CTAP (**D**).

with CML. One year later, blast crisis occurred and she underwent allogeneic bone marrow transplantation (BMT) from her daughter in addition to receiving total body irradiation (TBI) and several blood transfusions. She developed amenorrhea after TBI and started to receive hormone replacement therapy (estrogen and progesterone) from 26 years of age to maintain uterine and ovarian functions. She remained relatively healthy without recurrence of CML after BMT. However, liver tumors were found on regular examination 8 years after BMT.

She had no history of glycogen storage disease or usage of anabolic steroid. General physical examination was normal. Blood tests and urinalysis were normal except for elevated serum iron (2810 µg/L and ferritin (2508.2 µg/L). Hepatitis B surface antigen (HBsAg), anti-HBs antibody, and anti-hepatitis C virus antibody were negative. Serum alpha-fetoproteins (AFP), protein induced by the absence of vitamin K (PIVKA)-II, carcinoembryonic antigen (CEA), and carbohydrate antigenic determinant (CA) 19-9 were within normal limits.

Abdominal ultrasonography (US) demonstrated an iso-echoic mass lesion measuring 2 cm in diameter located in the right posterior segment of the liver. Although US showed only one tumor, abdominal CT showed several low-density lesions (up to 2 cm in diameter) in the liver (segments 4, 5, 7, and 8 according to Couinaud's classification). Dynamic CT revealed enhancement of the masses during arterial phase, which showed low-density lesions during portal venous phase. These abnormal masses in the liver were also detected as high-intensity on T1-weighted and iso-intensity on T2-weighted magnetic resonance imaging (MRI). Moreover, both T1-weighted and T2-weighted MRI showed decreased liver parenchymal intensities, suggestive of hemosiderosis (Figure 1A). Celiac

angiography demonstrated multiple hypervascular mass lesions in the liver (segments 4, 5, 7, and 8) (Figure 1B). However, neither arteriovenous shunts nor vessel invasion were observed. CT during hepatic angiography (CTHA) showed these mass lesions with increased arterial supply, which reduced portal supply on CT during arterial portography (CTAP) (Figures 1C and 1D).

A tissue specimen of the tumor obtained by fine needle biopsy revealed monotonous growth of tumor cells, but no atypia was observed. Based on the above findings, the preoperative diagnosis was hepatic adenomatosis, although HCC could not be completely ruled out. Therefore, subsegmental hepatectomy for segment 7 was performed. The tumor was yellowish and well-defined without encapsulation. Microscopically, the tumor cells were mostly normal in size. Their nuclei were round and regular in size, and their cytoplasm was eosinophilic and partly clear. The tumor cells were arranged predominantly in a thin trabecular pattern without pseudo-glandular structures and no portal triad was observed in the tumor (Figure 2A). The non-tumorous part of the liver showed marked hepatocellular and reticuloendothelial hemosiderosis (Figure 2B). Several small nodules could also be seen in the normal parenchyma around the tumor. The pathological diagnosis was hepatic adenomatosis in hemosiderosis of the liver. The patient was advised to stop hormonal therapy and remained healthy during the follow-up. At 3 years after discontinuation of hormonal therapy, the residual tumors did not change in size as shown by CT.

## DISCUSSION

We have described here a woman with hepatic adenomatosis who had not used oral contraceptives

**Figure 2** Macroscopic and microscopic examinations of tumor specimen. **A:** Macroscopic examination showing well-defined non-encapsulated tumor. Microscopically, the tumor cells are arranged predominantly in a thin trabecular pattern. No portal triad can be seen in the tumor (HE×200); **B:** The non-neoplastic hepatocytes are almost normal, but contain cytoplasmic hemosiderin (Berlin Blue×20). On the other hand, no iron deposition is seen in the adenoma nodule.

but received estrogen and progesterone for 8 years as hormone replacement therapy for early menopause caused by TBI. Baum *et al*<sup>[2]</sup> have reported that the incidence of hepatic adenoma has increased among women on the usage of oral contraceptives<sup>[1]</sup>. For example, about 90% of patients with hepatic adenoma had continuously taken oral contraceptives in the USA<sup>[12]</sup>. In contrast, hepatic adenoma is rare in Japan because of the lack of widespread use of oral contraceptives; the incidence of hepatic adenoma in Japanese women on oral contraceptives is about 5%<sup>[13]</sup>. On the other hand, hepatic adenomatosis is an extremely rare syndrome and defined as the presence of multiple (at least 10) adenomas in the liver. Flejou *et al*<sup>[5]</sup> have indicated that liver adenomatosis affects both men and women, and it is not related to the usage of oral contraceptives, usage of androgenic steroid and glycogen storage disease. Our case had not used oral contraceptives but had received estrogen and progesterone.

Differential diagnosis of hepatic adenomatosis from multiple hemangiomas, multifocal nodular hyperplasia, multifocal HCC, and hypervascular liver metastases is sometimes difficult<sup>[9]</sup>. In general, HCC shows a rapid progression resulting in the tumorous obstruction of the intrahepatic portal veins, and it is associated with increased serum AFP concentration and liver cirrhosis<sup>[1]</sup>. On the other hand, hepatic adenomatosis shows a slow progression<sup>[9]</sup>, although it sometimes causes impaired liver function, hemorrhage, rupture, and malignant degeneration of the lesion<sup>[8,14]</sup>. In our case, it was difficult to make differential diagnosis of hepatic adenomatosis from HCC based on the clinical, radiological, and histological examinations. Therefore, subsegmental hepatectomy was performed. Histopathological examination of a large specimen showed non-encapsulated nodule of tumor cells arranged predominantly in a thin trabecular pattern without portal vein or bile ducts. Several small nodules were also seen in the normal parenchyma around the tumor. These findings were compatible with hepatic adenomatosis. The extratumorous parenchyma showed hemosiderosis in hepatocytes; however, no iron deposition

was noted in the adenoma nodules.

The pathogenesis of hepatic adenomatosis remains unknown. Hepatocellular adenomas in beta-thalassemic patients with secondary iron overload have been reported<sup>[7,8]</sup>. The development of HCC is associated with a variety of iron overload states, particularly hemochromatosis<sup>[7]</sup>. Recently, a case with hepatic adenomatosis related to primary hemochromatosis was reported<sup>[10]</sup>. Based on these findings, iron overload might be involved in the development of hepatocarcinogenesis. Moreover, Kebapci *et al*<sup>[9]</sup> reported a patient with hepatic adenomatosis who developed blood transfusion-related hemosiderosis and had received anabolic steroids for the treatment of aplastic anemia. In this regard, elevated body iron stores is reported as a risk factor for the appearance of several tumors in human beings<sup>[15]</sup>. Furthermore, it is considered that estrogen stimulates iron uptake and metabolism *in vivo* and the interaction of estrogen metabolites and metal ions produces free radical damage<sup>[11,15]</sup>. Therefore, the relation between estrogen administration and hepatic hemosiderosis induced by secondary iron overload is likely involved in the development of hepatic adenomatosis in our case.

To the best of our knowledge, this is the first report of hepatic adenomatosis associated with hormone replacement therapy and secondary hemosiderosis. Thus, our case represents a human prototype of liver tumor formation induced by excessive iron and administration of sex steroid. Iron overload and sex hormone therapy may act synergistically to enhance the development of liver adenomatosis.

## Abstract

The antibiotics, metronidazole and ciprofloxacin, are the first-line treatment for pouchitis. Patients who do not respond to antibiotics or conventional medications represent a major challenge to therapy. In this report, we have described a successful treatment of severe refractory pouchitis with a novel agent, rebamipide, known to promote epithelial cell regeneration and angiogenesis. A 27-year-old male with ileo-anal pouch surgery presented with worsening anal pain, diarrhea, and abdominal pain. The patient was diagnosed to have pouchitis and was given metronidazole together with betamethasone enema (3.95 mg/dose). However, despite this intensive therapy, the patient did not improve. On endoscopy, ulceration and inflammation were seen in the ileal pouch together with contact bleeding and mucous discharge. The patient was treated with rebamipide enema (150 mg/dose) twice a day for 8 wk without additional drug therapy. Two weeks after the rebamipide therapy, stool frequency started to decrease and fecal hemoglobin became negative at the 4<sup>th</sup> wk. At the end of the therapy, endoscopy revealed that ulcers in the ileal pouch had healed with no obvious inflammation. The effect of rebamipide enema was dramatic and was maintained throughout the 11-mo follow-up. The patient continued to be in remission. No adverse effects were observed during the treatment or the follow-up period. The sustained response seen in this case with severe and refractory pouchitis indicates that agents, which promote epithelial cell growth, angiogenesis and mucosal tissue regeneration, are potential therapeutic agents for the treatment of refractory colorectal lesions.

## INTRODUCTION

Ulcerative colitis is a debilitating inflammatory bowel disease that poorly responds to the current medical interventions with aminosaliclates, corticosteroids, immunomodulators, and more recently with novel biologicals. Patients who fail to respond to the mainstays of therapy until now have had limited options, but submit to colectomy<sup>[1]</sup>. Accordingly, proctocolectomy and ileo-anal pouch surgery (IPAA) have become the standard choices for curative resections in patients with ulcerative colitis who require surgical removal of the colorectum<sup>[1,2]</sup>. However, the majority of patients with curative resection subsequently develop complications including pouchitis which is the most frequent long-term complication after IPAA<sup>[2-4]</sup>. Pouchitis was first reported by Kock *et al*<sup>[5]</sup> in 1977 as a non-specific acute inflammation of the ileal reservoir in patients who had undergone proctocolectomy. Since then, pouchitis has become a widely recognized complication of restorative proctocolectomy.

The etiology of pouchitis is unknown, theories range from genetic susceptibility, bacterial overgrowth, ischemia, and fecal stasis to a recurrence of ulcerative colitis in the pouch, a missed diagnosis of Crohn's disease, or possibly a novel third form of inflammatory bowel disease<sup>[6]</sup>. Some patients with suspected pouchitis may not have inflammation of the pouch, but rather, irritable pouch syndrome. Hence, endoscopic investigations with biopsy are essential to decide whether a patient has pouchitis or not. Indeed, the more commonly used scores like the pouch disease activity index incorporate both endoscopic and histologic criteria. Furthermore, unlike common inflammatory bowel disease in which numerous controlled clinical trials have been conducted and data have become available, very limited number of controlled trials, to our knowledge, have been conducted on pouchitis<sup>[7,8]</sup>.

## CASE REPORT

A 27-year-old male developed ulcerative colitis in 1992. He had been treated with conventional medications including corticosteroids. However, the ulcerative colitis had

**Figure 1** Endoscopic findings of refractory pouchitis. **A:** Ulcers in the ileal pouch together with inflammation, contact bleeding and mucous discharge before the treatment with rebamipide enema; **B:** Healing of ulcers in the ileal pouch with a remaining minor scar after the treatment with rebamipide enema (arrow head).

become refractory to conventional medication, and the patient therefore underwent total colectomy with mucosal proctocolectomy in 1993 and IPAA in 1994. In 1996, he presented with anal pain as well as protracted symptoms of diarrhea, abdominal pain, and incontinence which were worsening with time. The patient was diagnosed to have pouchitis and was treated with metronidazole together with betamethasone enema (3.95 mg/dose). However, despite this intensive therapy, the patient did not improve. In 2002, oral prednisolone (20 mg/dose) was given, and the patient improved for a few days. Then the patient's symptoms went into a relapsing-remitting pattern with serum C-reactive protein (CRP) levels oscillating between 50 and 10 mg/L. On endoscopy in 2003, ulceration and inflammation were seen in the ileal pouch together with contact bleeding and mucous discharge (Figure 1A). After providing written informed consent, the patient was treated with rebamipide (2-(4-chlorobenzoylamino-3-[2 (1H)-quinolinon-4-yl]-propionic acid) enemas (150 mg/dose) twice a day for 8 wk without additional drug therapy.

Two weeks after the rebamipide therapy, stool frequency started to decrease and fecal hemoglobin became negative. Endoscopic findings showed that ulcers in the ileal pouch had healed with no obvious inflammation (Figure 1B). The effect of rebamipide enema was very dramatic and was maintained throughout the therapeutic period and the 11-mo follow-up. The patient continued to be in remission. No adverse effects were observed during the treatment or the follow-up period.

## DISCUSSION

Although a recent Cochrane analysis had difficulty in identifying evidence-based support, the antibiotics, metronidazole and ciprofloxacin, are often used as the first-line treatment for pouchitis<sup>[4,6,9]</sup>. Some patients respond to this regimen and a smaller fraction respond to conventional medications with aminosalicylates, corticosteroids and immunomodulators. However, a proportion of patients with chronic pouchitis does not respond to any of these therapies and represent a major challenge to physicians. Thorough endoscopy reveals that mucosal damage (inflammation and ulcers) in refractory pouchitis and ulcerative colitis is similar. Therefore, substances that have both anti-inflammatory activity and promote epithelial cell growth (restore the integrity of the colonic mucosa and maintain its barrier function)

should be effective in refractory pouchitis. In line with this thinking, we came to know a drug called rebamipide with striking potency to promote the epithelial cell growth factor (EGF) activity and EGF-receptor expression<sup>[10]</sup>. This prompted us to test its efficacy in a case of severe pouchitis, which did not respond to intensive conventional medication including antibiotics and corticosteroids.

The use of metronidazole in pouchitis is intended to inhibit colonization of the pouch by the bacteria which are suspected to be associated with the perpetuation of the disease in the pouch, as described for patients with an intact large bowel<sup>[11]</sup>. However, when the disease does not respond to metronidazole and conventional therapy for inflammatory bowel disease, it may respond to a novel medication like the response to rebamipide by the present refractory case. Rebamipide has a proven anti-ulcer effect in animal models of colitis<sup>[12]</sup>. Recently, it has been proposed that rebamipide activates in gastric epithelial cells a genetic program that promotes angiogenesis and signals cell growth and tissue regeneration<sup>[12,13]</sup>.

Thus, both the actions of rebamipide, such as the anti-ulcer effect and the activation of epithelial cell regeneration, may be attributed to the efficacy in the present case of severe pouchitis.

## Abstract

The outcome of infection with hepatitis C virus (HCV) varies substantially from self-limiting infection to chronic hepatitis, liver cirrhosis, and hepatocellular carcinoma among the individuals. The mechanisms that determine the clearance or the persistence of HCV have not yet been clarified. Here, we experienced two cases of hospital-related infection with HCV from the same origin but with quite different outcomes. One case resolved after an episode of acute hepatitis, while the other case developed a chronic hepatitis although they were infected with HCV of the same origin. Although infected with the virus of the same origin, the clinical and virological courses were completely different. This suggests that host factors play a major role in conditioning the outcome of acute HCV infection.

Kakizaki S, Takagi H, Yamazaki Y, Sohara N, Sato K, Nagamine T, Mori M. Different outcomes of nosocomial infection with hepatitis C virus from the same origin. *World J Gastroenterol* 2006; 12(4): 659-661

<http://www.wjgnet.com/1007-9327/12/659.asp>

## INTRODUCTION

The outcome of infection with hepatitis C virus (HCV) varies from self-remission, chronic hepatitis, liver cirrhosis, and hepatocellular carcinoma<sup>[1-3]</sup>. About 20% of the people

infected with HCV spontaneously clear the virus<sup>[4]</sup>. On the other hand, the rest of the patients cannot clear the virus and suffer from chronic infection<sup>[4]</sup>. The mechanisms that determine the clearance or the persistence of HCV have not yet been elucidated. Viral factors such as genotype could be involved in the outcome of the infection<sup>[5]</sup>. However, what determines the outcome of HCV infection is not totally clear. Here, we experienced two cases of hospital-related infection with HCV from the same origin but with two different outcomes. One case resolved subsequent to an acute hepatitis and the other case became a chronic hepatitis although they were infected with the same viral origin according to viral sequencing. This implies that host factors play a major role in conditioning the outcome of acute HCV infection.

## CASE REPORT

A 32-year-old woman (patient 1) and a 71-year-old man (patient 2) were admitted to the same floor of Gunma University Hospital on December 2001. Clinical, biochemical, and serologic profile of patients 1 and 2 are shown in Figure 1.

Patient 1 was diagnosed with idiopathic interstitial pneumonia on February 2001 and followed up as an out patient. She was complicated by a bacterial respiratory infection with dyspnea and she was readmitted on December 21. She showed normal aminotransferase level and was negative for hepatitis B surface antigen (HBsAg) and hepatitis C antibody (HCVAb) on admission. The respiratory infection was treated with antibiotics and the patient gradually improved. Although there were no typical acute hepatitis-like symptoms except for appetite loss, the patient's serum aminotransferase level was elevated during a routine check-up on February 28, 2002. Anti-hepatitis A (HA) IgM antibody, HBsAg and hepatitis B core (HBc) IgM antibody were negative. However, HCVAb became positive at this time. HCV RNA was also positive (850 KIU/mL) and genotype was 1b. Peak level of aspartate aminotransferase (AST) was 1199 IU/L, alanine aminotransferase (ALT) was 1348 IU/L on March 25, respectively. Aminotransferase level became normal on April 15 and continued at a normal level. HCV RNA became negative on April 6 and continued to be negative. She was diagnosed with acute hepatitis C and finally recovered.

Patient 2 was first diagnosed with diabetes mellitus at the age of 44. He was treated with insulin and subsequently admitted for the control of blood sugar on December

**Figure 1** Clinical, biochemical, and serologic profile of patients. **A:** patient 1; **B:** patient 2. HCV antibodies were detected by third-generation tests and HCV RNA was detected in serum by reverse-transcription PCR. Alanine aminotransferase values are shown on a logarithmic scale, and the horizontal lines indicate the upper limit of the normal range.

18, 2001. At the age of 69, he was diagnosed with myelodysplastic syndrome. Upon admission aminotransferase levels were normal, and both HBsAg and HCVAb were negative. He was discharged on January 8, 2002 and followed up with his primary physician. He subsequently developed elevated aminotransferase levels and became positive for HCVAb in June 2002. There were no typical acute hepatitis-like symptoms during the follow-up period with his primary physician. Retrospectively, the aminotransferase level of the patient was elevated during a routine check-up in January 31, 2002. HCV RNA was also positive (250 KIU/mL) and genotype was 1b. Peak level of AST was 102 IU/L, ALT was 168 IU/L on March 28. Aminotransferase levels continued to be abnormal for 3 years after the onset. He was diagnosed with chronic hepatitis C.

We believe that HCV infection of both patients occurred during December 2001 to January 2002. There was no suspicious event in the history of the patient suggesting infection such as intravenous drug abuse, blood transfusion, tattoo nor transmission by sexual contact in both cases. Nosocomial infection was suspected and surveyed. HCV genotyping and the nucleotide sequence analysis of coding region for the envelope glycoprotein E1 were performed for the two patients. For the nucleotide sequence analysis, after reverse transcription, the first round of polymerase chain reaction used primers EF1 (sense: 5'-CGCCGACCTCATGGGGTA-3', nt 721 to 739) and ER1 (antisense: 5'-CGACCAGTTCATCATCATATCCCA-3', nt 1 289 to 1 313), and the second-round primers EF2 (sense: 5'

**Figure 2** Phylogenetic tree analysis comparing coding sequences in the HCV regions for the envelope glycoproteins E1. For phylogenetic tree analysis, 13 sequences obtained from the 13 patients involved in this study were compared with 33 sequences taken as unrelated controls (genotype and GenBank accession numbers are indicated).

-TTGCCCGGTTGCTCTTTTCTATC-3', nt 837 to 860) and ER2 (antisense: 5'-GCGGTGACCTGATACATGGC-3', nt 1 264 to 1 283). We performed direct-sequence analysis of nested polymerase chain reaction products of 447 bp (nt 837 to 1 283) encompassing the HCV envelope glycoprotein E1. The polymerase chain reaction products were gel purified and sequenced by automated sequencer. The HCV genotype of both patients was 1b. The sequences of HCV E1 region from both the patients were 99.7% in agreement. We considered that the origins of both infections were the same and these two hepatitis infections were hospital related. We checked up on all the patients who were admitted to the same floor from December 18, 2001 to January 8, 2002, the suspicious infection period in question. There were 16 patients positive for HCV antibody. These 16 patients were examined for the genotype of HCV and 11 of them were 1b. The nucleotide sequences of E1 region in these 11 patients (numbered patient 3-13) were compared by the same method. Phylogenetic tree analysis comparing coding sequences in the HCV E1 region are shown in Figure 2. For phylogenetic tree analysis, 13 sequences obtained from the 13 patients involved in this study were compared with 33 sequences taken as unrelated controls. One patient had close nucleotide sequenc-

ing with patients 1 and 2. A 70-year-old man (patient 10, named as *propositus*) with liver cirrhosis was considered as the *propositus* of this hospital-related infection of HCV. He was admitted for treatment of hepatic encephalopathy from December 26-29.

Thus, patient 1 had a complete resolution of acute hepatitis C, while patient 2 developed a chronic hepatitis C infection although both were infected by the same HCV strain (*propositus*, patient 10). Although it was not fully elucidated how the nosocomial infection occurred, intravenous catheter flushing with heparin retrieved from a multidose heparin solution in saline was thought to be one of the causes of the infection.

## DISCUSSION

Although the same HCV strain infected two patients, each patient showed a completely different outcome. One case was cured from acute hepatitis and the other case developed chronic hepatitis although they were infected with HCV of the same origin. Primary HCV infection is poorly characterized because most patients are asymptomatic and, therefore, it is rarely diagnosed<sup>[3,6,7]</sup>. Larghi *et al.*<sup>[8]</sup> reported the outcome of an outbreak of acute hepatitis C supposedly infected from a common source. Among the 14 patients followed up, 8 patients resolved spontaneously and 6 patients developed chronic infection<sup>[8]</sup>. The incubation period and the outcome of the acute phase of the disease were highly variable. The average incubation period was 10 wk, but the range was from 6 to 28 wk. In our case, the supposed incubation periods of patients 1 and 2 were 9 and 5 wk, respectively.

The clinical and virologic course also varied, both in patients in whom the infection resolved spontaneously and in those developing chronic infection<sup>[8]</sup>. This suggests that host factors play a major role in conditioning the outcome of acute HCV infection<sup>[9,10]</sup>. Thus, the host immune system is important for the clearance of virus. In view of the host factors, specific MHC class II alleles were reported to influence susceptibility or resistance to persistent HCV infection<sup>[10,11]</sup>. The associations of self-limiting HCV infection with HLA-DRB1\*1101 and HLA-DQB1\*0301 have been independently reported by some groups<sup>[10,11]</sup>. Persistent HCV infection was associated with HLA-DRB1\*0701, and HLA-DRB4\*0101. In our case, HLA was not fully evaluated in all the patients. However, *propositus* had DRB1\*0901, DRB1\*1502, DQB1\*0303, and DQB1\*0601. Patient 2 had DRB1\*0901, DRB1\*1403, DQB1\*0303, and DQB1\*0301. HLA-DQB1\*0301 was not a self-limiting factor in our case.

We were able to determine the *propositus* of the HCV infection; however, the route of infection was not fully understood. There was no procedure identified in these patients to directly cause the infection, such as endoscopy, surgery or hemodialysis. Finally, flushing of intravenous catheters with heparin retrieved from a

multidose heparin solution in saline was thought to have caused the infection. Since January 2002, our department has been using heparin solution packed for individual use for flushing of intravenous catheters. The period of this nosocomial infection was before the use of individual packed heparin solution was instituted. All had long-lasting intravenous catheters. Multidose vials used for flushing or treatment had probably been contaminated during periods of overlapping treatment. Contamination of multidosing vials was the most likely mode of HCV transmission<sup>[12]</sup>. Therefore, use of such vials should be avoided.

We experienced two cases of hospital-related infection of HCV from the same origin followed by different outcomes. One patient was cured of acute hepatitis and the other case developed chronic hepatitis although both were infected by the same *propositus*. Although they were infected by the same source, the clinical and virologic course was completely different. This suggests that the host factors play a major role in determining the outcome of acute HCV infection.

## Abstract

We report a case of surgically proved left-sided torsion of the greater omentum that caused secondary by untreated inguinal hernia. Case A 36-year-old man presented to our hospital with abdominal pain. He had been diagnosed with a left inguinal hernia, but he had not received any treatments. Contrast-enhanced computed tomography (CT) of the abdomen showed a large fat density mass below the Sigmoid colon and left inguinal hernia with incarcerated fat. Exploratory laparotomy revealed torsion of the greater omentum with small bloody ascites. The greater omentum was twisted into one and a half circles and entered into a left inguinal hernia. An omentectomy with a repair of left inguinal hernia was performed. A resected omentum was submitted for pathological examination, which showed hemorrhagic infarction. Omental torsion is a rare cause of acute abdominal pain but should be included in the differential diagnoses of acute abdomen, especially in patients with untreated inguinal hernia.

## INTRODUCTION

Torsion of the omentum is a rare cause of acute abdomen, and twisting of the omentum may lead to subsequent

vascular impairment and eventually progress to infarction of the segment of the omentum distal to the twisting point. In most cases, torsion occurs on the right side of great omentum and left-side torsion is infrequent<sup>[1,2]</sup>.

We have reported a case of surgically proved left-sided torsion of the greater omentum that caused secondary torsion by untreated inguinal hernia.

## CASE REPORT

A 36-year-old man presented to our hospital with abdominal pain of sudden onset. He had been diagnosed with a left inguinal hernia, but he had not received any treatment. Physical examination revealed tenderness in the left lower quadrant of the abdomen, but left inguinal swelling was not present. Blood examination showed leukocytosis (white blood cell count =  $14\,700/\text{mm}^3$ ), and the C-reactive protein (CRP) level was elevated (3.84 mg/dL). Plain abdominal X-rays showed a right upper deviation of the sigmoid colon. Contrast-enhanced computed tomography (CT) of the abdomen showed a large fat density mass below the sigmoid colon and left inguinal hernia with incarcerated fat (Figure 1). Conservative therapy including intravenous administration of antibiotics was performed. However, his symptoms were not resolved and a small collection of free fluid was noted within the peritoneal cavity by CT. Exploratory laparotomy was performed on March 29, 2004, which revealed torsion of the greater omentum with small amount of bloody ascites. The greater omentum was twisted into one and a half circles and entered into a left inguinal hernia (Figure 2). An omentectomy with a repair of left inguinal hernia was performed. A resected omentum was submitted for pathological examination, which showed hemorrhagic infarction. Post-operative course was uneventful, and the patient has remained healthy with no clinical evidence of recurrent disease since then.

## DISCUSSION

Torsion of the omentum is a rare cause of acute abdomen and the majority of cases have right-side torsion. Left-side torsion is extremely rare and there are only sporadic reports in the literature<sup>[1,2]</sup>. The greater susceptibility to torsion of the right side is due to its greater length and size in relation to the left side and its greater mobility<sup>[3]</sup>.

Omental torsion can be classified as primary and secondary torsion, the latter being more common. Primary

**Figure 1** Contrast-enhanced computed tomography showing a large fat density mass below the sigmoid colon and left inguinal hernia with incarcerated fat (arrow).

torsion is believed to be related to local omental anomalies, such as bulky bifid or accessory omentum or abnormally redundant omental veins, but the exact pathogenesis is yet to be uncovered<sup>[4]</sup>. Secondary torsion is associated with adhesions to cysts, tumors, inflammatory foci, scars, or hernias. The precipitating factors are shared in both omental torsions, which include sudden increase in intra-abdominal pressure following a heavy meal or exertion, change in body position, coughing or sneezing, and occupational use of vibrating tools<sup>[2,3]</sup>. These events may result in sudden displacement of the omentum, thus exposing the omentum to greater risk of torsion. Torsion leads to omental infarction and usually presents as acute abdominal pain.

The majority of the cases of omental torsion are torsion involving the right-side of the omentum with the right lower quadrant or right paraumbilical pain. Thus, the differential clinical diagnoses of omental torsion include acute appendicitis, acute cholecystitis, cecal diverticulitis, or appendagitis. Left-sided omental torsion as in our patient is unusual and clinically mimics sigmoid diverticulitis, or appendagitis.

Diagnosis of omental torsion is rarely made preoperatively but should become more frequent with the increasing use of CT in the diagnosis of acute abdominal conditions<sup>[5]</sup>. The CT findings of fatty mass with a whirling pattern in the greater omentum suggest omental torsion. Although this typical CT finding has been documented in literature from various countries<sup>[6,7]</sup>, it should be made clear that not all omental torsions show this relatively characteristic appearance as in our case. The whirling pattern may not be apparent in cases where the axis of rotation is not perpendicular to the transverse scanning plane.

**Figure 2** Twisting of greater omentum into one and a half circles and entering into a left inguinal hernia (arrow).

Concerning the treatment of omental torsion, resection of the involved segment of the omentum has traditionally been the treatment of choice<sup>[2]</sup>. However, a few reported cases of omental torsion that were successfully treated conservatively have been reported<sup>[2,5]</sup>, especially in patients without associated complications. This may suggest that surgical treatment should be limited to the patients with complications. However, in cases where conservative treatments are not effective, as in our case, surgical treatments should be considered.

In conclusion, omental torsion is a rare cause of acute abdominal pain but should be included in the differential diagnoses of acute abdomen, especially in patients with untreated inguinal hernia. It is necessary to consider radiographic findings to determine how to best manage these patients and treat them.

### Abstract

Malignant gastrointestinal stromal tumors (GIST) are rare mesenchymal tumors originating from the wall of the gastrointestinal tract. Their coexistence with other tumors originating from other germ layers is unique. We have reported a case of a 63-year-old GIST patient presenting as an epigastric mass associated with hepatic tumor. Histologically, the mesenteric tumor was composed of spindle cells showing both neural and smooth muscle differentiation. Immunohistochemical examination showed positive staining for CD117, vimentin, S-100, and SMA, while CD34 antigen was negative. The hepatic tumor was diagnosed as hepatocellular carcinoma (HCC). To the best of our knowledge, this is the first case of GIST and HCC coexistence. The rarity of the case, however, should not lead to ignoring such a possibility in differential diagnosis.

### INTRODUCTION

Malignant gastrointestinal stromal tumors (GIST) are rare mesenchymal tumors originating from the wall of the gastrointestinal tract<sup>[1,2]</sup>. Majority of GIST are positive for

CD117 and vimentin in immunohistochemical staining<sup>[3-5]</sup>. Coexistence of malignant GIST and other malignancies have been reported in some unique cases<sup>[6-10]</sup>. Such cases always require differential diagnosis for metastatic GIST<sup>[3,4]</sup>. We have described a case of a 63-year-old male patient who was admitted to our clinic with liver tumor mass and mesenteric tumor. Preoperative biopsy performed under computed tomography (CT) scanning showed a mesenteric tumor as GIST, which was confirmed by postoperative histopathology. The liver tumor was verified as hepatocellular carcinoma (HCC). This case presents a coexistence of two independent tumors. To our knowledge, the coincidence of GIST and HCC has not been reported in the literature.

### CASE REPORT

A 63-year-old male patient with a palpable epigastric mass was admitted to the Department of Surgical Oncology, Medical University of Gdansk. His medical history was significant for insulin dependent diabetes mellitus and ischemic heart disease. No other clinical symptoms were present. The morphology, serum alpha-fetoprotein (AFP), liver enzymes and other blood tests were normal.

CT of the patient's abdomen showed an 80 mm×50 mm pathological mass in the right side of abdomen and a 65 mm×53 mm solid mass within the liver (Figures 1A and 1C). Abdominal sonography showed a 80-mm mass in diameter in the mesentery at the right side of the abdomen with mediocre flow in Doppler option and a 60-mm solid mass in diameter in the left lobe of the liver with low flow in Doppler option (Figures 1B and 1D). Laparotomy revealed a mesenteric tumor on the intestinal wall and a hepatic tumor of the same size as in ultrasonographic description (Figures 2A and 2B). No other malignant pathologies in the abdomen were found. Left hemihepatectomy and resection of mesenteric tumor with side-to-side jejunojejunostomy were performed.

Histologically, the liver tumor was described as HCC. The mesenteric tumor 70 mm×80 mm×60 mm in size was composed of spindle cells showing both neural and smooth muscle differentiation. Resection margins were histologically negative. Immunohistochemically, the tumor cells were positive for CD117, vimentin, SMA, S-100, and negative for CD34. Mitotic index was 10/50 HPF (10 pathological mitoses per 50 high-power field). The final pathological diagnosis of this tumor was gastrointestinal stromal tumor (GIST). The patient was discharged 9 d

Figure 1 Computed tomography and sonography of mesenteric mass (A and B) and liver tumor (C and D).

Figure 2 Mesenteric (A) and hepatic (B) tumors (intraoperative view).

after tumor resection without surgical complications. No adjuvant therapy was prescribed, because the liver tumor was not metastasized from GIST. The patient after 18 mo of follow-up showed no signs of recurrent disease.

## DISCUSSION

GIST are rare tumors that may arise from anywhere in the tubular gastrointestinal tract and give rise to metastases predominantly in the liver (more than 60% of metastases) or in the peritoneum<sup>[1,2,4,11,12]</sup>. In the present case, the solid mass in the liver was metastasized from the GIST. The histopathology showed that the tumor was a HCC. Coexistence of GIST and other primary tumors: renal carcinoma, bilateral pheochromocytoma, gastric cancer, and leiomyoma of the anorectum has been reported<sup>[6-10]</sup>.

GIST may coexist also with inflammatory pseudotumors of the liver. These lesions are benign and characterized by proliferating fibrovascular tissue with inflammatory cells. They are associated with fever, pain and a mass effect. These clinical symptoms were not observed in our patient. The inflammatory pseudotumors are commonly mistaken for malignant tumors<sup>[13]</sup>.

The described case is unique and should draw physicians' attention to the possibility of independent tumor coexistence when GIST occurs. In patient with two tumors in the abdomen, GIST and HCC coexistence must be excluded. This is especially important in making a decision of adjuvant therapy. The current GIST treatment guidelines established by European Society for Medical Oncology (ESMO) for adjuvant therapy with imatinib can be applied in non-operable and/or metastatic tumors. Patients with resectable tumors without metastases should not receive adjuvant therapy. The radiotherapy value as an adjuvant treatment method for GIST is not documented in the literature<sup>[5]</sup>.

The presence of hepatic tumor in patients with GIST should not judge the metastatic nature of liver tumors,

though in the literature it is the most common cause of the coexisting liver tumor. Although two independent tumors in patients with GIST are unique, we must not exclude such a possibility and only careful histopathological examination gives us a correct diagnosis.

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7<sup>th</sup>, 14<sup>th</sup>, 21<sup>st</sup> and 28<sup>th</sup> of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc.*, from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

**Published by**  
The WJG Press

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297mm×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

#### Online submission

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to [wjg@wjgnet.com](mailto:wjg@wjgnet.com) for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

#### Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4(297 mm×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or \*.rtf format to:

#### Editorial Office

**World Journal of Gastroenterology**  
Editorial Department: Apartment 1066, Yishou Garden,  
58 North Langxinzhuang Road,  
PO Box 2345, Beijing 100023, China  
E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)  
<http://www.wjgnet.com>

### MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

#### Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full

address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

#### Abstract

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

#### Key words

Please list 3-10 key words that could reflect content of the study mainly from *Index Medicus*.

#### Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

#### Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm×76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

#### Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

#### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P*<0.05, <sup>b</sup>*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P*<0.05 and <sup>d</sup>*P*<0.01 are used. Third series of *P* values can be expressed as <sup>e</sup>*P*<0.05 and <sup>f</sup>*P*<0.01. Other notes in tables or under illustrations should be expressed as <sup>1</sup>*F*, <sup>2</sup>*F*, <sup>3</sup>*F*; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

#### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

### PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

### Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>)

### Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

### Format

Standard journal article (list all authors and include the PubMed ID [PMID] where applicable)

- 1 **Das KM**, Farag SA. Current medical therapy of inflammatory bowel disease. *World J Gastroenterol* 2000; 6: 483-489 [PMID: 11819634]
- 2 **Pan BR**, Hodgson HJF, Kalsi J. Hyperglobulinemia in chronic liver disease: Relationships between *in vitro* immunoglobulin synthesis, short lived suppressor cell activity and serum immunoglobulin levels. *Clin Exp Immunol* 1984; 55: 546-551 [PMID: 6231144]
- 3 **Lin GZ**, Wang XZ, Wang P, Lin J, Yang FD. Immunologic effect of Jianpi Yishen decoction in treatment of Pixu-diarrhoea. *Shijie Huaren Xiaobua Zazhi* 1999; 7: 285-287

Books and other monographs (list all authors)

- 4 **Sherlock S**, Dooley J. Diseases of the liver and biliary system. 9th ed. Oxford: Blackwell Sci Pub, 1993: 258-296

Chapter in a book (list all authors)

- 5 **Lam SK**. Academic investigator's perspectives of medical treatment for peptic ulcer. In: Swabb EA, Azabo S. Ulcer disease: investigation and basis for therapy. New York: Marcel Dekker, 1991: 431-450

Electronic journal (list all authors)

- 6 **Morse SS**. Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1):24 screens. Available from: URL: <http://www.cdc.gov/ncidod/EID/eid.htm>

### Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

### Statistical data

Present as mean  $\pm$  SD and mean  $\pm$  SE.

### Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as *r* (in italics), degree of freedom as  $\gamma$  (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

### Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4  $\pm$  2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5  $\mu$ g/L; CO<sub>2</sub> volume fraction, 50 mL/L CO<sub>2</sub> not 5% CO<sub>2</sub>; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

### Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

### Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindII*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *Helicobacter pylori*, *H pylori*, *E coli*, etc.

## SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

### Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

### Copyright assignment form

It is the policy of *WJG* to acquire copyright in all contributions. Papers accepted for publication become the copyright of *WJG* and authors will be asked to sign a transfer of copyright form. All authors must read and agree to the conditions outlined in the Copyright Assignment Form (which can be downloaded from <http://www.wjgnet.com/wjg/help/9.doc>).

### Final check list for authors

The format is at: <http://www.wjgnet.com/wjg/help/13.doc>

### Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: <http://www.wjgnet.com/wjg/help/10.doc>

### Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

### Publication fee

Authors of accepted articles must pay publication fee.

EDITORIAL and LETTERS TO THE EDITOR are free of charge.

