Abstract

The purpose of this article is to review the evidence regarding transmission of infection during gastrointestinal endoscopy, factors important in endoscope reprocessing and infection control, areas to focus on to improve compliance, and recent developments and advances in the field.

INTRODUCTION

Gastrointestinal (GI) endoscopy is an important tool for the identification and treatment of disorders of the gastrointestinal tract. A thorough understanding of infection control and its application to GI endoscopy is crucial to prevent lapses in reprocessing and the possibility of transmission of infection. Endoscopes reprocessed appropriately, in accordance with reprocessing and infection-control guidelines, pose virtually no risk of transmission of patient-borne or environmental microorganisms. In the absence of defective equipment, every reported case of nosocomial infection associated with a contaminated GI endoscope has been linked to a specific breach or violation of at least one of several requisite reprocessing steps^[1].

TRANSMISSION OF INFECTION DURING GASTROINTESTINAL ENDOSCOPY

In a recent review of the published medical literature and the US FDA database, only 35 cases of transmission of infection during GI endoscopy have been reported in the last decade (again, all of which have been associated with breaches in reprocessing protocols)^[1]. It has been estimated that 17 million lower GI procedures (colonoscopy and flexible sigmoidoscopy) are performed annually in the U.S.^[2], and a similar number of upper GI procedures are performed^[3,4]. If this procedure rate was constant during the past decade, these 35 cases occurred during an estimated 340 million procedures, yielding an infection rate that approaches 1 in ten million procedures. It is very likely that this simple calculation underestimates the actual incidence of transmission of infection, (unreported or unrecognized infections), however it does put the documented risk into perspective. Even if reported infections represented only 1% of the actual infection rate ("tip of the iceberg"), the transmission rate would be extremely low. We review the published literature with regard to documented cases of transmission of infection. Although there are few published data regarding some novel pathogens (SARS, Avian Influenza), their physical properties and anticipated susceptibility to current disinfection practices are discussed.

Viruses

Hepatitis C virus (HCV): There have been 8 cases of HCV transmission that have attributed to gastrointestinal endoscopy^[5-10]. A serious attempt at investigation (other than temporal association) and genotyping was performed in only three cases, in which transmission was firmly established by nucleotide sequencing^[7,8]. While both reports implicated inadequate disinfection of the colonoscope, they each also raised the possibility of contamination of syringes or multi-dose vials as the source of transmission. There have been several epidemiologic studies that have suggested an association between gastrointestinal endoscopy and HCV infection from several countries^[11-18]. The relevance of these observations may be limited. All of the studies relied on self-reports of exposure risks, which are unreliable for many of the socially stigmatized behaviors associated with hepatitis C virus (HCV) transmission, particularly IV substance abuse^[19]. A major concern for studies utilizing cross-sectional methodology is the inability to verify when infection occurred relative to

the procedure (i.e., the studies do not establish causality). It is not known whether currently accepted reprocessing protocols were being used during the periods under study, or even the degree to which endoscope reprocessing complied with these protocols. Finally, compliance with general infection control practices was not assessed, and the improper use (or reuse) of syringes and multiple-dose vials for sedation is increasingly recognized as an important risk factor for pathogen transmission^[20-23]. In a particularly notable example in 2001 it was extensively reported in the lay press that eight individuals having undergone endoscopy at a New York City endoscopy center had become infected with hepatitis C. Although initial reports suggested that it was due to the endoscopic equipment, a subsequent investigation by the New York City Department of Health concluded that the cause was in fact not the endoscopy, but rather improper handling of contaminated needles, syringes, and or multi-dose vials^[24]. Although transmission of infection resulted from a contact with the medical system, it did not reflect on the adequacy of endoscope reprocessing. Unless this aspect is controlled for in epidemiologic studies, the resulting association might reflect more on the need for better general infection control measures, rather than focusing on changes in endoscope reprocessing.

In fact, there are numerous studies demonstrating that HCV can be completely removed/eradicated from endoscopes during reprocessing^[25-29]. It could be argued that these results are somewhat artificial, and do not represent the state of endoscope reprocessing out in the community, i.e. endoscope reprocessing may have been more rigorous in the setting of the study. However, a landmark study comprising 8260 patients undergoing endoscopy who were tested for HCV seropositivity before and 6 mo after the procedure found no cases of seroconversion^[30]. This large study is the best evidence that appropriate endoscope reprocessing as performed in the community effectively prevents the transmission of hepatitis C virus.

Human immunodeficiency virus (HIV): While HIV may arguably be the most concerning pathogen for transmission of infection, it is actually a fragile virus that is highly susceptible to chemical disinfection. Mechanical cleaning alone can often completely remove the virus from contaminated endoscopes, and complete chemical disinfection is easily accomplished with glutaraldehyde^[26,31-34]. There are no reported cases of endoscopic transmission of HIV in the world literature.

Hepatitis B virus (HBV): There have been 5 cases of HBV transmission attributed to GI endoscopy^[6,35-38]. In the two cases reported by Morris and Birnie, reprocessing practices now known to be insufficient were used (failure to disinfect between patients, and when performed at the end of the day an inadequate disinfectant was used; failure to brush all channels in the second report)^[35,37]. The case mentioned in the introduction of the report as the impetus for the study by Seefeld in 1981 gives no details about the reprocessing practices and thus it is difficult to ascertain whether these were adequately performed. Reprocessing practices common at that time (now known to be suboptimal) included failure to disinfect between patients,

being performed only at the end of the day, the use of inadequate disinfectants, or inadequate exposure times^[39,40]. Fully immersible endoscopes were not introduced until 1983 (leaving a substantial part of the endoscope unexposed to the disinfectant) and the nature of the report suggests that the use of an aldehyde disinfectant was a new practice. In two later cases reported by Davis and Federman^[6,38], the association with endoscopy may be spurious. In each case, no investigation was performed to substantiate the association or evaluate other possible etiologies of transmission; in each case HBV infection was simply attributed to a prior colonoscopy due to the absence of self-reported risk factors. There are a number of prospective studies in which patients were followed for serologic evidence of HBV transmission following endoscopy. In six studies, a total of 223 patients in whom endoscopy was performed with an instrument known to have been used on a patient with HBV were followed for 6 mo; there were no seroconversions^[41-46]. Three other studies conducted in patient populations with relatively high rates of HBV infection followed a total of 600 seronegative patients for up to one year after endoscopy and found no episodes of seroconversion attributable to endoscopy^[47-49]. What makes these findings even more remarkable is that the reprocessing in all of the studies was, by current standards, suboptimal (endoscope "disinfection" performed with detergents rather than disinfectants, use of low-level disinfectants, or in one study exposure to glutaraldehyde for less than two minutes) implying that current reprocessing standards may provide an additional safety margin.

SARS-associated coronavirus (SARS-CoV): Severe acute respiratory syndrome is a recently identified, potentially fatal atypical pneumonia clinically characterized by fever, cough, myalgias, and shortness of breath. It was first recognized in 2003 in the Guangdong Province of China, but has since affected more than 8000 people in 25 countries across 5 continents. The etiologic agent has been identified as the SARS-associate coronavirus (SARS-CoV), a virus not previously endemic to humans. The mechanism of transmission is predominantly infectious respiratory droplets, although aerosolization and fomites may also be contributory^[50]. SARS CoV has been identified in respiratory secretions and feces, and can be found in intestinal epithelial cells of affected individuals, suggesting that GI endoscopes can be exposed to potentially infectious material^[51,52]. It is not known whether the virus can be transmitted *via* the oral route. One recent study evaluated a variety of hand and surface disinfectants (low-level disinfectants), as well as a glutaraldehyde-based medical instrument disinfectant. The study found that SARS-CoV was readily inactivated by all the disinfectants^[53]. Thus it appears likely that current reprocessing protocols and high-level disinfectants are adequate to prevent transmission of the virus as a result of endoscopy itself; there are no published reports of transmission of SARS *via* contaminated GI endoscopes. However, the endoscopy suite itself may serve as a vector of transmission (including the health care workers in it), and the most important factors in preventing nosocomial transmission are respiratory precautions (face masks) and appropriate hand hygiene^[54].

Avian influenza A virus (H5N1): The H5N1 virus is a specific subtype of the avian influenza A virus that has recently received significant media attention. This virus infects the respiratory and gastrointestinal tracts of poultry, is highly contagious, spreads rapidly, and has been identified as the cause of several recent outbreaks of avian influenza in a number of countries. Of greatest concern to public health, this avian influenza virus can mutate quickly and cross the species barrier. Once thought to be exclusive to birds, the H5N1 virus was first reported to infect humans in Hong Kong in 1997^[55]. Since then, more cases of human infection with this highly pathogenic strain have been reported in Asia. These cases resulted from direct or close contact with infected poultry, infected respiratory tract secretions and feces, and/or contaminated environmental surfaces. Person-to-person transmission of the H5N1 influenza virus has also been reported but to date this mode of transmission appears to be very limited. The recent surge of the H5N1 (avian influenza) virus has raised questions about whether current endoscope disinfection protocols are sufficient in the healthcare setting to prevent its transmission. Although there are few data specific to GI endoscopy, there are several reasons to suggest that current reprocessing guidelines are sufficient. Because the natural reservoir hosts of the virus are waterfowl, the risk of nosocomial patient-to-patient transmission during any type of surgical/endoscopic procedure is (currently) negligible. Geographically, there have been no reported cases in North America. More importantly, the H5N1 virus is lipid-enveloped, and like other viruses in this class (e.g. other influenza viruses, SARS virus, HIV), they are the easiest to inactivate by physical or chemical decontamination methods compared to all other types of pathogenic microorganisms. An EPA-registered cleaner/disinfectant labeled to achieve low-level (or intermediate-level) disinfection is sufficient to remove and destroy virtually all enveloped viruses including the H5N1 virus. Therefore, current recommended reprocessing practices for GI endoscopes and other types of flexible endoscopes—specifically, cleaning, followed by at least high-level disinfection and drying—provide a sufficient margin of safety to prevent GI endoscopes from transmitting the H5N1 virus from patient-to-patient. Additionally, cleaning followed by either low-level disinfection (which lacks a tuberculocidal claim) or intermediate-level disinfection (which includes a tuberculocidal claim, but not a sporicidal claim) of environmental surfaces (e.g., bedside tables, bed stands, table tops) are similarly sufficient to destroy the H5N1 virus and prevent its nosocomial spread. Review of the cleaner/disinfectant's label is necessary to ensure proper dilution and adequate contact time to effect its outcome. Frequent hand washing is also necessary to prevent transmission of the H5N1 virus.

Bacterial infections

Salmonella: Since 1974, there have been 48 cases of endoscopic transmission of various *Salmonella* species^[56-64]. Each of these cases has been associated with at least one breach in currently accepted reprocessing guidelines, usually a failure to mechanically clean the internal instrument channel, although the use of an inappropriate

disinfectant, or an inadequate disinfection time were also common. It is interesting to note that there have been no reported cases of salmonella transmission since the publication in 1988 of standardized cleaning and disinfection recommendations from the American Society of Gastroenterology (ASGE), the Society for Gastrointestinal Nurses and Associates (SGNA), and the British Society of Gastroenterology (BSG)^[65,66].

Pseudomonas aeruginosa: *Pseudomonas aeruginosa*, a Gram-negative bacillus that is an opportunistic pathogen found widely in the environment, is of particular concern in the endoscopy setting due to its predilection for a moist environment (e.g., endoscope water/irrigation systems, wet internal channels after reprocessing, or even the hospital water supply itself). Unlike *salmonella*, which does not appear to be a persistent infection control problem, *Pseudomonas aeruginosa* continues to pose a challenge to endoscope reprocessing, and is the most commonly reported organism responsible for transmission of infection during endoscopy. There have been 216 reported cases of *Pseudomonas aeruginosa* transmission^[67-83]. While early reports of pseudomonas infection resulting from endoscopy were most commonly related to inadequate cleaning or the use of inadequate disinfectants, later reports tend to implicate three major areas: (1) the automated endoscope reprocessor (AER) or the water supply to the endoscope that become colonized with the organism, (2) failure to disinfect the elevator channel of duodenoscopes, and most importantly, (3) failure to completely dry any or all channels of the endoscope with a 70% alcohol solution and forced air.

H pylori: There have been 12 reported cases of *H pylori* infection that have been attributed to endoscopic transmission^[84-88]. In each case, suboptimal cleaning and disinfection were implicated (most commonly an inappropriate liquid chemical germicide, or LCG). Several studies have addressed whether current reprocessing protocols are sufficient to eradicate the organism. Three studies reported the presence of the organism after cleaning and disinfection (2 using culture methods and the third using PCR amplification)^[89-91]; however in two of the studies an inadequate exposure time to the LCG was used, and in the third the reprocessing protocol was not described at all. In a study using both manual and automated disinfection, well-described conventional reprocessing protocols consistent with currently accepted guidelines resulted in 100% eradication of the organism as determined by PCR analysis^[92]. Of interest, there have been numerous studies suggesting a higher incidence of *H pylori* in healthcare workers, and in most studies particularly endoscopy-related staff, than in age-matched controls^[93-104]. Four studies, however, found no such association^[105-108], although it has been suggested that failure to find an association may be due to inadequate study power or residual confounding from other exposure risks. The possibility of transmission of pathogens from patients to health care workers underscores the need for good general infection control practices, including the use of appropriate personal protective equipment (PPE), such as gloves, gowns, masks and protective eyewear.

Miscellaneous Organisms: One study raised the

possibility of 2 cases of endoscopic transmission of *Tropheryma whipplei*, the organism responsible for Whipple's disease, although this conclusion is tenuous at best. The sole rationale for this association was that each patient had undergone an endoscopy for upper gastrointestinal tract symptoms approximately 3 years preceding the final diagnosis^[109]. Given the rarity and novelty of the disease, it would not be difficult to determine if any other cases had been reported at the institution, and whether or not they had undergone endoscopy prior to either index case, thus providing at least a temporal association. The authors themselves make the point that the organism has a very slow growth rate, and a more plausible explanation is that the initial procedure was performed for symptom investigation in patients that already harbored the organism in an early stage of the disease that was simply undetected. There are also methodologic problems that undermine the conclusions of the article about the *in-vitro* resistance of the organism to high-level disinfection^[110]. Two studies have reported transmission of various *Enterobacteriaceae* strains during biliary endoscopy (ERCP), including *E. coli*, *Klebsiella*, *Enterobacter*, and *Serratia marcescens*^[82,111]. In both studies, flaws in the cleaning and disinfection process were noted.

Transmissible spongiform encephalopathy (TSE)

Creutzfeldt-Jakob disease (CJD) and variant CJD (vCJD) are degenerative neurological disorders known as transmissible spongiform encephalopathies (TSEs). These disorders are associated with aberrant proteins referred to as prions. The incubation period from acquisition to overt clinical disease is thought to range from months to years (in some cases decades). Prions present a unique challenge to endoscope reprocessing because of their extraordinary resistance to traditional disinfection and sterilization processes. Because endoscopic procedures such as percutaneous endoscopic gastrostomies (PEGs) are commonly performed on patients with dementia that may harbor occult TSEs, concern had been expressed that endoscopy may serve as a vector for transmission of these agents.

Creutzfeldt-Jakob disease (CJD): CJD is the most common form of TSE, and approximately 90% of CJD is sporadic^[112,113]. Iatrogenic transmission has been reported after use of contaminated neurosurgical equipment, or after inadvertent inoculation with infectious materials (dura matter grafts, pituitary hormones). From animal studies, transmission is most efficient with intracerebral or intracranial inoculation; peripheral (extracranial inoculation) requires substantially larger doses. Unfortunately, there is general agreement that currently available liquid chemical germicides used for high level disinfection of gastrointestinal endoscopes are unable to eliminate prion infectivity. Although one study claimed to show that peracetic acid could inactivate prion protein^[114], the controls (without peracetic acid) also demonstrated the absence of detectable protein after two cycles. Other studies have demonstrated that peracetic acid is unable to reliably inactivate prions^[115-118]. While oral transmission has been reported in primates, it requires ingestion of large

quantities of highly infectious material^[119]. Although prions have recently been found in the spleen, skeletal muscle, and olfactory epithelium of individuals with sporadic CJD^[120,121], fortunately, they are not found in bodily secretions or gut mucosa^[122,123]. Because gastrointestinal endoscopes do not contact prion-containing tissue or secretions, and even trace contamination would be reduced or eliminated with simple mechanical cleaning, thus rendering any potential inoculum far below the threshold for oral acquisition, infection control experts have stated that currently accepted cleaning and disinfection protocols should be adequate for reprocessing endoscopes^[113,124,125]. The adequacy of current guidelines for endoscope reprocessing with regard to CJD are supported by the fact that there have been no reported cases in the world literature of transmission of CJD or other TSEs by endoscopy.

Variant Creutzfeldt-Jakob disease (vCJD): Variant Creutzfeldt-Jakob disease (vCJD) is a more recently described TSE that is believed to be caused by the consumption of contaminated beef products containing the bovine spongiform encephalopathy (BSE) agent^[126]. The disease may also require a person to have a susceptible genotype. To date approximately 155 cases of vCJD have been reported in the world. The one reported case in the United States was found in a 22 year-old patient that had contracted the disease in the UK and developed symptoms after moving to the US^[127]. Unlike CJD, the prions associated with vCJD can be detected in the lymphoid tissue of affected individuals (although at much lower concentrations than the CNS), notably the tonsil, the appendix, and possibly the ileum and rectum (with obvious relevance to GI endoscopy)^[126,128-131]. However, this tissue was approximately 50% less infective than CNS tissue when homogenated and injected intracerebrally in mice^[132]. The infectivity of intact tissue that might be encountered at endoscopy and subsequent transmissibility is unknown, but would presumably be much lower. Given the virtual absence of this disease in the US, rigorous adherence to current guidelines for the cleaning and disinfection of endoscopes would seem to be the best protection for the public. There is no evidence that changes to current endoscopic practices or endoscope reprocessing guidelines are warranted, but these should be responsive to new information as it evolves. The fact that the risk of transmission of prions associated with CJD or vCJD is negligible should not be seen as advocating complacency. In the absence of an endoscope-compatible germicide that can completely and reliably inactivate prion infectivity, there is a window of vulnerability (albeit a small one) and further work is needed. Conversely, we should not rush to adopt a new technology without considering the overall risk to the patient. As an example, the adoption of single-use surgical equipment for tonsillectomy in the UK (to prevent the theoretical risk of prion transmission) actually led to a substantial increase in the rate of postoperative hemorrhage, and subsequently the recommendation was abandoned by health authorities in the UK^[133-135].

ENDOSCOPE CLEANING AND DISINFECTION

The US Multi-Society guidelines and the WGO-OMGE/OMED guidelines provide comprehensive recommendations for reprocessing gastrointestinal endoscopes^[136,137]. Briefly, endoscope-reprocessing is a three-stage process that includes: (1) pre-processing, or cleaning the endoscope and its detachable components using a detergent solution and brushes; (2) processing, or high-level disinfection of the endoscope using an LCG (in the US, cleared by the Food and Drug Administration [FDA]) followed by thorough water rinsing to remove residual LCG from the instrument; and (3) post-processing, which includes proper handling and storage of the endoscope. This third and final step also includes drying the endoscope and its internal channels after terminal water rinsing^[138]. Review of these guidelines is beyond the scope of the present article, but the importance of endoscope drying and water quality will be discussed below.

In addition to patient-to-patient transmission of pathogens during endoscopy, environment-to-patient transmission of gram-negative bacteria during GI endoscopy has been reported, primarily during endoscopic retrograde cholangiopancreatography (ERCP)^[76,79,81,82]. Due in part to the anatomy, physiology, and sterile nature of the biliary tract, the design of the side-viewing duodenoscope (elevators channel), and the nature and characteristics of the procedure, ERCP is probably more vulnerable to bacterial infection than other GI endoscopic procedures. Several of these reports highlight, first, an association between wet or improperly dried GI endoscopes and true and pseudo-outbreaks of waterborne microorganisms, and, second, the abrupt termination of these outbreaks following the implementation of endoscope drying. Moreover, some of these reports identified the rinse water used during endoscope reprocessing as the source of the microorganisms responsible for these outbreaks^[76,79,81,82]. Despite the thoroughness and success of cleaning and high-level disinfection, failure to dry the endoscope can render the reprocessing procedure invalid and clinical use of the endoscope an infection risk. The contribution of post-processing in general and drying in particular to the prevention of disease transmission *via* a GI endoscope cannot be overstated.

Endoscope drying and storage

Although the importance of cleaning and high-level disinfection of GI endoscopes after each procedure is well recognized, the contribution of post-processing—particularly endoscope drying and storage—to the prevention of disease transmission and nosocomial infection is sometimes overlooked. Surveys indicate that not all GI endoscopy units dry the endoscope after water rinsing and prior to reuse or storage^[139,140]. Rinse water that is not removed during drying and remains in the endoscope's narrow internal channels between patient procedures or more importantly during storage can provide the ideal environment for waterborne microorganisms to colonize and multiply. Indeed, cases of nosocomial infection due to the transmission of

microorganisms that have colonized and proliferated in the moist internal channels of inadequately dried and improperly stored endoscopes to the patients undergoing GI endoscopy have been reported, resulting in patient injury and death^[70,71,76,79,82].

Allen^[76] reported that bile cultures from ten patients who had undergone ERCP were contaminated with *Pseudomonas aeruginosa*. Inadequate drying after reprocessing of the ERCP endoscope using an AER was identified as the cause of this outbreak. *P. aeruginosa* was found to have survived and proliferated in the moist internal channels of an ERCP endoscope that transmitted this bacterium to patients during ERCP. Contamination ended and this outbreak was terminated only after modifying the facility's reprocessing procedure to include after cleaning and high-level disinfection a manual drying step achieved by suctioning alcohol through the ERCP endoscope's channels followed by air drying. Classen *et al.* reported the identification of seven cases of *P. aeruginosa* bacteremia within 5 d following ERCP^[79]. In addition to each infected patient having undergone the first or only scheduled ERCP of the day, the mean duration between reprocessing the ERCP endoscope and its clinical use was significantly longer for infected patients than for matched controls, suggesting that improper storage of the endoscope played a role in this outbreak. Each patient was found to be infected with the same serotype of *P. aeruginosa* as microbiologically sampled from, among other surfaces, the tap water basin used to rinse the ERCP endoscopes with water after disinfection. This report's authors suggest that inadequate drying of the endoscope's channels prior to storage was, at least in part, responsible for this outbreak. *P. aeruginosa* remaining in the endoscope's moist internal channels after reprocessing and water rinsing likely colonized and multiplied to high numbers during overnight storage, posing an increased risk of nosocomial infection to the first scheduled patient of the day. Among other control measures including more frequent changing of, and addition of chlorine into, the tap water bath, no additional infections were identified once the endoscope's channels were flushed with 70% alcohol followed by forced air.

Provided the endoscope is properly reprocessed and dried prior to storage, reprocessing the endoscope immediately before its first use of the day does not appear to be necessary^[141]. There are few data that provide insight into the number of days a specific type of GI endoscope may remain in storage without posing an infection risk and requiring reprocessing before its reuse. Two studies, however, suggest that properly reprocessed and dried endoscopes may remain in storage for five to seven days without requiring reprocessing before reuse^[142,143]. The type of endoscope, its frequency of reuse, and the effectiveness of the reprocessing and drying protocols may all be factors that influence and affect the number of days a GI endoscope can remain safely in storage without posing a risk of bacterial colonization and nosocomial infection. Research to determine storage intervals is encouraged.

Water quality

While proper mechanical cleaning (stage 1) and high-level disinfection (stage 2) are crucial to the prevention

of disease transmission during GI endoscopy, the success of an endoscope reprocessing procedure also depends on the adequacy of the drying step and the microbial quality of the water used to remove the residual liquid chemical germicide from the endoscope after disinfection. In general, three types of water are used to rinse endoscopes after chemical immersion: tap water, bacteria-free water, and “sterile” or “sterile filtered” water. Despite their label claim, however, all of these water types, including “sterile” water, have been linked to bacterial contamination and nosocomial infection following endoscopy^[76,79,81,82,144-147]. Because the water used to rinse the endoscope after chemical immersion is not generally microbiologically monitored (i.e., periodically cultured), its microbial quality is almost always unknown^[148]. The rinse water contacts the endoscope after high-level disinfection (or “liquid sterilization”), whether achieved manually or using an automated endoscope reprocessor (AER), and in many cases just prior to clinical use (if not exposed to a drying cycle). Thus any contamination of the rinse water will inevitably lead to contamination of the endoscope regardless of the potency, strength, or effectiveness of the preceding cleaning process or of the LCG, AER, or automated processing system. Drying the endoscope during post-processing (stage 3) is necessary, no matter the claimed microbial quality of the rinse water, to prevent potential re-contamination of the endoscope with waterborne microorganisms during terminal water rinsing^[149].

The importance of microbiological monitoring of the rinse water used during the reprocessing of GI endoscopes is controversial. Whereas some countries encourage this practice^[150,151], others (including the United States) do not, having concluded that the relationship between the presence of bacteria in the rinse water and nosocomial infection has not been adequately defined^[148]. As discussed previously, contamination of endoscopes with waterborne, gram-negative bacteria has been linked to adverse patient outcomes. Unless the rinse water is monitored to evaluate its microbial quality and content, the potential exists for the rinse water to contain pathogenic microorganisms capable of re-contaminating the endoscope during terminal water rinsing, compromising the effectiveness of the reprocessing procedure, invalidating the disinfection (or “liquid sterilization”) claim, and posing a risk of nosocomial infection. Periodic sampling of the rinse water used during endoscope reprocessing also provides independent verification that the bacterial filter, which is used to improve the microbial quality of the rinse water used by virtually all AERs, is working properly and producing “bacteria-free” or “sterile” water as labeled^[148]. Bacterial filters have a limited life-span and have been reported to fail, allowing bacteria to pass, resulting in true and pseudo outbreaks^[82,151-154]. It is for these and other reasons that some reports recommend microbiological monitoring of the rinse water, to preempt re-contamination of the endoscope^[148,150,151]. The importance and necessity of this practice, and the recommendation that the rinse water be bacteria-free or sterile^[151,155], is minimized, however, by thoroughly drying the endoscope after completion of every reprocessing cycle (i.e., between-

patient procedures and before storage) to prevent the transmission of waterborne microorganisms that may reside in the rinse water^[81]. Professional organizations and governmental agencies are encouraged to develop standards that establish permissible levels of waterborne bacteria (and endotoxins) for the rinse water, to ensure its microbial quality does not pose an infection risk during endoscopy.

GENERAL INFECTION CONTROL

When discussing infection control during gastrointestinal endoscopy, attention is almost invariably focused on the adequacy of the endoscope reprocessing for the prevention of patient-to-patient transmission of pathogens. Good general infection control practices are critical for the prevention of infection in any medical setting. There are now numerous examples of pathogen transmission from the improper use/reuse of syringes, multiple-dose drug vials, and IV equipment^[21-23,156-159]. As mentioned previously, the widely publicized outbreak of HCV at an endoscopy clinic in New York that was initially attributed to improper endoscope reprocessing was subsequently found to be due to contaminated multiple-dose sedative medication vials^[24].

As alluded to earlier in the discussion regarding the higher rate of *H pylori* infection in healthcare workers, patients may serve as a vector for transmission of infection to endoscopy staff. Although rare, there are case reports of transmission of HCV from a blood splash to the conjunctiva of health care workers^[160-162], and one case of bacterial conjunctivitis from a splash during colonoscopy^[163]. One study reported that the overall splash rate to the eyes was 4.1%, and was not altered by the use of video endoscopy, highlighting the need for appropriate personal protective equipment^[164]. Compliance with published infection control guidelines is necessary to minimize the potential for nosocomial transmission of infection, both to patients and health care workers.

NEW TECHNOLOGIES

Cleaning, disinfection and sterilization processes and technologies are crucial to the prevention of disease transmission and nosocomial infection caused by both patient-borne and environmental microorganisms and other types of contagions. While current reprocessing products are effective and meet the requirements of infection-control and endoscope-reprocessing guidelines, the search for better-performing LCGs that are more effective in less time without damaging gastrointestinal endoscopes continues. The market's demand for new and more innovative products remains strong, primarily because the advantages that current reprocessing products offer are typically offset by disadvantages that limit their applications and usefulness. As an example, although 2% glutaraldehyde is cost-effective, can be used during manual reprocessing or with most automated endoscope reprocessors, and has a long track record of effectiveness and endoscope compatibility, its vapors may be irritating to endoscopy staff and requires a

relatively longer exposure time. Alternatively, ortho-phthalaldehyde (OPA) is tuberculocidal in 5 minutes, does not require activation, and has not been reported to cause endoscope damage. But these favorable characteristics are overshadowed to some extent by OPA's propensity for staining instrument surfaces and skin, significantly higher cost, and contraindication for reprocessing urological equipment, due to the identification of serious allergic reactions in some bladder cancer patients who underwent repeated cystoscopies. Development of an LCG that is compatible with flexible endoscopes and other delicate materials, rapidly tuberculocidal (and sporicidal), cost-effective, environmentally-friendly, not associated with allergic reactions for patients or healthcare workers, does not contain a high concentration of soapy surfactants or require heating to achieve high level disinfection, and can be used during both manual and automated reprocessing has proved challenging. While current products may satisfy several of these criteria, none satisfies all of them.

In the quest to improve the current standard of reprocessing for GI endoscopes and other types of flexible endoscopes, several new products have been developed and recently cleared by the US *Food and Drug Administration* (FDA) for marketing in the U.S. These new products and technologies range from enzymatic detergents that claim to facilitate the removal of different types of organic debris including fats from the surfaces of flexible endoscopes; to glutaraldehyde-based disinfecting solutions that are rapidly tuberculocidal at room temperature; to low-temperature sterilization processes that use a hydrogen peroxide based-plasma labeled to achieve sterilization of bronchoscopes and other instruments with narrow lumens or channels. Sheath-based technologies that cover the flexible endoscope's insertion tube to prevent its contact with the patient and contamination have been applied to GI endoscopes and other types of flexible endoscopes with measured results. Whether any of these reprocessing products or sheathed technologies improves the status quo and provides clear advantages over currently available technology will need to be established. Some of these new reprocessing technologies are discussed, below.

Cidex OPA concentrate (Advanced Sterilization Products, or ASP; FDA clearance No. K032959)

This liquid chemical concentrate was cleared by the FDA in April, 2005, and is manufactured by ASP. It contains 5.75% (w/v) *ortho*-phthalaldehyde (OPA) and is a concentrated form of its predecessor, Cidex OPA (0.55% *ortho*-phthalaldehyde), which was cleared by the FDA in October, 1999. This concentrate is mixed with tap water to achieve a diluted, single-use solution of 0.05% OPA, which is labeled to achieve high-level disinfection of flexible endoscopes and other types of reusable medical and dental devices in 5 min at an elevated temperature of 50°C. Cidex OPA Concentrate is contraindicated for manual reprocessing and is labeled exclusively for use in the EvoTech Integrated Endoscope Disinfection System, an automated endoscope reprocessor also recently cleared by the FDA and marketed by ASP.

Because this product will be marketed in tandem with the Evotech disinfecting system, the success of Cidex

OPA Concentrate will depend on the success of the Evotech, and vice versa. Whether healthcare facilities will replace 2% glutaraldehyde or Cidex OPA-both of which are versatile and can be used manually or with any automated endoscope reprocessor-with Cidex OPA Concentrate and its accompanying reprocessor, is unclear. Because its active ingredient is *ortho*-phthalaldehyde, which has not been reported to cause endoscope damage, Cidex OPA Concentrate is likely to be compatible with a wide range of delicate and heat-sensitive instruments and, therefore, is not likely to void the warranty provided with most endoscope models. As with any LCG, adequate room ventilation is required.

Of particular clinical importance, Cidex OPA Concentrate, like Cidex OPA, is likely to be contraindicated for reprocessing cystoscopes and other types of urological instrumentation to be used to treat patients who have a history of bladder cancer, due to reports of an association between these patients experiencing anaphylaxis-like reactions after having undergone repeated cystoscopies and contact with cystoscopes reprocessed using Cidex OPA (*ortho*-phthalaldehyde). Whether contraindications for Cidex OPA Concentrate will include cystoscopes and possibly other types of flexible endoscopes is unclear. The labeling of Cidex OPA Concentrate does not include a sporicidal claim.

Aldahol III high level disinfectant (Healthpoint, LTD; FDA clearance No: K041360)

This product was cleared by the FDA in May, 2005, and uses a novel mixture of two well known chemicals to achieve high-level disinfection of flexible endoscopes. Aldahol III (pH 7.6 after activation) contains a mixture of 3.4% glutaraldehyde and 26% isopropanol and, like most 2% glutaraldehyde formulations, can be reused for up to 14 d, depending on several factors including usage and how effectively the instrument is cleaned and dried prior to chemical immersion. This product achieves high-level disinfection in 10 min at 20°C (room temperature), suggesting that the addition of alcohol (i.e., 26% isopropanol) to a solution of 3.4% glutaraldehyde enhances its tuberculocidal properties, reducing the time and temperature required to achieve high-level disinfection. Aldahol III is sporicidal in 10 h at 20°C, and its concentration of glutaraldehyde is monitored for effectiveness using chemical test strips, to ensure its concentration is above 2.1%, this product's minimum effective concentration.

Aldahol III contains isopropyl alcohol, which is ordinarily flammable and can, under certain conditions, pose a risk of injury to staff and to patients if not adequately removed from the endoscope during thorough water rinsing. Whether the chemistry of this product eliminates this risk is unclear. Prolonged immersion of the endoscope in solutions that contain isopropyl alcohol (as opposed to brief flushing of the endoscope's internal channels with alcohol to facilitate drying) may damage the endoscope. Most published reprocessing guidelines contraindicate the use of LCG that contain high concentrations of surfactants. Before using this product to reprocess flexible endoscopes in an automated endoscope

reprocessor (AER), contact both respective manufacturers to ensure use of Aldahol III will not void the endoscope's or AER's warranty. Also, the powdered contents of the activator added to each gallon of this solution may not immediately dissolve into solution as required prior to its use.

Acicide™ high level disinfectant and sterilant (Minntech; FDA clearance No: K041984)

This product, which is similar in chemical composition to some products that are used for dialyzer reprocessing (Acril, Renalin) and endoscope reprocessing (Peract 20), was cleared by the FDA in May, 2005. It contains a mixture of 8.3% hydrogen peroxide and 7.0% peracetic acid. These two chemical agents, referred to as Solution 1 and Solution 2, are packaged separately and for reasons of chemical instability are mixed by medical staff at the time of use. Acicide is labeled to achieve high-level disinfection of flexible endoscopes and other types of reusable medical and dental devices in 5 min at 25°C. Acicide is sporicidal in 5 h at 25°C and can be reused for a maximum of 5 d, depending on several factors including usage (i.e., the number of endoscopes reprocessed using the solution) and how effectively the instrument is cleaned and dried prior to chemical immersion. This product's concentration of peracetic acid is monitored for effectiveness using chemical test strips, to ensure its concentration is above 1900 parts-per-million, which is Acicide's minimum effective concentration.

Acicide can be reused for a maximum of 5 d. As a result, its cost-per-cycle is likely to be more expensive than other LCGs (such as 2% glutaraldehyde) which may be reused for as many as 14 d. Acicide uses a mixture of hydrogen peroxide and peracetic acid which may be incompatible with delicate materials and result in endoscope damage. Contact the endoscope's manufacturer before using Acicide to ensure its use will not void the endoscope's warranty. Like other recently introduced LCGs that require an elevated immersion temperature to be effective, acicide may be contraindicated for manual reprocessing and require use of an automated endoscope reprocessor (AER)

STERRAD NX system (Advanced Sterilization Products, or ASP; FDA clearance No. K042116)

This sterilizing system was cleared by the FDA in April, 2005, and launched in the U.S. in May, 2005. It uses an electrical field in a low-temperature, negative-pressure chamber to convert a solution of hydrogen peroxide and water to a hydrogen peroxide plasma cloud that contains ultraviolet light and free radicals with sporicidal properties. Known as the Sterrad NX, this device is marketed as a safe and rapid-acting sterilizer designed to replace ethylene oxide (EtO) gas sterilizers, which pose a potential hazard to personnel and the environment and require as long as 24 h, with aeration, to complete a processing cycle. This device is labeled to sterilize a wide range of surgical instruments, including flexible endoscopes, although it is indicated only for those models of flexible endoscopes that feature a single working channel (no air, water, or accessory channels) with an inner diameter of at least 1

mm and a length not longer than 850 mm. Importantly, the Sterrad NX is contraindicated for reprocessing gastrointestinal endoscopes.

In summary, transmission of infection during gastrointestinal endoscopy is an extremely rare event, and in each case has been associated with a breach in currently accepted reprocessing guidelines or faulty equipment. When appropriate reprocessing guidelines are followed, endoscopes pose virtually no risk of transmission of infection. It is also important that general infection control measures, particularly during the administration of intravenous sedative agents, be meticulously adhered to in the endoscopy suite. Although novel pathogens may pose particular challenges to endoscope disinfection, current protocols appear to be sufficient to protect the patient from cross-infection. However, endoscope design improvements and new germicides to facilitate reprocessing and specifically address these challenges should be encouraged.

Abstract

AIM: To study the expression of Sonic hedgehog pathway-related molecules, Sonic hedgehog (Shh) and Gli1 in gastric carcinoma.

METHODS: Expression of Shh in 56 gastric specimens including non-cancerous gastric tissues, gastric adenocarcinoma, gastric squamous cell carcinoma was detected by RT-PCR, *in situ* hybridization and immunohistochemistry. Expression of Gli1 was observed by *in situ* hybridization.

RESULTS: The positive rate of Shh and Gli1 expression was 0.0%, 0.0% in non-cancerous gastric tissues while it was 66.7%, 57.8% respectively in gastric adenocarcinoma, and 100%, 100% respectively in gastric squamous cell carcinoma. There was a significant difference between the non-cancerous gastric tissues and gastric carcinoma ($P < 0.05$). Elevated expression of Shh and Gli1 in gastric tubular adenocarcinoma was associated with poorly differentiated tumors while the expression was absent in gastric mucinous adenocarcinoma.

CONCLUSION: The elevated expression of Shh and Gli1 in gastric adenocarcinoma and gastric squamous cell carcinoma shows the involvement of activated Shh signaling in the cellular proliferation of gastric carcinogenesis. It suggests Shh signaling gene may be a new and good target gene for gastric tumor diagnosis and therapy.

INTRODUCTION

Sonic hedgehog (Shh), a mammalian homologue of *Drosophila* secreted morphogen Hedgehog, is crucial for the development of various embryonic tissues in invertebrate and vertebrate development, including brain, spinal cord, axial skeleton, limbs, lungs, gut, and hematopoietic cells^[1-4]. Shh is synthesized in epithelial cells. Its membrane receptor Patched1 (Ptc1) is expressed in adjacent mesenchymal cells. Ptc1, a 12-transmembrane protein, does not transduce the intracellular signals by itself. This task is executed by smoothened (Smo), a 7-transmembrane protein that belongs to heterotrimeric G protein-coupled receptor (GPCR) family. In the absence of Shh, Ptc1 suppresses the activity of Smo by binding to Smo. Upon Shh stimulation, Shh binds to Ptc1, and then Smo is de-repressed from the suppression of Ptc1 and is able to transduce the intracellular signals to transcription factor Gli. Gli transfers the signals into the nucleus^[5].

Shh is implicated in the early expansion of developing midbrain and also in the proliferation of granular cell precursors in the cerebellum^[6-8]. In human, likewise in experimental models, the activated Shh signaling is thought to predispose to the development of tumors^[9-12]. The role of the Shh pathway in the regulation of oncogenic transformation is a new and exciting field. The study by Berman *et al* suggests that this pathway may well offer the potential for new treatments for medulloblastoma^[11]. The recent finding that Shh pathway activity is important for growth of small cell lung cancers, a tumor type not associated with Gorlin's syndrome, suggested that other, non-Gorlin's tumors might require Shh pathway activity for growth^[12-14]. In the longer term, better understanding of the regulatory role of this pathway may offer new targets for therapeutic manipulation.

Gastric cancer is the second most common cause of cancer-related death in the world. Many Asian countries, including Korea, China, and Japan, have very high rates of gastric cancer^[15]. By far, the mechanism of Hedgehog signal in gastric cancer is still unclear. Here we studied the role of Shh signaling pathway-related molecules, Shh and Gli1, in gastric adenocarcinoma and squamous cell carcinoma by RT-PCR, immunohistochemistry and *in situ* hybridization.

MATERIALS AND METHODS

Samples

A total of 56 specimens of gastric tissues were used in our study. Fifty-six patients, who had undergone curative gastrectomy between 2002 and 2005 from the Department of General Surgery, Shandong Qilu Hospital affiliated to Shandong University, or from Jinan Central Hospital, Shandong Province, China, were enrolled in this study. All of the resected primary tumors were histologically examined by hematoxylin and eosin staining, and confirmed by pathologists. These samples included five resection specimens of non-cancerous gastric tissues, ten well differentiated tubular adenocarcinoma, ten moderately differentiated tubular adenocarcinoma, fifteen poorly differentiated adenocarcinoma, seven papillary adenocarcinoma, three gastric mucinous adenocarcinoma and six gastric squamous cell carcinoma.

Immunohistochemistry

Representative formalin fixed and paraffin embedded tissue sections (6 μ m thick) were used for immunohistochemistry with specific antibodies to human Shh (Cat# 9024, Santa Cruz Biotechnology Inc, Santa Cruz, CA). First, tissue sections were deparaffinized, followed by rehydration with serially decreased concentrations of ethanol, and immersed in 3% H₂O₂ (in distilled water) for 10 min to inhibit endogenous peroxidase activity. Following antigen retrieval in citrate buffer (pH 6.0), the tissue sections were incubated with normal goat serum to block nonspecific antibody binding for 20 min at room temperature. The sections were then incubated with primary antibodies (at 1:200 dilution) at 37°C in humid chambers for 2 h. After washing with PBS 3 times, the sections were incubated with biotinylated secondary antibody (goat anti-rabbit IgG) and streptavidin conjugated to horseradish peroxidase for 20 min at 37°C, followed by PBS wash. The sections were incubated with DAB substrate for less than 30 min. Haematoxylin was used for counterstaining. Negative controls were performed in all cases by omitting the first antibodies.

RT-PCR

Total RNA of cells was extracted by using RNA extraction kit (Promega). Total RNA templates were isolated from 10 μ g sections (10 μ m) of paraffin-embedded tissue as described elsewhere^[16]. Three micrograms of total RNA were reverse transcribed by using M-MLV reverse transcriptase (Promega) with mixture of oligo(dT)₁₅ and random primers (Promega). One-tenth of each RT

reaction mixture was then subjected to PCR amplification using Taq DNA polymerase (TAKARA). The PCR primers for detecting specific transcripts are as below: for *Shh* sense 5'-ACCGAGGGCTGGGACGAAGA-3' and antisense 5'-ATTTGGCCGCCACCGAGTT-3' respectively. Following denaturation at 94°C for 10 min, 35 PCR cycles were performed at 94°C for 60 s, at 52°C for 50 s, and at 72°C for 60 s. The PCR products were analyzed by 0.7% agarose gel electrophoresis.