## World Journal of Gastroenterology standard of quantities and units

Number	Nonstandard	Standard	Notice
1	4 days	4 d	In figures, tables and numerical narration
2	4 days	four days	In text narration
3	day	d	After Arabic numerals
4	Four d	Four days	At the beginning of a sentence
5	2 hours	2 h	After Arabic numerals
6	2 hs	2 h	After Arabic numerals
7	hr, hrs,	h	After Arabic numerals
8	10 seconds	10 s	After Arabic numerals
9	10 year	10 years	In text narration
10	Ten yr	Ten years	At the beginning of a sentence
11	0,1,2 years	0,1,2 yr	In figures and tables
12	0,1,2 year	0,1,2 yr	In figures and tables
13	4 weeks	4 wk	
14	Four wk	Four weeks	At the beginning of a sentence
15	2 months	2 mo	In figures and tables
16	Two mo	Two months	At the beginning of a sentence
17	10 minutes	10 min	
18	Ten min	Ten minutes	At the beginning of a sentence
19	50% (V/V)	500 mL/L	
20	50% (m/V)	500 g/L	
21	1 M	1 mol/L	
22	10 μM	10 μmol/L	
23	1N HCl	1 mol/L HCl	
24	1N H <sub>2</sub> SO <sub>4</sub>	0.5 mol/L H <sub>2</sub> SO <sub>4</sub>	
25	4rd edition	4 <sup>th</sup> edition	
26	15 year experience	15- year experience	
27	18.5 kDa	18.5 ku, 18 500u or M:18 500	
28	25 g.kg <sup>-1</sup> /d <sup>-1</sup>	25 g/(kg·d) or 25 g/kg per day	
29	6900	6 900	
30	1000 rpm	1 000 r/min	
31	sec	s	After Arabic numerals
32	1 pg L <sup>-1</sup>	1 pg/L	
33	10 kilograms	10 kg	
34	13 000 rpm	13 000 g	High speed; g should be in italic and suitable conversion.
35	1000 g	1 000 r/min	Low speed. g cannot be used.
36	Gene bank	GenBank	International classified genetic materials collection bank
37	Ten L	Ten liters	At the beginning of a sentence
38	Ten mL	Ten milliliters	At the beginning of a sentence
39	umol	μmol	
40	30 sec	30 s	
41	1 g/dl	10 g/L	10-fold conversion
42	OD <sub>260</sub>	A <sub>260</sub>	"OD" has been abandoned.
43	One g/L	One microgram per liter	At the beginning of a sentence
44	A260 nm <sup>b</sup> P<0.05	A <sub>260</sub> nm <sup>a</sup> P<0.05	A should be in italic. In Table, no note is needed if there is no significance instatistics: <sup>a</sup> P<0.05, <sup>b</sup> P<0.01 (no note if P>0.05). If ther is a second set of P value in the same table, <sup>c</sup> P<0.05 and <sup>d</sup> P<0.01 are used for a third set: <sup>a</sup> P<0.05, <sup>b</sup> P<0.01.
45	<sup>*</sup> F=9.87, <sup>§</sup> F=25.9, <sup>#</sup> F=67.4	<sup>1</sup> F=9.87, <sup>2</sup> F=25.9, <sup>3</sup> F=67.4	Notices in or under a table
46	KM	km	kilometer
47	CM	cm	centimeter
48	MM	mm	millimeter
49	Kg, KG	kg	kilogram
50	Gm, gr	g	gram
51	nt	N	newton
52	l	L	liter
53	db	dB	decibel
54	rpm	r/min	rotation per minute
55	bq	Bq	becquerel, a unit symbol
56	amp	A	ampere
57	coul	C	coulomb
58	HZ	Hz	
59	w	W	watt
60	KPa	kPa	kilo-pascal
61	p	Pa	pascal
62	ev	EV	volt (electronic unit)
63	Jonle	J	joule
64	J/mm <sup>3</sup>	kJ/mol	kilojoule per mole
65	10×10×10cm <sup>3</sup>	10 cm×10 cm×10 cm	
66	N·km	KN·m	moment
67	x±s	mean±SD	In figures, tables or text narration
68	Mean±SEM	mean±SE	In figures, tables or text narration
69	im	im	intramuscular injection
70	iv	iv	intravenous injection
71	Wang et al	Wang <i>et al.</i>	
72	EcoRI	EcoRI	<i>Eco</i> in italic and RI in positive. Restriction endonuclease has its prescript form of writing.
73	Ecoli	<i>E.coli</i>	Bacteria and other biologic terms have their specific expression.
74	Hp	<i>H pylori</i>	
75	Iga	<i>Iga</i>	writing form of genes
76	igA	IgA	writing form of proteins
77	~70 kDa	~70 ku

## Contents

### EDITORIAL

- 673 Novel mechanisms in functional dyspepsia  
*Choung RS, Talley NJ*

### REVIEW

- 678 Liver cirrhosis and arterial hypertension  
*Henriksen JH, Moller S*

### GASTRIC CANCER

- 686 Construction of retroviral vector of p<sup>125FAK</sup> specific ribozyme genes and its effects on BGC-823 cells  
*Guan GX, Jian HX, Lei DY, Lu HS, Zhang XF*
- 691 Down-expression of tumor protein p53-induced nuclear protein 1 in human gastric cancer  
*Jiang PH, Motoo Y, Garcia S, Iovanna JL, Pébusque MJ, Sawabu N*

### BASIC RESEARCH

- 697 Cyclosporine *versus* tacrolimus in patients with HCV infection after liver transplantation: Effects on virus replication and recurrent hepatitis  
*Hilgard P, Kahraman A, Lehmann N, Seltmann C, Beckebaum S, Ross RS, Baba HA, Malago M, Broelsch CE, Gerken G*
- 703 STI571 (Glivec) suppresses the expression of vascular endothelial growth factor in the gastrointestinal stromal tumor cell line, GIST-T1  
*Jin T, Nakatani H, Taguchi T, Nakano T, Okabayashi T, Sugimoto T, Kobayashi M, Araki K*
- 709 Effect of increased hepatic platelet activating factor and its receptor portal hypertension in CCl<sub>4</sub>-induced liver cirrhosis  
*Yang YP, Ma XM, Wang CP, Han J, Lu YY, Xiang Y, Su SH, Feng YY*
- 716 IL-1 $\beta$  activates p44/42 and p38 mitogen-activated protein kinases via different pathways in cat esophageal smooth muscle cells  
*Lee TS, Song HJ, Jeong JH, Min YS, Shin CY, Sohn UD*
- 723 GFAP promoter directs *lacZ* expression specifically in a rat hepatic stellate cell line  
*Maubach G, Lim MCC, Zhang CY, Zhuo L*
- 731 Variable expression of cystatin C in cultured trans-differentiating rat hepatic stellate cells  
*Gressner AM, Lahme B, Meurer SK, Gressner O, Weiskirchen R*

### CLINICAL RESEARCH

- 739 Microproteinuria in patients with inflammatory bowel disease: Is it associated with the disease activity or the treatment with 5-aminosalicylic acid?  
*Poulou AC, Goumas KE, Dandakis DC, Tympas I, Panagiotaki M, Georgouli A, Soutos DC, Archimandritis A*
- 747 Prospective, randomized, and active controlled study of the efficacy of alginate acid and antacid in the treatment of patients with endoscopy-negative reflux disease  
*Lai IR, Wu MS, Lin JT*
- 755 Clinical application of self-expanding metallic stent in the management of

acute left-sided colorectal malignant obstruction

*Fan YB, Cheng YS, Chen NW, Xu HM, Yang Z, Wang Y, Huang YY, Zheng Q*

- 760** Objective assessment of the antispasmodic effect of Shakuyaku-kanzo-to (TJ-68), a Chinese herbal medicine, on the colonic wall by direct spraying during colonoscopy

*Ai M, Yamaguchi T, Odaka T, Mitsuhashi K, Shishido T, Yan J, Seza A, Saisho H*

- RAPID COMMUNICATION** **765** Surgical treatment of patients with intermediate-terminal pancreatic cancer  
*Liu YB, Huang L, Xian ZY, Jian ZX, Ou JR, Liu ZX*

- 768** Portal vein pulsatility index is a more important indicator than congestion index in the clinical evaluation of right heart function

*Shih CY, Yang SS, Hu JT, Lin CL, Lai YC, Chang CW*

- 772** Successful laparoscopic management for cholecystoenteric fistula

*Wang WK, Yeh CN, Jan YY*

- 776** Interleukin-1 $\beta$  gene polymorphism associated with hepatocellular carcinoma in hepatitis B virus infection

*Hirankarn N, Kimkong I, Kummee P, Tangkijvanich P, Poovorawan Y*

- 780** Increased heat shock protein 70 expression in the pancreas of rats with endotoxic shock

*Wang XL, Li Y, Kuang JS, Zhao Y, Liu P*

- 784** Interferon alpha plus ribavirin combination treatment of Japanese chronic hepatitis C patients with HCV genotype 2: A project of the Kyushu University Liver Disease Study Group

*Furusyo N, Katoh M, Tanabe Y, Kajiwaru E, Maruyama T, Shimono J, Sakai H, Nakamuta M, Nomura H, Masumoto A, Shimoda S, Takahashi K, Azuma K, Hayashi J, Kyushu University Liver Disease Study Group*

- 791** Omeprazole maintenance therapy prevents recurrent ulcer bleeding after surgery for duodenal ulcer

*Demertzis K, Polymeros D, Emmanuel T, Triantafyllou K, Tassios P, Ladas SD*

- 796** Involvement of mitochondrial Na<sup>+</sup>-Ca<sup>2+</sup> exchange in intestinal pacemaking activity

*Kim BJ, Jun JY, So I, Kim KW*

- 800** Combined resection and multi-agent adjuvant chemotherapy for desmoplastic small round cell tumor arising in the abdominal cavity: Report of a case

*Chang CC, Hsu JT, Tseng JH, Hwang TL, Chen HM, Jan YY*

## CASE REPORTS

- 804** Ruptured angiosarcoma of the liver treated by emergency catheter-directed embolization

*Leowardi C, Hormann Y, Hinz U, Wente MN, Hallscheidt P, Flechtenmacher C, Büchler MW, Friess H, Schwarzbach MHM*

- 809** First report of a *de novo* germline mutation in the *MLH1* gene

## Abstract

Functional dyspepsia (FD) is a highly prevalent but heterogeneous disorder in which multiple pathogenetic mechanisms are involved. Although there are many studies that have investigated various pathophysiologic mechanisms, the underlying causal pathways associated with FD remain obscure. The currently proposed pathophysiologic mechanisms associated with FD include genetic susceptibility, delayed as well as accelerated gastric emptying, visceral hypersensitivity to acid or mechanical distention, impaired gastric accommodation, abnormal fundic phasic contractions, abnormal antroduodenal motility, acute and chronic infections, and psychosocial comorbidity. A greater understanding of the abnormalities underlying FD may lead to improved management. The aim of this editorial is to provide a critical overview of current pathophysiologic concepts in functional dyspepsia.

## INTRODUCTION

Dyspepsia, or pain or discomfort centered in the upper abdomen, is a common condition accounting for 2-5% of all primary care consults; the annual prevalence is 25%<sup>[1-3]</sup>. Dyspepsia is a major cause of morbidity and economic loss in the community<sup>[4]</sup>. A heterogeneous group of pathophysiologic mechanisms have been implicated in the etiology of functional dyspepsia (FD).

Delayed gastric emptying<sup>[5]</sup>, antral hypomotility and altered intestinal motility<sup>[6]</sup>, diminished gastric accommodation<sup>[7]</sup>, *Helicobacter pylori* infection<sup>[8]</sup>, abnormal duodenal sensitivity to acid<sup>[9]</sup>, enhanced visceral sensitivity<sup>[10]</sup>, carbohydrate maldigestion<sup>[11]</sup>, food intolerance<sup>[12]</sup>, and psychological factors<sup>[13]</sup> have all been identified in subgroups of patients with functional dyspepsia, with much overlap.

Despite the high prevalence of FD and its significant impact on social and health care costs, the underlying causal pathways are still obscure. Therefore, our objective here is to briefly provide an overview of the known pathophysiology of FD, and highlight recent advances in our knowledge.

## GENETICS

Recent evidence supports the relevance of a genetic milieu in FD. A case-control study by Holtmann *et al*<sup>[14]</sup> suggested that there is a significant link between GN $\beta$ 3(C825T) CC genotype and functional dyspepsia (OR = 2.2, 95% CI = 1.4-3.3). Although their study<sup>[14]</sup> had some limitations including the high prevalence of the CC genotype among control subjects and the relatively modest excess of the genotype in FD subjects, their findings do represent the first identification of a putative genetic predisposition. The association has been independently confirmed<sup>[15]</sup>. Further studies of the relationship between genetic polymorphisms and other pathophysiologic factors in FD are now needed.

## ABNORMALITIES IN UPPER GUT MOTOR FUNCTION

A prevalence of disturbances in gut motor function of about 20-40% in FD patients is now accepted<sup>[6,7,16]</sup>. The disturbances of gastric motor function most often reported in FD include delayed gastric emptying<sup>[16]</sup>, abnormalities in antral contractility<sup>[6]</sup> and an impaired accommodation response (a vagally-mediated reflex relaxation of the fundus in response to a meal)<sup>[7]</sup>.

### Gastric emptying

Delayed gastric emptying has been described in 25-50% of patients with FD<sup>[16-19]</sup>. The majority of small sample sized investigations failed to identify association between delayed gastric emptying and any dyspeptic symptoms<sup>[20-22]</sup>. Stanghellini *et al*<sup>[16]</sup>, in a large study with 343 patients with FD, showed that female sex, relevant and severe postprandial fullness, and severe vomiting were independently associated with delayed gastric emptying of solids. Other European studies have generally confirmed

these findings<sup>[17,18]</sup>, but studies from the US have not<sup>[23,24]</sup>. Recently, accelerated gastric emptying in FD has also been associated with postprandial fullness, bloating, nausea, and pain, presumably through an early dumping syndrome<sup>[25]</sup>. These findings imply that administration of a prokinetic agent to accelerate gastric emptying may actually lead to worsening, rather than to improvement of symptoms, in at least a proportion of patients with FD.

### **Impaired gastric accommodation**

Gastric accommodation is a vagally mediated reflex that occurs post-prandially, results in reduction of tone, and provides a reservoir for the meal; it enables the stomach to handle increases in intragastric volume without proportional increases of intragastric pressures<sup>[7,26,27]</sup>.

Studies by the barostat, scintigraphy, ultrasonography, single photon emission computed tomography (SPECT), and non-imaging assessments (satiation drinking test) have all suggested abnormal accommodation in up to 40% of patients with functional dyspepsia<sup>[7,26-30]</sup>. The mechanism of impaired gastric accommodation is, however, not clearly understood. Tack *et al*<sup>[26]</sup> proposed that impaired proximal stomach accommodation of an ingested meal was associated with early satiety and weight loss in FD, but other studies have not confirmed these symptom associations<sup>[24,28]</sup>.

Relaxation of the proximal stomach can be activated by duodenal distension or nutrient infusion, or via a vagovagal reflex pathway, and it requires activation of intrinsic nitrergic neurons in the stomach. Recent reports<sup>[31,32]</sup> have suggested that a defect at the level of the gastric intrinsic nitrergic neurons may be relevant. Abnormal vagal reflexes may also play a role, because postvagotomy patients have a similar impairment of gastric accommodation, and abnormal vagal function is observed in patients with FD<sup>[33,34]</sup>.

### **Abnormal phasic contractility of the proximal stomach**

Phasic fundic contractions induce transient increases in gastric wall tension and can be perceived in FD<sup>[8,35]</sup>. In the recent study using a gastric barostat, unsuppressed postprandial phasic activity in the proximal stomach was present in a small subgroup of patients with FD<sup>[36]</sup>. This was associated with symptoms of severe postprandial bloating. However, the mechanisms underlying unsuppressed phasic contractility are unclear and further studies will be required.

### **Abnormalities of gastric myoelectrical rhythm**

Electrogastrography obtains a cutaneous recording of gastric myoelectrical activity from abdominal surface electrodes. Some studies<sup>[37-39]</sup> have reported gastric myoelectrical abnormalities are found in up to two-thirds of patients with FD. A close relationship between the presence of delayed gastric emptying and abnormalities of gastric electrical rhythm has been reported<sup>[37-39]</sup>. However, their relevance to symptom generation is still uncertain.

### **Antro-duodenal dysmotility**

Manometric studies have demonstrated antral hypomotility in a large proportion of those with FD<sup>[27,40,41]</sup>.

Antral hypomotility could be associated with gastric stasis manifested by a slower emptying rate of meals<sup>[40]</sup>, but its correlation with specific symptoms is poor.

## **DISTURBANCES IN VISCERAL SENSITIVITY**

The gut wall contains three kinds of neural receptors: chemoreceptors in the mucosa, which respond to chemical stimuli; mechanoreceptors in the smooth muscle layer, which respond to stretch or compression; and nociceptors, the most numerous receptors in all layers, which are commonly silent, but can be recruited by any stimulus strong enough to induce pain<sup>[42]</sup>.

### **Visceral hypersensitivity to mechanical distension**

Increased perception to visceral physiological or minor noxious stimuli, i.e., a lower threshold for sensation, has been considered one of major pathophysiologic mechanisms in the functional gastrointestinal disorders<sup>[28,43-44]</sup>. The level of abnormality where visceral hypersensitivity is located is not clear, but several observations suggest that alterations exist at the level of the central nervous system or in addition to hyperexcitability of visceral afferents<sup>[43-46]</sup>.

Several studies have found dyspeptic patients have lower thresholds for first perception and discomfort or pain during isobaric gastric distension or jejunal distension<sup>[29,47,48]</sup>. Mertz *et al*<sup>[44]</sup> reported that hypersensitivity to gastric balloon distension was specific for FD, and Holtmann *et al*<sup>[49, 50]</sup> have shown a failure of sensory thresholds to increase in patients with FD. While Tack *et al*<sup>[43]</sup> have shown hypersensitivity to gastric distension was associated with a higher prevalence of post-prandial pain, belching and weight loss. The symptom correlations remain to be confirmed.

Abnormal central nervous system processing of afferent information during gastric stimuli has been suggested to be one of the mechanisms of visceral hypersensitivity<sup>[46]</sup>. Ladabaum *et al*<sup>[51]</sup> performed PET scanning during distal gastric distension in healthy volunteers, and found increases in activation of somatic and visceral pain processing areas that were proportional to the distension-evoking stimuli. Vandenberghe *et al*<sup>[52]</sup> also performed PET scanning after proximal gastric distension in healthy volunteers, and found a neuronal network processing distention stimuli from the proximal stomach. Further study is needed to assess whether abnormalities in central processing of visceral stimuli occur in FD.

### **Visceral hypersensitivity to chemical stimuli**

Several studies<sup>[53-55]</sup> have been conducted to evaluate chemical sensitivity in FD, but its mechanism is not clear. In both healthy subjects and in patients with FD, perception of gastric distension was enhanced by nutrient lipids but not by glucose<sup>[55]</sup>. Feinle *et al*<sup>[56,57]</sup> studied the effects of lipid on gastrointestinal sensation in healthy and dyspeptic subjects and suggested that cholecystokinin A (CCK-A) and serotonergic (5-HT<sub>3</sub>) receptors mediate, at least in part, gastrointestinal sensation. They reported that intravenous administration of a CCK-A receptor antagonist reduced the effects of duodenal lipid on gastric

relaxation and gastrointestinal sensations during gastric distension. Although they studied only small numbers of patients, these findings support changes in chemical sensitivity in FD; this needs to be validated in larger studies.

In a subset of FD patients, but not in healthy controls, intraduodenal infusion of hydrochloric acid (HCl) was found to induce nausea<sup>[9]</sup>, suggesting duodenal hypersensitivity to acid. Some patients had impaired clearance of acid from the duodenum and impaired duodenal motor response to acid. Recently, Tack *et al.*<sup>[58]</sup> observed that duodenal acidification increased proximal gastric mechanosensitivity, induced proximal gastric relaxation, and inhibited proximal gastric accommodation to a meal. However, the underlying mechanisms remain to be elucidated in future studies.

## INFECTIOUS AGENTS

Acute and chronic infections may be involved in the pathogenesis of the functional bowel disorders<sup>[31,59-61]</sup>.

### *Helicobacter pylori* infection

Many studies and several meta-analysis have tried to establish a relationship between *Helicobacter pylori* (*H. pylori*) infection and FD<sup>[59-63]</sup>. The most recently published meta-analysis<sup>[64]</sup> suggests that *H. pylori* eradication at 12 months has a small but statistically significant benefit in the treatment of FD (relative risk of remaining dyspeptic with *H. pylori* eradication therapy = 0.91; 95% CI = 0.87-0.99). While statistically significant, the clinical significance of this finding is less clear because the effect is small, that is, 15 *H. pylori*-positive dyspeptic patients will need to be treated to achieve just one cure.

The association between *H. pylori* infection and pathophysiologic mechanisms has been investigated; however, no consistent differences in the prevalence and severity of individual symptoms, gastric emptying rate, or gastric relaxation after a meal were found between *H. pylori*-positive and *H. pylori*-negative subjects<sup>[60,61]</sup>.

### Post-infectious dyspepsia

It has now been well established that irritable bowel syndrome may follow an acute intestinal infection. Post-infectious dyspepsia has been recognized as a possible clinical entity by Tack *et al.*<sup>[31]</sup>. In a large retrospective, tertiary referral center study, they showed that a subset of dyspeptic patients has a history suggestive of post-infectious dyspepsia. Compared with patients with unspecified-onset dyspepsia, patients with presumed post-infectious dyspepsia have more prevalent symptoms of early satiety, weight loss, nausea, and vomiting and had a significantly higher prevalence of impaired accommodation of the proximal stomach, whereas both groups did not differ in the prevalence of delayed gastric emptying, or hypersensitivity to gastric distention<sup>[31]</sup>. They suggested that impaired accommodation in patients with presumed post-infectious dyspepsia is attributable to a dysfunction at the level of gastric nitrergic neurons. In this study, the lack of prospective design limited the validity of the results.

In a prospective cohort study, Mearin *et al.*<sup>[65]</sup> found

that development of dyspepsia was increased 5-fold at 1 year after acute *Salmonella* gastroenteritis as compared with control subjects without baseline infection. There were some limitations because of the low response rate in the 1-year follow-up survey and lack of information on psychological status and stressful events<sup>[65]</sup>. Further studies are needed to identify the underlying pathophysiology and risk factors, and define the long-term prognosis.

## PSYCHOSOCIAL ABNORMALITIES

In FD patients, a number of psychological and personality factors have been observed, including somatization, depression, and anxiety as well as health seeking behavior and alterations in illness behavior and coping styles<sup>[66-68]</sup>. These psychosocial factors are influenced by and influence GI symptoms; this bidirectional flow is mediated through the brain-gut axis<sup>[43]</sup>. The value of psychological therapies in FD, to date, is promising, but further studies of psychological treatment of FD are needed<sup>[69]</sup>.

## CONCLUSIONS

FD is a highly heterogeneous disorder. Traditional pathophysiological paradigms are still inadequate to explain the variation in the symptoms observed. Current symptom subclassifications have also largely failed to identify responders to specific therapies. A new classification based on mechanisms and specific symptoms needs to be considered to further advance the field. The contributors to this heterogeneity need to be better defined, and be environmental, pathological, psychological, or genetic. This could lead to better targeting of treatment in FD patients with unexplained epigastric pain or discomfort.

### Abstract

Characteristic findings in patients with cirrhosis are vasodilatation with low overall systemic vascular resistance, high arterial compliance, increased cardiac output, secondary activation of counter-regulatory systems (renin-angiotensin-aldosterone system, sympathetic nervous system, release of vasopressin), and resistance to vasopressors. The vasodilatory state is mediated through adrenomedullin, calcitonin gene-related peptide, nitric oxide, and other vasodilators, and is most pronounced in the splanchnic area. This constitutes an effective (although relative) counterbalance to increased arterial blood pressure. This review considers the alterations in systemic hemodynamics in patients with cirrhosis in relation to essential hypertension and arterial hypertension of the renal origin. Subjects with arterial hypertension (essential, secondary) may become normotensive during the development of cirrhosis, and arterial hypertension is rarely manifested in patients with cirrhosis, even in cases with renovascular disease and high circulating renin activity. There is much dispute as to the understanding of homeostatic regulation in cirrhotic patients with manifest arterial hypertension. This most likely includes the combination of vasodilatation and vasoconstriction in parallel.

### INTRODUCTION

Arterial hypertension is seldom found in patients with liver disease, but patients with alcoholic fatty liver quite often present with raised arterial blood pressure. Renal involvement is seen in hepatitis B and in certain cases this may be accompanied by arterial hypertension. Otherwise, the clinical course of most liver diseases is characterized by low arterial blood pressure. This paper focuses on the circulatory dysfunction in cirrhosis, which is the most common characteristic of the chronic liver diseases.

Abnormalities in the splanchnic circulation are well described in patients with cirrhosis<sup>[5-7]</sup>. These include increased inflow to the splanchnic system and portal venous hypertension. Moreover, such patients are often hyperkinetic with increased heart rate and cardiac output. The hyperkinetic systemic circulation is related to the severity of cirrhosis, sodium-water retention, and presence of ascites<sup>[8]</sup>. The overall systemic vascular resistance is decreased, the blood volume is abnormally distributed with relative and absolute central hypovolemia, and cardiovascular, renal, and other organ dysfunction is common, including abnormal neurohormonal regulation<sup>[8-10]</sup>. Essential hypertension is frequently reported in both developed and developing countries, and the prevalence of essential hypertension in patients with cirrhosis would be expected to be around 15%<sup>[11,12]</sup>. However, most reports put the coexistence of cirrhosis and arterial hypertension much lower. As in patients with essential hypertension, most circulatory changes in cirrhosis are dysfunctional, rather than structural.

This review considers the cardiovascular system, neurohormonal regulatory systems, kidney function, and sodium-water retention with respect to arterial blood pressure and its regulation in patients with cirrhosis with the purpose of analyzing the background of the profound circulatory changes, their development, and complications. These elements are considered with respect to essential hypertension and arterial hypertension of renal origin.

### HEPATOSPLANCHNIC CIRCULATION

The mechanisms behind the circulatory changes in the hepatosplanchnic system are both functional and structural<sup>[13]</sup>. Thus, a reduced hepatic vascular cross-sectional area, owing to the formation of fibrosis and noduli, is well known<sup>[13]</sup>. Swelling of hepatocytes and contraction of myofibrillary cells also contribute to hinder the hepatic outflow. Low content in endothelial cells of the vasodilator, nitric oxide (NO), may contribute to

hepatic vasoconstriction<sup>[14]</sup>. In addition, vasodilators are produced in excess and escape degradation by the diseased liver, which may play a role in splanchnic and systemic vasodilatation in concert with local factors, especially shear stress<sup>[6,15,16]</sup>. The result is an increased splanchnic inflow that aggravates and prolongs the portal hypertension, which is an essential element in cirrhosis<sup>[7]</sup>. The formation of portosystemic collaterals with a highly increased flow through the azygos venous system contributes to the decreased overall vascular resistance<sup>[5,7]</sup>.

## SYSTEMIC CIRCULATION

### Overall systemic vascular resistance

Overall systemic vascular resistance is decreased in most patients with cirrhosis. Recent studies have shown that the circulation in most vascular territories is disturbed. A close look at the individual organs and tissues reveals vascular beds with decreased perfusion, normal perfusion, and increased perfusion. This indicates areas with high resistance (such as the kidneys), normal resistance (such as the brain), and low resistance (such as the splanchnic system)<sup>[6,7]</sup> (Table 1). The pathogenesis of hyporeactivity of the vascular system in cirrhosis is multifactorial<sup>[17]</sup>. Clinical and experimental observations favor the presence of a surplus of circulating vasodilators. Combined with

a decreased sensitivity to pressor substances, this leads to vasodilatation and reduced vascular resistance<sup>[7,17]</sup>. Vasodilatation and the resulting activation of counter-regulatory mechanisms are closely related to the circulatory dysfunction in chronic liver disease<sup>[18,19]</sup>. The reduced vascular responsiveness may be generated by a decrease in the number of receptors, a change in receptor affinity, and several postreceptor defects<sup>[20]</sup>. Recent evidence suggests that all of these mechanisms are working in concert in cirrhosis<sup>[20]</sup>.

The coexistence of decreased splanchnic resistance (as in cirrhosis) and increased peripheral resistance (as in essential arterial hypertension) is likely and may depend on the altered circulating vasoactive substances, reactivity of vasomotor and regulatory systems, etc<sup>[21,22]</sup>. The result may be increased, normal, or decreased systemic vascular resistance. However, most evidence indicates that a decreased overall systemic vascular resistance with a low arterial blood pressure is most often the outcome, even in patients with primary essential hypertension<sup>[23-25]</sup>. Research on vascular hyporeactivity has primarily focused on calcitonin gene-related peptide (CGRP), NO, tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), adrenomedullin, and endocannabinoids<sup>[17,18]</sup>. In addition, there is substantial evidence of autonomic defects in patients with cirrhosis. Thus, the sympathetic nervous system is both dysfunctional and overactivated. The reason for vasoconstriction in some vascular areas is mainly overwhelming activity of pressor systems, but dysfunctional elements are also present<sup>[5,19,26]</sup>.

### Arterial blood pressure

The arterial blood pressure depends on the cardiac output and the systemic vascular resistance. The former is primarily determined by heart rate, venous return, and myocardial contractility. The latter is determined by the tone of smooth muscle cells in the small arteries and arterioles, which is governed by complex local and central neurohumoral factors. Arterial blood pressure has a circadian rhythm, but is kept within its habitual range by negative feedback baroreceptor reflexes, volume regulation, and other regulatory systems<sup>[12]</sup>.

According to standardized recommendations, arterial blood pressure in patients with cirrhosis is often measured in the morning. However, 24-h determinations of blood pressure show that, during the day, the arterial blood pressure is substantially reduced compared with that of the controls, but at night it is normal<sup>[27]</sup>. The shifted and flat blood pressure-heart rate relation in patients with cirrhosis suggests that the regulation of their blood pressure is abnormal<sup>[27]</sup>. Moreover, the hemodynamic dysregulation is more pronounced with increasing severity of the liver disease<sup>[9]</sup>. The abnormal diurnal variation of the arterial blood pressure and the drastic activation of the neurohormonal systems probably contribute to the sodium-water retention.

Studies of patients with cirrhosis and arterial hypertension show that the prevalence is substantially reduced with raised arterial blood pressure in only 3-7% of such patients<sup>[21,24,28,29]</sup>. In addition, a few longitudinal studies have indicated that in patients with essential arterial hypertension, the raised arterial blood pressure is

**Table 2 Haemodynamics and neuroendocrine mechanisms in patients with cirrhosis and different types of arterial hypertension**

reduced to normal values after the onset of cirrhosis<sup>[23]</sup>. Thus, patients with essential hypertension may become normotensive during the development of chronic liver disease. In patients with cirrhosis, the liver disease may protect against the development of arterial hypertension, and in patients with advanced cirrhosis raised arterial pressure is very uncommon<sup>[24,30]</sup>.

Gentilini *et al.* have investigated patients with early non-alcoholic cirrhosis and arterial hypertension<sup>[21]</sup>. They found that the arterial hypertensive cirrhotic patients were normodynamic with a normal heart rate and cardiac output. By contrast, their normotensive cirrhotic counterparts were hyperdynamic in the supine position and normodynamic in the upright position. They concluded that hypertensive cirrhotic patients had an impaired cardiovascular response to postural changes, but a lesser degree of renal dysfunction while standing than that of their normotensive counterparts<sup>[21]</sup>. No difference in the plasma renin activity of the normotensive and hypertensive cirrhotics was present<sup>[21]</sup>. By contrast, Veglio *et al* had previously found that hypertensive cirrhotic patients had a lower plasma renin activity, both supine and upright<sup>[29]</sup>. They concluded that the peripheral pressor effect of vasoactive hormones was increased and the effective blood volume was enhanced in arterial hypertensive cirrhotic patients<sup>[29]</sup>. The authors of the present review have been unable to confirm Gentilini *et al*'s result of a normodynamic circulation in early hypertensive cirrhotic patients and Veglio *et al*'s hypothesis of an enhanced effective blood volume in these patients<sup>[31]</sup>. However, Henriksen *et al*'s study showed that hypertensive cirrhotic patients are less vasodilated than their normotensive counterparts<sup>[31]</sup>, (Figure 1). Essential differences in arterial hypertension and cirrhosis are summarized in Table 2.

### Arterial compliance

Arterial compliance (i.e., an increase in intra-arterial volume relative to an increase in transmural arterial blood pressure) is raised in patients with decompensated cirrhosis<sup>[9,21]</sup>. Recent investigations have shown that the altered static and dynamic characteristics of the wall

of large arteries in patients with cirrhosis are closely associated with the circulatory and homeostatic derangement<sup>[9,21,32-35]</sup>. The changes in arterial mechanics are, at least in part, reversible<sup>[32]</sup>. Arterial compliance is an important determinant of the coupling between the heart and the arterial system and of the dynamics of intravascular volume relocation<sup>[36]</sup>. Reduced arterial blood volume and blood pressure are the most likely elements in the elevated arterial compliance in advanced cirrhosis<sup>[9,13]</sup>. The increased arterial compliance in patients with cirrhosis is directly related to the severity of the liver disease and the circulating level of the vasodilator CGRP<sup>[32]</sup>. It is inversely related to circulating adrenaline, but is not significantly related to the indicators of the potent vasoconstrictor systems (sympathetic nervous system (SNS) and endothelin-1)<sup>[32-35]</sup>. In addition, the abnormal arterial compliance is related to blood volume abnormalities, hypoxia, and to the abnormalities in the C-type natriuretic peptide (CNP), but not to the atrial natriuretic peptide (ANP)<sup>[33,35]</sup>. Arterial compliance is not affected by beta-adrenergic blockade, but infusion of the vasopressin analog terlipressin almost normalizes it<sup>[37]</sup>. Both types of drugs are used in the treatment of portal hypertension<sup>[38]</sup>. In arterial hypertensive cirrhotic patients, arterial compliance is normal or almost normal<sup>[31]</sup>.

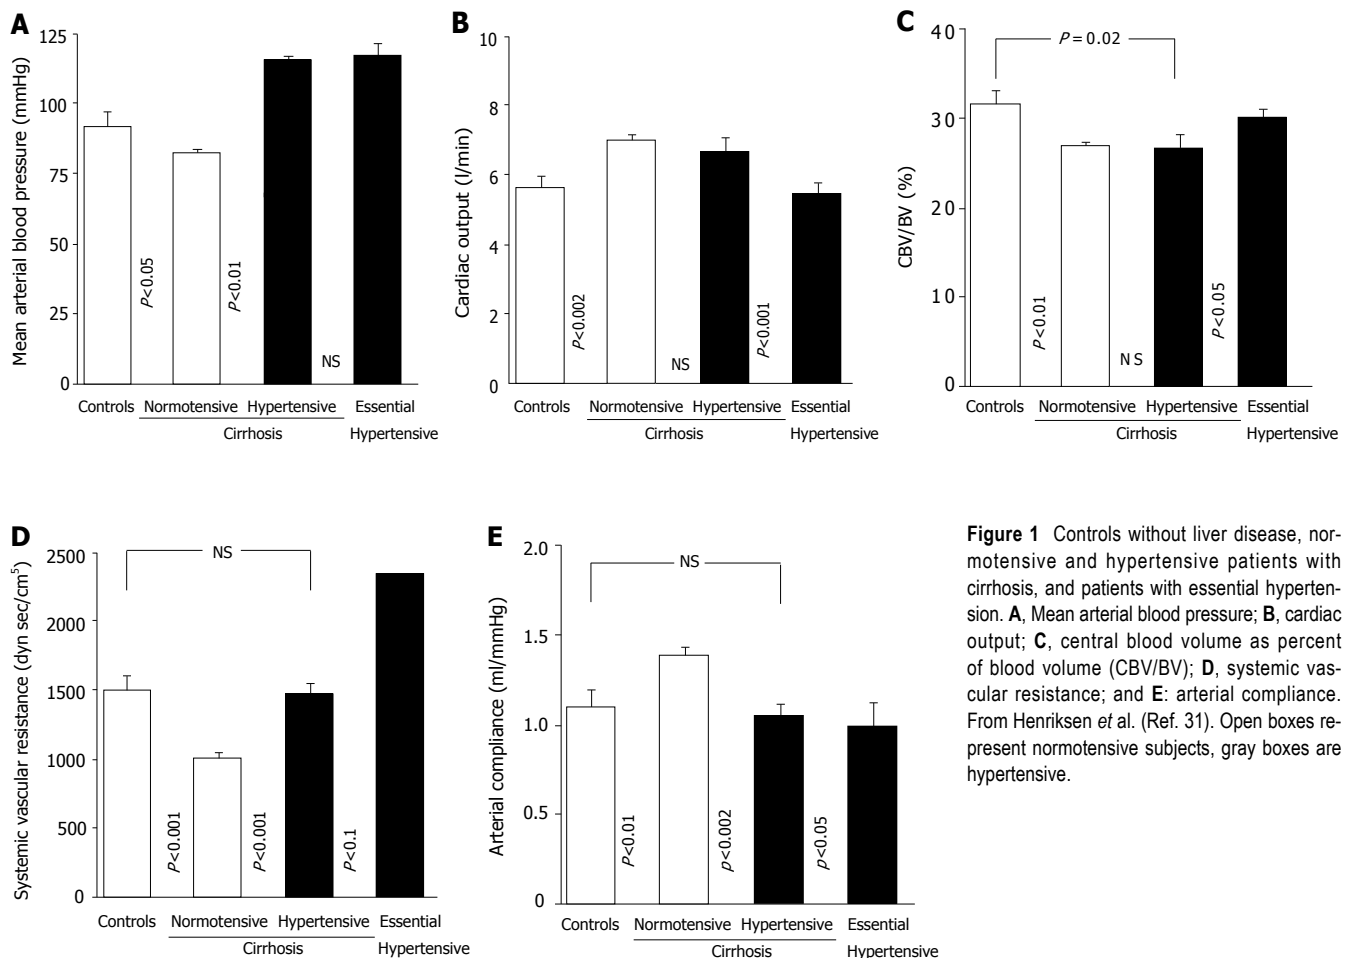

### Blood volume distribution

Patients with cirrhosis have increased blood and plasma volumes<sup>[8,10]</sup>. Distribution of blood to the different vascular beds is abnormal and more so in severe liver disease<sup>[39-42]</sup>. Moreover, dynamic, as well as static, methods have revealed that the central (thoracic) blood volume is most often decreased, (Figure 1c), whereas the non-central (especially splanchnic) blood volume is increased in patients with cirrhosis<sup>[10,39]</sup>. The effective arterial blood volume is decreased, and the abnormal volume distribution contributes to the systemic circulatory derangement<sup>[42]</sup>. Thus, the central circulation time (that is, central blood volume relative to the cardiac output) in cirrhosis has a significant relation to the survival and is substantially reduced also in cirrhotic patients with arterial hypertension<sup>[31]</sup>. During volume expansion (either by blood transfusion, or infusion of albumin or osmotic material) most cirrhotic patients respond with a further reduction in systemic vascular resistance rather than an increase in arterial blood pressure<sup>[33,42]</sup>. Future studies may disclose whether raised arterial blood pressure is indicative of normal arterial filling or the result of arterioconstrictive adaptation to a low arterial blood volume. Moreover, the balance between vascular areas with vasodilatation and vasoconstriction may be substantially altered in arterial hypertensive patients with cirrhosis<sup>[31]</sup>.

### Cardiac dysfunction

In patients with advanced cirrhosis increased heart rate and stroke volume led to a high cardiac output<sup>[18,36]</sup>. A left ventricular failure may be latent, because of the decreased afterload (as reflected by reduced systemic vascular resistance and increased arterial compliance)<sup>[20,36]</sup>. Cardiac dysfunction may become manifest under strain or treatment with vasoconstrictors. Cirrhotic cardiomyopathy includes

**Figure 1** Controls without liver disease, normotensive and hypertensive patients with cirrhosis, and patients with essential hypertension. **A**, Mean arterial blood pressure; **B**, cardiac output; **C**, central blood volume as percent of blood volume (CBV/BV); **D**, systemic vascular resistance; and **E**: arterial compliance. impaired cardiac contractility (systolic dysfunction), diastolic dysfunction, prolonged *Q-T* interval, reduced beta-adrenoceptor density, postreceptor signal defects, abnormal excitation-contraction coupling, and molecular abnormalities<sup>[20,36,43]</sup>. Recently, it has been substantiated that the elevated levels of circulating pro-brain natriuretic peptide (pro-BNP) and brain natriuretic peptide (BNP) found in patients with cirrhosis are not related to the decreased disposal of these peptides, but to the increased production in the cirrhotic heart, thus indicating cardiac dysfunction in cirrhosis<sup>[44]</sup>. In cirrhotic patients with arterial hypertension signs of myocardial involvement may be especially pronounced<sup>[21,30]</sup>.

Cirrhotic cardiomyopathy must be differentiated from alcoholic heart muscle disease, which is caused by impaired contractile protein synthesis and formation of immunogenic cardiac protein-acetaldehyde adducts. The presence of antibodies to these adducts may be a marker for alcoholic heart muscle disease and possibly for its pathogenesis<sup>[36]</sup>.

## NEUROHUMORAL REGULATION OF ARTERIAL BLOOD PRESSURE AND VOLUME DISTRIBUTION IN CIRRHOSIS

Splanchnic arteriolar vasodilatation may lead to abnormal distribution of the circulating medium with a decrease in the effective blood volume and low arterial blood

volume and pressure, and to an expansion of the non-central blood volume, including the splanchnic bed<sup>[14,26,42]</sup>. Most patients with advanced decompensated cirrhosis have a highly increased activity of vasopressor systems with a highly elevated plasma renin activity, circulating noradrenaline, and plasma vasopressin<sup>[5,6,26]</sup>. In most cases there is a progressive increase from normal values to moderately increased values in preportal hypertensive patients to a further increase in portal hypertensive patients to highly increased values in ascitic patients, especially in those with functional renal failure<sup>[5,45]</sup>. Recent studies indicate that infusion of albumin may suppress the renin-angiotensin-aldosterone system (RAAS), especially in patients with advanced cirrhosis, and this may prevent further circulatory dysfunction and even reduce it<sup>[33]</sup>.

In addition to the activation of the SNS, RAAS, and vasopressin, several studies have shown increased circulating endothelin-1, which indicates that endothelin systems are also activated in advanced cirrhosis<sup>[46]</sup>. Systemic vasodilatation is a key feature in the activation of vasoconstrictive and sodium-water retaining systems<sup>[5,16,22]</sup>. Systemic hemodynamic alterations are also important for the low renal blood flow and renal dysfunction in cirrhosis. The pressor systems most often counter-regulate the otherwise low arterial blood pressure in cirrhosis to a level almost within the normal range. Whereas a significant negative correlation of endothelin-1 to arterial blood pressure has been described, most studies have focused on the very low arterial blood pressure after the blockade

of the SNS (for instance, by clonidine, prazosin), RAAS (for instance by ACE-inhibitors, A II blockers), and the vasopressin effect ( $V_1$  antagonists)<sup>[16,45-48]</sup>. The activity in the pressor systems in advanced cirrhosis is among the most extreme known to pathophysiology. The presence of autonomic defects in patients with cirrhosis is evident from various studies on hemodynamic response to standardized cardiovascular reflex tests, such as heart rate variability, the Valsalva ratio, and isometric exercise<sup>[17]</sup>. Most studies on these issues have found a high prevalence of autonomic dysfunction in cirrhosis directly associated with liver dysfunction and survival. The results point to receptor and postreceptor defects as important elements of the hyporeactive response in cirrhosis. Other studies suggest that the autonomic dysfunction secondary to liver dysfunction is temporary, and potentially reversible after liver transplantation<sup>[48]</sup>. Arterial hypertensive cirrhotic patients may have less impaired blood pressure regulation and cardiovascular reflexes<sup>[21]</sup>, but this topic needs further investigation. In cirrhosis the plasma concentration of CGRP, a powerful vasodilating neurotransmitter, is increased<sup>[18,32]</sup>. Circulating CGRP relates to cardiac output, systemic vascular resistance, arterial compliance, and liver dysfunction. In experimental studies, specific antagonists of CGRP partly reverse the vasodilatation and hyperdynamic circulation. Vallance and Moncada have proposed that NO could be implicated in the vasodilatation in cirrhosis<sup>[49]</sup>. Several human and animal studies have supported this concept, whereas others have been unable to do so. To support the hypothesis, blockade of NO formation significantly improves the systemic hyperdynamic circulation, and infusion of the NO donor, L-arginine, aggravates the systemic vasodilatation and hyperdynamic circulation. Other vasodilating substances, such as adrenomedullin, the natriuretic peptides, and cannabinoids, may also be involved<sup>[18]</sup>. Adrenomedullin, a polypeptide similar to CGRP, is increased in patients with decompensated cirrhosis. From the family of natriuretic peptides, ANP, BNP, CNP, urodilatin, the two cardiac peptides, ANP and BNP, may be raised in patients with cirrhosis<sup>[35,45]</sup>. ANP is often increased in patients with ascites, owing to an enlarged left atrium and atrial stretching caused by a change in anatomical location of the heart. Circulating BNP (and pro-BNP) is especially increased in patients with cirrhotic cardiomyopathy<sup>[36,44]</sup>. Urodilatin is often normal and CNP may be reduced in advanced cirrhosis<sup>[35]</sup>. The increased natriuretic peptides and other vasodilators in cirrhosis may contribute to vasodilatation, and thereby counteract any increased arterial blood pressure from the coexistence of essential or secondary arterial hypertension.

According to the peripheral arterial vasodilatation theory of Schrier and co-workers, peripheral and splanchnic vasodilatation leads to a reduction in systemic vascular resistance and arterial blood volume and pressure, which are primary events in the retention of sodium and water<sup>[6]</sup>. Over the past few years several vasodilators have been candidates, and those mentioned above are involved in the cirrhotic vasodilatation, but further research is needed in order to answer a number of unsolved questions, especially in relation to the vascular beds which are dilated and constricted.