In situ hybridization

Shh (L38518) was subcloned in PbluescriptKS⁺. The linearized pBlueScript-shh was obtained by digestion with *Sph* I or *Xmn* I restriction endonuclease. Gli1 (X07384) was cloned into pBluescript M13+KS. The plasmid was digested with *Nru* I to generate the sense fragment, with *Nde* I to generate the antisense fragment. Sense and antisense probes were obtained by T3 and T7 *in vitro* transcription using a kit from Roche (Mannheim, Germany). Tissue sections (6 μ m thick) were mounted onto Poly-L-Lysine slides. Following deparaffinization, tissue sections were rehydrated in a series of dilutions of ethanol. To enhance signal and facilitate probe penetration, sections were immersed in 0.3% Triton X-100 solution for 15 min at room temperature and in proteinase K (2 mg/mL) solution for 20 min at 37°C, respectively. The sections were then incubated with 4% (v/v) paraformaldehyde/PBS for 5 min at 4°C. After washing with PBS and 10 \times saline citrate, the slides were incubated with prehybridization solution (50% formamide, 50% 4 \times SSC) for 2 h at 37°C. The probe was added to each tissue section at a concentration of 1 g/mL and hybridized overnight at 42°C. After high stringency washing (2 \times SSC twice, 1 \times standard saline citrate twice, 0.5 \times SSC twice at 52°C), sections were incubated with an alkaline phosphatase-conjugated sheep anti-digoxigenin antibody, which catalyzed a color reaction with the NBT/BCIP (nitro-blue-tetrazolium/5-bromo-4-chloro-3-indolyl phosphate) substrate (Roche, Mannheim, Germany). Blue indicated strong hybridization. As negative controls, sense probes were used in all hybridization and no positive signal was observed.

Statistical analysis

Analysis was performed by using chi-square test and correlation analysis with SPSS 11.0 software. $P < 0.05$ was considered statistically significant.

RESULTS

Expression of Shh-mRNA in non-cancerous gastric tissues and gastric carcinoma

Total RNA extracted in paraffin-embedded tissue was pure enough to meet the need for RT-PCR. The length of RT-PCR product was 211 bp. The results of RT-PCR showed that expression of Shh was different in various tissue, including non-cancerous gastric tissues, well differentiated and poorly differentiated adenocarcinoma. Expression of Shh was higher in gastric adenocarcinoma than in non-cancerous gastric tissues (Figure 1), which was confirmed by *in situ* hybridization. The results of *in situ* hybridization

Figure 1 Results of Shh RT-PCR. M: MarkerDL-2000; 1: Non-cancerous gastric tissues; 2: Well differentiated tubular adenocarcinoma; 3: Poorly differentiated tubular adenocarcinoma.

Figure 2 Results of Shh expression by *in situ* hybridization, blue represents positive. A: Non-cancerous gastric tissues ($\times 100$); B: Well-moderately differentiated tubular adenocarcinoma ($\times 100$); C: Poorly differentiated tubular adenocarcinoma ($\times 100$); D: Papillary adenocarcinoma ($\times 100$); E: Mucinous adenocarcinoma ($\times 200$); F: Squamous cell carcinoma ($\times 100$).

showed that Shh mRNA was expressed in cytoplasm of the fundic glandular epithelium and some stromal cells. Shh was not or lowly expressed in non-cancerous gastric tissues' glandular epithelium while overexpressed in about 66.7% (30/45) adenocarcinoma patients and in 100% (6/6) gastric squamous cell carcinoma (Figure 2A-F) (Table 1). In tubular and papillary adenocarcinoma glandular epithelium, the expression of Shh showed an increasing trend among well differentiated, moderately differentiated and poorly differentiated adenocarcinomas (Figure 2B-D), while expression of Shh was absent in gastric mucinous adenocarcinoma (Figure 2E). In gastric squamous cell carcinoma, expression of Shh was obvious (Figure 2F). There was a significant difference between the non-cancerous gastric tissues and gastric carcinoma ($P < 0.05$) (Table 1).

Figure 3 Results of Shh expression by immunohistochemistry (brown represents positive). A: Non-cancerous gastric tissues ($\times 100$); B: Well-moderately differentiated tubular adenocarcinoma ($\times 100$); C: Poorly differentiated adenocarcinoma ($\times 100$); D: Papillary adenocarcinoma ($\times 100$); E: Mucinous adenocarcinoma ($\times 200$); F: Squamous cell carcinoma ($\times 100$).

High expression level of Shh protein in gastric carcinoma

The results of immunohistochemistry showed that Shh staining was detected in the fundic glandular epithelium and in the stroma of the stomach (Figure 3A-F). Shh protein was not or lowly expressed in non-cancerous gastric tissues (Figure 3A) and was highly expressed in gastric adenocarcinoma and gastric squamous cell carcinoma (Figure 3B-D, F). The results of Shh expression in various gastric tissue were consistent with results of *in situ* hybridization. Shh was overexpressed in gastric adenocarcinoma epithelium and squamous cell carcinoma epithelium compared with non-cancerous stomach tissues glandular epithelium. Shh expression was increased with malignant degree aggravation in gastric adenocarcinoma (Figure 3B-D), while there was no or less expression of Shh in gastric mucinous adenocarcinoma (Figure 3E).

Expression of transcripter Gli1 in non-cancerous gastric tissues and gastric carcinoma

As an Shh signaling transcripter, Gli1, was detected by *in situ* hybridization. It showed Gli1 was not or lowly expressed in non-cancerous gastric tissues glands and highly expressed in epithelium cytoplasm, in 57.8% (26/45) gastric adenocarcinoma and 100% (6/6) squamous cell carcinoma (Figure 4A-F) (Table 1). There was a higher expression level of Gli1 in squamous cell carcinoma (Figure 4F). Also, it presented an increasing trend in tubular adenocarcinoma with malignant degree aggravation (Figure 4B-D), while there was no or lower expression of Shh in gastric mucinous adenocarcinoma (Figure 4E). There was a significant difference between the non-cancerous gastric

Table 1 Summary of expression of Shh and Gli1 in various types of gastric tissues

	Tumor (n)	Expression of Shh n (%)	Expression of Gli1 n (%)	P value
Non-cancerous gastric tissues	5	0 (0.0)	0 (0.0)	0.01 < P < 0.05
Adenocarcinoma	45	30 (66.7)	26 (57.8)

Mucinous	3	0 (0.0)	0 (0.0)	
Squamous cell carcinoma	6	6 (100)	6 (100)	

Figure 4 Results of Gli1 *in situ* hybridization (blue represents positive). **A:** Non-cancerous stomach tissues ($\times 100$); **B:** Moderately differentiated tubular adenocarcinoma ($\times 100$); **C:** Poorly differentiated tubular adenocarcinoma ($\times 100$); **D:** Papillary adenocarcinoma ($\times 100$); **E:** Mucinous adenocarcinoma ($\times 200$); **F:** Squamous cell carcinoma ($\times 100$).

tissues and gastric carcinoma ($P < 0.05$) (Table 1).

DISCUSSION

Shh is an important endodermal signal in endodermal-mesenchymal interaction during vertebrate development of the gut tube, especially to gastric gland^[17]. Because Shh is expressed consistently in the endodermal epithelium of the gut throughout the period of organogenesis and late embryonic life, it is natural to suppose that its expression is crucial for the differentiation and maintenance of gut tube epithelium. Indeed, the heterozygous mutant mouse for Shh shows various gastrointestinal defects, such as intestinal transformation of stomach, annular pancreas, and duodenal stenosis^[18]. Some of these defects may be caused by the absence of Shh effects on the mesenchyme, while others may reflect a direct action of Shh on epithelial

cells. Although the expression of Shh is essential for the development of gut tube and the fundic glands of the adult gastrointestinal tract, the role of Shh expression has not been described in the gastric carcinogenesis^[14,15]. We examined Sonic hedgehog signaling pathway related molecules expression in non-cancerous gastric tissues and in various types of gastric carcinoma. The results indicated that Shh protein expression is closely correlated with glandular epithelium differentiation in adenocarcinoma and gastric squamous cell carcinoma. The increase of Shh expression in tumor tissue is consistent with the results of Berman *et al*^[14].

Gastric cancer is one of the leading causes of cancer death worldwide. Because of its heterogeneity, gastric cancer has been an interesting model for studying carcinogenesis and tumorigenesis^[15]. This study mainly detected the expression of Shh and Gli1 in various types of gastric carcinoma. The elevated expression of Shh and Gli1 in gastric adenocarcinoma and squamous cell carcinoma suggested the involvement of activated Shh signaling in the cellular proliferation of certain type of gastric carcinoma. Interestingly, there was no activation of Shh signaling in mucinous adenocarcinoma. It implies that there may exist different mechanisms in various gastric carcinoma.

In all the tumors with elevated levels of Gli1, expression of Shh was also increased, suggesting that overexpression of Shh may be responsible for elevated expression of Gli1 in gastric adenocarcinoma. However, a high level of sonic hedgehog expression was not always accompanied by elevated Gli1 expression in adenocarcinoma (Table 1), indicating additional regulatory mechanisms for the hedgehog pathway activation. In addition to the hedgehog overexpression, other genetic alterations may be required to activate the hedgehog pathway in gastric cancers, such as Wnt, Notch signal pathway. Further study of the relationship between Sonic Hedgehog and other signal pathways may provide more evidences for a new and good target gene for gastric cancer diagnosis and therapy.

Abstract

AIM: To investigate the correlations between the expression of urokinase-type plasminogen activator (uPA) mRNA, uPA receptor (uPAR) mRNA and vascular endothelial growth factor (VEGF) protein and clinicopathologic features, microvessel density (MVD) and survival time.

METHODS: *In situ* hybridization and immuno-histochemistry techniques were used to study the expressions of uPA mRNA, uPAR mRNA, VEGF and CD34 protein in 105 gastric carcinoma specimens.

RESULTS: Expressions of uPA mRNA, uPAR mRNA and VEGF protein were observed in 61 (58.1%) cases, 70 (66.7%) cases and 67 (63.8%) cases, respectively. The uPA mRNA and uPAR mRNA positive expression rates in infiltrating-type cases (73.7%, 75.4%), stage III-IV (72.1%, 75.4%), vessel invasion (63.2%, 69.9%), lymphatic metastasis (67.1%, 74.4%) and distant metastasis (88.1%, 85.7%) were significantly higher than those of the expanding-type ($\chi^2 = 15.57$, $P = 0.001$; $\chi^2 = 6.91$, $P = 0.046$), stage I-II ($\chi^2 = 19.22$, $P = 0.001$; $\chi^2 = 16.75$, $P = 0.001$), non-vessel invasion ($\chi^2 = 11.92$, $P = 0.006$; $\chi^2 = 14.15$, $P = 0.002$), non-lymphatic metastasis ($\chi^2 = 28.41$, $P = 0.001$; $\chi^2 = 22.5$, $P = 0.005$) and non-distant metastasis ($\chi^2 = 12.32$, $P = 0.004$; $\chi^2 = 17.42$, $P = 0.002$; $\chi^2 = 11.25$, $P = 0.012$; $\chi^2 = 18.12$, $P = 0.002$). The VEGF positive expression rates in infiltrating-type cases (75.4%), stage III-IV (88.5%), vessel invasion (82.9%), lymphatic metastasis (84.3%) and distant metastasis (95.2%) were significantly higher than those of the expanding-type ($\chi^2 = 9.61$, $P = 0.021$),

stage I-II ($\chi^2 = 16.66$, $P = 0.001$), non-vessel invasion ($\chi^2 = 29.38$, $P = 0.001$), non-lymphatic metastasis ($\chi^2 = 18.68$, $P = 0.005$), and non-distant metastasis ($\chi^2 = 22.72$, $P = 0.007$; $\chi^2 = 21.62$, $P = 0.004$). The mean MVD in the specimens positive for the uPA mRNA, uPAR mRNA and VEGF protein was markedly higher than those with negative expression groups. Moreover, a positive relation between MVD and uPA mRNA ($r_s = 0.199$, $P = 0.042$), uPAR mRNA ($r_s = 0.278$, $P = 0.035$), and VEGF ($r_s = 0.398$, $P = 0.048$) expressions was observed. The mean survival time in cases with positive uPA mRNA, uPAR mRNA and VEGF protein expression or MVD value ≥ 54.9 was significantly shorter than those in cases with negative expression or MVD value < 54.9 .

CONCLUSION: uPA and uPAR expressions are correlated with enhanced VEGF-induced tumor angiogenesis and may play a role in invasion and nodal metastasis of gastric carcinoma, thereby serving as prognostic markers of gastric cancer.

INTRODUCTION

Degradation of extracellular matrix (ECM) and basement membrane is essential for tumor invasion and metastasis. The ECM is degraded by extracellular proteolytic enzymes, such as metalloproteases and serine proteases. Plasminogen activators (PA) catalyze the conversion of the inactive pro-enzyme plasminogen to plasmin^[1]. Plasmin acts to degrade the ECM and activates latent enzyme, such as type-IV collagenase. Among the plasminogen activators, urokinase-type plasminogen activator (uPA) and uPA receptor (uPAR)

have been reported to play an important role in tumor progression. uPA activation occurs on the cell surface after binding to its specific receptor and is regulated by the number of uPAR^[2]. The relevance of uPA or uPAR in tumor progression has been demonstrated by the poor prognosis of patient with a high content of uPA or uPAR in tumor tissue.

Angiogenesis is important for tumor growth and metastasis^[3,4]. The formation of tumor microvessels is stimulated by angiogenic factors, especially vascular endothelial growth factor (VEGF). Previous studies have shown that over-expression of VEGF is correlated with the progression of human malignancies, and a significant correlation has been demonstrated between microvessel density (MVD) and VEGF expression in tumor cells^[5,6]. Recently, a role of the PA system in tumor angiogenesis has also been demonstrated^[7]. Simultaneous study of uPA, uPAR and VEGF is of practical value to reveal the mechanism and progression of gastric carcinoma. In this study, we observed the expressions of uPA, uPAR and VEGF in gastric carcinomas so as to explore the relationship of the carcinoma angiogenesis with its infiltration, metastasis and other carcinoma biological behaviors as well as prognosis.

MATERIALS AND METHODS

Patients and tumor tissues

One hundred and five gastric carcinoma samples were collected in our hospital from October 1986 to November 1998. All the samples were fixed with formaldehyde and embedded in paraffin. Complete over 5 years follow-up data were available for all these cases (follow-up ended in October 2002). Survival period was calculated from the day of operation to the end of the follow-up or to the date of death due to recurrence and metastasis. In all samples, uPA and uPAR mRNA expressions were detected using *in situ* hybridization, and VEGF and CD34 expressions were detected using immunohistochemistry. The average age of the cases was 57.6 (range 38-78) years and the male to female ratio was 2:1. According to the standard classification of WHO (1999), 17 cases had papillary adenocarcinomas, while 37, 34, 9 and 8 had the tubular adenocarcinomas, poorly differentiated adenocarcinomas, mucinous adenocarcinomas, and signet-ring cell carcinomas, respectively. Highly and intermediately differentiated carcinomas were found in 63 cases, while poorly and undifferentiated carcinomas were found in 42 cases. Forty-eight cases showed expansive growth, while 57 cases had infiltrative growth of carcinomas; and 20, 24, 32 and 29 cases had T1, T2, T3, and T4 carcinoma, respectively. Carcinomas with vascular invasion were found in 76 cases, and non-vascular invasion carcinomas in 29 cases. Seventy cases had lymph node metastasis, while 35 cases had no lymph node metastasis. Distant metastasis of carcinomas were found in 42 cases (liver metastasis: 18 cases, peritoneum metastasis: 24 cases), while no distant metastasis in 63 cases. Twenty control samples were collected from the same gastric mucosa 5 cm away from the carcinoma tissues.

Histological treatment

In order to avoid the RNase contamination, all the glass slides, slide covers and stain containers were treated with 100 g/L DEPC for 24 h. Gloves were used when handling tissue cutting and 100 g/L SDS was used to clean the cutter. All the sections were spread on glass using 100 g/L DEPC-treated ddH₂O. The tissues were cut into 5-7 μ m thickness and kept in 4°C, and foil covered for HE stain, immunohistochemistry and *in situ* hybridization.

Reagents

Digoxin-labeled oligonucleotides probes of uPA (No. MK1194) and uPAR (No. MK2117) were purchased from Boshide Biological Technology Limited Company, Wuhan, China. The sequences were 5'-CTAGGCCTGGGGAAACACAATTACTGCAGG-3' and 5'-TGTCTACACGAGGGTCTCACACTTCCTGGA-3' for uPA, and 5'-GCCTCTTGGGCAGTGCATGCAGTGT-3', 5'-GAGCTGTGAGAGGGCCGGCAGCAAAGCCT-3' and 5'-ACTGCCGTGACCAATGAATCAATGTCTGG-3' for uPAR. Mouse anti-human VEGF and mouse anti-human CD34 and SP kit were purchased from Zhongshan Biotech Co., Beijing, China. The working concentrations of VEGF and CD34 were 1:100 and 1:150, respectively.

In situ hybridization

All the slides, cover-slips and other containers were autoclaved and treated with 100 g/L DEPC-treated ddH₂O for 24 h. All the buffers were also treated with 100 g/L DEPC. The tissues were routinely treated before *in situ* hybridization. DEPC (100 g/L)-treated ddH₂O was used to spread out the sections. Moderate temperature was used for drying the sections; gradient ethanol was used for dehydration with 30 mL/L H₂O₂ incubation for 10 min at room temperature. Digestion was enabled with pepsin at 37°C for 20 min, followed by washing thrice with 0.5 mol/L PBS (5 min each time). Then 20 mL hybridization solution was used for each group with probes, sealed, incubated in wet chamber for 20 h at 45°C. Then the slides were washed with 2 \times SSC for 5 min, followed by incubation with 20 mL hybridization stabilization solution (2 mL A solution, 18 mL B solution) at 45°C for 5 h in a wet chamber. Post-hybridization washing was done with 2 \times SSC-0.05 \times SSC for 2 h, and then the slides were blocked with normal serum at 37°C for 30 min. After directly adding mouse-anti-digoxin antibody for 1 h at 37°C, slides were washed thrice with 0.5 mol/L PBS (5 min each time), followed by incubation with streptavidin-biotin complex (SABC) at 37°C for 20 min and biotin-peroxidase at 37°C for 20 min. Finally, the slides were washed thrice with 0.5 mol/L PBS (5 min each time), stained with DAB for 10 min and counterstained with hematoxylin solution for 8 min. Hybridization solution and RNase-treated sample served as negative controls.

Immunohistochemistry

Consecutive 5-7 μ m paraffin-embedded tissue sections were subjected to immunostaining according to the streptavidin peroxidase (SP) methods. Briefly, the tissue

Figure 1 In situ hybridization of uPA mRNA in gastric cancer tissue. **A:** Negative in the plasma of non-tumor gastric mucosa (ISH $\times 100$); **B:** Positive in the plasma of gastric adenocarcinoma (ISH $\times 220$); **C:** Positive in plasma of gastric adenocarcinoma with lymphangial cancer embolus (ISH $\times 180$); **D:** Positive in the plasma of gastric adenocarcinoma with greater peritoneum infiltration (ISH $\times 180$).

sections were deparaffinized, and then endogenous peroxide was blocked by incubating the slides with 30 mL/L H_2O_2 for 10 min at $37^\circ C$. After being thoroughly washed with distilled water 3 times (2 min each time), the slides were heated in the jar containing antigen retrieval solution (0.01 mol/L citrate buffer, pH 6.0) in an oven at $92-98^\circ C$ for 15 min for the retrieval of the antigens and cooled to room temperature. After being washed with PBS (0.01 mol/L, pH 7.4) for 5 min, the sections were further blocked by goat serum for 20 min at $37^\circ C$ to reduce nonspecific antibody binding and then incubated separately with primary antibodies (mouse anti-human VEGF or mouse anti-human CD34) at $4^\circ C$ overnight. After being washed 3 times (3 min each time) in PBS, the sections were incubated with the biotin-labeled goat anti-mouse IgG at $37^\circ C$ for 30 min, washed again with PBS, followed by incubation with streptavidin-peroxidase complex for 30 min at $37^\circ C$. Staining was visualized with DAB for 10 min at room temperature. Finally, the sections were counterstained by hematoxylin solution. To examine the specificity of immunostaining, PBS was used to replace the primary antibodies as the control.

Results evaluation

The cytoplasm of the uPA and uPAR mRNA appeared as brown in color. Two hundred cells were randomly chosen by microscopy to evaluate the stained cell number against the total cell number in the field. Based on the positive cell number, the criteria were set as follows: negative (-) = less than 10% positive cells or without positive staining; (+) = 11%-50% positive cells; (++) = 51%-75% positive cells; and (+++) = more than 75% positive cells. Based on the VEGF-positive cell number, the criteria were set as follows: negative (-) = no positive staining; (+) = less than 25% positive cells; (++) = 26%-50% positive cells; and (+++) = more than 50% positive cells. The MVD in the carcinoma tissue was calculated as previously described^[8]. Briefly, positive stainings for MVD, in five most highly vascularized areas ('hot spots') in each slide, were counted

in $200 \times$ fields and MVD was expressed as the average of the microvessel count in these areas. Any endothelial cell or endothelial cluster positive for CD34 (brown yellow staining) was considered to be a single countable microvessel. All 105 cases were divided into high MVD ($MVD \geq 54.9/mm^2$) group and low MVD ($MVD < 54.9/mm^2$) group according to the MVD mean value of 105 cases ($54.9/mm^2$)^[9].

Statistical analysis

Statistical evaluation was performed using χ^2 test or Fisher's exact test to differentiate the rates of different groups, *t*-test was used to analyze quantitative data, and rank sum correlation was analyzed with Spearman's test. The survival rate was estimated by the Kaplan-Meier method and analyzed by log-rank test. $P < 0.05$ was considered statistically significant. SPSS11.0 software for windows was employed to analyze all the data.

RESULTS

uPA mRNA, uPAR mRNA and VEGF protein expression

Twenty cases of non-cancer gastric mucosa had no uPA mRNA and uPAR mRNA expression, while positive staining for uPA and uPAR was observed mainly in cancer cells, but also in number of stromal cells including macrophages and fibroblasts. However, the number of these cells was too small to allow quantitative evaluation of the correlation with clinicopathologic factors. The rates of uPA mRNA and uPAR mRNA positive expression in cancer cells were 58.1% and 66.7%, respectively. The carcinoma cells had brown staining in the cytoplasm and invaded the muscular layer, peritoneum and greater omentum (Figure 1 and Figure 2). Moreover, the front of carcinoma infiltration areas, lymphangial cancer embolus had positive uPA mRNA and/or uPAR mRNA expression (Figure 1 and Figure 2). The positive relationships of each factor with the clinicopathologic parameters are shown in Table 1.

No correlation was found between uPA mRNA and/or

Figure 2 *In situ* hybridization of uPAR mRNA in gastric cancer tissue. **A:** Negative in the plasma of non-tumor gastric mucosa (ISH × 100); **B:** Positive in the plasma of gastric adenocarcinoma infiltrated to muscularis (ISH × 180); **C:** Positive in plasma of gastric adenocarcinoma with lymphangial cancer embolus (ISH × 240); **D:** Positive in the plasma of gastric adenocarcinoma with greater peritoneum infiltration (ISH × 120).

cytoplasm of tumor cells (Figure 3). About 63.8% gastric carcinoma showed positive expression for VEGF. The positive relationships of the expression of each factor with clinicopathologic parameters are shown in Table 1 (Figure 3). No correlation was found between VEGF protein expression and the carcinoma types ($\chi^2 = 2.21$, $P = 0.078$), differentiation ($\chi^2 = 2.14$, $P = 0.531$). In contrast, twenty cases of non-cancer gastric mucosa had no VEGF protein expression.

Correlation of MVD, uPA mRNA, uPAR mRNA, VEGF expression and survival time

The correlation between MVD, uPA mRNA, uPAR

mRNA and VEGF expression is shown in Table 2. uPA mRNA, uPAR mRNA, VEGF and MVD value within gastric tumor tissue correlated significantly with each other (uPA mRNA and VEGF: $r_s = 0.278$, $P = 0.032$, and MVD: $r_s = 0.199$, $P = 0.042$; uPAR mRNA and VEGF: $r_s = 0.308$, $P = 0.001$, and MVD: $r_s = 0.268$, $P = 0.035$; VEGF and MVD: $r_s = 0.398$, $P = 0.048$; uPA mRNA and uPAR mRNA: $r_s = 0.369$, $P = 0.005$).

The correlation of uPA mRNA, uPAR mRNA expression and MVD value, and survival time were in Table 3 (Figure 4). The survival rate of patients with positive uPA mRNA, uPAR mRNA, VEGF expression and MVD value ≥ 54.9 was significantly lower than that of the patients without these expressions (Figure 5).

DISCUSSION

Degradation of extracellular matrix (ECM) is important in cell migration and tissue remodeling. In cancer tissue, degradation of the ECM is considered to be pro-requisite for cancer invasion and metastasis^[10]. uPA, which belongs to the family of serine proteases, activates plasminogen into plasmin which degrades several components of the ECM, such as fibronectin, laminin and collagen. uPA is released from various cells as an inactive form (pro-uPA). Pro-uPA is converted into an active form after binding to a cell-surface receptor (uPAR). Previous report showed various cell types in which ligand binding to the uPA receptor does induce intracellular phosphorylation on tyrosine^[11], proto-oncogene expression^[12], cell proliferation and cell migration^[13], promoting tumor cell infiltration and metastasis^[14].

In the present study, uPA mRNA and/or uPAR mRNA tended to express more in those patients with serosal invasion, lymph node metastasis, vessel invasion, lymphangial cancer embolus, advanced stage of diseases, and distant metastasis. The results indicated that uPA mRNA and uPAR mRNA was closely related with the clinicopathologic features that reflect the invasion and metastatic potential and prognosis. Up to now, invasion depth, lymph node metastasis or distant metastasis and TNM stage were considered to be the prognostic factors for gastric carcinomas^[15]. uPA mRNA and uPAR mRNA expression statistically related with these factors implied that the invasion and metastasis facilitated by uPA and/or uPAR might indicate prognosis of gastric carcinomas. The results showed that the cancer cells with uPA mRNA and/or uPAR mRNA expression located mainly at invasion front, lymphangial cancer embolus, and involved in gastric wall lymphatic nodule. Our study also revealed that high aggressive cancer with uPA mRNA and/or uPAR mRNA positive expression, which infiltrated muscularis and metastasized to peritoneum, as well as greater omentum, formed cancer glands in the majority. Thus, these results indicated that uPA mRNA and/or uPAR mRNA might be independent biological marker of tumor differentiation. Our data revealed the positive rates of uPA mRNA and/or uPAR mRNA expression in gastric carcinoma with vessel invasion, lymph node metastasis, liver and peritoneum metastasis were significantly higher than that without these clinicopathologic features, and also showed the obvious positive correlation between uPA mRNA and uPAR mRNA, thereby indicating that synergetic high expression of uPA and/or uPAR in tumor cells infiltration area plays a very important role in gastric cancer infiltration and metastasis. Showing that aggressive ability from infiltrating-type growth cancer was stronger than that of expanding-type cancer, our data implied that the more aggressive gastric cancer cells with uPA mRNA and/or uPAR mRNA positive expression degraded ECM strengthenly, thereby facilitating the cancer cells infiltration to the tissue depth, lymphatic and metastatic to the distant organs^[16,17]. So uPA and /or uPAR can be used as a marker of gastric carcinoma infiltration and metastasis.

Both the PA system and VEGF are key factors in

tumor angiogenesis. The PA system degrades the basement membrane and stimulates the migration and progression of endothelial cells in the early phase of angiogenesis^[18]. Beside induction of tumor angiogenesis, VEGF has several additional functions that serve to enhance tumor progression, including enhancing the permeability of tumor vessels^[19] and inhibition of apoptosis of endothelial cells^[20]. An association between the PA system and angiogenesis has been reported. VEGF has been shown to cause up-regulation of uPA and uPAR in endothelial cells. Moreover, a previous study demonstrated that the PA system and VEGF synergistically contributed to liver metastasis of colorectal cancer^[21]. VEGF promotes proliferation of endothelial cells and tube formation after degradation of the ECM by the PA system and/or MMPs^[22,23]. We observed a significant relation of VEGF with both uPA and uPAR in present study. We also observed positive expression of uPA mRNA, uPAR mRNA or VEGF protein in the tumor cells, suggesting that cancer cells with positive expression of uPA, uPAR or VEGF may play an important role in gastric cancer angiogenesis. Interestingly, stepwise analysis demonstrated that uPA mRNA, uPAR mRNA and VEGF protein expression was significantly correlated with MVD. The uPA, uPAR and VEGF produced from gastric cancer cells destroy ECM, which may promote migration of both cancer cells and endothelial cells. On the other hand, cancer cells with high invasive ability may have various malignant potentials, including VEGF production. Since we found a positive correlation between VEGF expression and both uPA mRNA and uPAR mRNA expression, it is possible that the PA system enhances VEGF-induced tumor angiogenesis, which is in agreement with Kaneko *et al.*^[24]. Recently, it has been reported that endostatin inhibits angiogenesis through the down-regulation of the PA system. Thus, the inhibition of uPA and/or uPAR activity may inhibit not only tumor invasion, but also angiogenesis in gastric cancer, and uPA and/or uPAR can be used as a marker of gastric cancer biological behavior.

Previous studies have shown that t-PA and PAI-1 levels are independently associated with survival^[25], and also proved that over-expression of uPA protein is associated with several clinicopathologic features and prognosis^[26,27]. Heiss *et al.*^[28] reported that univariate analysis revealed highly significant inverse correlations between uPA, uPAR and survival time, while multivariate analysis showed PAI-1 was an independent prognostic factor. Lee *et al.*^[29] demonstrated that uPAR level of gastric cancer tissues was correlated with advanced tumor staging and poor survival rates, suggesting that the measurement of uPAR in tumor tissues may be used to predict disease recurrence and the prognosis of gastric cancer. In the present study, survival analysis with the Kaplan-Meier method demonstrated that patients with expression of uPA mRNA and/or uPAR mRNA, VEGF protein had a significantly lower survival rate than those without these. The results suggest that PA system contributes synergistically to tumor invasion, angiogenesis of gastric cancer. uPA mRNA and/or uPA mRNA might be identified as independent prognostic factors.

Abstract

AIM: To study the expression level and localization of insulin-like growth factor -I receptor (IGF-IR) in HepG2 cells and Chang liver cells, and to observe the effect of anti-IGF-IR monoclonal antibody (α IR3) on the growth of HepG2 cells.

METHODS: The expression of IGF-IR in HepG2 cells and Chang liver cells was detected by immunohistochemistry. The influences of α IR3 on proliferation and apoptosis were examined by the 3- (4, 5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide (MTT) assay and electron microscopy, respectively. Flow cytometry (FCM) was applied for the analysis of cell cycle and apoptosis was observed under electron microscope.

RESULTS: IGF-IR was located in the membranes of both HepG2 and Chang liver cell lines, and the expression level of IGF-IR was higher in HepG2 cells than in Chang liver cells. Treated with 0.1 μ g/mL α IR3 for 48 h *in vitro*, the cell growth index (GI) of HepG2 cells was significantly higher than that of control (103.41% vs 100%, $P < 0.01$). However, the α IR3 for 24 h at final concentration of 4.0 μ g/mL made the GI of HepG2 cells lower than that of control (93.37% vs 100%, $P < 0.01$). Compared with control, treated with α IR3 for 48 h at final concentrations ranging from 1.0 μ g/mL to 4.0 μ g/mL markedly reduced the GIs of HepG2 cells (97.63%, 97.16%, 95.13%, 92.53% vs 100%, $P < 0.05$ or $P < 0.01$), treated with α IR3 for 72 h at final concentrations ranging from 0.2 μ g/mL to 4.0 μ g/mL decreased the GIs of HepG2 cells obviously (95%, 91.63%, 90.77%, 89.84%, 88.51% vs 100%, $P < 0.01$), and treated with α IR3 for 96 h at final concentrations ranging from 0.5 μ g/mL to 4.0 μ g/mL made GIs of HepG2 cells lower significantly (88.86%, 83.97%, 79.81%, 77.24%, 70.51% vs 100%, $P < 0.05$

or $P < 0.01$). Moreover, treated with α IR3 from 24 h to 96 h at final concentrations ranging from 0.2 μ g/mL to 4.0 μ g/mL reduced the GI of HepG2 cells from 97.63% to 70.51% in a dose- and time-dependent manner. Also, α IR3 treatment for 72 h at final concentration from 0.5 μ g/mL to 2.0 μ g/mL increased the proportion of G₀/G₁ phase cells (61.73%, 67.1%, 83.7%, 76.87% vs 44.47%, $P < 0.01$) and significantly decreased that of S phase cells (28.63%, 25.13%, 15.63%, 23.13% vs 53.17%, $P < 0.01$), in contrast to the proportion of G₂/M phase cells. The apoptotic rates of HepG2 cells were increased more than that of control (7.83%, 16.13%, 21.1%, 37.73% vs 4.13%, $P < 0.01$).

CONCLUSION: The malignant cell phenotype of human hepatocarcinoma cell is related to overexpression of IGF-IR. The blockage of IGF-IR with α IR3 may contribute to the inhibition of proliferation and induction of apoptosis in HepG2 cells.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common malignancy in the world and is estimated to cause half a million deaths annually. The incidence of HCC is dramatically increasing in the USA, Europe and Asia, most probably due to the increasing prevalence of chronic hepatitis C, liver cirrhosis and obesity^[1,2]. Unfortunately, the majority of patients suffer from advanced disease at presentation. Curative ablation or resection of HCC, or liver transplantation can be achieved only in a minority of patients. Local tumor destruction, chemoembolization, or systemic chemotherapy are the remaining treatment options in advanced HCC. However, overall survival is poor^[3]. Apart from chemoembolization, which improves survival in well-selected patients with

unresectable HCC, treatment options do not appear to greatly improve overall survival^[4]. Therefore, innovative treatment approaches are urgently needed. Evidence has been accumulated that the insulin-like growth factor-I receptor (IGF-IR) is a promising target for cancer therapy. A great variety of tumors show abnormal, enhanced and/or constitutive expression of IGF-IR. Several reports indicate that IGF-IRs are expressed frequently in HCC^[5], most likely contributing to the aggressive growth characteristics of tumors. Hence, the IGF-IRs are promising targets for innovative treatment strategies in HCC. IGF-IR is a transmembrane heterotetrameric protein, which has two extracellular α -chains and two membrane-spanning β -chains in a disulfide-linked β - α - α - β configuration^[6]. The binding of its ligands (IGF-I, IGF-II) to the extracellular domains of IGF-IR activates its intracellular tyrosine kinase domain resulting in autophosphorylation of the receptor. Activated IGF-IR phosphorylates its substrates and initiates proliferative and antiapoptotic signal transduction pathways that involve phosphatidylinositol-3-kinase and mitogen-activated protein kinase^[7,8]. The high degree of homology to insulin receptor presents a considerable challenge for the development of specific small molecule inhibitors of IGF-IR tyrosine kinase activity. IGFs are known to display mitogenic, transforming, and antiapoptotic properties in various human tumors, including HCC, by stimulating distinct intracellular signaling pathways^[9]. In addition to its role in proliferation of cancer cells, the IGF-IR protects cells from apoptosis caused by growth factor deprivation, anchorage independence, or cytotoxic drug treatment^[10]. Down-regulation of IGF-IR function by antisense and dominant negative techniques reduces the growth and tumorigenicity of several cancer cell lines *in vivo* and *in vitro*, including colon cancer, melanoma, lung carcinoma, ovarian cancer, glioblastoma, neuroblastoma, and rhabdomyosarcoma^[11-17]. IGF-IR is thus an attractive therapeutic target based on the hypothesis that inhibition of IGF-IR function would result in selective apoptosis and growth inhibition of tumor cells^[18]. An effective strategy to inhibit the function of IGF-IR in cancer cells is to use anti-IGF-IR antibodies that bind to the extracellular domains of IGF-IR and inhibit receptor activation. Suppression of the growth of various tumors has been evaluated, but IGF-IR inhibition for the treatment of human HCC remains unexplored. The expression and activity of IGF-IR was shown to be upregulated in HCC cells, which contributes to the process of malignant transformation and growth of liver tumors. Increased expression of IGF may further potentiate the mitogenic effects of IGF in the development of hepatocellular carcinoma^[19]. Hence, in the present study we examined the antineoplastic potency of the IGF-IR inhibitor α IR3 in human HCC cell lines. Our study provides evidence that monoclonal antibody (α IR3) inhibits growth and induces apoptosis and cell cycle arrest in human HCC cells.

MATERIALS AND METHODS

Cells and reagents

HepG2 human hepatocellular carcinoma cells and Chang

liver human normal hepatocytes were from Shanghai Institute of Cell Biology, and grown in RPMI 1640 with 10% heat-inactivated FCS (GIBCO BRL, Carlsbad, California, USA). IGF-IR Ab-1(24-31) was purchased from NeoMarkers, and α IR3 was from Oncogene Science. SABC and DAB kits were purchased from Boster.

Cell culture

HepG2 human hepatocarcinoma cells, normal human hepatocytes were from Shanghai Institute of Cell Biology, Chinese Academy of Sciences. The cells were maintained in RPMI 1640 (Life Technologies Inc.), supplemented with 10% heat-inactivated fetal calf serum (FCS), 0.3% L-glutamine, 1% penicillin/streptomycin solution, which contained 10 000 U/mL penicillin G and 10 mg/mL streptomycin sulfate. Cells were grown as adherent cells in a humidified atmosphere at 37°C in 50 mL/mL CO₂.

Immunohistochemistry

HepG2 and Chang liver cells were passaged onto 22 mm square glass coverslips in a 6-well plate (Nalge Nunc International, Rochester, NY). After 72 h, cells were washed twice with phosphate-buffered saline (PBS) and fixed in methanol (95%) at room temperature for 30 min. After two washes with PBS, cells were incubated in 0.3% H₂O₂ for 30 min to block endogenous peroxidase, then washed three times with PBS. Nonspecific antibody staining was blocked by preincubation with 5% bovine serum albumin (BSA) in PBS for 30 min, then incubated with the primary antibody IGF-IR Ab-1(24-31) at a 1:100 dilution overnight at 4°C. Cells were washed three times for 5 min in PBS. Then they were incubated with the biotinylated goat anti-mouse IgG. After incubation with the secondary antibody, cells were washed three times for 5 min with PBS again and incubated with streptavidin-biotin complex (SABC). After incubation for 30 min at room temperature, cells were then washed four times for 5 min in PBS and detected by using DAB as the substrate. All incubations were carried out in humidified chambers to prevent evaporation. All stainings were compared with negative controls. For each cell line PBS was used in representative negative control instead of primary antibody.

Cell proliferation/Survival assays

The effect of α IR3 treatment on the growth and survival of human cancer cell lines was measured using the 3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide (MTT) assay or by cell counting. In brief, when the cultured HepG2 cells reached 70%-80% confluence, the medium was replaced by FCS-free RPMI 1640 and the cells were cultured for 24 h, and then trypsinized with 0.25% trypsin, adjusted to a density of about 1500-3000 cells/well with complete medium. Two hundred microliters of the cells containing the different α IR3 (seven different concentrations ranging from 0.1-4.0 μ g/mL) were plated in 96-well plates and maintained for 24, 48, 72, 96 h separately. At the indicated periods of time, a solution of MTT (20 μ L of a 5 mg/mL solution in PBS) was then added, and the cells were incubated for another 3-4 h. The medium was removed and replaced by 200 μ L of Me₂SO,

and the units of absorption (UA) were measured at 490 nm. Triplicate values were obtained for each well, and each experiment was repeated three times. Growth index (GI, %) = $(UA_E/UA_C) \times 100\%$ (UA_E : average UA value of experimental group; UA_C : Average UA value of control group). The proliferation of HepG2 cells was inhibited at $GI < 100\%$; the proliferation of HepG2 cells was stimulated at $GI > 100\%$.

Flow cytometry

After the cultured cells have reached 70%-80% confluency, the medium was replaced by FCS-free RPMI 1640 and the cells were cultured for 24 h, and then trypsinized with 0.25% trypsin. Five $\times 10^4$ cells were plated in 25 mL culture-flasks in 2 mL of RPMI 1640 medium supplemented with 10% FBS, and simultaneously, α IR3 was separately added to cells at final concentrations ranging from 0.5-2.0 μ g/mL. After being treated for 72 h, the five groups of cells were digested and collected by centrifugation. Cells were washed once with 0.01 mol/L PBS (pH 7.2), and fixed in 70% ethanol at 4°C for 18 h. Next, cells were washed once with PBS, digested by Rnase (50 μ g/mL) and stained with propidium iodide (PI, 100 μ g/mL) for 30 min. The cell cycle phases and DNA content were detected and apoptosis was quantified by determining the percentage of PI-stained nuclei in the subdiploid peak in cell samples analyzed by FCM (Coulter, EpicsXL).

Electron microscopy

When the cultured HepG2 cells reached 70%-80% confluence, the medium was replaced by FCS-free RPMI 1640 and the cells were cultured for 24 h, and then trypsinized with 0.25% trypsin, 2.5×10^5 cells were plated in 50 mL culture-flasks in 10 mL of complete medium, and α IR3 was added to cells at final concentration of 1.0 μ g/mL as reported previously^[20]. Being treated for 72 h, the harvested cells were fixed with 2.5% glutaraldehyde in 0.1 mol/L PBS (pH 7.2) for 4 h. After washed in PBS, the cells were treated with 1% osmium tetroxide in 0.1 mol/L PBS overnight at 4°C, washed three times with PBS, dehydrated with a graded series of acetone and embedded in Epon812, which were polymerized at 60°C for 48 h. Ultrathin sections 50-80 nm thick were counterstained with uranylacetate and lead citrate and then observed under transmission electron microscope (EM) (H-600, Japan) at 100 kV.

Statistical analysis

The data were analyzed using one-way analysis of variance followed by least significant difference test (SPSS11.0 statistical software). The results were expressed as the mean \pm standard deviation (SD). A statistically significant difference was considered to be present at $P < 0.05$.

RESULTS

Expression of IGF-IR in HepG2 cells and Chang liver cells

IGF-IR expression was detected in both HepG2 cells and Chang liver cells, and appeared to be localized (Figure 1A and 1B). The positive reaction for IGF-IR was distinctly

Figure 1 A: Immunohistochemical findings of IGF-IR in Chang liver cells. Chang liver cells showing positive-staining of IGF-IR in the cell membranes of the cells (SABC, original magnification $\times 100$); B: Immunohistochemical findings of IGF-IR in HepG2 cells. HepG2 cells showing stronger positive-staining of IGF-IR in the cell membranes of the cells than that of Chang liver cells (SABC, original magnification $\times 100$).

different between HepG2 cells and Chang liver cells. Compared with Chang liver cell (Figure 1A), a stronger positive reaction for IGF-IR was detected in HepG2 cells (Figure 1B).

Cell growth index (GI) of HepG2 cells

MTT assay was used to investigate the proliferation rates of the cells treated with various concentrations of α IR3 for different periods of time. Unexpectedly, having being treated with α IR3 at final concentration of 0.1 μ g/mL for 48 h, GI of the cells was 104.13%, higher than that of the control group ($P < 0.01$). The result suggests that α IR3 of 0.1 μ g/mL could stimulate HepG2 cells to proliferate. However, after treatment with α IR3 at final concentration of 4.0 μ g/mL for 24 h, GI of the cells was 93.37%, lower than that of the control group ($P < 0.01$). Treated with α IR3 at final concentrations ranging from 1.0-4.0 μ g/mL for 48 h, GI of the different concentration groups was 97.63%, 97.16%, 95.13% and 92.53%, respectively, lower than that of the control group (1.0 μ g/mL group, $P < 0.05$; for the others, $P < 0.01$). After treatment with α IR3 at final concentrations ranging from 0.2-4.0 μ g/mL for 72 h, GI of the different concentrations groups was inhibited by 95%, 91.63%, 90.77%, 89.84%, 88.51% and 86%, respectively, significantly lower than that of the control group ($P < 0.01$). Treated with α IR3 at final concentrations ranging from 0.5-4.0 μ g/mL for 96 h, GI of the different concentration groups decreased by 88.86%, 83.97%, 79.81%, 77.24% and 70.51%, respectively,

Figure 2 Effects of α IR3 on in vitro growth of HepG2 cells treated with various concentrations of α IR3 for different periods of time. α IR3 of 0.1 μ g/mL could stimulate HepG2 cells to proliferate, while α IR3 inhibited HepG2 cell proliferation in a dose- and time-dependent manner at a concentration ranging from 0.2 μ g/mL to 4.0 μ g/mL.

Table 1 Effect of α IR3 on growth and proliferation of HepG2 cells treated with various concentrations of α IR3 for 24, 48, 72 and 96 h

Group	Cell growth index (GI)			
	24 h	48 h	72 h	96 h
Control	100	100	100	100
0.1 μ g/mL	100.640	103.4133 ^a	97.654	95.032
0.2 μ g/mL	104.716	98.952	94.9961 ^b	103.125
0.5 μ g/mL	99.840	98.175	91.6341 ^b	88.8622 ^a
1.0 μ g/mL	99.041	97.6343 ^a	90.774 ^b	83.9744 ^b
1.5 μ g/mL	97.042	97.1612 ^b	89.8358 ^b	79.8077 ^b
2.0 μ g/mL	96.883	95.1335 ^b	88.5066 ^b	77.2436 ^b
4.0 μ g/mL	93.3653 ^b	92.5313 ^b	86.0047 ^b	70.5128 ^b

^a $P < 0.05$, ^b $P < 0.01$ vs control.

dramatically lower than that of the control group (0.5 μ g/mL group, $P < 0.05$; the others, $P < 0.01$). These results indicate that with the increase of concentration of α IR3 and prolongation of treatment time, the effect of α IR3 inhibiting HepG2 cells proliferation was enhanced also in a dose- and time-dependent manner (Figure 2 and Table 1).

Analysis of cell cycle and apoptosis

To further study the anti-proliferation effect of α IR3 on HepG2 cells, FCM was used. After being treated with α IR3 at final concentration ranging from 0.5-2.0 μ g/mL for 72 h, cell growth was obviously inhibited. The proportion of HepG2 cells in the G₀/G₁ phase increased significantly from 44.47% (of control group) to 83.7%, and in the S phase decreased dramatically from 53.17% (of control group) to 15.63%, but there was no significant change in the proportion of cells in G₂/M phase (Table 1). These results suggest that α IR3 has an anti-proliferation effect on HepG2 cells. To determine whether cell death induced by α IR3 occurred through an apoptotic pathway, genomic DNA fragmentation was assayed as a hallmark of apoptotic cell death. Flow-cytometric analysis was performed to detect the subdiploid (apoptotic) cell population. The apoptotic index (AI) increased in HepG2 cells from 4.13% (of control group) to 37.73%. After treatment with α IR3 at final concentration ranging from 0.5-2.0 μ g/mL for 72 h, the cells exhibited an increase of subdiploid cell population in a dose-dependent manner (Table 2).

Table 2 Effect of α IR3 on cell cycle and apoptosis of HepG2 cells induced at various concentrations

Cell groups	Distribution of cell cycle (%)			Apoptotic index(%)
	G ₀ /G ₁ phase	S phase	G ₂ /M phase	
Control	44.47 \pm 0.4163	53.17 \pm 1.955	2.367 \pm 2.122	4.133 \pm 0.3215
0.5 μ g/mL	61.73 \pm 0.3786 ^b	28.63 \pm 0.5686 ^b	9.633 \pm 0.3512	7.833 \pm 0.4726 ^b
1.0 μ g/mL	67.10 \pm 0.8185 ^b	25.13 \pm 0.7506 ^b	7.800 \pm 0.2000	16.13 \pm 0.3512 ^b
1.5 μ g/mL	83.70 \pm 0.4000 ^b	15.63 \pm 0.3055 ^b	0.6667 \pm 0.5774	21.10 \pm 0.5292 ^b
2.0 μ g/mL	76.87 \pm 1.401 ^b	23.13 \pm 1.401 ^b	0 \pm 0	37.73 \pm 0.1528 ^b

^b $P < 0.01$ vs control group.

Figure 3 A: Transmission electron micrographs of HepG2 cells from the control group(EM , original magnification \times 6200); B: Transmission electron micrographs of HepG2 cells from the α IR3 group (EM, original magnification \times 6200).

Morphological changes of apoptosis

In HepG2 cells treated with α IR3 at final concentration of 1.0 μ g/mL for 72 h, many characteristic morphological changes of apoptosis were observed under EM. Histological evidence for apoptosis included shrinkage of cells, condensation of cytoplasm, expansion of rough endoplasmic reticulum (RER) and formation of small bubbles, destruction of mitochondria cristae and balloon-shaped mitochondria formation, disappearance or shrinkage of the nuclear membrane, condensation of karyoplasm or chromatin adherence to edge of nuclear membrane with different forms and sizes, formation of apoptotic bodies (Figure 3A and 3B). In the control group, HepG2 cells showed regular nuclei and uniform chromatin distribution within the nuclei, and there were no morphological changes in the mitochondria and other intracellular structures (Figure 3A). These results indicated

that apoptosis could be triggered in HepG2 cells treated with α IR3.

DISCUSSION

IGF-IR is expressed widely in the cell membranes of many cell types, and is essential for normal growth, development, and differentiation and mediates signals for the suppression of apoptosis, enhancement of mitogenesis, and anchorage-independent growth^[21]. Several studies indicate that the number of IGF-IRs on cells is critical in affecting the cell phenotype^[22]; overexpression of IGF-IR may induce transformation from the normal cell phenotype into the malignant cell phenotype. High levels of expression of IGF-IR have been reported in a broad range of human malignancies. Studies of treating IGF-IR as therapeutic target have often been reported. Our immunohistochemical results showed that IGF-IR is expressed in normal human hepatocytes Chang liver cells, suggesting that expression of IGF-IR in the normal tissue and cell plays a pivotal role in cell biological behaviors. Compared with Chang liver cell, the expression level of IGF-IR, which was located in the cell membranes of both cells, was higher in the cell membranes of HepG2 cells, suggesting that overexpression of IGF-IR induces transformation from the normal cell into the malignant cell. In another word, overexpression of IGF-IR is related to the biological behaviors of human malignancies.

Chemotherapy of advanced HCC is still unsatisfactory. Moreover, patients are frequently in poor clinical condition precluding aggressive chemotherapy. Thus, there is a strong need for new, effective and well-tolerated treatment strategies. Some people have focused attention on IGF-IR monoclonal antibody, and the experimental studies of treating some malignancies with the antibody alone or synergistically enhancing the efficacy of cytokines and chemotherapeutic agents have been reported, but its single effect on HCC remains unexplored. In the present study, we investigated the antineoplastic effects of α IR3, a specific IGF-IR inhibitor, on human HCC cells. According to MTT and FCM assay results, α IR3 inhibited the growth of HCC cells by inducing cell cycle arrest and apoptosis. Surprisingly, α IR3 also stimulated *in vitro* growth of cells in 48 h cultures. This was contrary to our expectation as we undertook these studies to explore the mechanism by which α IR3 inhibits *in vitro* growth of HepG2 cells. To characterize the underlying mechanisms of α IR3's anti-proliferative action on HCC cells, we performed cell cycle analyses. Upon α IR3-treatment the proportion of cells in the G₀/G₁-phase significantly increased, and S-phase significantly decreased in HepG2, suggesting that α IR3 acts at the G₁/S checkpoint. G₁/S cell cycle arrest induced by α IR3 has already been described in hepatocellular carcinoma^[23]. A second mechanism by which α IR3 could inhibit tumor growth is by its down-regulation effect on IGF-IR levels^[24]. α IR3 causes increased endocytosis but may not allow for receptor recycling, causing a net decrease in cell surface receptor levels over time^[24]. Hailey *et al.*^[25] suggest that IGF-IR is also internalized and degraded by a combination of both lysosome-dependent and lysosome-

independent pathways. Induction of apoptosis by α IR3 has been reported previously. In order to confirm this, we used two methods to detect the apoptosis induced by α IR3. Morphological changes of apoptosis in the α IR3 treated cells were seen under an EM, and apoptotic index was measured by FCM, which increased in a dose-dependent manner. Hailey *et al.*^[25] reported that α IR3 inhibited the phosphorylation of AKT, a downstream anti-apoptotic signaling component of the IGF-IR pathway. The activation of both mitochondria-dependent and -independent apoptosis pathways have been reported^[23]. Regulation of cell growth and apoptosis of HCC cells was already shown to be tightly associated with IGF-IR signaling^[26]. It can be speculated that IGF-IR inhibition by α IR3 diminishes mitogenic inputs of the IGF receptor system in HCC cells. Sachdev *et al.*^[24] reported that 250 nmol/L chimeric humanized single-chain antibody (scFv-Fc) activated IGF-IR and downstream signaling pathways, and stimulated the *in vitro* monolayer and anchorage-independent growth of MCF-7 cells, but when treated with 500 nmol/L scFv-Fc, the activity of IGF-IR and *in vitro* proliferation of MCF-7 cells were inhibited. It has been reported that the inhibitory or stimulatory behavior of some antibodies may be dependent on cell surface receptor number^[27]. Surprisingly, in our experiments, lower dose of α IR3 stimulated *in vitro* proliferation of HepG2 cells in 48 h cultures instead of inhibiting HepG2 cells. The mechanism by which lower dose of α IR3 stimulated *in vitro* proliferation of cells needs to be explored further. The mechanisms by which α IR3 inhibited *in vitro* growth of HepG2 cells were through inhibition of the IGF-IR and downstream signaling pathways, inducing cell cycle arrest and apoptosis, IGF-IR level down-regulation, and IGF-IRs degradation; but how the lower dose of α IR3 stimulated *in vitro* proliferation of HepG2 cells is unclear.

Although efficacious in our *in vitro* models of HCC, α IR3 as monotherapy may not be effective in cancers displaying mitogen dependent proliferation. Nevertheless, α IR3 has been shown to synergistically enhance the efficacy of chemotherapeutic agents^[20]. The underlying mechanisms include interference with damage repair mechanisms, maintenance of chemotherapy-induced apoptosis^[28], and the overcoming of growth factor-mediated resistance to chemotherapy^[29]. Thus, α IR3 may well be of clinical benefit for HCC patients, either as single agent or when added to conventional chemotherapy. To conclude, our study provides evidence that the IGF-IR inhibitor α IR3 inhibits the growth of human hepatocellular cancer cells by inducing cell cycle arrest and apoptosis, or stimulates proliferation of the cells. Monoclonal antibody may qualify for the development of targeted therapies for HCC. Further studies are needed to investigate the antitumor effects of monoclonal antibody combined with conventional chemotherapy on HepG2 cells.

Abstract

AIM: To investigate the inhibitory effects of a recombinant adenovirus vector that expresses NK4, a truncated form of human hepatocyte growth factor (HGF), on human colonic adenocarcinoma cells *in vitro* to establish a basis for future NK4 gene cancer therapy.

METHODS: Cells from the LS174T human colonic adenocarcinoma cell line were infected with recombinant adenovirus rvAdCMV/NK4 and the effects of the manipulation on tumor cell proliferation, scatter, migration, and basement membrane invasion were assessed. Cells infected with a recombinant adenovirus vector (Ad-LacZ) expressing β -galactosidase served as the controls.

RESULTS: We found that rvAdCMV/NK4 expression attenuated HGF-induced tumor cell scatter, migration, and basement membrane invasion ($P < 0.05$), but did not inhibit tumor cell proliferation.

CONCLUSION: HGF-induced LS174T tumor cell scatter, migration, and invasion can be antagonized by the recombinant NK4-expressing adenovirus.

INTRODUCTION

Hepatocyte growth factor (HGF), a glycoprotein consisting of 728 amino acids with a 69 kD α -chain and a 34 kD β -chain, affects tumor metastasis^[1,2]. HGF binds to c-Met, the only HGF receptor, and causes a cascade of enzyme catalyzed reactions, triggers signal transduction and the corresponding biological effects^[3]. In the normal condition, the paracrine influence of HGF between the epithelial and interstitial cells is strictly controlled. However, when abnormal HGF/c-Met signaling occurs, such as there is a mutation of the c-Met gene, over-expression of HGF and/or c-Met, or there is co-expression of HGF and c-Met within the same cells, c-Met may be persistently over-expressed and thereby exhibit a high-level of self-phosphorylation. All these biological activities, in turn, facilitate the occurrence, growth, infiltration, metastasis, and angiogenesis of many kinds of tumors^[4,5]. The HGF/c-Met signaling pathway has been thought to play an important role in the production of many kinds of human tumors^[6,7]. Studies discovering the ways to block this pathway will provide new targets for the anti-metastasis tumor treatment.

NK4, a specific antagonist of HGF discovered by Date *et al*^[8] in 1997, is a fragment from the HGF molecule that has been cut by elastase between the 478th and the 479th amino acid. NK4 derives its name from its structure: It is composed of the NH₂-terminal hairpin domain and four subsequent kringle domains of the α -chain of HGF. NK4 contains 447 amino acids, and the molecular weight is about 50 kD. Although NK4 competes with HGF for c-Met receptor binding, it cannot activate the c-Met receptor and induce its phosphorylation. Consequently, NK4 suppresses the interaction between HGF and c-Met, interrupts the HGF/c-Met signaling pathway, and thereby inhibits HGF-induced invasion and metastasis of tumor cells^[9,10].

In this study we used the replication-defective recombinant adenovirus rvAdCMV/NK4 expressing NK4 gene^[11] to investigate the anti-tumor effects of NK4 in LS174T human colonic adenocarcinoma cells. The objective of this study was to explore whether NK4 may be used as a human colonic tumor treatment- a possibility that would require an experimental basis for the clinical application of manipulations of the NK4 gene product.

MATERIALS AND METHODS

Virus and cell culture

The construction and identification of the recombinant adenovirus rvAdCMV/NK4 with E1-E3 deletions have been described previously^[11]. The recombinant adenovirus expressing β -galactosidase (Ad-LacZ) was generated in our laboratory using the same vector (data not published). These two viruses were replicated in a HEK293 human embryonic kidney cell line (American Type Culture Collection, Manassas, VA), which was maintained in DMEM medium (Invitrogen, Carlsbad, CA) supplemented with 100 mL/L fetal bovine serum (FBS) (Invitrogen). Culture titers were 8.9×10^{12} infection focus unite (ifu)/L and 6.4×10^{12} ifu/L, respectively. LS174T human colonic adenocarcinoma and MRC-5 human fetal lung fibroblast cell lines were purchased from the Shanghai Institute of Cell Biology at the Chinese Academy of Sciences and cultured in RPMI 1640 medium (Invitrogen) supplemented with 100 mL/L FBS, 100 U/mL penicillin, and 100 mg/L streptomycin (Invitrogen).

Western blots

Total cellular proteins were extracted and aliquots were separated by 12% SDS-polyacrylamide gel electrophoresis and transferred to nitrocellulose membranes. The blots were incubated with rabbit anti-human c-Met polyclonal antibody [1:250] (Zymed Laboratories, San Francisco, CA) or goat anti-human HGF- α polyclonal antibody [1:500] (Santa Cruz Biotechnology, Santa Cruz, CA) for 2 h at room temperature, followed by the addition of alkaline phosphatase (AP) conjugated secondary antibodies [1:5000] (Pierce, USA). AP was reacted with BCIP/NBT to visualize the bands.

Adenovirus transduction efficiency analysis

LS174T cells were seeded in 24-well plates until they reached 80% confluency, at which time they were infected with 1, 10, 25, 50 or 100 multiplicity of infection (MOI) with Ad-LacZ for 48 h. The cells were washed with phosphate buffered saline (PBS) and fixed in 100 mL/L formaldehyde for 10 min. Fixed cells were then stained with X-gal overnight at 37°C. The number of positive cells in each well was counted by viewing under a light microscope. Transduction = (the number of positive cells/number of total cells) \times 100%.

Cell proliferation assay

Two thousand five hundred LS174T cells/well were seeded in 96-well plates in triplicate and divided into a control group, an Ad-LacZ group, and a rvAdCMV/NK4 group.

The cells were cultured for 24 h (d 0), then mock infected or infected with viruses at 50 MOI for 1 h. The medium was then replaced with RPMI 1640 containing 100 mL/L FBS, and the cells were further cultured and harvested on d 0, 1, 3, and 5. Cell proliferation was analyzed using the CellTiter 96 Aqueous One Solution Regent (Promega, Madison, WI) according to the manufacturer's protocol.

Cell scatter assay

LS174T (2.5×10^3 cells/well) was seeded in 12-well plates. After culturing for 4 to 7 d at 37°C, the medium was replaced with 20 mL/L FBS RPMI 1640 medium. The cell cultures were divided into a control group, an Ad-LacZ group (50 MOI), and a rvAdCMV/NK4 group (50 MOI) and treated with recombinant human HGF (PeproTech EC, Rocky Hill, NJ) at a final concentration of 10 μ g/L for 48 h. The cell colony scattering was observed and photographed.

In vitro scratch wound healing assay

Cell migration was measured by an *in vitro* scratch wound healing assay as described elsewhere^[12]. Briefly, after LS174T cells were infected by 50 MOI of rvAdCMV/NK4 or Ad-LacZ for 48 h, the cells were trypsinized and adjusted to a density of 2×10^9 cells/L, then seeded in 12-well plates. Monolayer cells were scratched with a sterile pipette tip, and the cell migration was evaluated by counting the number of cells that had migrated from the wound edge after culturing for 24 h in 20 mL/L FBS-supplemented RPMI 1640 medium.

Invasion Assay

Invasion assay was carried out as previously described^[13]. Matrigel, an artificial matrix gel extracted from mice EHS sarcoma (purchased from the Department of Cellular Biology, Center for Health Sciences, Peking University, Beijing, China), was diluted by DMEM medium to 1 g/L. Polycarbonate membranes of the upper wells in a Transwell chamber (Corning Costar No. 3422) were loaded with 50 mL of Matrigel gel and exposed to UV for 30 min. Serum free medium was added to the chamber for polymerizing at 37°C for 30 min before using. LS174T cells that had been transduced with rvAdCMV/NK4 or Ad-LacZ at an MOI of 50 for 72 h were adjusted to a density of 1.5×10^9 cells/L. Cell suspension (100 μ L) was seeded on the upper wells and 600 μ L of serum-free RPMI 1640 media, with or without 10 μ g/L HGF, was added to the lower wells of the Transwell chamber. After cultivating for 72 h, the cells that degraded from the Matrigel and migrated through the 8 μ m pores of the membrane at the bottom of the upper wells to the opposite side of the membrane were stained with Hematoxylin and Eosin and counted. Five microscopic fields (\times 200) were randomly selected for cell counting. The inhibitory rate = [(the number of invading cells in control group-the number in treated group)/the number of invading cells in control group] \times 100%.

An inhibitory rate of more than 30%, $P < 0.05$, when compared with the group in which tumor cells in the upper wells and lower wells contained HGF, was considered to be evidence of an anti-invasion effect.

Figure 1 c-Met and HGF expression by Western blot.

Statistical analysis

All data are expressed as means \pm SD. Statistical comparisons were made using the Student's *t*-test. $P < 0.05$ was considered significant.

RESULTS

Expression of c-Met in the LS174T cell line

In this study we first examined the expression of c-Met, in order to test the reliability of using the colon cancer cell line LS174T as a study model. Western blot results showed that two specific bands were detectable in both LS174T and MRC-5 (Control): One was the 145 kD β -subunit of c-Met protein and the other was the 170 kD c-Met protein existing in the heterogeneous dimer form. This finding suggests that LS174T cells could be used as target cells of HGF and thus employed in further experimental studies. Expression of HGF was detected in MRC-5 cells, but was not detected in LS174T cells (Figure 1).

Adenovirus transduction optimization and NK4 gene expression

In order to optimize the gene transduction mediated by the adenovirus, we used the recombinant adenovirus Ad-LacZ, containing the report gene β -galactosidase, to infect LS174T cells at different MOI. We found that the infection rate increased with increasing MOI in a dose-dependent manner (data not shown). When the infection intensity reached 50 MOI, Ad-LacZ achieved a LS174T cell infection rate of more than 90% without pathological changes. Since overdose recombinant adenovirus infection will hurt cells and disturb cell growth, the optimal infection dose in all of our experiments was set as 50 MOI. rvAdCMV/NK4 infection of LS174T cells was confirmed by Western blot analysis. A specific NK4 protein band at 50 kD was detected, demonstrating that efficient expression of the NK4 gene mediated by the adenovirus was achieved in the LS174T cells (Figure 2). Thus, rvAdCMV/NK4-infected LS174T cells were found to be suitable for our experiments.

rvAdCMV/NK4 suppression of LS174T cell proliferation

We measured the effect of rvAdCMV/NK4 transduction on proliferation of LS174T cells. The proliferation rate of the tumor cells infected by rvAdCMV/NK4 was similar to that of the control group and the Ad-LacZ group ($P > 0.05$). As summarized in Figure 3, these data suggest that expression of the NK4 gene mediated by the adenovirus

Figure 2 Recombinant adenovirus rvAdCMV/NK4 mediated NK4 expression in LS174T cells. Notes: 1: Protein molecular weight markers; 2: Mock; 3: rvAdCMV/NK4.

Figure 3 Effects of NK4 expression on LS174T cell proliferation *in vitro*.

had no suppressive effect on LS174T cell proliferation.

Inhibition of LS174T cell scattering by rvAdCMV/NK4

Since HGF facilitates cell colony scatter, we designed this experiment to determine whether NK4 has an inhibitory effect on cell scattering. The results showed that intercellular adhesion among untreated LS174T cell colonies grown for 4 to 7 d was strong and that cells were not prone to scatter. But after HGF treatment, adhesion was relatively weak and the cells scattered in a spider-like pattern. In contrast, this HGF-effect was inhibited in rvAdCMV/NK4-infected cells. However, sole Ad-LacZ or rvAdCMV/NK4 infection did not influence intercellular adhesion, indicating that NK4 could specifically antagonize HGF-induced cell scattering (Figure 4).

Inhibition of LS174T cell movement by rvAdCMV/NK4

We performed a scratch wound healing assay to determine whether NK4 expressing recombinant adenovirus could attenuate HGF-induced cell motility. Without HGF treatment, the number of Ad-LacZ or rvAdCMV/NK4 infected LS174T cells that migrated into the scratch wound area were similar with that of uninfected LS174T cells. However with HGF treatment, we observed that less NK4-expressing cells migrated to the scratch wound area than control cells did, indicating that HGF activity of promoting tumor cell movement was antagonized by NK4. The number of cells migrating into the scratch wound areas of each group after HGF treatment was: $28.8 \pm 7.1/\text{mm}^2$

Figure 4 Scattering assay for LS174T cells after treatment with rvAdCMV/NK4 or Ad-LacZ.

in the control group; $29.3 \pm 9.4/\text{mm}^2$ in the Ad-LacZ group ($P > 0.05$ vs control group); and $10.2 \pm 3.6/\text{mm}^2$ in the rvAdCMV/NK4 group ($P < 0.05$ vs control group, Figure 5). These results suggest that the recombinant NK4 expressing adenovirus selectively antagonized HGF-induced cell movement.

Inhibition of LS174T cell Invasion by rvAdCMV/NK4

Tumor cell invasion of the basement membrane is a key process during metastasis. Matrigel, which is a kind of artificial matrix gel extracted from mouse EHS sarcoma, forms a membrane structure similar to the natural basement membrane structure in serum-free medium. The malignant invasion capacity of cells is revealed by their ability to penetrate into the filter membrane under the influence of an inductive chemo-attractant. The influence of specific factors on tumor cell invasive capacity can be observed *in vitro* by counting the number of cells that penetrate the filter membrane. The ability of untreated LS174T cells to degrade and penetrate the basement membrane was poor, but was improved when HGF was present in the lower chamber. The number of Ad-LacZ or rvAdCMV/NK4 infected LS174T cells that penetrated through the membrane without HGF in the lower chamber was similar to that of non-infected LS174T cells ($P > 0.05$). However, the invasive capacity of LS174T cells decreased significantly when HGF was present in the lower chamber (inhibitory rate 71.6%) after infection with rvAdCMV/NK4; meanwhile the inhibitory rate was only 7.3% in the Ad-LacZ treated group. This difference ($P < 0.05$) suggests that NK4 can specifically inhibit HGF-induced LS174T cell invasion (Figure 6).

DISCUSSION

Despite considerable advances in anesthesiology and surgical techniques as well as the development of new radiotherapy and chemotherapy strategies, the survival rate associated with colonic cancer has not been greatly improved. Tumor metastasis, including local metastasis to

Figure 5 Scratch wounding healing assay for LS174T cells treated with rvAdCMV/NK4 (mean±SD). ^a $P < 0.05$ vs Ad-LacZ or Mock (with HGF).

peripheral viscera and distant metastasis, is thought to be an important factor in determining survivability. It is reported that 15% to 35% of patients suffering from primary colonic cancer had liver metastasis when their primary tumors were diagnosed. Even among those patients who accept radical treatment for colonic cancer, 25% will have liver metastasis^[14]. Accordingly, the prognosis of patients suffering from colonic cancer is primarily associated with the occurrence of metastasis, especially to the liver. Thus inhibition of metastasis will markedly improve the prognosis of colon cancer patients.

Changes in oncogenes and anti-oncogenes within cells contribute to tumorigenesis, but tumor metastasis behavior is primarily regulated by extracellular activated growth factors. Stroma cells can regulate tumor cell motility by releasing various cytokines, and consequently may initiate tumor metastasis^[15-17]. HGF is one such important factor, released primarily by stroma fibroblasts, and initially identified and cloned as a potential liver cell mitogen^[18,19]. HGF has also been found to facilitate cell movement and extracellular matrix breakthrough, resulting in the scatter of many kinds of tumor cells^[4,20-22] and stimulating tumor cell prolifera-

tion and stroma cell angiogenesis^[23]. All of the effects of HGF are realized through its binding with the c-Met receptor, and c-Met receptors are over-expressed in many kinds of tumor cells^[24-26]. In this study we used the recombinant NK4 expressing adenovirus to infect the LS174T human colonic cancer cell line. Our results showed that NK4 could efficiently antagonize the effects of HGF, that is, it could inhibit the migration, scatter, and invasion of tumor cells. This suggests that NK4 is capable of blocking the HGF/c-Met signaling pathway and thereby may play an important role in antagonizing the invasion and metastasis of colonic cancer.

Highly malignant LS174T cells were harvested from poorly differentiated epithelial adenocarcinoma tissue. Western blot analysis indicated that c-Met protein was expressed in the LS174T cells. These findings demonstrate the feasibility of using recombinant adenovirus expressing NK4 to block the HGF/c-Met signaling pathway as a clinical intervention for colonic cancer. We did not detect HGF expression in the LS174T cells; however, the c-Met receptor was triggered clearly after HGF treatment, producing enhanced scatter, motility and invasion. These findings indicate that the HGF treatment was sufficient for this study. In *in vitro* cell proliferation experiments, rvAdCMV/NK4 had no effect on tumor cell proliferation. This is consistent with the studies of Kubota *et al.*^[27] and Saimura *et al.*^[28] indicating that the virus itself does not influence scatter and invasion.

A close relationship between the ability of tumor cells to move and their invasion capacity has been demonstrated^[29]. Thus suppression of tumor cell movement would be expected to inhibit invasion and metastasis^[30]. Initially, tumor cell movement appears as a scattering of the cells away from one another. We used a scatter assay and a scratch wound healing assay to reveal the inhibitory effects of NK4 on HGF. HGF reduced the intercellular homogeneous adhesion of LS174T cells; such as LS174T cells scattered and migrated. These effects were inhibited by rvAdCMV/NK4; however rvAdCMV/NK4 alone (without the presence of HGF) did not have any biological effects on LS174T cells, indicating that the effects of NK4 were specific for the HGF signal. The findings of Parr *et al.*^[31] was shown that the growth factor TGF- β was able to facilitate tumor cell scattering in the presence of the NK4 protein and provide further evidence for the conclusion that NK4 specifically suppresses the influence of HGF.

Once tumor cells fall off the original tumors they invade the extracellular matrix of the host, and then penetrate the lymphatic system or the blood vessels, resulting in distant metastasis. The Matrigel material is similar to the extracellular matrix and therefore can be used to simulate tumor cell penetration into the cellular matrix around blood vessels. LS174T cells were able to degrade the Matrigel and migrate across the 8 μ m membrane pores under the inductive influence of the chemo-attractant HGF. rvAdCMV/NK4 weakened the HGF-induced cell capacity for penetrating the basement membrane, but rvAdCMV/NK4 alone did not produce this effect. Dormancy therapy aimed at preventing angiogenesis has become a hot topic of discussion regarding with anti-tumor treatment^[32]. We did not investigate the antagonizing effect of NK4 on

Figure 6 Invasion assay for LS174T cells treated with rvAdCMV/NK4 (means \pm SD). ^a $P < 0.05$ vs Ad-LacZ (with HGF).

HGF-induced angiogenesis, which plays an important role in tumorigenesis and distant metastasis. However, recent studies have shown that the anti-angiogenesis effects produced by NK4 appear to be the result of not only a blockade of HGF-mediated effects, but also a blockade of effects mediated by vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF)^[33,34]. Thus NK4 may be considered as a multi-potential anti-tumor therapeutic protein. Because NK4 has the potential to impact many aspects of tumorigenesis, it will be great applicable in the future clinical treatment of tumors.

In conclusion, this study demonstrated that adenoviral-mediated NK4 inhibits the invasion and metastasis of LS174T colonic cancer cells by blocking the HGF/c-Met signaling pathway *in vitro*. These findings establish an experimental basis for further studies *in vivo*.

CONCLUSION: FlgK encoded by *flgK* is important for flagella formation and *H. pylori* motility. Deficiency in FlgK or an enhanced serological response to r-FlgK can interfere with *H. pylori* colonization. FlgK of *H. pylori* could be a novel target for vaccination.

Abstract

AIM: To characterize the role of *flgK* and its protein product in *H. pylori* colonization.

METHODS: The PCR cloning method identified the *flgK* gene. An isogenic *flgK* mutant was constructed by gene replacement and confirmed by Southern blot analysis and PCR analysis. The recombinant FlgK protein (r-FlgK) was purified. Electron microscopy (EM) was applied to demonstrate the flagella of *H. pylori*. An in vitro motility test was assessed in semisolid medium. The densities of *H. pylori* colonization with either the wild-type strain or its *flgK* mutant were compared among BALB/c mice with or without pre-immunization with r-FlgK. The serological responses to r-FlgK were analyzed for 70 clinical patients with different densities of *H. pylori* colonization.

RESULTS: From a duodenal ulcer strain, the *flgK* gene was cloned and it contained 1821 bp, with a 95.7% identity to the published sequences. No flagella were observed under EM for the mutant strain, which had a loss of motility. *H. pylori* density was lower in the BALB/c mice inoculated by the mutant or with pre-immunization with r-FlgK compared to unimmunized mice or mice inoculated by the wild-type strain ($P < 0.05$). In the *H. pylori*-infected patients, the serological responses to r-FlgK were uniformly low in titer.

INTRODUCTION

H. pylori is now well established as a causative agent and predisposing factor for peptic ulcers and even gastric malignancy^[1-3]. However, the actual mechanism by which gastroduodenal diseases develop in response to *H. pylori* infection remains unknown. The putative pathogenic factors of *H. pylori* are categorized as colonization, persistence, and disease inducing factors^[4]. Colonization in the host is a prerequisite of bacterial infection and subsequent pathogenesis. The putative pathogenic factor of *H. pylori* for colonization could be the possible target for preventive or even therapeutic strategy, such as vaccination.

Besides urease production and adhesin (to contact with the gastric epithelium), motility enhanced by uni-polar flagella is essentially required for *H. pylori* colonization^[5-7]. The motility of *H. pylori* is provided by two to six polar, sheathed flagella, the filaments of which consist of two flagellin types, FlaA and FlaB^[5,6]. The *in vitro* experiments with *flaA* and *flaB* isogenic strains disclosed that both genes are required for full motility for colonization^[7]. Moreover, the establishment of persistent *H. pylori* infection in a mouse model requires full motility and the presence of both flagellins^[8]. Another *H. pylori* *fliD* gene, encoding a 76 kDa HAP-2 homologue, was also disclosed to be required for the assembly of flagellar filaments and motility^[9]. Infection of mice with a *fliD* mutant of *H. pylori* SS1, a mouse-adapted strain, demonstrated that the FliD protein is necessary for colonization^[9]. Therefore, flagellar genes and their associated proteins should be potential tar-

gets for therapy and vaccine development against *H pylori* infection.

However, there are several genes related to the flagella in *H pylori*. Besides *flaA*, *flaB*, *flaE*, and *fliD*, the other flagellar structural proteins, such as *flgK*, are not well understood. This study thus describes the molecular cloning and characterization of the *H pylori flgK*. Applying the isogenic mutant of *flgK* and the recombinant FlgK protein of *H pylori*, this study has introduced both the *in vitro* and *in vivo* assay to define the role of *flgK* and its associated FlgK protein for *H pylori* colonization. Furthermore, this study has elucidated the clinical relevance of the anti-FlgK serological response to the colonization density of *H pylori* in humans.

MATERIALS AND METHODS

Bacterial strains and plasmids

The *H pylori* isolate (hp250) from a Taiwanese patient with duodenal ulcer was selected for the cloning of the *flgK* gene. The *Escherichia coli* strains used were DH5 α and JM107. The *E. coli* BL21 strain was used to express the FlgK protein. Plasmid pZero-2 (Invitrogen, Carlsbad, CA) was used to clone the *flgK* gene. Plasmid pET30b (Novagen, Madison, WI) was used to express the FlgK protein. The growth and culture conditions of *H pylori* were described previously^[10].

Construction of *flgK*-mutant

Part of the *flgK* gene was amplified by PCR using *H pylori* hp250 DNA as a template with the first primer (5' CGGGATCCCGTCGCCACATCAAAATTCCC 3') in the *flgK* gene and the second primer (5' GCTC-TAGAGCTTCACTCAACACTTCTTA CACC 3') designed to be complementary to *flgK*. PCR was performed in a DNA thermal cycler (Perkin-Elmer Corporation, Norwalk, Conn.) that had been programmed for 30 cycles of 1 min at 94°C, 1 min at 60°C, and 2 min at 72°C. Following amplification, the 1.4 kb PCR product was digested with *Bam*HI and *Xba*I (New England Biolab, Beverly, MA) and ligated to pZero-2. The 0.8 kb chloramphenicol resistance cassette (*cat*) was inserted into an *Eco*RI site to construct plasmid pMW336. Analyzing digestion patterns obtained with appropriate endonucleases and DNA sequencing confirmed the construction.

Transformation

E coli and *H pylori* was transformed based on the methods applied before^[11,12], and the selection for chloramphenicol resistance was done with 5 μ g/mL.

FlgK expression and purification

The *flaK* gene was amplified by PCR using the sense primer 5'GGGGATCCAATGGGCGGGATCTTATC3' and the antisense primer 5'CGCTCGAGTTATTGTT TAATCCCCAA3'. The PCR product was purified and cloned into the pT7 blue T vector (Novagen) and then sub-cloned to the pET30b vector digested with *Bam*HI and *Xba*I. The recombinant plasmid was transformed into the *E. coli* BL21 strain. Cells were grown at 37°C for

2-3 h in LB medium to an A_{600} up to 0.4-0.6. Isopropyl- β -D-thio-galactopyranoside (1 mmol/L) was added to the culture, and it was further incubated at 30°C for 4 h to induce protein production. Cells were harvested by centrifugation and lysed by a French press. The supernatants were collected and went through the Ni²⁺-chelate chromatography (Amersham Biosciences, Piscataway, NJ). r-FlgK was eluted using a linear gradient of 60 mM-1 M imidazole (Merck, Rahway, NJ) with a flow rate of 60 mL/h, and 1-ml fractions were collected. SDS-PAGE was performed to analyze the proteins in the soluble fractions. The desired proteins contained in the gel slices were identified by amino acid sequencing (Applied biosystems 477A autosequencer) after the proteins had been eluted. The final proteins were stored at -70°C.

Preparation of anti-r-FlgK antibody

Rabbits were injected intramuscularly with 1 mg of r-FlgK mixed with complete Freund's adjuvant; four subsequent immunizations with 500 μ g of r-FlgK mixed with incomplete Freund's adjuvant were given at 2-wk intervals. The serum anti-r-FlgK titers were determined by enzyme-linked assay seven days after the final boost.

ELISA for mice and human serum

Wells of microtiter plates (Dynatech) were coated with r-FlgK and blocked with bovine serum albumin. Serially diluted patient's serum was then added to the wells and incubated at room temperature for 2 h. Goat-anti-rabbit-IgG-HRP as secondary antibody was added and incubated at room temperature for 2 h. After the wells were washed, a 1:1 mixture of hydrogen peroxide and tetramethylbenzidine was added and incubated at room temperature for 1 h. The reaction was stopped with 2N H₂SO₄, and the results were read with a microtiter reader (V-max; Molecular Devices Corporation, Menlo Park, Calif.) at a wavelength of 450 nm.

Electron microscopy for the bacterial morphology

Both the wild-type strain and its isogenic mutant were harvested from blood agar plates and gently suspended in phosphate-buffered saline. The negative stain was based on the method of Josenhans *et al*^[7]. The morphology, especially the flagella filaments, was compared between these two strains under the transmission electron microscope (Hitachi, H7000, Tokyo, Japan).

In vitro motility testing and in vivo animal experiments

Both the wild type strain and mutant were used in *in vitro* motility tests based on the method of Kim *et al*^[9]. Besides the *in vitro* motility test, *in vivo* animal experiments were conducted. A total of 90 six- to eight-wk-old male BALB/c mice (Iffa, L'Arbresle, France) were allocated into three study groups, challenged with wild-type *H pylori* (W group, *n* = 30), the *flgK* mutant (M group, *n* = 30), and wild-type strain plus pre-immunization with r-FlgK (I group, *n* = 30). In the I group, mice were immunized ip With 100 μ g of r-FlgK mixed with complete Freund's adjuvant, followed by one further immunization with 50 μ g of r-FlgK with incomplete Freund's adjuvant. These mice were inoculated through gastric gavage with

Figure 1 A: Southern blotting of genomic DNA from *H pylori* 250 and its *flgK* mutant digested with *Hind*III. The probes used were specific for the *flgK* gene, chloramphenicol resistance (*Cm*) gene and λ DNA. Lane W, wild-type strain. Lane M, mutant. Low molecular weight protein markers.

5×10^8 CFU of wild-type or mutant strains for consecutive 3 d periods^[13]. One week after inoculation, half of the surviving mice were sacrificed by spinal dislocation in each study group. The remaining mice were all sacrificed on the end of 4th wk. Gastrectomy was then performed in each mouse, to be stained with hematoxylin-eosin (HE) for severity of gastric inflammation and Warthin-Starry silver stain for colonization of *H pylori*. These slides were evaluated on a blind-coded basis to assess the total density of *H pylori* colonization (HPD) of each mouse ranging from 0-15^[13]. The serum of each sacrificed mouse was also collected for the serological assay.

Serological response of antibody to FlaA and r-FlgK

This study has prospectively enrolled 70 dyspeptic patients, who have no known history of anti-*H pylori* therapy, to receive panendoscopy and serum samplings. During panendoscopy, the endoscopic diagnosis and the gastric biopsy were taken for the checkup of *H pylori* density (HPD, range 0-15)^[14]. The serological responses of these clinical patients to r-FlgK, and also to the other *H pylori* flagella related proteins like FlaA^[15] were analyzed to test their correlation to the colonization density of *H pylori* in the human stomach. The sera of 70 dyspeptic patients were re-sorted for determination of the antibody titer to r-FlgK and FlaA (HPA 5040, Ibt-Immunological & biochemical test system GmbH, Reutlingen, Germany) by the ELISA method. In addition, the sera of the mice in 3 different study groups were also re-sorted to check the antibody titer to r-FlgK and FlaA.

Statistical analysis

The Student's *t*-test was applied as appropriate for the parametric difference of HPD between mice sacrificed on the 1st wk and on the 4th wk within the same group. The one-way-ANOVA test with Bonferroni's method was used for multiple testing of data, including HPD, titer of anti-r-FlgK, and titer of anti-FlaA in both human and mice settings. All tests of significance were two-tailed with a *P* value < 0.05 taken as significant.

RESULTS

Disruption of the *flgK* gene and cloning of the r-FlgK protein

A pair of primers was used to amplify the *flgK* gene. The PCR product was confirmed by sequencing analysis. The *flaK* gene of *H pylori* hp250 contained 1821 bp, coding for a predicted 606 amino acids, and had 95.7% identity with published sequences^[16]. It has been deposited in GenBank under the accession No. AF333079. Gene replacement was used to disrupt the *flgK* gene. The successful creation of the *flgK* mutant was confirmed with southern blotting (Figure 1A), and western blotting analysis was used to detect the protein phenotype (Figure 1B). The r-FlgK protein was present in a 73 kDa band on the SDS-PAGE gels (Figure 2A). The r-FlgK protein was efficiently eluted from the Ni²⁺-chelating chromatography column by 500 mmol/L imidazole (Figure 2B). Identification of the purified protein of FlgK was confirmed via N-terminal sequence analysis of the protein; the first 10 amino acids (Gly-Gly-Ile-Leu-Ser-Ser-Leu-Asn-Ala-Ser) were confirmed exactly as predicted from the sequence.

Morphological difference under electron microscopy and in vitro motility assay

Under EM, no flagellar filament was observed in the mutant strain (Figure 3B), whereas the polar flagella were observed in wild-type strain (Figure 3A). No motility (indicated by the absence of a halo) was observed in the mutant strain (Figure 3D), whereas the halo was observed in wild-type strain (Figure 3C). Adding a high titer (as high as 1:50) of anti-r-FlgK polyclonal antibody (Figure 3E) had a more evident inhibition of the motility of wild-type *H pylori* than adding a lower titer (1:200) of antibody (Figure 3F).

Colonization assay and serological responses of the in vivo mouse model

All the mice in the three study groups, sacrificed on either the 1st wk or the 4th wk, had *H pylori* colonization. In Table 1, on the 1st wk of the study, the mean HPD of the mice in M group infected by the *flgK* mutant was significantly lower than that of I group, receiving pre-immunization by r-FlgK, and that of W group, infected by the wild-type strain (*P* < 0.05). On the 4th wk, the mean HPD of the mice in the M group remained significantly lower than that

Figure 3 The electron microscopy disclosed wild-type *H. pylori* had full-length sheathed flagella (A), which was not observed in the *flgK* mutant (B). *In vitro* motility testing disclosed halos of wild-type strain (C), whereas the mutant was without halo (D). An evident halo (arrows) indicated a poorer inhibition of the motility of wild-type *H. pylori* by adding 1:200 anti-r-FlgK polyclonal antibody (F) than by adding 1:50 of the antibody (E).

of the W group. The mean HPD of mice in the I group had a significant decrease in those sacrificed on the 4th wk, when compared to those on the 1st wk (3.89 vs 5.24, $P < 0.005$). Moreover, the mean HPD of mice sacrificed on the 4th wk became significantly lower in the I group than in the W group (3.89 vs 6.59, $P < 0.05$).

The serological titers to FlaA, in either 1-wk or 4-wk experiments, were similar among the three mice groups (Table 1). In contrast, the serological titer to r-FlgK of both 1-wk and 4-wk serum samples, were (ranked in an downward order): I group, W group, and then M group ($P < 0.05$).

Serological response to flagella protein in clinical patients

In Table 2, the serological response to FlaA was significantly higher for patients with high *H. pylori* colonization than for patients with low or no *H. pylori* colonization ($P < 0.05$). However, the serologic response to r-FlgK were all less than 0.6 (in titer level) for the three patient groups, and thus were not different between any two patient groups (Table 2).

DISCUSSION

Besides urease production and adhesin, motility enhanced by unipolar flagella is required for *H. pylori* colonization^[5,6]. The motility of *H. pylori* is provided by sheathed flagella, consisting of two flagellins (FlaA and FlaB) encoded by *flaA* and *flaB*^[6,7]. *In vitro* experiments with isogenic *H. pylori* strains of mutated *flaA* and *flaB* confirmed both flagellins are required for motility^[8]. In our study, the isogenic *flgK* mutant of *H. pylori* was disclosed to be without flagella under EM (Figure 3B). *In vitro* experiments revealed the mutant (Figure 3D) had a worse motility than the wild-typed strain (Figure 3C). Our findings confirmed that loss of flagella in *H. pylori* could occur by the disruption of its *flgK*, as well as by other previously reported flagellar genes.