## KIDNEY FUNCTION AND FLUID RETENTION

Functional renal failure in cirrhosis (hepatorenal syndrome) is characterized by renal insufficiency consequent on hepatic failure<sup>[5,16,45,47]</sup>. No clinical or patho-anatomical signs of other known causes of renal failure are present. In general, the hepatorenal syndrome is characterized by a decrease in the renal blood flow and glomerular filtration rate, avid sodium-water retention, azotemia, and later oliguria. The condition may be considered as a progressive functional nephropathy, consequent on dyscirculatory and dysregulatory collapse<sup>[5,16]</sup>. The renal perfusion pressure is decreased, not only because of the low arterial blood pressure, but also because of the elevated renal venous pressure, especially in patients with tense ascites<sup>[16]</sup>. The enhanced sympathetic nervous activity may alter the autoregulation curve of the kidney with a shift to the right<sup>[50]</sup>. Patients with hepatorenal syndrome have the highest plasma levels of circulating catecholamines, and there are several indicators that enhanced renal SNS activity plays an important role in the renal vasoconstriction. The highly significant inverse relation between renal noradrenaline overflow on the one hand and renal blood flow on the other may illustrate this<sup>[16]</sup>.

Activation of the RAAS may contribute to decreased renal perfusion, but the RAAS may also have more complex regulatory effects inside the kidney<sup>[16,18,26]</sup>. It has been shown that vasopressin does not substantially change renal perfusion<sup>[26]</sup>. Noradrenaline, adrenaline, and endothelin-1 are important elements in the renal hypoperfusion and sodium-water retention in advanced cirrhosis<sup>[16,46,47]</sup>. Local vasodilators, such as prostaglandins and NO, most likely compensate for, at least in part, the progressive renal vasoconstriction seen in advanced cirrhosis<sup>[5]</sup>. In decompensated patients, normalization of or an increase in arterial blood pressure may increase renal perfusion and improve renal function<sup>[50]</sup>. Accordingly, a combination of prolonged administration of ornipressin or terlipressin and albumin has recently been reported to improve functional renal failure in cirrhosis<sup>[45]</sup>. Treatment with alpha-adrenergic blockers and potentially with endothelin-1 blockers may reverse renal vasoconstriction, but their lowering effect on arterial blood pressure may overrule beneficial local effects on the kidney<sup>[16]</sup>. Improvement of the cardiac dysfunction in cirrhosis may also improve the renal dysfunction<sup>[51]</sup>.

Loyke found that renal and neurogenic mechanisms able to elevate the blood pressure remained intact in patients with cirrhosis<sup>[25,28]</sup>. This conclusion was based on several patients with coexistent cirrhosis and glomerular nephritis. However, today this is a rather uncommon combination, at least in patients with alcoholic liver disease. Later, Loyke reported examples of renal hypertension, which returned to normotension when the patients developed cirrhosis<sup>[23]</sup>.

The hemodynamic changes in cirrhosis point towards renal hypoperfusion as being, at least initially, a physiological response to the changes in the systemic circulation. Increased SNS activity is a pathogenic factor, but other systems, such as the RAAS and endothelins, may also play a role. Angiotensin II mainly acts on the efferent arteriole and a low dose of an ACE-inhibitor

**Figure 2** Change in arterial blood pressure in two patients with arterial hypertension. (A, 39-year-old woman with essential hypertension; B, 59-year-old woman with hypertension of renal origin.) A decrease in the arterial blood pressure is seen when the patients develop cirrhosis. From Loyke 1962 (reproduced with the permission of Archives of Internal Medicine, Ref. 23).

may induce a significant reduction in glomerular filtration and a further reduction in sodium excretion, even in the absence of a change in arterial blood pressure. This suggests that the integrity of the RAAS is important for the maintenance of renal function in cirrhotic patients, and that RAAS overactivity does not solely contribute to the adverse renal vasoconstriction. Infusion of terlipressin or ornipressin has, along with a rise in arterial blood pressure, demonstrate beneficial effects with increased GFR in patients with hepatorenal syndrome.

A few cases have been reported where patients with cirrhosis with renal involvement may develop arterial hypertension, especially in patients with early cirrhosis<sup>[52]</sup>. After the onset of severe cirrhosis most patients with renal hypertension become normotensive, like patients with essential hypertension (Figure 2). However, nephropathy in cirrhosis most often leads to low arterial blood pressure, in spite of the highly increased activity in the RAAS system. In most types of bilateral organic renal failure with vascular involvement and sodium retention, hypertension will be the outcome, but not in patients with cirrhosis, where the mechanisms are quite the reverse. Alterations in hemodynamic and homeostatic mechanisms in renal hypertension and cirrhosis are summarized in Table 1.

## ARTERIAL HYPERTENSION IN CIRRHOSIS

The prevalence of arterial hypertension in cirrhotic patients is substantially reduced, especially in advanced cirrhosis. Characteristic findings in patients with cirrhosis are vasodilatation with low overall systemic vascular resistance, high arterial compliance, increased cardiac output, secondary activation of counter-regulatory systems (RAAS, sympathetic nervous system, release of vasopressin), and resistance to vasopressors. The vasodilatory state is mediated through adrenomedullin, CGRP, NO, and other va-

sodilators, and is most pronounced in the splanchnic area. This constitutes an effective (although relative) counterbalance to raised arterial blood pressure. Subjects with arterial hypertension may become normotensive during the development of chronic liver disease, and arterial hypertension is rarely manifested in patients with cirrhosis, even in cases with renovascular disease and high circulating renin activity. There is much dispute as to the understanding of homeostatic regulation in cirrhotic patients with manifest arterial hypertension. This condition most likely includes the combination of vasodilatation and vasoconstriction in parallel. As hypertensive patients are often effectively treated with diuretics, calcium channel antagonists, beta-blockers, ACE-inhibitors, etc., and some of these drugs are also applied in the treatment of cirrhosis and portal hypertension (Table 3), the natural history and prevalence of cirrhosis in patients with arterial hypertension, arterial hypertension in patients with cirrhosis, and the inter-relationship of these two diseases may be difficult to study today in prospective and untreated cases. Nevertheless, such studies are relevant, since there are many unsolved questions.

## Abstract

**AIM:** To construct the retroviral vector of p<sup>125FAK</sup> specific ribozyme genes and to explore the feasibility of ribozyme in BGC-823 gene therapy *in vitro*.

**METHODS:** A hammerhead ribozyme DNA targeting p<sup>125FAK</sup> mRNA from nt 1010 to nt 1032 was synthesized and recombined into the retroviral vector pLXSN forming pLRZXSXN recon. Using the lipofectin-mediated DNA transfection technique, pLRZXSXN was introduced into BGC-823 cells. The effects of ribozyme on the growth of BGC-823 cells and apoptosis were studied by cell colony assay, flow cytometry (FCM), reverse transcriptase-polymerase chain reaction (RT-PCR), detection of DNA fragmentation and electron microscopy.

**RESULTS:** The number of BGC-823 cell colonies was inhibited by 56% after the cells were treated for 48 h. The cell proliferation was inhibited effectively by p<sup>125FAK</sup> ribozyme and the inhibitory effect depended on the concentration and the time of incubation. The expression of p<sup>125FAK</sup> mRNA and protein P<sup>125</sup> decreased sharply in BGC-823 cells treated with p<sup>125FAK</sup> ribozyme. The characteristics of apoptosis, namely sub-G1 peak, DNA fragmentation and morphological changes, were revealed in BGC-823 cells treated with p<sup>125FAK</sup> ribozyme.

**CONCLUSION:** p<sup>125FAK</sup> ribozyme decreases p<sup>125FAK</sup> gene expression and induces apoptosis of human gastric cancer cells *in vitro*.

## INTRODUCTION

p<sup>125FAK</sup> is a non-receptor cytoplasm protein tyrosine kinase (PTK) with a molecular weight of 125 ku, which has unique structural and functional characteristics. Focal adhesion kinase (FAK) regulates multiple cellular processes including growth, differentiation, adhesion, motility and apoptosis<sup>[1-4]</sup>. The high expression of p<sup>125FAK</sup> is possibly a part of cell incidents contributing to the invasion and metastasis of tumors<sup>[5-7]</sup>. Ribozyme (RZ) is defined as a kind of small RNA molecule that has catalytic activity and can inhibit the translation process of mRNA after RZ combines with the complementary sequences of mRNA and incises it<sup>[8-11]</sup>. In this study, a hammerhead ribozyme DNA targeting p<sup>125FAK</sup> mRNA from nt 1010 to nt 1032 was synthesized according to p<sup>125FAK</sup> cDNA sequences, and recombined into the retroviral vector pLXSN forming pLRZXSXN recon. Using the lipofectin-mediated DNA transfection technique, pLRZXSXN was introduced into BGC-823 cells to study the expression of RZ and its effect on BGC-823 cells.

## MATERIALS AND METHODS

### Materials

BGC-823 cells were purchased from Shanghai Cytobiology Institute of Chinese Academy of Medical Sciences. *E. coli* DH-5 were donated by Hematopathy Laboratory of Fujian Medical University. Restriction enzymes (HindIII, pst I, BamH I, Xho I) and T4DNA ligase, X-gal, IPTG were all from Promega. pBluescript@SK plasmid was from Stratagene. RT-PCR kit was from Promega. Lipofectin<sup>TM</sup> was from Gibco/BRL. p<sup>125FAK</sup> (H-1) was from American Santa Cruz. S-P kit and DAB kit were from Maxim Biotechnology and Zymed Lab Inc, respectively.

### Design and synthesis of RZ template

GUU triplets of nt 1010 to nt 1032 in p<sup>125FAK</sup> cDNA base sequences were used as cleavage sites. Two small nucleotide sequences complementary to the cleavage

**Table 1** Primer sequence and fragment length

Primer	Sequence	Fragment length (bp)	Annealin Temp (°C)
p <sup>125FAK</sup>	A: 5'TTCTTCTATCAACAGGTGAAG3' B: 5'CTGCGAGGTTCATTACCAG3'	632	55
β-actin	A: 5'GGCATGGGTGAGCAAGGATTCC3' B: 5'ATGTCACGCACGATTTCCTCCG3'	500	55

Note: A and B represent the sense and anti-sense primers, respectively.

sites of target RNA were put at the two ends of the conservative core sequence-(the hammerhead structure) to form a typical active incisive secondary structure of RZ as previously described<sup>[12]</sup>. The two limbs and complementary ribonucleotides of target RNA were all 10 nt. RZ gene consisted of 2 completely complementary trains called trains A and B, consisting of 60 bases respectively. Two cleavage sites and 3 protective bases were synthesized by Shanghai Sangon Technology Corporation. The sequences of RZ gene were 5'CGGACTCATCAGCAAGCTGGAT AAGCTTCGT-3' for train A and 3'GCCTGAGTAGTCG TTCGACCTATTCTGAAGCA-5' for train B.

### Construction of sequencing vector and DNA sequence analysis

Plasmid extraction, restrictive enzymolysis reaction, ligase coupled reaction, preparation of competent germ, *E. coli* transfection, agarose gel electrophoresis and DNA fragment retrieval were routinely carried out. DNA sequencing was undertaken by Shanghai Sangon Technology Corporation.

### Construction of pLRZSN recon

Sequencing of a fragment of 81 bp was carried out with Bam HI and Xho I, retrieved by polyacrylamide gel electrophoresis(PGE), recombined into pLXSN cleavage sites of Bam HI and Xho I and then labeled as pLRZSN. The pLRZSN from QIAGEN was exactly quantified and sub-packaged for later use.

### Transfection of BGC-823 cells

BGC-823 cells in log growth phase were divided into BGC 823 cell blank group, BGC-823 cells + Lipofectin<sup>TM</sup> group, BGC-823 cells + pLXSN group and BGC-823 cells + pLRZSN group. Liguor A was obtained by adding 4 μg DNA (pLXSN or pLRZSN) to 100 μL serum-free RPMI1640, while liguor B was obtained by adding 10 μL Lipofectin<sup>TM</sup> to 90 μL serum-free RPMI1640. Liguors A and B were mixed after 30 min and stood for 15 min. At the same time, 1×10<sup>6</sup> BGC-823 cells in log growth phase were washed. After resuspension in 0.8mL serum-free RPMI1640, the mixture of liguors A and B was added into the suspension and incubated at 37 °C in an atmosphere containing 5% CO<sub>2</sub> for 6 h. Four mL RPMI1640 containing 10% serum was added into the suspension and incubated for 48-72 h and then the BGC823 cells were collected.

### Colony forming experiment

After incubated for 48 h, the 4 groups of cells were digest-

ed in monoplast suspensions and inoculated into 24-well plates (200/well). At the same time, 3 parallel wells were being designed. After being incubation for 7 d, colonies formed when the number of cells was over 50. The number of colonies was calculated under microscope and the colony forming efficiency was determined.

### Detection of p<sup>125FAK</sup> protein

After being incubated for 48 h, the 4 groups of cells were digested in monoplast suspensions and inoculated onto slides. When the slides were open-air dried and fixed in cold acetone for 10 min, immunocytochemistry dyeing was carried out by S-P method. Positive cell cytoplasm was buffy, nuclei and negative cells were not stained. p<sup>125FAK</sup> positive cell labeling index (PI = p<sup>125FAK</sup> positive cell number under one field of vision/1000×100%) was calculated. After being incubated for 48 h, the 4 groups of cells were digested in monoplast suspensions and prepared into specimens. p<sup>125FAK</sup> protein was detected by flow cytometry (Bio-Rad, Bryte-HS).

### Evaluation of p<sup>125FAK</sup> mRNA

Total RNA was extracted from the cells after incubation for 48 h. cDNA synthesis and PCR amplification were performed as previously described<sup>[13]</sup>. p<sup>125FAK</sup> gene nucleotide sequence to be amplified the primers used are listed in Table 1.

### Detection of apoptosis of BGC-823 cells

After being incubated for 48 h, the 4 groups of cells were digested in monoplast suspensions, poached with PBS, centrifuged and incubated for 30 min in Kenesis50 kit (BioRad) and the DNA contents were analyzed by FCM. The ultra-structure of BGC-823 cells was observed under transmission electron microscope. The 4 groups of cells incubated for 48 h were prepared and photographed. Extraction and electrophoresis of DNA apoptotic fragments were carried out following the directions of apoptotic DNA ladder kit (Roche Corporation).

### Statistical analysis

The data were expressed as mean ± SD. The variance analysis and significant difference test were carried out by SPSS 10.0.

## RESULTS

### Effect of RZ on colony forming efficiency (CFE) of BGC-823 cells

The results of colony forming experiment are summarized in Table 2. RZ could inhibit colony formation of BGC-823 cells ( $P < 0.05$ ).

### Effect of RZ on expression of BGC-823 p<sup>125FAK</sup> protein

After the cells were incubated for 48 h, the expression rate of p<sup>125FAK</sup> protein was 88.4% in control group, 79.55% in liposome group, 77.08% in kenovector group, and 46.09% in ribozyme group. A significant difference was found among the 4 groups. The positive number of BGC823 cells expressed in the p<sup>125FAK</sup> protein decreased sharply and the intensity of expression also weakened. PI was obviously smaller in RZ group than in other three groups

**Figure 1** Expression of p<sup>125FAK</sup> protein (A) and mRNA (B) in BGC 823 cells M: Marker; lane 1: control; lane 2: liposome; lane 3: keno-vector; lane 4: RZ

**Table 2** Effect of RZ on colony formation of BGC-823 cells

Groups	CFE (%)	CIE (%)
Control group	51.24±6.8 <sup>a</sup>	
Liposome group	46.43±8.6 <sup>a</sup>	9.38
Kenovector group	45.32±5.2 <sup>a</sup>	11.55
Ribozyme group	16.14±3.5 <sup>a</sup>	68.50

<sup>a</sup>*P* < 0.05 vs other groups.

(Figure 1A).

#### Effect of RZ on p<sup>125FAK</sup> mRNA expression in BGC 823 cells

PCR product electrophoresis showed 632 bp and 500 bp bands. The fluorescence intensity value of p<sup>125FAK</sup> and β-actin was 1.23 in control group, 0.98 in liposome group, 0.92 in keno-vector group, and 0.38 in RZ group, indicating that the level of p<sup>125FAK</sup> mRNA in BGC-823 cells decreased sharply than that in other three groups (Figure 1B).

#### Apoptosis of BGC-823 cells induced by RZ

Apoptotic peak (sub-diploid peak) appeared in RZ group but not in other three groups (Figure 2).

Karyopynosis, chromatin margination, complete caryotheca, condensed kytoplasm with deep staining were found in RZ group. Larger karyoplasmic ratio, puffed

**Figure 2** Cell cycle analysis of cells cultivated for 48 h in liposome group (A), keno-vector group (B) and RZ group (C).

chromatin, clear plasmosome, and abundant cytoplasm were seen in other three groups. These cells were poorly-differentiated BGC-823 cells which did not undergo apoptosis (Figure 3).

Typical DNA fragments were seen in RZ group but not in other three groups (Figure 4).

## DISCUSSION

Recent studies showed that when malignant cells adhere to extra-cellular matrix (ECM), p<sup>125FAK</sup> tyrosine self phosphorylation takes place and its activity increases<sup>[14-16]</sup>. The precise mechanism of p<sup>125FAK</sup> underlying apoptosis is not clear. But when malignant cells spread or migrate, p<sup>125FAK</sup> regulates the formation of adhesion plaque or takes part in signal cascade conduction and inhibits apoptosis by informing karyoplasts to that cells are ECM-anchored<sup>[17,18]</sup>. Anti-sense oligonucleotides of p<sup>125FAK</sup> have been used to

**Figure 3** Apoptotic changes of BGC-823 cells in RZ group.

inhibit the expression of p<sup>125FAK</sup> gene in order to induce apoptosis of malignant cells<sup>[19,20]</sup>, but the result is not satisfactory because the number of target RNAs is so larger that complete blocking is impossible and anti-sense oligonucleotides are so easy to be degraded. RZ may solve the above problems. Ribozyme is a small RNA molecule that has catalytic activity. On the one hand, it can combine with complementary sequences of mRNA to block the translation of mRNA. moreover, it can incise mRNA and promote the degradation of mRNA<sup>[10,21]</sup>. Symons<sup>[8]</sup> reported that RZ can be used in treatment of viral disease and tumor. RZ genes such as c-erbB-2, P53, Ras, TGF- $\beta$ , can be used in oncotherapy<sup>[22-25]</sup>. Qian *et al.*<sup>[26]</sup> reported that FGFR3 RZ gene could inhibit the growth of myeloma cells and promote their apoptosis. But studies on p<sup>125FAK</sup> RZ gene are relatively fewer. In the present study, a hammerhead ribozyme DNA targeting p<sup>125FAK</sup> mRNA from nt 1010 to nt 1032 was synthesized according to p<sup>125FAK</sup> cDNA sequences, and recombined into the retroviral vector pLXSN forming pLRZXSXN recon. Using the lipofectin-mediated DNA transfection technique, pLRZXSXN was introduced into BGC-823 cells to inhibit the growth of BGC-823 cells to observe the typical changes of apoptosis under electron microscope. The results demonstrate that p<sup>125FAK</sup> RZ gene is sequence specific and can be used in treatment of gastric carcinoma.

## Abstract

**AIM:** Overexpression of tumor protein p53-induced nuclear protein 1 (TP53INP1) induces G<sub>1</sub> cell cycle arrest and increases p53-mediated apoptosis. To clarify the clinical importance of TP53INP1, we analyzed TP53INP1 and p53 expression in gastric cancer.

**METHODS:** TP53INP1 and p53 expression were examined using immunohistochemistry in 142 cases of gastric cancer. The apoptosis of gastric cancer cells was analyzed using the TUNEL method. The relationship between the expression of TP53INP1 and clinicopathological factors was statistically analyzed.

**RESULTS:** TP53INP1 was expressed in 98% (139/142 cases) of non-cancerous gastric tissues and was down-expressed in 64% (91/142 cases) of gastric cancer lesions from the same patients. TP53INP1 expression was significantly decreased (43.9%) in poorly differentiated adenocarcinoma compared with well or moderately differentiated adenocarcinoma (81.6%). Cancers invading the submucosa or deeper showed lower positivity (59.1%) compared with mucosal cancers (85.2%). Decrease or loss of TP53INP1 expression was significantly correlated with lymphatic invasion (54.3% *vs* 82.0% without lymphatic invasion) and node-positive patients (31.3% *vs* 68.3% in node-negative patients). P53 was expressed in 68 (47.9%) patients of gastric cancer, whereas it was absent in normal gastric tissues. A significant association was also observed between TP53INP1 status and the level of apoptosis in tumor cells: the apoptotic index in TP53INP1-positive tissues was significantly higher than that in TP53INP1-negative portions. Finally, when survival data were analyzed, loss of TP53INP1 expression had a significant effect in predicting a poor prognosis ( $P=0.0006$ ).

**CONCLUSION:** TP53INP1-positive rate decreases with the progression of gastric cancer. TP53INP1 protein negativity is significantly associated with aggressive pathological phenotypes of gastric cancer. TP53INP1 is related to the apoptosis of gastric cancer cells. The decreased expression of the TP53INP1 protein may reflect the malignant grade of gastric cancer and is regarded as an adverse prognostic factor.

## INTRODUCTION

Tumor protein 53-induced nuclear protein 1 (TP53INP1) is a p53-inducible gene encoding two protein isoforms able to modulate p53 biological activities<sup>[1-4]</sup>. TP53INP1 expression is strongly induced *in vivo* in mice with acute pancreatitis<sup>[1]</sup>, and *in vitro* in several cell lines submitted to various stress agents<sup>[2,4]</sup>. Over-expression of TP53INP1 induces cell cycle arrest in G<sub>1</sub> phase and enhances the p53-mediated apoptosis<sup>[3]</sup>. TP53INP1 co-localizes with p53 and the serine-threonine p53-kinase HIPK2<sup>[5]</sup> within the promyelocytic leukemia protein nuclear bodies (PML-NBs) and physically interacts with these proteins modifying the p53 transcriptional activity on several p53 target genes<sup>[3]</sup>. TP53INP1 thus appears as a key-element in p53-mediated cell death and cell cycle arrest, induced by cellular stresses. The multi-step model of carcinogenesis in gastric cancer, the second most common cancer leading to death in the world, suggests accumulation of genetic alterations, epigenetic changes and posttranslational modifications. It often metastasizes to other organs, including the liver, lung, and ovary<sup>[6]</sup>. Multiple factors are known to be related to gastric carcinogenesis, including Epstein-Barr virus<sup>[7]</sup> and *H. pylori* infections<sup>[8]</sup>, microsatellite instability<sup>[9]</sup>. From the molecular point of view, it has now been established that gastric carcinogenesis is involved the accumulation

of mutations in oncogenes and tumor suppressor genes controlling epithelial cell growth and differentiation<sup>[10-14]</sup>. In particular, TP53 mutations are frequently seen in gastric cancers and correlates with gastric cancer prognosis<sup>[15,16]</sup>. However, the molecular alterations and their role in gastric cancer still remain to be fully defined.

Previous works implied that *TP53INP1* is a pro-apoptotic gene induced by p53<sup>[2]</sup>. Overexpression of TP53INP1 promotes G1 arrest and apoptosis through the p53-mediated pathway<sup>[3]</sup>. The aim of the present study was to analyze the expression patterns of TP53INP1 in a large series of gastric carcinomas to (1) identify the possible modulation of TP53INP1 expression; (2) investigate the association with apoptotic activity; (3) analyze the relationship with clinicopathologic parameters, and evaluate its prognostic value.

## MATERIALS AND METHODS

### Patients and specimens

One hundred and forty-two patients with gastric cancer were enrolled in this study. The areas adjacent to cancer lesions were used as non-malignant gastric tissue. The patients underwent operation at the Cancer Research Institute Hospital, Kanazawa University. The histological classification was defined using the Japanese classification of gastric carcinoma<sup>[17]</sup>. Intestinal type was defined as either papillary or well to moderately differentiated tubular adenocarcinoma. Diffuse type was defined as poorly differentiated adenocarcinoma, signet-ring cell carcinoma, or mucinous adenocarcinoma. The series included 104 men and 38 women, and the mean age was  $63.1 \pm 10.6$  years. There were 76 and 66 cases of differentiated and undifferentiated type, respectively.

### Immunohistochemistry

A standard avidin-biotin-peroxidase complex method (ABC) was used for immunostaining. Deparaffinized sections were treated by microwaving at a high power for 5 min twice in a 10 mmol/L citrate buffer to retrieve antigenicity. After washing with PBS, the sections were immersed in 3% hydrogen peroxide in methanol for 20 min to block any endogenous peroxidase activity. Then the ABC staining system kit (Santa Cruz Biotechnology Inc., Santa Cruz, CA, USA) was used for the detection. Sections were incubated with 10% normal serum for 1 h to inhibit nonspecific antibody binding. Then, sections were incubated overnight at 4 °C with 6 µg/mL of rat anti-human monoclonal antibody raised against *TP53INP1* (kindly provided by Carrier). After washing with PBS, detection was done by successively incubating the sections with biotinylated goat anti-rat IgG for 30 min, and avidin-biotin-HRP for 30 min. After extensive washings with PBS, sections were stained with 3,3'-diaminobenzidine for 2-10 min. Then, sections were counterstained with hematoxylin, dehydrated, and mounted. Nuclei were lightly counterstained with Mayer's hematoxylin. TP53INP1-positive cells were counted in fields chosen at random (100 × magnification), and the percentage of the number of positive cells per 1 000 cells was expressed as TP53INP1-positive index (%). Using the same method we counted the

TP53INP1-positive in nucleus and in cytoplasm under the microscopy with a 200× magnification. The normal IgG was used as a negative control.

Immunohistochemistry for p53 was performed using a DAKO LSAB kit (DakoCytomation, Kyoto, Japan). The primary antibody was mouse monoclonal antibody against human p53 (DO-7, Nichirei Inc., Tokyo, Japan). The procedure was according to the protocol from the company. Finally the sections were incubated with DAB substrate as a chromogen. The cell nuclei were also lightly counterstained with Mayer's hematoxylin.

### Terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL)

TUNEL-positive epithelial cells were detected in the sections using ApopTag Plus peroxides *in situ* apoptosis detection kit (Chemicon International, Inc., Temecula, CA, USA). Briefly, after pretreatment with 20 µg/mL of proteinase K and 3% hydrogen peroxide, sections were incubated with a labeling mixture for 1 h at 37 °C. Then 55 µL of anti-digoxigenin-peroxidase was deposited on the sections and incubated for 30 min. The reaction products were visualized by 3,3'-diaminobenzidine substrate. Nuclei were counterstained with methyl green for 10 min. After washing with *n*-butanol, the sections were dehydrated, and mounted. Apoptotic index (%) corresponding to the number of labeled nuclei per 1 000 nuclei was calculated.

### Statistical analysis

Experimental results were expressed as mean ± SE. Difference between the means was evaluated by the Mann-Whitney *U* test.  $P < 0.05$  was considered statistically significant. The statistical analysis in this paper such as Kaplan-Meier analysis and Cox regression model was performed by using the software of StatView-5.0 Macintosh (Tokyo, Japan).

## RESULTS

### TP53INP1 was expressed in non-malignant gastric tissues and its expression was reduced in gastric cancer tissues

In the non-neoplastic gastric mucosa, TP53INP1 was mainly located in the cytoplasm of epithelial cells (Figures 1A and 1B). Some nuclei were also stained for TP53INP1 (Figure 2). Similar patterns were observed for intestinal metaplasia samples (Figure 1A). To determine if TP53INP1 is differentially expressed in gastric carcinomas or if it is stage-related, we did immunohistochemical analysis on 142 samples (76 cases of intestinal type, and 66 cases of diffuse type). All the cancer samples had accompanying non-malignant tissues, 98% of them were positive for TP53INP1 expression (Table 1) and thus could be used as internal control. In contrast, the expression of TP53INP1 protein was seen in 91 cases (64%), the other 51 samples (36%) were TP53INP1-negative (Figure 1B, arrow). Overall, TP53INP1 expression in gastric cancers was significantly lower both in cell cytoplasm and nucleus than in non-malignant gastric tissue ( $P < 0.0001$ , Table 1 and Figure 2). However, the expression of TP53INP1 was decreased in well-differentiated tubular adenocarcinoma (Figure 1C), and was markedly diminished in poorly

**Figure 1** Immunohistochemical analysis of TP53INP1 expression in gastric carcinoma. **A:** TP53INP1 was strongly expressed in normal gastric mucosa or intestinal metaplasia foci (inset); **B:** TP53INP1 expression decreased in gastric carcinoma (arrow); **C:** well differentiated tubular carcinoma exhibited moderate alteration of TP53INP1 expression; **D:** poorly differentiated carcinoma showed weak staining with TP53INP1 antibody; **E:** P53 expression increased in gastric carcinoma (arrow).

**Table 1** TP53INP1 expression in gastric cancer *n* (%)

		Non-malignant gastric tissue ( <i>n</i> = 142)	Gastric cancer ( <i>n</i> = 142) <sup>1</sup>	<i>P</i> value
TP53INP1	Positive	139 (98)	91 (64)	<0.0001
	Negative	3 (2)	51 (36)	
P53	Positive	0 (0)	68 (47.9)	<0.0001
	Negative	142 (100)	74 (52.1)	

<sup>1</sup>In gastric cancer the *P* value between TP53INP1 and P53 was 0.006.

differentiated-type cancer (Figure 1D).

We next examined whether TP53INP1 expression is associated or not with the development and progression of gastric carcinoma. The clinical details of the cohort of patients and the statistical analysis are listed in Table 2. Only two non significant associations were observed, i.e., age and gender. TP53INP1 negativity was associated with gastric body and antrum tumor location ( $P=0.0193$ ), with poorly differentiated adenocarcinoma (diffuse type) ( $P<0.0001$ ). With regard to the depth of invasion, the positive TP53INP1 expression rate was 100% in intramucosal tumors (5/5), 81.8% when mucosa was invaded (18/22), 76.5% in muscularis propria (26/34), 54.3% in subserosa (25/46), and 48.6% in serosa (17/35). These results showed that alteration of TP53INP1 expression was correlated to the staging of the tumors. The difference was statistically significant when T1 tumors were compared to the other stages ( $P=0.0111$ , Table 2). In addition, TP53INP1 was significantly expressed in node-negative patients ( $P=0.0037$ ), and significantly associated with lymphatic invasion-negative patients ( $P=0.0010$ ). Taken together, these results indicated that loss of TP53INP1 expression was significantly associated with poorly differentiated histology, deep invasion, lymph node invasion, and metastasis.

### TP53INP1 and apoptosis

TP53INP1 modulates the cell cycle arrest and programmed cell death<sup>[3]</sup>. To investigate whether the modulation of TP53INP1 expression is associated with differences in apoptotic activity, TUNEL assays were done in all the

**Table 2** Correlation between TP53INP1 expression levels and clinicopathologic features in gastric cancer

	TP53INP1-positive ( <i>n</i> = 91 of 142 patients)	TP53INP1-negative ( <i>n</i> = 51 of 142 patients)	<i>P</i> value

142 cases. TUNEL-positive nuclei were clearly seen in TP53INP1-positive (Figure 3A) and negative (Figure 3B) cancer lesions. As shown in Figure 3C, the apoptotic index in the TP53INP1-positive group ( $7.48 \pm 2.66\%$ ) was significantly higher than that in the TP53INP1-negative group ( $4.16 \pm 2.41\%$ ).

### TP53INP1 expression and prognosis

On univariate analysis, patient survival according to

**Figure 2** Comparison of TP53INP1 expression (in cell cytoplasm and nucleus) between normal gastric mucosa and gastric cancer tissues ( $P < 0.0001$ ).

**Table 3** Multivariate survival analysis using the Cox regression model

Factor	Reference	Odds Ratio	<i>p</i>
TP53INP1	+ vs -	1.250	0.3680
Age	<60 vs ≥60	1.388	0.1077
Gender	Male vs female	1.158	0.5217
Location	Body+cardia vs antrum	1.253	0.4847
Histological type	Poor vs well/moderately	2.043	0.0026

Lymph node invasion	+ vs -	3.121	0.0032

pathological stage was significantly different between TP53INP1-positive and TP53INP1-negative groups. Those patients with TP53INP1-positive expression had significantly better survival than those without TP53INP1 expression ( $P = 0.0006$ , Figure 4A). Survival for TP53INP1-positive patients with poorly differentiated adenocarcinoma was significantly longer than that of TP53INP1-negative patients ( $P = 0.0199$ , Figure 4B), whereas the survival of TP53INP1-positive patients in well or moderately differentiated adenocarcinoma was not significantly different from that of TP53INP1-negative patients ( $P = 0.1110$ , Figure 4C). Taken together, the results indicated that alteration of TP53INP1 expression was associated with a poor prognosis. Nevertheless, no prognostic value for TP53INP1 expression was evidenced from the multivariate analysis (Table 3). Histological type, apoptotic index, metastasis, and lymph node invasion were the most important independent prognostic factors, TP53INP1 could not be considered as an independent prognostic marker.

#### **P53 was not expressed in non-malignant gastric tissues but expressed in gastric cancer tissues**

As shown in Table 1 and Figure 1E, the p53 protein was expressed in gastric cancer regions, whereas it was absent in non-malignant portions. The staining was nuclear. Cytoplasmic staining without nuclear staining was regarded

**Figure 3** Apoptosis analysis in gastric cancer. **A and B:** Representative patterns of TP53INP1-positive (**A**) and negative (**B**) carcinoma in TUNEL staining. Arrows indicate TUNEL-positive nuclei (original magnification  $\times 20$ ); **C:** Statistical analysis of apoptotic index in TP53INP1-positive and -negative cancer tissues ( $P < 0.0001$ , positive vs negative).

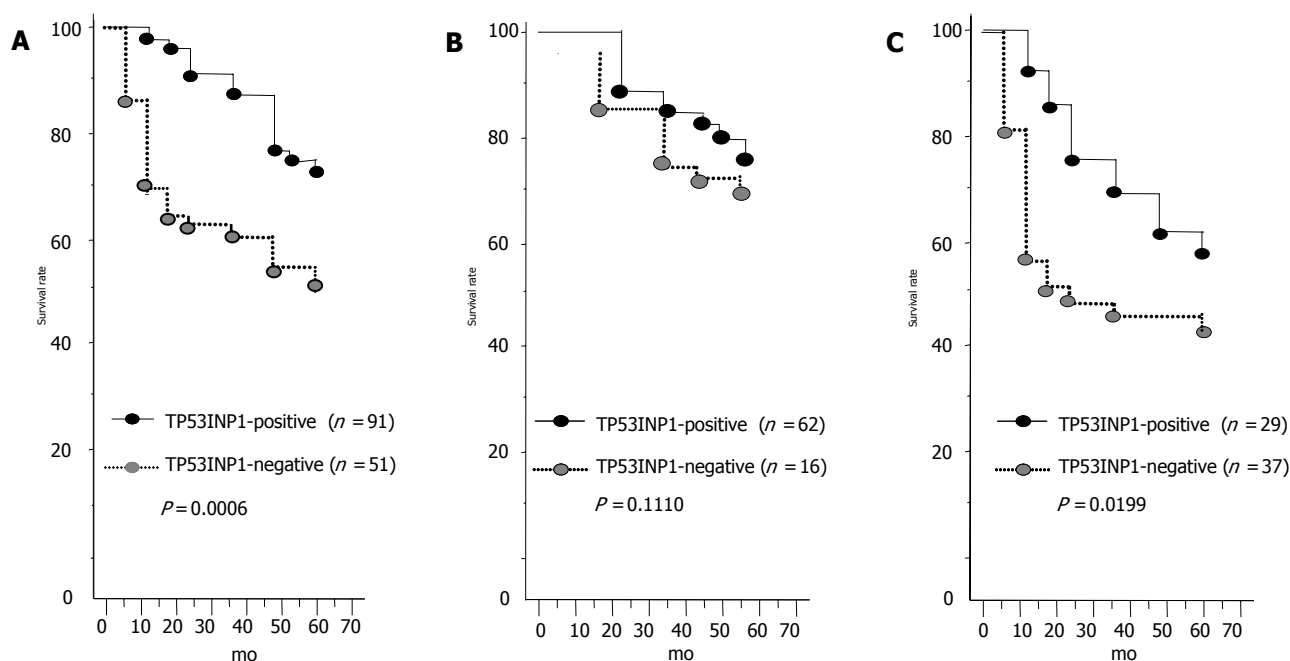

as negative. The p53 positive rate in gastric cancer was significantly higher (47.9%) than that in non-malignant tissues ( $P < 0.05$ ).

## **DISCUSSION**

The development and progression of gastric cancer involve many types of genes that need to be activated or inactivated in order to promote malignancy. Gastric cancer is a heterogeneous pathology, classified into two general subtypes: intestinal (differentiated) and diffuse (undifferentiated)<sup>[17]</sup>. The intestinal type gastric carcinoma presents tumor suppressor gene alterations similar to colorectal tumors and distinct from diffuse type gastric cancer<sup>[18]</sup>. An accumulation of multiple genetic and epigenetic alterations of oncogenes, tumor suppressor genes, DNA repair genes, cell cycle regulators, cell adhesion molecules, and growth factor/receptor systems are involved during the multi-step conversion from normal epithelial cells to clinical gastric cancer<sup>[10-14]</sup>. TP53 gene alterations have been observed in both histological subtypes<sup>[19]</sup>. TP53INP1 is a tumor suppressor gene, located on the chromosome band 8q22<sup>[20]</sup>. Its expression is dependent on the activation of wide-type p53<sup>[3]</sup>.

In this study, we have showed that TP53INP1 protein expression was significantly reduced in gastric cancer cells compared with non-cancerous adjacent tissues. We also reported that reduced TP53INP1 expression was associated with the diffuse cancer phenotype. Tomasini *et al*<sup>[2]</sup> have shown that TP53INP1 and HIPK2 are partners in regulating p53 activity. It is increasingly evident that methylation of CpG islands in the promoter of specific

**Figure 4** TP53INP1 expression and patient survival by Kaplan-Meier analysis. **A:** Survival curves for TP53INP1-positive and negative gastric cancers. The 60-mo survival rates were 74.7% and 54.9%, respectively. The difference between the values was highly significant ( $P=0.0006$ ). **B:** In well or moderately differentiated adenocarcinoma (intestinal-type), the survival of TP53INP1-positive patients was not significantly different from that of TP53INP1-negative group ( $P=0.1110$ ). **C:** In poorly differentiated adenocarcinoma (diffuse-type), the 60-mo patient survival rates were 62.1% and 45.9% for TP53INP1-positive and -negative gastric cancers, respectively. This difference was statistically significant ( $P=0.0199$ ).

tumor suppressor genes, such as *p16*, is associated with their silencing in human gastric cancer<sup>[21]</sup>. The 5'-upstream region of TP53INP1 contains a CpG island. The sequences from nucleotide -792, the region on exon 1 and part of the first intron, to nucleotide +839 have the highest content of CpG dinucleotides. However, there was no mutation of TP53INP1 gene in pancreatic carcinoma (unpublished data). In addition, the reduced TP53INP1 expression in gastric cancer especially in the diffuse type, may relate to the wide-type p53 inactivation in gastric cancer.

We showed that p53 was expressed in 68 cases of gastric cancer, whereas it was not present in normal gastric epithelial cells. We observed that in non-gastric cancer regions the expression of TP53INP1 was opposite to that of p53. The expression of TP53INP1 was dependent on the wild type p53 since the wild-type p53 protein is biologically unstable and has a shorter half-life than mutant p53 protein<sup>[24]</sup>. This characteristic of wide-type p53 protein does not allow it to be detected by immunohistochemical methods, but mutant p53 can be detected by immunostaining. Our data was similar to Carvalho *et al*<sup>[22]</sup> who showed that there was no difference of the p53 expression between the intestinal type and the diffuse type in gastric cancer. Whereas Lin *et al*<sup>[23]</sup> showed the expression of p53 in the intestinal type was more frequent than that in the diffuse type. The precise mechanisms of TP53INP1 suppression in gastric cancer need further research.

The mechanism of the suppression of these genes in poorly differentiated gastric carcinoma is not clear. Many studies suggested that most tumor suppressor genes play a role in mediating cell cycle arrest in the

G<sub>1</sub> phase following DNA damage and also function in the removal of damaged cells by initiating apoptosis in certain physiological situations<sup>[10]</sup>. TP53INP1 and HIPK2 are partners in regulating p53 activity<sup>[2]</sup>. Overexpression of TP53INP1 induces G<sub>1</sub> cell cycle arrest. TP53INP1 expression was significantly decreased in advanced gastric cancers. These results suggest that decrease of TP53INP1 expression might play an important role in the progression of gastric cancer. Assessment of TP53INP1 expression level may serve as a novel biomarker for predicting the malignant grade of cancers, like another marker for poor prognosis genes<sup>[25,26]</sup>.

Lymphatic involvement is thought to be important as an initial step of lymph node metastasis<sup>[27]</sup>. Our study showed that TP53INP1 expression was significantly reduced in lymphatic invasion-positive groups. TP53INP1 expression decreased in node-positive. Taken together, these results suggested that loss of TP53INP1 expression is associated with lymph node metastasis of gastric cancer.

Deregulation of genes involved in cell cycle and cell signaling pathways has been described and classified as early events for cyclin D1 and p16 genes or late events for p53, DPC4 and BRCA2 genes in the progression model studies<sup>[28]</sup>. TP53INP1 is a pro-apoptotic gene strongly activated during cell stress. Overexpression of TP53INP1 is related to G<sub>1</sub> cell cycle arrest and induces p53-mediated cell death<sup>[3]</sup>. In the present study, we showed that the apoptotic index in TP53INP1-positive lesions was higher than that in TP53INP1-negative lesions in gastric cancer tissues as detected by TUNEL assay, indicating that TP53INP1 is related to apoptosis and tumor aggressiveness in gastric carcinoma.

TP53INP is an acute gene that is induced by various

stresses such as UV, heat shock, etc.<sup>[1]</sup>. Up to now, we have known little function of it. We for the first time revealed the impact of the TP53INP1 on the survival in gastric cancer. We showed that the survival rate of the TP53INP1-positive cases was longer than that of the TP53INP1-negative cases, especially in the diffuse type gastric cancer.

In conclusion, the present study has showed that the reduction of TP53INP1 expression might play roles in gastric carcinogenesis and tumor aggressiveness. Analysis of the TP53INP1 may be useful to evaluate the malignant grade of gastric cancer.

### Abstract

**AIM:** To determine the effects of the calcineurin inhibitors, cyclosporine and tacrolimus, on hepatitis C virus (HCV) replication and activity of recurrent hepatitis C in patients post liver transplantation.

**METHODS:** The data of a cohort of 107 patients who received liver transplantation for HCV-associated liver cirrhosis between 1999 and 2003 in our center were retrospectively analyzed. The level of serum HCV-RNA and the activity of recurrent hepatitis were compared between 47 patients who received either cyclosporine or tacrolimus as the primary immunosuppressive agent and an otherwise similar immunosuppressive regimen which did not lead to biliary complications within the first 12 mo after transplantation.

**RESULTS:** HCV-RNA increased within 3 mo after transplantation but the differences between the cyclosporine group and the tacrolimus group were insignificant ( $P=0.49$  at 12 mo). In addition, recurrent hepatitis as determined by serum transaminases and histological grading of portal inflammation and fibrosis showed no significant difference after 12 mo ( $P=0.34$ ).

### INTRODUCTION

Hepatitis C virus (HCV) is a leading cause of chronic hepatitis with about 170-190 million people infected worldwide<sup>[1,2]</sup>. The treatment of choice for patients with end-stage liver disease associated with HCV infection is liver transplantation (LTx) and in fact, HCV is the main indication for liver transplantation among adults in Europe and USA, accounting for approximately 50% of cases<sup>[3]</sup>. Since HCV persists not only in hepatocytes but also in leukocytes, lymph nodes and most likely additional tissues<sup>[4-6]</sup>, the virus is redistributed to the donor liver after LTx almost immediately in virtually all patients<sup>[7,8]</sup>. However, the severity and clinical course of the resulting reinfection hepatitis vary widely, ranging from deleterious fibrosing cholestatic hepatitis with failure of the allograft within 1 year to a rather mild hepatitis with progression to cirrhosis within 5 years in 20-30% of cases<sup>[9,10]</sup>.

A main factor determining the severity of recurrent hepatitis C after transplantation may be immunosuppression<sup>[11]</sup>. Of particular concern is the fact that the prognosis of recurrent HCV infection seems to deteriorate in recent years, which has been attributed to the use of donor organs of less optimal quality as well as changes in the immunosuppressive therapy such as steroid-free regimens

or the combination of particular drugs<sup>[12,7]</sup>. Considering that retransplantation remains the only treatment for patients with graft failure due to HCV recurrence, optimization of the immunosuppressive regimens might be a key aspect to improve the prognosis of chronic hepatitis C after transplantation.

The two most frequently used basic immunosuppressive drugs are cyclosporine A (CsA) and tacrolimus (Tac). Although CsA and Tac are structurally different, they share a similar mode of immunosuppressive action by inhibition of the transcription factor NFAT and consecutive reduction of inflammatory gene expression in activated T cells<sup>[13-15]</sup>. The main mechanism by which immunosuppressive therapy with calcineurin inhibitors accelerates the clinical course of post-transplantation hepatitis C is their influence on the replication of the virus. Immunosuppressive therapy after LTx of patients with chronic HCV infection is associated with significantly increased serum viral load compared to the values of the same patients before transplantation<sup>[7,11]</sup>, suggesting decreased systemic immune responses against the virus. Locally in the liver, the uncontrolled replication of the virus may cause an enhanced immune response, resulting in accelerated hepatocellular damage and fibrosis.

Whether a particular calcineurin inhibitor has an advantage in immunosuppressive therapy of HCV-infected patients post LTx is still highly controversial<sup>[16-19]</sup>. To further clarify this issue, the aim of this study was to determine the effects of CsA and Tac on serum HCV-RNA level as well as on the inflammatory activity of recurrent hepatitis in patients with chronic HCV infection after LTx.

## MATERIALS AND METHODS

### Patients

The data of 107 consecutive patients within the first year after liver transplantation due to hepatitis C-associated liver cirrhosis were retrospectively reviewed. Patients underwent LTx between June 1998 and December 2003 at our center either as cadaveric-(orthotopic) or as living donor-related liver transplantation. In order to compensate for missing randomization in this retrospective study, only 47 patients who received either cyclosporine or tacrolimus as the primary immunosuppressive agent and an otherwise similar immunosuppressive regimen which did not lead to acute or chronic rejection and biliary complications within the first 12 mo after transplantation, forming a relatively homogenous subgroup, were included in this study. A further exclusion criterion was early death after transplantation. During the first year all patients underwent routine liver biopsy 3-5 mo after LTx, independent from serum liver enzyme activities. Every rise of transaminases or cholestasis parameters was followed by additional liver biopsies to differentiate between acute or chronic rejection, cholestasis and hepatitis C reinfection. The study protocol conformed to the ethical guidelines of the 1975 Declaration of Helsinki and was approved by the Local Ethics Committee.

The basic immunosuppressive agent used in all the patients was either CsA or Tac. The dose of the drugs was

controlled in light of the serum level, which was adjusted between 140 and 180 ng/mL for CsA, and 10 and 15 ng/mL for Tac within the first 3 mo. After 3 mo, the serum level of CsA and Tac was reduced to 100-120 ng/mL and 7-10 ng/mL, respectively. During the first 3 mo. after LTx, CsA, and Tac were routinely combined with corticosteroids (prednisolone) at an initial dose of 1 mg/kg body weight and reduced to 5 mg daily within 4 weeks. After 3 mo steroids were discontinued. In addition, all the patients included in this study received 1000-2000 mg mycophenolate mofetil (MMF), per day for the first 12 mo post LTx.

### Determination of HCV infection

HCV infection status was evaluated by the examination of the patients' sera for the presence of anti-HCV antibodies and HCV-RNA. Anti-HCV antibodies were detected by a commercially available enzyme immunoassay (Monalisa anti-HCV plus, Biorad, Munich) according to the manufacturer's instructions. Qualitative detection of serum HCV-RNA was performed by a RT-PCR-based (Cobas AmpliCor HCV 2.0 assay, Roche Diagnostics, Mannheim, Germany) assay or a transcription-mediated amplification (TMA)-based assay (VERSANT HCV-RNA qualitative, Bayer Diagnostics, Fernwald, Germany). HCV-RNA concentrations were determined by commercially available second and third generation branched DNA (bDNA) assays (VERSANT HCV-RNA 2.0 and 3.0, Bayer Diagnostics, Fernwald, Germany). To obtain HCV-RNA titers in IU/mL, the bDNA 2.0 assay was calibrated against the WHO HCV Standard 96/790<sup>[20]</sup>, as described in full details elsewhere<sup>[21,22]</sup>. Values below the lower limit of sensitivity of 615 IU/mL were set to 615 IU/mL divided by 2.

### Determination of inflammatory activity

Inflammatory activity in the graft due to hepatitis induced by HCV reinfection was in all patients under surveillance determined by routine measurement of transaminases (ALT or GPT and AST or GOT) as well as alkaline phosphatase and gamma-glutamyl-transferase and bilirubin (every 7-30 d, interval depending on the time after LTx and level of elevation). Every unexplained rise was immediately followed by B-mode and duplex-/Doppler ultrasonographic analysis of liver parenchyma and the supplying vessels. If thrombosis of the hepatic artery and congestion of the biliary system were excluded, liver biopsy was performed. In analogy to patients pre LTx, recurrent hepatitis C severity was routinely determined by the modified Knodell hepatic activity index (HAI) with subscores for piecemeal necrosis (0-4), confluent necrosis (0-6), lytic necrosis/apoptosis/focal inflammation (0-4) and portal inflammation (0-4), as well as fibrosis staging (0-6)<sup>[23]</sup>.

### Statistical analysis

Virological, biochemical, and histological data were collected in a computer database (Microsoft Excel). Statistical analyses were performed utilizing SAS System software, release 8.2 (SAS Institute Inc., Cary, NC, USA). Qualitative characteristics were analyzed by  $\chi^2$  test or

**Table 1** Baseline characteristics of 47 HCV-infected patients after LTx, orthotopic liver transplantation (OLT), and living donor liver transplantation (LDLT)

	CsA	Tac	P-value
Number of patients	35	12	
Age	28-64	27-61	0.20
Gender	f=9, m=26	f=3, m=9	0.96
OLT	31	10	
LDLT	4	2	0.64
HCV genotype	gt1=32/35, gt2=1/35, gt3=2/35	gt1=10/12, gt2=0/12, gt3=2/12	0.46

Fisher's exact test as appropriate. Two-sided *P*-values and changes in HCV-RNA concentrations and ALT activities were evaluated by Mann-Whitney *U*-test. Correlation coefficients were reported as rank (Spearman) correlations.  $P < 0.05$  was considered statistically significant. In this explorative analysis, no adjustment for multiple testing was performed.

## RESULTS

### Effect of CsA and Tac on HCV serum RNA levels in HCV-infected patients post LTx

Of the 47 patients included in this study, 35 received CsA and 12 received Tac as the primary immunosuppressive agent. The baseline characteristics of the two patient groups showed no statistically significant differences (Table 1). Patients underwent liver transplantation at least 12 mo before the study. In both groups of patients, serum HCV-RNA level was quantitatively assessed at 1, 3, 6, and 12 mo after liver transplantation and compared to the HCV-RNA level prior to the operation. Figure 1 depicts these data on logarithmic scale ( $\log_{10}$ ) as a box-whisker's plot of HCV-RNA in relation to the primary immunosuppressive drug (CsA or Tac) and the time after LTx. *P*-values (Mann-Whitney *U*-test) at the top of the Figure express the group differences of changes in HCV serum RNA level (virus load), after 1, 3, 6, and 12 mo and the last measurement pre transplantation as indicated. *P*-values at the bottom of the Figure are the group differences between HCV-RNA concentrations at the given time of measurement. Boxes indicate the lower and upper quartiles and median, '+' indicates mean.

Serum HCV-RNA concentrations showed a substantial rise (between 10- and 1000-fold) after LTx. The elevation of HCV-RNA levels developed between 1 and 3 mo post LTx, at which point the elevation was the most pronounced and continued then throughout the entire observation period of 12 mo. The patients who received tacrolimus for immunosuppression had a lower mean HCV-RNA level pre LTx than those who received CsA, but the difference was not statistically significant ( $P = 0.09$ ). One month post LTx this group difference in the HCV-RNA levels was still present and even slightly accentuated, reaching statistical significance at this point ( $P = 0.006$ ). However, 3 mo post LTx the difference was significantly diminished neither at this time ( $P = 0.84$ ) nor at 6 ( $P = 0.37$ ) or 12 mo ( $P = 0.40$ ) post LTx. The group difference reached statistical significance.

**Figure 1** Box-whisker's plot of  $\log_{10}$ -transformed HCV-RNA concentrations in dependence on group (immunosuppression) and time.

A statistical significance between the levels of HCV-RNA in CsA and Tac groups was evaluated by comparison of the group difference at each given time point after LTx with the group difference before LTx. This analysis revealed no relevant dissimilarity between serum HCV-RNA concentrations in patients who received CsA or Tac for immunosuppression. A slightly higher rise in the tacrolimus group particularly 3 mo post LTx was statistically insignificant ( $P = 0.49$ ). The differences at 6 and 12 mo between both the groups were also not significant ( $P = 0.72$ ,  $P = 0.49$ ). Table 2 lists the net group differences of the changes on a  $\log_{10}$ -scale in serum HCV-RNA between the pre-LTx and post LTx values.

A power analysis revealed that with the given patient number, the group differences of the changes in serum HCV-RNA concentrations should be on the order 10-fold higher in order to be detectable with a power of 80%. In fact, the strongest deviation from the null hypothesis of no group difference of changes was not a significantly ( $P = 0.11$ ) stronger increase by a factor of 2.5 from pre LTx to the 1 mo measurement in the CsA as compared to the tacrolimus group, opposing a possible superiority of CsA.

### Activity of recurrent hepatitis C in dependence of immunosuppression

The value of HCV serum RNA level in predicting the inflammatory activity and progression of fibrosis was analyzed by a scatter plot of serum ALT, mirroring the activity of recurrent hepatitis, in dependence of serum HCV-RNA levels (Figure 2). The correlation coefficient was almost equal to zero ( $r = 0.01$ ,  $P = 0.92$ ), suggesting no significant association between levels of HCV-RNA and intrahepatic inflammatory activity. Therefore HCV-RNA levels post transplantation may not be a valid predictor of allograft inflammation. Differences in the progression of recurrent hepatitis were examined by serum transaminase level and histology in the two patient groups. Figure 3 shows the ALT levels (logarithmically scaled) as a box-whisker's plot of enzyme activity in correlation to

**Table 2** Net group difference (CsA *vs* FK 506) of changes in virus load (log<sub>10</sub>-scale) between pre-LTx measurement and indicated time points post LTx

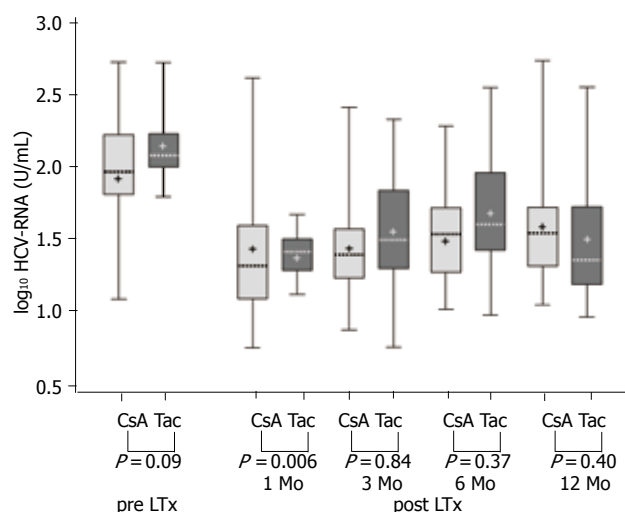

Mo	Mean	95%CI	P-value <sup>1</sup>
1	0.40	(-0.28; 1.08)	0.11
3	-0.50	(-1.46; 0.47)	0.49
6	-0.43	(-1.50; 0.64)	0.72
12	-0.56	(-1.64; 0.52)	0.49

<sup>1</sup>Mann-Whitney *U* test.**Figure 2** Correlation of HCV-RNA level in serum with ALT activity. Scatter plot with HCV-RNA concentrations on the y-axis and ALT activity on the x-axis, both on log<sub>10</sub>-scale.

immunosuppression (CsA group or FK 506 group) and the time after LTx. *P*-values (Mann-Whitney *U*-test) at the bottom of the Figure are for group differences between ALT activity at the time of measurement. Boxes indicate the lower and upper quartiles and median, '+' indicates mean.

In comparison to the level before LTx, the ALT level fell significantly immediately after the operation, with the lowest values 1 mo post LTx. After 3 mo especially after 6 mo ALT levels rose again and stayed elevated over the entire observation period of 12 mo, indicating the development of recurrent chronic hepatitis C. The ALT activity after 3 and 6 mo was increased in the CsA group, but the difference was not statistically significant (3 mo: *P*=0.36, 6 mo: *P*=0.65). Analysis of AST activity revealed similar kinetics post LTx with lower absolute values and also no statistically significant group differences (data not shown).

In conjunction with these analyses, examination of the proportion of patients with normal activities of transaminases post LTx revealed that 70% of patients in the CsA group and 83% in the Tac group had normal ALT activities 1 mo post LTx (Figure 4A). Recurrent hepatitis led to a significant decrease of the proportion of patients with normal ALT values after 3 and 6 mo (48% in the CsA group and 42% in the Tac group). While the proportion of patients with normal ALT at these time points was slightly higher in the CsA group than in the Tac group which was reversed after 12 mo, only 49% of patients in

**Figure 3** Box-whisker's plot of log<sub>10</sub>-transformed ALT activities in dependence on group (immunosuppression) and time.

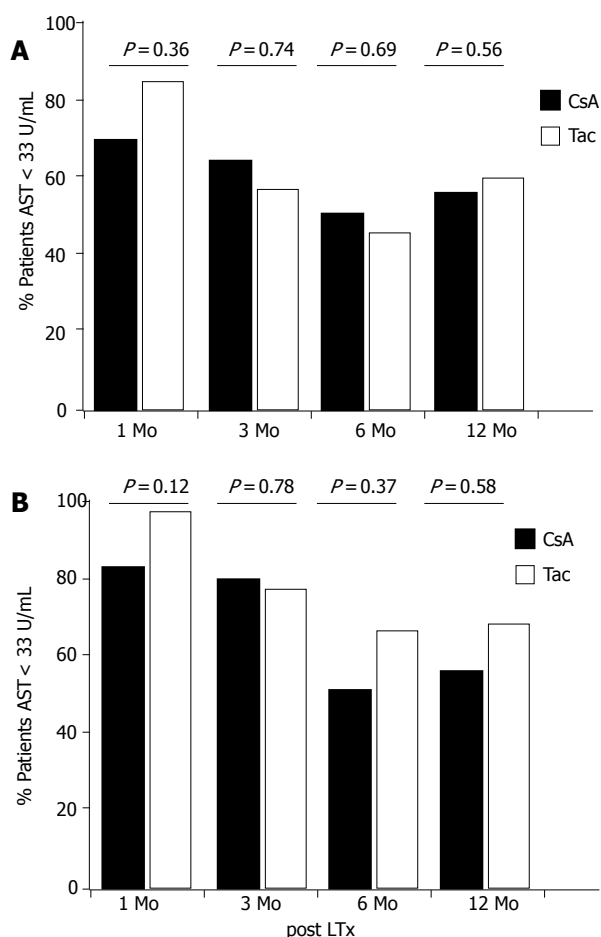

the CsA group but 58% of patients in the Tac group had normal ALT values. However, the group differences were statistically significant neither at 6 mo (*P*=0.69) nor at 12 mo (*P*=0.56). The proportion of patients with normal AST changed similarly (Figure 4B), indicating no advantage for CsA in suppressing inflammatory activity.

To further evaluate the potential differences in the activation and maintenance of recurrent hepatitis C between the two groups, we compared necroinflammatory activity and grade of fibrosis according to HAI scores in the liver histology taken 3-5 mo post LTx. The majority of patients in both groups had a grade II inflammation (74% of patients in the CsA group and 83% of patients in the Tac group), indicating that recurrent hepatitis occurred in a significant proportion of patients in the absence of elevated serum transaminases (Figure 5A). The total group differences including all inflammation grades between the CsA and Tac groups were statistically negligible (*P*=0.85). Examination of fibrosis revealed a larger proportion of patients in the CsA group than in the Tac group scored with grade 0 (26% *vs* 8.3%, Figure 5B). However, at grade I this relation was reversed (2.9% *vs* 25%). In addition, more patients in the CsA group were scored with grade II fibrosis, while patients in the Tac group were more frequently scored with grade III fibrosis. The number of patients presenting with grade IV fibrosis was very small in both groups. Due to the changes in grades 0 and I, these overall group differences were statistically significant (*P*=0.03). However, if grades 0 and I were analyzed as one group, no statistical differences were found (*P*=0.34).

## DISCUSSION

The marked increase in serum HCV-RNA levels after LTx is closely associated with the immunosuppressive therapy<sup>[7,11,24]</sup>. Our study also confirmed that serum HCV-RNA levels increased in the early (3 mo) post-transplant period, when immunosuppression was the highest. Although there is evidence that immunosuppression accelerates the progression of chronic HCV infection to cirrhosis, no clear

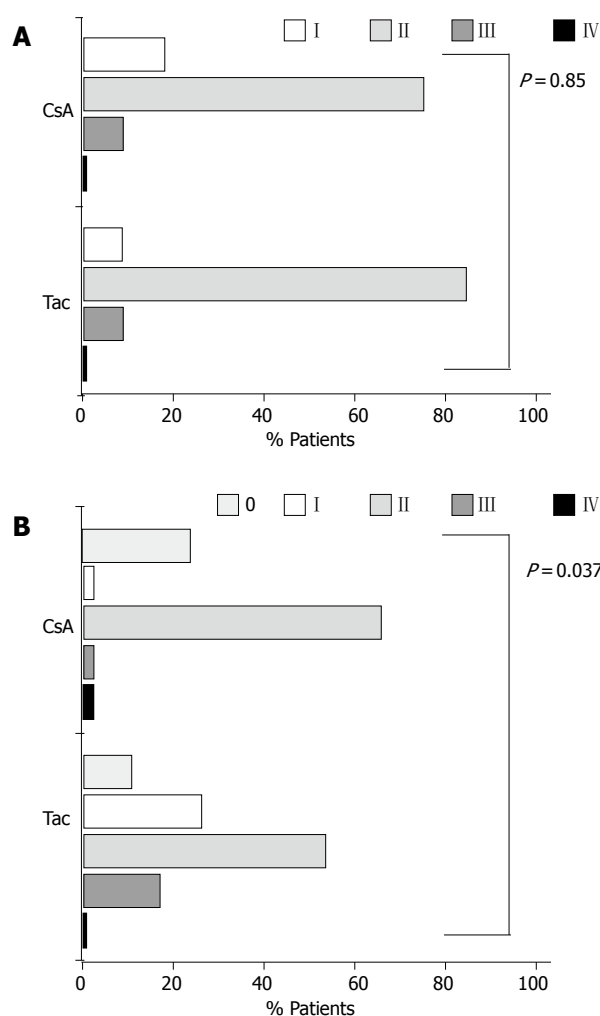

**Figure 4** Proportion of HCV-infected patients under CsA or Tac medication with normal transaminase activities at different time points post LTx. **A:** Percentage of patients with normal ALT; **B:** percentage of patients with normal and AST. *P*-values were calculated by  $\chi^2$  test.

association has been found between the type or dose of immunosuppressive regimen and the outcome of post-transplant HCV recurrence. CsA and Tac are the most common immunosuppressive drugs used after LTx, but their exact impact on the incidence, severity, time of onset and outcome of HCV recurrence is unclear<sup>[10]</sup>. In this context, Watashi *et al.*<sup>[17]</sup> showed that CsA but not Tac can inhibit HCV replication *in vitro*, which raises the question whether HCV-infected patients treated with CsA have an advantage with regard to the progression of recurrent hepatitis and therefore graft survival as compared to those treated with Tac.

Our results did not confirm the function of CsA in inhibiting HCV replication as compared to Tac. Neither the differences at any time of examination nor the differences in serum HCV-RNA levels after LTx were in favor of CsA. In addition, there were no significant differences in inflammation of the allograft between the CsA and Tac groups, as determined by serum transaminase activities and histological grading of intrahepatic necroinflammatory activity. The slight differences in the grade of fibrosis, suggesting a lower grade of fibrosis in the CsA group were not statistically significant. While a study showed that HCV-infected patients treated with Tac have an improved survival in comparison to those treated with CsA<sup>[16]</sup>, our results are in accordance with a recently published study, which also

**Figure 5** Intrahepatic inflammatory activity and fibrosis post LTx depending on immunosuppression. **A:** Necroinflammatory activity histologically scored by the subscores for portal inflammation of the Knodell's hepatic activity index (HAI); **B:** grade of fibrosis in the graft. Fibrosis was scored according to the appropriate subscores of the HAI.

found no advantage for either immunosuppressive agent<sup>[19]</sup>. However, Watashi *et al.*<sup>[17]</sup> showed that CsA can inhibit HCV replication in hepatocytes. In the last several years, a number of cell culture propagation systems based on the infection of primary human<sup>[25,26]</sup> or chimpanzee<sup>[27]</sup> hepatocytes or hepatic cell lines<sup>[28,29]</sup> have been reported. There is a general agreement that all these systems have a poor validity and reproducibility. Viral proteins and particles have never been convincingly detected and viral RNA can be quantified only by the sensitive PCR methodology<sup>[30,31]</sup>. In HCV research, these limitations of the infection-based cell culture systems have led to the development of a selectable HCV replicon system<sup>[32]</sup>. In this system, a subgenomic part of HCV-RNA can replicate in a human hepatoma cell line (HuH-7) to unphysiologically high levels, suggesting that this system is highly artificial and may not adequately mirror the situation *in vivo*. An additional important aspect regarding both cell culture systems is the absence of the immune system. Even if CsA has a HCV suppressing effect *in vivo*, this effect is by far outweighed by the immunosuppressive effects of the drug, resulting in a decreased control of HCV replication by the immune system.

In conclusion, our study does not justify a recommendation for CsA as a primary immunosuppressive agent for the treatment of HCV-infected patients post LTx. Further prospective studies should be conducted to clarify this issue. To vigorously improve the graft survival and prognosis of HCV-infected patients post LTx, development of new therapeutic agents directly modifying HCV-replication and/or inflammatory activity of recurrent hepatitis C in combination with alternative immunosuppressive regimens remains a high priority goal.

## Abstract

**AIM:** To estimate whether STI571 inhibits the expression of vascular endothelial growth factor (VEGF) in the gastrointestinal stromal tumor (GIST) cells.

**METHODS:** We used GIST cell line, GIST-T1. It has a heterogenic 57-bp deletion in exon 11 to produce a mutated c-KIT, which results in constitutive activation of c-KIT. Cells were treated with/without STI571 or stem cell factor (SCF). Transcription and expression of VEGF were determined by RT-PCR and flow cytometry or Western blotting, respectively. Activated c-KIT was estimated by immunoprecipitation analysis. Cell viability was determined by MTT assay.

**RESULTS:** Activation of c-KIT was inhibited by STI571 treatment. VEGF was suppressed at both the transcriptional and translational levels in a temporal and dose-dependent manner by STI571. SCF upregulated the expression of VEGF and it was inhibited by STI571. STI571 also reduced the cell viability of the GIST-T1 cells, as determined by MTT assay.

**CONCLUSION:** Activation of c-KIT in the GIST-T1 regulated the expression of VEGF and it was inhibited by STI571. STI571 has antitumor effects on the GIST cells with respect to not only the inhibition of cell growth, but also the suppression of VEGF expression.

## INTRODUCTION

Gastrointestinal stromal tumors (GIST) are characterized by the expression of both c-KIT and CD34 on the cell surface. Mutations in *c-kit* have recently been implicated with oncogenic activation associated with GISTs<sup>[1,2]</sup>. c-KIT, a type III receptor tyrosine kinase, is activated upon binding of the ligand, stem cell factor (SCF) to initiate a signaling pathway that is critical for the growth and development of mast cells, melanocytes, hematopoietic stem cells, and the interstitial cells of Cajal<sup>[3,4]</sup>. Gain-of-function mutations in *c-kit* are associated with a number of cancers in human beings<sup>[1,5-9]</sup>. The majority of GISTs show constitutive c-KIT phosphorylation due to a gain-of-function mutation in exon 11 (cytoplasmic juxtamembrane domain), with other mutations known to occur in exon 9 (extracellular membrane domain), exon 13 (first part of the split tyrosine kinase domain), and exon 17 (phosphotransferase domain)<sup>[8]</sup>.

STI571 is a specific tyrosine kinase inhibitor that acts on Bcr-Abl, platelet-derived growth factor receptor (PDGFR), and c-KIT. STI571 has been used successfully in patients with unresectable or metastatic GISTs that show constitutive activation of c-KIT<sup>[9]</sup>.

Vascular endothelial growth factor (VEGF) is a highly specific mitogen for vascular endothelial cells that is induced by hypoxia, oncogene activation, and a variety of cytokines. VEGF is important in angiogenesis and neovascularization of solid tumor growth<sup>[10]</sup>. Expression of VEGF in GISTs was reported by Takahashi *et al*<sup>[11]</sup>, who suggested a correlation between this expression

**Figure 1**  $4 \times 10^6$  of GIST-T1 cells were treated with STI571 (1  $\mu\text{g/mL}$ ) for 1 h. Treated cells were lysed in RIPA buffer and immunoprecipitation with anti-c-KIT antibody as described in "Materials and methods". Western blotting was performed using anti-phosphotyrosine antibody (upper panel) or anti-c-KIT antibody (lower panel). Lane 1, non-treated; lane 2, STI571 1  $\mu\text{g/mL}$ . WB, Western blot; IP, immunoprecipitation.

and poor prognosis. It is thought that the assessment of VEGF expression in GISTs is important clinically.

In the present study, we have analyzed the expression of VEGF in the GIST cell line, GIST-T1, with or without STI571 treatment. To our knowledge, there are only two GIST cell lines, including GIST-T1. The GIST-T1 line was established from a patient with metastatic GIST<sup>[12]</sup>, which showed the *c-kit* mutation in exon 11. In addition, we have analyzed the effect of STI571 on cell growth of the GIST-T1 cells.

## MATERIALS AND METHODS

### Materials

STI571, also known as Glivec capsule (Novartis, Basel, Switzerland), was dissolved in water (5  $\mu\text{g}/\mu\text{L}$ ) and stored at  $-20^\circ\text{C}$ . Antibodies were used to detect the c-KIT (K963, rabbit polyclonal IgG, Immuno-Biological Laboratories, Japan), phosphotyrosine (PY20, mouse monoclonal IgG, Zymed, USA), HIF-1 alpha (H-206, rabbit polyclonal IgG, Santa Cruz Biotechnology, USA), and VEGF (A-20, rabbit polyclonal IgG, Santa Cruz Biotechnology, USA).

### Cells and cell culture

The human GIST cell line, GIST-T1 has been characterized in detail by Taguchi *et al*<sup>[12]</sup>. GIST-T1 cells and DLD-1 cells (colon adenocarcinoma cell line) were cultured in Dulbecco's modified Eagle's medium (DMEM) supplemented with penicillin, streptomycin, and 80 mL/L fetal bovine serum maintained in a 50 mL/L  $\text{CO}_2$  atmosphere at  $37^\circ\text{C}$  in a humidified incubator.

### Western blot analysis

Cells were washed thrice with ice-cold phosphate buffered saline (PBS) and then lysed in RIPA buffer containing 20 mmol/L sodium pyrophosphate, 20 mmol/L NaF, 1 mmol/L orthovanadate, 2 mmol/L pyrophosphate, 1 mmol/L PMSF, 10  $\mu\text{g/mL}$  aprotinin, and 10  $\mu\text{g/mL}$  leupeptin. Cell lysates containing comparable amounts of proteins, estimated by a Bradford assay (BioRad, Munchen, Germany), were analyzed by Western blotting using antibodies as listed above.

### Immunoprecipitation analysis

A measure of  $4 \times 10^6$  cells was seeded on 10-cm dishes and

incubated for 24 h, prior to the treatment with STI571. Cells were treated with or without STI571 (1  $\mu\text{g/mL}$ ) for 1 h. Treated cells were collected and washed with ice-cold PBS thrice and lysed in RIPA buffer as described above. Cells lysates in RIPA buffer were subjected to immunoprecipitation with c-KIT antibody. The immunoprecipitates were reacted with protein A-agarose and washed with Tris buffered saline. They were then finally resuspended in 3 $\times$ SDS sample buffer containing 30 $\times$ DTT and boiled at  $95^\circ\text{C}$  for 5 min. Samples were separated by 75 g/L SDS-PAGE and transferred to a membrane for immunoblot analysis.

### Isolation of RNA and detection of VEGF or HIF-1 alpha mRNA

A measure of  $1 \times 10^6$  cells was seeded on 6-cm dishes and incubated for 24 h prior to the treatment with or without the reagents. Prior to the treatment with SCF, medium was changed to the serum-free medium. Treated cells were washed twice in ice-cold PBS and the total cellular RNA was isolated by using TRIzol reagent (Gibco-BRL) according to the manufacturer's protocol. Specific mRNA was assayed using the reverse transcription polymerase chain reaction (RT-PCR). VEGF PCR condition<sup>[13]</sup>: denaturation at  $94^\circ\text{C}$  for 1 min, annealing at  $60^\circ\text{C}$  for 1 min and elongation at  $72^\circ\text{C}$  for 1 min, for 35 cycles; HIF-1 alpha<sup>[14]</sup>: denaturation at  $94^\circ\text{C}$  for 10 min-1 cycle, followed by 35 cycles of 30 s at  $94^\circ\text{C}$ , 30 s at  $55^\circ\text{C}$  and 1 min at  $72^\circ\text{C}$ ; beta-actin: denaturing,  $94^\circ\text{C}$  for 30 s, annealing at  $50^\circ\text{C}$  for 40 s and elongation,  $72^\circ\text{C}$  for 1 min, for 30 cycles; and final elongation at  $72^\circ\text{C}$  for 10 min-1 cycle. PCR products were subjected to electrophoresis on 20 g/L agarose gel. The primer sequences were VEGF sense: 5' -CGAAGTGGTGAAGTTCATGGATG-3'; VEGF antisense: 5' -TTCTGTATCAGTCTTTCCTGGTGA-3'; HIF-1 alpha sense: 5' -CTCAAA GTCGGACAGCCTCA-3'; HIF-1 alpha antisense: 5' -CCCTGCAGTAGGTTTCTGCT-3'; beta-actin sense: 5'-ATTGGCAATGAGCGGTTCCGC-3'; beta-actin antisense: 5'-CTCCTGCTTGCTGATCCACATC-3'.

### Flow cytometry

A measure of  $2 \times 10^6$  cells was seeded on 6-cm dishes and incubated for 24 h, prior to the treatment with STI571 for 4 h. Following this, a Goldi plug (BD Bioscience, San Diego, CA, USA) was added to each dish for 2-h incubation. Cells were then washed with ice-cold PBS twice before the treatment with cytoplex (BD Bioscience) and cytoperm (BD Bioscience) according to the manufacturer's protocols. Anti-VEGF, anti-HIF-1 alpha, and FITC-labeled anti-rabbit antibodies were used. Normal rabbit IgG antibody and FITC-labeled anti-rabbit antibody were used for control staining.

### MTT assay

A measure of  $1 \times 10^4$  cells/100  $\mu\text{L}$  was seeded in each well of a 96-well plate. After 24 h with or without STI571 treatment, 100  $\mu\text{L}$  of a 2.5 mg/mL solution in PBS of the MTT (3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide; Sigma-Aldrich) tetrazolium substrate was added and incubated for 4 h at  $37^\circ\text{C}$ . The resulting violet

**Figure 2** RT-PCR,  $1 \times 10^6$  GIST-T1 cells were treated with STI571 (0.01, 0.1, and 1  $\mu\text{g/mL}$ ) for 6 h (A) or 1  $\mu\text{g/mL}$  of STI571 for 60, 120, and 360 min (B). **A:** Lane 1, non-treated; lane 2, 0.01  $\mu\text{g/mL}$ ; lane 3, 0.1  $\mu\text{g/mL}$ ; lane 4, 1  $\mu\text{g/mL}$ ; **B:** lane 1, 0 min; lane 2, 60 min; lane 3, 120 min; lane 4, 360 min. GIST-T1 cells were treated with SCF (10 ng/mL) for 1, 2, 6 h (C). **C:** lane 1, 0 h; lane 2, 1 h; lane 3, 2 h; lane 4, 6 h. GIST-T1 cells were treated with STI571 (1  $\mu\text{g/mL}$ ), LY294002 (50  $\mu\text{mol/L}$ ), PD98059 (50  $\mu\text{mol/L}$ ), or Wortmannin (100 nmol/L) for 6 h (D). **D:** Lane 1, non-treated; lane 2, STI571; lane 3, LY294002; lane 4, PD98059; lane 5, Wortmannin.  $1 \times 10^6$  DLD-1 cells were treated with SCF in different concentrations for 6 h (E). **E:** Lane 1, non-treated; lane 2, SCF 5 ng/mL; lane 3, SCF 10 ng/mL; lane 4, SCF 15 ng/mL; lane 5, SCF 20 ng/mL; lane 6, SCF 100 ng/mL. GIST-T1 cells were treated with STI571, SCF, or combination of both for 6 h to determine the transcriptional level of HIF-1 alpha (F). **F:** Lane 1, non-treated; lane 2, STI571 1  $\mu\text{g/mL}$ ; lane 3, SCF 10 ng/mL; lane 4, SCF 10 ng/mL+STI571 1  $\mu\text{g/mL}$ ; lane 5, SCF 10 ng/mL+STI571 10  $\mu\text{g/mL}$ .

formazan precipitate was solubilized by the addition of 100  $\mu\text{L}$  of a 50%  $N,N$ -dimethyl formamide/10% SDS solution, and incubated for 4 h at room temperature. Sample absorbances were then measured on a plate reader at 570 nm.

### Statistical analysis

Data were reported as mean  $\pm$  SD. Statistics were analyzed with the Student's  $t$ -test. A  $P$  value of less than 0.05 was considered statistically significant.

## RESULTS

### Tyrosine phosphorylation of c-KIT

c-KIT in the non-treated cells was tyrosine phosphorylated (Figure 1, upper panel, lane 1) in the GIST-T1 cells. This phosphorylation was inhibited by STI571 treatment (Figure 1, upper panel lane 2). c-KIT protein is also shown by Western blotting (Figure 1, lower panel).

### Transcription of VEGF and HIF-1 alpha

RT-PCR detected the transcription of VEGF or HIF-1 alpha in the GIST-T1 cells. In the GIST-T1 cells, VEGF121 and VEGF165 isoforms were detected (Figures 2A-2D). STI571 inhibited VEGF in a dose- and time-dependent manner (Figures 2A and 2B). On the contrary, STI571 could not inhibit HIF-1 alpha (Figure 2F, lane 2). SCF up-regulated VEGF (Figure 2C) but not HIF-1

alpha (Figure 2F, lane 3). PD98059, MEK inhibitor, did not inhibit the transcription of VEGF (Figure 2D, lane 4). LY294002 and Wortmannin, both the inhibitors of phosphatidylinositol 3-kinase (PI3K), also did not inhibit the transcription of VEGF in the GIST-T1 cells compared to STI571 (Figure 2D, lanes 3 and 5). SCF (10 ng/mL) upregulated the transcription of VEGF in the colon adenocarcinoma cell line, DLD-1 (Figure 2E, lane 3). However, in the case of high concentration of SCF stimulation (100 ng/mL for 6 h), transcriptions of VEGF were downregulated in the DLD-1 cells (Figure 2E, lane 6).

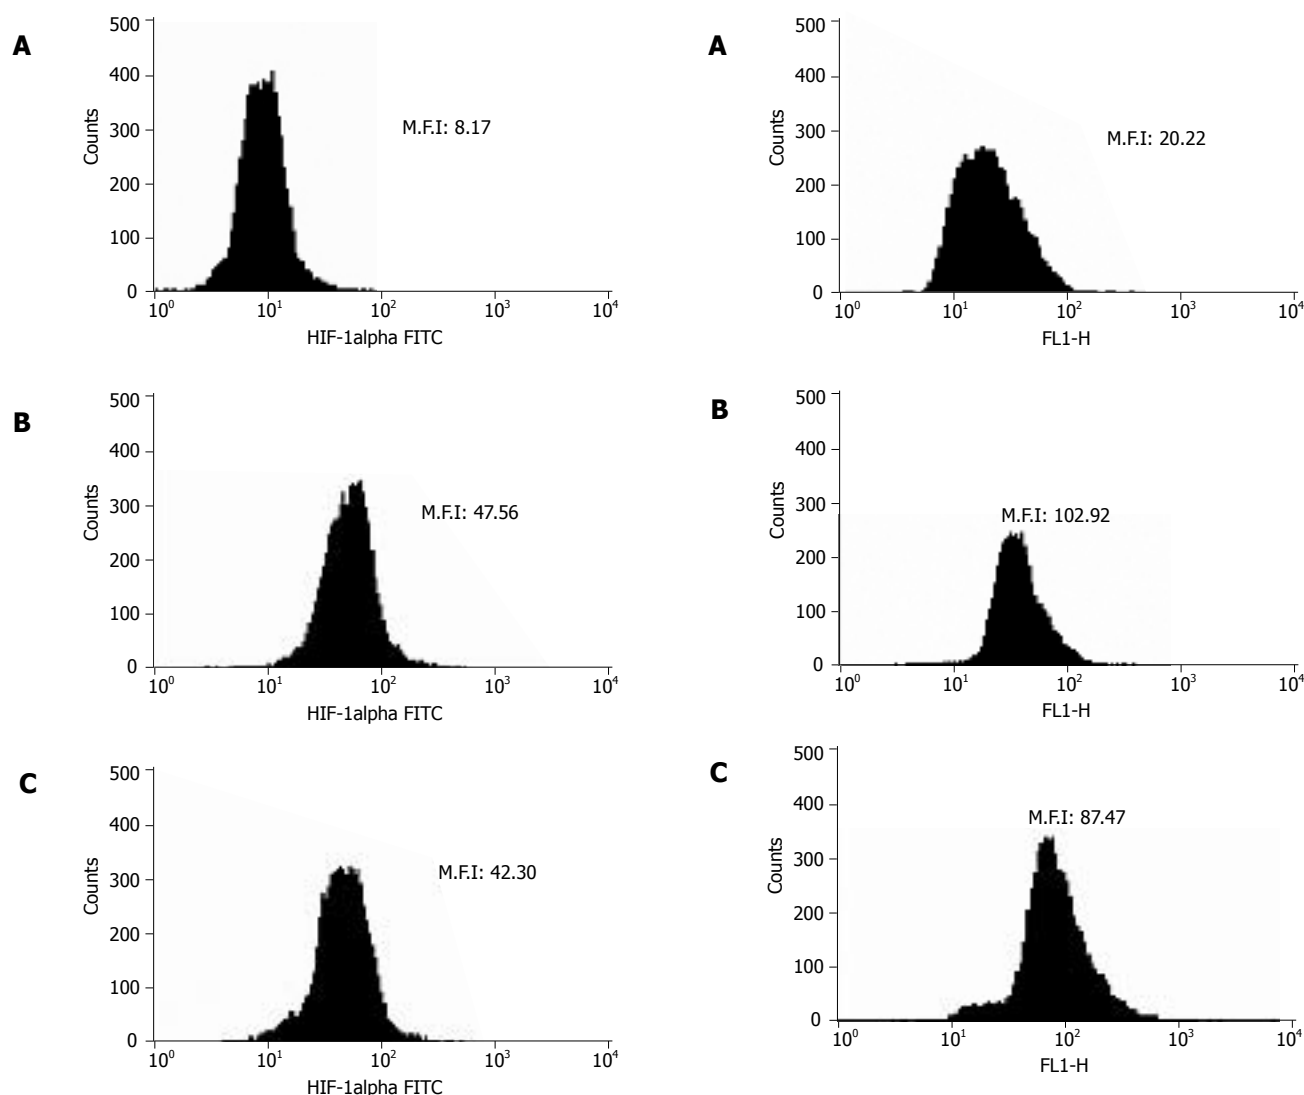

### Intracellular expression of VEGF and HIF-1 alpha in the GIST-T1

Flow cytometry was used to show that VEGF or HIF-1 alpha was expressed in the non-treated GIST-T1 cells (Figures 3B and 4B). STI571 reduced the expression of VEGF (Figure 4C). SCF upregulated the expression of VEGF in the GIST-T1 cells (Figure 4D) and STI571 inhibited the upregulation of VEGF by SCF stimulation in the GIST-T1 cells (Figure 4E). HIF-1 alpha could not be influenced by STI571 treatment (Figure 3C). SCF also did not influence the expression of HIF-1 alpha (data not shown). Western blotting revealed that VEGF was expressed as a 21-kDa band, which was downregulated by STI571 in a dose-dependent manner (Figure 5).