Linkages between flagella and virulence have been observed previously in bacteria other than *H. pylori* isolates. In bacterial species other than *H. pylori*, loss of the ability to produce flagella generally has resulted in a less virulent

Table 1 *H. pylori* gastric colonization and the corresponding serologic responses to FlaA and r-FlgK of *H. pylori* in different mouse groups

Mean (SD)	W group	M group	I group
1-wk mouse groups ($n = 15$)

W group: mice challenged with wild-type *H. pylori*; M group: mice challenged with isogenic *flgK*-mutant; I group: mice received pre-immunization of r-FlgK before challenge of wild-type *H. pylori*; HPD: total *H. pylori* density of the mice's stomachs by histology. The value of anti-FlaA and anti-r-FlgK was indicated as optical density (A) checked by ELISA with a 1:1000 dilution of serum. ^aindicated significant difference between W and M mice groups; ^bbetween W and I mice groups; ^cbetween I and M mice groups (One way ANOVA test with Bonferroni's method, $P < 0.05$); ¹ indicated significant difference of this parameter between the 1-wk and the 4-wk samples within the same mouse group (Student's *t* test, $P < 0.05$).

Table 2 The serologic responses against FlaA and r-FlgK of *H. pylori* among patients with different gastric colonization

Serological A titer	<i>H. pylori</i> -negative	Low colonization	High colonization
Mean (SD)	($n = 20$)	($n = 20$)	($n = 30$)
Anti-FlaA ^{a,b}	0.268 (0.152)	0.298 (0.118)	0.398 (0.159)
Anti-r-FlgK	0.468 (0.154)	0.501 (0.258)	0.521 (0.233)

Low colonization and high colonization were defined by the total *H. pylori* density in the human stomach scored as less or equal to 5 and more than 5, respectively. A: indicates the optical density of titer checked by ELISA with a 1:1000 dilution of serum. ^aindicated significant difference between patients without *H. pylori* infection and with high colonization; ^bindicated significant difference between patients with low and with high colonization (One way ANOVA test with Bonferroni's method, $P < 0.05$).

organism^[17-19]. With respect to *H. pylori*, nonmotile mutants of *flaA*, *flaB*, or *flaD* genes could decrease motility and thus decrease the ability to establish persistent colonization of *H. pylori* in an *in vivo* mouse model^[6-9]. Such data demonstrated that full motility, mediated by these three flagellar associated genes or others, should be an essential virulence factor of *H. pylori*. These flagellar associated genes are thus possible targets for novel therapeutic or preventive vaccination for *H. pylori* infection. Besides *flaA*, *flaB*, and *flaD*, our study should be the first study to reveal another novel target, *flgK*, as able to regulate the presence of flagella on *H. pylori*.

In Figure 2, the r-FlgK protein of *H. pylori* was purified in this study. The anti-r-FlgK polyclonal antibody was obtained from a rabbit challenged with such purified r-FlgK. The study thus further tested whether anti-r-FlgK polyclonal antibody could inhibit the motility of the wild-type *H. pylori* isolates. *In vitro* motility testing of wild-type *H. pylori* was more inhibited by a 1:50 titer (to give no halo) (Figure 3E) than by a 1:200 titer of anti-r-FlgK polyclonal antibody (which resulted in a faint halo) (Figure 3F).

These findings supported the hypothesis that the immune response to r-FlgK of *H pylori* could possibly interfere with *H pylori* colonization of the infected host.

In Table 1, on the 1st-week study, the mice inoculated with the mutant were found with significantly lower HPD than those inoculated with the wild-type strain (3.65 *vs* 5.35, *P* < 0.05). The titer of anti-r-FlgK was also lower in the M group than in W group (0.329 *vs* 0.459, *P* < 0.05). The poor serological response to r-FlgK in the M group indirectly indicated that deficient production of FlgK occurred after destruction of the *flgK* gene. Moreover, deficiency of FlgK in the mutant strain decreased its colonization ability in mice. Such above-mentioned difference was consistently found on the 4th wk (Table 1). On the 4th wk study, the titer of anti-r-FlgK of the immunized group was significantly higher than those of the other two groups (1.325 *vs* 0.682 and 0.351, *P* < 0.05). On account of this higher titer of anti-r-FlgK antibody (which has the ability to inhibit motility) (Figure 3E and 3F), mice receiving pre-immunization had lower HPD than those mice in W group (3.89 *vs* 6.59, *P* < 0.05). This evidence was also supported by the limited (< 1.0) titers to r-FlgK of the clinical *H pylori*-infected patients (Table 2). These interesting findings supported the ability of an enhanced immune response to r-FlgK to inhibit the motility of *H pylori*.

The mean titers of anti-FlaA in these three mouse groups were not different on either the 1st or 4th wk study (Table 1). This data suggested the interference with *H pylori* colonization in mice was mainly accounted for by the response to the *flgK* gene product rather than the *flaA* gene.

In contrast to the poor serological responses to anti-r-FlgK, these clinical patients were disclosed to have significant differences in the titer of anti-FlaA Ab among patients with different *H pylori* colonization density (Table 2). This implied the serological response to FlaA could be more sensitive than anti-r-FlgK to predict the presence of *H pylori* infection. However, the titer of anti-FlaA was increased with the increment of *H pylori* colonization (Table 2). The function of anti-FlaA antibody may just serve as a serological marker rather than a promising immune protection against *H pylori* infection.

In summary, FlgK encoded by the *flgK* gene plays an important role in flagella formation and motility of *H pylori*. The deficient FlgK of *flgK*-mutant and the pre-immunization with r-FlgK can effectively decrease *H. pylori* colonization. Therefore, FlgK of *H pylori* may serve as a potential target to inhibit the motility and colonization of *H pylori* in the infected host.

Abstract

AIM: To study the direct correlation between gastric dysrhythmias and *in vivo* gastric muscle tone.

METHODS: Five healthy dogs were implanted with 4 pairs of electrodes along the greater curvature, with a strain gauge (SG) being sutured parallel to the distal electrodes (2 cm above the pylorus). Intravenous vasopressin was given to induce gastric dysrhythmia. The percentage of regular slow waves and SG energy were calculated.

RESULTS: (1) the regularity of gastric myoelectric activity (GMA) was reduced during and after infusion of vasopressin; (2) SG energy was significantly decreased during the infusion of vasopressin; (3) the decrease in SG energy was well correlated with the reduction in GMA regularity; (4) SG energy was negatively correlated with bradygastria and tachygastria.

CONCLUSION: Vasopressin inhibits gastric contractions and impairs gastric slow waves; gastric dysrhythmias are associated with the reduced antral muscle contractions, and are indicative of antral hypomotility.

INTRODUCTION

Gastric motility is under the control of gastric myoelectric activity (GMA). Normally GMA originates from the junctional area of the fundus and proximal stomach, propagates aborally, controlling the frequency and direction of gastric contractions. Disturbances in GMA, so-called gastric dysrhythmias, have been frequently observed in patients with various diseases including gastroparesis^[1], dyspepsia^[2], anorexia nervosa^[3], gastroesophageal reflux diseases (GERD)^[4], motion sickness^[5,6] and pregnancy^[7], etc. Gastric dysrhythmias have also been linked to gastrointestinal symptoms such as nausea and vomiting^[5,6], and improvement of gastric dysrhythmias seems to be associated with relief of such symptoms^[5,8].

Gastric dysrhythmias are classified into tachygastria (frequency higher than normal), bradygastria (frequency lower than normal) and arrhythmia (no rhythmic activity), based on the dominant frequency of GMA. Although it is believed that gastric motility could be affected inevitably, the relationship between gastric dysrhythmias and gastric motility has not well been established. Various techniques including electrogastrography (EGG), gastric emptying and simultaneous recording of EGG and intraluminal pressure have been applied, and available evidence suggests that tachygastria may be associated with hypogastric motility^[9-12], while the effect of bradygastria on gastric motility remains controversial^[13,14]. The association between specific gastric dysrhythmia and gastric muscle contractions has never been carefully investigated.

To address these issues, in this study we specifically evaluated: (1) the effect of intravenous vasopressin on GMA; (2) the correlation between gastric muscle tone and GMA; (3) the effect of experimentally-induced gastric dysrhythmias on gastric muscle contractions, in a canine model.

MATERIALS AND METHODS

Animal preparations

Seven healthy female hound dogs (15-22 kg) were anesthetized with intravenous infusion of thiopental sodium (20 mg/kg) and maintained with inhalation of isoflurane (1%-2%). A midline laparotomy was performed, and four pairs of temporary cardiac pacing wires (A&E Medical, Farmingdale, NJ) were implanted under the serosal surface along the greater curvature of the stomach. The most distal pair was 2 cm above the pylorus, and the distance between adjacent pairs of electrodes was

Figure 1 Surgical preparations of stomach. Four pairs of temporary electrodes were implanted along the greater curvature at a distance of 4 cm. The most distal pair was 2 cm above the pylorus. A strain gauge was sutured on the serosal wall parallel to the most distal pair of electrodes.

4 cm (Figure 1). The electrodes in each pair were 1 cm apart. The electrodes were affixed to the gastric serosa by un-absorbable suture in the seromuscular layer of the stomach. The wires were brought out through the anterior abdominal wall, channeled subcutaneously along the right side of the trunk, and placed outside the skin for the attachment for recording gastric myoelectric activity. A strain gauge was sutured on the serosal wall parallel to the most distal pair of electrodes (Figure 1).

The study was initiated about 10 d after the surgery. The protocol was approved by the Animal Use and Care Committee of the University of Texas Medical Branch at Galveston, Texas, USA.

Experimental protocols

Experiments were performed in overnight fasted, fully recovered animals. One study session was performed in each animal. Vasopressin was administered intravenously to induce gastric dysrhythmias in each session. In brief, after a 20 min baseline recording, Vasopressin (0.5 U/kg) was infused continuously for 20 min, followed by another two 20 min recovery periods. GMA and strain gauge signal were recorded simultaneously throughout the session.

Recording of gastric myoelectrical activity and gastric muscle tone

Gastric electrical activity and gastric muscle tone were recorded using a multi-channel recorder system (Acknowledge, Biopac System, Santa Barbara, CA). All signals were displayed on a computer monitor and saved on a hard disk by an HP Pentium IV PC. For GMA, the low and high cutoff frequencies of the amplifier were 0.05 Hz and 35 Hz, and the sampling frequency was 20 Hz. The recordings were then low-pass filtered with a frequency of 1 Hz and re-sampled at a frequency of 24 Hz to reduce the volume of data and potential artifacts before the final review.

Analysis of gastric myoelectrical activity and gastric muscle tone

Regularity of GMA: The percentage of 4- to 6-cpm slow waves is a quantitative assessment of the regularity

Figure 2 Sample tracings of gastric myoelectric activity recorded from implanted temporary electrodes and gastric contractions from the attached gastric strain gauge. Top 4 channels are gastric myoelectrical activities recorded using serosal electrodes implanted along the greater curvature. The bottom tracing shows gastric contractions measured from a strain gauge implanted in the distal stomach parallel to Channel 4. It was noticed that slow waves propagate from proximal to distal stomach and each gastric slow wave was coupled with a gastric contractile event.

of the GMA measured from the EGG. It was defined as the percentage of time during which normal 4- to 6-cpm gastric slow waves were observed in a specific EGG recording. The percentage of normal 4- to 6-cpm slow waves was computed from the running power spectra of the GMA using an adaptive spectral analysis method^[15]. One power spectrum was generated for every 2 min of EGG data, and the spectral peaks in each spectrum were examined visually. A spectrum was defined as normal if it had a clear peak in the 4- to 6-cpm range. The percentage of regular 4- to 6-cpm slow waves was determined by computing the ratio between the numbers of normal and total spectra.

Gastric dysrhythmias: The percentage of time of gastric dysrhythmias was also computed using running spectral analysis. Bradygastria was defined as a frequency of 0.5-4.0 cpm. Tachygastria was defined as a frequency of 6.0-15.0 cpm. Arrhythmia was defined as any irregular rhythm.

Gastric muscle tone: Reflected by the energy of the strain gauge signals, which were derived by calculating the area under the curve.

Statistical analysis

GMA regularity within each session was compared with One-Way ANOVA. The correlation between gastric muscle tone and gastric dysrhythmias was analyzed with Pearson's correlation test. All data were presented as mean \pm SE. $P < 0.05$ was taken as significance.

RESULTS

Gastric myoelectrical activity and gastric muscle tone at baseline

Intrinsic, distally propagating gastric slow waves were observed in all animals at a mean frequency of 5.6 ± 0.3 cpm, with a range of 4.8-6.2 cpm. Rhythmic variations in gastric muscle tone were consistently present, and coupled with each gastric slow waves at an identical frequency (Figure 2).

Figure 3 The regularity of gastric myoelectric activity was reduced with and after infusion of vasopressin, and returned somewhat during the last 20-min recovery period. ANOVA, ^b $P < 0.001$ baseline vs 2nd or 3rd 20-min period ($n = 7$).

Figure 4 Distribution of gastric dysrhythmias induced by intravenous infusion of vasopressin. Similar percentage of tachygastria and bradycastria was observed, which contributed to the irregularity of gastric myoelectric activity. ANOVA, ^a $P < 0.05$ vs baseline and 3rd 20-min period ($n = 7$).

Effect of vasopressin on GMA

The regularity of GMA was $90.1\% \pm 5.0\%$ at baseline. It was reduced to $13.9\% \pm 3.9\%$ and $52.2\% \pm 6.4\%$ during the following two 20-min periods with and after infusion of vasopressin ($P < 0.01$), and returned to $84.7\% \pm 9.2\%$ during the last 20-min period (Figure 3).

The decrease in the regularity of GMA was attributed to an increase in both bradycastria ($48.0\% \pm 10.4\%$ vs $1.1\% \pm 0.8\%$) and tachycastria ($35.4\% \pm 8.2\%$ vs $8.7\% \pm 5.0\%$) (Figure 4).

Effect of vasopressin on strain gauge energy

The strain gauge energy was significantly decreased during the 20-min infusion of vasopressin. The total energy was 48.4 ± 1.3 dB at baseline, and decreased to 36.6 ± 4.5 dB, 44.5 ± 4.3 dB, 45.8 ± 1.9 dB during the following consecutive three 20-min periods during and after the infusion (vs baseline, $P < 0.05$).

Correlation of GMA and strain gauge energy

The decrease in strain gauge energy was positively correlated with the decrease of GMA regularity ($r = 0.96$, $P < 0.05$). Gastric muscle contractions were reduced or disappeared during periods of bradycastria or tachycastria

Figure 5 Illustration of gastric dysrhythmias induced by intravenous Vasopressin. Top 4 channels are gastric myoelectrical activities recorded using serosal electrodes implanted along the greater curvature. The bottom tracing shows gastric contractions measured from a strain gauge implanted in the distal stomach parallel to Channel 4. It was noticed that gastric muscle contractions were absent during periods of tachygastria and bradycastria.

(Figure 5). Strain gauge energy was negatively correlated with bradycastria ($r = -0.96$, $P < 0.05$) and tachycastria ($r = -0.95$, $P > 0.05$).

DISCUSSION

Through this study we have found: (1) Intravenous vasopressin at proper doses consistently produced gastric dysrhythmias; (2) strain gauge implanted on gastric wall could reliably detect gastric muscle contractions; gastric muscle contractions were coupled with intrinsic gastric slow waves, and each gastric slow wave was capable of inducing a change in gastric muscle tone; (3) gastric muscle contractions was positively correlated with the regularity of the gastric slow waves; and (4) the reduction or disappearance in gastric muscle contractions was associated with both bradycastria and tachycastria.

Considering the fact that all muscle contractions are coupled and superimposed with myoelectric activities, it is strongly believed that gastric dysrhythmias could cause disturbances in gastric motor functions^[16]. A larger number of clinical studies have been performed recently, and indeed, gastric dysrhythmias have been observed in various motility disorders like gastroparesis, functional dyspepsia and motion sickness, *etc*^[1-7]. In patients with gastroparesis, gastric emptying scintigraphy and EGG were performed concurrently, and it was found that postprandial gastric dysrhythmias correlated with delays in solid phase gastric emptying^[17]. Gastric dysrhythmias may also be in association with the occurrence of GI symptoms^[5,6]. We have noted on many occasions that degeneration of GMA preceded the occurrence of nausea and vomiting in our previous canine studies. Other investigators also reported similar findings^[5,6,18], and all these indicate a possible causative role for the dysrhythmia in the production of nausea and vomiting.

Only few studies have been conducted to qualitatively assess the association between gastric dysrhythmias and gastric motility and there have been no quantitative studies. The first report on tachycastria in humans was published by Telander *et al*^[11]. They reported a 5 month-

old male infant suffering from severe gastric retention and symptoms of intractable nausea, vomiting and weight loss. The symptoms were attributed to impaired motor function of the stomach. The patient underwent resection of the distal $\frac{3}{4}$ of the stomach. The excised tissues were studied *in vitro* by means of intracellular electrodes, and abnormally fast slow waves (> 5 cpm) were detected^[11]. The association between gastric dysrhythmia and gastric motor disorders was further substantiated by other studies. You *et al*^[12] observed tachygastria in a 26-year-old woman with persistent nausea, vomiting and abdominal pain who was found to have severe impairment of antral motor functions. In contrast to tachygastria, data on bradygastria are inconsistent. Van Der Schee *et al* observed bradygastria in dogs and found that it was correlated with strong antral contractions^[13], while Abell *et al*^[14] induced bradygastria in humans with glucagon, and found that it was associated with absence of antral contraction.

In our present study, we attached a strain gauge to the site of recording electrodes, which allows us to study the direct correlation of gastric contractions and GMA. In comparison to the traditional intraluminal manometry, strain gauge is more sensitive and more direct in the detection of subtle contractions of gastric wall than any other methods. In addition, gastric dysrhythmias in this study were assessed quantitatively rather than qualitatively in the previous studies. Our results indicate that both tachygastria and bradygastria are negatively associated with gastric muscle contractile activity, which is consistent with most of the previous report^[11-14].

The exact mechanisms causing gastric dysrhythmias have not been fully understood, though it is well known that GMA is generated by interstitial cells of Cajal, and is influenced by central and autonomic nerve systems, certain hormones and peptides. Tachygastria and bradygastria are different. Tachygastria usually originates from distal stomach, and can be considered as an ectopic rhythm, while transient or persistent bradygastria usually originates from the region of the normal pacemaker at a reduced frequency. Gastric dysrhythmia can be induced experimentally with various agents including vasopressin^[14,19-21]. Vasopressin is a peptide released into the peripheral circulation from the pituitary during experimental motion sickness, and has been confirmed to induce gastric and intestinal dysrhythmia and symptoms of nausea and vomiting^[20-22]. An elevated plasma level of vasopressin was reported in postsurgical patients with impaired gastrointestinal motility^[23]. Vasopressin was known to reduce mesenteric blood flow, which was frequently used in patients with esophageal variceal bleeding^[24], and this vasoconstrictive effect might be the mechanism involved in the induction of GI dysrhythmias.

Gastric myoelectric activity can be recorded in several ways including intraluminal electrodes, surface electrogastrogram and serosal electrodes. Placement of intraluminal electrodes is invasive and uncomfortable. It is very difficult to direct the electrodes to specific sites of stomach and electrodes can be easily dislodged. EGG is a convenient summation technique with various disadvantages: (1) derived data on frequency and power are not strictly region specific; (2) susceptible to a variety

of artifacts; (3) cannot discriminate chaotic rhythm from uncoupling; and (4) susceptible to myoelectric interference from other gut organs, and cutaneously acquired signals may not be gastric in origin^[25]. Serosal recordings, on the other hand, do not have these potential technical problems, and is the most reliable *in vivo* GMA recording except for the need for surgery. This method has allowed us to put the recording electrodes and strain gauge at the same location, thus providing an excellent tool for the study of the direct correlation of dysrhythmias and gastric contraction, which has never been done before.

Another interesting finding from this study is that under control conditions each gastric slow wave seems capable of inducing a certain level of mechanical contractions in gastric muscle. These contractions are so subtle that they could only be reflected by strain gauge, other than other techniques, including intraluminal manometry. This observation is inconsistent with traditional view that only gastric slow waves superimposed with spike activities are capable of inducing gastric contractions.

In summary, in this study we have observed that intravenous administration of vasopressin could impair gastric slow waves and gastric muscle contractions. Experimentally induced tachygastria and bradygastria are negatively correlated with the gastric muscle contractions, suggesting that gastric dysrhythmias, either tachygastria or bradygastria, may be indicative of gastric hypomotility.

Abstract

AIM: To study the histological and pancreatitis-associated protein mRNA accumulation changes of pancreas from acute phase of caerulein-induced pancreatitis to recuperation in rats.

METHODS: Acute pancreatitis was induced by caerulein in male Wistar rats and followed up for 90 d by histological and mRNA analyses of pancreas. Pancreases were dissected at 0, 9, 24 h and 3, 5, 15, 30, 60, 90 d post-induction. Edema (E), polymorphonuclear neutrophil (PMN) infiltration, cytoplasmic vacuolization (V), zymogen granule depletion (ZD) and acinar disorganization (AD) were microscopically evaluated. Accumulation of pancreatitis-associated protein (PAP) and L13A mRNAs were quantified by real-time PCR.

RESULTS: The main histological changes appeared at 9 h post-induction for PMN infiltration and cytoplasmic V, while at 24 h and 3 d for E and ZD, respectively. All the parameters were recovered after 5 d, except for ZD which delayed more than 30 d. The main AD was observed after 15 d and values returned to normal after 30 d. Similarly to histological changes, accumulation of the PAP mRNA was increased at 9 h with the highest accumulation at 24 h and differences disappeared after 5 d.

CONCLUSION: From the acute phase to recuperation of pancreatitis, regeneration and re-differentiation of pancreas occur and PAP expression is exclusively an acute response of pancreatitis.

Key words: Acute pancreatitis; Histological changes; PAP

INTRODUCTION

Acute pancreatitis (AP) is an inflammatory disease of the pancreas associated with autodigestion of the gland, as a consequence of the intrapancreatic activation and releasing of digestive enzymes^[1]. The pathogenic mechanisms involved in the development of acute pancreatitis are not well understood^[2,3] although many studies on it are available. The acute period of pancreatitis is characterized by exocrine insufficiency as a result of important morphological alterations and changes on the expression of a number of genes in the pancreas^[4,5]. If pancreatitis is not fatal, a stepwise regeneration of the morphology is followed^[6].

Some events that regulate the severity of acute pancreatitis are known, involving common inflammatory and repair pathways^[7,8]. Recently it was demonstrated that pancreatitis-associated protein (PAP), an acute phase protein, is itself an important determinant of disease severity^[9]. The expression of this gene is low in the normal pancreas and becomes strongly augmentation after even mild pancreatic inflammation^[10]. This augmentation is assumed in AP induced by caerulein, although it can be assayed in AP induced by retrograde injection of sodium taurocholate. Currently, pancreatitis is induced by supramaximal dose of caerulein and there is no report yet on histological and PAP mRNA changes in the pancreas as response of AP induction.

Therefore, the objective of this study was to evaluate the morphological and PAP mRNA changes in the acute and adaptive phases of pancreatitis induced by caerulein in rats. Morphological changes were evaluated by light microscopy and PAP mRNA levels by real-time PCR.

MATERIALS AND METHODS

Bioassay

The experiments were carried out on 33 male Wistar rats (mean weight 100.8 g and 4-wk old). The animals were fed with standard laboratory chow and water *ad libitum*

under controlled room conditions. Acute pancreatitis was induced according to the method of Dusseti *et al*^[11]. The rats were injected intraperitoneally with caerulein (Sigma Chemical Co., St. Louis, MO, USA) at a dose of 50 µg/kg of body weight per hour for 6 h. The rats were sacrificed at h 9 and 24, and on d 3, 5, 15, 30, 60 and 90 respectively. Three control rats without caerulein injection were sacrificed at h 0 and on d 30 and 90 and dissected. Prior to sacrifice, the rats were anesthetized with 10-15 mg of tiletamine chlorohydrate and zolazepam chlorohydrate (Zoletil 50®) per kg of body weight. Pancreas was dissected for histological or RNA analysis. Feeding protocol and animal handling were approved by the local ethics committee.

Histological examination

Pancreatic sections were fixed in 10% formaldehyde, embedded in paraffin, cut (3-5 µm in thickness) with a semi-motorized rotary microtome (Leica RM-2145) and mounted onto slides. The sections were processed for H&E staining and examined by conventional light microscopy (Olympus microscope B × 50) with 20 ×, 40 × and 100 × objectives. Eight random images by objective were recorded by microscope video camera. A pathologist who was blinded to the treatment protocol scored the tissues according to Kyogoku *et al*^[12] for zymogen granule depletion (0, absent; 1, less than 20%; 2, 20%-50%; 3, more than 50%), interstitial edema (0, absent; 1, expanded interlobular septa; 2, expanded intralobular septa; 3, separated individual acini), polymorphonuclear neutrophil (PMN) infiltration (0, absent; 1, less than 20 PMNs per intermediate power field (IPF); 2, 20-50 PMNs per IPF and 3, more than 50 PMNs per IPF), grade of vacuolization based on the percentage of acinar cells with cytoplasmic vacuoles per IPF (0, absent; 1, less than 20%; 2, 20%-50%; 3, more than 50%) and acinar disorganization based on the percentage of area without normal acinar distribution (0, absent; 1, less than 20%; 2, 20%-50%; 3, more than 50%).

RNA preparation

Extracted pancreas was immediately rinsed with RNase-free water (treated with 0.05% diethyl pyrocarbonate, DEPC), homogenized in 1 mL of TRIzol® reagent (GIBCO-BRL, Grand Island, NY, USA), frozen and stored at -70°C. Total RNA was extracted by phenol/chloroform extraction and isopropanol precipitation^[13]. Accumulation of PAP mRNA (GenBank access No. NM_053289.1) was analyzed as indicator of pancreatic injury. L13A mRNA (GenBank access No. X68282) was also analyzed as house-keeping gene presumed to be invariant^[14]. All the primers were designed with Primers3 software and synthesized by Sigma Genosys (Woodlands, TX, USA). Their sequences and PCR product sizes are listed in Table 1. Prior to the reverse transcription reaction, potentially contaminating residual genomic DNA was eliminated with DNase I (Invitrogen, Carlsbad, CA, USA) followed by reverse-transcribed using specific primers and SYBR Green RT-PCR reagents (PE Applied Biosystems, Foster City, CA) according to the manufacturer's instructions. Synthesized complementary DNA (cDNA) corresponding to 100 ng total RNA was used for real-time PCR.

Table 1 Oligonucleotide primer pairs used for real-time quantitative PCR, binding site and expected size

Primer	Sequence	GenBank No.	Product size (bp)

PAPrv	5' TTACTGCTTTCGAAGACATGAGG 3'		
rL13A/Fw	5' AAGCAGGTACTGCTGGG 3'	X68282	261
rL13A/Rv	5' CCAACACCTTGAGGCGTT 3'		

Standard synthesis

Standards for the absolute quantification for PAP and L13A mRNAs were synthesized by Titan one Tube RT-PCR system (Roche Biochemicals, Indianapolis, IN, USA) with the same PCR parameters described above, according to the manufacturer's instructions. Then, PCR products were purified with Wizard® SV gel and PCR clean-up system (Promega, Madison, WI, USA) and quantified by fluorometry.

Quantitative PCR analysis

Real-time quantification of PAP and L13A mRNAs was performed with an iCycler iQ detection system (BIO-RAD, Hercules, CA, USA). SYBR Green I assay was used for quantification of all specific genes. For PAP mRNA quantification of each 50 µL SYBR Green PCR, 9.0 µL cDNA (corresponding to 100 ng total RNA), 1.8 µL sense primer (10 µmol/L), 1.8 µL antisense primer (10 µmol/L), 25 µL SYBR Green PCR Master Mix (PE Applied Biosystems) and 12.4 µL PCR-grade water were mixed together. The PCR conditions were 1 cycle at 94°C for 4 min, then 35 cycles at 94°C for 30 s, at 61°C for 30 s and at 70°C for 30 s, with a single fluorescence measurement at the end of the 70°C for 30 s. For L13A mRNA quantification of each 50 µL SYBR Green PCR, 9.0 µL cDNA (corresponding to 100 ng total RNA), 1.2 µL sense primer (10 µmol/L), 1.2 µL anti-sense primer (10 µmol/L), 25 µL SYBR Green PCR Master Mix (PE Applied Biosystems) and 13.6 µL PCR-grade water were mixed together. The PCR conditions were 1 cycle at 94°C for 3 min, then 38 cycles at 94°C for 45 s, at 55°C for 45 s and at 72°C for 1 min, with a single fluorescence measurement at the end of the 72°C for 30 s. In both cases, a melting curve program (60-95°C with a heating rate of 0.5°C for 30 s and continuous fluorescence measurement) and a cooling step to 4°C were added.

Analysis and normalization of real-time PCR data

Optical data obtained by real-time PCR were analyzed by using the default and variable parameters available in the software provided with the iCycler iQ optical system (BIO-RAD, Hercules, CA, USA). The PCR threshold cycle number (CT) for each cDNA standard and cDNA sample was calculated at the point where the fluorescence exceeded the threshold limit. The threshold limit was fixed along the linear logarithmic phase of the fluorescence curves at 10-20 SDs above the average background fluorescence. The number of amplicon cDNA copies was expressed relative to the amount of total cDNA present (ng). Although it might be difficult to determine the absolute amount of a

Different letters within a same column differ significantly ($P < 0.05$).

cDNA present in different samples, quantification of test mRNA transcripts was normalized to a reference gene, the L13A gene.

Statistic analysis

Histological data were expressed as mean \pm SE of the scores assigned by the pathologist and evaluated by ANOVA. Also, relation between PAP and L13A after absolute quantification was expressed as mean \pm SE and compared using ANOVA test. $P < 0.05$ was considered statistically significant. NCSS 2001 statistical program was used.

RESULTS

Histological examination

At the beginning (0 h), the architecture of pancreas was normal (Figure 1) with acinar cells exhibiting the typical epithelial polarity. Basal portion of the cells contained their nuclei and apical portion of the secretory vesicles and zymogen granules. Acinar cells in AP displayed moderate vacuolization and light inflammatory infiltration of neutrophils, with the highest score after 9 h post-induction. After 5 d, levels returned to the normal scores maintained to the end of the study. Edema was increased 9 h post-induction with the highest score at 24 h and returned to the normal level on d 5. Zymogen granule depletion was most pronounced on d 3 with later recovery. However, an additional depletion occurred on d 15, returned to the normal levels 30 d post-induction (Table 2). Although some degree of acinar disorganization was observed in the pancreas 9 h after induction, a significant increase was observed on d 15, and returned to the normal level 30 d post-induction (Table 2).

Specific amplification

Melting curve analysis demonstrated that each of the primer pairs (Table 1) amplified a single predominant product with a distinct melting temperature (T_m) as shown for L13A and PAP cDNA in Figure 2. The T_m of products could be seen clearly as a peak in a first derivative plot. The rapid fall of T_m at 87.5°C and 82.0°C for L13A and PAP cDNA respectively indicated the presence of a specific product melting at this temperature.

Figure 1 Light-microscopic sections of pancreas (X 133) from 0 h (A) and rats with caerulein-induced acute pancreatitis at 9 h (B), 24 h (C), 3 d (D), 5 d (E), 15 d (F), 30 d (G) and 60 d (H). Normal pancreatic acinus (0 h) shows zymogen granules (GZ) concentrated in the apical pole of the cell close to the acinar lumen (L). The basal region of the cell contains nucleus (N). In AP, PMN infiltration (M), vacuoles (arrowhead), edema (star), zymogen granule depletion (Z) and acinar disorganization (arrow) were observed on d 15. On d 30, pancreatic acinus appearance was almost indistinguishable from that at 0 h.

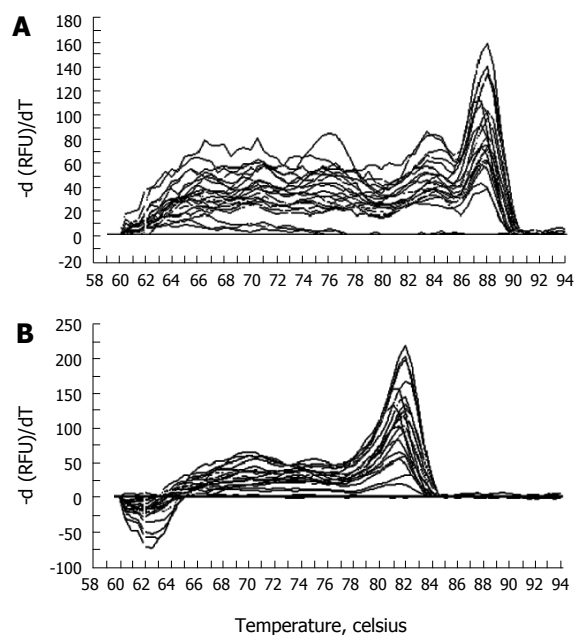

Figure 2 DNA melting curve analysis of amplification products for PAP mRNA (A) and L13A (B).

Absolute detection and quantification

The absolute quantification was estimated from real-time PCR analyses using a standard curve of tenfold serial dilutions ranging from 1.78×10^9 copies to 1.78×10^5 copies of L13A mRNA and 1.46×10^9 copies to 1.46×10^5 copies of PAP mRNA, in 50 μ L of volume reaction. As shown in Figure 3, the mRNA of PAP was detected in basal levels without caerulein (0 h). However, after induction of AP, the PAP mRNA expression was slightly augmented after 9 h, and 3.8-fold the basal level at 24 h. After 5 d, differences disappeared and the accumulation of PAP mRNA was decreased gradually to the basal level.

DISCUSSION

The acute phase of pancreatitis is characterized by a pattern of changes in the morphology of exocrine pancreas, expression of secretory proteins and mRNA levels of different genes^[4,6,15,16]. The observed changes in our study resemble a mild form of AP, characterized by edematous fluid in the extra-cellular space, causing separation of lobules

Figure 3 Relative quantification of PAP mRNA in caerulein-induced pancreatitis. Absolute quantification of PAP mRNA as copies was normalized to copies of L13A as determined from standard curves. All data are mean \pm SE.

and acini^[6]. Usually there is mild invasion by neutrophils, the acinar cells lose their zymogen granules, enlarging the acinar lumen. However, few studies^[17-19] have analyzed the morphological changes after the acute phase of pancreatic response.

After acute response, re-differentiation of acinar cells and transition begin with regular acinar cell replete with dense zymogen granules beside cells with a smaller quantity of zymogen granules, on the same microscopic preparation. Intermediate cells change the typical architecture of the pancreas due to the loss of zymogen granules in a particular section. Additionally, the rough endoplasmic reticulum might be reduced and/or rearranged^[6]. In this study, zymogen granule depletion and increase of acinar disorganization were presented after the acute phase of pancreatitis (determined by maximal PAP synthesis and its mRNA accumulation according to Iovanna *et al*^[4] and our results, respectively). These changes are explained in the context of reconstitution of the normal morphology and function of the pancreas.

De Lisle and Logsdon^[20] have shown the differentiation and re-differentiation of mouse pancreatic acinar cells. They immunolabeled acinar cells with monoclonal antibodies specific for acinar or duct cells and showed that more than 97% of the labeled area is acinar positive on d 3, which decreases to approximately 16% on d 9, and then returns to over 97% by day 21 of culture^[20]. Lechene de la Porte *et al*^[21] induced pancreatitis by the injection of trypsin in multiple sites of the rat pancreas and reported that pancreatic repair involves proliferation of cells from intact acini and tubular complexes. This process of differentiation and re-differentiation of pancreatic acinar cells explains our finding of the highest score for acinar disorganization on d 3 and 15 as well as complete recovering of zymogen granules 30 d post-induction.

In pancreatitis not only morphological changes were observed, but also molecular modifications occurred. Iovanna *et al*^[4] showed that PAP is significantly increased 48 h after induction of pancreatitis by retrograde injection of sodium taurocholate in rats, compared to normal pancreas. In spite of methodological differences in the quantified PAP, our results agree with those of Iovanna *et al*^[4]. However, PAP mRNA accumulation is quite differ-

ent between both studies. Differences could be attributable to the pancreatitis induction method, the severity of the problem, as well as the quantification method itself. In our study, after absolute quantification, values were normalized in respect to a housekeeping gene (L13A). Therefore, quantification by real-time PCR may better reflect the actual physiological changes.

Histology of pancreas showed a mild edematous pancreatitis induced by caerulein and the acute response was followed by recuperation process after 15 d of induction, according to acinar disorganization and zymogen granule depletion scores. Although PAP is related to the severity of pancreatitis, its function *in vivo* is not well established. Our findings support that PAP is a protein of acute response, because changes in levels are not observed in reconstitution of the pancreatic normal morphology. In addition, the PAP mRNA changes in AP induced by caerulein, measured by a most sensible technique of quantification as real-time PCR, are similar to those from AP induced by sodium taurocholate.

Abstract

AIM: To investigate the effect of telomerase hTERT gene antisense oligonucleotide (hTERT-ASO) on proliferation and telomerase activity of pancreatic cancer cell line Bxpc-3.

METHODS: MTT assay was used to detect the effect of different doses of hTERT-ASO on proliferation of Bxpc-3 cell for different times. To study the anti-tumor activity, the cells were divided into three groups: Control group (pancreatic cancer cell Bxpc-3); antisense oligonucleotide (hTERT-ASO) group; and nonsense oligonucleotide group decorated with phosphorothioate. Telomerase activity was detected using TRAP-PCR-ELISA. Cell DNA distribution was examined using flow cytometry assay. Cell apoptosis was observed by transmission electron microscope in each group.

RESULTS: After treatment with 6 mmol/L hTERT-ASO, cell proliferation was inhibited in dose- and time-dependent manner. The telomerase activity decreased after treatment with hTERT-ASO for 72 h. Flow cytometry showed the cell number of G₀/G₁ phase increased from 2.7% to 14.7%, the cell number of S phase decreased

INTRODUCTION

Telomerase is a ribonucleoprotein polymerase which adds telomeric sequences onto the ends of chromosomes to compensate for DNA end replication^[1]. Telomerase plays an important role in the development of cellular immortality and oncogenesis^[2]. It is different from reverse transcriptase DNA polymerase of commonly pure proteins. The activated telomerase takes the 3' distal end of telomeres as the primer and its RNA component acts as the template^[3]. In human, telomerase activity has been found in embryonic development, adult germ-line tissues, immortal cell^[4,5] and most malignant tumors^[6,7], while there is no evident expression in normal human tissue other than in germ cell, hemopoietic stem cells and cuticle basal cells^[8,9]. Human telomerase is a ribonucleo-protein complex, composed of a catalytic reverse transcriptase subunit (hTERT), an RNA component (hTR) that serves as a template for the synthesis of telomeric repeats, and an associated protein subunit (TP1)^[10-12]. Previous studies have shown that telomerase activity is found in 85%-90% of all human tumors, but not in their adjacent normal cells^[13,14]. This makes telomerase a good target not only for cancer diagnosis, but also for the development of novel therapeutic agents^[15,16]. Among them, only the expression

of hTERT mRNA is correlated with telomerase^[17], and mainly regulates the expression of human telomerase enzymatic activity^[18-20]. hTERT is a useful marker for telomerase activation^[21,22]. It is associated with the majority of human malignant cancers. Therefore, telomerase should be the target of anti-tumor drugs research.

In this study, we aimed to investigate the inhibitory effects of antisense phosphorothioate oligodeoxynucleotides on human pancreatic cancer cell line Bxpc-3 telomerase activity and cell growth, thereby exploring the potential value of telomerase hTERT gene as a target for antisense gene therapy in pancreatic cancer.

MATERIALS AND METHODS

Cell culture

Human pancreatic carcinoma cell line (Bxpc-3) was obtained from Chinese National Cancer Institute, Chinese Academy of Medical Sciences, Beijing. Cells were cultured in RPMI 1640 medium supplemented with heat-inactivated fetal bovine serum, 2 mmol/L L-glutamine, 100 kU/L penicillin and 100 mg/L streptomycin at 37°C in a humidified CO₂ incubator containing 50 mL/L CO₂ and 950 mL/L air. Cells were counted using 5 g/L trypan blue staining.

Oligodeoxynucleotides synthesis

Oligodeoxynucleotides synthesis was designed as described in GenBank, and they have not the same source searched with computer. Antisense oligodeoxynucleotides (ANS-ODN) with sequence 5'-CTCAGTTAGGGTTAGACA-3', which can recognize the RNA template region of telomerase, and nonsense oligodeoxynucleotides (NNS-ODN) with sequence 5'-CATTTCTTGCTCTCCACG-3' were prepared on the 391 DNA synthesizer, and synthesized by Huamei Engineering Company of Beijing. The synthesized oligodeoxynucleotides were subjected to polyacrylamide gel electrophoresis and purified by running at 300 V for 1.5 h.

MTT assay

Cells were seeded at 2×10^6 cells /well in a 96-well plate, 100 μ L per well in three wells. The ANS-ODN and NS-ODN were added to the cultured cells with the final concentrations of 1, 2, 4, 6 μ mol/L, and further cultured for 24, 48, 72, 96 h, respectively. Four hours before the end of culture, 50 μ L (1 g/L) 3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide (MTT, Sigma) was added, which was used to assay the activity of mitochondrial dehydrogenases. Four hours later, DMSO was added to solubilize the crystal product. The plate was then incubated at 37°C for another 12 h. The absorbance at 630 nm was measured with a model 550 microplate reader (Bio-Rad). The percent of cell growth inhibition was calculated as follows: $(A_c - A_e) / A_c \times 100\%$, where A_c is the absorbance value for the controls and A_e for the experimental cells.

Flow cytometry analysis of cell cycle and apoptosis

Approximately 2×10^6 cells were harvested and washed twice with PBS, fixed with 700 mL/L alcohol for 24 h, prepared as single-cell suspension and stored at 4°C,

thawed rapidly at room temperature and centrifuged to collect the cells. The cells were resuspended in a solution containing 10 g/L RNase A (833.5 μ kat/g, 50 mg/L) and 20 mg/L propidium iodide (PI) for 10 min. The cell cycle distribution and apoptosis were determined by the fluorescence of individual cells measured with flow cytometry^[23]. All data were analyzed using Cell Quest software.

Telomerase activity assay

Polymerase chain reaction enzyme-linked immunosorbent assay (PCR-ELISA) was performed following the manufacturer's instructions (Huamei Engineering Company of Beijing). Briefly, 2×10^6 cells were isolated, mixed with 50 μ L lysis buffer and incubated on ice for 30 min. Supernatant was collected after centrifugation at 14 000 g for 20 min at 4°C. In an Eppendorf tube, 2 μ L of the supernatant, 45 μ L of reaction mixture and 30 μ L of liquid olefin were added, and centrifuged for several seconds, placed in the water-bath at 25°C for 30 min, and then subjected to PCR amplification. The PCR conditions were as follows: primer elongation at 94°C for 2 min; telomerase inactivation at 94°C for 30 s; and 35 amplification cycles, each cycle consisted of denaturation at 48°C for 30 s, primer annealing at 72°C for 90 s, and extension at 72°C for 5 min. Then 50 μ L of amplified product and 100 μ L of hybridization reagent solution B were added and mixed; 25 μ L of the mixture was distributed in the wells of a microtitering plate incubated at 37°C for 60 min. The mixture was washed at 37°C for 15 min using 100 μ L of the hybridization reagent solution C, followed by addition of 25 μ L of solution A and B in microtitering and incubation at 37°C for 15 min. Finally, 2 μ L of stop reagent was added. The value in each well was read at the wave length of 450 nm. The negative control value was considered as 0.05. Sample's value ≥ 2.1 times of the negative control was considered positive. Each sample was examined for more than twice. The final value was presented as mean \pm SD, after analyzing with *t* test.