### Effect of STI571 on GIST-T1 cell viability

Cell viability of the GIST-T1 cells was measured by MTT

**Figure 3** Expression of HIF-1 alpha was determined by flow cytometry.  $2 \times 10^6$  GIST-T1 cells were treated with/without STI571 as described in "Materials and the methods". **A:** Control (normal rabbit IgG); **B:** non-treated (HIF-1 alpha antibody); **C:** STI571 (1  $\mu$ g/mL). MFI, mean fluorescent intensity.

assay, which showed a reduction in viability following the treatment with STI571 to  $37.9 \pm 1.3\%$ ,  $36.5 \pm 1.7\%$ , and  $36.3 \pm 0.3\%$  at the concentrations of 0.1, 1, and 2  $\mu$ g/mL, respectively ( $P < 0.01$  *vs* non-treated). Cell viability in the case of non-treated cells was indicated as  $100 \pm 0.5\%$ .

## DISCUSSION

The present study demonstrated that the recently developed compound STI571 inhibited the tyrosine phosphorylation of c-KIT in GIST-T1 tumor cells, as well as inhibiting both the transcription and translation of VEGF. Tyrosine phosphorylation of c-KIT was inhibited after 30 min treatment with STI571 at different concentrations (0.1 and 1  $\mu$ g/mL), as assessed by Western blot analysis (data not shown). In contrast, Tuveson *et al*<sup>[13]</sup> reported that tyrosine phosphorylation of another GIST cell line, GIST882, was not inhibited by a 1-h treatment with STI571 when used at 1  $\mu$ mol/L (0.59  $\mu$ g/mL), as assessed by Western blot analysis. GIST882 has a

**Figure 5** Assessment of expression of VEGF by Western blotting.  $3 \times 10^6$  cells were treated with STI571 (0.01, 0.1, and 1  $\mu\text{g/mL}$ ) for 12 h, and then cells were rinsed with ice-cold PBS and lysed in RIPA buffer as described in "Materials and methods". Fifty micrograms of protein was applied in each lane. Lane 1: non-treated; lane 2: STI571 0.01  $\mu\text{g/mL}$ ; lane 3: STI571 0.1  $\mu\text{g/mL}$ ; lane 4: STI571 1  $\mu\text{g/mL}$ .

homogenic mutation in the *c-kit* gene resulting in a K642E amino acid change and the constitutive activation of c-KIT<sup>[15]</sup>. On the other hand, GIST-T1 has a heterogenic 57-bp deletion in exon 11 of the *c-kit* mutation, and the c-KIT protein in the GIST-T1 cells constitutively activated. Furthermore, Frolvo *et al*<sup>[16]</sup> reported that STI571 inhibits the activation of p44/42 mitogen activated protein kinase (p44/42MAPK) in GIST882 cells, but we could not detect the same effect in our cells following STI571 treatment (data not shown). Oncogenic Ras family proteins activate the p44/42MAPK pathway, and this activation contributes to the increased proliferative rate of tumor cells<sup>[17]</sup>. Phosphorylated c-KIT also activates the p44/42MAPK pathway as well as plays a role in the process of oncogenic activation<sup>[18]</sup>. MEK is upstream of p44/42MAPK, and MEK inhibitors could inhibit the activation of p44/42MAPK. In our hands, the MEK inhibitor, PD98059, partially inhibited the activation of p44/42MAPK (data not shown). These results suggested that activation of p44/42MAPK was independent of the activation of c-KIT in GIST-T1 cells.

In a previous study, Ebos *et al*<sup>[19]</sup> reported that STI571 reduced VEGF expression in the Bcr-Abl positive chronic myelogenous leukemia cells. They reported that activation of Bcr-Abl played an important role in VEGF expression. In our study, RT-PCR and flow cytometry analysis revealed that both the transcription and translation of VEGF in GIST-T1 cells were suppressed by STI571 treatment. Western blot analysis revealed that STI571 inhibited the expression of VEGF for 12-h incubation. SCF activated c-KIT and upregulated the expression of VEGF. These results suggested that activation of c-KIT was an important role in both the transcription and the translation of VEGF in the GIST-T1 cells. Furthermore we investigated the signal transduction cascade which was involved in the expression of VEGF in the GIST-T1 cells using MEK inhibitor or PI3K inhibitors. In our study, PD98059, LY294002 and Wortmannin had no such effect on these cells. LY294002 and Wortmannin are both inhibitors of PI3K and thereby inhibit activation of the AKT pathway<sup>[20]</sup>. AKT promotes angiogenesis through eNOS activation<sup>[20]</sup>. STI571 inhibited the activation of AKT in GIST882 cells<sup>[16]</sup>, but the same result was not obtained in our GIST-T1 cells by Western blotting (data not shown). These results suggested that neither the p44/42MAPK nor PI3K signaling pathways are involved in the regulation of VEGF expression in GIST-T1 cells.

Hypoxia inducible factor-1 (HIF-1) plays an important role in the expression of VEGF in the malignant tumors. HIF-1 activity is primarily regulated by the levels of

HIF-1 alpha in the cells<sup>[21]</sup>. In our study, transcriptional or translational levels of HIF-1 alpha were not regulated by STI571 treatment or SCF stimulation.

c-KIT is expressed in the colon adenocarcinoma cell line, DLD-1<sup>[22]</sup>. It is clear that c-KIT regulates the expression of VEGF in other cells. So, we observed whether c-KIT was involved in the upregulation of the transcriptional levels of VEGF using SCF in DLD-1 cells. SCF induced VEGF transcription at a concentration of 5–10 ng/mL. These results suggested that the expression of VEGF might be concerned with the activation of c-KIT.

MTT assay revealed that STI571 inhibited the cell viability of GIST-T1 cells. Activation of c-KIT in the GIST-T1 cells played an important role in cell survival signaling.

In conclusion, our results on the treatment of GIST-T1 cells with STI571 suggest that the expression of VEGF in these cells might be regulated via the c-KIT signal transduction cascade. STI571 inhibited not only cell viability but also the expression of VEGF in GIST-T1 cells, and it could be a useful compound for GIST therapy. Further studies are required to investigate the mechanism underlying VEGF regulation in more detail.

## Abstract

**AIM:** To evaluate the changes in hepatic platelet activating factor (PAF) and its receptors and their effect on portal pressure of cirrhotic rats induced by CCl<sub>4</sub>.

**METHODS:** A model of liver cirrhosis was replicated in rats by intra-peritoneal injection of CCl<sub>4</sub> for 8 wk. We determined the effect of hepatic PAF and its receptor level on portal and arterial pressure by EIA, saturation binding and RT-PCR technique.

**RESULTS:** Compared to control rats, cirrhotic rats had higher hepatic PAF levels and output as well as higher plasma PAF levels ( $P < 0.01$ ,  $P < 0.01$ ,  $P < 0.05$ , respectively). Both hepatic PAF receptor mRNA levels and PAF binding were nearly 3-fold greater in cirrhotic rats ( $P < 0.01$ ). Portal injection of PAF (1 g/kg WT) increased the portal pressure by 22% and 33% in control and cirrhotic rats, respectively. In contrast, the arterial pressure was decreased in the both groups (54% in control rats and 42% in cirrhotic rats). Injection of the PAF antagonist BN52021 (5 mg/kg WT) decreased the portal pressure by 16% in cirrhotic rats but had no effect in the control rats.

**CONCLUSION:** The upregulation of the PAF system contributes to hepatic hemodynamic and metabolic abnormalities in cirrhosis, and the increased release of PAF into the circulation has impacts on the systemic hemodynamics.

## INTRODUCTION

Platelet activating factor (PAF: 1-O-alkyl-2-acetyl-sn-glycero-3-phosphocholine) is a phospholipid exhibiting diverse biological actions. PAF acts both as a multifunctional, soluble, proinflammatory agent and as a specific membrane-bound adhesion molecule. PAF receptors have been identified in smooth muscle cells, cardiomyocytes, endothelial cells, neutrophils, monocyte-macrophages, Kupffer cells and eosinophils<sup>[1]</sup>. The physiological actions of PAF play a role in platelet secretion and aggregation, bronchoconstriction, vascular permeability and systemic arterial hypotension<sup>[1-4]</sup>. Exogenous PAF administration via the portal vein increases portal venous pressure and activates glycogenolysis both in perfused organs<sup>[5]</sup> and *in vivo*<sup>[6]</sup>. In contrast, systemic infusion of PAF reduces arterial blood pressure<sup>[7,8]</sup>. Portal hypertension and hyperdynamic systemic circulation are two prominent clinical features of human and animal experimental liver cirrhosis<sup>[9-11]</sup>. Circulatory responses to intravenous infusion of PAF resemble the hemodynamic change in advanced liver cirrhosis. Excessive deposition of extracellular matrix is a cause of the increased resistance to hepatic blood flow and consequent portal hypertension in cirrhosis, but studies in animals indicate that increased vascular tone is also a contributing factor<sup>[12]</sup>.

The PAF content in intact liver is elevated by various types of injury, including ischemia-reperfusion<sup>[13]</sup>, obstructive jaundice<sup>[14]</sup>, and endotoxin exposure *in vivo*. Based on these observations, we hypothesized that increased hepatic synthesis of PAF in cirrhosis could lead to increased plasma levels, and that PAF might play a role in portal hypertension. Our results have confirmed that hepatic PAF levels are elevated and PAF receptors are upregulated in cirrhosis. The reactivity of the hepatic vasculature to PAF is consequently increased, while that of the systemic vasculature is attenuated.

## MATERIALS AND METHODS

### Induction of cirrhosis

Cirrhosis was induced in male Sprague-Dawley rats

weighing 230-250 g as described previously<sup>[10,15,16]</sup>. Briefly, intraperitoneal injection of CCl<sub>4</sub> (0.15 mL/kg WT, twice a week for 8 wk) was combined with drinking water containing phenobarbital (0.4 g/L). Control rats received injection of the vehicle (peanut oil) and phenobarbital water.

#### **Determination of portal venous and systemic arterial pressure**

Rats were anesthetized with 50 mg/kg (i.p.) pentobarbital, and placed on a heated water blanket maintained at 38°C. A PE-50 catheter (Thomas Scientific, Swedesboro, NJ, USA) was inserted into the femoral artery to monitor arterial blood pressure via a strain gauge pressure transducer connected to a 4-channel Grass polygraph (Model no. 79E, Quincy, MA, USA). The hepatic trigone was exposed via laparotomy, and the portal vein was skeletonized. The intestines and the abdominal cavity were covered with warm saline-soaked sponges, and a catheter was inserted into the portal vein and connected to a pressure transducer coupled to a 4-channel Grass polygraph to monitor portal pressure. After stable recordings of both portal and arterial blood pressure were obtained, 1 mL of blood was withdrawn from the femoral artery, portal vein and suprahepatic vena cava, respectively. Then, the liver was rapidly excised and washed in ice-cold phosphate buffered saline containing 0.1 mmol/L EDTA and 0.1 mmol/L EGTA. A portion of the liver tissue was stored in 10% buffered formalin, a portion in OCT, and the rest was snap-frozen in liquid nitrogen and stored at -80 °C.

#### **Morphometric analysis**

An established histological grading system was employed for the determination of pathological scores of liver injury<sup>[17-19]</sup>. Paraffin-embedded liver sections of 4-μm thickness were stained with hematoxylin-eosin and Masson's trichrome. Steatosis, inflammation, necrosis and fibrosis were scored in at least three random fields of view in each tissue section and a score for each specific parameter was estimated. Steatosis was assessed by estimating the percentage of cells with micro- and macrovesicular fat as follows: 0 (absent), 1 (1-25%), 2 (26-50%), 3 (51-75%), and 4 (76-100%). Necrosis was scored as follows: 0 (absent), 1 (1-10 necrotic cells per view), 2 (11-20 necrotic cells per view), 3 (21-30 necrotic cells per view), 4 (31-40 necrotic cells per view), and 5 (41-50 necrotic cells per view). Inflammation was assessed as follows: 0 (absent), 1 (rare), 2 (scattered), 3 (scattered with localized foci), 4 (abundant with foci), and 5 (extensive). Architectural change, fibrosis and cirrhosis were estimated as follows: 0 (absent), 1 (rare), 2 (scattered deposition), 3 (scattered with localized deposition), 4 (abundant with minor bridging fibrosis), 5 (bridging fibrosis) and 6 (cirrhosis). A total pathology score was calculated by combining and summing the scores for the above pathological parameters, and the average score per animal/treatment group was calculated.

#### **Determination of PAF in liver and blood**

Lipids were extracted as previously described<sup>[20]</sup>. Briefly, 100 mg of liver or 1 mL of blood was homogenized in 9.5 mL

of a mixture of methanol, chloroform and water (2:1:0.8, v:v:v). The homogenates were kept at room temperature for 1 h, followed by the addition of chloroform (2.5 mL) and water (2.5 mL). After being thoroughly mixed, the mixture was kept at room temperature for 1 h and centrifuged at 1200 r/min for 15 min. The chloroform layer was aspirated and dried under nitrogen at 35 °C. The residue was dissolved in 200 μL chloroform, and applied to the Bond Elut SI column (Amprep silica mini-columns; Amersham Pharmacia Biotech, Piscataway, NJ, USA). The column was washed with 3 mL of chloroform, 2 mL of chloroform-methanol (6:4; v/v) and 3 mL of chloroform-methanol-28% aqueous ammonia (70:85:7, v:v:v). PAF was eluted with 2 mL of chloroform-methanol-28% aqueous ammonia (50:50:7, v/v). The elute was evaporated to dryness under nitrogen, and the residue was dissolved in 200 μL of saline containing 0.01% Triton X-100. PAF concentration was determined by [<sup>3</sup>H]-PAF scintillation proximity assay (Amersham-Pharmacia Biotech).

#### **Determination of hepatic PAF binding**

Hepatic membranes were prepared as described previously<sup>[10,16]</sup> and suspended in 50 mmol/L Tris-HCl (pH 8.0) containing 5 mmol/L MgCl<sub>2</sub>, 125 mmol/L choline chloride, 0.1 mol/L PMSF, 0.1 μg/mL leupeptin and 1 μg/mL pepstatin. The membrane suspension was stored at -80 °C in aliquots after the protein concentration was adjusted to 10 mg protein/mL. Membranes (100 μg protein) were incubated in 50 mmol/L Tris-HCl (pH 7.2) containing 5 mmol/L MgCl<sub>2</sub>, 125 mmol/L choline chloride, 0.25% BSA and 0.125-32 nmol/L 1-O-[<sup>3</sup>H]octadecyl-2-acetyl-sn-glycero-3-phosphocholine (151 Ci/mmol, 9.96 GBq/mg; Amersham) ± 10 μmol/L unlabeled PAF (Bachem Americas, King of Prussia, PA, USA) at 30 °C for 1 h. The reaction was terminated with the addition of 5 mL ice-cold assay buffer and filtration through Whatman GF/C filters (Whatman, Hillsboro, OR, USA) presoaked in assay buffer for 1 h. Filters were washed thrice with 4 mL of assay buffer, and the radioactivity was determined in a β-scintillation counter.

#### **Determination of hepatic PAF receptor mRNA levels**

The mRNA expression of PAF receptors was determined by semi-quantitative reverse transcriptase polymerase chain reaction (RT-PCR). RNA was isolated from the livers using a RNA isolation kit (ToTALLY RNA™, Ambion, Austin, TX, USA). Two micrograms of total RNA was used for the preparation of cDNA by reverse transcription as described. cDNA equivalent of 5 ng original RNA was used in PCR. The reaction mixture (50 μL) contained 10 mmol/L Tris-HCl (pH 8.3), 50 mmol/L KCl, 1.5 mmol/L MgCl<sub>2</sub>, 0.2 mmol/L dNTPs, 20 pmol of PCR primers and 2U platinum Taq DNA polymerase (GIBCO-Invitrogen, Carlsbad, CA, USA). Thirty-five cycles of reaction were carried out as follows: denaturation at 94 °C for 1 min, annealing at 60 °C for 30 s, and extension at 72 °C for 30 s. The PCR primers used for PAF cDNA were: 5'-GCCACAACAGAGGCTTGA-3'(forward) and 5'-TC CATTGCTCTGGGCAGGAA-3'(reverse) [product size, 121 bp<sup>[21]</sup>]. For normalization, β-actin mRNA levels were measured as described previously<sup>[15]</sup>, using cDNA primers:

**Figure 1** Morphometric analysis of cirrhotic liver 8 wk after CCl<sub>4</sub> or vehicle treatment (A) and scores for necroinflammatory NFS, architectural change, fibrosis and cirrhosis (AFCS) (B). <sup>b</sup>*P*<0.01 vs control.

**Table 1** Characteristics of cirrhosis (mean ± SD)

	Control	Cirrhotic rats	<i>P</i>
Liver/body weight ratio (%)	4.80±0.25	4.90±0.44	NS
Weight of spleen (g)	0.73±0.06	1.36±0.15	0.001

NS: not significant.

5'-TTCTACAATGAGCTGCGTGTG-3' (forward) and 5'-TTCATGGATGCCACAGGATTC-3' (reverse) [product size, 561 bp<sup>[22]</sup>]. The PCR products were resolved in a 25 g/L agarose gel and stained with SYBR Green I (FMC Bioproduct, Rockland, ME, USA). The gels were scanned under blue fluorescent light using a phosphorimager and the band intensity was quantified using ImageQuaNT software (Molecular Dynamics, Sunnyvale, CA, USA).

#### Determination of PAF effect on portal venous and systemic arterial pressure

The experiment was essentially conducted for the measurement of baseline pressure. After a stable recording of portal and systemic mean arterial pressure (MAP) was

**Figure 2** Effect of cirrhosis on circulating PAF levels. Concentrations of PAF in blood from femoral artery, portal and hepatic vein (suprahepatic vena cava) were determined. Values are mean±SD. <sup>a</sup>*P*<0.05 vs control; <sup>b</sup>*P*<0.01 vs control.

obtained, 1 mL of a solution containing PAF (1 µg/kg) was infused over 1 min from a 975 Harvard apparatus compact infusion pump into the portal vein via a 23 gauge needle/PE50 catheter. Portal venous pressure and MAP were monitored continuously for 15 min.

#### Statistical analysis

The values were presented as mean±SD. Student's *t*-test was employed for statistical comparison between the groups. *P*<0.05 was considered statistically significant.

## RESULTS

#### Characteristics of cirrhosis

There were no notable changes in liver histology throughout the 8 wk in control rats (Figure 1A1). In contrast, CCl<sub>4</sub>-treated rats demonstrated extensive changes in liver morphology, including steatosis, inflammation, hepatocyte ballooning, and necrosis. Extensively distorted architecture due to excessive deposition of extracellular matrix was observed, which caused bridging of fibrosis, and infiltration of inflammatory cells in sinusoids and their accumulation around the islands of hepatocytes (Figure 1A3). Hepatic fibrosis was further validated histologically with Masson's trichrome staining (Figures 1A2 and A4).

The liver/body weight ratio was not significantly different between control and cirrhotic rats, whereas spleen weight of cirrhotic rats was nearly doubled (Table 1). MAP was significantly lower in cirrhotic rats (10.9±1.3 kPa) than in control rats (15.2±1.2 kPa). Portal venous pressure was higher in cirrhotic rats (1.63±0.09 kPa) than in control rats (0.71±0.08 kPa), indicating portal hypertension (Table 1).

#### Effect of cirrhosis on hepatic and circulating PAF and hepatic PAF receptor levels

Hepatic PAF concentrations were increased by 44% in cirrhotic rats (Table 1). Concentrations of PAF in the femoral arterial, portal venous, and hepatic arterial blood were significantly greater in cirrhotic rats than in control rats (Figure 2). Moreover, the concentration of PAF was significantly greater in hepatic venous blood than in

**Figure 3** Effect of cirrhosis on hepatic PAF binding. **A:** Results of the saturation binding assay.  $^3\text{H}$ -PAF was incubated with 100  $\mu\text{g}$  membrane protein, in the presence or absence of 10  $\mu\text{mol/L}$  at 30  $^{\circ}\text{C}$  for 1 h; **B:** Scatchard plot analysis of  $^3\text{H}$ -PAF binding to hepatic tissue of cirrhotic and control rats. Values are mean of separate experiments. Cirrhosis:  $R=0.98$ ,  $K_d=8.013$  nmol/L,  $B_{\text{max}}=2.8\pm0.213$  fmol/ $\mu\text{g}$  membrane protein; control:  $R=0.99$ ,  $K_d=5.794$  nmol/L,  $B_{\text{max}}=0.9\pm0.061$  fmol/ $\mu\text{g}$  membrane protein.

portal venous blood in cirrhotic rats (Figure 2). No such difference in hepatic venous and portal venous blood of control rats was observed.

Scatchard analysis of the saturation binding data revealed a 3-fold increase in PAF binding capacity in cirrhotic liver as compared to the control ( $B_{\text{max}}$  of  $2.8\pm0.21$  vs  $0.9\pm0.06$  fmol/ $\mu\text{g}$  protein,  $P<0.01$ ), whereas receptor affinity was unaltered ( $K_d$ :  $8.01\pm1.33$  nmol/L for cirrhotic rats and  $5.79\pm0.96$  nmol/L for control rats,  $P<0.05$ , Figure 3). Consistent with the increased receptor density, a similar increase in the PAF receptor mRNA transcript was observed in the cirrhotic liver as determined by RT-PCR (PAFR/ $\beta$ -actin mRNA ratio of  $0.51\pm0.03$  vs  $0.16\pm0.015$ ,  $P<0.01$ , Figure 4).

#### Effect of PAF on portal and arterial pressure in cirrhotic rats

A separate set of control and cirrhotic rats were used to determine the PAF-induced changes in portal and systemic blood pressure. Infusion of PAF (1 g/kg WT) via the portal vein after a short delay caused a greater increase ( $P<0.01$ ) in portal pressure in cirrhotic rats (from  $1.61\pm0.08$  to  $2.13\pm0.09$  kPa; 33% increase) than in control rats (from  $1.07\pm0.10$  to  $1.30\pm0.09$  kPa; 22% increase) (Figures 5 and 6). Following the initial rise, the portal pressure decreased progressively with time and was lower than the basal value 9 min after the administration

**Figure 4** Effect of cirrhosis on mRNA expression of hepatic PAF receptor. **A:** PCR products of PAF and  $\beta$ -actin from control (CT) and cirrhotic (CR) rat livers; **B:** ratio of the PAF receptor and  $\beta$ -actin mRNA from six samples.  $^aP<0.01$  vs control.

of PAF.

The effect of PAF administered into the portal vein on arterial pressure was opposite to that observed on portal pressure (Figures 5 and 6). In contrast to the delay onset of the rise in portal venous pressure, MAP fell immediately after the administration of PAF. The decrease in MAP ( $P<0.01$ ) was greater in control rats (54%) than in cirrhotic rats (42%). With the fall in MAP, pulse pressure fell markedly and did not recover, suggesting a reduction in cardiac contractility.

#### Effect of PAF antagonist BN52021 on portal and arterial pressure in cirrhotic rats

Administration of BN52021 (5 mg/kg WT) via the portal vein caused a 16% decrease in the portal pressure of cirrhotic rats (from  $1.95\pm0.21$  to  $1.64\pm0.15$  kPa,  $P<0.01$ ). This effect occurred 2 to 3 min after the administration of BN52021. On the other hand, arterial pressure did not change upon treatment with BN52021 (from  $11.0\pm0.8$  to  $11.3\pm0.67$  kPa). In control rats, BN52021 had no effect on either portal or arterial pressure (Figure 7).

## DISCUSSION

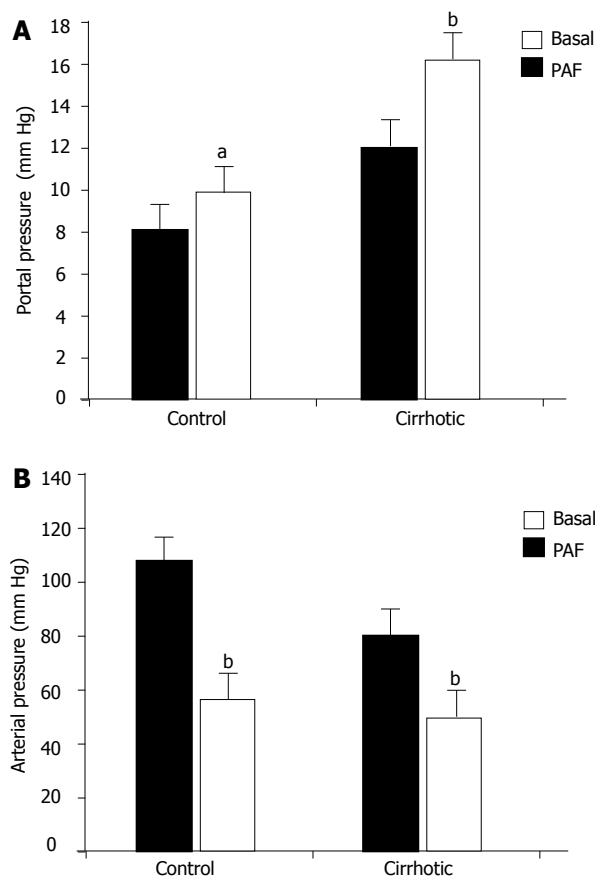

This investigation showed that increased production of PAF in the cirrhotic liver could lead to an increased circulating level of PAF, which is likely responsible for the arterial hypotension associated with the disease. In addition, hepatic PAF receptor mRNA expression was upregulated with a concomitant increase in PAF binding. Since PAF potentially increases portal pressure and hepatic vascular resistance<sup>[6,7,23]</sup>, it can be concluded that the up-regulated PAF system in the liver plays an important role in portal hypertension.

In the present study, the source of the increased hepatic PAF and the site of increased PAF receptors were not

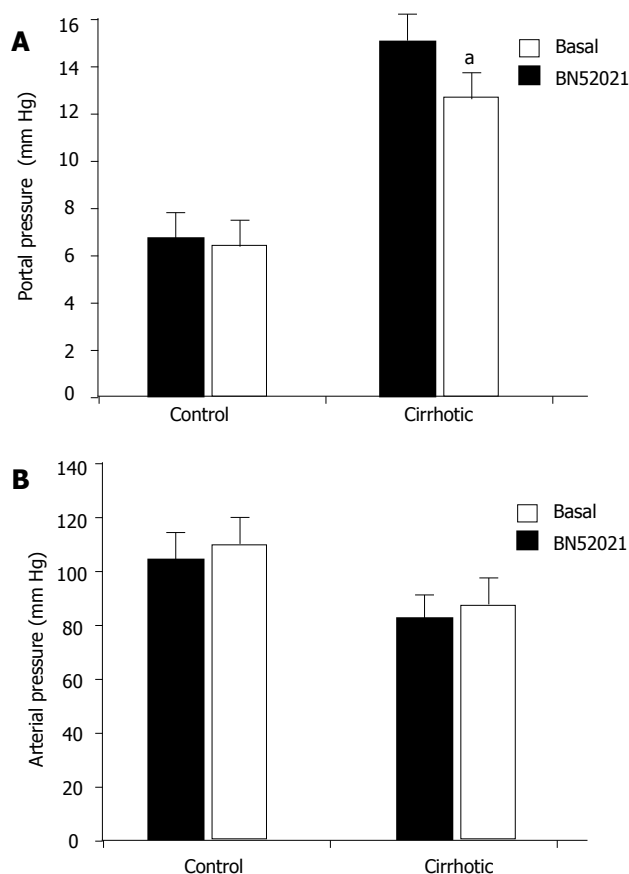

**Figure 5** Tracings of the femoral arterial and portal venous pressure. After stabilization of arterial and portal venous pressure, PAF (1 µg/kg WT) was infused and the pressure was recorded continuously.

**Figure 6** Effect of cirrhosis on PAF-induced changes in arterial and portal pressure. Arterial and portal venous pressure before and after portal administration of PAF were measured. Values are mean±SD of six determinations. <sup>a</sup> $P < 0.05$  vs basal value; <sup>b</sup> $P < 0.01$  vs basal value.

determined. Yang *et al.*<sup>[10]</sup> reported that Kupffer cells are a major source of increased PAF in CCl<sub>4</sub>-induced cirrhotic rat liver. Synthesis of PAF by Kupffer cells is stimulated by a number of inflammatory mediators and bacterial endotoxin (ET)<sup>[2,24,25]</sup>. Increased circulating ET is a strong candidate contributor to the elevation of hepatic portal pressure in cirrhosis<sup>[15,26]</sup>. We have previously reported that hepatic ET-1 and its receptors increase in rats 24 h after the administration of CCl<sub>4</sub><sup>[15]</sup> and progressively thereafter during the development of cirrhosis. In the present study, hepatic PAF did not increase during the first

**Figure 7** Effect of BN52021 on femoral arterial and portal venous pressure of cirrhotic rats 8 wk after vehicle or CCl<sub>4</sub> treatment. Values are mean±SD 5-6 min after introduction of BN52021. <sup>a</sup> $P < 0.05$  vs basal value.

week of CCl<sub>4</sub> treatment ( $2.70 \pm 0.75$  ng/g in control rats and  $2.74 \pm 0.46$  ng/g in CCl<sub>4</sub>-treated rats,  $P > 0.05$ ) but increased after 2 wk of treatment. Since PAF synthesis by Kupffer cells is increased by ET-1<sup>[24]</sup>, the early elevation of ET-1 may contribute to the long-term increase in hepatic PAF. To further investigate the interaction between these two potent mediators during cirrhosis, we infused the powerful vasoconstrictor ET-1 into some experimental animals. After stabilization of the portal and arterial pressures following the administration of PAF, ET-1 (0.75 nmol) was infused as a bolus into the portal vein. The magnitude of ET-1 effect was much greater in control rats (200% increase) than in cirrhotic rats (80% increase,  $P < 0.01$ ). We have previously reported that portal infusion of ET-1 alone causes a 150% increase in portal pressure in control rats and a 23% increase in cirrhotic rats<sup>[15]</sup>, suggesting that with or without prior infusion of PAF, the qualitative responses to ET-1 are similar between control and cirrhotic rats. Quantitatively, prior infusion of PAF appears to sensitize the hepatic vasculature to ET-1 moderately in control rats (200% vs 150%) and greatly in cirrhotic rats (80% vs 23%). The interaction between these two potent mediators during cirrhosis warrants further investigation.

Potentially, PAF could be increased by a decrease in the activity of plasma PAF-acetylhydrolase, which is predominantly responsible for the hydrolysis of PAF to lyso-PAF<sup>[27,28]</sup>. Plasma PAF-acetylhydrolase activity is similar

in normal individuals and patients with alcohol-induced liver cirrhosis<sup>[29]</sup>. Patients with primary and secondary biliary cirrhosis have elevated levels of circulating PAF and serum PAF-acetylhydrolase activity<sup>[30]</sup>, suggesting that synthesis of PAF increased by plasma PAF-acetylhydrolase is the mechanism underlying the elevated circulating levels of PAF.

The augmented effect of PAF on the vasculature of chronically injured liver appears to be independent of the hemodynamic state of the liver (i.e. normotensive or portal hypertensive). The vasoconstrictor effect of PAF in the perfused livers is greater in rats with thioacetamide-induced hepatic fibrosis than in control rats, even though the fibrosis rats have no portal hypertension<sup>[31]</sup>. In the present study, PAF-induced portal hypertension was of greater magnitude in the cirrhotic rats than in the control rats. These results suggest that the increased reactivity to PAF is associated with the pathology of hepatic cirrhosis or injury rather than the pre-existing presence or absence of portal hypertension. That is to say, the response to PAF is not dependent upon the already increased hepatic vascular tone.

The reduction of portal pressure in cirrhotic rats induced by the PAF antagonist BN52021 provides convincing evidence that endogenous PAF is involved in the development of portal hypertension. The mechanisms of PAF-induced hepatic vasoconstriction are very complex and remain to be defined. PAF receptors have been found in smooth muscle cells<sup>[32]</sup>. PAF elevates cytosolic free calcium in smooth cells<sup>[33,34]</sup>, which is necessary for muscle contraction. Exogenous PAF causes contraction of smooth muscle from ileal and peripheral lung strips<sup>[35,36]</sup> and contributes to endothelin-induced vascular constriction in rat mesentery<sup>[37]</sup>. Therefore, the contractile effect of PAF on the hepatic vasculature may be elicited by its direct action on smooth muscle cells. PAF may also act by stimulating the synthesis of eicosanoids such as thromboxane, PGE<sub>2</sub> and PGD<sub>2</sub>, which are known to cause portal vasoconstriction<sup>[38-41]</sup>.

The combination of portal hypertension and peripheral vasodilatation with systemic arterial hypotension is characteristic of liver cirrhosis and implicates PAF. The observation that PAF induces smooth muscle contraction of ileal<sup>[35]</sup> and pulmonary strips<sup>[36]</sup>, and micro-vessels<sup>[37]</sup> is apparently in contradiction with the observation that it induces hypotension when administered intravenously to rats<sup>[42]</sup>. In fact, PAF produces hypotension in all animal species studied<sup>[8]</sup>. Increased plasma levels of PAF in cirrhosis are associated with low peripheral vascular resistance that is reversed by PAF antagonist BN52021<sup>[9,29,43]</sup>. Sakaguchi *et al*<sup>[44]</sup> and Hines *et al*<sup>[6]</sup> reported that intravenous administration of PAF (1.5 µg/kg WT) causes arterial hypotension. The mechanisms of PAF-induced systemic arterial hypotension are not clearly understood. PAF-induced hypotension is not mediated by the central nervous system, renin-angiotensin system, β-adrenergic and dopaminergic eicosanoids, as well as Ca<sup>2+</sup> influx and thyrotropin releasing steroids<sup>[45,46]</sup>. However, PAF-induced delay and persistent hypotension is inhibited by the nitric oxide synthase inhibitor, N<sup>ω</sup>-nitro-L-arginine<sup>[47]</sup> while nitric oxide plays a role in PAF-induced relaxation

of rat thoracic aorta<sup>[48]</sup>. This can be partially explained by the observation that PAF released by the liver may regulate systemic hemodynamics or stimulate the release of very powerful hypotensive agents such as nitric oxide<sup>[47,48]</sup>. The involvement of nitric oxide requires clarification.

In conclusion, PAF is an important mediator of hepatic pathology during chronic liver injury. Cirrhotic liver is a source of circulating PAF and a major contributor to the systemic hypotension associated with liver cirrhosis.

## Abstract

**AIM:** To examine the pathway related to the IL-1 $\beta$ -induced activation of mitogen-activated protein (MAP) kinases in cat esophageal smooth muscle cells.

**METHODS:** Culture of the esophageal smooth muscle cells from cat was prepared. Specific inhibitors were treated before applying the IL-1 $\beta$ . Western blot analysis was performed to detect the expressions of COX, iNOS and MAP kinases.

**RESULTS:** In the primary cultured cells, although IL-1 $\beta$  failed to upregulate the COX and iNOS levels, the levels of the phosphorylated forms of p44/42 MAP kinase and p38 MAP kinase increased in both concentration- and time-dependent manner, of which the level of activation reached a maximum within 3 and 18 h, respectively. The pertussis toxin reduced the level of p44/42 MAP kinase phosphorylation. Tyrphostin 51 and genistein also inhibited this activation. Neomycin decreased the density of the p44/42 MAP kinase band to the basal level. Phosphokinase C (PKC) was found to play a mediating role in the IL-1 $\beta$ -induced p44/42 MAP kinase activity. In contrast, the activation of p38 MAP kinase was inhibited only by a pretreatment with forskolin, and was unaffected by the other compounds.

**CONCLUSION:** Based on these results, IL-1 $\beta$ -induced p44/42 MAP kinase activation is mediated by the Gi protein, tyrosine kinase, phospholipase C (PLC) and PKC. The pathway for p38 MAP kinase phosphorylation is different from that of p44/42 MAP kinase, suggesting that it plays a different role in the cellular response to IL-1 $\beta$ .

## INTRODUCTION

Esophageal reflux is a common condition that affects both children and adults. If left untreated, it can result in chronic esophagitis, aspiration pneumonia, esophageal strictures and Barrett's esophagus, which is a premalignant condition<sup>[1]</sup>. Reflux esophagitis (RE) is a multifactorial disease that may depend on the relaxation of the transient lower esophageal sphincter (LES), the speed of esophageal clearance, the mucosal resistance and other factors, and is often associated with the LES pressure<sup>[2]</sup>. Cytokines exhibit potent chemotactic activity toward different populations of leukocytes, and are essentially involved in the induction of acute and chronic inflammatory reactions<sup>[3,4]</sup>. The selective infiltration of various leukocyte subsets into the esophagus indicates the participation of chemokines in the immune and inflammatory processes of RE.

Interleukin-1 (IL-1) has several biological effects on many cell types, and plays a key role in regulating the inflammatory reaction<sup>[5]</sup>. The IL-1 family is an important part of the innate immune system, which regulates functions of the adaptive immune system. In the presence of excess IL-1, inflammatory and autoimmune diseases can develop in many organs, including the joints, lungs, gastrointestinal track, central nervous system, or blood vessels. Stimulation of the cells by IL-1 initiates the transcription of many pro-inflammatory genes, including IL-6 and IL-8. The levels of the inflammatory genes are higher in the esophageal mucosa of those patients with RE<sup>[6]</sup>. IL-1 has its own identical biological functions and it is induced by gastric ulceration in rats<sup>[7,8]</sup>. Increased mucosal levels of IL-1 are constantly observed during acute and chronic intestinal inflammation in human beings<sup>[9,10]</sup> and animals<sup>[11,12]</sup>. The immunoneutralization of the IL-1 activity has been reported to greatly reduce the severity of colitis in a murine model of the disease,

suggesting that this cytokine plays an important role in initiating inflammation<sup>[12]</sup>. The IL-1 mRNA and protein were strongly expressed in the gastric mucosa of gastritis and ulcer patients<sup>[13,14]</sup>. Therefore, it is suggested that the pro-inflammatory effects of IL-1 are due to the induction of COX-2 gene expression in many tissues, including mucous<sup>[14]</sup>. However, there are few reports about the effect on the smooth muscle.

In mammalian cells, there have been at least three different subfamilies of mitogen-activated protein (MAP) kinases reported. They include the extracellular signal-regulated kinases (ERKs, p44/42 MAP kinase), *c*-Jun N-terminal kinase (JNK), and p38. These kinases are activated by distinct upstream MAP kinases (MEKs), which phosphorylate the residues within a tripeptide motif (Thr-X-Tyr) on the MAP. Once activated, MAP kinases, in turn, phosphorylate a variety of intracellular substrates, including certain transcription factors<sup>[15]</sup>. IL-1 $\beta$  is known to activate all three MAP kinase subfamilies in human airway smooth muscle cells. IL-1 $\beta$  stimulation has been associated with several MAP kinases cascades involved in the transmission of a signal from the cell surface to the nucleus. Although these pathways have not been demonstrated to be involved in the IL-1 $\beta$ -mediated effects on the esophageal smooth muscle, p38 and ERK have been shown to contribute to such effects in human<sup>[16]</sup> or canine airway<sup>[17]</sup> or myometrial<sup>[18]</sup> smooth muscle. Therefore, in this study, we examined the mechanism associated with IL-1 $\beta$ -induced MAP kinases activation in cat esophageal smooth muscle cells.

## MATERIALS AND METHODS

### Materials

Fetal bovine serum (FBS) was purchased from Biofluids (Rockville, MD, USA). Dulbecco's modified Eagle's medium (DMEM), antibiotic-antimycotic (penicillin, streptomycin, amphotericin B), and trypsin-EDTA were obtained from Invitrogen (Grand Island, NY, USA). Phospho-p44/p42 monoclonal MAP kinase antibody, phospho-SAPK/JNK monoclonal antibody, phospho-p38 monoclonal MAP kinase antibody, p44/42 MAP kinase antibody, SAPK/JNK antibody and p38 MAP kinase antibody were acquired from Cell Signaling (Beverly, MA, USA). Goat anti-mouse IgG-HRP was purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). The rainbow prestained molecular weight marker was obtained from Amersham (Arlington Heights, IL, USA). The enhanced chemiluminescence agents were purchased from PerkinElmer Life Sciences (Boston, MA, USA). Sodium dodecyl sulfate (SDS) sample buffer was acquired from Owl Scientific, Inc. (Woburn, MA, USA). Nitrocellulose membrane, Tris/glycine/SDS buffer and Tris/glycine buffer were purchased from BioRad (Richmond, CA, USA). Phosphate-buffered saline (PBS) was acquired from Boehringer Mannheim (Indianapolis, IN, USA). The PD 98059 and SB202190 were obtained from Calbiochem (La Jolla, CA, USA). The GF 109203X was purchased from Tocris (Ellisville, MO, USA). Restore<sup>TM</sup> Western Blot Stripping Buffer was obtained from Pierce (Rockford, IL, USA). Horseradish peroxidase-conjugated goat anti-

rabbit antibody, phorbol-12-myristate-13-acetate (PMA), genistein, tyrphostin 51 and other reagents were purchased from Sigma Chemical Co. (St. Louis, MO, USA).

### Preparation of feline esophageal smooth muscle tissue and cell culture

Adult cats of either gender, weighing between 2.5 and 3.5 kg, were used in this study. The cats were anesthetized with ketamine (50 mg/mL per kg) and the abdomen was then opened with a midline incision. The esophagus and stomach were excised together, cleaned and maintained in Krebs buffer with the following composition (mmol/L): NaCl 116.6, NaHCO<sub>3</sub> 21.9, NaH<sub>2</sub>PO<sub>4</sub> 1.2, KCl 3.4, CaCl<sub>2</sub> 2.5, glucose 5.4 and MgCl<sub>2</sub> 1.2. The esophagus and stomach were opened along the lesser curvature. The location of the squamocolumnar junction was identified and the mucosa was peeled off. The high-pressure zone was identified by a visible thickening of the circular muscle layer in conjunction with the squamocolumnar junction and immediately proximal to the sling fibers of the stomach. It has been shown that a 5- to 8-mm band of tissue coinciding with the thickened area constitutes the LES, and has distinct *in vivo* characteristics in an organ bath or as single cells after enzymatic digestion<sup>[19,20]</sup>.

After opening the esophagus and stomach and identifying the LES, the mucosa and submucosal connective tissues were removed via a sharp dissection. The LES was excised and a 3- to 5-mm wide strip at the junction of the LES and esophagus was discarded in order to avoid potential overlap. The circular muscle layer from the esophagus was cut into 0.5-mm-thick slices using a Stadie Riggs tissue slicer (Tomas Scientific Apparatus, Philadelphia, PA, USA). The last slices containing the myenteric plexus, the longitudinal muscle and the serosa were discarded, and the remaining slices were then cut into 2 mm  $\times$  2 mm tissue squares by hand.

The sliced tissue was then placed into DMEM supplemented with 500 mL/L FBS containing 100 U/mL penicillin, 0.1 mg/mL streptomycin, and 0.25  $\mu$ g/mL amphotericin B and incubated at 37  $^{\circ}$ C in a humidified atmosphere containing 50 mL/L CO<sub>2</sub> and 950 mL/L air. On the following day, fresh DMEM containing 100 mL/L FBS was added. Ten days later, the tissue explants were removed and the medium was exchanged with fresh DMEM containing 100 mL/L FBS. After the cells reached confluence, the cells were detached with 10 g/L trypsin-EDTA in HBSS with sodium bicarbonate. The cells were then counted, seeded at  $1 \times 10^6$  cells/mL on 100-mm culture dishes, and maintained in DMEM containing 100 mL/L FBS. The medium was changed every 48 h until the cells reached confluence. The experiments were performed on the cells of passage 2.

In order to characterize the isolated and cultured esophageal smooth muscle cells as well as to exclude contamination by epithelial cells and fibroblasts, the cells were identified using an indirect immunofluorescent staining method with a monoclonal antibody of a light chain myosin<sup>[21]</sup>. More than 95% of the cell preparation was found to be composed of smooth muscle cells.

### Preparation of cell extracts and Western blot analysis

For the animal esophagitis model, esophageal smooth

**Figure 1** No increase of COX and iNOS expression levels by IL-1 $\beta$ . (A) The cultured cat ESMCs were treated with IL-1 $\beta$  for 18 h at each dose scale. The COX-1 and COX-2 expression levels were not altered by IL-1 $\beta$  at concentrations up to 50 ng/mL. (B) The IL-1 $\beta$  (25 ng/mL) treatment also failed to elevate the level after 24 h. (C) iNOS expression was unaffected by IL-1 $\beta$ .

muscle tissue squares were homogenized in an homogenizing buffer containing 20 mmol/L Tris (hydroxymethyl) aminomethane (Tris), 160 mmol/L HCl (pH 7.5), 0.5 mmol/L EGTA, 0.5 mmol/L EDTA, 10  $\mu$ g/mL leupeptin, 10  $\mu$ g/mL aprotinin, 10 mmol/L  $\beta$ -mercaptoethanol and centrifuged at 14000  $g$  for 15 min at 4°C. The supernatants were used as the whole cell extract.

For the IL-1 $\beta$  treatment experiments, the cells were plated in six-well culture plates and made quiescent at confluence by incubating them in serum-free DMEM for 24 h. The growth-arrested esophageal smooth muscle cells were incubated with or without IL-1 $\beta$  at 37°C at various times. When the inhibitors were used, they were added 1 h before applying the IL-1 $\beta$  according to the inhibitors, with the exception that the cells were pretreated with the pertussis toxin 24 h prior to IL-1 $\beta$ . After incubation, the cells were rapidly washed with ice-cold PBS and lysed for 5 min in an ice-cold lysis buffer containing 25 mmol/L Tris-HCl (pH 7.4), 25 mmol/L NaCl, 25 mmol/L NaF, 25 mmol/L sodium pyrophosphate, 1 mmol/L sodium vanadate, 2.5 mmol/L EDTA, 2.5 mmol/L EGTA, 0.5 g/L Triton X-100, 5 g/L SDS, 0.5 g/L deoxycholate, 0.5 g/L NP-40, 5  $\mu$ g/mL leupeptin, 5  $\mu$ g/mL aprotinin, and 1 mmol/L PMSF. After incubation, the lysates were scrapped and collected by centrifugation at 45000  $g$  for 1 h at 4°C to yield the whole cell extract.

Equal amounts of the protein from each sample were resolved on a SDS-polyacrylamide gel by electrophoresis. Prestained molecular mass markers were also run in an adjacent lane to determine the molecular mass. The separated proteins were transferred to a 0.45- $\mu$ m nitrocellulose membrane in 25 mmol/L Tris (pH 8.3), 192 mmol/L glycine, and 100 mL/L methanol using a power supply (Power Pac 1000, BioRad, Melville, NY, USA). The membranes were incubated in a PBS buffer containing 50 g/L non-fat dry milk for 1 h at room temperature in order to block the nonspecific binding. After washing thrice with PBS, the blots were incubated

with the primary antibodies in a PBS solution containing 1 g/L BSA at 4°C overnight. The membranes were washed using PBS containing 0.5 g/L Tween 20 and then incubated with the horseradish peroxidase-conjugated secondary antibody (1:1000 dilution) for 1 h. The immunoreactive bands were visualized by enhanced chemiluminescence (ECL; Amersham). The total MAP kinase expression level was determined by subsequently stripping the same blot with a stripping buffer and reprobing the blot with p44/42 MAP kinase antibodies. Developed films from ECL were scanned and analyzed densitometrically using Scion Image.

### Protein determination

The protein concentration of the supernatant in each reaction vial was measured spectrophotometrically at a wavelength of 595 nm using a BioRad assay (BioRad Chemical Division, Richmond, CA, USA).

### Statistical analysis

The data were expressed as mean  $\pm$  SE of three separate experiments, and the statistical differences between means were determined by using Student's  $t$  test. A  $P < 0.05$  was considered statistically significant.

## RESULTS

The treatment of the esophageal smooth muscle cells (ESMC) with IL-1 $\beta$  did not increase the COX-2 expression level (Figure 1). In other cell types such as canine tracheal smooth muscle cells<sup>[22]</sup>, human gastric cancer cells<sup>[23]</sup>, and human myometrial smooth muscle cells<sup>[18]</sup>, it has been reported that IL-1 $\beta$  exerts its biological effects partly by inducing COX-2 expression. However, the cells treated with IL-1 $\beta$  at a concentration of 0.5-50 ng/mL for 18 h did not show an increased COX-1 and COX-2 expression levels (Figure 1A). In addition, when treated with 25 ng/mL IL-1 $\beta$  for 15 min to 24 h, the COX expression level in the cat ESMC was not altered (Figure 1B). These results corresponded to previous results showing that an experimentally induced rat esophagitis did not cause an increase in the COX-2 level, suggesting that COX-2 might not mediate esophagitis (unpublished data).

It is also known that IL-1 $\beta$  mediates inflammation, at least in part, by inducing the expression of inducible nitric oxide synthase (iNOS)<sup>[7]</sup>, with the concomitant enhanced synthesis of NO, which is a critical effector molecule, in rat pulmonary artery smooth muscle cells. The cat ESMCs were treated with IL-1 $\beta$  (25 ng/mL) for 18 h and the iNOS level was determined by using Western blotting analysis (Figures 1C and 1D). This treatment did not increase the iNOS expression level, suggesting that iNOS, like COX-2, might not be a mediator of the cellular response to IL-1 $\beta$  in ESMC.

Although there was no change in the COX and iNOS levels, which is similar to other reports, IL-1 $\beta$  activated p44/42 MAP kinase with increasing concentration (Figure 2). After a treatment with 0.5-50 ng/mL IL-1 $\beta$  for 3 h, p44/42 MAP kinase was phosphorylated at concentrations above 10 ng/mL. Densitometric assessments demonstrated that the exposure of ESMCs to 25 ng/mL IL-1 $\beta$  for 3 h significantly increased the level of

**Figure 2** Concentration- and time-dependent activation of MAP kinases after IL-1 $\beta$  treatment. (A) To obtain dose-dependent course of p44/42 MAP kinase and p38 MAP kinase, the cat ESMCs were treated with IL-1 $\beta$  for 3 and 18 h, respectively. The levels of p44/42 MAP kinase and p38 MAP kinase phosphorylation were increased above a dose of 10 ng/mL, which was maintained up to 50 ng/mL. (B) After treatment the cells with IL-1 $\beta$  (25 ng/mL), the level of p44/42 MAP kinase phosphorylation reached a maximum within 3 h with a subsequent decrease to the basal level (upper panel). The phosphorylated forms of p38 MAP kinase were increased within 12 h, which were sustained to 24 h.

activation of p44/42 MAP kinase by  $2.9 \pm 0.1$  times over the level of control samples (Figure 2A). Furthermore, IL-1 $\beta$  (25 ng/mL) produced a time-dependent increase in p44/42 MAP kinase phosphorylation (Figure 2B). The effect of IL-1 $\beta$  on p44/42 MAP kinase was observed within 30 min. The maximum increase ( $2.6 \pm 0.1$ -fold increase over the control) in this response was observed within 3 h, and a gradual decrease to the basal level within 18 h was observed. Based on the concentration-response and time-course data, the ESMCs were exposed to IL-1 $\beta$  at a final concentration of 25 ng/mL for 3 h in later experiments, aiming at identifying the signaling pathway of p44/42 MAP kinase activation. Similarly, p38 MAP kinases were activated by IL-1 $\beta$  in the cat ESMCs. As shown in Figure 2A, an 18-h IL-1 $\beta$  treatment caused phosphorylation of p38 MAP kinase in a concentration-dependent manner. A clear increase ( $1.9 \pm 0.1$ -fold) was observed at concentrations above 10 ng/mL IL-1 $\beta$ . The time course of p38 MAP kinase phosphorylation indicated that the IL-1 $\beta$  increased the activity within 12 h, which was maintained up to 24 h ( $1.5 \pm 0.04$ -fold increase over the control). Therefore, even though IL-1 $\beta$  activated p38 MAP kinase as well as p44/42 MAP kinase, a difference in the activated time of the two MAP kinases was also observed. This suggests that IL-1 $\beta$  can evoke these cellular responses via at least two pathways, involving p38 MAP kinase and p44/42 MAP kinase, in the cat ESMCs.

In order to determine if the effects of IL-1 $\beta$  on p44/42 and p38 MAP kinases were mediated through the activation of a receptor coupled to the pertussis toxin (PTX)-sensitive G protein, the ESMCs were pretreated with 100 ng/mL PTX for 24 h, followed by stimulation with IL-1 $\beta$  for 3 and 18 h, respectively (Figure 3A). Previous studies showed that various types of G proteins, such as Gs, Gq, Go and Gi-1,3, could be detected in the cat ESMCs<sup>[24]</sup>. As shown in Figure 3A, pretreatment of these cells with PTX caused a slight attenuation of p44/42 phosphorylation, indicating that IL-1 $\beta$  exerts its effects through the receptor-coupled Gi protein. However, p38 MAP kinase phosphorylation was maintained without being mediated by the Gi protein. In order to determine the involvement of adenylate cyclase (AC) in the activation

**Figure 3** Relation of Gi protein and tyrosine kinase with activation of p44/42 MAP kinase, and negative regulation of p38 MAP kinase by adenylate cyclase. (A) Pretreatment with the pertussis toxin (100 ng/mL, 24 h) decreased the density of phosphorylated p44/42 MAP kinase only. On the other hand, forskolin (10  $\mu$ mol/L) attenuated p38 MAP kinase phosphorylation by IL-1 $\beta$ . (B) The receptor tyrosine kinase inhibitor, tyrphostin 51 (30  $\mu$ mol/L), markedly reduced the IL-1 $\beta$ -induced phosphorylation of p44/42 MAP kinase. The activation of p38 MAP kinase was unrelated to the tyrosine kinases.

of MAP kinases, the cells were pretreated with forskolin 24 h before IL-1 $\beta$  in order to activate the AC (Figure 2A). AC had little effect on p44/42 MAP kinase activation, but was found to decrease the phosphorylated forms of p38 MAP kinase. Therefore, it is believed that IL-1 $\beta$ -induced p38 MAP kinase activation is negatively regulated by cAMP.

Recently, it has been proposed that IL-1 $\beta$  causes the activation of tyrosine kinase and regulates protein tyrosine phosphorylation<sup>[22]</sup>. There are two classic tyrosine kinases, namely, receptor and nonreceptor tyrosine kinase. The receptor tyrosine kinases are actually the growth factor receptors located in the inner side of the cytoplasmic membrane and undergo dimerization and autophosphorylation upon activation. In this study, we examined the possibility that the observed increase in the level of MAP kinases phosphorylation after an IL-1 $\beta$  treatment might be mediated by tyrosine kinase (Figure 3B). Therefore, the cells were pretreated with genistein for 1 h prior to adding IL-1 $\beta$ . This resulted in a decrease in IL-1 $\beta$ -induced p44/42 MAP kinase activation. In addition, tyrphostin 51, which is a member of the genistein family of tyrosine kinase inhibitors and is specific to the receptor tyrosine kinase, significantly decreased the level of p44/42 MAP kinase phosphorylation, suggesting that tyrosine kinase might participate in these responses to IL-1 $\beta$ .

The involvement of phospholipase in the IL-1 $\beta$ -induced p44/42 MAP kinase activation was examined using a phospholipase C (PLC) inhibitor (neomycin), a PLA<sub>2</sub> inhibitor (DEDA), and a PLD inhibitor ( $\alpha$ CMB). As shown in Figure 4A, pretreatment of the ESMCs with neomycin attenuated the p44/42 MAP kinase activation. DEDA also slightly decreased the band density, but could not reach statistical significance. In addition, pretreatment of the ESMCs with  $\alpha$ CMB did not decrease the level of p44/42 MAP kinase activation induced by IL-1 $\beta$ , suggesting that IL-1 $\beta$ -stimulated p44/42 activation in ESMC might be mediated via the activation of PLC. In this study, we therefore investigated whether or not

**Figure 4** IL-1 $\beta$ -induced activation of p44/42 MAP kinase is mediated by PLC and PKC. (A) Neomycin (10  $\mu$ mol/L, 1 h) decreased the phosphorylated forms of p44/42 MAP kinase. DEDA (10  $\mu$ mol/L, 1 h) and pCMB (10  $\mu$ mol/L, 1 h) had no effect on the IL-1 $\beta$ -induced activation of p44/42 MAP kinase. (B) PKC inhibitors chelerythrine (10  $\mu$ mol/L, 1 h) and GF109203X (10  $\mu$ mol/L, 1 h) decreased the active form of p44/42 MAP kinase. All the phospholipase inhibitors and PKC inhibitors failed to regulate the activation of p38 MAP kinase by IL-1 $\beta$ .

phosphokinase C (PKC) activation enhanced the p44/42 MAP kinase levels. The ESMCs were pretreated with the PKC inhibitor, GF109203X and chelerythrine (Figure 4B), which reduced the level of p44/42 MAP kinase phosphorylation induced by IL-1 $\beta$ . It was assumed that there was no relationship between p38 MAP kinase phosphorylation and the phospholipases (Figure 4A). As the pretreatment with the phospholipase inhibitors had no effect on phospho-p38 MAP kinase band density, the PKC inhibitors did not decrease the level of activation by IL-1 $\beta$  (Figure 4B). Overall, IL-1 $\beta$  might activate p38 MAP kinase in cat ESMCs via a pathway other than the phospholipase- and PKC-associated pathway.

The relationship between the activation of the two MAP kinases was identified after treating the ESMCs with either 10  $\mu$ mol/L PD98059 (a synthetic inhibitor of MEK1/2 activation) or 30  $\mu$ mol/L SB202190 (a p38 MAP kinase inhibitor) for 1 h (Figure 5A). PD98059 resulted in inhibition of the IL-1 $\beta$ -induced p44/42 MAP kinase activation. However, SB202190 had little effect, indicating that p44/42 MAP kinase activation in ESMCs was mediated by the upstream kinase MEK, which was not affected by p38 MAP kinase. SB202190 markedly decreased the level of p38 MAP kinase phosphorylation to almost the basal control level, whereas PD98059 had little effects on this activation. This means that the IL-1 $\beta$ -induced p38 MAP kinase and p44/42 MAP kinase activation might be accomplished by independent pathways.

Although IL-1 $\beta$  did not enhance the COX-2 and iNOS expression levels, the participation of COX and NOS in the activation of p44/42 MAP kinase by IL-1 $\beta$  is still unclear. Therefore, the cells were treated with a COX inhibitor, indomethacin, and a NOS inhibitor, L-NAME, for 1 h before IL-1 $\beta$  stimulation in order to determine whether COX and NOS play a role in the activation (Figure 5B). The increase in the phosphorylated forms of MAP kinases was maintained even with the pretreatment of inhibitors. This suggested that COX and NOS played no role in IL-1 $\beta$ -induced MAP kinases activation.

**Figure 5** MAP kinase activation by IL-1 $\beta$  was not affected by other kind of MAP kinase, COX and iNOS. (A) MEK inhibitor PD98059 (10  $\mu$ mol/L, 1 h) reduced the level of p44/42 MAP kinase phosphorylation by IL-1 $\beta$ . SB202190 (30  $\mu$ mol/L, 1 h), p38 MAP kinase inhibitor, had no effect on the p44/42 MAPK phosphorylation, which blocked p38 MAP kinase activation. (B) Indomethacin (10  $\mu$ mol/L) and L-NAME (10  $\mu$ mol/L) had no effect on the activations of p44/42 MAP kinase and p38 MAP kinase by IL-1 $\beta$ .

## DISCUSSION

It is evident that the proinflammatory cytokines and chemokines play an important role in the pathogenesis of various inflammatory conditions<sup>[3,4,25]</sup>. Recently, it was reported that there was a significantly higher expression level of IL-8 mRNA in biopsy specimens obtained from RE patients than that from non-inflamed samples, which was determined by competitive reverse transcriptase polymerase chain reaction<sup>[26]</sup>. Furthermore, in addition to IL-8, the MCP-1 and RANTES levels were also significantly higher in esophagitis patients. In that report, although there were no significant differences in the mucosal IL-1 $\beta$  levels between the RE samples and the control group, the tissue IL-1 $\beta$  levels correlated significantly with the level of IL-8 production<sup>[6]</sup>. Cytokines, such as IL-1 $\beta$  and TNF- $\alpha$ , act locally and systemically to recruit and activate the target cells that can produce additional cytokines. IL-1 induces the gene expression of neutrophils and monocyte chemotactic cytokines, such as IL-8, IL-9, and macrophage inflammatory proteins that in turn stimulate migration and degranulation of neutrophils *in vivo*<sup>[27]</sup>. The surgically induced esophagitis rats resulted in an approximately two-fold increase in the level of TNF- $\alpha$  and IL-1 $\beta$  production<sup>[28]</sup>.

Previous studies demonstrated that COX-2 and iNOS were the effectors of the IL-1 $\beta$ -induced cellular responses, products of which were PGE2 and NO, respectively. In our previous study, although iNOS expression and nitrite levels in the tissue were higher after inducing esophagitis in rats (unpublished data), the COX-2 level was unaffected by each IL-1 $\beta$  concentration ranged from 0.5 to 50 ng/mL. In addition, the IL-1 $\beta$  treatment by 24 h failed to increase the iNOS concentration in the cultured cat ESMCs. Therefore, IL-1 $\beta$  did not play a direct role in the inflammatory process in the esophagus, suggesting that IL-1 $\beta$  might be related to the induction of other cytokines, which would be an immediate cause of the inflammatory cellular response, such as COX-2 and iNOS, in cat ESMC.

IL-1 $\beta$  plays its own role in the cellular signaling components in the cat ESMC. The MAP kinase pathway has been suggested to be a mechanism by which various signals are transduced from the cell surface to the nucleus in response to a variety of different stimuli. These proteins participate in several intracellular processes by further inducing the level of phosphorylation of various intracellular substrates, such as other protein kinases and transcription factors. This signaling mechanism is believed to control a wide spectrum of cellular physiological and pathophysiological processes including cell growth, differentiation, and the stress response<sup>[29]</sup>. The treatment of the ESMC with >10 ng/mL IL-1 $\beta$  resulted in the activation of p44/42 MAP kinase, which was generated by 30 min and reached a maximum within 3 h, with a subsequent decrease. A similar pattern was observed with p38 phosphorylation, which was also concentration-dependent above 10 ng/mL. This increase was observed after 12 h, suggesting that p44/42 MAP kinase might participate in the early phase response to IL-1 $\beta$ , and p38 MAP kinase might be a mediator of the late phase IL-1 $\beta$  effects.

In order to determine whether IL-1 $\beta$  interacts with the G proteins, the requirement of the G protein was evaluated using ESMC pretreated with the pertussis toxin (PTX). PTX has been shown to inhibit the intrinsic GTPase activity of the G $\alpha$  subunit by the ADP-ribosylation of specific residues. A previous report demonstrated that Gq, G11, Gi1, Gi2, and Gi3 were present in the esophagus and LES<sup>[24]</sup>. In this study, the IL-1 $\beta$ -induced activation of p44/42 MAP kinase was affected by the PTX pretreatment, suggesting the involvement of a PTX-sensitive G protein in these processes. However, PTX had little effect on the IL-1 $\beta$ -induced activation of p38 MAP kinase. This inhibitory effect of the toxin might result from the increases in the cyclic AMP (cAMP) level via the abrogation of the Gi protein in ESMC. A previous report demonstrated that IL-1 $\beta$  activated AC in vascular smooth muscle via COX-2<sup>[30]</sup>. Therefore, a cAMP elevating agent, forskolin, was used to activate adenylate cyclase in order to evaluate its role in IL-1 $\beta$ -induced responses. Forskolin failed to attenuate the IL-1 $\beta$ -induced p44/42 MAP kinase activation, excluding the involvement of elevated cAMP. In contrast, the cAMP concentration affected the level of p38 MAP kinase phosphorylation, suggesting that the delayed activation of p38 MAP kinase is due to the elevation of cAMP by IL-1 $\beta$ .

It is well known that IL-1 $\beta$  triggers the activation of PI-PLC and PC-PLC in U937 cells and tracheal smooth muscle cells to generate DAG and IP<sub>3</sub><sup>[31,32]</sup>. DAG and IP<sub>3</sub> activate PKC and release Ca<sup>2+</sup> from the intracellular stores, respectively, and may play an important role in regulating the cellular functions in several cell types<sup>[33]</sup>. PKC is a major component in the kinase cascade that is initiated by ligand attachment to both the G protein-coupled receptors and the receptors possessing intrinsic tyrosine kinase activity. Different PKC isozymes appeared to mediate the LES tone as well as the phasic contraction of the ESMC<sup>[34]</sup>. In order to confirm the participation of phospholipase in the IL-1 $\beta$ -induced activation of MAP kinases, the cells were pretreated with inhibitors of each phospholipase.

Neomycin markedly decreased the activity of p44/42 MAP kinase, but failed to reduce the activity of p38 MAP kinase. Therefore, p44/42 MAP kinase and p38 MAP kinase are on a different IL-1 $\beta$  signaling pathway at least downstream from the receptors. The regulatory mechanisms involved in IL-1 $\beta$ -induced MAP kinase activation by PKC were further investigated. These results showed that pretreatment with the PKC inhibitors attenuated the IL-1 $\beta$ -induced p44/42 MAP kinase activation in the ESMC. These results were consistent with those showing that cytokine activated the PLC-coupling signaling pathways in the human histiocytic lymphoma cell line, U937<sup>[31]</sup>. Despite the relationship between p44/42 MAP kinase activation by IL-1 $\beta$  and PKC, the PKC inhibitors did not exert any inhibitory effects on p38 MAP kinase activation.

The implication of a tyrosine kinase in the activation MAP kinases by IL-1 $\beta$  was investigated using tyrosine kinase inhibitors, genistein and tyrphostin 51. Genistein and tyrphostin 51 inhibited p44/42 MAP kinase phosphorylation, indicating the involvement of tyrosine kinase in this response. In contrast, these inhibitors did not block the phosphorylation of p38 MAP kinase by IL-1 $\beta$ .

The activation of p44/42 MAP kinase requires both tyrosine and threonine phosphorylation as a result of the dual specificity MEK1/2. PD98059, a synthetic and highly specific MEK1/2 inhibitor, has been shown to inhibit p44/42 MAP kinase activation by several stimuli<sup>[35]</sup>. In this study, a PD98059 pretreatment attenuated the p44/42 MAP kinase activation, leaving p38 MAP kinase phosphorylated. In addition, IL-1 $\beta$  has been shown to phosphorylate p38 MAP kinase, which appears to be distinct from p44/42 MAP kinase in several cell types<sup>[36,37]</sup>. SB202190 inhibited the IL-1 $\beta$ -induced p38 MAP kinase activation, but did not show any inhibitory effect on p44/42 MAP kinase activation. Overall, the activation of p44/42 MAP kinase and p38 MAP kinase appears to involve independent pathways.

The absence of a role of COX and iNOS in these pathways was confirmed by their respective inhibitors, indomethacin and L-NAME. Indomethacin plays a role in preventing COX-2 from producing prostaglandin, and L-NAME blocks NO synthesis by NOS. The IL-1 $\beta$ -induced activity of p44/42 MAP kinase and p38 MAP kinase remained unchanged even after the indomethacin and L-NAME treatment, thereby excluding the role of prostaglandin and NO in this responses.

In conclusion, IL-1 $\beta$ , which is believed to act as a pro-inflammatory mediator by evoking other cytokines in the esophagitis, can induce p44/42 MAP kinase and p38 MAP kinase activation. The pathway related to p44/42 MAP kinase is composed of a PTX-sensitive G protein, tyrosine kinase, PLC and PKC. These components are believed to play a role in the early cellular responses via IL-1 $\beta$ -induced p44/42 activation, but have little effect on p38 MAP kinase phosphorylation, which is generated later and is regulated negatively by cAMP.

## Abstract

**AIM:** The GFAP was traditionally considered to be a biomarker for neural glia (mainly astrocytes and non-myelinating Schwann cells). Genetically, a 2.2-kb human GFAP promoter has been successfully used to target astrocytes *in vitro* and *in vivo*. More recently, GFAP was also established as one of the several makers for identifying hepatic stellate cells (HSC). In this project, possible application of the same 2.2-kb human GFAP promoter for targeting HSC was investigated.

**METHODS:** The GFAP-*lacZ* transgene was transfected into various cell lines (HSC, hepatocyte, and other non-HSC cell types). The transgene expression specificity was determined by X-gal staining of the  $\beta$ -galactosidase activity. And the responsiveness of the transgene was tested with a typical pro-fibrotic cytokine TGF- $\beta$ 1. The expression of endogenous GFAP gene was assessed by real-time RT-PCR, providing a reference for the transgene expression.

**RESULTS:** The results demonstrated for the first time that the 2.2 kb hGFAP promoter was not only capable of directing HSC-specific expression, but also responding to a known pro-fibrogenic cytokine TGF- $\beta$ 1 by upregulation in a dose- and time-dependent manner, similar to the endogenous GFAP.

**CONCLUSION:** In conclusion, these findings suggested novel utilities for using the GFAP promoter to specifically manipulate HSC for therapeutic purpose.

## INTRODUCTION

Hepatic stellate cell (HSC, also known as Ito cell) is a minor cell type (roughly 5-8% of the total liver cells) most commonly found in the sinusoidal area of adult livers. The major physiological functions of HSC include fat storage, vitamin A uptake and metabolism, and the production of extracellular matrix (ECM) proteins. It has been demonstrated in the past decade that HSC is a major player in mounting defense during hepatic injury, and mediating hepatic fibrogenesis by over-producing pro-fibrotic cytokines and consequently the ECM molecules. Hence the HSC itself also became a target for the development of anti-fibrotic therapy<sup>[1-3]</sup>.

Traditionally antibodies against desmin<sup>[4]</sup>, vimentin and smooth muscle- $\alpha$ -actin (SMAA)<sup>[5,6]</sup>, despite their poor tissue and cell specificity, remained the common battery for identifying rat HSC both *in vitro* and *in vivo*, until the re-introduction of GFAP in the mid-1990s<sup>[7-9]</sup>, even though GFAP was first documented as a marker for rat HSC in 1985<sup>[10]</sup>. It was suggested that the GFAP could be a more reliable marker for marking quiescent HSCs<sup>[7]</sup>. More recently, the GFAP was also adopted as a marker for human HSCs<sup>[11-13]</sup>.

Several gene promoters have been investigated for their ability to genetically manipulate HSC both *in vitro* and *in vivo*, which include the human collagen alpha 1 (Col1)<sup>[14-16]</sup>, SMAA<sup>[17]</sup>, LIM domain protein CRP2 (CSRP2), tissue inhibitor of metalloproteinases-1 (TIMP-1) and smooth muscle-specific 22-ku protein (SM22  $\alpha$ )<sup>[18,19]</sup>. However, none of the promoters tested thus far showed sufficient tissue and cell specificity.

In our own efforts, we constructed a transgene consisting of a 2.2-kb hGFAP promoter<sup>[20,21]</sup> and the *E. coli lacZ* coding sequence and tested its expression in a rat HSC line HSC-T6<sup>[22]</sup>. Our results showed that the 2.2-kb hGFAP promoter was not only capable of directing HSC-specific expression *in vitro*, but also responding to a known pro-fibrogenic cytokine transforming growth factor (TGF- $\beta$ 1) by upregulation in a dose- and time-dependent

**Figure 1** GFAP-*lacZ* transgene construct. The bacterial *lacZ* reporter coding sequence was under the control of a 2.2-kb human GFAP promoter. The SV40-Zeo (R) gene provides a resistance to antibiotic selection for stable clones. Primer locations for PCR and RT-PCR were also indicated.

manner. Similarly, an induction of the endogenous GFAP by TGF- $\beta$ 1 was also observed. These findings suggested novel utilities for the 2.2 kb hGFAP promoter for specifically manipulating HSC, and developing anti-fibrotic therapy. Furthermore, these findings raised fundamental questions on possible GFAP function in the HSC development and pathobiology.

## MATERIALS AND METHODS

### Construction of the 2.2 kb hGFAP-*lacZ* transgene

The plasmid vector pcDNA4/TO/LacZ (Invitrogen, CA, USA) was used as a cloning backbone, providing the *E. coli*  $\beta$ -galactosidase coding sequence and the Zeocin resistance gene. The 2.2-kb hGFAP promoter, which was originally mapped for its astrocytic specificity<sup>[20,21]</sup>, was excised from another transgene GFAP-GFP-S65T<sup>[23]</sup> by *Bgl*II/*Hind*III digest and used to replace the CMVtetO2 promoter in the pcDNA4/TO/LacZ vector. The cloning junction sequences were verified by DNA sequencing. The resultant 9.5 kb plasmid (as depicted in Figure 1) was designated as pcDNA4/GFAP2.2-LacZ in our vector depository.

### Cell line and culture conditions

The rat HSC-T6 cell line<sup>[22]</sup> was a generous gift from Dr Scott Friedman of the Mount Sinai School of Medicine in New York through Dr Alex Hui (Chinese University of Hong Kong). The HepG2, C3A, HeLa and NIH/3T3 were from American Type Culture Collection (ATCC, VA, USA), and the C6 was from Japanese Collection of Research Bioresources (JCRB, Osaka, Japan). All the cell culture media and reagents were from Invitrogen, unless specified otherwise. All cell lines were routinely cultured in full Dulbecco's modified Eagle medium (DMEM), supplemented with 10% FBS, 100 units penicillin/100  $\mu$ g streptomycin per mL at 37°C in a humidified atmosphere of 50 mL/L CO<sub>2</sub>. The cells were routinely split twice weekly in a ratio of 1:3.

### Cell transfection and selection

The T6, C6, and HeLa cells were stably transfected with

0.5-1.0  $\mu$ g of the SalI-linearized transgene plasmid using the Lipofectamine 2000 kit, according to the manufacturer's instructions (Invitrogen). Twenty-four hours after the transfection, the medium was changed and supplemented with 250-500  $\mu$ g/mL Zeocin for selection for at least 6 wk before further analyses (as described below) were performed. The final concentration for maintaining the stable transfected cells was 500  $\mu$ g/mL Zeocin. Alternatively, HepG2, C3A, and NIH/3T3 were transiently transfected with the circular transgene plasmid using the FuGene 6 kit (Roche Diagnostics).

### Genomic detection of the transgene

In order to confirm the transgene integrity and its integration into the genome, genomic DNA was isolated from cell clones stable for at least 2 mo under 500  $\mu$ g/mL Zeocin selection, using the NucleoSpin blood kit (Macherey-Nagel, Düren, Germany). A PCR method was used to verify the structural integrity of the inserted construct(s), with a forward primer 5'-ACTCCTTCATAAAGCCCTCG-3' (complementary to the GFAP promoter), and a reverse primer 5'-AACTCGCCGCACATCTGAACCTCAGC-3' (complementary to the *lacZ* coding sequence), using the Platinum PCR SuperMix High Fidelity (Invitrogen) on a thermal cycler (MJ Research, FL, USA). The expected PCR product was 944 bp in size.

### RT-PCR GFAP-*lacZ* transcript

Total cellular RNAs were extracted from cells grown in 6-well plates by using the NucleoSpin RNAII kit (Macherey-Nagel) following the manufacturer's instructions. The RNA concentration was determined on a ND-100 spectrophotometer (Nanodrop Technologies, DE, USA). Fifty nanograms of total RNA was used to perform a one-step RT-PCR (Qiagen, Hilden, Germany) according to the user's manual, using forward primer (5'-TCAGCTTG GAGTTGATCCCGTCG-3') and reverse primer (5'-AAC AACGGCGGATTGACCGTAATGG-3'). The thermal cycling profiles were 50°C 30 min (cDNA synthesis), 95°C 15 min (denaturation), and followed by 94°C 10 s 55°C 10 s, and 72°C 19 s for 35 cycles (PCR). The target product size was 337 bp, and the  $\beta$ -actin reference was 332 bp in size.

### X-gal staining of $\beta$ -galactosidase activity in fixed cells

A *lacZ* reporter cell staining kit (InvivoGen, CA, USA) was used to detect the reporter gene activity in both stable and transient transfectants. Development of the blue end product was monitored at different time intervals (15, 30, 60, 90, and 120 min). The staining results were documented with a digital camera (DP12) attached to an Olympus inverted bright field microscope (IX51).

### Quantitative solution assay of $\beta$ -galactosidase activity in cell extracts

To quantify the  $\beta$ -galactosidase activity in cell extracts, an enzyme assay kit (E2000, Promega, WI, USA) was used to measure the specific activity of  $\beta$ -galactosidase, according to the manufacturer's instructions in a 96-well format. Briefly, the cells were washed twice with 1×PBS buffer (pH 7.4), lysed for 15 min at room temperature with the reporter lysis buffer, and harvested using a cell scraper. The total cell extracts were appropriately diluted

**Figure 2** Transient transfection with CMV-*lacZ* and GFAP-*lacZ* transgenes. Hepatocyte cell lines C3A (A), HepG2 (B), and fibroblast cell line NIH/3T3 (C) transfected with the ubiquitous CMV-*lacZ* transgene displayed blue color after 2 h of X-gal staining. In contrast, C3A (D), HepG2 (E) and NIH/3T3 (F) transfected with the GFAP-*lacZ* transgene did not show any blue color. Scale bar=60  $\mu$ m.

(5-10 folds), and assayed for the enzyme activity. The specific  $\beta$ -galactosidase activity was presented in milliunit per milliliter (mU/mL) using a standard curve established from the  $\beta$ -galactosidase standard (provided with the kit). The protein concentration was measured with a BCA protein assay kit (Pierce, IL, USA), and used to further convert the specific  $\beta$ -galactosidase activity from mU/mL to mU/ $\mu$ g total cellular protein. Final data were summed from six independent experiments.

#### Treatment of cells with TGF- $\beta$ 1

Cells were seeded into 12-well plates in full DMEM with 500  $\mu$ g/mL Zeocin. Twelve hours prior to the cytokine treatment, medium was changed so that the cells were allowed to grow in low serum (0.5% FBS) DMEM. The cells at a confluence of 70-80% were incubated with various concentrations (0, 0.1, 1, and 10 ng/mL) of rhTGF- $\beta$ 1 (BioVision, CA, USA) for 0, 2, 8, 16, 24, 48, and 72 h before they were harvested for  $\beta$ -galactosidase activity assay and real-time RT-PCR GFAP assay.

#### Real-time RT-PCR quantification of rat GFAP mRNA

Total RNA was reversely transcribed to cDNA using Taqman's reverse transcription reagent (Cat. # N808-0234). A total of 400 ng of RNA in 7.7  $\mu$ L nuclease-free water was added to 2  $\mu$ L 10 $\times$  reverse transcriptase buffer, 4.4  $\mu$ L 25 mmol/L magnesium chloride, 4  $\mu$ L deoxyNTP mixtures, 1  $\mu$ L random hexamers, 0.4  $\mu$ L RNase inhibitor

and 0.5  $\mu$ L reverse transcriptase (50 U/ $\mu$ L) in a final reaction volume of 20  $\mu$ L. The reaction was performed for 10 min at 25 $^{\circ}$ C (annealing), 30 min at 48 $^{\circ}$ C (cDNA synthesis) and 5 min at 95 $^{\circ}$ C (enzyme denaturation).

Real-time quantitative PCR was carried out with an ABI 7500 Real Time PCR System (Applied Biosystems, CA, USA). One microliter of sample cDNA was used in each PCR reaction, with the actin gene as a reference. The primers and probes for rat  $\beta$ -actin and GFAP were purchased from Taqman's assay-on-demand database. The PCR reaction was performed under a default profile consisting of 50 $^{\circ}$ C for 2 min (UNG activation), 95 $^{\circ}$ C for 10 min (enzyme denaturation) and 40 cycles of amplification (denaturation 15 s, annealing and extension 60 s).

Relative quantitation of the target mRNA was calculated using the comparative threshold cycle ( $C_T$ ) methods as described in the User Bulletin #2 (ABI Prism 7700 Sequence Detection System).  $C_T$  indicates the fractional cycle number at which the amount of amplified target reaches a fixed threshold within the linear phase of gene amplification.  $\Delta C_T$ , which reflects the difference between  $C_{T \text{ target}}$  and  $C_{T \beta\text{-actin}}$ , is inversely correlated to the abundance of mRNA transcripts in the samples.  $\Delta C_T$  for each sample was normalized against control experiment or calibrator and expressed as  $\Delta\Delta C_T$ . Relative quantitation is given by  $2^{-\Delta\Delta C_T}$  to express the upregulation or downregulation of the target gene under the treatments compared to the control.

Six independent experiments were performed for each data point and three  $\Delta C_T$  were measured for each experiment.

#### Statistical analysis

All quantitative results were presented as mean  $\pm$  SE. Experimental data were analyzed using two-tailed Student's *t*-test assuming unequal variances. A *P*-value < 0.05 was considered significant.

## RESULTS

#### Lack of GFAP-*lacZ* expression in non-GFAP-expressing cell lines

To investigate if there is any possible aberrant expression of the transgene, three non-GFAP expressing cell lines, HepG2, C3A and NIH/3T3, were transiently transfected with the circular transgene plasmid, using a CMV-*lacZ* plasmid as a positive control. After the transfected cells were grown in full DMEM medium free of selection agent for 2 days, all three cell lines were examined for the  $\beta$ -galactosidase expression by X-gal staining method. Approximately 10-30% of the cells in each of the three lines transfected with the ubiquitous CMV-*lacZ* showed positive blue color after 2 h of staining. In contrast, none of the three lines transfected with the GFAP-*lacZ* showed any blue staining, indicating a total lack of *lacZ* expression driven by the GFAP promoter in these cell lines. Representative images from two independent experiments for all three cell lines are shown in Figure 2. After 24 h of X-gal staining, a few cells from the HepG2 line displayed blue color in both the transfected and

**Figure 3** Verification of GFAP-*lacZ* transgene integration into host genome and legitimate expression in appropriate cell types. **A:** PCR of genomic DNA isolated from the transfected T6 (lane 3), C6 (lane 5) and HeLa (lane 7) showed the presence of a transgene band at 944 bp, and the absence of such band from the nontransfected T6 (lane 2), C6 (lane 4), and HeLa (lane 6); **B:** RT-PCR of total RNAs demonstrated that transgene only expressed in the transfected T6 (lane 3) and C6 (lane 5), but not in the transfected HeLa (lane 7); **C:** RT-PCR of  $\beta$ -actin as a reference ensuring equal sample loading. Lane 1 is the 1-kb ladder marker.

**Figure 4** X-gal staining of stable transfectants. The GFAP-*lacZ* transgene expressed in the rat hepatic stellate cell line T6 (**A**), and the positive control rat astrocytic cell line C6 (**B**), but not in the non-GFAP-expressing cell line HeLa (**C**). Scale bar=60  $\mu$ m.

nontransfected groups alike (data not shown), most likely due to endogenous galactosidase-like activity.

#### Specific expression of GFAP-*lacZ* in GFAP-expressing cell line T6

The 2.2-kb hGFAP promoter has been consistently shown to direct gene expression specifically in the neural stellate cells-astrocytes<sup>[20,21,24]</sup>. It was completely unknown whether a GFAP promoter can direct gene expression specifically in the HSC type. Since stellate cells of both neural and hepatic origins have been reported to share many morphological, immunocytochemical and even developmental features<sup>[7-9,25]</sup>, we decided to test this possibility by stably transfecting a rat HSC line T6<sup>[22]</sup> with the GFAP-*lacZ* transgene, using the rat astrocytic C6 cell line as a positive and the human HeLa cell line as a negative control. After selection in 250-500 mg/mL Zeocin for at least 6 wk, several independent stable cell clones were obtained for each cell line. Subsequently, PCR analysis of genomic DNA isolated from the stable clones confirmed the transgene integrity and integration into the host genome, as evidenced by the presence of an anticipated product size of 944 bp (Figure 3A). To check for transgene expression, total RNA was isolated from the stable transfectants and RT-PCR was performed to

verify for the *lacZ* transcript. The presence of a specific band with a predicted size of 337 bp indicated the *lacZ* transcription in the positive control C6 line, and more importantly in our target T6 line as well, but not in the negative control line HeLa (Figure 3B). The  $\beta$ -actin sample is shown in Figure 3C as a control for equal RNA loading. Next, one clone from each of the three cell lines was randomly chosen for X-gal staining for 1 h. As expected, both the C6 and the T6 were positive and the HeLa was negative in blue staining (Figure 4). Therefore for the first time, a GFAP-based reporter gene was shown to specifically express in a HSC line. The representative staining results are shown in Figure 4. From this point onward, a T6 cell clone stably transfected with the 2.2 kb hGFAP-*lacZ* transgene (designated as T6/*lacZ*/C1 clone) was used for further experiments below. It was worth noting that the T6 cells transiently transfected with the GFAP-*lacZ* transgene stained positive for X-gal reaction as well.