Cytologic morphology

Cytologic morphological changes were observed under the Olympus optical microscope and transmission electron microscope.

Statistical analysis

Results were expressed as follows. Statistical analyses were carried out with the software package SPSS11.0. The means of the groups were compared with repeated measures analysis of variance. $P < 0.05$ was considered statistically significant.

RESULTS

Growth arrest of Bxpc-3 cell in vivo

No significant difference in absorbance value of the control group and the NS-ODN group was observed ($F = 0.013$, $P > 0.05$), whereas a significant difference was observed compared to the Ans-hTERT group ($F = 35.347$, $P < 0.01$), thus indicating an obvious inhibition of cell growth caused by Ans-hTERT (Tables 1 and 2). This

Figure 1 The absorbency value was reduction, companied by the increase of ans-hTERT's time and dose.

Figure 2 The inhibition ratio was enhancement, companied by the increase of ans-hTERT's dose and time.

Table 1 Absorbance values of the different groups (mean \pm SD)

Groups	24 h	48 h	72 h	96 h
Control	0.48 \pm 0.10	0.60 \pm 0.10	0.61 \pm 0.03	0.65 \pm 0.05
NS-ODN (6 μ mol/L)	0.50 \pm 0.07	0.61 \pm 0.19	0.60 \pm 0.08	0.66 \pm 0.19
ANS-ODN (1 μ mol/L)	0.60 \pm 0.03	0.48 \pm 0.06	0.37 \pm 0.03	0.31 \pm 0.05
ANS-ODN (2 μ mol/L)	0.56 \pm 0.02	0.47 \pm 0.09	0.34 \pm 0.04	0.29 \pm 0.03
ANS-ODN (4 μ mol/L)	0.51 \pm 0.10	0.39 \pm 0.08	0.33 \pm 0.04	0.28 \pm 0.03
ANS-ODN (6 μ mol/L)	0.43 \pm 0.10	0.27 \pm 0.02	0.26 \pm 0.06	0.19 \pm 0.00

Table 2 Ratio of inhibition of Ans-hTERT group (mean \pm SD)

ANS-ODN	24 h	48 h	72 h	96 h
1 μ mol/L	1.2 \pm 6.4	19.6 \pm 10.6	39.9 \pm 4.8	52.0 \pm 8.1
2 μ mol/L	2.5 \pm 7.5	21.1 \pm 15.4	43.9 \pm 6.6	55.4 \pm 4.6
4 μ mol/L	5.6 \pm 9.7	34.6 \pm 13.4	46.4 \pm 6.1	57.3 \pm 5.3
6 μ mol/L	11.4 \pm 19.2	55.6 \pm 3.6	57.9 \pm 9.0	71.3 \pm 0.4

growth inhibitory effect was dose- and time-dependent (Figures 1 and 2).

Effect of antisense hTERT ODNs on induction of Bxpc-3 cells apoptosis

After incubation of the cells with 6 μ mol/L ans-hTERT for 72 h, the G₀/G₁ stage cell had obvious difference ($3.6 \pm 1.6\%$ vs $13.6 \pm 1.0\%$, $t = 9.522$, $P = 0.01$), and a sub-G₁ stage cell apoptosis peak appeared in front of G₁ stage.

Effect of antisense hTERT ODNs on telomerase activity in Bxpc-3 cells

After incubation of the cells with 6 μ mol/L ans-hTERT for 72 h, a significant increased telomerase activity of ans-hTERT group was observed (1.209 ± 0.308 vs 0.447 ± 0.087 , $t = 4.128$, $P < 0.05$) compared to the control group. The ratio of inhibition of the telomerase activity was 63% (Ratio of inhibition = $1 - \text{ans-hTERT group/control group} \times 100\%$).

Change in cytologic morphology

After incubation of the cells with 6 μ mol/L ans-hTERT

Figure 3 Chromatin of nucleolus congregated and distributed inside karyotheca, appearing half-moon type. A: Bxpc-3 cell control group; B: ans-hTERT group.

for 72 h, the chromatin in the nucleolus was congregated, distributed in the karyotheca and appeared as half-moon type. The villus on the surface of karyotheca died away and came into being the big and small varied apophysis of vesicular shape. The cell appeared undergone apoptosis (Figure 3A and B).

DISCUSSION

Telomeres form the ends of eukaryotic chromosomes consisting of an array of tandem repeats of hexanucleotide 5'-TTAGGG-3'. Telomeres protect the chromosomes from DNA degradation, end-to-end fusions, rearrangements and maintain nuclear structure^[24]. Human telomerase is a ribonucleoprotein complex, composed of a catalytic reverse transcriptase subunit (hTERT), an RNA component (hTR) that serves as a template for the synthesis of telomeric repeats, and an associated protein subunit (TP1)^[10,12,25]. It adds telomeric repeats to the 3' end of telomeric DNA. This telomere stabilization by telomerase can lead to unlimited cell proliferation. Therefore, inhibition of telomerase activity will be a new therapeutic modality for cancer^[26-32]. In most researches, the target gene was hTR, which is the replication template for telomere, but not the regulatory region of hTERT, the most important region which regulates the activity

of telomerase. Studies have reported that anti-hTERT complementary to the template region of hTERT is sufficient to inhibit P3 cell telomerase activity and cell proliferation *in vitro*^[3,33]. But the expression level of hTERT has no relation with the tumor's development. Most current studies have proposed that reactivation of telomerase is a critical step in tumorigenesis^[34-38]. There is a close correlation between hTERT and telomerase activity. Several researchers, using ISH techniques, have demonstrated high levels of hTERT expression in malignant tissues but not in non-malignant tissues. Du *et al*^[39] showed that the telomerase activity was correlated with the cell growth. Our findings also revealed a good correlation between the inhibition of telomerase activity and reduction in cell growth. However, in our study, the cell growth inhibition was mainly the result of cell cycle arrest, not the increased cell apoptosis rate.

In conclusion, growth of pancreatic cancer cell Bxpc-3 is inhibited by ans-hTERT oligodeoxynucleotides in a dose- and time-dependent manner, which is associated with the cell cycle accumulation in G₀/G₁ phase. The cell ratio of G₀/G₁ phase increased from 2.70% to 14.69%, the cell ratio of S phase decreased from 72.7% to 51.0% and a sub-G₁ stage cell apoptosis peak appeared in front of G₁ stage. Our results showed that ans-hTERT oligodeoxynucleotides can effectively inhibit hTERT gene expression, decrease telomerase activity, and trigger apoptosis. It is likely to raise the possibility that antitumor effect of ans-hTERT oligodeoxynucleotides occurs through following two pathways: (1) a short-term effect on apoptosis is induced rapidly by as-hTERT^[40]; and (2) a long-term effect on telomerase activity is inhibited, and cell death is caused when telomere length is critically shortened by telomeric DNA. Apoptosis induction may be one of the potential mechanisms of ans-hTERT oligodeoxynucleotides-mediated inhibition for tumor cell growth. Continuous ans-hTERT oligodeoxynucleotides treatment might shorten the telomere to a size that leads to cell senescence. The treatment with ans-hTERT oligodeoxynucleotides may be a potential strategy for cancer with telomerase activity.

Abstract

AIM: To study the effects of disruption of *sarA* gene on biofilm formation and antibiotic resistance of *Staphylococcus epidermidis* (*S. epidermidis*).

METHODS: In order to disrupt *sarA* gene, the double-crossover homologous recombination was applied in *S. epidermidis* RP62A, and tetracycline resistance gene (*tet*) was used as the selective marker which was amplified by PCR from the pBR322 and inserted into the locus between *sarA* upstream and downstream, resulting in pBT2 Δ *sarA*. By electroporation, the plasmid pBT2 Δ *sarA* was transformed into *S. epidermidis*. Gene transcription was detected by real-time reverse transcription-PCR (RT-PCR). Determination of biofilm was performed in 96-well flat-bottomed culture plates, and antibiotic resistance was analyzed with test tube culture by spectrophotometry at 570 nm respectively.

RESULTS: A *sarA* disrupted strain named *S. epidermidis* RP62A Δ *sarA* was constructed, which was completely defective in biofilm formation, while the *sarA* complement strain RP62A Δ *sarA* (pHPS9*sarA*) restored the biofilm formation phenotype. Additionally, the knockout of *sarA* resulted in decreased erythromycin and kanamycin resistance of *S. epidermidis* RP62A. Compared to the original strain, *S. epidermidis* RP62A Δ *sarA* had an increase of the sensitivity to erythromycin at 200-400 μ g/mL and kanamycin at 200-800 μ g/mL respectively.

CONCLUSION: The knockout of *sarA* can result in the defect in biofilm formation and the decreased erythromycin and kanamycin resistance in *S. epidermidis* RP62A.

INTRODUCTION

Staphylococcus epidermidis (*S. epidermidis*), a normal inhabitant of human skin and mucous membranes, is the predominant cause of foreign-body-associated infections. The pathogenesis of *S. epidermidis* infections is correlated with its ability to form biofilms on polymer surfaces^[1,2]. Biofilm formation proceeds in two phases^[3,4]. Primary attachment of bacterial cells to a polymer surface is a complex process influenced by a variety of factors, including hydrophobic interactions, presence of host proteins, and specific bacterial proteins and polysaccharides like the capsular polysaccharide adhesin, the autolysin AtlE, and other staphylococcal surface proteins^[5,6]. This is followed by the second phase leading to accumulation of bacteria in a multilayered biofilm embedded in an amorphous glycocalyx. This phase is a multifactorial process that is influenced by a number of factors. Among the most important of these is polysaccharide intercellular adhesion (PIA). Synthesis of polysaccharide intercellular adhesin is essential for bacterial cell accumulation because it mediates cell-to-cell adhesion of proliferating cells^[7,8]. PIA consists of two polysaccharide species which are composed of β -1, 6-linked 2-deoxy-2-amino-D-glucopyranosyl residues containing non-N-acetylated amino groups, phosphate, and succinate. The enzymes required for polysaccharide intercellular adhesin synthesis are encoded within the *icaADBC* operon, mutation of which results in a reduced capacity to form a biofilm in *S. epidermidis*^[7]. *SarA*, a central regulatory element that controls the production of *Staphylococcus aureus* (*S. aureus*) virulence factors, is essential for the synthesis of PIA and the ensuing biofilm development in this species^[9,10]. Based on the presence of a *sarA* homolog, we hypothesized that SarA could also be involved in the regulation of the biofilm formation process in *S. epidermidis*. To elucidate the possible role of SarA in biofilm formation, we used

a genetic approach and constructed an *S. epidermidis* *sarA::tet* knockout mutant of the biofilm-forming strain *S. epidermidis* RP62A. Biofilm formation and *ica* expression of the mutant were compared with the phenotypes of the corresponding wild-type strain and a complemented strain that carried a *sarA* copy in an expression vector.

We were interested in the potential role of SarA in the response of *S. epidermidis* to antimicrobial agents. Therefore, we used this *sarA* knockout mutant and determined its influence on erythromycin and kanamycin resistances in *S. epidermidis* RP62A (i.e. ATCC35984).

MATERIALS AND METHODS

Bacterial strains, plasmids, and growth medium

The bacterial strains and plasmids used in this study are listed in Table 1. Tryptic soy broth (TSB) was used to grow *Staphylococcus* strains. Luria-Bertani (LB) was used for *E. coli*. Chloramphenicol was used at 15 μg/mL, ampicillin at 100 μg/mL and tetracycline at 10 μg/mL. Bacteria were grown on Congo red agar (CRA) plates, which were composed of TSB agar supplemented with 5% sucrose (A.R.) and 0.8 mg of Congo red/L (A.R.). All DNA manipulations and handling of *E. coli* were performed in accordance with standard protocols^[11]. Manipulations with *Staphylococcus* were performed as described previously^[12,13].

Construction of plasmids and *sarA::tet* allele replacement

In order to analyze its function in *S. epidermidis*, *sarA* was replaced by a tetracycline resistance gene (*tet*) by homologous recombination. The upstream of 836 bp, fragment 1, was amplified using primer pairs (1) 5'-ACGAAGCTTC TGTAACATCT AGTGACAA-3' and (2) 5'-ACGCTGCAGT TTAATCTGTC AGCATAAGTG-3' with *HindIII* and *PstI* respectively. The downstream of 857 bp, fragment 2, was amplified using primer pairs (3) 5'-ACGCTGCAGA TTATAAACAA CCTCAAGTTG-3' and (4) 5'-ACGGAATTCG GGCATCATTG CGAGTGA-3' with *PstI* and *EcoRI* respectively. The two fragments were cloned into the multi-

cloning region of temperature-sensitive *E. coli-Staphylococcus* shuttle vector pBT2^[16], resulting in plasmid pBT2-1. A fragment of 1276 bp containing the entire *tet* gene was amplified by PCR from the pBR322, using the primers (5) 5'-CGCGCGGCCG CTTCTCATGT TTGACAGCTT-3' and (6) 5'-GCGAGATCTT CAGGTTCGAGG TGGCC-3'. The *tet* gene was inserted into the vector pBT2-1, resulting in plasmid, pBT2Δ*sarA*. Following passage through the restriction-negative strain *S. aureus* RN4220, pBT2Δ*sarA* was reisolated and transformed into *S. epidermidis* RP62A by electroporation. Replacement of the chromosomal *S. epidermidis* RP62A *sarA* wild-type gene was obtained by double-crossover integration of the *sarA::tet* insert of pBT2 Δ*sarA* following a temperature shift to the nonpermissive temperature (42°C) of the shuttle vector^[18]. Tetracycline-resistant and chloramphenicol-sensitive colonies were isolated. The *sarA::tet* integrations were confirmed by PCR detection (Figure 1 step 4) and the nucleotide sequencing was carried out by Shanghai Bioasia.

RNA purification and RT-PCR

RNA purification, real-time reverse transcription-PCR (RT-PCR) and analysis of RT-PCR data were performed as previously described^[19], with the following oligonucleotide primer pairs: for *gyrB* transcript, (7) 5'-TTATGGTGCT GGACAGATAC A-3' and (8) 5'-CACCGTGAAG ACCGCCAGAT A-3'; for *icaA* transcript, (9) 5'-AACAAGTTGA AGGCATCTCC-3' and (10) 5'-GATGCTTGTT TGATTCCCT-3'. The *gyrB* gene was compositively expressed in *S. epidermidis* and thus used as an internal standard in these RT-PCR experiments^[19].

Phenotypic assay on biofilm production

The biofilm production assay was performed by cultivation of the *S. aureus* and *S. epidermidis* strains on CRA plates as described by Freeman *et al*^[14]. The black, rough and dry colonies on CRA plates indicated the biofilm production. In contrast, the biofilm-negative strains formed red, smooth colonies.

Figure 1 Disruption and detection of chromosomal *sarA* locus in *S. epidermidis*. 1. Insertion of *tet* gene into *sarA* locus to form recombinant plasmid pBTΔ*sarA*. 2. Double-exchange homologous recombination between chromosomal DNA and plasmid DNA. 3. Locus *sarA* of chromosome was destroyed by DNA recombination. 4. Detection of recombination by PCR amplification with primers TB and SA2.

Quantitative determination of biofilm formation

Strains were cultivated overnight (16 h) in 96-well flat-bottomed tissue culture plates at 37°C in TSB growth medium. Based on the optical densities (OD₅₇₀) of the biofilm, the strains were classified as non-adherent strains (OD₅₇₀ ≤ 0.120).

Determination of antibiotic susceptibilities

Three antibiotics were used to determine the impact of *sarA* mutant on *S. epidermidis* resistance to erythromycin or kanamycin. Erythromycin or kanamycin was added into test tubes with a twofold serial dilution scheme (0, 25, 50, 100, 200, 400, 800 μg/mL)^[20,21]. The inoculum was derived from overnight liquid cultures in TSB and was inoculated into shaking liquid cultures containing erythromycin or kanamycin. After overnight incubation (16 h) at 37°C, these inocula were determined with spectrophotometer at 570 nm.

RESULTS

Disruption of *sarA* gene on the chromosome DNA of *S. epidermidis* RP62A

A strain termed *S. epidermidis* RP62AΔ*sarA* (sarA::tet) derived from RP62A with an allele replacement of the *sarA* gene was obtained (Figure 1).

PCR analysis of DNA from strains RP62A and RP62AΔ*sarA* was performed with two primers as shown below: TB: 5'-ACGGAGCTCA AGCCTATGCC TACAGCA-3' (in the central part of the *tet* gene) (Figure 1); SA2: 5'-ACGGAATTCG GGCATCATTG CGAGTGA-3' (next to the downstream of *sarA2* fragment) (Figure 1). The fragment was obtained as shown in Figure 2, which indicated that allelic replacement had taken place. The PCR-amplified fragment was further demonstrated by DNA sequencing, and the result revealed that a 1025 bp fragment was composed of part of *tet* gene and chromosomal DNA (the datum of DNA sequence not shown).

Figure 2 Detection of *sarA* gene locus in chromosome DNA by PCR with primers SA2 and TB. Lane 1, The product was amplified from *S. epidermidis* RP62AΔ*sarA* with *tet* insertion; lane 2, No product was amplified from *S. epidermidis* RP62A without *tet* insertion; lane 3, DNA markers.

Figure 3 Identification of the genes *icaA* and *gyrB* transcription in *S. epidermidis* by RT-PCR analysis. 1. *S. epidermidis* RP62A; 2. *S. epidermidis* RP62AΔ*sarA*; 3. *S. epidermidis* RP62AΔ*sarA* (pHPS9*sarA*).

Repression of *icaA* transcription in *S. epidermidis* RP62A by disruption of *sarA*

To investigate whether the transcription of *ica* operon expression was altered in the *sarA* mutant strain, RT-PCR was used to measure *icaA* transcription in variants grown in TSB. Total RNA of the original RP62A strain, its *sarA* mutant and corresponding complementary strain were isolated at early exponential and mid-log exponential phases, as the expression of *ica* operon was at maximum during this period. After treatment with DNase to remove contaminant DNA, RNA was reverse transcribed in the presence and absence of reverse transcriptase. The level of expression of *icaA* was normalized to *gyrB* expression^[19]. Our results showed that the level of *ica* operon transcription was apparently reduced in the *sarA* mutation compared to that of the wild-type strain at exponential and mid-log exponential phases (Figure 3, Lane 2). Interestingly, in the *sarA* complementation strain, designated as RP62AΔ*sarA* (pHPS9*sarA*), the *icaA* transcription was activated (Figure 3, lane 3). Consistent with this, at the phenotypic level, the capacity of RP62AΔ*sarA* (pHPS9*sarA*) to form biofilm was restored in TSB. These data suggested that the gene of *sarA* in the strain of RP62A is responsible for activating *ica* operon expression.

Depression of biofilm formation of *S. epidermidis* RP62A by inactivation of *sarA*

Phenotypic assay on biofilm production: The *S. epidermidis* RP62A strain formed typical black, rough colonies after 24 h of incubation. The non-slime producing *S. epidermidis* ATCC 12228 formed smooth, red colonies. RP62AΔ*sarA* strain produced smooth, red colonies after 24 h, demonstrating the mutant was biofilm-negative. As to the

Figure 4 Biofilm formation on the glass surface in the tube culturing *S. epidermidis*. 1. TSB medium not inoculated; 2. Biofilm-positive strain RP62A (biofilm-forming); 3. *sarA* complemented strain RP62A Δ *sarA* (pHPS9*sarA*) (biofilm-forming); 4. *sarA* deletion strain RP62A Δ *sarA* (non-biofilm-forming); 5. Biofilm-negative strain ATCC12228 (non-biofilm-forming).

Figure 5 Biofilm formation on polystyrene tissue culture plates of *S. epidermidis* in TSB medium. 1. biofilm-negative strain *S. epidermidis* ATCC12228; 2. original strain *S. epidermidis* RP62A; 3. *sarA::tet* insertion mutant *S. epidermidis* RP62A Δ *sarA*; 4. complemented strain *S. epidermidis* RP62A Δ *sarA* (pHPS9*sarA*).

RP62A Δ *sarA* (pHPS9*sarA*) strain, black, rough colonies phenotype was restored.

Biofilm formation on a glass surface of the shaking tube with overnight culture: The *sarA* mutant showed loss of the ability to produce a ring of biofilm adherent to the glass wall at the air-liquid interface (Figure 4, Lane 2). While the complementary strain RP62A Δ *sarA* (pHPS9*sarA*) displayed a biofilm positive phenotype similar to that of the wild-type strain (Figure 4, Lane 3).

Quantitative determination of biofilm formation: All strains were then tested of their ability to form biofilms on polystyrene surfaces. The isolates were grown overnight in 96-well flat-bottomed tissue culture using TSB as growth medium. As shown in Figure 5, the biofilm formation of *S. epidermidis* RP62A was biofilm-positive when the strain was grown in TSB. In contrast, the *S. epidermidis* RP62A Δ *sarA* insertion mutant and *S. epidermidis* ATCC12228 failed to produce any detectable biofilm. In the case of *S. epidermidis* RP62A Δ *sarA* (pHPS9*sarA*), in which the deleted chromosomal locus of *sarA* was complemented by a plasmid carrying *sarA*, biofilm formation was restored.

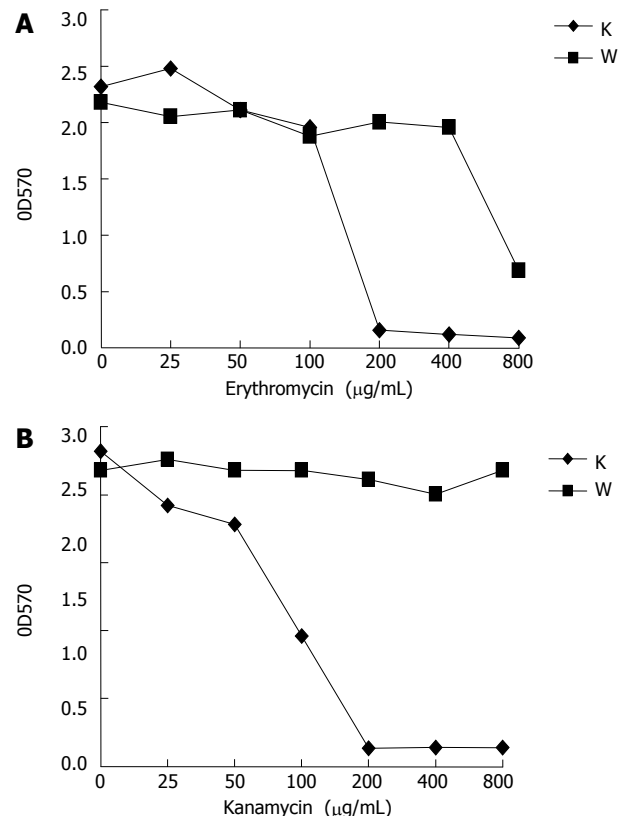

Figure 6 Response of RP62A (original) and RP62A Δ *sarA* (mutant) to two antibiotics in shaking tube cultures. The cultures of the wild type RP62A (W) and the mutant RP62A Δ *sarA* (K) were incubated in a shaking incubator (250 r/min) at 37°C for 24 h, and diluted in fresh TSB medium. Determination of optical density (OD) values was carried out at 570 nm.

Increase in some antibiotic sensitivity of *S. epidermidis* RP62A by deletion of *sarA*

The *sarA* mutation had a dramatic effect on the antibiotics resistance of strain RP62A. Two antibiotics, erythromycin and kanamycin, were investigated. The *sarA::tet* mutant demonstrated a significant increase of susceptibility along with the increasing concentration of erythromycin and kanamycin compared to its parental strain (Figure 6). At erythromycin concentrations above 200 μg/mL, RP62A Δ *sarA* did not grow, while RP62A survived at concentrations over 800 μg/mL (Figure 6A). RP62A appeared at all kanamycin concentrations investigated, whereas RP62A Δ *sarA* did not survive at concentrations over 200 μg/mL (Figure 6B).

DISCUSSION

To investigate the impact of *sarA* on biofilm formation, we constructed a *sarA* mutant of *S. epidermidis* RP62A. At the phenotypic level, the *sarA* mutant revealed a biofilm-negative phenotype, and the capacity of biofilm formation was restored when *sarA* mutant strains were complemented by a plasmid carrying *sarA*. RT-PCR was used to measure the transcription of *icaA* in variants grown in TSB. Consistent with the biofilm-negative phenotype, the results showed that the *sarA* mutation caused a significant

repression of the *ica* operon transcription compared with that of the wild-type strains. The absence of an identifiable *sigB*-consensus binding site on the upstream of the *ica* operon in *S. aureus* has suggested that *sigB* may not regulate *ica* operon directly^[22], and the foundation of the SarA-consensus binding site implied that SarA controls directly the transcription of *ica* operon and subsequently regulates biofilm formation^[23,24]. However, it is possible that both SigB and SarA are also involved in the posttranscriptional regulation of PIA synthesis in *S. epidermidis* according to previous reports.

The knockout of *sarA* resulted in decreased erythromycin and kanamycin resistance in *S. epidermidis* RP62A. This implies that a protein(s) whose production is controlled by SarA is involved in resistance to these antibiotics. However, the exact role that SarA plays in the response of *S. epidermidis* to multiple antibiotics deserves further attention.

In conclusion, the current studies demonstrate that SarA is typically associated with the transcription of the *ica* operon, the capacity of biofilm-formation and antibiotic resistance of *S. epidermidis*. To answer the question of whether SarA is directly or indirectly involved in those processes, more experimental work, including primer extension analyses under different growth conditions, is needed.

Abstract

AIM: To study the condition and potentiality of human umbilical cord blood stem cells (HUCBSC) to differentiate into hepatocytes *in vivo* or *in vitro*.

METHODS: In a cell culture study of human umbilical cord blood stem cell (HUCBSC) differentiation, human umbilical cord blood mononuclear cells (HUCBMNC) were separated by density gradient centrifugation. Fibroblast growth factor (FGF) and hepatocyte growth factor (HGF) and the supernatant of fetal liver were added in the inducing groups. Only FGF was added in the control group. The expansion and differentiation of HUCBMNC in each group were observed. Human alpha fetoprotein (AFP) and albumin (ALB) were detected by immunohistochemistry. In the animal experiments, the survival SD rats with acute hepatic injury after carbon tetrachloride (CCl₄) injection 48 h were randomly divided into three groups. The rats in group A were treated with human umbilical cord blood serum. The rats in group B were treated with HUCBMNC transplantation. The rats in group C were treated with HUCBMNC transplantation followed by intraperitoneal cyclophosphamide for 7 d. The rats were killed at different time points after the treatment and the liver tissue was histopathologically studied and human AFP and ALB detected by immunohistochemistry. The human X inactive-specific transcript gene fragment in the liver tissue was amplified by PCR to find human DNA.

RESULTS: The results of cell culture showed that adherent cells were stained negative for AFP or ALB in control group. However, the adherent cells in the inducing groups stained positive for AFP or ALB. The result of animal experiment showed that no human AFP or ALB positive cells present in the liver tissue of group

A (control group). However, many human AFP or ALB positive cells were scattered around sinus hepaticus and the central veins of hepatic lobules and in the portal area in group B and group C after one month. The fragment of human X chromogene could be detected in the liver tissue of groups B and C, but not in group A.

CONCLUSION: Under certain conditions HUCBSC can differentiate into liver cells *in vivo* and *in vitro*.

INTRODUCTION

Umbilical cord blood (UCB) remains in the placenta and umbilical cord after birth. The placenta and umbilical cord blood is usually discarded after delivery as a medical waste. The presence of hematopoietic stem cells (HSC) in UCB was first demonstrated in 1974. There is evidence that UCB is a rich source of HSC. However, it was not until 1989 that experimental and clinical studies were published, indicating that UCB can be used in clinical settings. Since then, UCB has been used as an alternate source of HSC for transplantation. Some data suggest that UCB is a better source of HSC than bone marrow (BM)^[1,2]. It has been found that multipotent adult progenitor cells can differentiate into hepatocyte-like cells *in vitro*^[3]. Neurons, astrocytes and oligodendrocytes can be propagated *in vitro* from UCB cells^[4,5], indicating that stem cells can differentiate into hepatocytes^[6,7]. These experiments studied the conditions and potentiality of human umbilical cord blood cells (HUCBSC) to differentiate into hepatocyte *in vivo* or *in vitro*.

MATERIALS AND METHODS

Reagents

Fetal bovine serum (Hyclone, USA), Dulbecco's modi-

fied Eagle's medium (DMEM) (Gibco, USA), β -fibroblast growth factor (FGF) and hepatocyte growth factor (HGF) (Preprotech, USA), immunohistochemistry kit (PV900, Beijing), alpha fetoprotein (AFP) and mouse anti human monoclonal antibody (Maixin, Foochow), albumin and (ALB) rabbit anti human polyclonal antibody (DAKO), protease K, NaI, glass powder, Taq DNA polymerase, $10 \times$ buffer, random primer (2.5 mmol/L , dNTP) were provided by Promega Co.

Collection and storage of umbilical cord blood

Immediately after birth of the baby, the umbilical cord was cut off and the baby was separated from the placenta and mother. A sterile needle was inserted into the umbilical vein and UCB was drawn into a sterile blood collection bag containing ACD-B or heparin anticoagulant. Once the collection was completed, the specimen was packaged and sent to blood bank for processing and storage at low temperatures. The maternal blood sample was also collected for infectious disease analysis.

Separation of human umbilical cord blood mononuclear cells

Human umbilical cord blood mononuclear cells (HUCBMNC) were separated from UCB by density gradient centrifugation. When cell motility rate was more than 95%, the cell concentration was adjusted to 5×10^5 /mL.

Cell Culture

FGF 2.5 ng/mL and HGF 20 ng/mL and supernatant of fetal liver (5%, V/V) were added into the HUCBMNC culture flasks in the inducing groups. Only FGF was added into the HUCBMNC culture flasks in the control group. The expansion and differentiation of HUCBMNC in each group were observed. Human AFP and ALB were detected by immunohistochemistry.

Animal experiment

Adult SD rats, weighing $180 \pm 20 \text{ g}$ were provided by the Animal Laboratory of the Second Xiangya Hospital. Carbon tetrachloride (CCl_4 , $0.7 \text{ mL}/100 \text{ g}$, 10%) was intraperitoneally injected into SD rats to establish an acute hepatic injury model. Surviving rats 48 h after CCl_4 injection were randomly divided into three groups. Rats in group A were treated with 1 mL human umbilical cord blood serum. Rats in group B were treated with 1 mL HUCBMNC. Rats in group C were treated with 1 mL HUCBMNC followed by intraperitoneal cyclophosphamide $2 \text{ mg}/100 \text{ g}$ per d for 7 d. The general state of the rats in each group was observed.

Detection of human AFP and ALB in rat liver tissue

The rats were killed at different time points after treatment and the liver tissue was histopathologically studied and detected for human AFP and ALB by immunohistochemistry.

PCR amplification of human X inactive specific transcript gene

The primers of PCR were designed according to human X

Figure 1 Cells positively stained for AFP (A) and ALB (B) in inducing groups (400 \times).

inactive specific transcript (XIST) gene (upstream primer P1: 5'- TTA CTG GCTGTATTGCCTTG C- 3'; downstream primer P2: 5'- ATTATCTCCA CCGCTTCACT -3'). DNA was extracted from the rat liver tissue imbedded in paraffin and amplified by PCR. Gel electrophoresis was performed to find whether human DNA was present in the rat liver tissue.

RESULTS

Expansion and differentiation of HUCBSC

The result showed that most adherent cells had fusiform shape. No polygon shape cells were found in the control group. However, round shape, spherical and polygon shape adherent cells as well as fusiform cells were found in the inducing groups.

Immunohistochemistry staining of AFP and ALB

The adherent cells in the control group were stained negative for AFP or ALB by immunohistochemistry, thus these adherent cells were most probably fibroblasts. The adherent cells in the inducing groups were stained positive for AFP or ALB by immunohistochemistry (Figures 1A and 1B) and therefore they might be hepatocytes.

Influence of two different decoagulants on HUCBMNC

Heparin or natrium citricum was used as a decoagulant when UCB was collected. The expansion and differentiation of HUCBMNC anti-coagulated with heparin were better than those of HUCBMNC anti-coagulated with natrium citricum.

Figure 2 Expression of human ALB (A) and AFP (B) in rat liver tissue (200 ×).

Figure 3 Human ALB positively conjugated nuclear cells in rat liver tissue (400 ×).

Effects of two different inducing factors

Two different inducing factors, HGF and fetal liver supernatant were used to induce differentiation of HUCBSC into hepatocytes. The inducing effect of each was compared. The result showed that the inducing effect of HGF was better than that of fetal liver supernatant.

Expression of human AFP and ALB in rat liver tissue

No human AFP or ALB positive cells were found in rat liver tissue of group A (control group) by immunohistochemistry. However, many human AFP or ALB positive cells were scattered around sinus hepaticus and central veins of hepatic lobules and portal area in groups B and C after one month (Figures 2A and 2B). Moreover, a few human ALB positively conjugated nuclear cells were found in rat liver tissue of group C (Figure 3).

M: 100 bp marker; N: Negative control, the products of PCR templated by water; H: Positive control, the products of PCR templated by human fetal liver tissue DNA; 1-5: DNA extracted from rat liver tissue embedded in paraffin in group A; 6-10: DNA extracted from rat liver tissue embedded in paraffin in group B; 11-15: DNA extracted from rat liver tissue embedded in paraffin in group C.

Fragment of human X chromogene in rat liver

XIST fragment of human X chromogene could be detected in rat liver tissue of groups B and C by DNA extraction and PCR amplification, but no human X chromogene fragment was found in group A (Figure 4).

DISCUSSION

Stem cells present in adult BM and UCB are undifferentiated long-lived cells that have the ability to proliferate extensively and maintain the ability to differentiate into multiple cell types including bone cells, cartilage cells, fat cells, tendon cells, muscle cells, marrow stromal cells, astrocytes, *etc.* Potential liver-cell progenitors have been identified from BM, peripheral blood, UCB, fetal liver, adult liver and embryonic stem cells. Differences and similarities are found among cells isolated from rodents and humans^[8].

Stem cells are present in UCB and possess several typical traits^[9]. Clonal culture of fluorescence-activated cell sorter CD34+ UCB and BM cells revealed a higher incidence of colony-forming cells with greater proliferation capacity in UCB than BM CD34+ cells. UCB CD34+ cells also demonstrated a higher secondary plating efficiency than BM cells. Rats transplanted with UCB mononuclear cells showed significantly higher levels of chimerism than those transplanted with BM mononuclear cells.

Recipients of UCB transplants from HLA-identical siblings have a lower incidence of acute and chronic graft-versus-host disease than recipients of BM transplants from HLA-identical siblings^[10]. Immature human UCB cells with high proliferative, replating, *ex vivo* expansion and mouse NOD/SCID engrafting ability can be stored frozen for > 15 years, and efficiently retrieved, and most likely remain effective for clinical transplantation^[11]. Intravenous injection of adult BM cells in FAH-/-mice, an animal model of tyrosinemia type I, could rescue the mice and restore their liver biochemical function. Within BM, only rigorously purified HSCs give rise to donor-derived hematopoietic and hepatic regeneration^[12].

Adult human liver cells can be derived from stem cells originating in the BM or circulating outside the liver, so that blood-system stem cells could be used clinically to generate hepatocytes for replacing damaged tissue^[13]. BM-derived hepatocyte stem cells integrate with hepatic cell plates and differentiate into mature hepatocytes. In a culture system simulating liver regeneration and containing cholestic serum, these cells differentiate into mature hepatocytes and metabolize ammonia into urea depending

on a yet non-defined humoral signal existing in cholestatic serum. Transmission electron microscopy and three-dimensional digital reconstruction have confirmed hepatocyte ultrastructure of cultured BM-derived hepatocyte stem cells^[14]. In a primary culture system supplemented with growth/differentiation factors, about 50% of UCB cells in 21-d cultures express ALB, and ALB+ cells co-express hepatocyte lineage markers. ALB-expressing cells are able to proliferate in the culture system. In the cell-transplantation model of liver-injured SCID mice, inoculated UCB cells develop into functional hepatocytes in the liver, which release human ALB into the sera of the recipient mice. Thus, human UCB is a source of transplantable hepatic progenitor cells^[15].

It was reported that human UCB cells can migrate into NOD-SCID liver and become mature hepatocytes. No cell fusion can be detected in any of the human cells found in mouse liver^[16]. Human albumin expression can be detected only in CCl₄-treated mice receiving transplants of human stem cells, and recovery is increased by administration of human HGF 48 h after CCl₄-mediated liver injury^[17]. As the cells are morphologically transformed into hepatocyte-like cells, UCB-derived human MSC can express Thy-1, c-Kit and Flt-3 on the cell surface, as well as albumin, AFP and cytokeratin-18 and 19 in the interior. About a half of the cells are found to acquire the ability to transport DiI-Ac-LDL^[18].

In this study, UCB transplantation demonstrated a good therapeutic effect on severe viral hepatitis without obvious side effects. UCB attenuated the liver lesions and reproduced hepatocytes. The effect of UCB transplantation combined with plasma exchange (PE) is much better than that of PE alone, suggesting that UCB transplantation can enhance the therapeutic effect of plasma exchange on severe viral hepatitis^[19]. After 4 wk of induction of HGF and oncostatin M, stem cells isolated from human BM and UCB showed cuboidal morphology of hepatocytes and cells expressed marker genes specific for liver cells in a time-dependent manner. Differentiated cells have *in vitro* functions of liver cells, including albumin production, glycogen storage, urea secretion, uptake of low-density lipoprotein, and phenobarbital-inducible cytochrome P450 activity^[20]. Human UCB stem cells are able to transdifferentiate into hepatocytes, to improve liver regeneration after damage and mortality rate. Intraperitoneal administration of UCB stem cells contributes to a rapid liver engraftment^[21].

CD34+ UCB cells are rich fractions in hepatic progenitor cells, and trans-differentiation from UCB cells into hepatocytes and cell fusion simultaneously occur^[22]. UCB stem cell transplantation displays good therapeutic effects on severe viral hepatitis and improves heart injury of the patients. The rat liver immunohistochemistry in this study indicated that UCB stem cells could decrease liver damage and increase hepatocellular regeneration. Human UCB stem cells can differentiate into liver cells in acutely damaged SD rat liver^[23]. Xeno-transplantation of human UCB CD34+ (hCB34+) cells during pre-immune stages of development in immunocompetent mice might also lead to human-mouse liver chimerism. Freshly isolated hCB34 (+) cells were xeno-transplanted into non-immunosuppressed

mice by both intra-blastocyst and intra-fetal injections in our study. One and four weeks after birth, immunostaining was carried out for different human-specific hepatocyte markers, such as human hepatocyte-specific antigen, human serum albumin, and human alpha-1-antitrypsin indicated the presence of human hepatocyte-like cells in the livers of transplanted animals. The results indicate that detection of human albumin mRNA further corroborates the development of pre-immune human-mouse chimeras^[24].

A new intrinsically pluripotent CD45- population called unrestricted somatic stem cells (USSC) has been isolated from human UCB. These cells grow adherently and can be expanded to at least 10¹⁵ cells while maintaining a normal karyotype and a pluripotency including hematopoietic, neural, and hepatic cell differentiation in the noninjured fetal sheep model. More than 20% albumin-producing human parenchymal hepatic cells have been obtained in the absence of cell fusion in this model. One major biological difference between USSCs and human MSC is the ease of generation of USSCs in cytokine-free cultures and the potential to generate hematopoietic cells *in vitro*. Besides their differentiation potential, USSCs can also be distinguished from MSC by their phenotype. But similar to adult and fetal MSCs, they are also nonimmunogenic and even immunosuppressive^[25].

Some studies have shown that UCB may contain some hepatic progenitors. MSC has been isolated from UCB harboring a broader potential than expected. Single clonally expanded cells isolated from either UCB or BM, can differentiate not only into osteoblasts, adipocytes, and chondrocyte-like cells (as expected for MSCs), but also into different cell types including functional hepatocytes *in vitro*. When UCB-derived cells are cultured under hepatogenic conditions all cells acquire a cuboidal morphology as opposed to the fibroblast-like morphology of undifferentiated cells. In this study, low level expression of AFP, an early developmental marker gene of hepatoblasts, was detectable by d 7 and remained detectable up to d 35. Expression of cytokeratin-18 and albumin was detectable at all time points, and the expression of tyrosine aminotransferase, a late marker gene of hepatocytes, was detectable by d 14 and increased with time of differentiation. Furthermore, by d 7, differentiated cells were stained positive for albumin. Undifferentiated cells did not express AFP or tyrosine aminotransferase, but expressed low levels of albumin and cytokeratin-18. However, undifferentiated cells were negative for albumin. After 6 wk of differentiation the hepatocyte-like cells demonstrated the ability to take up low-density lipoprotein, a function characteristic of hepatocytes, whereas undifferentiated cells failed to take up low-density lipoprotein^[26].

By seeding UCB β 2 m-c-Met+ cells (UCBCCs) on the cirrhotic fat-storing cells (CFSC)/HGF feeder layers without any cytokine added, distinct morphological changes in some UCBCCs emerged after co-cultured for 4 d, and the changes increased even more as time went on. Morphological characteristics of hepatocytes occurred after 7 d of coculture in about 38%-46% of UCBCCs, which were identified to possess hepatocyte-like functions. UCBCCs could also differentiate into hepatocyte-like cells by co-

culturing with CFSC/HGFs separately using trans-wells, although the differentiation efficiency was lower than the former. Moreover, the tests showed limited contribution of control CFSC/neo to the induction, which proved the important sustainment of nonparenchymal cells and extracellular matrices on the stem cell differentiation and prompted us to consider the insufficient factor secretion in nontransfected hepatic stellate cells only^[27].

Transplantation of human HSC in sheep has led to the establishment of human hematopoiesis and formation of a significant number of long-lasting, functional human liver cells, with some animals exhibiting levels as high as 20% of donor (human) hepatocytes 11 mo after transplantation. Human hepatocytes generated in sheep retain functional properties of normal hepatocytes, constitute hepatic functional units with the presence of human endothelial and biliary duct cells, and secrete human albumin that is detectable in circulation. Transplanting populations of HSC can efficiently generate a significant number of functional hepatic cells in sheep^[28].

Characterization of UCB-derived USSCs with the capacity to differentiate into hematopoietic and nonhematopoietic cells in the absence of cell fusion has highlighted the great potential of stem cell plasticity. A great variety of stem cell types have been defined and even the most pure marrow stem cells are highly heterogeneous. Data suggest that stem cells may exist in a continuum with continually and reversibly changing phenotype^[29].

Our study showed that with the induction of HGF or fetal liver supernatant, HUCBSC could expand *in vitro* and differentiate into polygon cells expressing AFP and ALB. These cells are most likely hepatocytes. Moreover, the expansion and differentiation of HUCBSC anti-coagulated with heparin were better than those of HUCBSC anti-coagulated with natrium citricum, suggesting that natrium citricum may be toxic for HUCBSC or heparin can promote the expansion of HUCBSC *in vitro*. Therefore, heparin is better than natrium citricum as a UCB collection decoagulant. We also showed that the role of HGF in inducing HUCBSC differentiation into hepatocytes was better than that of fetal liver supernatant, indicating that HGF can promote the expansion of HUCBSC and induce the differentiation of HUCBSC into liver cells. Thus, it is better to use HGF as an inducing factor for the differentiation of HUCBSC.

Our animal experiment showed that after one month treatment with HUCBSC, the rats with acute liver failure were positive for human AFP and ALB in liver tissue. The DNA fragment of human X chromagene could be found in rat liver tissue of HUCBSC-treated group. However, human DNA fragment could not be detected in the control group, indicating that the transfused human ALB and AFP were destroyed in the rats. Therefore, human AFP and ALB detected in rat liver tissue of HUCBSC treated-group were products of liver cells differentiated from HUCBSC. The number of positive human AFP and ALB cells found in HUCBSC-treated groups with or without cyclophosphamide was not obviously different, indicating that immunosuppression has mild or no effect on HUCBSC differentiation in rats. Moreover, a few AFP or human ALB positively conjugated nuclear cells were found in rat

liver tissue of HUCBSC-treated group, suggesting that cell fusion and cell division may occur in conjugated nuclear cells.

In conclusion, HUCBSC can differentiate into liver cells *in vitro* and *in vivo* under hepatogenic conditions. Stem cells from UCB are able to differentiate into functional hepatocyte-like cells and may serve as a cell source of cell therapy and transplantation for intractable liver diseases.

Abstract

AIM: To validate the statistic utility of both the Maddrey Discriminant Function score and the Model for End-Stage Liver Disease as predictors of short term (30 d and 90 d) mortality in patients with alcoholic hepatitis and to assess prognostic factors among clinical characteristics and laboratory variables of patients with alcoholic hepatitis.

METHODS: Thirty-four patients with the diagnosis of alcoholic hepatitis admitted to Hippokration University Hospital of Athens from 2000 to 2005 were assessed in the current retrospective study and a statistical analysis was conducted.

RESULTS: 30- and 90-d mortality rates were reported at 5.9% (2/34) and 14.7% (5/34), respectively. Significant correlation was demonstrated for the Model for End-Stage Liver Disease ($P_{30} = 0.094$, $P_{90} = 0.046$) and the Maddrey Discriminant Function score ($P_{30} = 0.033$, $P_{90} = 0.038$) with 30- and 90-d mortality whereas a significant association was also established for alanine aminotransferase ($P = 0.057$), fibrin degradation products ($P = 0.048$) and C-reactive protein ($P = 0.067$) with 90-d mortality. For 30-d mortality the Area Under the Curve was 0.969 (95%CI: 0.902-1.036, $P = 0.028$) for the Model for End-Stage Liver Disease score and 0.984 (95%CI: 0.942-1.027, $P = 0.023$) for the Maddrey Discriminant Function score with the optimal cut off point of 30.5 (sensitivity 1, specificity 0.937) and 108.68 (sensitivity 1, specificity 0.969), respectively. Accordingly, for 90-d mortality the Area Under the Curve was 0.762 (95%CI: 0.559-0.965, $P = 0.065$) for the Model for End-Stage Liver Disease score and 0.752 (95%CI: 0.465-1.038, $P = 0.076$) for the Maddrey Discriminant Function score with the optimal cut off point of 19 (sensitivity 0.6, specificity 0.6) and 92 (sensitivity 0.6, specificity 0.946), respectively. The observed Kaplan Meier survival rates

for different score-categories were compared with log-rank tests and higher score values were correlated with a lower survival.

CONCLUSION: Equivalency of the Model for End-Stage Liver Disease and the Maddrey Discriminant Function score is implied by the current study, verified by the plotted Receiver Operative Curves and the estimated survival rates. A statistically significant utility of C-reactive protein, fibrin degradation products and alanine aminotransferase as independent predictors of 90-d mortality has also been verified.

INTRODUCTION

Alcoholic hepatitis (AH) is an acute or acute-on-chronic inflammatory hepatic syndrome manifesting as a result of severe alcohol consumption and correlating with increased mortality rates^[1]. Assessing the severity of the disease is essential for the stratification of patients in need of aggressive therapeutic intervention including corticosteroids and pentoxifylline. A disease severity index for such a purpose should not only have statistical and clinical validity but should preferably rely on a few, readily available, objective parameters and be generalizable to a heterogeneous group of patients^[2].

In 1964 Child and Turcotte introduced the first classification index modified to assess prognosis in patients with severe liver disease. In 1972 Pugh improved that first classification in line with the criticisms of Conn^[3]. The CTP classification is based on serum albumin, serum bilirubin, prothrombin time, ascites and encephalopathy. Although its statistical accuracy has not been methodically evaluated, CTP classification is used as a disease severity

index to determine priority in organ allocation.

The Maddrey Discriminant Function ($DF = 4.6 \times [PT_{\text{sec}} - \text{control } PT_{\text{sec}}] + \text{serum total bilirubin}_{\text{mg/dL}}$) was introduced in 1978 as a predictor of significant mortality risk in patients with AH and need for aggressive therapeutic intervention. A DF score of greater than 32 identified those patients who had greater than 50% mortality in 30 d outcome^[4,5].

The Model For End-Stage Liver Disease (MELDscore = $3.8 \times \log_e[\text{total bilirubin, mg/dL}] + 11.2 \times \log_e[\text{INR}] + 9.6 \times \log_e[\text{creatinine, mg/dL}]$) was derived from a heterogeneous group of patients from 4 medical centres in the United States and validated in an independent data set from the Netherlands to assess short term survival in cirrhotic patients undergoing elective Transjugular Intrahepatic Portosystemic Shunt (TIPS)^[6]. In the MELD score variables are expressed as logarithm values to avoid extreme values, creatinine is co-evaluated and PT is expressed as an INR which does not depend on the sensitivity of the thromboplastin used by the laboratory.

The aim of the current study is to validate the statistic utility of both DF and MELD scores as predictors of short term (30-d and 90-d) mortality in patients with AH and to assess prognostic factors from among clinical characteristics and laboratory variables of patients with alcoholic hepatitis.

MATERIALS AND METHODS

Materials

Thirty four patients with the diagnosis of AH admitted to Hippokration University Hospital of Athens between January 1, 2000 and April 30, 2005 were assessed in the current retrospective study. The patients were diagnosed with AH based on the following clinical characteristics: (1) total bilirubin > 1.5 mg/dL, (2) aspartate/alanine aminotransferase ratio above 1.5 with an aspartate aminotransferase level above 45 U/L, (3) alcohol consumption within 2 mo exceeding 40 g/d for male and 20 g/d for female patients and finally (4) absence of a coexistent primary cause of liver disease^[7]. Patients with preexisting viral hepatitis were not excluded from the study on the basis that regeneration of the viral infection could not be established nor an acute viral hepatitis verified as the cause of hospital admission. Survival at 30 and 90 d following hospital admission was verified by chart review or telephone follow-up.

Only laboratory values obtained within 24 h of admission were utilized for calculation purposes. In those patients presenting several hospital admissions only the initial episode was included. The probability of 90-d mortality was calibrated to $P = e^{(-4.3+0.16 \times \text{MELD})} / [1 + e^{(-4.3+0.16 \times \text{MELD})}]$ ^[7]. The epidemiological data included age, gender, history of alcohol consumption and days of abstinence. Several clinical characteristics and laboratory values were evaluated as independent prognostic variables including fever, corticosteroids or diuretic treatment, infection, hemoglobin, mean corpuscular volume, platelets' count, white blood cell count, spurr cells, aminotransferases, alkaline phosphatase, gamma-glutamyl transpeptidase, bilirubin, creatinine, C-reactive protein, erythrocyte sedimentation rate, α -fetoprotein, prothrombin time, international normalized ratio, fibrinogen, d-dimers, fibrin degradation products,

albumin, ammonia. Clinical features of decompensated hepatic disease including ascites, encephalopathy and edema and also the presence of jaundice were reviewed from the admission history charts. Diagnosis of ascites was based on ultrasound findings and diagnosis of a coexisting infection was established by a positive culture. Hepatic encephalopathy was verified after exclusion of space occupying intracranial lesions, concurrent metabolic, endocrine, traumatic or epileptiform disorders and alcoholic or drug intoxication. Regarding diuretics only those patients receiving diuretics before their hospital admission were evaluated as positive. Non sufficient data was demonstrated regarding the patients' history of alcohol consumption or alcohol abstinence resulting in a request for more detailed documentation of such information in the future.

We searched the database PubMed (1995-2005) using the following key-words: "alcoholic hepatitis", "MELD score", "DF score", "prognosis in alcoholic hepatitis". We also included review articles, book chapters, or commonly referenced older publications. We reviewed the reference lists of articles identified by the search strategy and selected those we judged relevant. The search was restricted to papers published in English.

Methods

Data were analysed using SPSS 11.0 for Windows. Descriptive statistics including mean, median, ranges and standard. Deviation values were calculated for all the continuous baseline demographic, clinical and laboratory characteristics. Univariate logistic regression (backward elimination) was used to screen the variables for statistically significant association with respect to 30- and 90-d mortality. Variables that were statistically significant formed a pool of potential independent predictors. Multivariable logistic regression (backward elimination variables selection procedure) was performed for those variables. The significant factors were kept in the model if the maximum likelihood ratio criterion had a *P*-value below 0.10. Prognostic utility of the different scores was determined by generating a receiver operating characteristic curve (ROC curve). Concordance (range 0.0-1) is equivalent to the area under the curve (AUC) and quantifies the prognostic validities of the variables. Excellent diagnostic accuracy is indicated by AUC between 0.8-0.9 and a c-statistic greater than 0.7 is generally considered a useful test. From the ROC curve coordinates, cut-off points with best sensitivity and specificity of the different scores were determined and predictive values, likelihood and odds ratios were calculated. Overall survival was estimated from the admission data of the patient to the hospital to the date of last follow up or until the patient's death. Kaplan Meier method was used to calculate median follow up and survival curves while the log rank test was used to compare time to events distributions with respect to MELD and DF categories. The death incidences in correlation with MELD and DF values were displayed on scatter plot diagrams.

RESULTS

Thirty four patients with a median age of 49 (± 7.74 , 9 female and 25 male patients) who met the inclusion cri-

¹N = number of patients with known laboratory values, yrs: years, alc: alcohol consumption, Hb: hemoglobin, WBC: white blood count, PLT: platelets, PT: prothrombin time, INR: international normalized ratio, SGOT: aspartate aminotransferase, SGPT: alanine aminotransferase, γGT: γ glutamyl transpeptidase, ALP: alkaline phosphatase, BIL: bilirubin, CREAT: creatinine, ESR: erythrocyte sedimentation rate, CRP: C-reactive protein, FIBR/GEN: fibrinogen.

teria were enrolled in the patients cohort. Patients were assessed for a median follow up period of 13 mo (Accrual: February 2000-April 2005; range, 0.6-61.8+; 95%CI: 2.5-23.4). Demographical, clinical and laboratory data were reviewed and mean, median values and ranges are presented (Table 1). Median admission MELD and DF values were 19 (range, 3-46) and 42.25 (range, 15.3-180.72), respectively. 30-d mortality was reported at approximately 5.9% (2/34) whereas 90-d mortality was calculated at 14.7% (5/34). Clinical features of decompensated hepatic disease including ascites, encephalopathy and edema were reported in 64.7%, 32.4% and 52.9% of the patients, respectively. Jaundice was documented in 94.1% of the patients whereas infection was verified in 20.6% of the patients. The presence of serum IgG antibodies indicating an underlying hepatitis A or hepatitis B viral infection was reported in 11.8% (4/24) and 14.7% (5/24) of the patients respectively whereas there was no laboratory confirmation of active viral hepatic infection.

The variables that were significantly associated with 30- and 90-d mortality in univariate logistic regression analysis are presented (Table 2). Significant correlation was demonstrated for MELD ($P_{30} = 0.094$, $P_{90} = 0.046$) and DF scores ($P_{30} = 0.033$, $P_{90} = 0.038$) with 30- and 90-d mortality whereas a significant association was also established for alanine aminotransferase, SGPT ($P = 0.057$), fibrin degradation products, FS ($P = 0.048$) and C-reactive protein, CRP ($P = 0.067$) with 90-d mortality. Notable variables that were not independently correlated with mortality in univariable logistic regression analysis included encephalopathy, ascites, jaundice and albumin.

Table 2 Univariate and multivariate logistic regression assessing 30 d and 90 d mortality

Univariate logistic regression		Variable	P value	Odds ratio	95.0%CI
30-d mortality		DF	0.033	1.051	1.004-1.101
		MELD	0.094	1.357	0.950-1.939
90-d mortality		DF	0.038	1.026	1.001-1.050
		MELD	0.046	1.132	1.002-1.278
		FS	0.048	0.059	0.004-0.979
		SGPT	0.057	7.199	0.944-54.931
		CRP (< 100)	0.910	0.001	0.000-53.00
		CRP (> 100)	0.067	14.000	0.83-235.080
Multivariate logistic regression					
30-d mortality ¹	Step 1	DF	0.484	1.034	0.942-1.134
		MELD	0.707	1.120	0.621-2.021
	Step 2	DF	0.033	1.051	1.004-1.101
90-d mortality ²	Step 5	DF	0.994	12.488	0.00-1.91+297
		MELD	0.997	0.129	0.000

¹30-d mortality: Variable(s) entered on step 1: DF, MELD, variable(s) entered on step 2: DF; ²90-d mortality: Variable(s) entered on step 1: DF, MELD, FS, SGPT, variable(s) entered on step 5: MELD. Only the statistically significant variables are documented.

A statistically significant association couldn't be verified for components that comprise the MELD and DF scores (creatinine, total bilirubin and INR). Variables that exhibited a significant correlation in univariate evaluation were thereafter entered in a multivariate logistic regression process. No additional variables increased the predictive accuracy of either MELD or DF score. In fact all the variables lost significance when they were co-evaluated in a backward variable selection procedure.

MELD and DF scores were plotted in correlation with 30- and 90-d mortality (Figures 1 and 2). Visual inspection of these plots demonstrates that higher MELD and DF values are correlated with an increased death incidence.

Receiver operating characteristics curves were generated in order to validate the predictive accuracy of different scores in assessing 30- and 90-d mortality (Figures 3 and 4). For 30-d mortality the AUC was 0.969 (95%CI: 0.902-1.036, $P = 0.028$) for the MELD score and 0.984 (95%CI: 0.942-1.027, $P = 0.023$) for the DF with the optimal cut off points of 30.5 (sensitivity 1, specificity 0.937) and 108.68 (sensitivity 1, specificity 0.969), respectively. Accordingly for 90-d mortality the AUC was 0.762 (95%CI: 0.559-0.965, $P = 0.065$) for the MELD score and 0.752 (95%CI: 0.465-1.038, $P = 0.076$) for the DF score with the optimal cut off points of 19 (sensitivity 0.6, specificity 0.6) and 92 (sensitivity 0.6, specificity 0.946), respectively.

Kaplan Meier survival rates were estimated for Maddrey score values < 108, ≥ 108 ($P = 0.0098$) and ≥ 92, < 92 ($P = 0.0002$) and MELD scores ≥ 30.5, < 30.5 ($P = 0.027$) and ≥ 19, < 19 ($P = 0.084$). The observed survival rates for different score-categories were compared with log-rank tests and higher score values were correlated with a lower survival. (Figures 5-8)

Prognostic equivalency of MELD and DF scores is implied by the current study, verified by the plotted ROC curves and the cumulative survival curves. A statistically significant utility of CRP, FS and SGPT as independent predictors of 90-d mortality has also been verified.

Figure 1 Scatter plot graphed for patient death events within 90 d in correlation with corresponding MELD and DF values.

Figure 2 Scatter plot graphed for patient death events within 30 d in correlation with corresponding MELD and DF values.

DISCUSSION

Alcoholic liver disease (ALD) encompasses a clinicohistological spectrum of abnormalities ranging from fatty liver, to AH and irreversible liver cirrhosis (Laennec's cirrhosis). The potentially fatal clinicopathological syndrome of AH develops in a minority of patients^[9,10].

The major focus of management in AH is abstinence from alcohol, supportive care, treatment of clinical features of decompensated hepatic disease and maintenance of positive nitrogen balance through nutritional support. Although controversy is documented regarding therapeutic issues it is generally agreed that patients with mild disease need not be treated beyond general supportive and symptomatic care and patients with severe disease in extremis may be too ill to correspond in any form of therapy. Identification of those patients who might benefit from aggressive intervention, including corticosteroids or controversial treatment approaches (antioxidant therapy, stimulation of liver regeneration, supplemental amino-acids, inhibition of tumour necrosis factor α and stimulation of collagen degradation^[11]) as well as patients in whom the therapeutic benefit/risk ratio is unfavourable, is currently an issue of great clinical interest.

Figure 3 Predicting utility of MELD score in assessing 30- and 90-d mortality rates in alcoholic hepatitis. Receiver operating characteristic curves were generated and the area under the curve and confidence intervals are indicated.

Figure 4 Predicting utility of DF score in assessing 30- and 90-d mortality rates in alcoholic hepatitis. Receiver operating characteristic curves were generated and the area under the curve and confidence intervals are indicated.

On that ground the utility of prognostic models in predicting the short-term mortality in AH has been recently assessed by three series in the literature. In 2002 Sheth *et al* verified the fact that the MELD score performs as well as the DF score in predicting 30-d mortality in AH. A MELD score of greater than 11 or the presence of both ascites and an elevated bilirubin greater than 8 mg/dL should prompt consideration of aggressive therapeutic interventions such as corticosteroids or pentoxifylline according to the authors^[11]. Three years later a retro prospective cohort study assessing 73 patients was conducted by Dunn *et al*^[7], which identified a MELD score of 21 as having the highest sensitivity and specificity for predicting mortality with an estimated 90-d mortality of 20% for patients with this score also manifesting in ascites and encephalopathy. Recommendations were made for such patients to receive aggressive therapeutic agents. According to the authors MELD score maintained some practical and statistical advantages over DF in predicting mortality rates in these patients. Finally in the latest clinical trial conducted in a large cohort of 202 patients with AH, admission, first week and first week change in the MELD score were justified

Figure 5 Kaplan Meier survival curves estimated for DF values < 92 and ≥ 92. Higher score values were correlated with a lower survival (*P*-value 0.0002).

Figure 7 Kaplan Meier survival curves estimated for MELD values < 19 and ≥ 19. Higher score values were estimated to be correlated with a lower survival (*P*-value 0.0848).

Figure 6 Kaplan Meier survival curves estimated for DF values < 108 and ≥ 108. Higher score values were correlated with a lower survival (*P*-value 0.0098).

Figure 8 Kaplan Meier survival curves estimated for MELD values < 30.5 and ≥ 30.5. Higher score values were correlated with a lower survival (*P*-value 0.0277).

as independent predictors for in-hospital mortality. Also the MELD score outranked the DF and CTP scores when considering prognostic accuracy and cut off points of ≥ 18 for admission MELD score, ≥ 20 for the first week MELD score and ≥ 2 for the first week change in MELD score which were significantly correlated with mortality^[8].

In our study a prognostic equivalency of MELD and DF scores was verified whereas the predictive utility of ascites or encephalopathy could not be established. On the other hand, a statistically significant utility of CRP, FS and SGPT as independent predictors of 90-d mortality has been demonstrated. No additional variables significantly changed the prognostic utility of the MELD or DF scores when they were entered in a multivariable analysis. The cut off points were 19 and 30.5 for MELD score and 92 and

108.68 for DF score for 90- and 30- d mortality, respectively.

Despite statistical analysis some practical points favouring the use of the MELD score in this setting should be considered. When compared with the Child-Pugh score the MELD score surpasses in the setting in that: (1) it uses objective parameters which are not subject to center-to-center variability, (2) it increases as the three constituent parameters deteriorate, whereas the individual scoring elements in the Child score remain fixed once a defined threshold has been reached^[12]. Presumably CTP classification is an instrument of its time and implementation of the newest therapeutic strategies will require a more refined scale that accurately represents disease severity. Disadvantages were also demonstrated regarding the utility of the DF classification

for AH including: the use of PT, a variable that is poorly standardized across different laboratories, an established risk of death of up to 17% in patients with a DF score greater than 32^[13,14], and the fact that initial validation of DF correlation to mortality rates is based on series from several decades ago^[7].

In summary, physicians should keep in mind that ALD when complicated by AH should be considered with skepticism and aggressive therapeutic options should be regarded. On that basis prognostic scores should be assessed with a MELD score dominating and presenting sufficient prognostic accuracy.

Abstract

AIM: To investigate histological characteristics of gastric polyps in the Korean population.

METHODS: We reviewed endoscopic photographs and medical records of patients with gastric polyps who underwent endoscopic mucosal resection from April 1996 through February 2003.

RESULTS: A total of 85 gastric polyps from 74 patients were reviewed. Male-to-female ratio was 1:1.96. Mean age was 59.9 ± 10.8 years. Multiple polyps were observed in 10.8%. Gastric polyps occurred most frequently in the antrum (58.8%). Pathological results on resected specimens were as follows: tubular adenoma 45.9%, hyperplastic polyp 31.8%, inflammatory polyp 9.4%, hamartoma 3.5%, fundic gland polyp 2.4%, tubulovillous adenoma 2.4%, adenocarcinoma 2.4%, dysplasia 1.1%, and mucosal pseudolipomatosis 1.1%. Discrepancy rate between endoscopic biopsy and pathology of resected specimens was 27.1%. There was no relationship between the size of the polyp and concordance rate.

CONCLUSION: There is considerable discrepancy in histologic findings between endoscopic forceps biopsy and resected specimens. Approaches to review of the histology of an entire polyp should be performed, especially when an adenoma is suspected.

INTRODUCTION

A gastric polyp is a discrete lesion protruding to the gastric lumen. In autopsy series, the prevalence of gastric polyps is 0.12%-0.8%. However, due to widespread utilization of flexible endoscopy, the frequency of gastric polyps is increasing^[1]. The majority of gastric polyps are adenomatous, hyperplastic and fundic gland polyps, the latter two being the most common^[2-9]. While adenomatous polyps are considered true neoplasms with malignant transformation rates ranging from 6 to 47%^[6,10-13], no such transformations are reported in fundic gland polyps^[6,14]. Although rare, malignant transformations in hyperplastic polyps have been reported^[15,16]. There are reports of discrepancy between endoscopic forceps biopsy (EFB) specimens and endoscopic mucosal resection (EMR) specimens^[17]. Once an adenomatous gastric polyp is found, it is recommended to completely remove the entire polyp to confirm the diagnosis and to remove precancerous lesions. We conducted this study to find out histologic characteristics of gastric polyps in Korean population with an emphasis on the discrepancy in the results of EFB and EMR specimens.

MATERIALS AND METHODS

Patients

We retrospectively analyzed medical records of the patients who underwent EMR of gastric polyps from April 1996 to February 2003 at Seoul Municipal Boramae Hospital. Patients without biopsy results prior to EMR were excluded.

Endoscopic procedures

In the presence of gastric polyps, the size of the polyps was measured using biopsy forceps (open size = 6 mm in diameter). Two to 4 biopsy specimens were taken from each polyp. They were fixed in formalin and sent to the pathologists for further investigation. EMR was performed on a different occasion. Resection margins were marked with a needle knife. Saline was injected submucosally to lift the diseased mucosa off the muscularis propria. After grasping the lesion with forceps, resection was done with a snare that was placed around the lesion.

Histological procedures

EMR specimens were compared with the previous biopsy specimens by a single pathologist. Sections were assessed according to the WHO classification of gastrointestinal tumors published in 1990.

Statistical analysis

Statistical analysis was done using SPSS-PC 11.0 (Statistical package for the social sciences, SPSS Inc., Chicago, IL, USA) for MS Windows®. Data were expressed as mean \pm SD. Categorical data were compared using the χ^2 test. Two-tailed *P* values < 0.05 were considered statistically significant.

RESULTS

Patient characteristics

A total of 74 patients were enrolled to this study. Twenty-five patients were male (a male : female ratio of 1:1.96). Mean age was 59.9 ± 10.8 years (Table 1).

Number of polyps

Sixty-six patients had one polyp (89.2%), 2 patients had 2 polyps (6.8%), and 3 patients had 3 polyps (4.0%). A total of 85 polyps were identified in 74 patients (Table 1).

Location of polyps

Fifty polyps were located in the antrum, 16 in the low body, 9 in the midbody, 5 in the high body, 3 in the angle, and 2 in the fundus (Table 1).

Diameter of polyps

Thirty-six polyps (42.4%) were < 1 cm in diameter, 38 (44.7%) were 1-1.9 cm in diameter, 11 (12.9%) were 2-3 cm in diameter (Table 1).

Classification of polyps according to Yamada classification

Thirty-three (38.8%) polyps were Yamada type I, 24 (28.2%) were Yamada type II, 12 (14.1%) were Yamada type III, and 16 (18.9%) were Yamada type IV (Table 1).

Results of endoscopic forceps biopsy (EFB)

Forty-one (48.2%) polyps were tubular adenoma, 26 (30.6%) were hyperplastic polyps, 13 (15.3%) were inflammatory polyps, 2 (2.4%) were fundic gland polyps, 2 (2.4%) were dysplasia, and 1 (1.1%) was tubulovillous adenoma (Table 1).

¹MP, Mucosal pseudolipomatosis

hamartoma, and 1 was tubulovillous adenoma. When hyperplastic polyps with positive *H. pylori* were compared with other polyps positive with *H. pylori*, hyperplastic polyps showed a correlation with *H. pylori* infection ($P = 0.005$).

Comparison of histology between EFB and EMR specimens (Table 3)

Of 41 polyps diagnosed as tubular adenoma in EFB, 35 (85.4%) were tubular adenoma, 2 (4.9%) were inflammatory polyps, 1 (2.4%) was tubulovillous adenoma, 2 (4.9%) were adenocarcinoma, and 1 (2.4%) was a dysplasia. Four cases (9.8%, 1 tubulovillous adenoma, 2 adenocarcinoma, and 1 dysplasia) were underdiagnosed in EFB group when compared with EMR specimens. Two cases (4.9%, inflammatory polyps) were overdiagnosed in EFB as against EMR specimens.

Of 26 polyps diagnosed as hyperplastic polyps in EFB, 1 (3.8%) was a tubular adenoma, 22 (84.8%) were hyperplastic polyps, 1 (3.8%) was an inflammatory polyp, 1 (3.8%) was a hamartoma, and 1 (3.8%) was a mucosal pseudolipomatosis. One case (3.8%, tubulovillous adenoma) was underdiagnosed in EFB compared with EMR specimen.

Of 13 polyps diagnosed as inflammatory polyps in EFB, 2 (15.4%) were tubular adenoma, 5 (38.5%) were hyperplastic polyps, 4 (30.7%) were inflammatory polyps, and 2 (15.4%) were fundic gland polyps. Two cases (15.4%, tubular adenoma) were underdiagnosed in EFB compared with EMR specimens.

Two polyps diagnosed as fundic gland polyps in EFB were proven to be hamartomas in EMR specimen. Two polyps diagnosed as dysplasia in EFB were found to be a tubular adenoma and an inflammatory polyp, respectively. One polyp diagnosed as a tubulovillous adenoma was found to be a tubulovillous adenoma in EMR.

Concordance rate between EFB and EMR was 72.9%. When stratified according to the diameter of polyps, concordance rate was 66.7% (24/36) in polyps < 1 cm in diameter, 78.9% (30/38) in polyps 1-1.9 cm in diameter, 72.7% (8/13) in polyps 2-3 cm in diameter. The concordance rate was not associated with polyp diameter ($P > 0.05$). Concordance rate was not associated with Yamada type or with *H. pylori* infection ($P > 0.05$).

DISCUSSION

Gastric polyps are found in less than 1% of the general population^[4]. The rate of malignant transformations in this polyp is less than 1%, usually occurring in polyps with a diameter larger than 1 cm^[15]. Most polyps that undergo malignant transformations are adenomatous polyps. It has been reported that about 11% of adenomatous polyps progress to carcinoma in situ within 4 years of detection^[13].

Contrary to previous reports^[2-9], adenomatous polyps were most frequently encountered in our study. Although this may be due to selection bias, the high frequency of adenomatous polyps (> 40%) in our series imply racial difference in gastric polyp histology.

Discrepancy between EFB and EMR specimen has been reported, with rates ranging from 10 to 25%^[18-20]. In our study, the discrepancy rate between EFB and EMR specimen was 27.1%. Of interest, 2 cases which were diagnosed as tubular adenoma in EFB were later proven to be adenocarcinoma in EMR specimen. Fujiwara and colleagues^[21] reported that 14 of 50 borderline gastric adenomas were diagnosed as containing adenocarcinoma after EMR and that adenocarcinoma could not be detected despite a repeated EFB in 9 patients. In our study, 4 of 41 polyps (9.8%) diagnosed as tubular adenoma were underdiagnosed. This suggests that EFB specimens may not be representative of the entire lesion. Therefore, to obtain a final diagnosis and as well as definitive treatment, lesions should be completely resected by EMR.

It may be expected that as the size of gastric polyp decreases, the biopsy specimen will be more representative of the entire lesion. This was not the case in our study. Although not reaching statistical significances, we found greater discrepancy in smaller polyps.

H. pylori infection is reported to be associated with the development of hyperplastic polyps^[8,22]. In our study, hyperplastic polyps were associated with *H. pylori* infection. However, *H. pylori* infection was not associated with the diagnostic discrepancy observed.

In conclusion, results of our observation of EFB and EMR specimens of gastric polyps showed a certain degree of discrepancy. The size of polyps was not associated with the diagnostic discrepancy. Therefore, especially when adenoma is suspected, evaluation of entire polyp by EMR is warranted regardless of size, to obtain an accurate diagnosis and management plan.

Abstract

AIM: Rectal carcinoid tumors smaller than 10 mm can be resected with local excision using endoscopy. In order to remove rectal carcinoid tumors completely, we evaluated endoscopic mucosal resection with a ligation device in this pilot control randomized study.

METHODS: Fifteen patients were diagnosed with rectal carcinoid tumor (less than 10 mm) in our hospital from 1993 to 2002. There were 9 males and 6 females, with a mean age 61.5 years (range, 34-77 years). The patients had no complaints of carcinoid syndrome symptoms. Fifteen patients were randomly divided into 2 groups: 7 carcinoid tumors were treated by conventional endoscopic resection, and 8 carcinoid tumors were treated by endoscopic resection using a ligation device.

RESULTS: All rectal carcinoid tumors were located at the middle to distal rectum. The size of the tumors varied from 3 mm to 10 mm and background characteristics of the patients were not different in the two groups. The rate of complete removal of carcinoid tumors using a ligation device (100%, 8/8) was significantly higher than that of conventional endoscopic resection (57.1%, 4/7). The three patients had tumor involvement of deep margin, for which additional treatment was performed. No complications occurred during or after endoscopic resection using a ligation device. All patients in the both groups were alive during the 3-year observation period.

CONCLUSION: Endoscopic resection using a ligation device is a useful and safe method for resection of small rectal carcinoid tumors.

INTRODUCTION

It is widely accepted that rectal carcinoid tumors smaller than 10 mm can be treated with local excision using endoscopy because they rarely metastasize^[1,2]. Complete resection of rectal carcinoid tumors is, however, not easy with conventional endoscopic resection methods, as most of these tumors are located in the submucosal layer of the rectal wall of the lower portion of the rectum. As a result, there is a high incidence of residual tumor or tumor near the resection margin, requiring additional surgical intervention^[3,4].

A previous study demonstrated that endoscopic mucosal resection with a ligation device facilitated complete resection of early gastric carcinoma and adenoma^[5]. We previously suggested the possibility of this method for complete resection of rectal carcinoid tumor^[6]. The historical control study performed by Ono *et al*^[4] indicated usefulness of this method for complete resection of rectal carcinoid tumor. In this pilot randomized control trial, we aimed to compare clinical usefulness of ligation device for carcinoid resection with that of conventional endoscopic resection with snaring, and to evaluate a 3-year survival after resection.

MATERIALS AND METHODS

Fifteen patients diagnosed as rectal carcinoid tumor (less than 10 mm) in our hospital from 1993 to 2002 were enrolled in this study. No patients had symptoms of carcinoid syndrome. Examination with a high-frequency ultrasonographic probe (EU-M20; 20MHz, Olympus, Tokyo, Japan) inserted through the biopsy channel of the endoscope was performed for evaluation of carcinoid tumors remained in submucosal layer (Figure 1). After

Age (yr)	Sex	Size (mm)	Margin	Additional therapy
Group 1				
74	M	3	Negative	(-)
34	F	5	Negative	(-)
61	M	7	Negative	(-)
46	F	8	Positive	Transanal resection
64	M	6	Negative	(-)
75	M	6	Positive	Ligation
Group 2				
55	M	5	Negative	(-)
77	M	9	Negative	(-)
70	M	7	Negative	(-)
51	F	4	Negative	(-)
63	M	10	Negative	(-)
74	F	4	Negative	(-)
60	F	5	Negative	(-)
51	M	6	Negative	(-)

informed consent was obtained, these patients were randomly assigned into two groups according to a table of random permutations. Group 1 ($n = 7$) carcinoid tumors were treated with endoscopic mucosal resection using a snare with a conventional single-channel colonoscopy. Briefly, after injection of submucosal saline, the lesion was simply resected with snaring. Group 2 ($n = 8$) carcinoid tumors were treated by endoscopic resection using a ligation device (varioligator kit; TOP Co. Ltd, Tokyo, Japan), with modification of the method used in gastric carcinoma^[4,5]. A ligation device attached to a conventional single-channel colonoscopy (PCF200, PCF240 Olympus, Co., Tokyo, Japan), and endoscopic resection using a ligation device was performed as follows: (1) submucosal saline solution was injected beneath the tumor to elevate it for reducing a risk of perforation and resection margin involvement; (2) the carcinoid tumor was aspirated into the ligation device; (3) snare resection was performed below the band by using blend electrosurgical current (Figure 2). This study was performed according to the guidelines of the Committee on Clinical Practice of our hospital.

All resected specimens were examined microscopically for histopathological diagnosis, cut (lateral) and deep (vertical) margin involvement, and vascular and/or lymphatic invasion (Figure 3). Completeness of resection was evaluated by the histopathological examination as absence of carcinoid in the margin of the resected specimen.

Statistical analysis

Tested groups were evaluated using chi-square test or student's *t* test. *P* values of 0.05 or less were considered statistically significant.

RESULTS

The results are shown in Table 1. Average age of group 1 patients was 60.2 years (range: 34-75 years), and average age of group 2 was 62.6 years (range: 51-77

years). Female/male ratios were 3:4 in group 1 and 3:5 in group 2. Thirteen tumors were located in the lower and 2 in the upper portion of the rectum, as 9 sessile and 6 semipedunculated small protrusions of the mucosa. The size of the tumors varied from 3 mm to 9 mm with mean diameter of 6.3 mm in group 1, and from 4 mm to 10 mm with mean diameter of 6.2 mm in group 2. Neither vascular nor lymphatic invasion was observed in any resected carcinoid tumor. Background characteristics of patients were not different between groups 1 and 2.

Complete resection rate was compared in two groups with histopathological examination. The rate of complete removal of carcinoid tumor in group 1 with simple snaring resection was 42.9% (3/7), which was significantly lower compared to that in group 2 with resection using a ligation device (100%, 8/8; $P = 0.024$). The three patients had tumor involvement of deep margin without lateral resection margin. These patients of carcinoid tumor in group 1 were treated with additional treatment: one patient was treated by trans-anal resection and two patients were resected with a ligation device. All patients were followed up more than 3 years, and recurrence of carcinoid tumors was not observed in any patient enrolled in this study.

DISCUSSION

Rectum is the most common part of carcinoid tumors in the gastro-intestinal tract in Japan^[7]. Prevalence of rectal carcinoid has been reported as 0.07% (16/21 522) in healthy subjects^[3] and 0.10% (8/7 665) in subjects of total colonoscopy in Japan^[8]. Most of rectal carcinoid tumors are less than 10 mm in size, and these tumors remain in the rectum without metastasis and can be treated by local resection^[1,2]. These carcinoid tumors are mainly located in the lower part of rectum as shown in this study^[3,8-10].

Rectal carcinoid tumors are treated by several methods including endoscopic resection^[11-13] and surgical operation with trans-anal approach^[14]. Carcinoid tumors less than 10 mm can be treated by local resection, but most of carcinoid tumors extend into the submucosa, and polypectomy can not remove these tumors completely as shown in the previous study^[4]. Complete resection of submucosal tumors requires other method than simple polypectomy. Endoscopic mucosal resection following submucosal injection of saline solution should be useful for the resection.

This randomized control study compared endoscopic resection with a ligation device to conventional endoscopic resection with a snare just after saline injection. As a result, rectal carcinoid tumors less than 10 mm could be removed completely by endoscopic resection with a ligation device without any procedure-related complications. This result confirmed the previous historical control trial performed

by Ono *et al*^[4] who showed usefulness of endoscopic resection with a ligation device but their follow-up period was limited (median follow-up period: 10.5 mo). In this study, we followed up all patients for 3 years without any recurrence.

In conclusion, endoscopic resection with a ligation device might be a most applicable procedure for rectal carcinoid tumors less than 10 mm remained within submucosal layer, because this procedure is simple, minimally invasive, and safe for resection.

RESULTS: Thirty-five of 45 (77.8%) histologically characterized tumor samples had analogous somatic mutation as opposed to 1 of 45 normal sample obtained from adjacent region from the same patient showed germline mutation. The SSCP analysis demonstrated that most common *p53* gene alterations were found in exon 6 (77.7%), that did not correlate with the age of the individual and clinicopathological parameters but showed significant concordance ($P < 0.05$) with familial history of cancer (CD = 58), suggesting germline predisposition at an unknown locus, and dietary habit of consuming locally grown *Brassica* vegetable "Hakh" (CD = 19.5), red chillies (CD = 20.2), hot salty soda tea (CD = 2.37) and local baked bread (CD = 1.1).

CONCLUSION: Our study suggests that somatic chromosomal mutations, especially in exon 6 of *TP53* gene, among esophageal cancer patients of an ethnically homogenous population of Kashmir valley are closely related to continued exposure to various common dietary risk factors, especially hot salty tea, meat, baked bread and "Hakh", that are rich in nitrosoamines and familial cancer history.

Abstract

AIM: To systematically examine the extent of correlation of risk factors, such as age, consumed dietary habit and familial predisposition with somatic *TP53* molecular lesion causal to elevate carcinogenesis severity of esophageal squamous cell carcinoma (ESCC) among the Kashmiri population of Northern India.

METHODS: All cases ($n = 51$) and controls ($n = 150$) were permanent residents of the Kashmir valley. Genetic alterations were determined in exons 5-8 of *TP53* tumor suppressor gene among 45 ESCC cases histologically confirmed by PCR-SSCP analysis. Data for individual cancer cases ($n = 45$) and inpatient controls ($n = 150$) with non-cancer disease included information on family history of cancer, thirty prevailing common dietary risk factors along with patient's age group. Correlation of genetic lesion in *p53* exons to anamnestic data from these parameters was generated by Chi-square test to all 45 histologically confirmed ESCC cases along with healthy controls.

INTRODUCTION

Among human cancer, esophageal carcinogenesis appears to be a complex multi-step process with a multi-factorial etiology, where environmental, geographical, and genetic factors appear to play major roles^[1]. Apparently 400 000 new cases of esophageal cancer occur each year, and esophageal cancer as such is the sixth leading cause of

cancer death worldwide^[2]. Extended epidemiological studies in high incidence areas, such as Northern Iran, Northern China and South Africa, provide evidence that exposure to specific diet-related nitroso compounds in parallel with nutritional deficiencies and consuming food contaminated by mycotoxins are the most important determinants of the disease^[3]. Also in some parts of India, esophageal cancer is alarmingly rising and is as such the third leading cancer in men and fourth leading cancer in women in these regions^[4]. Reports from Southern India suggest that esophageal squamous cell carcinoma (ESCC) occurs in more than 80% of cases in chronic tobacco smokers that is further potentiated by heavy use of alcohol and additional prevailing risk factors, including nutritional factors and vitamin deficiencies^[5]. In the Kashmir valley, belonging to the Northern part of India, esophageal cancer has been reported to exceed 40% of all cancers, however, very few reports have associated this malignancy with specific risk factors prevalent in the area^[6].

With the advent of molecular biology, new strategies are being carried out for the prevention and treatment of cancer. Cumulating evidence indicates that changes in both dominant oncogene and tumor suppressor genes are likely for malignant transformation of normal cell^[7]. Among these genetic abnormalities, *p53* tumor suppressor gene, a critical regulator of cell growth, differentiation and apoptosis, is frequently affected in most human cancer^[8]. The frequencies of *Tp53* alterations in esophageal carcinoma vary from 26% to 87% that occur in multiple sites throughout the open reading frame, which are mostly limited to DNA binding domain that spans exon 5 through exon 8^[9]. The current study was initiated to find out the risk factors of esophageal cancer in Kashmiri inhabitants and to correlate *p53* alterations in ESCC with prevalent risk factors.

MATERIALS AND METHODS

Collection of tumor samples and data from case-control population

Hospital and general population-based case-control study of permanent inhabitants of Kashmir was performed between March 2003 and December 2005. Cases were selected from the Government Medical College, Srinagar, Kashmir and controls from three districts of Kashmir valley, India viz. Srinagar, Anantnag and Pulwama. From each of the three districts, 150 healthy individual families (controls) were randomly selected and evaluated along with selected patients on a detailed questionnaire for demographic information as well as exposure to etiological factors, including dietary nitrosoamines, intake of pickled vegetables, meat, hot salty tea, source of water, *etc* as well as the incidence of any family history of cancer in them. Family history of cancer was defined as the presence of esophageal cancer in one or more relatives for both cases and controls. One hundred milligram of tumor specimen and other 100 mg of macroscopically normal adjacent esophageal tissues were obtained from each selected ESCC patient (cases) that were admitted in different Wards of Government Medical College, Srinagar, Kashmir and were diagnosed for the first time for such type of cancer. The selected cases diagnosed for the first time for ESCC

having no chemotherapy or radiotherapy prior to biopsies were interviewed 3 d prior to the surgery. From 51 histopathologically confirmed ESCC samples, information related to histopathological grade *etc* was collected from the Division of Pathology, Government Medical College, Srinagar. For evaluating the association between the common dietary risk factors and genesis of ESCC in Kashmiri inhabitants, the dietary habits of all the 45 cases were compared with two groups of controls (Group II and Group III), each representing 45 normal subjects taken from total of 150 healthy individual families. Group II represented the controls with family history of cancer and group III represented the controls without any family history of cancer.

DNA extraction and PCR amplification

High molecular genomic DNA from the fresh ESCC and from adjacent normal tissue samples was extracted using DNAzol reagent (Imperial Bio-Medics, India). The extracted DNA was used for PCR amplification reactions. PCR primers used were same as used previously for the amplification of 5-8 exons of *TP53* gene^[10]. Out of total 51 ESCC cases, 6 with apparent cancer of other origin were excluded from PCR amplification and only 45 were used for the further study. All the reactions were carried out in a total volume of 50 μ L in Techgene (0.2 mL) PCR System (Techne, UK). Typical PCR conditions were as follows: denaturation at 94°C for 10 min, followed by 35 amplification cycles at 94°C for 1 min, 55°C for 1 min, and 72°C for 1 min. An elongation step at 72°C for 10 min was added to the final cycle for all the exons. PCR products were separated on 40 g/L agarose gel continuously and visualized by 600 g/L ethidium bromide staining.

SSCP analysis

Non-radioactive SSCP was performed as described previously^[10] with slight modification. A 60 g/L non-denaturing gel conditions were used with 60 mL/L glycerol (dissolved in 0.5 \times TBE buffer). Aliquots of amplified products were mixed with equal amounts of denaturing buffer (500 mL/L deionized formamide and 500 mL/L glycerol with 0.5 g/L xylene cynol and 0.5 g/L bromophenol blue). Samples were denatured at 95°C for 5 min, kept on ice until loading on the 60 g/L non-denaturing gel and run in vertical electrophoretic plates (Banglore Genei, India) with 0.5 \times TBE as running buffer at 150 V for 3-4 h at room temperature. SSCP fragments were visualized by silver staining.

Statistical analysis

Analysis of the data was performed on the original data by using chi-square (χ^2) test to determine correlation between *p53* alterations in ESCC and dietary risk factors as well as with clinicopathological status of ESCC tissue samples. $P < 0.05$ was considered statistical significant.