#### Time- and dose-dependent induction of transgene by TGF- $\beta$ 1 in T6/*lacZ*/C1 cells

TGF- $\beta$ 1 has been reported to exert broad biological effects on the cells, including the regulation of GFAP in astrocytes<sup>[26-29]</sup>, and the fibrogenesis in the

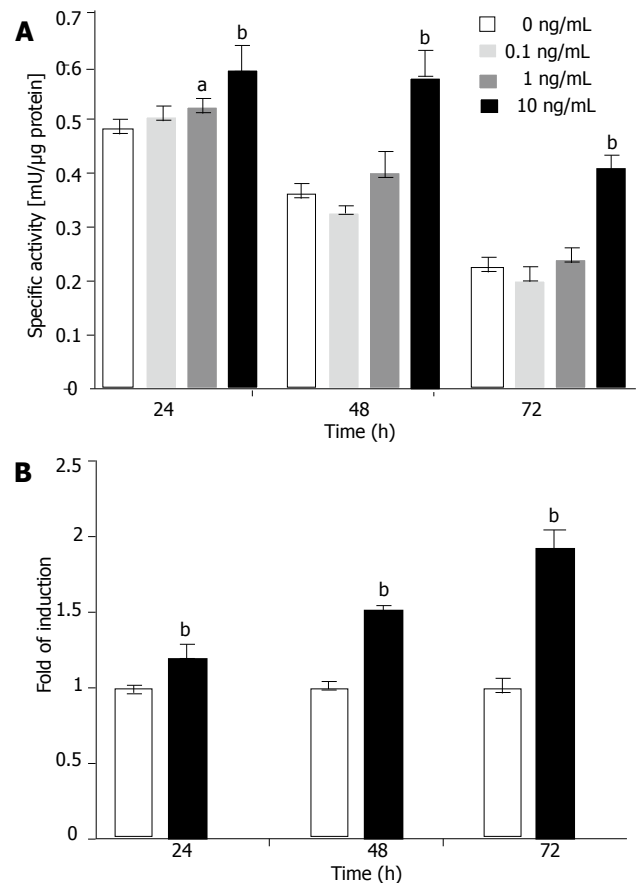

**Figure 5** Induction of GFAP-*lacZ* transgene expression by TGF- $\beta$ 1. The T6/*lacZ*/C1 cells were cultured and incubated in full DMEM supplemented with 0 (A), 0.1 (B), 1 (C), and 10 (D) ng/mL of TGF- $\beta$ 1 for 3 days, and stained with X-gal substrate for 1 h. Cells treated TGF- $\beta$ 1 displayed more intense blue staining and more activated morphology (thickened processes). Scale bar = 60  $\mu$ m.

**Figure 6** Time-dependent induction of GFAP-*lacZ* gene by TGF- $\beta$ 1 in the T6/*lacZ*/C1 cells. Cells were grown in full DMEM was assayed for basal  $\beta$ -galactosidase activity (control). Cells adopted in low serum DMEM for 12 h were supplemented with 1 ng/mL of TGF- $\beta$ 1 for various times (0, 2, 8, 24, 48, and 72 h), and assayed for enzymatic activity. When compared to the basal level, cells cultured in low serum DMEM had elevated level of transgene expression ( $^bP < 0.001$ ). When compared the 0 h, transgene expression level was significantly induced at 2 h ( $^aP < 0.05$ ), 8 h ( $^cP < 0.005$ ), and 24 h ( $^dP < 0.001$ ), but significantly reduced at 72 h ( $^fP < 0.001$ ) compared with 0 h. Data presented as mean  $\pm$  SE.

HSC<sup>[30-33]</sup>. However, very little was known about the potential regulation of GFAP (and GFAP-based transgene) by the potent pro-fibrogenic TGF- $\beta$ 1 in HSC. To obtain a first hint, the T6/*lacZ*/C1 cells were treated with TGF- $\beta$ 1 at various concentrations (0, 0.1, 1, and 10 ng/mL) in the full DMEM medium for 72 h. The cells were then stained with X-gal for one hour and photographed. When compared to the untreated cells, cells cultured with TGF- $\beta$ 1 displayed a more intense blue staining and activated morphology (thickened cellular processes), as shown in Figure 5.

To examine time-dependent induction, the T6/*lacZ*/C1 cells stimulated with 1 ng/mL of TGF- $\beta$ 1 for

**Figure 7** Dose-dependent induction of transgene. (A) The T6/*lacZ*/C1 cells cultured in low serum DMEM supplemented with different concentrations of TGF- $\beta$ 1 (0, 0.1, 1, and 10 ng/mL) for various times (24, 48, and 72 h) were assayed for  $\beta$ -galactosidase activity. The transgene was significantly induced by 10 ng/mL of TGF- $\beta$ 1 at all time points. (B) Data extracted from (A) illustrated that the fold of induction increased with times, despite the drop in absolute enzymatic activity. Data presented as mean  $\pm$  SE.  $^aP < 0.05$ ,  $^bP < 0.001$  compared with no cytokine treatment.

various times (0, 2, 8, 24, 48, and 72 h) were assayed for  $\beta$ -galactosidase activity. Firstly, it was interesting to note that the transgene expression was significantly increased ( $P < 0.001$ ) from 0.29 mU/ $\mu$ g to 0.42 mU/ $\mu$ g (or a 24% increase) by simply lowering the serum concentration from 10% to 0.5% and culturing for 12 h. This acute and transient increase in the transgene expression could be a stress response for cells adopted from full- to lower-serum medium. Secondly, under 1 ng/mL of TGF- $\beta$ 1 the transgene was rapidly induced when measured at 2 h ( $P < 0.05$ ) and 8 h ( $P < 0.005$ ), and eventually peaked at 24 h ( $P < 0.001$ ), with a specific activity being 0.52 mU/ $\mu$ g. At 48 h, the expression level dropped to the same level as at 0 h. After 72 h, the level slipped to 58% of the value at 0 h ( $P < 0.001$ ). The assay results are depicted in Figure 6.

To investigate dose-dependent induction, the T6/*lacZ*/C1 cells were grown in low serum DMEM with various concentrations of TGF- $\beta$ 1 (0, 0.1, 1, and 10 ng/mL) for various times (24, 48, and 72 h) and assayed for  $\beta$ -galactosidase activity. Significant transgene induction was observed for the 10 ng/mL TGF- $\beta$ 1 treatment at all time points ( $P < 0.001$ ). However the only other (less) induction was seen with 1 ng/mL of TGF- $\beta$ 1 at 24 h ( $P < 0.05$ ). The assay results are plotted in Figure 7A. It is

**Figure 8** Time-dependent induction of the endogenous GFAP gene by TGF- $\beta$ 1. T6/GFAP-LacZ cells were incubated with 1 ng/mL of TGF- $\beta$ 1 in low serum DMEM for various times (0, 8, 16, 24, 48, and 72 h), and the endogenous rat GFAP mRNA was quantified with real-time RT-PCR. Data were presented as mean  $\pm$  SE. <sup>a</sup> $P < 0.01$ , <sup>b</sup> $P < 0.005$  and <sup>d</sup> $P < 0.001$ , when compared to treatment at 0 h.

interesting to note that when the values of control groups (for 10 ng/mL) were normalized to 1 and the highest induction (nearly two fold) was seen at 72 h, though the absolute enzymatic activity (0.43 mU/ $\mu$ g) was the lowest among the three time points (Figure 7B).

#### Induction of endogenous GFAP expression by TGF- $\beta$ 1

The GFAP, along with other HSC markers desmin, SMAA, and vimentin, was known to express in the HSC-T6 cells<sup>[22]</sup>. In order to investigate whether the endogenous GFAP expression is also subject to TGF- $\beta$ 1 regulation as the transgene, the T6/*lacZ*/C1 cells treated with TGF- $\beta$ 1 (1 ng/mL) for various times (0, 2, 8, 16, 24, 48, and 72 h), and the rat GFAP transcripts were quantified using a real-time RT-PCR method. When compared to the basal level (normalized to 1) at 0 h, the GFAP mRNA level remained relatively steady within the first 24 h (except a brief but significant 0.5-fold suppression at 16 h,  $P < 0.005$ ), then sharply elevated to 7- and 8.5-folds of the basal level at 48 and 72 h, respectively (Figure 8).

## DISCUSSION

### Cell specificity of transgene expression

To our best knowledge, this is the first report demonstrating that a GFAP promoter can drive HSC-specific expression of a reporter gene, in a similar fashion as the endogenous GFAP does. The current findings also provided molecular biology support to the early immunocytochemical observations on the GFAP staining on HSC<sup>[7-11,36,37]</sup>. Based on our transfection studies of multiple cell types, the 2.2 kb hGFAP promoter is both necessary and sufficient to confer HSC-specific expression *in vitro*, which was reminiscent to the conclusion made on cultured astrocytes using the same promoter<sup>[20]</sup>. Several key *cis*-acting elements, especially the AP-1 site (for binding fos/jun family transcription factors), have been mapped to the so-called B box in the human GFAP promoter

from position-1612 to-1489, and proved to be critical for mediating astrocyte-specific transgene expression<sup>[20,38,39]</sup>. We therefore attempted to speculate that the rat T6 cells should also express a similar set of relevant transcription factors as the astrocytes do, to permit selective GFAP-*lacZ* expression in HSC. On the contrary, the non-GFAP expressing cell lines (HepG2, C3A, HeLa, and NIH/3T3) may lack appropriate *trans*-acting factor profile, leading to the complete null expression of the transgene, as judged by RT-PCR and prolonged X-gal staining.

### GFAP promoter elements for mediating the induction by TGF- $\beta$ 1

Our quantitative data showed that the 2.2 kb hGFAP-*lacZ* transgene, as well as the endogenous rat GFAP, were induced by TGF- $\beta$ 1 in a time- and dose-dependent manner in the T6/*lacZ*/C1 cells. This observation on the HSC was similar to earlier reports on the astrocytes<sup>[28,40]</sup>. The molecular mechanism underlying the TGF- $\beta$ 1 induction has been extensively studied. A sequence motif resembling the NF-1 (nuclear factor-1) site located in the near upstream (-106 to -153) of the rat GFAP promoter was shown to confer a full response to TGF- $\beta$ 1 induction in cultured astrocytes<sup>[40]</sup>. Similarly, two NF-1-like sites were mapped to the B (-1612 to -1489) and D (-132 to -57) boxes in the human GFAP promoter<sup>[20]</sup>. It was also known that some factor(s) in the nuclear extracts from astrocytes could bind to the NF-1 sites and possibly mediates the TGF- $\beta$ 1 induction process.

The endogenous GFAP gene displayed a similar trend in response to TGF- $\beta$ 1 as the 2.2 kb GFAP-*lacZ* transgene did. However, different responding dynamics were noted between the endogenous GFAP gene and the artificial GFAP-*lacZ* transgene. First, the transgene induction was obvious within the first 2 h of TGF- $\beta$ 1 stimulation, while the endogenous gene did not show any significant induction until day 2 of the TGF- $\beta$ 1 treatment. The difference in induction time line could be partially due to assay detection sensitivities, presumably with the enzymatic assay (with amplification capability) being more sensitive, therefore showing an earlier induction. An earlier detection of a similar 2.2-kb hGFAP-*lacZ* transgene was documented in a transgenic mouse model during brain development, in which the transgene showed up several days ahead of the endogenous GFAP<sup>[21]</sup>. In addition, unknown regulatory elements residing outside the 2.2-kb fragment could also contribute to the different responding profiles between the transgene and the endogenous GFAP. Nevertheless, both the endogenous and transgene at least displayed the same upward trend in responding to the same TGF- $\beta$ 1 cytokine, legitimizing the use of GFAP-*lacZ* transgene as a surrogate for the endogenous GFAP in studying TGF- $\beta$ 1 stimulation.

### Relationship between HSC activation and GFAP (and GFAP-*lacZ*) expression

Early studies on the rat HSC showed that GFAP expression decreased as quiescent HSCs were activated or transdifferentiated to myofibroblast-like during fibrosis<sup>[7-9]</sup>. However, the notion of an inverse relationship between the GFAP expression and the HSC activation may not be

as simple and straightforward. For example, whether the activated HSCs and myofibroblasts *in vivo* represented different activation stages of the same cell lineage, or two distinct cell types of different origins remained controversial<sup>[41]</sup>. It is worthy noting that some recent data showed that activated HSCs expressed higher level of GFAP<sup>[11,34,37]</sup>. Our current data clearly showed that both the endogenous GFAP and the hGFAP-*lacZ* transgene were upregulated in a time- and dose-dependent manner in the rat HSC-T6 cells activated by TGF- $\beta$ 1.

Our data demonstrated for the first time that the 2.2 kb hGFAP promoter is capable of expressing the *lacZ* reporter specifically in the rat HSC-T6 line and responding to TGF- $\beta$ 1 activation by re-regulation, in a similar manner as the rat astrocytic cell line C6. Furthermore our data also suggested that the molecular and cellular mechanisms (relevant *trans*-acting factors and signaling pathways) underlying the specific GFAP expression and induction are likely conserved in HSC line T6 and in the neural stellate cell line C6 alike. The current findings should provide a valuable genetic tool for manipulating HSCs towards the development of anti-fibrotic therapies.

## Abstract

**AIM:** To study the expression of cystatin C (CysC), its regulation by transforming growth factor- $\beta$ 1 (TGF- $\beta$ 1) and platelet-derived growth factor (PDGF) and the potential interference of CysC with TGF- $\beta$ 1 signaling in this special cell type.

**METHODS:** We evaluated the CysC expression in cultured, profibrogenic hepatic stellate cells and trans-differentiated myofibroblasts by Northern and Western blotting and confocal laser scanning microscopy.

**RESULTS:** CysC was increased significantly in the course of trans-differentiation. Both TGF- $\beta$ 1 and PDGF-BB suppressed CysC expression. Furthermore, CysC secretion was induced by the treatment with TGF- $\beta$ 1. Although CysC induced an increased binding affinity of TGF- $\beta$  receptor type III (beta-glycan) as assessed by chemical cross-linking with [ $^{125}$ I]-TGF- $\beta$ 1, it did not modulate TGF- $\beta$ 1 signal transduction as shown by evaluating the Smad2/3 phosphorylation status and [CAGA]-MLP-luciferase reporter gene assay. Interestingly, the shedding of type III TGF- $\beta$  receptor beta-glycan was reduced in CysC-treated cells. Our data indicated that CysC expression was upregulated during trans-differentiation.

**CONCLUSION:** Increased CysC levels in the serum of patients suffering from liver diseases are at least partially due to a higher expression in activated hepatic stellate cells. Furthermore, TGF- $\beta$ 1 influences the secretion of CysC, highlighting a potentially important role of cysteine proteases in the progression of hepatic fibrogenesis.

## INTRODUCTION

Cystatin C (CysC), belonging to the type II cystatin gene superfamily, is the most abundant extracellular inhibitor of cysteine proteinases<sup>[1]</sup>. Mature CysC is a 13-kD, positively charged, secreted protein composed of 120-122 amino acids expressed by many cell types. It is present in large quantities in cerebrospinal fluid, seminal plasma, serum and other body fluids. One of the most prominent functions of CysC is related to the inactivation of the cathepsin family members of cysteine proteinases, which are involved in the cleavage of membrane and extracellular matrix proteins among others and thus in disease-related tissue remodeling. The diagnostic value and prognostic significance of CysC determination have been reported for several diseases<sup>[2,3]</sup>, and correlations have been found between CysC expression, mutations, and clinical status of patients with autoimmune disease, cerebral amyloid angiopathy, hereditary brain hemorrhage, atherosclerosis, aortic aneurysms, and multiple sclerosis<sup>[4-8]</sup>.

A further highly relevant function of CysC has been recently reported, which is concentrated on the inhibitory effect on transforming growth factor- $\beta$  (TGF- $\beta$ )-signal transduction in normal and malignant cells<sup>[9]</sup>. The TGF- $\beta$  antagonizing mechanism is at least partially due to the interference of ligand binding to the type II TGF- $\beta$  receptor. *In vitro*, TGF- $\beta$ 1 is a potent inducer of CysC secretion in vascular smooth muscle cells<sup>[8]</sup>. Furthermore, expression of CysC mRNA in astrocyte precursor cells is directly linked to the activity of TGF- $\beta$ <sup>[10]</sup>. TGF- $\beta$  is known to be the fibrogenic master cytokine in human and experimental liver fibrosis due to its ability to stimulate the expression and inhibition of degradation of extracellular matrix (ECM) proteins and to promote the trans-differentiation of profibrogenic hepatic stellate cells (HSCs) to ECM-producing hepatic myofibroblasts (MFBs)<sup>[11]</sup>. The phenotypic and functional trans-differentiation of

HSCs is initiated in acute and chronic inflammatory liver diseases, ultimately leading to organ fibrosis and cirrhosis. Significantly elevated serum concentrations of CysC have been recently described in chronic liver diseases showing a strong correlation between the degree of elevation and the severity of disease<sup>[12,13]</sup>. Based on these new findings, we tried to figure out the potential functional relevance of CysC in the profibrogenic liver cell subtype, HSCs. Therefore, we studied in cultured rat HSCs, the expression of CysC, its regulation by TGF- $\beta$ 1 and platelet-derived growth factor (PDGF) and the potential interference of CysC with TGF- $\beta$  signaling in this special cell type. The results showed that CysC expression in HSCs was modulated by TGF- $\beta$  and platelet-derived growth factor-BB (PDGF-BB) depending on the trans-differentiation status of the cells. However, CysC had no direct effect on TGF- $\beta$  signaling itself.

## MATERIALS AND METHODS

### Cell isolation and culture

HSCs, Kupffer cells (KCs), and sinusoidal endothelial cells (SECs) were isolated from male Sprague-Dawley rats by the pronase-collagenase method<sup>[14]</sup>. HSCs were further purified by a single-step density gradient centrifugation as previously described<sup>[15]</sup>. KCs and SECs were enriched by centrifugal elutriation<sup>[16]</sup> and RNA was directly isolated without cell cultivation. HSCs were seeded in Dulbecco's modified Eagle's medium (DMEM) (BioWhittaker Europe, Verviers, Belgium) supplemented with 100 mL/L fetal calf serum (FCS) (Hyclone Fetal Bovine Serum, Perbio), 4 mL glutamine (PAA Laboratories GmbH, Linz, Austria), 100 IU/mL penicillin and 100  $\mu$ g/mL streptomycin (PAA Laboratories). Hepatocytes (PCs) were isolated following the collagenase method of Seglen<sup>[17]</sup>. The medium was renewed one day after initial plating and then every day. Cultures were maintained at 37 °C in a humidified atmosphere containing 50 mL/L CO<sub>2</sub>. Prior to treatment with recombinant human CysC (rhCysC), TGF- $\beta$ 1, and PDGF-BB (R&D Systems, Wiesbaden, Germany), the cells were starved for 16 h in 0.2% FCS.

### RNA isolation and Northern blot analysis

Total RNA was purified using the RNeasy Mini kit (Qiagen, Hilden, Germany) according to the manufacturer's instructions. After resuspension in water, the concentration was determined by UV absorbance. Northern blot analysis was carried out as previously described<sup>[18]</sup>.

### cDNA preparation, RT-PCR, real time PCR

To generate a probe for Northern blot analysis of CysC expression, total RNA (2  $\mu$ g) from rat HSCs was reverse transcribed using the Omniscript transcriptase (Qiagen) and random hexamer primers (Invitrogen, Karlsruhe, Germany). The reaction was allowed to proceed at 37 °C for 60 min and cDNA products were stored at -20 °C until use. For amplification of rat CysC, aliquots of first strand cDNAs were subjected to PCR with primers 5'-AGT ACA ACA AGG GCA GCA ACG ATG-3' and 5'-AGG AGA AGA GAA CCA GGG GAC AGC-3', dNTPs (each 10 mmol/L dATP, dCTP, dGTP, dTTP) in 1 $\times$  PCR

reaction buffer and 2.5 U *Taq* DNA polymerase (Roche Molecular Biochemicals, Mannheim, Germany) resulting in the amplification of a 454-bp CysC fragment<sup>[19]</sup>. PCR conditions were at 94 °C for 5 min (initial denaturation), at 94 °C for 60 s, at 60 °C for 60 s, at 72 °C for 3 min (40 cycles), and at 72 °C for 10 min (final extension). Aliquots of the reaction products were separated and visualized on 1% (w/v) agarose gels and the identity of the fragment was demonstrated by sequencing. Quantitative analysis of rat CysC mRNA was performed with a LightCycler (LC) System in 20  $\mu$ L reaction volume using the LC-FastStart DNA Master SYBR Green I kit (Roche). Thermocycling was performed with 2  $\mu$ L of cDNA products and 0.75  $\mu$ mol/L of each primer specific for CysC. No-template controls were prepared by adding 2  $\mu$ L PCR grade, sterile H<sub>2</sub>O to 18  $\mu$ L of master mix. Cycling conditions were one cycle of denaturation at 95 °C for 10 min, followed by 45 amplification cycles at 95 °C for 10 s, at 60 °C for 5 s, at 72 °C for 22 s. The PCR products were melted in a temperature transition procedure from 65 °C to 95 °C in steps of 0.1 °C/s and fluorescence was measured and plotted online against the temperature to obtain the fragment-specific melting points. Differences between crossing points were taken to estimate the relative concentrations.

### SDS-polyacrylamide gel electrophoresis (SDS-PAGE) and immunoblotting

For immunoblotting, proteins from rat liver cells were separated under reducing conditions on 4-12% Bis-Tris gradient gels using MES running buffer (Invitrogen). The electroblotting onto 0.2- $\mu$ m protran NC membranes (Schleicher & Schuell, Dassel, Germany) was carried out according to standard procedures. Blocking and incubation of the membranes with individual antibodies were performed as described previously<sup>[18]</sup> with slight modifications. Briefly, membranes were blocked with 5% (w/v) non-fat milk powder in Tris-buffered saline-Tween 20 (TBST). For Western blot analysis, the following primary antibodies were diluted in 2.5% (w/v) non-fat milk powder in TBST: clone asm-1 (Cymbus Biotech., Chandlers Ford, UK) against  $\alpha$ -smooth muscle actin ( $\alpha$ -SMA) (1:10 000), rabbit anti-human CysC rat/human CysC and its precursor (1:500) (Upstate Biotechnology, Lake Placid, USA), rabbit anti-phospho-Smad2 (Ser465/467) (1:1000) (New England Biolabs GmbH, Frankfurt/Main, Germany), rabbit anti-Smad2 (1:200) (Zymed Laboratories, San Francisco, CA, USA), goat anti-Smad2/3 (N-19), (Santa Cruz Biotechnology, Santa Cruz, CA, USA) (1:100), mouse anti- $\beta$ -actin (1:10 000) (Cymbus). The antiserum PS1 was raised against a phosphorylated C-terminal peptide of Smad1 and showed cross-reactivity with phosphorylated Smad3 (1:1 000)<sup>[20]</sup>. Primary antibodies were visualized using horseradish peroxidase (HRP)-conjugated anti-mouse, -rabbit or -goat IgG (Santa Cruz Biotechnology) or alkaline phosphatase (AP)-conjugated anti-rabbit or mouse IgG (Santa Cruz Biotechnology). Alternatively, the primary antibodies against CysC and Smad2/3 (N-19) were detected with swine anti-rabbit and rabbit anti-goat IgG biotin antibody followed by streptavidin-HRP conjugate (DAKO Diagnostics, Hamburg, Germany). Staining was

performed with the SuperSignal West Dura Extended chemiluminescent substrate (Pierce, Rockford, IL, USA) for HRP exposed in a Lumi-Imager<sup>TM</sup> (Roche) or a color staining using NBT/BCIP substrate (Perbio Science, Bonn, Germany).

### Sequence analysis

All primers were obtained from MWG-Biotech (Ebersberg, Germany) and sequencing was done with the ABI PRISM BigDye<sup>®</sup> termination reaction kit (PE Applied Biosystems, Weiterstadt, Germany) as described<sup>[21]</sup>.

### Enzyme linked fluorescence cytological labeling assay (ELF 97 assay)

Ten thousand cells per well were cultured in black 96-well plates for different times under standard conditions and fixed with 4% (w/v) paraformaldehyde in phosphate buffered saline (PBS) (pH 7.4). For generation of myofibroblasts (MFBs), HSCs cultured for seven days were trypsinized and subcultured for further 3 days. The cells were permeabilized on ice in 0.1% (w/v) Triton X-100/0.1% (w/v) sodium citrate, blocked in 1% (w/v) BSA/PBS pH 7.4 and incubated with anti- $\alpha$ -smooth muscle actin (1:500) or anti-CysC antibody (1:200). Non-immune IgGs were used as negative controls. The ELF-97 assay (Molecular Probes Europe; Leiden, NL) was performed according to an established procedure<sup>[22]</sup>. The fluorescence intensity was measured in a Multilabel counter (Victor, Wallac ADL GmbH, Freiburg, Germany) for the quantitative evaluation of  $\alpha$ -SMA and CysC (excitation 365 nm, emission 515 nm). The staining intensity of negative controls was subtracted from the determined values and in parallel the fluorescence was also recorded in an inverted fluorescence microscope (Axiovert M135, Zeiss, Frankfurt, Germany). Subsequently, to normalize the fluorescence values (FU) of  $\alpha$ -SMA or CysC, the DNA content of parallel cultures was measured fluorometrically (excitation 485 nm, emission 525 nm) and quantified against calf thymus DNA as standard using the SYBR Green I dye (Molecular Probes Europe).

### Immunofluorescence staining and confocal microscopy

Forty thousand cells per well (1.8 cm<sup>2</sup>) were cultured in 4 chamber polystyrene vessels (Becton, Dickinson, Franklin Lakes, NJ, USA) for different times under standard conditions and fixed with 4% (w/v) paraformaldehyde in PBS (pH 7.4). Permeabilization, blocking and CysC antibody (Upstate Biotechnology, 1:200) incubation were carried out as described above. After washing, a biotin-linked swine anti-rabbit IgG (DAKO) (1:300) was used as the secondary antibody followed by incubation with streptavidin-FITC (DAKO) (1:150). For the detection of  $\alpha$ -SMA, a direct CY3-conjugated antibody (clone AC-40; Sigma, Taufkirchen, Germany) was used (1:200). Non-immune IgGs (Santa Cruz) served as negative controls. After washing and mounting with antifade, the cells were subjected to high-resolution confocal laser scanning microscopy in a LS 410 inverse microscope (Zeiss) using a standard objective (40 $\times$ 1.3 oil).

### Adenoviral infection of HSCs and luciferase measurement

Adenoviral stocks of Ad (CAGA) $\beta$ -MLP-luciferase were

prepared as previously described<sup>[23]</sup>. Two thousand cells per well were cultured in black 96 well plates. After infection at a multiplicity of infection (MOI) of 50, cells were serum starved at 0.2% FCS for 16 h, pre-incubated with or without rhCysC for 1.5 h, respectively, followed by cytokine stimulation as indicated. The luciferase activity was measured with the Steady-Glo luciferase assay substrate (Promega, Madison, WI, USA) according to the manufacturer's protocol.

### Affinity labeling and cross-linking of TGF- $\beta$ receptors

Affinity labeling with [<sup>125</sup>I]-TGF- $\beta$ 1 (Amersham Pharmacia Biotech, Freiburg, Germany) and cross-linking were performed as described previously<sup>[24]</sup>. Briefly, confluent monolayers of HSCs (5 $\times$ 10<sup>5</sup> cells/10 cm<sup>2</sup>) were cultured for 4 days in medium containing 10% FCS. After aspiration of medium, monolayers were washed with Krebs-Ringer-HEPES binding buffer (128 mmol/L NaCl, 5 mmol/L KCl, 5 mmol/L MgSO<sub>4</sub>, 13 mmol/L CaCl<sub>2</sub>, 50 mmol/L HEPES) containing 0.5% (w/v) BSA (radioimmunoassay grade) and pre-incubated with or without CysC for 1 h at 37 °C. Cells were washed with ice-cold buffer and receptor binding was performed in the presence or absence of CysC. After equilibration for 10 min on ice, cells were incubated with 2.8 ng/mL [<sup>125</sup>I]-TGF- $\beta$ 1 (1 621 Ci/mmol) with or without a 200-fold excess of unlabeled TGF- $\beta$ 1 (R&D Systems, Minneapolis, USA) for 3 h at 4 °C. As a further control, an antibody directed against the extracellular domain of betaglycan was used to suppress ligand binding. Bound ligand was cross-linked to its receptor in Krebs-Ringer-HEPES buffer lacking the BSA with disuccinimidyl suberate (Perbio Science) for 15 min at 4 °C. The reaction was stopped by aspiration of the supernatant followed by washing with STE buffer [10 mmol/L Tris-HCl pH 7.4, 250 mmol/L sucrose, 1 mmol/L ethylenediaminetetraacetic acid (EDTA)] including 1 mmol/L phenyl methyl sulfonyl fluoride (PMSF). Cross-linked [<sup>125</sup>I]-TGF- $\beta$ 1 was extracted with TTE buffer (10 mmol/L Tris-HCl, pH 7.4, 10 mL/L (v/v) Triton X-100, 1 mmol/L EDTA) including proteinase inhibitor cocktail complete (Roche). The detergent soluble, cell debris-free fraction was precipitated by ice-cold 10% TCA (w/v) in the presence of 0.1 mg/mL sodium deoxycholate (DOC). The protein precipitates were subsequently washed with acetone, air dried, and dissolved in a small volume of LDS electrophoresis sample buffer (Invitrogen). Sample volumes corresponding to the normalized DNA contents were subjected to NuPAGE SDS-PAGE. For autoradiography, dried gels were exposed to KODAK X-OMAT AR films (Eastman Kodak Company, Rochester, NY, USA) using intensifying screens.

### CysC secretion in HSCs

Serum-starved HSCs were treated with rhTGF- $\beta$ 1 (10 ng/mL) for 24 or 48 h and the cell-free supernatants were subjected to standard immunoprecipitation using goat antibody (sc-16989) directed against CysC (Santa Cruz). The resulting precipitates were washed and analyzed for CysC expression by Western blotting using a primary rabbit antibody directed against CysC (Upstate) and

**Figure 1** CysC mRNA expression in different rat liver cell types. **A:** Equal amounts of total RNA samples (10  $\mu$ g) isolated from cultured SECs, MFBs, HSCs, KCs, and PCs were analyzed by Northern blot. The blot was hybridized with a  $^{32}$ P-labeled probe specific for rat CysC; **B:** total RNA samples (5  $\mu$ g/lane) of trans-differentiating HSCs/MFBs at indicated time intervals were analyzed for CysC expression by Northern blot analysis. As internal loading controls (**A and B**), the 18S and 28S rRNA as well as signals obtained after hybridization with a GAPDH-specific probe are shown. The blots were exposed for 4 (GAPDH) or 24 h (CysC), respectively; **C:** protein extracts (20  $\mu$ g/lane) from primary rat HSCs cultured for 1 to 7 days or rat MFBs cultured for 3 days were analyzed for CysC expression by Western blotting under reducing conditions (50 mmol/L DTT) using antibody P-14 (sc-16989). To verify cellular trans-differentiation, the blot was stripped, and tested for  $\alpha$ -SMA expression using a mouse monoclonal antibody (clone asm-1).

visualized with a goat anti-rabbit IgG-HRP conjugate.

## RESULTS

### Expression of CysC in isolated liver cells

To analyze the expression of CysC in different liver cell subpopulations, we performed Northern blot analysis (Figure 1A). In agreement with the general assumption that CysC is a constitutive active gene expressed in all nucleated cells at a constant rate<sup>[25]</sup>, we found a single CysC transcript of 0.8-0.9 kb in size in SECs, KCs, PCs, HSCs and their trans-differentiated myofibroblastic phenotype. However, compared to HSCs, we found a significant increase of CysC transcripts in their trans-differentiated phenotype. Subsequent analysis revealed that the activation of HSCs was accompanied with an upregulation of CysC expression during the trans-differentiation process (Figure 1B). In these analyses, the levels of mRNA encoding the enzyme glyceraldehyde-3-phosphate dehydrogenase (GAPDH) as well as the 28S and 18S rRNAs were used as internal quality and loading controls. To demonstrate CysC expression at the protein level, we further performed Western blot analysis using cellular extracts isolated from cells at different time points of trans-differentiation (Figure 1C). We found that the amount of CysC protein correlated with the amounts of transcripts. To illustrate and confirm the increase of CysC protein more quantitatively, we further performed confocal immunocytochemistry (Figure 2A) and ELF-assay (Figure 2B), respectively. Again, both visualizations of cellular CysC expression by confocal laser scanning microscopy and quantitative ELF-assay indicated that CysC expression was strongly increased during cellular activation and trans-differentiation.

### CysC did not modulate TGF- $\beta$ 1 signal transduction in HSCs

A recent report demonstrated that CysC is able to antagonize TGF- $\beta$  binding to its cell surface receptors thereby inhibiting TGF- $\beta$  signaling<sup>[9]</sup>. To test if this antagonizing effect on TGF- $\beta$  signaling was also present in HSCs, we monitored the changes in the TGF- $\beta$  sensitive CAGA-MLP-luciferase reporter assay system<sup>[26]</sup>. Therefore, cultured HSCs were first infected with 50 MOI Ad-(CAGA)<sub>9</sub>-MLP-luciferase<sup>[22]</sup>, preincubated with different concentrations of rhCysC and then exposed to TGF- $\beta$ 1. The TGF- $\beta$ -stimulated luciferase activity was compared to unstimulated control cells, which revealed that preincubation with CysC had no effect on the reporter assay (Figure 3A). Similarly, Western blot analysis further revealed that TGF- $\beta$ -induced phosphorylation of Smad2 and Smad3 did not change in the presence of CysC, again demonstrating that this cysteine protease inhibitor could not antagonize TGF- $\beta$  signaling in cultured HSCs (Figure 3B).

### CysC promoted TGF- $\beta$ binding to TGF- $\beta$ type III receptor betaglycan

Based on a recent report demonstrating that CysC could dose-dependently inhibit the physical interaction of TGF- $\beta$  to murine TGF- $\beta$  type II receptor<sup>[9]</sup>, we performed cross-linking experiments to test if CysC had the same

**Figure 2** Confocal laser scanning microscopy and ELF assay for quantitative determination of CysC expression in HSCs and MFBs. **A:** HSCs/MFBs were seeded on glass cover slides for indicated time intervals. After fixation, cells were permeabilized and incubated with primary antibodies directed against CysC or  $\alpha$ -SMA. Primary antibodies were visualized with a FITC-labeled secondary antibody (CysC, green fluorescence) or a Cy3-labeled secondary antibody ( $\alpha$ -SMA, red fluorescence). Original magnification was  $\times 400$ . Negative controls, using normal IgGs instead of primary antibodies showed no staining (data not shown); **B:** HSCs/MFBs cultured in 96-well plates for indicated time intervals were fixed and stained for CysC. The staining was visualized by fluorescence microscopy (original magnification  $\times 200$ ). Fluorescence intensities were measured quantitatively using a 96-well fluorescence reader (excitation 365 nm, emission  $\geq 515$  nm).

effects in the rat system. Interestingly, we found that the binding of TGF- $\beta$  to the type II receptor was not affected in the presence of physiological concentration of CysC (data not shown). Since the transmembrane signaling by TGF- $\beta$  was critically modulated in the presence of the type III receptor (betaglycan), which was expressed at high level in HSCs and in turn associated with the type II receptor in a second step, we next addressed the question if CysC was able to modify the binding of TGF- $\beta$  to this receptor. Binding of TGF- $\beta$ 1 to betaglycan was analyzed by cross-linking experiments using iodinated TGF- $\beta$ 1. HSCs cultured for 4 days were first incubated with rhCysC. Thereafter, the cells were exposed to [ $^{125}$ I]-TGF- $\beta$ 1 and the iodinated ligand was chemically cross-linked to the receptors. Subsequently, betaglycan was separated by SDS-PAGE, and the amount of ligand bound to this receptor was visualized by autoradiography (Figure 4, lanes 1 and 2). Interestingly, we found that the binding to betaglycan was elevated after preincubation with CysC. The specificity for the betaglycan labeling was demonstrated by preincubation with a betaglycan-specific antibody (Figure 4, lanes 3 and 4).

### TGF- $\beta$ and PDGF-BB suppressed CysC expression in HSCs

Several reports demonstrated that CysC transcript expression could be stimulated by TGF- $\beta$ 1<sup>[9,10,27]</sup>. To test if CysC expression was induced in HSCs by TGF- $\beta$ 1, we performed Northern blot analysis with RNA isolated from HSCs that were treated with TGF- $\beta$ 1 (5 ng/mL) for 18 or 38 h, respectively (Figure 5A, lanes 2 and 5). Surprisingly,

the contents of CysC transcripts were decreased in TGF- $\beta$ -stimulated HSCs. Furthermore, the same effect was observed when PDGF-BB was applied causing a significant decrease of CysC transcript expression (Figure 5A, lanes 3 and 6). To confirm that CysC expression in HSCs was indeed suppressed by TGF- $\beta$  and PDGF-BB, we repeated our experiments at the protein level. As shown in Figure 5B, both TGF- $\beta$ 1 and PDGF-BB significantly suppressed the synthesis of CysC in HSCs.

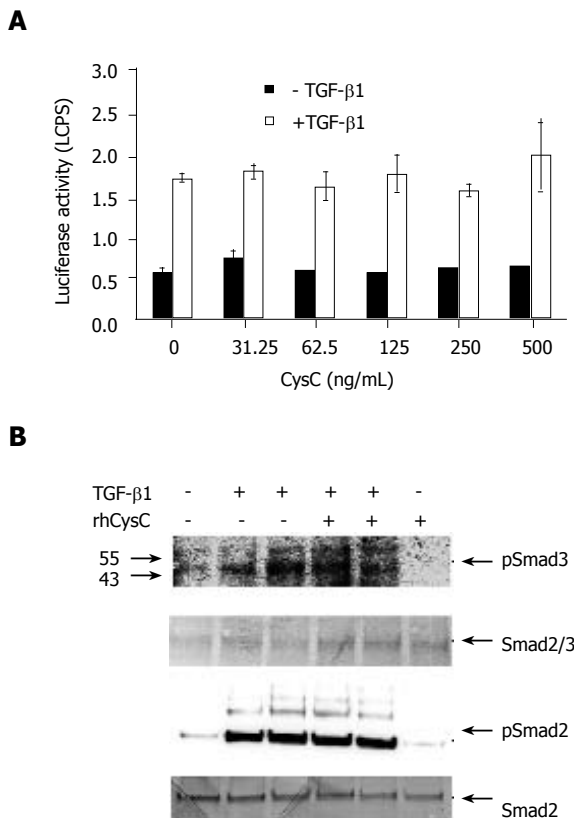

### TGF- $\beta$ increased secretion of CysC in HSCs

To further explore the impact of TGF- $\beta$  on CysC regulation, we tested if TGF- $\beta$ 1 could modify CysC secretion. Therefore, we treated serum-starved HSCs with TGF- $\beta$ 1 (10 ng/mL) for 24 or 48 h and determined the amount of CysC in the cell-free supernatants. Compared to control cells, the amount of secreted CysC was markedly increased in cultures stimulated with TGF- $\beta$ 1 (Figure 6). Furthermore, we detected two different CysC protein bands with an approximate molecular mass of 13 and 18 ku most likely representing proteins with a different N-glycosylation status<sup>[28]</sup>.

## DISCUSSION

The response to chronic liver injury is wound healing and subsequently fibrosis representing the enhanced ECM production and deposition ending in cirrhosis. In the last decades a growing body of evidence indicates that HSCs and their trans-differentiated phenotype, the MFBs, as

**Figure 3** Effect of rhCysC on TGF-β1-induced reporter gene activity and Smad2/3 phosphorylation. **A:** Cultured HSCs were infected with 50 MOI Ad-(CAGA)<sub>3</sub>-MLP-luciferase followed by 1 h incubation with the indicated doses of rhCysC prior to exposure with TGF-β1 (1 ng/mL) for 4 h or left untreated. The mean ± SD of the measured luciferase activities ( $n=4$ ) was given; **B:** phosphorylated Smad2 (pSmad2) and Smad3 (pSmad3) were detected by immunoblotting of whole cell protein lysates prepared after treatment of HSCs with or without 500 ng/mL rhCysC for 1 h followed by incubation with 1 or 5 ng/mL TGF-β1, respectively for an additional hour. The amount of total Smad2/3 or Smad3 was used as internal loading control.

well as TGF-β1 and PDGF-BB are central cell types and mediators in this wound healing process. In healthy livers, the balance between synthesis and degradation of ECM is tightly controlled. During injury and fibrosis progression, there is increased expression of matrix metalloproteinases (MMPs) and their tissue inhibitors (TIMPs) resulting in an imbalance in the turnover of ECM and a conversion of the low-density subendothelial matrix into matrix-rich interstitial collagens. Additionally, the activity of collagenolytic cathepsins is elevated in experimental and clinical hepatic fibrogenesis<sup>[29,30]</sup> and elevated serum concentrations of CysC are found in patients suffering from chronic liver diseases<sup>[12,13]</sup>. Therefore, it is possible that an imbalance between cathepsins and CysC contributes to liver fibrosis. The demonstration that members of the cystatin superfamily can physically interact with metalloproteinases thereby protecting them from autolytic activation, further suggesting that there is a direct linkage between the MMP/TIMP and the cathepsin/cystatin enzyme systems<sup>[31]</sup>. Although all these studies have clearly shown that elevated serum CysC concentrations are clinically important for the progression of liver fibrogenesis, the exact cellular source and the regulation

**Figure 4** Effect of rhCysC on TGF-β1 binding to beta-glycan. Cultured HSCs were incubated for 1 h with or without rhCysC or an antibody specific for the extracellular domain of beta-glycan followed by the application of [<sup>125</sup>I]-TGF-β1. The ligand was chemically cross-linked to the receptor and subsequently TβRIII was immunoprecipitated, separated by SDS-PAGE, and visualized by autoradiography. Control experiments including a 200-fold excess of unlabeled TGF-β1 showed no receptor labeling (data not shown).

of CysC within different liver cell subpopulations have not been explored.