RESULTS

Samples, clinicopathological parameters and *p53* mutations

Forty-five cases without any apparent cancer of other

¹Chi-square (χ^2) test with Fisher's exact test was used to test the frequency distribution of *p53* alteration.

origin, and 150 inpatient controls were enrolled in the current study, among which most of the cases (77.8%, 35/45) were older than 60 years (Table 1). Thirty-three of 45 (73.3%) tissue samples were histologically confirmed to be well-differentiated, 15.5% (7/45) moderately differentiated and 11.1% (5/45) poorly differentiated cancer. Regarding depth of tumor invasion, 5 (11.1%) cases belonged to T1, 7 (15.5%) cases belonged to T2, 22 (48.8%) cases belonged to T3 and 11 (24.4%) cases belonged to T4. Our results demonstrated no difference in the incidence of *p53* alterations among the patients below and above 55 years. With respect to *p53* alterations and depth of tumor invasion, T3 and T4 demonstrated higher frequency of mutations (> 72%) as compared to T1 and T2. However, statically no positive correlation was found between tumorous *p53* alterations and age (P = 0.848), depth of tumor (T) invasion (P = 0.128), lymph node metastasis (M) (P = 0.114) and cell differentiation (P = 0.210) (Table 1).

Risk factors of esophageal cancer

In the general population (controls)-based survey representing 50 individual families, each from three districts of Kashmir valley, matched for different life styles and dietary habits revealed some common food habits that were also common in the selected ESCC cancer patients (Table 2). Total 51 ESCC cases, 45 cases without cancer of any other origin and represented by Group I showed 35 (77.7%) cases with family history of esophageal cancer. Two groups of controls were used representing 51 families, with one group designated as Group II showing the family history of cancer and Group III without any family history of cancer. Interestingly, more than 80% subjects in Group I and Group II showed the same pattern of dietary habits i.e. heavy consumption of hot salty tea,

**Figure 1** Single-strand conformational polymorphism (SSCP) of *p53* exon 6 in ESCC specimens showing 8 anomalous bands with altered mobility and indicates the presence of *p53* mutation (arrows).

local baked bread, meat, red chillies as well as consumed “Hakh”, a locally grown green leafy vegetable belonging to the *Brassica* family, very heavily (0.57 kg/person per wk) as compared to subjects in group III. Statistically, we also could not find any remarkable difference quantity-wise in consumption of Hakh, hot salty tea, baked bread, meat and red chillies between the group I and Group II. However, both of these two groups differed significantly from the Group III with respect to consumption of these aforementioned food items at very lower amounts (Table 2).

Correlation of *p53* alterations in ESCC with the prevalent risk factors

Interestingly, 32 of 35 (91.42%) tumor samples from selected 45 cases (Group I) with family history of cancer showed positive for *p53* alterations as compared to only 3 of 10 (30%) samples from cases without any family history of cancer. On SSCP analysis, a total of 82 anomalous bands from these tumor DNA of 35 ESCC patients in exons 5-8 with single exon and multiple exon alterations were observed (Table 3). One case also showed an anomalous band in DNA from both normal constitutional DNA as well as tumor DNA. Statistically, the genetic alterations in 5-8 exons of *p53* gene in total of 45 cases differer significantly with respect to each other (χ^2 = 11.25, P = 0.0105) and most of the mutations (77.7%) were confined to exon 6 (Figure 1), followed by exon 7 (38.9%), exon 8 (33.3%) and exon 5 (27.7%) in decreasing order. Statistically, *p53* alterations, especially in exon 6, were closely related to familial history of cancer (CD = 58), suggesting germline predisposition at an unknown locus, and also to prevalent dietary habit of consuming locally grown *Brassica* vegetable “Hakh” (CD = 19.5), red chillies (CD = 20.2), hot salty soda tea (CD = 2.37) and local baked bread (CD = 1.1).

DISCUSSION

Reports indicate that the Kashmir valley of Jammu and Kashmir State of India ranks among the highest incidence area for esophageal cancer in the world^[6]. Despite the gravity of the problem, very little work has initiated in the area. In the current study, 77.7% patients were older than 60, and thus indicating ESCC to be the malignancy of adults with 80% of them found to seek treatment in the

Table 2 Some specific dietary habits of three groups consisting each of 51 individuals

Dietary group	Group I	Group II	Group III	At <i>P</i> values < 0.05, CD
Baked bread (Kandaroo Roti)	41/51 (5 roti/d per person)	50/51 (4 roti/d per person)	45/51 (2 roti/d per person)	1.1
Hot salty tea with soda	43/51 (5 cups/d per person)	51/51 (4 cups/d per person)	48/51 (2 cups/d per person)	2.37
Meat	48/51 (0.82 kg/wk per person)	51/51 (0.75 kg/wk per person)	48/51 (0.500 kg/wk/person)	0.25
Red chillies	51/51 (78 g/wk per person)	50/51 (90 g/wk per person)	30/51 (38 g/wk per person)	20.2
<i>Brassica oleracea</i> (Hakh)	51/51 (0.35 kg/wk per person)	51/51 (0.57 kg/wk per person)	51/51 (0.55 kg/wk per person)	19.5

advanced stage of their cancer and diagnosed for the first time^[5]. These results indicate the lack of general awareness of this disease among the general population and remain a major health concern that needs immediate medical attention in the area.

The important cause for high incidence of disease in the Kashmir valley may be defined on the basis that unlike Ladakh and Jammu constituencies of Jammu and Kashmir state that are the low incidence area for ESCC, the Kashmiri population on account of climatic conditions practice an exclusively different dietary life-styles, including use of hot salty tea, red chillies, baked bread, meat, high-nitrate diet especially locally grown *Brassica* leaves, the Hakh (Table 2). To our knowledge, scant literature that have been documented till date suggests diet-related *N*-nitroso compounds in parallel with nutritional deficiency to be most important determinants of disease in this area^[11,12]. Our investigation provides evidence that the controls with family history of cancer (group II) followed more or less the same dietary habits as that of patients (Group I), indicating consumption of such types of dietary risk factors rich in nitroso compounds associated with carcinogenesis of ESCC. It is noteworthy that Group II subjects developed much more chance of getting ESCC than subjects from Group III that consumed very low quantity of such foods (Table 2). Thus, in accordance with earlier findings, our results also suggest that there is a chance of higher rate of new esophageal cancer in the population that is exposed to common dietary risk factors than those without such exposures^[13]. Among such dietary risk factors, heavy consumption of hot salty soda tea provides chronic irritation of esophageal epithelium causing predisposition of carcinogenic substances to initiate tissue-specific malignant transformation and at the same is also a rich source of carcinogens like *N*-nitrosopropylamine and nitrosopiperic acid^[11]. On individual basis, the daily dietary nitrate intake (237 mg) in Kashmir valley is much higher than the values reported for most of the Western countries (i.e., Germany 75 mg/d and Britain 95 mg/d) and that through consumption of "Hakh" alone that seems to have also a great importance as potential source of nitroso compounds and their precursors^[14,15]. Thus, the results clearly indicate that on daily basis, the Kashmiri population gets exposed to high amounts of nitrate, nitrite and precursor of nitroso

Table 3 Frequencies of *p53* genetic alternations detected by PCR-SSCP in esophageal squamous cell carcinoma (*n* = 45)

	<i>p53</i> exons 5-8							
	Exon 5		Exon 6		Exon 7		Exon 8	
	(+)	(-)	(+)	(-)	(+)	(-)	(+)	(-)

compounds that are in high enough quantity to be one of the responsible dietary risk factor for this malignancy in the area^[11,14]. Additionally, high consumption of red chilli pepper in the region also indicates higher risk for them towards gastric cancer than non-consumers^[6]. Thus exposure of Kashmiri inhabitants to such high or even to low levels of these dietary compounds throughout the life could be involved in the carcinogenesis of esophagus in this high-risk area.

Most of the researchers now suggest various food-borne carcinogens associated with the genesis of ESCC through the involvement of *p53* tumor suppressor gene. Such reports thus suggest a molecular epidemiology approach to investigation of cancers for which the causes have remained elusive^[6,17]. In accordance to earlier reports, interestingly, our study could not find any positive association between clinicopathological variables and *p53* alterations in the collected samples^[18] (Table 1). On the other hand, current study, in contradiction to earlier report, demonstrates most of the alterations (14/18) confined to exon 6 of *p53* gene^[1]. These results are in consonance with most of the other earlier reports that showed more than 50% of mutations confined to exon 6 of *p53* gene among selected ESCC cancer patients^[19].

Finally, this preliminary investigation of tumor gene alterations in patients from Kashmir valley thus supports a large body of epidemiological observations, pointing to dietary mutagenic carcinogenesis and family history of cancer peculiar to populations at high risk of esophageal cancer. The results clearly indicate that such somatic alterations of *p53* gene, especially in its exon 6, in ethnically homogenous population of Kashmir valley are closely related to specific dietary habit and family history of cancer^[6]. However, family history of cancer depends on many factors and cannot as such conclude that the positive

familial history of cancer is due to genetic susceptibility. It is finally suggested that the gradual change in dietary and cultural features in the population should produce a significant decrease in esophageal carcinogenesis in the area, and at the same time, in order to draw some logical conclusion, further studies with large set of samples and data are strictly warranted from this part of India.

Abstract

AIM: To evaluate the antiviral effect of the effective ingredient of *Styela plicata* in a murine model of hepatitis B virus carrier.

METHODS: HBV-transgenic mice were divided into 3 groups (control group, lamivudine treatment group and the effective ingredient of *Styela plicata* treatment group) and assigned to receive normal diet, lamivudine or the effective ingredient of *Styela plicata* for consecutive weeks. Serum hepatitis B surface antigen was detected by enzyme-linked immunosorbent assay (ELISA) method. Serum HBV DNA was detected by real-time polymerase chain reaction (RT-PCR). Serum T helper (h) 1 cytokine interleukin (IL)-2 and Th2 cytokine IL-6 were detected by the quantitative sandwich enzyme immunoassay technique. Another group of HBV-transgenic mice was assigned to receive the effective ingredient of *Styela plicata* for consecutive weeks. The histology of liver tissue was evaluated before and after treatment.

RESULTS: Twelve weeks after starting the therapy, serum hepatitis B surface antigen was significantly lowered in *Styela plicata*-treated mice and lamivudine-treated mice compared with the mice receiving normal diet ($F_{12wk} = 88.81$, $P_{12wk} = 0.000 < 0.01$). Serum HBV DNA was significantly lowered in *Styela plicata*-treated mice and lamivudine-treated mice compared with the mice receiving normal diet ($F_{12wk} = 20.71$, $P_{12wk} = 0.000 < 0.01$). However, like lamivudine, the effective ingredient of *Styela plicata* could not inhibit the replication of HBV completely. A rebound phenomenon of hepatitis B sur-

face antigen and HBV DNA in sera could be found 4 wk after withdrawal of medication. Eight weeks after starting the therapy, serum levels before and after *Styela plicata* treatment of IL-2 were 2.41 ± 0.38 and 10.56 ± 0.78 ng/L, respectively ($t_{8wk} = -16.51$, $P_{8wk} = 0.000 < 0.01$). Compared with the serum levels of IL-2 in the normal diet-treated mice (2.48 ± 0.17 ng/L; $t_{8wk} = 13.23$, $P_{8wk} = 0.000 < 0.01$). Serum levels before and after *Styela plicata* treatment of IL-6 were 63.62 ± 6.31 and 54.52 ± 6.22 ng/L, respectively, compared with the serum levels of IL-6 in the normal diet-treated mice (60.84 ± 4.21 ng/L). Histological analysis of liver from *Styela plicata*-treated HBV-transgenic mice also showed catabatic status in inflammation and hepatitis B surface antigen.

CONCLUSION: *Styela plicata* may be an effective antiviral medicine in treating chronic hepatitis B.

INTRODUCTION

Chronic hepatitis B virus (HBV) infection is a serious clinical problem because of its worldwide distribution and possible adverse sequelae, such as hepatic decompensation, cirrhosis, and hepatocellular carcinoma (HCC)^[1,2]. Although interferon and lamivudine are recommended for patients with chronic liver disease (CLD)^[3,4,6], the high cost, adverse side effects, lower levels of efficacy, and the inability to block the progression to HCC have tremendously limited the use of them^[5-7].

In the absence of an ideal therapy many chemicals with biological activities are used in patients with chronic hepatitis. Ascidians, an intertidal marine, are known for their capacity to inhibit tumors, bacterium and virus^[8-10]. Recent data have indicated that the effective components of the ascidian *Styela plicata* (Sp) can inhibit the secretion of hepatitis B surface antigen (HBsAg) and hepatitis B e

antigen (HBeAg) in 2.2.15 cells^[11].

HBV-transgenic mice (HBV-Tg), which express products of the HBV genome and also show signs of HBV replication, are a suitable animal model to study the process of destruction of hepatocytes, the critical role of antiviral medicines in controlling HBV replication and gene expression^[3,12,13]. In the current study, we evaluated the anti-HBV activity of the alcohol extract of Sp by conducting therapeutic trials in four groups of HBV-Tg expressing similar levels of HBV-markers. A highly significant therapeutic effect of Sp was demonstrated. The mechanism underlying the therapeutic role of Sp in anti-HBV therapy needs to be further investigated.

MATERIALS AND METHODS

Animals

The HBV (adr subtype) transgenic mice (HBV-Tg) were prepared by microinjection of complete 2.0 copy HBV genome into pronuclei of fertilized eggs^[14]. The HBV DNA can be expressed and replicated in the transgenic mice. HBV genomic DNA in mouse line could be transmitted to next generations. The transgenic mice are tolerant to HBV gene products and similar to human chronic HBV carrier^[14,15]. Their serum HBsAg can be expressed highly, but serum HBeAg is expressed inapparently.

We purchased the HBV-Tg of either sex from the Infectious Diseases Center of 458 Hospital of Chinese PLA at 6 wk of age. All animals were housed with controlled temperature at 28°C ± 2°C and 16:8 h light-dark cycle.

Animal grouping

HBV-Tg were divided into three groups. Group 1 (9 mice, the control group) was administrated with normal foodstuff and physiological saline. Group 2 (9 mice, a treatment group) was allowed to receive lamivudine (50 mg/kg per day), normal foodstuff and physiological saline. Group 3 (9 mice, a treatment group) was administrated with the foodstuff containing the effective ingredient of Sp (5 g/kg per day) and physiological saline. Every group was gastrogavaged for 12 wk. The sera of HBV-Tg were collected before administration of drugs, at the 4th, 8th and 12th wk after administration of drugs, and the 4th wk after withdrawal of drugs.

Another group of HBV-Tg (5 mice) were anesthetized by an injection of amobarbital (70 µg/g). Then an abdominal incision was made. Parts of their livers were immediately excised. Then the incisions were closed. After 2-wk feeding with ordinary foodstuff and physiological saline, the mice were assigned to the foodstuff containing the effective ingredient of Sp (5 g/kg per day) and physiological saline for 10 wk and later the livers were obtained with the method described before.

Assay of hepatitis B surface antigen

HBsAg in sera was detected quantitatively by the enzyme-linked immunosorbent assay (ELISA) method, as described in commercial kits (Rongsheng Biotech Co., Ltd, Shanghai, China). The HBsAg levels were expressed

in optical density (OD) values. All performance strictly followed the manuals of the ELISA kits.

Quantitative detection of serum HBV DNA

For HBV DNA quantification by real-time polymerase chain reaction (RT-PCR), viral DNA was extracted from serum using viral DNA extraction solution (DaAn Gene Co., Ltd, Guangzhou, China) according to the manufacturer's instructions. PCR amplification was performed with a set of PCR primers and a probe corresponding to the surface antigen gene of HBV^[15]. The PCR primers are: P1, 5'-ATCCTGCTGCTATGCCCTCA TCTT; P2, 5'-ACAGTGGGGGAAAGCCCTACGAA. The TaqMan probe is 5'-TGGCTCAGTTTACTAGT-GCCATTTG. The PCRs were performed according to the manufacturer's instructions (DaAn Gene Co., Ltd, Guangzhou, China)^[16] using a LightCyclerTM (Roche Diagnostics, Germany). The PCR cycling program consisted of an initial denaturing step at 93°C for 2 min, followed by 40 amplification cycles at 93°C for 5 s, 57°C for 45 s. The HBV DNA titers > 1.00 × 10³ (1.00E03) copies/mL were considered to be positive.

Detection of serum cytokines

Sera were collected before administration of drugs, at the 4th, 8th wk after drug administration. Levels of IL-2 and IL-6 in sera were detected by using ELISA kits specific for IL-2 and IL-6 (Senxiong Technology Industry Co., Ltd, Shanghai, China). The assay used the quantitative sandwich enzyme immunoassay technique. All operations strictly followed the manuals of the ELISA kits.

Histological analysis

Some of the specimens obtained were fixed with 4% buffered formalin and embedded in paraffin. Then they were stained with haematoxylin and eosin (HE) and examined on a video monitor. The normal and inflamed regions of the specimens were easily discriminated by HE stains. The degree of liver cell degeneration and inflammation was evaluated according to previous method^[17].

The other specimens obtained were fixed with 4% buffered formalin and embedded in paraffin. Then they were stained with orcein and examined on a video monitor. The HBsAg could be observed by orcein stains.

Statistical analysis

The experiment results were analyzed by SPSS12.0 statistical software. The data for the negative rate were expressed as percentage. The data for the concentration of HBV DNA in serum were expressed as mean ± SD. Difference before and after therapy within one group was analyzed using paired *t*-test. Difference among the groups was evaluated using analysis of variance (One-way ANOVA). Statistical significance was accepted at the level of *P* < 0.05.

RESULTS

Changes of HBsAg titers

The changes of HBsAg titers are shown in Table 1. The

Table 1 Changes of HBsAg titers (mean \pm SD)

Treatment group	OD values

paired t -test showed that the HBV-Tg which responded to lamivudine therapy had reduced serum HBsAg compared with that prior to therapy from wk 4 to wk 12 ($t_{4wk} = 2.94$, $P_{4wk} = 0.039 < 0.05$; $t_{8wk} = 7.37$, $P_{8wk} = 0.000 < 0.01$; $t_{12wk} = 13.54$, $P_{12wk} = 0.000 < 0.01$). The HBV-Tg which responded to the effective ingredient of Sp showed reduced level of serum HBsAg from wk 4 to wk 12 significantly ($t_{4wk} = 2.89$, $P_{4wk} = 0.020 < 0.05$; $t_{8wk} = 3.61$, $P_{8wk} = 0.007 < 0.01$; $t_{12wk} = 11.11$, $P_{12wk} = 0.000 < 0.01$). Although these treatment groups all exhibited a rebound phenomenon 4 wk after withdrawal of medication, they still exhibited a significant lower level of serum HBsAg compared with that prior to therapy ($t_{lami} = 2.39$, $P_{lami} = 0.043 < 0.05$; $t_{sp} = 10.15$, $P_{sp} = 0.000 < 0.01$). One-way ANOVA showed that the HBV-Tg which responded to lamivudine had a significant reduced level of serum HBsAg compared with the control group which responded to normal diet from wk 4 to wk 12 ($F_{4wk} = 5.47$, $P_{4wk} = 0.003 < 0.01$; $F_{8wk} = 11.59$, $P_{8wk} = 0.000 < 0.01$; $F_{12wk} = 88.81$, $P_{12wk} = 0.000 < 0.01$); the HBV-Tg which responded to the effective ingredient of Sp showed a significant reduced level of serum HBsAg compared with the control group which responded to normal diet from wk 8 to wk 12 ($F_{8wk} = 11.59$, $P_{8wk} = 0.001 < 0.01$; $F_{12wk} = 88.81$, $P_{12wk} = 0.000 < 0.01$). Although these treatment groups all exhibited a rebound phenomenon 4 wk after withdrawal of medication, they still exhibited a significant lower level of serum HBsAg compared with the control group which responded to normal diet ($F_{16wk} = 14.79$, $P_{lami} = 0.011 < 0.05$, $P_{sp} = 0.000 < 0.01$).

Anti-HBV DNA production

The anti-HBV DNA production is summarized in Table 2. The paired t -test showed that the HBV-Tg which responded to lamivudine therapy had reduced serum HBV DNA compared with the level of HBV DNA prior to therapy from wk 4 to wk 12 ($t_{4wk} = 5.76$, $P_{4wk} = 0.000 < 0.01$, $t_{8wk} = 4.23$, $P_{8wk} = 0.003 < 0.01$, $t_{12wk} = 4.00$, $P_{12wk} = 0.004 < 0.01$).

The HBV-Tg which responded to the effective ingredient of Sp showed a significant reduced level of serum HBV DNA from wk 8 to wk 12 ($t_{8wk} = 2.43$, $P_{8wk} = 0.041 < 0.05$; $t_{12wk} = 3.57$, $P_{12wk} = 0.007 < 0.01$). One-way ANOVA showed that the HBV-Tg which responded to lamivudine had a significant reduced level of serum HBV DNA compared with the control group which responded to normal diet from wk 8 to wk 12 ($F_{8wk} = 11.36$, $P_{8wk} = 0.000 < 0.01$; $F_{12wk} = 20.71$, $P_{12wk} = 0.000 < 0.01$). The HBV-Tg which responded to the effective ingredient of Sp showed a significant reduced level of serum HBV DNA compared with the control group which responded to normal diet from wk 8 to wk 12 ($F_{8wk} = 11.36$, $P_{8wk} = 0.001 < 0.01$; $F_{12wk} = 20.71$, $P_{12wk} = 0.000 < 0.01$). Both the two groups exhibited a rebound phenomenon 4 wk after withdrawal of medication.

Antiviral effect

HBV-Tg receiving lamivudine showed a fast cure rate compared with HBV-Tg receiving the effective ingredient of Sp. However, their long-term effects were similar (Figure 1). HBV-Tg receiving either the effective ingredient of Sp or lamivudine exhibited the same cure rate (33%) 12 wk after the start of therapy. Both groups showed a rebound phenomenon 4 wk after withdrawal of medication.

Changes of cytokine titers

Before treatment, there was no significant difference in the serum levels of IL-2 and IL-6, respectively, between the control group and the treatment group. After weeks of treatment, the paired t -test showed that the HBV-Tg which responded to the effective ingredient of Sp therapy increased serum IL-2 compared with the level of IL-2 prior to therapy from wk 4 to wk 8 ($t_{4wk} = -6.74$, $P_{4wk} = 0.000 < 0.01$; $t_{8wk} = -16.51$, $P_{8wk} = 0.000 < 0.01$); and the IL-2 serum

Table 3 Data are expressed as mean \pm SD

Treatment group	IL-2 (ng/L)			IL-6 (ng/L)		
	0 wk	4 wk	8 wk	0 wk	4 wk	8 wk
Group 1 normal diet recipients (<i>n</i> = 9)	2.13 \pm 0.23	2.33 \pm 0.26	2.48 \pm 0.17	63.59 \pm 1.82	65.40 \pm 10.3	60.84 \pm 4.21
Group 3 Sp recipients (<i>n</i> = 9)	2.41 \pm 0.38	7.91 \pm 1.09 ^{b,d}	10.56 \pm 0.78 ^{b,d}	63.62 \pm 6.31	61.80 \pm 4.58	54.52 \pm 6.22

Figure 1 Rate of responses following therapy. Thirty-three percent (3 of 9) of HBV-Tg receiving lamivudine became completely negative for HBV-DNA compared with 22% (2 of 9) of HBV-Tg receiving the effective ingredient of Sp 8 wk after the start of therapy. They had the same cure rate (33%, 3 of 9) 12 wk after the start of therapy. But the inhibitory effect could not last long. A rebound phenomenon could be found 4 wk after withdrawal of medication. HBV-Tg receiving normal diet did not show such therapeutic response.

Figure 2 Representative examples of haematoxylin and eosin (HE) staining of HBV-Tg liver (\times 400). The expression of infiltrating lymphocyte was strongly positive (white arrow) before drug administration. The structure of hepatic lobule was obscure and the swelling degree of liver cells was serious. Many vacuoles (black arrow) could be seen in (A). However, these findings were alleviated after 10 wk of therapy by Sp (B).

levels were higher in the Sp-treated group compared with those of the control group ($I_{4wk} = 6.58$, $P_{4wk} = 0.000 < 0.01$; $I_{8wk} = 13.23$, $P_{8wk} = 0.000 < 0.01$). Although a slight decline could be seen, there was no significant difference in the serum levels of IL-6 before and after treatment (Table 3).

Histological observation

HBV-Tg receiving the effective ingredient of Sp for 10 wk exhibited improvement in inflammation and HBsAg in

Figure 3 Representative examples of orcein staining of HBV-Tg liver (\times 400). HBsAg was seen as nigger-brown granules before drug administration (A) and after 10 wk of therapy by Sp (B). However, a decrease in the signals for HBsAg was seen in (B) compared with that in (A).

Table 4 Inflammatory degree and degeneration degree of hepatocytes in HBV-Tg liver after 10 wk of treatment (mean \pm SD, *n* = 5)

	0 wk	10 wk
Degeneration degree of hepatocytes	8.00 \pm 0.63	5.60 \pm 0.68 ^b
Inflammation degree of hepatocytes	5.20 \pm 0.37	4.00 \pm 0.32 ^a

^a*P* < 0.05, ^b*P* < 0.01 vs T0 in one group.

liver compared with HBV-Tg receiving normal diet (Figures 2 and 3). The semi-quantitative evaluation of inflammatory degree and hepatocytes degeneration degree in mouse liver proved the above findings (Table 4).

DISCUSSION

Ascidians are marine animals with a high ability to synthesize bioactive substances. The extracts of ascidians are most commonly used in antimicrobial assays and anticancer treatments^[18-20]. Bioactivity-guided ingredientation of an ethyl acetate extract of the marine ascidian, *Pseudodistoma* sp., collected in the Tsitsikamma Marine Reserve, revealed that the antimicrobial properties in this extract resided in a group of acyclic amino alcohols, isolated as their peracetylated derivatives^[18]. The extract of *Eudistoma vancouveri* Millar, obtained from the northeastern Brazilian coast showed a high toxicity in tumor cell lines tested^[20].

Sp is a dominant component of the marine benthos

of South China Sea. In recent years, we carried out basic research on the marine organism. The alcohol extracts of the animal have a definite inhibition effect on HBsAg and HBeAg *in vitro*, although the exact mechanism is not known^[11,21,22].

This study suggested that the effective ingredient of Sp might have potential therapeutic value for chronic hepatitis B infection. Thirty-three of the HBV-Tg receiving Sp responded to the therapy and became completely negative for HBV-DNA 12 wk after the start of therapy (Figure 1). The level of serum HBsAg titers was also reduced, though not significantly. But like most present antiviral drugs, the effective ingredient of Sp could not inhibit the replication of HBV completely. Relapse after cessation of the alcohol extract of Sp could be observed, similar to that of lamivudine (Table 1 and Table 2).

In our experiment, we found that the gait and status of psychosis between the effective ingredient of Sp-treated HBV-Tg and the normal diet-treated ones were similar. Histological analysis of mouse liver revealed that the alcohol extract of Sp could ameliorate the inflammation in liver, alleviate hepatocytes degeneration and eliminate HBsAg (Figures 2 and 3, Table 4). Besides, the histological observation showed that there was no distinct toxicity in tissue. However, we did not have further virological/molecular study of HBV markers in the liver. To find more molecular/pharmacological mechanisms of the effect of Sp, we need to measure the HBV DNA and cccDNA levels, as well as HBsAg and HBeAg expression in liver in the following experiments.

Then, we investigated the effects of the effective ingredient of Sp on the serum levels of Th1/Th2 cytokines. It is well known that the identification of functionally distinct CD4⁺ T helper subpopulations, producing distinct patterns of cytokines, has provided an important insight into the mechanisms by which polarized immune response occurs *in vivo* in response to pathogens^[23]. T helper 1 cytokines, including IFN- γ , IL-2 and TNF- β are involved principally in cell-mediated immunity and play a crucial role in the protection from intracellular pathogens, including a number of viruses, while Th2-derived cytokines (IL-4, IL-5, IL-6 and IL-10) stimulate antibody production and promote mast cell and eosinophil proliferation^[24,25]. The cytokine pattern secreted by T cells on viral antigen recognition is believed to exert a profound influence on both the type of disease caused by the infecting agent and the final outcome of the viral infection. In recent years, researchers have found that the prevalent Th1 pattern of secreted cytokines can be regarded not only as a mechanism contributing to inflammation and local tissue damage, but also as an appropriate response of the immune system to create conditions that hamper viral replication and eventually lead to HBV eradication^[26]. Our experiment results showed that the effective ingredient of Sp could selectively increase the serum level of IL-2 (which is helpful for normal biologic immunity) and prevent the further increase of serum IL-6 (which can promote hepatocytes degeneration) in HBV-Tg (Table 3). These are important clues to therapeutic mechanism of Sp on chronic hepatitis B.

Then, what is the therapeutic mechanism of Sp? It is

still undefined. We suppose the explanations as follows: First, there are many chemical compositions such as peptide, alkaloids, saponin, macrolide, terpenoid in Sp. Coordinated action of them may be the main mechanism. Second, Sp is abundant in polypeptide and polysaccharide. Some compositions of them can stimulate cellular immunity, induce the differentiation of T lymphocyte and the generation of endogenous interferon, kill target cells and inhibit the replication of HBV. Third, mineral substances and vitamins in Sp also play main roles. Mineral substances are important in liver enzyme metabolism. Vitamins participate in multifold metabolism of liver. They can induce the generation of hepatocytes and enhance the detoxification function of liver.

In conclusion, the effective ingredient of *Styela plicata* has a definite effect on chronic hepatitis B. Our data provide valuable information for understanding the therapeutic role and the potential therapeutic mechanism of *Styela plicata* as an effective antiviral medicine in treating chronic hepatitis B.

Abstract

AIM: To detect multiple *H pylori* antibodies in serum samples of individuals who carry *H pylori* by protein array.

METHODS: Recombinant *H pylori* antigens, urease B subunit (UreB), vacuolating toxin A (VacA) and cytotoxin associated gene A protein (CagA), were prepared and immobilized in matrixes on nitrocellulose membrane by robotics to bind the specific immunoglobulin G (IgG) antibodies in serum. Staphylococcus protein A (SPA) labeled by colloid gold was used to integrate the immuno-complex and gave red color signal. The scanner based on charge-coupled device (CCD) could collect the image signal and convert it into digital signal.

RESULTS: When human IgG was printed on the membrane in increasing concentrations and incubated with immunogold, a linear dose response curve was obtained and the detection limit for IgG was about 0.025 ng. The cutoff values, which were defined as the mean grey level plus 3 times of standard deviation, were 27.183, 28.546 and 27.402, for anti-UreB IgG, anti-CagA IgG and anti-VacA IgG, respectively, as 400 human serum samples with negative *H pylori* antibodies were detected by the protein array. When 180 serum samples from patients in hospital were employed for detection of IgG against UreB, CagA and VacA, the sensitivity of the protein array was 93.4%, 95.4%, 96.0%, and the specificity was 94.8%, 94.4% and 97.5%, respectively, as compared with the results obtained by ELISA. The assay also showed high reproducibility, uniformity and stability, and the results were available within 30 min.

CONCLUSION: The protein array is a very practical method for rapid detection of multiple antibodies in

INTRODUCTION

H pylori chronically infect more than half of the world population and are associated with chronic gastritis, peptic ulcer and even gastric cancer^[1-7]. Several virulence factors of *H pylori*, such as urease, vacuolating toxin A (VacA) and cytotoxin associated gene A protein (CagA) have been characterized^[8-11]. Urease is produced by all *H pylori* and functions to hydrolyze urea into CO₂ and NH₃ which can buffer the acid environment and permit the bacterium survival in stomach. All *H pylori* strains carry *vacA* gene and only 50% of them express VacA protein, which assembles into a flower-shaped oligomer, alters intracellular vesicular trafficking and induces vacuole formation in eukaryotic cells. The most important feature that distinguishes *H pylori* strains is the presence or absence of the *cag* pathogenicity island (*cag* PAI). It contains about 30 genes and codes for a type IV secretion machinery system (TFSS), through which CagA is introduced into host cell^[12,13]. Phosphorylated CagA in cytoplasm dephosphorylates host cell protein (cortactin), altering cytoskeletal structure and forming a hummingbird phenotype^[14,15]. CagA is implicated in host cell signal transduction system^[16,17], and CagA positive *H pylori* are much more closely related with peptic ulcer and gastric cancer in western country^[4,6]. When *H pylori* infect human being, multiple antibodies are generated against various antigenic compounds and an antibody library may form in serum. Therefore, screening the antibodies against these virulence factors in serum of *H pylori* infected individual is useful for detection and classification of the pathogen.

Serological assays for diagnosis of *H pylori* infection are included among the noninvasive methods recommended

by the European *H. pylori* study group^[18,19]. At present, the common method to detect *H. pylori* antibodies in serum is enzyme-linked immunosorbent assay (ELISA). The procedure is time-consuming especially when multiple antibodies are detected at the same time. Although there are reports regarding the detection of multiple proteins in an antibody-based protein microarray system^[20-21], the labor-intensive procedures and the expensive instrumentations have limited its application^[22]. Based on the previous work, we developed a low-cost protein array system for rapid detection of multiple *H. pylori* antibodies in serum samples.

MATERIALS AND METHODS

Preparation of antigens

Recombinant urease B subunit (UreB, 40 Ka), N-terminal fragment (amino acid: 1-284, 38 Ka) of CagA and middle region fragment (amino acid: 579-907, 30 Ka) of VacA were produced in our institute previously^[23]. The purity of these proteins was 95%, 96% and 96%, respectively, as identified by coomassie stained gel and evaluated by dual-wave length flying-spot scanner CS-9000 (Shimadzu). The antigenicity was defined as the dilution titer of the antigen to give 1.0 OD in ELISA when the standard positive serum samples (Xinkang Company, Shenzhen) were used. If the original concentration was 1 mg/mL, the dilution titer of UreB, CagA, and VacA was 1:800, 1:1000, and 1:600, respectively.

Preparation of protein array

Nitrocellulose membrane (Pharmacia) with a pore diameter of 0.45 μm was immersed in 0.05 mol/L carbonate buffer (pH 9.0) and dried at room temperature. The antigens (0.1%) in 0.01 mol/L phosphate-buffered saline (PBS, pH 7.0) were transferred from the micro-well plate to the membrane by use of the stainless steel solid pin (0.7 mm in diameter) and dotted on the nitrocellulose membrane by using computer-controlled high speed robotics, MicroGrid II (BioRobotics). The printing was performed in a cabinet at 4°C, with 60% humidity. Each pin was estimated to transfer 10 nL of the solution. The protein array consisted of 4 matrixes, in three of which the antigens were printed in 9 replicates. Another one was the control matrix printed of rabbit myosin (R.M, Sigma) and human IgG (H. IgG, Sigma) (Figure 1A). The membrane was blocked by 5% bovine serum albumin (BSA, Sigma) at 4°C for 2 h and then washed twice by weakly shaking in the wash buffer for 10 min. After drying at room temperature, the membrane was cut into small pieces (1.2 cm \times 1.2 cm) according to the positions properly marked and assembled into the *H. pylori* protein array apparatus. The longitudinal section of the protein array apparatus was illustrated in Figure 2.

Preparation of immunogold

Colloid gold was made according to the sodium citrate reduction method^[23]. In brief, 200 mL of 0.01% chloroauric acid (analytical grade) was heated to the boiling point and 8 mL of the 1% sodium citrate (analytical grade) was then added under vigorously stirring condition. When the solution became dark red in color, the boiling was

Figure 1 A: Schematic map of protein distribution on the protein array. Four squares were involved and different proteins were printed in different areas: UreB in upper left area; VacA in upper right area; CagA in left bottom area; R.M (10 ng) in the upper row of right bottom area for negative control (Ctrl), H. IgG in the middle row for positive control and at the bottom row for strong positive control; B: positive results of anti-UreB IgG, anti-CagA IgG and anti-VacA IgG detected by the protein array.

Figure 2 Longitudinal section of the protein array apparatus. The shell of the apparatus was made of plastic materials. A window was opened on the top of the outer shell and the margin of the nitrocellulose membrane printed with antigens was sealed to the inner surface of the window. Under the nitrocellulose membrane was the macromolecular bilubous material.

lasted further for 5 min. The colloid gold should have the highest light absorbance at 525 nm. The shape and size were observed and the diameter (15 nm) was measured under transmission electron microscope. One hundred microlitres of colloidal gold was taken and the pH value was adjusted to 6.2 by 0.1 mol/L potassium carbonate. Staphylococcus protein A (SPA) was added to the final concentration of 1.5 mg% under stirring condition. Ten minutes later, 10 mL of 5% BSA was added and the colloidal gold was stirred for 5 min, making sure that there was no bubble. The immunogold was centrifuged at 4000 g, 4°C for 5 min. The supernatant was then loaded to the Sephacryl S-400 column (Pharmacia) and eluted with 0.02 mol/L tris-buffered saline (pH 7.4). The main red portion was collected and centrifuged at 12 000 g, 4°C for 10 min. The pellets were then suspended in 100 mL solution (0.01 mol/L PBS, 1% BSA) and stored at -20°C for further use.

Procedures to detect antibodies in serum samples

The procedures are as follows: Firstly, 4 drops of the washing solution were added to the center of the nitrocellulose membrane to immerse it evenly. Secondly, 100 μL of the five times diluted serum was added onto the membrane, and 6 drops of the washing solution were dripped onto it to wash the residual serum 5 min later. Thirdly, 100 μL of the immunogold was added onto the membrane, and again, 6 drops of the washing solution were dripped onto it 5 min later. Finally, the protein array was placed into the scanner, which adopts charge-coupled device (CCD) camera to collect the grey level of the central part (0.5 mm in diameter) of every spot and converts the image signal into digital signal. The results

Figure 3 The mean grey level of the spot against various amount of H.IgG immobilized on the protein array. The concentrations of human IgG spotted from lane 1 to lane 6 are as follows: 1.25, 2.5, 5, 10, 20, 40 μ g/mL. The optimized amount of SPA binding to colloid gold was 12 μ g/mL. The data in the plot were obtained from the image of CCD by averaging the mean grey levels of the 6 replicate spots.

were given according to the positions of the matrixes and the mean grey levels of the spots in the matrixes.

Detection of the antibodies in serum samples

Eight hundred and sixty-five serum samples were collected from blood centers in Xi'an and Shenzhen. *H. pylori* antibodies (anti-UreB IgG, anti-CagA IgG and anti-VacA IgG) negative serum samples were screened by using the ELISA kits (kit to detect IgG against *H. pylori* CagA, Jingying Company, Shanghai; kits to detect IgG against *H. pylori* CagA and VacA, Xingkang Company, Shenzhen). The cutoff values of anti-UreB IgG, anti-CagA IgG and anti-VacA IgG were then determined. One hundred and eighty serum samples, collected from patients with different background in Xi'an Center Hospital, were employed to evaluate the sensitivity and specificity of the protein array in detection of *H. pylori* antibodies. Rapid urease test (RUT) and ELISA were also used to detect the infection of *H. pylori*.

Statistical analysis

All experiments were performed in replicate. χ^2 and Student's *t* test were used for statistic analysis.

RESULTS

Limit of detection

Human IgG was printed in 6 replicates in increasing concentrations and incubated with 100 μ L of immunogold on nitrocellulose membrane. A linear dose response curve was obtained (Figure 3) and the detection limit for IgG was about 0.025 ng bound on membrane in this system.

Amount of antigen immobilized

Each antigen with different concentrations ranging from 0.1 to 2.0 ng/nL was printed on the membrane to make the protein array. Five serum samples with *H. pylori* antibody titer of 1:32 in ELISA were used as references to detect the relevant antibody by protein array. The least amount

Table 1 Cutoff values determined in *H. pylori* antibody negative sera

Items	Number	Mean grey values	SD	Cutoff values
Anti-UreB IgG	400	18.060	3.041	27.183
Anti-CagA IgG	400	17.992	3.518	28.546
Anti-VacA IgG	400	17.730	3.224	27.402

of antigen that defined all the samples as positive was designated as the optimized one. In this way, the amount of antigen chosen to immobilize on membrane was 12, 10, and 16 ng for UreB, CagA and VacA, respectively.

Determination of the cutoff values

The cutoff values, which were defined as the mean grey level plus 3 SD, were 27.183, 28.546 and 27.402, for anti-UreB IgG, anti-CagA IgG and anti-VacA IgG, respectively, as 400 serum samples with negative *H. pylori* antibodies were detected by the protein array (Table 1).

Uniformity and reproducibility

When a protein array was randomly chosen from the same batch and subjected to detection of the antibodies in a serum sample, the coefficient variation (CV) of the grey values of the 9 spots in every matrix was less than 8%. When 10 protein arrays were randomly chosen to detect the antibodies in a serum sample, the mean grey value of every matrix in every protein array was obtained and the CV of the mean grey values from the ten relevant matrixes was less than 10%. Ten quality control serum samples, 5 positive and 5 negative for the three antibodies detected by ELISA, were used to screen the antibody profiles by protein array. The results were the same when the test was repeated 5 times.

Sensitivity and specificity

For the 180 serum samples collected from clinical patients, the antibodies were screened by both ELISA and protein array. The results showed that, of these samples, 117, 108 and 99 were positive for anti-UreB IgG, anti-CagA IgG and anti-VacA IgG respectively by protein array (positive results of the three antibodies are shown in Figure 1B), and 122, 109 and 101 were positive respectively by ELISA. The sensitivity of protein array in detection of anti-UreB IgG, anti-CagA IgG and anti-VacA IgG was 93.4%, 95.4%, and 96.0%, and the specificity was 94.8%, 94.4% and 97.5% respectively, compared with the results detected by ELISA (Table 2).

Relation of *H. pylori* antibody profiles to diseases

The positive rates of anti-UreB IgG in groups of gastric cancer (GC, 26/32) and peptic ulcer (PUD, 39/45) were significantly higher than that in group of non-ulcer dyspepsia (NUD, 52/103) ($P < 0.005$). There was no significant difference in the positive rates of anti-CagA IgG or anti-VacA IgG between different patient groups (Table 3).

Table 2 Results detected by ELISA and protein array

Protein array	ELISA					
	Anti-UreB IgG		Anti-CagA IgG		Anti-VacA IgG	
	P	N	P	N	P	N
P	114	3	104	4	97	2
N	8	55	5	67	4	77

P : positive; N: negative.

DISCUSSION

Biochip technique is an advanced tool that enables the binding of multiple molecules in a small area at one time^[24,25]. The molecules (protein, nucleic acid or amino acid) can be immobilized on a piece of support substance such as glass, silica, plastic, nitrocellulose and even metal. The fixation of the molecules to the support substance is by means of non-specific absorption, affinity absorption or covalent attachment, depending on the purpose to design the biochip. Methods based on protein array by non-specific absorption are successfully used for serodiagnosis of infectious diseases in some laboratories^[26-28]. The protein array in the current investigation was designed in accordance with the recent trends including mini-turization of assays and the simultaneous measurement of a panel of antibodies in a single assay.

Actually, this protein array is an immunoassay based on dot immunogold filtration assay. Nitrocellulose membrane was chosen as the chip and the recombinant antigens were immobilized on it by non-specific adsorption. The membrane can bind more amount of protein compared with the glass surface, as each pore of the membrane can be considered as a column and the antibodies can be accumulated when they pass through the membrane. Moreover, the proteins in the membrane are in three-dimensional structure and the binding of antigen and antibody is highly efficient^[29]. Colloid gold was used to label SPA as it was red in color and did not need any substance to produce signal for detection. The reader, which was CCD based video collection system to convert image signal into digital signal, made the results more objective. The entire system offers the simultaneous determination of several antibodies in one test with low cost and faster kinetic. It takes less than 30 min to finish the whole procedures. The stability was quite good and the specificity and sensitivity were close to those of ELISA when *H pylori* antibody profiles of 180 serum samples were detected. Therefore, it is the most practical means of obtaining accurate and precise results. All these make the method a promising future for application, especially for large scales investigation of *H pylori* infection.

In western countries, about 50% to 60% *H pylori* isolates are cagA positive, and the rates are much higher in Asia-Pacific areas^[30-32]. In this study, the positive rates of anti-UreB IgG in groups of GC and PUD were significantly higher than that in group of NUD, indicating that *H pylori* infection was more closely related with GC and PUD, whereas the role of anti-CagA IgG or anti-VacA IgG in prediction of specific diseases was limited.