In the present study, all liver cell types tested were able to synthesize CysC, CysC expression was up-regulated in activated HSCs and trans-differentiated MFBs, TGF-β1 and PDGF-BB suppressed CysC expression at the RNA and protein level, CysC did not modulate TGF-β1 signal transduction in HSCs but induced affinity of betaglycan for TGF-β1, TGF-β1 induced secretion of this inhibitor of cysteine proteinases.

The finding that all liver cells tested express CysC (Figure 1A) is not surprising since it has been well established that CysC behaves like a “housekeeping gene” expressed in all nucleated cells, in all tissues and cell types, although mRNA levels vary several-fold between and among the tissues<sup>[25]</sup>. However, the finding that CysC expression is strongly increased in activated HSCs and trans-differentiated MFBs is somewhat unexpected since previous studies have demonstrated that the CysC promoter is of constitutive nature<sup>[32]</sup>. This upregulation is consistent with the findings that patients with liver cirrhosis have an average three-fold greater serum CysC concentration which closely matches to the degrees of fibrosis and is elevated even in patients with mild fibrosis. Thus, increased CysC levels in serum of these patients are at least partially due to a higher expression of this protein inhibitor of cysteine proteinases. The observation that both TGF-β and PDGF-BB could suppress the expression of CysC is at first somewhat striking and unexpected since TGF-β1 and PDGF-BB are the main effectors during hepatic fibrogenesis and, moreover, TGF-β1 can stimulate CysC expression in murine embryo cells, uterine decidual and 3T3-L1 cells<sup>[9,10,27]</sup>. The conflict might be explained by the finding that only HSCs respond to TGF-β1, whereas fully trans-differentiated MFBs are insensitive to the treatment with TGF-β1<sup>[24]</sup>. Thus, in ongoing hepatic fibrogenesis, when HSCs become refractory against

**Figure 5** Effect of PDGF-BB and TGF- $\beta$ 1 on CysC expression in HSCs. **A:** Cultured HSCs were serum starved to 2 mL/L FCS followed by treatment with or without PDGF-BB or TGF- $\beta$ 1 for 18 and 36 h, respectively. Total RNA (5  $\mu$ g/lane) was isolated and analyzed by Northern blot for CysC expression. As internal loading controls, the 18S and 28S rRNA as well as signals obtained after hybridization with a GAPDH-specific probe were shown; **B:** for CysC protein expression, cells were treated with or without PDGF-BB or TGF- $\beta$ 1 for 72 h and protein lysates (20  $\mu$ g/lane) were subjected to Western blot analysis using an antibody specific for CysC. The expression of  $\beta$ -actin was used as internal protein loading control.

TGF- $\beta$ , they start to increase CysC expression potentially leading to the observed higher serum concentrations.

In HSCs, TGF- $\beta$  signaling is not influenced by the presence of CysC. Although CysC has been found to increase the ligand binding to betaglycan, we observed that it had no effects on TGF- $\beta$  receptor type II binding (data not shown) and TGF- $\beta$  reporter gene assay or Smad2/3 phosphorylation. Possibly, CysC inhibits a specific proteinase required for shedding of betaglycan. In line with such a hypothesis, the shedding of betaglycan is mediated by membrane type MMP-1<sup>[33]</sup> and members of the cystatin superfamily can interact with MMPs and protect them from autolytic degradation<sup>[31]</sup>. The missing impact of CysC on TGF- $\beta$ -binding to the type II receptor might be due to the absence of specialized spliced forms of the type II receptor, i.e. type IIb present in mice<sup>[34]</sup> but not in rat HSCs/MFBs (Meurer, Gressner, Weiskirchen, unpublished observation).

Finally, we found that TGF- $\beta$  induced secretion of CysC in HSCs. This ability of TGF- $\beta$  is also described in

**Figure 6** TGF- $\beta$ 1-induced CysC secretion in HSCs. Serum-starved HSCs were treated with TGF- $\beta$ 1 (10 ng/mL) for 24 or 48 h and the cell-free supernatants were subjected to immunoprecipitation using goat antibody P-14 directed against CysC. Subsequently, the precipitates were analyzed for CysC expression by Western blotting using an independent primary rabbit antibody directed against CysC and visualized with a goat anti-rabbit IgG-HRP conjugate.

vascular smooth muscle cells<sup>[8]</sup>, suggesting that it might be a general hallmark of smooth muscle cells. It is also conceivable that the observed decrease of cellular CysC content upon stimulation with TGF- $\beta$ 1 is a consequence of CysC release from intracellular storage sites. However, this effect might only in part contribute to the intracellular decrease of CysC since we observed a clear decrease of CysC mRNA in cells stimulated with TGF- $\beta$ 1.

In conclusion, the concentration of serum CysC is correlated with the severity of liver dysfunction. CysC expression is upregulated in the course of HSC activation and trans-differentiation into MFB, which gives a plausible explanation for the correlation of CysC concentrations with the progression of liver fibrosis.

**Key words:** Inflammatory bowel disease; Microproteinuria; 5-aminosalicylic acid

Poulou AC, Goumas KE, Dandakis DC, Tympas I, Panagiotaki M, Georgouli A, Soutos DC, Archimandritis A. Microproteinuria in patients with inflammatory bowel disease: Is it associated with the disease activity or the treatment with 5-aminosalicylic acid? *World J Gastroenterol* 2006; 12(5): 739-746

<http://www.wjgnet.com/1007-9327/12/739.asp>

### Abstract

**AIM:** To investigate whether microproteinuria in patients with inflammatory bowel disease (IBD) is associated with the disease activity or the treatment with 5-aminosalicylic acid (5-ASA).

**METHODS:** We prospectively studied microproteinuria in 86 consecutive patients with IBD, 61 with ulcerative colitis (UC) and 25 with Crohn's disease (CD), before as well as 2 and 6 months after their inclusion in the study. Forty-six patients received 5-ASA for a period of 28.8 months (range 1-168 mo). Microalbuminuria (mALB) and urine levels of the renal tubular proteins  $\beta_2$ -microglobulin ( $\beta_2$ mGLB) and  $\beta$ -N-acetyl-D-glucosaminidase ( $\beta$ -NAG) as well as the creatinine clearance were determined in a 12-h overnight urine collection. Tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) serum levels were also measured.

**RESULTS:** A total of 277 measurements (194 in UC patients and 83 in CD patients) were performed. The prevalence of abnormal microproteinuria in UC and CD patients was 12.9% and 6.0% for mALB, 22.7% and 27.7% for  $\beta_2$ mGLB, and 11.3% and 8.4% for  $\beta$ -NAG, respectively. mALB was not associated with IBD activity.  $\beta_2$ mGLB and  $\beta$ -NAG urine levels were correlated to UC activity (UCAI:  $P < 0.01$ ; UCEI:  $P < 0.005$ ). mALB in UC patients and  $\beta$ -NAG urine levels in CD patients were related to TNF- $\alpha$  serum levels. An association was noticed between microproteinuria and smoking habit. Treatment with 5-ASA was not correlated to the severity of microproteinuria or to the changes of creatinine clearance.

### INTRODUCTION

Complications of the urinary system are not uncommon in patients with inflammatory bowel disease (IBD). Their incidence has been reported to vary from 4% to 23% and is greater in patients with more severe and long-standing disease<sup>[1]</sup>. Apart from secondary complications, such as nephrolithiasis, hydronephrosis and amyloidosis, other associations between IBD and renal disorders have also been described, regardless of treatment<sup>[2-5]</sup>. Membranous glomerulonephritis, rapidly progressive glomerulonephritis, mesangiocapillary glomerulonephritis, IgA nephropathy, thin basement membrane disease and kidney granuloma are connected with IBD<sup>[6-10]</sup>. In addition, non-specific morphological changes in the glomeruli of patients with IBD, such as podocyte effacement and mesangial deposition of immunoglobulin and complement have also been well documented<sup>[11]</sup>. On the contrary, cases of interstitial nephritis are attributed to the nephrotoxic effect of aminosalicylates<sup>[11]</sup>. However, before the establishment of 5-ASA as a treatment of choice in IBD, studies have identified renal tubular lesions in a proportion of patients<sup>[12]</sup>. Till date, more than 37 cases implicating the drug in interstitial nephritis (mainly mesalazine but also sulfasalazine, balsalazide, and olsalazine) have been reported to the Committee on Safety of Medicines (CSM)<sup>[13]</sup>.

Abnormal microproteinuria [microalbuminuria (mALB) and/or tubular proteinuria] has been reported both in patients with ulcerative colitis (UC) and in those with Crohn's disease (CD)<sup>[13-17]</sup>. Increased mALB, equivalent to an albumin excretion rate of 20-200  $\mu\text{g}/\text{min}$ , is generally regarded as a sensitive indicator of glomerular disease and has been widely used as a clinical marker of incipient diabetic nephropathy<sup>[18]</sup>. Mahmud *et al.*<sup>[14]</sup> have found that there is a significant correlation between mALB and IBD activity. Increased urine levels of some tubular proteins, such as  $\beta$ -N-acetyl-D-glucosamidase ( $\beta$ -NAG),  $\alpha$ <sub>1</sub>-microglobulin,  $\beta$ <sub>2</sub>-microglobulin ( $\beta$ <sub>2</sub>mGLB), alkaline phosphatase and gamma-glutamyltransferase, have been reported to be reliable indirect indices of renal tubular dysfunction<sup>[19]</sup>. Moreover, Riley *et al.*<sup>[15]</sup> have also found that the incidence of elevated urinary  $\beta$ -NAG is low in patients with quiescent UC, which is irrelevant to the dose and duration of mesalazine treatment. Kreisel *et al.*<sup>[17]</sup> reported that there is a strong correlation between abnormal tubular proteinuria and the activity of UC but not the activity of CD. On the contrary, Schreiber *et al.*<sup>[20]</sup> showed that increased prevalence of tubular proteinuria is attributed to high dosages of 5-ASA.

The etiology of abnormal microproteinuria in patients with IBD remains ambiguous. We conducted the present 6-month prospective study in order to investigate the incidence of mALB and tubular proteinuria in patients with IBD, emphasizing on the possible relationship between microproteinuria and the disease activity or the treatment with 5-ASA.

## MATERIALS AND METHODS

### Patients and sample selection

A total of 86 out of 166 screened consecutive Caucasian patients with confirmed chronic IBD (61 with UC and 25 with CD), treated at the Gastroenterology Department of the Red Cross Hospital of Athens from June 1998 to April 2001, were prospectively included in this study. Patients with signs of urinary tract infection and a history of acute or chronic nephropathy, diabetes mellitus, hypertension, severe liver disease, cardiac failure, use of non-steroidal anti-inflammatory drugs (NSAIDs) or other nephrotoxic drugs, patients with a present or recent pregnancy, patients treated with olsalazine, and patients who refused to participate in this study were excluded. Fifty patients were male, 36 were female and their mean age was 42.7 (range 15-77 years) years. Fifty-nine were out-patients and 27 were in-patients. At the time of their inclusion in this study, the IBD was active in 38 patients (27 with UC and 11 with CD) and inactive in 48 patients. Thirty out of eighty-six patients were first diagnosed with IBD (23 with UC and 7 with CD). The mean duration of the disease was 69.8 months (range 0-576 months). The group of patients with UC consisted of 16 patients with total colitis and 45 with left sided colitis (two of them with rectal disease only). The group of patients with CD included 11 patients with ileo-colonic disease, 8 with small bowel disease only and 6 with colonic disease only. Due to the small number of patients, two subgroups of patients with CD were considered in the subsequent analysis, one consisted of the

patients with ileo-colonic or colonic disease and the other consisted of those suffering from small bowel disease only. Extra-intestinal manifestations at present or during the last 2 months before the first meeting or during follow-up, were recorded in 29 patients (14 with UC, 15 with CD). Forty-six patients received mesalazine (Salofalk 2-3 g/day or Asacol 1.6-2.4 g/day) for a mean period of 28.8 months (range 1-168 months). During the last year, 20 of them were treated with prednisolone for a mean period of 1.9 months (range 1-12 months) and 6 with azathioprine for a mean period of 4.9 months (range 1-10 months).

According to the study design, all patients were evaluated at the time of their inclusion in the study (stage 1), two (stage 3) and six (stage 4) months afterwards. Twenty-seven patients (19 with UC, 8 with CD) with severely exacerbated disease at the time of their inclusion in the study were re-evaluated 10 days after intensive corticosteroid-based treatment (stage 2). A meticulous routine and more specific clinical and laboratory evaluation of the patients was conducted in each stage of the study, including determination of the hematocrit value, white blood cell and platelet count, serum levels of C-reactive protein (CRP) and tumor necrosis factor-alpha (TNF- $\alpha$ ), usual urinalysis, levels of mALB and tubular proteinuria ( $\beta$ <sub>2</sub>mGLB,  $\beta$ -NAG) and creatinine clearance. Measurements of microproteinuria and creatinine clearance were performed using a 12-h urine collection, which has been proved equivalent to a 24-h urine collection<sup>[21]</sup> or an 8-h urine collection<sup>[22]</sup>. The criterion of our choice was the better compliance of our patients. The clinical disease activity quantifications were performed on the day of urine collection, using reliable activity indices for UC<sup>[23]</sup> and CD<sup>[24]</sup>. All patients with UC underwent colonoscopy at the 1<sup>st</sup>, 3<sup>rd</sup>, and 4<sup>th</sup> stages of the study and an endoscopic index of the activity of UC (UCEI)<sup>[25]</sup> was calculated for these patients<sup>[25]</sup>. Finally, a detailed drug history was taken from all the patients to confirm the type, dose and duration of medication.

The blood samples for the measurement of serum levels of TNF- $\alpha$  after centrifugation were stored at -48 °C. The urine samples for the determination of urine levels of microalbumin were stored at 2-8 °C for a time not exceeding 2 weeks, at -20 °C for  $\beta$ <sub>2</sub>mGLB and at -48 °C for  $\beta$ -NAG, respectively.

Microproteinuria (mALB and tubular proteinuria) was correlated to patients' characteristics including sex, age, smoking habits; features of the diseases including activity, extent, duration, presence of extraintestinal manifestations; medication including type (mesalazine, corticosteroids, azathioprine) and duration. Furthermore, separate analyses of the courses of microproteinuria were conducted for patients with highly active disease at the time of their inclusion in the study and those with a first diagnosis of the disease, who did not receive any medication.

### Analytical techniques (chemical analysis)

Urea and creatinine in serum as well as creatinine in urine were measured with standard techniques. Serum CRP concentrations were determined by nephelometry.

Urinary albumin concentrations were measured using a radioimmunologic assay (<sup>125</sup>I radioimmunologic analysis, EURO/DPC, Glyn Rhonwy, UK), which could indicate

Table 1 Incidence of abnormal microproteinuria in patients with active and inactive IBD (%)

subtle increases in albumin excretion above the normal range but below that was detected by standard “dipstick” analysis (equivalent to a urinary albumin excretion rate of 20–200 µg/min)<sup>[26]</sup>.

Urinary β<sub>2</sub>mGLB concentrations were measured using a radioimmunologic assay (<sup>125</sup>I radioimmunologic analysis, RADIM)<sup>[27]</sup>.

Urinary β-NAG concentrations were determined colorimetrically using a commercially available kit (Boehringer-Mannheim, Germany). The optical density of the samples was measured at 580 nm (Cobas Bioanalyser, Roche). Results were calculated by reference to a standard curve<sup>[15,28]</sup>.

Serum TNF-α was measured using a sandwich enzyme-linked immunosorbent assay (ELISA; Quantikine, R&D Systems Inc., Minneapolis, MN, USA; sensitivity 0.35 pg/mL)<sup>[29,30]</sup>.

### Quantification of disease activity

The activity of UC was quantified using the UC activity index (UCAI) introduced by Rachmilewitz<sup>[23]</sup>. A score greater than or equal to six was considered to be suggestive of active UC. The activity of CD was estimated according to the Best CD activity index (CDAI)<sup>[24]</sup>. CD was considered to be active in cases with CDAI greater than 150. Finally, the endoscopic activity of UC was also evaluated according to a reliable endoscopic index established by other researchers<sup>[25]</sup>.

### Statistical analysis

The Mann-Whitney *U*-test, the Wilcoxon rank-sum *W*-test

and the Spearman's rank correlation test were used for statistical evaluation of the non-parametric data. Student's *t*-test was applied for statistical analysis of all parametric data. *P*<0.05 was considered statistically significant.

## RESULTS

Eighty-two out of eighty-six patients participating in three stages of the study (time: 0, 2<sup>nd</sup>, and 6<sup>th</sup> month) completed the follow-up. Twenty-seven of them participated in one more stage (time: 10<sup>th</sup> day). Two out of eighty-six patients participated in two stages (time: 0, 10<sup>th</sup> day) and two in one stage only (time: 0). A total of 277 distinct evaluations were performed in 86 IBD patients, 194 in patients with UC and 83 in patients with CD. The IBD was active in 38 out of 86 patients at the 1<sup>st</sup> stage, in none out of 27 patients at the 2<sup>nd</sup> stage, in 7 out of 82 patients at the 3<sup>rd</sup> stage and in 6 out of 82 patients at the 4<sup>th</sup> stage of the study.

Abnormal urine levels of albumin (>18 µg/min), β<sub>2</sub>mGLB (>120 µg/min) and β-NAG (>5.9 U/L) were found in 12.9%, 22.7%, and 11.3% of the patients with UC and in 6%, 27.7%, and 8.4% of those with CD, respectively, more frequently in active than in inactive disease (Table 1). The mean values of mALB, tubular microproteinuria and creatinine clearance in active and inactive IBD are shown in Table 2. No differences in albuminuria were found between active or inactive UC and CD. In contrast, significantly higher urine levels of β<sub>2</sub>mGLB were detected both in patients with active UC and in those with active CD. Urine levels of β-NAG were

*r<sub>s</sub>*: Spearman's correlation coefficient; *r<sub>P</sub>*: Pearson's correlation coefficient.

higher in active UC, but not in active CD.

#### Serum creatinine and its clearance

The levels of serum creatinine were normal in all the patients. Although creatinine clearance values varied widely, its mean values did not differ significantly between the patients with active and those with inactive UC (114.4 ± 6.03 mL/min *vs* 120.3 ± 3.24 mL/min, *P* > 0.10) as well as between the patients with active and those with inactive CD (135.6 ± 8.34 mL/min *vs* 127.7 ± 3.96 mL/min, *P* > 0.10). Our male IBD patients showed higher creatinine clearance values than female IBD patients (UC: 134 ± 3.19 mL/min *vs* 95 ± 4.07 mL/min, *P* < 0.001; CD: 137.1 ± 5.16 mL/min *vs* 118.8 ± 4.22 mL/min, *P* < 0.05). Creatinine clearance values were inversely correlated with the age of UC patients (ulcerative colitis: *r<sub>P</sub>* = -0.374, *P* < 0.001; CD: *r<sub>P</sub>* = -0.164, *P* > 0.10).

In addition, creatinine clearance values were higher in smokers with UC (smokers: 127 ± 4.04 mL/min; non-smokers: 114 ± 3.81 mL/min, *P* < 0.05) and in those with CD (smokers: 137.3 ± 4.50 mL/min; non-smokers: 113.1 ± 4.50 mL/min, *P* < 0.001). Finally, no correlation of creatinine clearance values with 5-ASA treatment was observed (UC patients treated with and without 5-ASA: 119 ± 3.11 mL/min and 117 ± 7.25 mL/min, respectively,

*P* = 0.987; CD patients treated with and without 5-ASA: 129 ± 4.05 mL/min and 130 ± 7.62 mL/min, respectively, *P* = 0.713).

#### Microproteinuria and IBD patients' parameters

No correlation was found between microproteinuria (mALB or tubular proteinuria) and the age or the sex of our IBD patients (data not shown). However, albuminuria was significantly lower in smokers with UC than in non-smokers (smokers: 8.22 ± 2.16 μg/min; non-smokers: 10.6 ± 1.23 μg/min, *P* = 0.021) and the urine levels of β-NAG were significantly lower in non-smokers with CD than in smokers (non-smokers: 1.62 ± 0.19 U/L; smokers: 2.93 ± 0.37 U/L, *P* = 0.023).

#### Microproteinuria and IBD activity

In our patients with UC, urinary concentrations of β-NAG were significantly correlated with the UCAI (*r<sub>s</sub>* = 0.26, *P* < 0.0005), the UCEI (*r<sub>s</sub>* = 0.23, *P* < 0.005) and the serum CRP levels (*r<sub>s</sub>* = 0.14, *P* < 0.05). Similarly, in these patients urinary levels of β<sub>2</sub> mGLB were significantly associated with the UCAI (*r<sub>s</sub>* = 0.2, *P* < 0.01) but not with the UCEI or the serum CRP levels (Table 4). On the contrary, the patients with CD did not show any correlation of tubular microproteinuria with the parameters of their disease activity (Table 5).

No significant relationship was found between the levels of mALB and the disease activity in patients with UC neither in those with CD (Tables 4 and 5). A significant association between mALB and serum levels of TNF-α was noticed only in UC patients. Finally, a history of recent or present extra-intestinal manifestations did not influence the levels of mALB and tubular microproteinuria in IBD patients (data not shown).

#### Microproteinuria and IBD duration and extent

A significant inverse relationship was found between the levels of mALB and the duration of UC (*r<sub>s</sub>* = -0.24, *P* < 0.001). In contrast, a tendency towards a positive association was noticed between the severity of mALB and the duration of CD (*r<sub>s</sub>* = 0.19, *P* = 0.078). No significant differences were found between the levels of microproteinuria (mALB and tubular microproteinuria)

**Table 5** Correlation between microproteinuria in patients with Crohn's disease and disease activity parameters ( $n = 83$  measurements)

		Crohn's disease activity parameters

**Figure 1** Correlation of IBD patients' microproteinuria (mALB,  $\beta_2\text{mGLB}$ ,  $\beta\text{-NAG}$ ) with 5-ASA treatment.

and the extent of UC (total *vs* left side colitis) as well as the extent of CD (small intestine+colon *vs* small intestine only).

### Microproteinuria and IBD therapy

No differences were found in the levels of mALB and tubular microproteinuria between the IBD patients who received or did not receive 5-ASA therapy (Table 3 and Figure 1). Moreover, no differences were found between the duration of 5-ASA treatment and the levels of mALB (UC:  $r_s = -0.06$ ,  $P = 0.43$ ; CD:  $r_s = 0.05$ ,  $P = 0.70$ ), the urinary levels of  $\beta_2\text{mGLB}$  (UC:  $r_s = 0.06$ ,  $P = 0.42$ ; CD:  $r_s = 0.17$ ,  $P = 0.16$ ) and  $\beta\text{-NAG}$  (UC:  $r_s = -0.02$ ,  $P = 0.77$ ; CD:  $r_s = 0.02$ ,  $P = 0.88$ ). The levels of microproteinuria were also similar in the patients treated and those not treated with corticosteroids and/or azathioprine (data not shown).

### Microproteinuria in the first-diagnosed patients with active IBD

Among the 30 IBD patients with a first diagnosis of the

**Figure 2** Changes of microproteinuria in the first-diagnosed patients with active IBD ( $n = 22$ ) before and after inducing remission.

disease at the time of their inclusion in this study, 22 had active IBD (17 had UC, 5 had CD). The 6-month course of mALB and tubular microproteinuria in the patients with an initially active IBD never treated with 5-ASA, exhibited a particular interest (Figure 2). In these patients, microproteinuria showed a tendency of gradual reduction by the time when IBD remission was achieved, although this reduction was statistically significant for  $\beta\text{-NAG}$  only.

### Microproteinuria in patients with severely active IBD

Twenty-seven of the patients (19 with UC, 8 with CD) were admitted to our hospital due to severely active disease. In these patients, we also evaluated the levels of microproteinuria in one more stage 10 days after the initiation of an intensive therapy (including corticosteroids). An early (10 days after) reduction of mALB ( $10.56 \pm 2.27 \mu\text{g}/\text{min}$  *vs*  $6.13 \pm 1.43 \mu\text{g}/\text{min}$ ,  $P < 0.01$ ) as well as urine levels of  $\beta\text{-NAG}$  ( $5.60 \pm 1.10 \text{ U/L}$  *vs*  $3.17 \pm 0.60 \text{ U/L}$ ,  $P < 0.05$ ) and  $\beta_2\text{mGLB}$  ( $241.2 \pm 96.82 \mu\text{g}/\text{min}$  *vs*  $99.6 \pm 33.33 \mu\text{g}/\text{min}$ ,  $P > 0.10$ ) was observed.

## DISCUSSION

Although the incidence of renal complications is relatively low in patients with IBD, none of our patients developed clinically significant renal disease. No significant changes in serum creatinine and its clearance were recorded during the 6-month follow-up period. Furthermore, creatinine clearance was not correlated with the type, activity or the extent of IBD, which is in accordance with the majority of the published studies<sup>[13-17]</sup>.

We observed a moderately abnormal mALB in 12.9% and 6% of our patients with UC and CD, respectively, which is in agreement with Fraser *et al.*<sup>[13]</sup>, Riley *et al.*<sup>[15]</sup>, Bonnet *et al.*<sup>[31]</sup> and Zehnter *et al.*<sup>[32]</sup>. Increased mALB reliably predicts diabetic nephropathy and an increased incidence of cardiovascular-related morbidity and mortality in diabetic and hypertensive patients as well as in the elderly<sup>[18,33,34]</sup>. Moreover, mALB has been described as a non-specific marker for acute illness<sup>[35]</sup>, most probably as a result of the acute phase response to inflammatory

mediators. It has been suggested that mALB in IBD patients may result from increased renal microvascular permeability in response to increased circulating cytokines<sup>[14,30,36]</sup>. This hypothesis is compatible with our finding of a significant relationship between mALB and serum TNF- $\alpha$  levels in our UC patients ( $P < 0.05$ ), a thesis which is also supported by other researchers<sup>[13,15,31,32]</sup>.

We did not find any significant correlation between the levels of mALB and the IBD activity, which is in agreement with many published studies<sup>[13,15]</sup>. In contrast, Mahmud *et al.*<sup>[14,37]</sup> found that increased mALB in the vast majority of IBD patients is related to both clinical and histopathological activities of the disease. Differences between these studies may be attributed to the varied disease activity. In our study, a relatively small proportion of the patients had a considerable disease activity.

Abnormal tubular microproteinuria, reflecting sub-clinical tubular damage, is a quite common finding among IBD patients<sup>[15,17]</sup>. However, its incidence varies widely<sup>[13-17,31,32,38]</sup>, from 0% in the studies by Biddle *et al.*<sup>[38]</sup> ( $\beta$ -NAG and  $\beta$ 2mGLB) and Mahmud *et al.*<sup>[14]</sup> (glutathione-S-transferase) to 75% in the study by Bonnet *et al.*<sup>[31]</sup> ( $\gamma$ -glutamyl transferase and alkaline phosphatase). Hitherto, it has been difficult to prove whether tubular microproteinuria results from the effect of 5-ASA or is an extra-intestinal manifestation of the IBD itself<sup>[13]</sup>. Its structural similarity to other salicylates and non-steroidal anti-inflammatory drugs has led to the speculation that 5-ASA may cause tubulointerstitial damage of the kidney<sup>[11]</sup>.

A significant correlation between tubular microproteinuria and IBD activity was found only in our patients with UC. This might be due to the fact that our patients with severely active CD were much fewer than those with UC. Kreisel *et al.*<sup>[17]</sup> have observed an increased urinary  $\beta$ -NAG excretion in 28% of the patients with UC and in 19% of those with CD, especially higher in active disease. Schreiber *et al.*<sup>[28]</sup> acknowledged their inability to determine whether high levels of tubular microproteinuria are attributable to the severity of the disease's activity or 5-ASA treatment (or both), since 11% of their patients not receiving 5-ASA also had a tubular microproteinuria. Fraser *et al.*<sup>[13]</sup> found that urinary excretion of  $\beta$ -NAG and  $\alpha$ 1-microglobulin was increased in 48% and 52% of patients with IBD at diagnosis, respectively. A positive relationship between the urine levels of several tubular proteins and the IBD activity has been proposed by the majority of the investigators<sup>[13-17,31,39]</sup>. In contrast, Zehnter *et al.*<sup>[32]</sup> showed that increased urine levels of  $\beta$ 2-mGLB, alanine aminopeptidase and  $\beta$ -NAG in IBD patients were not correlated with the disease activity.

In this study, 22 first-diagnosed patients with active IBD had increased levels of tubular microproteinuria at diagnosis, which decreased after treatment with corticosteroids and 5-ASA. Moreover, 27 IBD patients with severely active disease manifested an early significant decrease of both microalbuminuria and tubular microproteinuria after being treated with corticosteroids. In addition, we found that there was a positive relationship between microalbuminuria and serum TNF- $\alpha$  levels, as well as between tubular microproteinuria and serum CRP

and TNF- $\alpha$  levels, suggesting that microproteinuria in IBD patients may be related to a systemic inflammatory response and that it is an extra-intestinal manifestation of the active disease rather than a consequence of a subclinical renal injury due to 5-ASA treatment<sup>[13,15,17,20,31,32,37]</sup>. However, We did not find any differences in the severity of microproteinuria between the IBD patients with and those without a recent or present extra-intestinal manifestation of the disease, which is in agreement with Kreisel *et al.*<sup>[17]</sup> and Mahmud *et al.*<sup>[30]</sup>.

Activation of the intestinal immune system, production of inflammation mediators or imbalance between activating and suppressing mediators play a pivotal role in the pathogenesis of IBD. In particular, TNF- $\alpha$  may play an important role in the inflammatory cascade of IBD and increased serum TNF- $\alpha$  levels have been reported in active IBD<sup>[40]</sup>. It has been reported that interleukin-1 and TNF- $\alpha$  inhibit the synthesis and induce a shedding of cell surface glycosaminoglycans<sup>[41]</sup>, which might lead to an increased microvascular permeability and tissue damage<sup>[36,42]</sup>.

No relationship was found between the severity of microproteinuria and the extent as well as the duration of IBD in our study, which is in concordance with other studies<sup>[14,20,32,43]</sup>. It is worth emphasizing on our finding of a significant correlation between microproteinuria and the smoking habit, which was negative in UC and positive in CD, because smoking alters the colonic mucosal blood flow<sup>[44]</sup> and decreases its permeability. Epidemiologic data suggest that smoking exerts a protective effect against UC<sup>[45]</sup> and is harmful to CD<sup>[45,46]</sup>. Consequently, differences in microproteinuria between smokers with UC and those with CD may be related to these pathophysiologic and epidemiologic data.

In this study, mALB was not correlated with the IBD treatment as it is almost universally accepted<sup>[13,15,31,32,37]</sup>. In addition, using sensitive markers of renal tubular toxicity<sup>[19]</sup>, we were unable to find any evidence that treatment with mesalazine, corticosteroids or azathioprine was related to an increased tubular damage. However, this lack of correlation does not necessarily exclude nephrotoxicity. A potential nephrotoxicity of aminosaliclates, although rare, remains an existent possibility<sup>[11]</sup>.

Riley *et al.*<sup>[15]</sup> showed that there was no evidence of nephrotoxicity in a cohort of patients with quiescent UC receiving mesalazine or sulfasalazine. Furthermore, Kreisel *et al.*<sup>[17]</sup> have demonstrated that there is no positive relationship between the cumulative dose of 5-ASA and the severity of tubular microproteinuria. In accordance to these studies, we observed that tubular microproteinuria in patients with active IBD at diagnosis decreased after inducing remission of the disease, even though the patients received the treatment with 5-ASA and corticosteroids. Fraser *et al.*<sup>[13]</sup> have demonstrated that both the prevalence and degree of tubular microproteinuria in patients with a new diagnosis of IBD are relatively unaffected by 5-ASA treatment, which is in agreement with a number of studies<sup>[14,38,43,47]</sup>. In contrast, Schreiber *et al.*<sup>[20]</sup> have reported that there is a positive relationship between tubular microproteinuria and cumulative 5-ASA exposure, but they questioned whether their study could provide a definite answer to the possible impact of chronic inflammation on

microproteinuria. A similar positive relationship between tubular microproteinuria and 5-ASA treatment has also been reported<sup>[31,32]</sup>.

In conclusion, abnormal mALB and tubular microproteinuria are quite frequent in IBD patients. Subclinical renal tubular and/or glomerular damage are related to the IBD itself, representing an extra-intestinal manifestation of the disease. Moreover, treatment with 5-ASA does not affect microproteinuria in IBD patients, microproteinuria in IBD patients does not predict an adverse renal response to 5-ASA.

## Abstract

**AIM:** To assess the efficacy and safety of a compound containing alginic acid plus antacid (Topaal®) compared to equal-strength antacid (Nacid®) in patients with endoscopy-negative reflux disease (ENRD).

**METHODS:** A total of 121 patients with ENRD were randomized to receive Topaal® (65 patients) or Nacid® (56 patients) for 6 weeks, with a consultation every 3 weeks. The primary end-point assessment was the change in the severity of heartburn as evaluated using a visual analog scale (VAS) at 6 weeks. The secondary end-point assessments were the VAS at 3 weeks, the change of frequency of the reflux symptom, the change of quality of life and the adverse effects.

**RESULTS:** Demographics of randomized subjects in each treatment group were comparable except that the Topaal® group included more males. The baseline characteristics between the groups were similar. After 6 weeks of treatment, the reduction of VAS of heartburn was more prominent in the Topaal® group (-6.29 cm vs -4.11 cm). At the 3<sup>rd</sup> week, Topaal® group showed greater reduction of VAS for heartburn ( $P=0.0016$ ), regurgitation ( $P=0.0006$ ), vomiting ( $P=0.0373$ ), and belching ( $P<0.0001$ ). The patients of the Topaal® group had lower frequency of heartburn ( $P=0.0015$ ) and pain ( $P=0.0163$ ) at the end of the 6-week treatment period. From the doctor's point of view, the Topaal® group also showed significant reduction in the severity of heartburn ( $P=0.0020$ ), regurgitation ( $P=0.0081$ ), vomiting ( $P=0.0182$ ), and belching ( $P=0.0018$ ) at the end of the treatment. The improvement of the quality of life was

more remarkable in the Topaal® group at the end of the 6-week treatment period ( $P<0.0001$ ). For the adverse effect, there was no difference in both the groups.

**CONCLUSION:** Topaal® is more effective than Nacid® for the treatment of symptoms presented by patients with ENRD.

## INTRODUCTION

The incidence of gastroesophageal reflux disease (GERD) in Taiwan has been increasing. According to the endoscopic surveillance reports, the rate of erosive esophagitis in Taiwan has increased from 2.4% to 14.5% in the past 20 years<sup>[1,2]</sup>.

GERD is a disorder in which the gastric contents are refluxed into the esophagus, causing irritation and injury to the esophageal mucosa<sup>[3]</sup>. The typical symptoms of GERD include heartburn and regurgitation. Less common symptoms or symptoms suggestive of more aggressive reflux disease include dysphagia, odynophagia, or gastrointestinal bleeding. Atypical complaints include chest pain, hoarseness, sore throat, chronic cough, and asthma<sup>[3]</sup>. It has been shown that defective lower esophageal sphincter (LES) is the major mechanism underlying in most patients with reflux<sup>[4]</sup>.

Endoscopy is the most common diagnostic tool to grade and to define GERD. However, only one-third of patients with GERD have esophageal mucosal erosion or ulceration<sup>[3]</sup>. Patients who experience typical heartburn despite that no evident mucosal lesions found at endoscopy are defined to have endoscopy-negative reflux disease (ENRD)<sup>[5]</sup>. Compared with patients who have reflux-related erosive esophagitis, those with ENRD

are more likely to be younger, of lower body weight, and without a hiatal hernia<sup>[6]</sup>. Approximately 50% of those with ENRD have abnormal intra-esophageal acid exposure<sup>[6]</sup>. Although persons with ENRD experience similar decrements in their quality of life as those for individuals with erosive esophagitis, their complaints were often ignored if the diagnosis and treatment are based only on endoscopic finding. It has been proposed that the analysis of symptoms is probably the most useful method for the diagnosis of GERD<sup>[7]</sup>. The pharmacological treatment of ENRD comprises two therapeutic classes: (1) local antacids or anti-secretory drugs including histamine receptor and proton pump inhibitors (PPI)<sup>[8]</sup>, which act by decreasing the acidity of the reflux contents; (2) alginates which act by decreasing the gastric reflux into the esophagus and by protecting the esophageal mucosa<sup>[9]</sup>. PPI were shown to provide symptom relief in patients with ENRD<sup>[8,10]</sup> but these treatments are not curative and not cheap. A cohort study of patients with ENRD has shown that after a median time of 10 years following the original diagnosis, 75% of patients are on prolonged antisecretory therapy because of recurrent symptoms/lesions of gastro-esophageal reflux disease<sup>[11]</sup>. The study confirms that ENRD is a protracted disease, which requires long-term medical therapy in most of the patients. Besides, Taiwan's reimbursement system covers the PPI only when patients have endoscopic evidence of erosive esophagitis. Local antacid and alginates are more convenient and cheap options for patients with ENRD<sup>[9]</sup>. However, there were few studies comparing the efficacy of these two classes of drug on the treatment of ENRD. We therefore carried out a prospective, randomized trial comparing the efficacy and tolerance of sodium alginate (Topaal®) vs antacid (Nacid®) in the treatment of patients with ENRD.

## MATERIALS AND METHODS

### Selection of patients

**Disease definition:** All patients who presented with the classic symptoms including heartburn and/or regurgitation, but who did not have either Barrett's esophagus or definite endoscopic esophageal mucosal breaks (esophageal mucosal erosion or ulceration) were referred to have ENRD<sup>[7,10]</sup>.

**Entry procedures:** The patients prior to the participation in this study signed the informed consent document, which has been approved by an ethical review board of National Taiwan University Hospital.

This study enrolled outpatients of both sexes, who were aged between 18 and 75 years, and were diagnosed to have ENRD. The included patients were asked to discontinue antacid, metoclopramide, cisapride, H<sub>2</sub> blocker and PPI for at least 3 days before entering the study. Those patients who had a history of intolerance or allergy to alginic acid and antacid, endoscopic evidence of esophagitis, history of partial or total gastrectomy, or had esophageal stricture, pregnancy or lactation were excluded from the enrollment.

### Study endpoints

**Primary efficacy endpoint:** The primary efficacy endpoint was the change in the severity of heartburn as evaluated by using a visual analog scale (VAS) at the 6<sup>th</sup>

week of treatment compared to baseline in the intention-to-treat (ITT) population. The VAS<sup>[12,13]</sup> is a 100-mm straight line with anchors (0 cm indicated no symptom and 10 cm indicated terrible) placed at both poles. Patients were asked to place a mark somewhere along the line that best described the actual status of their symptoms. The ITT population was defined as randomized patients who received at least one dose of study medication, had a baseline value and at least one post-baseline efficacy assessment. In this analysis, data from the Topaal® group were compared with data from Nacid® group.

**Secondary efficacy endpoints:** There were three secondary endpoints evaluated in this trial: (1) the change in the severity of reflux symptoms including heartburn, regurgitation, dysphagia, epigastric pain, nausea, vomiting and belching by VAS at the 3<sup>rd</sup> week of treatment compared to baseline; (2) the change in the frequency of heartburn, regurgitation, pain, and sleeping disturbance according to patient's diary; and (3) the change in the quality of life from doctor's point of view. All of these secondary efficacy endpoints were assessed in the ITT population.

During the 7<sup>th</sup> day before the first visit and the entire study period, each patient had to record the frequency (number of episodes per day) on the patient's diary. Each patient was asked to record the symptom of reflux disease at the moment it happened. At least a 4-d record in a week was necessary for this evaluation.

The patient's quality of life judged by the investigator's point of view was graded by modified visick grading<sup>[11]</sup> on each visit as the following scores: no symptoms (= 1), mild symptoms easily controlled (= 2), moderate symptoms not controlled but not interfering daily life (= 3), moderate symptoms interfering daily life (= 4), and symptoms as bad or worse (= 5).

**Safety endpoint:** The incidence of adverse drug reaction (ADR), whether reported spontaneously, elicited by questioning, or observed by the investigators, of both Topaal® and Nacid® groups was calculated in the safety population. Safety population was defined as patients who received at least one dose of study medication after randomization. The ADR was recorded and graded according to the WHO definition<sup>[14]</sup>. The investigators also assessed the causal relationship of any adverse event to the study medication by using the ADR probability scale which was generated from Naranjo *et al*<sup>[15]</sup>.

All routine laboratory variables (hematology and serum chemistry) were recorded at each visit. Every assessment was compared with baseline values.

### Allocation of patients

This was a prospective, randomized, open-label and active-controlled study. Doctors prescribed the test drugs according to the random number sheet, which is generated by SAS. Eligible patients were allocated the next sequential patient number based on preprinted numbers on the study drug labels.

Patients with symptomatic GERD will underwent endoscopy. Randomization occurred within 7 days of the baseline endoscopy. Patients with ENRD were enrolled into the study and then randomly allocated to treat with

Symptom as bad/worse	31 (23.1)	15 (21.7)	16 (24.6)	

<sup>1</sup>Fisher's exact test; <sup>2</sup>ANOVA model; <sup>3</sup>Mantel-Henszel test; VAS: visual analog scale.

either Topaal<sup>®</sup> or Nacid<sup>®</sup>. No other medical treatment for reflux esophagitis such as other antacid, metoclopramide, cisapride, H<sub>2</sub> blocker and PPI was allowed.

The duration of treatment was 6 wk and each patient returned for assessment every 3 wk. At randomization (visit 1) and visit 2, all patients will received one plastic bottle of study medication. Every bottle contains 200 chewable tablets of Topaal<sup>®</sup> or Nacid<sup>®</sup>, including 4-day supply in the event of a delay in the scheduled appointment. The dosage of Topaal<sup>®</sup> and Nacid<sup>®</sup> is two chewable tablets t.i.d. and h.s.