Table 3 Relation of diseases to *H pylori* antibody (IgG) profiles

Diseases	Numbers				
	Total	RUT	Anti-UreB	Anti-CagA	Anti-VacA
GC	32	30	26 ^a	25	22
PUD	45	43	39 ^c	37	36
NUD	103	58	52	46	41

^aP < 0.005 vs NUD; ^cP < 0.005 vs NUD.

In the pathogenesis study of the *H pylori*, we know very well that the living conditions of this bacterium *in vivo* and *in vitro* are quite different. Some proteins contributing to virulence of the bacterium may not be expressed under *in vitro* culture conditions, and their expression may depend on certain *in vivo* stimuli, such as, cell to cell contact^[33]. So antibody profile may be a reliable indication to reflect the host immune response to the bacterium. Since two genomes of this bacterium have already been sequenced, functional study of these genes is becoming the most important target and many studies have been carried out in the disease related gene screening and identification^[34-37]. With more *H pylori* pathogenic genes being known, more proteins may be added onto the protein array. Obviously, to optimize the binding condition of antigen and antibody and to select one that is suitable for a panel of reactions are the key to success. By accumulating more data about the clinical background of the patients and the antibody profiles in sera, we can draw a clear picture of the relationship between the two aspects.

In summary, detection of multiple *H pylori* antibodies in serum by protein array has the prospect in clinical application, especially in developing countries or small hospitals. Further studies are still going on to increase the density of the protein array.

Abstract

AIM: To investigate the perioperative changes of nitric oxide (NO) and endothelin (ET), thromboxane A₂ (TXA₂) and prostaglandin (PGI₂) during liver transplantation in end-stage liver disease patients.

METHODS: Twenty-seven patients with end-stage cirrhosis undergoing liver transplantation were enrolled in this prospective study. Blood samples were obtained from superior vena at five different surgical stages. Plasma concentrations of nitrate and nitrite were determined to reflect plasma NO levels. Plasma levels of ET-1, 6-keto-PGF₁ alpha and thromboxane B₂ (TXB₂), the latter two being stable metabolites of PGI₂ and TXA₂ respectively, were measured.

RESULTS: The NO level decreased significantly after vascular cross-clamping and increased significantly at 30 min after reperfusion. While the ET levels at 30 min after clamping and after reperfusion were significantly elevated. The ratio of NO/ET decreased significantly at 30 min after vascular cross-clamping and at the end of surgery. The PGI₂ level and the TXA₂ during liver transplantation were significantly higher than the baseline level, but the ratio of TXA₂/PGI₂ decreased significantly at 30 min after clamping.

CONCLUSION: NO/ET and TXA₂/PGI₂ change during liver transplantation. Although the precise mechanism remains unknown, they may play a role in the pathobiology of a variety of liver transplant-relevant processes.

INTRODUCTION

Liver transplantation is becoming a more and more common treatment method of end-stage liver disease. The hemodynamic alterations occurring after graft reperfusion and the subsequent complications may result from the changes of some biotic activators^[1]. Nitric oxide (NO) and endothelin (ET), thromboxane A₂ (TXA₂) and prostaglandin (PGI₂) are two groups of important vasoactive substance. The clinical and animal experiment documented that the two groups of substance are involved in a variety of liver transplant-relevant processes, including ischemia-reperfusion injury, acute cellular rejection, and circulatory changes characteristic of advanced liver disease^[2]. However, there is considerable controversy in the perioperative plasma concentrations of the two groups of substance and the precise mechanism of these changes is not fully known.

This study monitored blood levels of NO and ET, TXA₂ and PGI₂ at different time points perioperatively in cirrhotic patients undergoing liver transplantation.

MATERIALS AND METHODS

Patients

During a 10-mo period, all patients with end-stage cirrhosis undergoing liver transplantation were enrolled in this prospective study. With the approval of the institutional ethics committee from Sun Yet-Sen University, informed consent was obtained from patient before each assessment. We excluded patients receiving liver transplantation more than one time and patients losing blood more than 3500 mL during operation.

Anesthesia was induced with midazolam (0.05-0.1 mg/kg), propofol (1-2 mg/kg) and fentanyl (5 µg/kg) intravenously (IV) and neuromuscular blockade was accomplished with nocurium (0.1 mg/kg). Mechanical ventilation was performed with O₂, using a tidal volume necessary to maintain ET/CO₂ tension between 4-4.66 kPa (30-35 mmHg). Anesthesia was maintained with both isoflurane at a concentration of 1.0%-3.5% (inhalation) and intermittent fentanyl (50-100 µg, IV). After induction of anesthesia, a continuous dopamine infusion (2-6 µg/kg per min) was administered. Blood samples were obtained from the superior vena cava at five different surgical stages: induction of anesthesia (T1), 60 min after beginning of operation (T2), 30 min after vascular cross-clamping (T3), 30 min postreperfusion of new liver (T4) and at the end of surgery (T5). Plasma concentrations of nitrate and nitrite, two metabolites of NO, were determined to reflect plasma NO levels. Plasma ET-1 levels were measured by radioimmunoassay (RIA) and systemic 6-keto-PGF₁α and TXB₂, stable metabolites of PGI₂ and TXA₂ respectively, were measured by RIA also.

Detection of NO

Two milliliters of superior vena cava blood were collected and placed in ice-cooled polypropylene tubes. These samples were immediately centrifuged at 3000 r/min for 10 min and stored at -40°C for late assay. Test kits (Science and Technology Development Center of The General Hospital of PLA, Beijing, China) for NO analysis were used. The optical density value was read in a spectrophotometer set at 546 nm. The NO numeric value was calculated based on a standard and empty tube according to the equation. The calculated results were expressed as µmol/L.

Detection of ET

Two milliliters of superior vena cava blood were collected and placed in ice-cooled polypropylene tubes containing 40 µL aprotinin and 30 µL EDTA. These samples were immediately centrifuged at 3000 r/min for 10 min. Collected plasma was stored at -40°C until batched assays were performed. Plasma ET levels were evaluated with ET detection kit (Science and Technology Development Center of The General Hospital of PLA, Beijing, China) according to the manufacturer's instructions.

Detection of TXA₂ and PGI₂

Three milliliters of superior vena cava blood were collected with a five-milliliter syringe containing 200 µL EDTA·2Na, mixed fully and injected into a tube. These tubes were immediately centrifuged at 3500 r/min for 15 min. Collected plasma was stored at -40°C until use. Detection of the level of TXA₂ and PGI₂ was performed according to the manufacturer's instructions (Science and Technology Development Center of The General Hospital of PLA, Beijing, China).

Statistical analysis

Data are shown as mean ± SD. Data of the various time points were compared using ANOVA analysis (SPSS statistical package, version 11.0). Significant difference was accepted at $P < 0.05$.

Table 1 Changes of NO₂/NO₃ and ET levels in plasma during liver transplantation (mean ± SD, $n = 27$)

	NO ₂ /NO ₃ (µmol/L)	ET (ng/L)	NO/ET
T1	27.45 ± 5.70	61.21 ± 25.38	0.54 ± 0.25
T2	35.19 ± 7.72 ^a	74.84 ± 29.22	0.49 ± 0.25
T3	25.64 ± 5.64 ^c	110.61 ± 24.65 ^{a,c}	0.24 ± 0.07 ^{a,c}
T4	35.30 ± 11.23 ^{a,e}	114.00 ± 26.73 ^{a,c}	0.32 ± 0.13 ^a
T5	33.86 ± 8.94 ^c	116.92 ± 27.08 ^{a,c}	0.28 ± 0.07 ^{a,c}

^a $P < 0.05$ vs T1; ^c $P < 0.05$ vs T2; ^e $P < 0.05$ vs T3. T1: induction of anesthesia; T2: 60 min after operation beginning; T3: 30 min after vascular cross-clamping; T4: 30 min postreperfusion of new liver; T5: the end of operation.

Table 2 Changes of TXB₂ and 6-keto-PGF₁α levels in plasma during liver transplantation (mean ± SD, $n = 27$)

	6-keto-PGF ₁ α (ng/L)	TXB ₂ (ng/L)	TXB ₂ /6-keto-PGF ₁ α
T1	152.94 ± 68.67	118.27 ± 63.99	0.89 ± 0.37
T2	932.71 ± 25.66 ^a	297.45 ± 127.13 ^a	0.48 ± 0.25
T3	895.83 ± 300.71 ^a	265.15 ± 127.34 ^a	0.33 ± 0.14 ^a

T5	591.12 ± 336.57 ^{a,c,e}	208.32 ± 90.98 ^{a,c,e}	0.43 ± 0.20

^a $P < 0.05$ vs T1; ^c $P < 0.05$ vs T2; ^e $P < 0.05$ vs T3. T1: induction of anesthesia; T2: 60 min after operation beginning; T3: 30 min after vascular cross-clamping; T4: 30 min postreperfusion of new liver; T5: the end of operation.

RESULTS

A total of 27 patients (81% men, age 49 ± 11 year, BSA 1.72 ± 0.15) were enrolled in this study. Among these patients, 15 had hepatitis B virus associated cirrhosis, 12 had cirrhosis and liver cancer.

The changes of nitrate, nitrite and ET levels in plasma during liver transplantation are shown in Table 1. The mean baseline value of NO (reflected by nitrate and nitrite) was 27.45 ± 5.70 µmol/L. The NO level decreased significantly after vascular cross-clamping, from 35.19 ± 7.72 µmol/L to 25.64 ± 5.64 µmol/L ($P < 0.05$). At 30 min after reperfusion, a significant elevation of NO was found, from 25.64 ± 5.64 µmol/L to 35.30 ± 11.23 µmol/L ($P < 0.05$).

The baseline ET concentration was 61.21 ± 25.38 ng/L. Compared with the baseline level, the ET levels at 30 min after clamping and after reperfusion were significantly elevated (110.61 ± 24.65 ng/L, 114.00 ± 26.73 ng/L respectively).

The changes of TXB₂ and 6-keto-PGF₁α levels in plasma during liver transplantation are shown in Table 2. The prostaglandin level and the TXA₂ level presented the same changes. The concentrations at every time point were significantly higher than the baseline level. Peak levels of prostaglandin were 932.71 ± 25.66 ng/L and 895.83 ± 300.71 ng/L, detected at 60 min after operation and 30 min after vascular cross-clamping respectively.

The mean baseline value of NO/ET was 0.54 ± 0.25. The ratio decreased significantly at 30 min after vascular cross-clamping and at the end of surgery. The mean

baseline value of TXA₂/PGI₂ was 0.89 ± 0.37 , the ratio decreased significantly at 30 min after clamping. Compared with the value at 30 min after clamping, the ratio increased significantly at 30 min after reperfusion, from 0.33 ± 0.14 to 0.49 ± 0.21 .

DISCUSSION

In this study we measured systemic NO and ET, TXA₂ and PGI₂ at five different surgical stages: basal, hepatectomy, anhepatic, 30 min after graft reperfusion and the end of surgery. Overall results showed that the levels of these two groups of vasoactive substances changed at each stage during liver transplantation. Previous studies have demonstrated that NO and ET, TXA₂ and PGI₂ play an important role in the pathobiology of ischemia-reperfusion injury and postreperfusion syndrome^[3,4]. It suggests that disturbed balance between these vasodilators and vasoconstrictors may contribute to some liver transplantation-relevant syndromes.

NO and ET are the most important local vasodilator and vasoconstrictor respectively. They seem to play a role in almost every organ and tissue. However, there is considerable confusion in understanding their roles. Some researches suggest that the important factors in determining the beneficial versus harmful effects of NO are the amount, duration, and site of NO production^[5]. Ovadia *et al* demonstrated that the fetal pulmonary vasoconstriction after acute constriction of the ductus arteriosus is mediated by NO/ET-1 interactions^[6]. Shirakami *et al* reported that the plasma ET level was increased before transplantation compared with that of healthy children, but decreased during the anhepatic phase^[7]. It increased again after reperfusion and remained at high level in the early postoperative period. These suggest that ET production in the cirrhotic liver is augmented and ET plays some role in circulatory regulation during the perioperative period of pediatric liver transplantation. In the present study, although both NO and ET increased after graft reperfusion, the ratio of them was decreased. It suggested that the imbalance of NO and ET level may participate in the pathophysiology of systemic and local circulation disorders.

Many data about the relationship between another group of vasoactive substances, PGI₂/TXA₂ and hemodynamics have been reported^[8,9]. TXA₂ is both a vasoconstrictor and a potent stimulus for platelet aggregation. Its effect is antagonized by prostacyclin, which is released by vascular endothelial cells. Prostacyclin exerts a variety of effects on the cardiovascular system, including a decrease in blood pressure associated with a decrease in systemic vascular resistance. In clinical liver transplantation, Khoury *et al*^[10] demonstrated 60% of patients undergoing orthotopic liver transplantation accumulated prostacyclin in the portal vein, which could be one of the causes of hypotension seen at reperfusion of the donor liver. As previously demonstrated, we found that the baseline levels of PGI₂ and TXA₂ in our patients

were higher than normal values. It was most likely due to the decreased metabolism of them in patients with end-stage liver disease. In addition, we found PGI₂ and TXA₂ had the same changes during liver transplantation. The levels of PGI₂ and TXA₂ after reperfusion were elevated compared with the baseline level. However, the ratio of TXA₂ and PGI₂ was significantly lower than that of pre-reperfusion. This indicated that the disorder of TXA₂ and PGI₂ might also be involved in the circulation disorders during orthotopic liver transplantation.

In summary, two groups of endogenous vasoactive substance, NO/ET and TXA₂/PGI₂, are changed during liver transplantation. Although the precise mechanism remains unknown, they may play a role in the pathobiology of a variety of liver transplant-relevant processes.

ACKNOWLEDGMENTS

We thank Professor Bing-Xue Chen for his good advice and Xiu-Qin Liu for his assistance with the study.

Abstract

AIM: To explore the antioxidant and free radical scavenger properties of mistletoe alkali (MA).

METHODS: The antioxidant effect of mistletoe alkali on the oxidative stress induced by carbon tetrachloride (CCl₄) in rats was investigated. The rats were divided into four groups ($n = 8$): CCl₄-treated group (1 mL/kg body weight), MA -treated group (90 mg/kg), CCl₄+MA-treated group and normal control group. After 4 wk of treatment, the level of malondialdehyde (MDA), a lipid peroxidation product (LPO) was measured in serum and homogenates of liver and kidney. Also, the level of glutathione (GSH), and activities of glutathione reductase (GR), glutathione peroxidase (GSPx), superoxide dismutase (SOD), and glutathione-S-transferase (GST) in liver and kidney were determined. Scavenging effects on hydroxyl free radicals produced *in vitro* by Fenton reaction were studied by ESR methods using 5,5-dimethyl-1-pyrroline-N-oxide (DMPO) as a spin trap reagent and H₂O₂/UV as the OH[•] source. Urinary 8-hydroxydeoxyguanosine (8-OHdG) was determined by competitive ELISA.

RESULTS: In CCl₄-treated group, the level of LPO in serum of liver and kidney was significantly increased compared to controls. The levels of GSH and enzyme activities of SOD, GSPx and GR in liver and kidney were significantly decreased in comparison with controls. In CCl₄+MA-treated group, the changes in the levels of LPO in serum of liver and kidney were not statistically significant compared to controls. The levels of SOD, GSPx and GR in liver and kidney were significantly increased in comparison with controls. There was a significant difference in urinary excretion of 8-OHdG between the CCl₄-treated and MA-treated groups.

CONCLUSION: Oxidative stress may be a major mechanism for the toxicity of CCl₄. MA has a protective

INTRODUCTION

Recently, great attention has been focused on the role of the antioxidative defense system in oxidative stress. Endogenous antioxidants in medicinal herbs may play an important role in antioxidative defense against oxidative damage, possibly protecting the biological functions of cells^[1]. There is increasing interest in the protective biological function of natural antioxidants contained in Chinese medicinal herbs, which are candidates for the prevention of oxidative damage^[2,3].

Viscum coloratum (Komar.) Nakai has long been categorized as a traditional Chinese medicine in China, USA and other countries. A number of lipid-soluble antioxidants have been isolated from *Viscum coloratum* (Komar.) Nakai, such as mistletoe alkali, thionins, glucoprotein, polysaccharose^[4,5]. In the present study, we investigated the antioxidant activities of mistletoe alkali using a rat model of carbon tetrachloride (CCl₄)-induced hepatotoxicity and nephrotoxic nephritis, which could assess *in vivo* antioxidant activities of Chinese medicinal herbs.

Lipid peroxidation is one of the reactions induced by oxidative stress and is especially active in tissues rich in polyunsaturated fatty acid. There have been few comparative studies on the antioxidant ability of traditional Chinese medicine to modify the susceptibility of organs or tissues to oxidative stress and to alter the cellular antioxidant defense system^[6,7]. We have recently found that some compositions of *Viscum coloratum* (Komar.) Nakai can act effectively *in vitro* as antioxidants and peroxyl radical scavengers. Mistletoe alkali is one of these antioxidant compositions.

As the liver is the main target organ of CCl₄, and the

kidney is the main site of CCl₄ accumulation, the present study was to investigate the oxidative status of both organs in rats simultaneously exposed to CCl₄. To determine the ability of mistletoe alkali to act as antioxidants *in vivo*, we fed rats with mistletoe alkali (90 mg/kg per day) and examined the metabolism of this compound as well as its effects on oxidative stress *in vitro*.

MATERIALS AND METHODS

Mistletoe alkali preparation

Viscum coloratum (Komar.) Nakai was immersed into the acidity aqueous solution and smashed to particles, and then the alkaloid was taken out by precipitation with alkaline. In brief, *Viscum coloratum* (Komar.) Nakai was smashed to particles and soaked in the acidity aqua for 48 h, the liquid was added to the alkali to precipitate and remove infusible part and the alkali was added again to precipitate its total alkali. The acidity aqua of *Viscum coloratum* (Komar.) Nakai was proceeded to precipitate the different alkalinity with the aqua.

CCl₄-induced hepatotoxicity and nephrotoxic nephritis

Female Sprague Dawley rats (200-250 g) were maintained in a 12-h light/dark cycle at 22°C with free access to food and water. Vitamin E was used as positive control. In each experiment, the animals were randomly assigned into groups (*n* = 8). In the pretreatment groups, the animals were treated intragastrically with the drug preparation at a desired daily dose for 6 d. Mistletoe alkali and vitamin E were dissolved or suspended in olive oil. Twenty-four hours after the last dosing, the animals were administered intragastrically with CCl₄ (11% (v/v) in olive oil at a dose of 1 mL/kg. Control animals were given the appropriate vehicle, and all treatments were conducted between 900 and 1000 h to minimize variations in animal response due to circadian rhythm. The animals were killed 24 h after CCl₄ treatment. After 2 wk of mistletoe alkali treatment, the rats were starved for 12 h and killed by anesthetization with diethyl ether. Blood was taken from the abdominal aorta and plasma was separated. The kidneys, liver, stomach, large and small intestines were removed and washed with cold PBS. Plasma and tissue homogenates were stored at -80°C. Protein concentrations were determined with bicinchonic acid (BCA) protein assay kit (Pierce, Rockford, IL) with bovine serum albumin as the standard.

Chemicals

Vitamin E, 5,5-dimethyl pyrrole-N-oxide (DMPO), thiobarbituric acid (TBA) were bought from the Sigma Company (USA). "8-OHdG Check" kit was purchased from Fukuroi (Japan) for the control of aging. All other chemicals were of analytical grade.

Hydroxyl radical scavenging assay by electron spin resonance trapping method

Hydroxyl radical (\cdot OH) scavenging activity of mistletoe alkali was determined by spin trapping ESR using DMPO as a spin trap reagent as previously described^[8]. Both

Fenton reaction and H₂O₂/UV system were used as the \cdot OH source. Comparative study on the \cdot OH scavenging activity of mistletoe alkali was carried out in the presence of liver and kidney homogenates and serum using the Fenton system as \cdot OH generator. Briefly, rat liver and kidney homogenates (0.923 mg protein) were incubated with an aliquot of mistletoe alkali at 37°C for 30 min. The homogenates (100 mL) were mixed with 160 mL of distilled water, 30 mL of 100 mol/L H₂O₂ and 30 mL of 200 mol/L DMPO. Then, 30 mL of 2 mmol/L FeSO₄ was finally added to the mixture to initiate the Fenton reaction. DMPO-OH adduct formation was measured in a silica flat cell 2 min after the addition of FeSO₄ using a JEOL JESTE 200 electron spin resonance (ESR) spectrometer (X-Band Microwave Unit). The spectrometer settings were as follows: microwave power: 8 mW; microwave frequency: 9.20 GHz; modulation amplitude: 0.1 mT; time constant: 0.03 s; sweep time: 30 s; center fields: 332.6/322.6 mT.

TBARS formation determination

Briefly, an aliquot of liver and kidney homogenates was mixed with 0.2 mL of 8.1% SDS, 1.5 mL of 20% acetic acid and 1.5 mL of 0.8% TBA, then the volume was adjusted to 4.0 mL with distilled water. After boiled at 95°C for 60 min, the reaction solution was extracted with 1.0 mL of distilled water and 5.0 mL of *n*-butanol and pyridine (15:1 v/v). The absorbance at 532 nm of the organic layer was determined after centrifugation. The whole procedure was performed as previously described^[9].

GSH-Px activity determination

Briefly, an aliquot of liver and kidney homogenates (4 mg wet tissue) in 0.05 mol/L phosphate buffer containing 1.15% (w/v) KCl was mixed in a quartz cuvette with 935 mL of the coupling solution prepared by dissolving 33.6 mg disodium EDTA, 6.5 mg Na₂N₃, 30.7 mg of GSH, 16.7 mg NADPH and 100 units of GSH reductase in 100 mL of 50 mmol/L Tris-HCl (pH 7.6). Kinetic decay of NADPH fluorescence (Ex. 355 nm/Em. 465 nm) was measured after the addition of 25 mL of 1 mmol/L H₂O₂ as substrate using a Hitachi model 650-60 fluorescence spectrophotometer. The whole procedure was carried out as previously described^[10].

SOD activity measurement

One unit of SOD activity was defined as the amount of enzyme causing 50% inhibition of epinephrine auto-oxidation to adrenochrome. For Mn SOD activity measurement 1 mmol/L KCN was added to the reaction mixture to inhibit CuZn SOD activity which was approximated by subtracting Mn SOD activity from total SOD activity as previously described^[11]. Protein content was assayed by the Bradford method (Bio-Rad, Hercules, Calif., USA).

Determination of urinary 8-OHdG by competitive ELISA

Urine samples were centrifuged at 10 000 r/min for 15 min, and the supernatant was used for determination of 8-OHdG by competitive ELISA using the "8-OHdG Check" kit. The determination range was 0.64-2000 µg/

mL and the specificity of the monoclonal antibody used in the competitive ELISA kit was established.

Statistical analysis

Significance was tested by the paired *t*-test or analysis of variance. Results were presented as mean \pm SD. $P < 0.05$ was considered statistically significant.

RESULTS

MDA and LPO formation in liver and kidney homogenate and plasma was considerably increased in the model group. However, in the mistletoe alkali-treated groups, no significant increase in MDA and LPO formation was observed (Table 1, Table 2 and Table 3). Results showed that hepatotoxicity and nephrotoxic nephritis in rats were induced by CCl₄ with formation of lipid peroxide. However, mistletoe alkali was effective in reducing malonyl dialdehyde (MDA) content in the tissues, and had good scavenging effects on hydroxyl free radicals.

The effective protection of liver and kidney against oxidative damage induced by mistletoe alkali was further demonstrated by determining GPx and SOD activity in the Liver and kidney homogenate and plasma. GPx and SOD activity decreased markedly in the liver and kidney homogenate and plasma in model group, but activity loss was prevented by mistletoe alkali in the pretreatment groups. GPx and SOD activity increased slightly compared to normal group. The data in the present study suggested that mistletoe alkali could be a potential herbal medicine for improving GPx and SOD activity in liver and kidney tissue and plasma. The enzymes level is shown in Table 1, Table 2 and Table 3. The scavenging activity was steadily increased with the increase of drug density, suggesting that the free radical scavenging activity was related with

mistletoe alkali density.

The DMPO-OH signal produced by the Fenton reaction was reduced by the addition of mistletoe alkali in a concentration dependent manner (Table 4). The 50% inhibitory concentration of mistletoe alkali for DMPO-OH formation was compared to that for Trolox as a reference radical scavenger. The results indicated that mistletoe alkali not only scavenged \cdot OH directly but also inhibited \cdot OH generation in the Fenton reaction. This was further confirmed when the \cdot OH scavenging activity of mistletoe alkali was determined in the H₂O₂/UV system as \cdot OH source. In this system, the Trolox equivalence of the mistletoe alkali solution was about 0.1 mmol/L (data not shown).

There was a significant difference in urinary excretion of 8-OHdG between the control group and 900 mg/kg mistletoe alkali-fed group (7.84 ± 3.72 , 3.26 ± 1.92 μ mol/L/d, $P < 0.05$).

DISCUSSION

There is a growing body of evidence that oxygen-derived free radicals are involved in the pathogenesis of over 50 human diseases^[12]. Antioxidant therapy aimed at reducing free radical-mediated tissue damage represents a rational approach in preventing the onset and/or progression of free radical-related tissue damage. In this connection, the measurement of antioxidant activity should form an additional basis for drug screening and selection^[13]. In the present study, we examined the antioxidant potential of a traditional Chinese medicine, *Viscum coloratum* (Komar.) Nakai.

Recently, rapid progress has been made in research of *Viscum coloratum* (Komar.) Nakai. The preparation of Oujisheng has already been applied extensively in

treatment of cancer^[14]. China has a long history in research of *Viscum coloratum* (Komar.) Nakai. In 1934, Jingli Tong discovered that the Chinese *Viscum coloratum* (Komar.) Nakai (Huangguo *Viscum coloratum* (Komar.) Nakai) can lower blood pressure^[15].

The involvement of free radical-mediated oxidative process in the development of CCl₄ hepatotoxicity is well established^[16]. It was reported that impairment of hepatic antioxidant status is associated with a substantial hepatocellular damage induced by CCl₄^[17]. GSH is a crucial determinant of tissue susceptibility to oxidative damage, and the depletion of hepatic GSH content has been shown to be associated with an enhanced toxicity to chemicals including CCl₄^[18]. The liver protection afforded by pretreatment with NAC, a precursor for GSH synthesis, and vitamin E, an inhibitor of lipid peroxidation, indicates that both the sustained hepatic GSH content and the lipid peroxidation inhibition are important factors involved in protecting against CCl₄ hepatotoxicity. Changes in the sensitivity of tissue homogenates to *in vitro* oxidative challenge have been used as an indicator of altered tissue susceptibility to free radical-induced oxidative injury *in vivo*^[19]. Our results, indicating an increase in sensitivity of tissue homogenates to ferric ion-induced lipid peroxidation following CCl₄ treatment, have validated the application of "forced peroxidation" assays in measuring alterations in tissue after oxidative challenge.

To our knowledge, there is no report indicating that the use of MA *in vivo* studies counteracts CCl₄ toxicity. Mistletoe alkali pretreatment at a daily dose of 900 mg/kg body weight for 6 d significantly enhanced hepatic antioxidant status in CCl₄-treated rats, with a concomitant reduction of hepatocellular damage, suggesting that the involvement of GSH-enhancing action can protect liver against damage.

8-OHdG, a DNA base-modified product generated by reactive oxygen species, is mutation prone and a good marker for oxidative damage. It has been hypothesized that oxidative damage can occur in DNA during the peroxidative breakdown of membrane polyunsaturated fatty acids. Lipid peroxidation can mediate 8-OHdG formation *in vitro* and may play a role in carcinogenesis by inducing 8-OHdG generation *in vitro*. In this study, the amount of 8-OHdG in the urine of rats fed with mistletoe alkali was significantly lower than that in the control rats, suggesting that mistletoe alkali plays a role in the prevention of oxidative DNA damage *in vivo*.

In conclusion, increased level of free radicals is associated with decreased antioxidant status in liver and kidney of rats treated with CCl₄. This finding is similar with other investigations^[20,21]. Mistletoe alkali strongly inhibits lipid peroxidation and thereby decreases liver and kidney damage.

Abstract

AIM: To investigate the effects on telomerase activity of transfection of human T-STAR gene full-length sense cDNA or partial antisense cDNA into human colon cancer cell line HCT-116.

METHODS: mRNA and protein expression levels of T-STAR gene were determined by RT-PCR and western blot, and telomerase activity was measured by PCR-ELISA, after transfection of T-STAR sense or antisense gene into HCT-116 cells with lipofectamine.

RESULTS: T-STAR gene expression was enhanced or knocked down both at mRNA and protein levels, and telomerase activity was significantly increased or decreased.

CONCLUSION: The T-STAR gene may participate in regulation of telomerase activity in human colon cancer HCT-116 cells in a parallel fashion.

INTRODUCTION

T-STAR, a recently cloned member of STAR gene family, is highly expressed in testis, muscle, and brain and contains a STAR domain, an RNA-binding domain present in a growing family of proteins involved in developmental processes^[1-3]. The protein can bind to a variety of signal-transducing proteins and may act as an adaptor in signal-transduction pathways. T-STAR was identified as a protein interacting with the protein RNA-binding motif (RBM) in spermatogenesis. Down-regulation of T-STAR expression was found in SV40-transformed immortal fibroblasts, and this protein may interact with telomerase^[4]. In most progressive phase malignant tumor tissues and cancer cell lines, the telomerase activity maintained at a high level, whereas, at a lower or undetectable level in normal cells. The activation of telomerase is involved in tumorigenesis and progression^[5-8]. In this study, we transfected the sense or antisense T-STAR gene into human colon cancer cell line HCT-116 to overexpress or inhibit T-STAR protein, and to further observe whether T-STAR gene participates in the regulation of telomerase activity in HCT-116 cells.

MATERIALS AND METHODS

Materials

The eukaryotic expression plasmid, pcDNA3.1 was purchased from Invitrogen. Human T-STAR full length cDNA was a gift by Dr. Chew of Leicester University. The full length cDNA of T-STAR was inserted into pcDNA3.1 vector at *EcoRI* site in a sense orientation to generate a recombinant sense expression plasmid, pcDNA-STAR. The fragment of T-STAR cDNA digested by *ApaI* restriction enzyme was ligated in the *ApaI* site of pcDNA3.1 in an antisense orientation to construct a recombinant antisense plasmid, pcDNA-asSTAR. Human colon cancer cell line HCT-116 was provided by Department of Abdominal Surgery of Southwest Hospital, Chongqing. The transfection reagent of Lipofectamine2000 was purchased from Invitrogen. RPMI1640, fetal calf serum, and other reagents for cell culture were purchased from Hyclone. Monoclonal antibody against T-STAR, mAbT was purchased from Santa Cruz Biotech. Rabbit antigoat IgG polyclonal antibodies HRP-conjugated were purchased from Beijing Zhongshan Biotech (China). RNA PCR reagent kit was

from Dalianbo Biotech. Telomerase PCR ELISA reagent kit was from Roche.

Methods

Human colon cancer cell line HCT-116 cells were maintained in RPMI1640 medium, supplemented with 10% heat-inactivated fetal calf serum, 100 U/mL of penicillin and 100 µg/mL of streptomycin and were grown at 37°C, in a humidified incubator containing 5 mL/L CO₂. Transfection was performed according to the LipofectAMINE2000 method (Invitrogen) using 2 µg of each plasmid DNA (empty vector pcDNA3.1 as control, antisense plasmid pcDNA-asSTAR and sense plasmid pcDNA-STAR as experimental group). Briefly, adherent cells were seeded in six-well plates (5 × 10⁵ cells per well) grown overnight to 50%-60% confluency and were washed three times with phosphate-buffered saline, and medium was replaced with 500 µL of OPTI-MEM medium before a mixture of LipofectAMINE and DNA was added to the well for 8 h. And then the medium containing transfection mixture was replaced with 2 mL fresh RPMI1640. After 24 h of transfection, the cells were selected in RPMI1640 supplemented with 500 µg/mL G418 (Geneticin, GIBCO) for 10 d. Furthermore, the cells of selected single colonies were grown in same medium with 200 µg/mL G418 for another two weeks. Total RNA was extracted from each group of transfected cells using TRIzol reagent (Invitrogen Life Technologies). Concentration and purity were confirmed by spectrophotometry and electrophoresis on the denaturing formaldehyde-agarose gel. Reverse transcription reactions were performed on 5 µg of the isolated total RNA using the ProSTAR RT-PCR kit (Stratagene, La Jolla, CA). The following specific primers were used for PCR assay, for human T-STAR gene: P1-5'CAGGATGGGACATGCTTTG3', P2-5'TCTGTAGACGCCCTTTGCT3', for inner control β-actin: P1-5'GTGGGC CGCTCTAGGCACCAA3', P2-5'CTCTTTGATGTCACGCACGATTTC3'. All PCR reactions were incubated at 95°C for 5 min, and then cycled at 95°C for 45 s, 48°C for 30 s and 72°C for 1 min for 35 cycles and, finally, at 72°C for 10 min for extension. The PCR products were electrophoresed on 10 g/L agarose gel to calculate the amount of T-STAR mRNA expression. The densities of target DNA bands of each group on the electrophoresis were analysed by software of Quantity One, and was normalized to inner control β-actin. The relative quantities are given as mean ± SD. The experiment was done in triplicates. Total cellular proteins were isolated from each group of transfected cells. Briefly, 90% confluency live cells were washed twice with 10 mmol/L PBS, and then were completely lysed with 200 µL 1 × SDS loading buffer. The lysate was transferred to a new 1.5 mL eppendorf tube, and heated to 100°C for 10 min. Then cellular genomic DNA was broken by sonication. About 10 µL protease inhibitor of PMSF per mL extract was mixed together. Protein concentration was determined according to Bradford, and samples were stored at -20°C. For western blot analysis, 40 µg total cellular proteins were separated on a 4%-15% sodium dodecyl sulfate-polyacrylamide gel. After electrotransfer to nitrocellulose membranes (BioRad),

uniformity of loading and transfer was confirmed by Poncea staining. The membranes were blocked overnight in TS complete (20 mol/L Tris-HCl, 150 mol/L NaCl, 5% non-fat dry milk, and 0.1% Tween 20) at 4°C. Blots were incubated for 1 h at room temperature with T-STAR mAb (Santa Cruz Biotech.) antibodies. Blots were washed and then incubated with horseradish peroxidase-conjugated secondary antibody (1:2000) (Sigma, St. Louis, MO) at room temperature for 2 h. The immune complexes were detected by the automated image documentation systems and bands density was analyzed by Quantity One software. The telomerase activity was measured with PCR ELISA kit^[9].

Statistical analysis

Data are expressed as mean ± SD. Differences between experimental groups were assessed for significance by using the two-tailed unpaired Student's *t* test. A *P* value of < 0.05 was considered to be statistically significant.

RESULTS

Cellular T-STAR mRNA expression level

Three clear bands were present at 5S, 18S and 28S on the electrophoresis of total RNA of each group of cells. The brightness of the band at 28S was about 2-fold compared with that at 18S. There was no significant degradation with the mRNA, which could be applied in further experiments (data not shown). Both cDNA of T-STAR gene and β-actin gene simultaneously being reverse transcribed from the mRNA were electrophoresed on an agarose gel (Figure 1A). The semi-quantitative analysis was applied to the bands of T-STAR cDNA (Figure 1B). Compared with the average expression level of HCT-pcDNA transfected control cell group, T-STAR mRNA expression was increased to 296% in HCT-STAR group (*P* < 0.01), decreased to 59% in HCT-asSTAR group (*P* < 0.01), and remained slightly changed in HCT-116 group (*P* < 0.01).

T-STAR protein expression level

The T-STAR protein could be specifically detected at the molecular weight *Mr*55 on the immuno-blots in all the HCT-116 cell groups transfected with different constructs (Figure 2A). The T-STAR protein amount was enhanced in HCT-STAR group, reduced in HCT-asSTAR group, and not significantly changed in HCT-116 group in contrast to HCT-pcDNA group. Densitometry analysis showed that the T-STAR protein expression was increased about 180.8% in HCT-STAR cells (*P* < 0.01), decreased about 83.80% in HCT-asSTAR cells (*P* < 0.01) compared with HCT-pcDNA cells (Figure 2B).

Telomerase activity

No significant changes of cellular telomerase activity were observed between HCT-116 cell group and HCT-pcDNA transfected cell group (Figure 3). Interestingly, the telomerase activities were significantly decreased in HCT-asSTAR group (*P* < 0.01), in which the expression of T-STAR gene was inhibited; whereas, the telomerase activities were significantly increased in the HCT-STAR group (*P* < 0.05) with up-regulation of T-STAR gene expression.

DISCUSSION

T-STAR is a 55 kDa protein, one of three members of the SAM68 family of RNA-binding proteins with proline and tyrosine-rich regions that have been shown to be involved in various gene expression pathways including the developmental processes and/or extracellular signals to control the cellular fate of mRNA^[10,11]. T-STAR gene is localized to chromosome 8q24.3, and the full length cDNA ranged in size from 1.2 kb to 1.9 kb. T-STAR is highly expressed in testis, muscle, and brain^[10]. The STAR proteins have multiple functions in pre-mRNA splicing, signalling and cell cycle control. T-STAR generally acts as a growth suppressor, which is down-regulated upon immortalization of many cell lines^[9-11]. Our previous study found that T-STAR may interact with hTERT, participating in processes of cell growth and proliferation. In this study, we successfully established stable colon cancer cell lines in which T-STAR gene was specially up-regulated or down-regulated both at protein and mRNA levels in HCT-STAR cells or HCT-asSTAR cells. Meanwhile, the changes of telomerase activities had a parallel fashion with the expression level of T-STAR in those two cell lines, which was enhanced in HCT-STAR and reduced in HCT-asSTAR. Similar results have been found in our previous study in other tumor tissues or cell lines (unpublished data). The current data further demonstrated that the expression of T-STAR is positively correlated with hTERT and telomerase activity. In other words, it is possible that up-regulation of T-STAR may lead to hTERT and

Figure 2 A: Western blot analysis of the T-STAR protein expression level of each group of cells; B: Densitometry analysis of the amount of T-STAR protein expression in each group of cells, ^a*P* < 0.01 vs 2. 1: HCT; 2: HCT-pcDNA; 3: HCT-asSTAR; 4: HCT-STAR.

telomerase activity increase in tumor cells, and vice versa.

Telomeres are thought to play a critical role in cellular immortalization and carcinogenesis^[12]. Our study on different pathologic types of tumor tissues found that T-STAR mainly expressed in adenoma cells. T-STAR may also be involved in cellular immortalization which is one of the basic characteristics of tumor cells^[2,4,13]. Kool *et al*^[4] have found that T-STAR is down-regulated in SV40-transformed immortalized fibroblasts (VH10/SV) compared with the corresponding nonimmortal SV40-transformed cells. In normal cells, T-STAR expression is clearly present and comparable with expression levels in SV40-transformed precrisis cells. No changes are observed in T-STAR expression as cells progress toward senescence. The down-regulation in the immortalized cells was not restricted to VH10/SV, but was also observed in other fibroblast cell lines transformed by SV40 large T^[5,14]. Interestingly, the common feature of the SV40-transformed cell lines showing down-regulation of T-STAR is that they displayed a distinct proliferative crisis before immortal clones arose. In contrast, both immortal cell lines that do not show abrogation of T-STAR expression, arose without a clear crisis. These data suggest

that loss of T-STAR expression might be a prerequisite to escape from crisis. If immortalization occurs in earlier stages after SV40 transformation, these immortal cells will gradually overgrow the population before crisis and apparently do not need the downregulation of T-STAR. This could indicate that T-STAR plays a role during crisis, and that immortalization cannot occur unless T-STAR expression is down-regulated. T-STAR is likely one of important components in proliferative crisis or immortalization pathway^[15,16]. So far, there is rarely experimental data to investigate the T-STAR expression in cell lines characterized with high telomerase activity and that immortalization has already been completed. Recent observation has shown that the mature male germ cells, as one kind of immortalized cells, with high telomerase activities also maintained abounding T-STAR protein^[2], which is consistent with our results. That is T-STAR expression might be positively correlated with telomerase activity in some kinds of immortalized cells, and T-STAR might be one component in the systems of telomerase activity regulation. Although the exact mechanism of this is unclear yet, from the analysis of T-STAR known functions, it can be speculated that T-STAR might play a role in phosphorylation and pre-mRNA splicing of hTERT.

Telomerase consists of an RNA component, telomerase RNA (TER), which includes the template for synthesis of telomere DNA, and a protein catalytic component, the telomerase reverse transcriptase (TERT), which mediates RNA template-dependent synthesis of telomere DNA. The phosphorylation^[17,18] by PKC, AKT and PTK or dephosphorylation by PP2A for hTERT, the key component of the telomerase complex, can modulate telomerase activity^[19-21]. The interaction of hTERT with c-Ab1 tyrosine kinase binding domain SH3 may result in phosphorylation and inhibit telomerase activity *in vitro* or *in vivo*^[21-23]. Tyrosine phosphorylation of Sam68, the homologues of T-STAR and as an adaptor protein in signal transduction, promotes its interaction with SH2 containing proteins. The association of Sam68 with SH3 domain-containing proteins, and its tyrosine phosphorylation may negatively regulate its RNA binding activity^[24,25]. T-STAR can form hetero-multimers^[4,9,13] with Sam68 to inhibit the interaction of Sam68 with its target protein. So T-STAR might interfere with Sam68 binding with Ab1 SH3 by reverse phosphorylation, and lead to impairment of Ab1 SH3 function of increasing telomerase activity. Another possible mechanism is that T-STAR may take part in the splicing of hTERT pre-mRNA. Different length of hTERT transcripts by alternative-splicing sites exists in cells^[26-28], but only the full length transcripts for hTERT is functional, which is associated with telomerase activity. The selective-splicing for hTERT may be one of the modes that regulate telomerase activity. The 3'-UTR of T-STAR is the binding site for target mRNA^[29]. T-STAR may play a role in processing of target pre-mRNA and selection of splicing sites^[30], and also interact with the protein involved in the selective splicing^[30,31]. We assume that T-STAR might control pre-mRNA splicing for hTERT. The enhancement of full length transcripts for hTERT may up-regulate telomerase activity. However, the exact mechanism needs to be further investigated.

CONCLUSION: Lamivudine has remarkable inhibitory effects on HBV replication both in serum and in PBMCs. The inhibitory effect on HBV DNA in PBMCs is weaker than that in serum.

Abstract

AIM: To study the dynamic changes of hepatitis B virus (HBV) DNA in serum and peripheral blood mononuclear cells (PBMCs) of patients after lamivudine therapy.

METHODS: A total of 72 patients with chronic HBV infection were included in this study. All patients were confirmed to have the following conditions: above 16 years of age, elevated serum alanine aminotransferase (ALT), positive hepatitis B e antigen (HBeAg), positive HBV DNA in serum and PBMCs, negative antibodies against HAV, HCV, HDV, HEV. Other possible causes of chronic liver damages, such as drugs, alcohol and autoimmune diseases were excluded. Seventy-two cases were randomly divided into lamivudine treatment group ($n = 42$) and control group ($n = 30$). HBV DNA was detected both in serum and in PBMCs by fluorescence quantitative polymerase chain reaction (PCR), during and after lamivudine treatment.

RESULTS: In the treatment group, HBV DNA became negative both in serum and in PBMC, of 38 and 25 out of 42 cases respectively during the 48 wk of lamivudine treatment, the negative rate was 90.5% and 59.5% respectively. In the control group, the negative rate was 23.3% and 16.7% respectively. It was statistically significant at 12, 24 and 48 wk as compared with the control group ($P < 0.005$). The average conversion period of HBV DNA was 6 wk (2-8 wk) in serum and 16 wk (8-24 wk) in PBMC.

INTRODUCTION

Lamivudine (LAM) is a new antiviral agent against hepatitis B virus (HBV) infection. It has been shown that lamivudine therapy can rapidly reduce HBV DNA levels in serum and improve liver histology^[1-3]. However, the dynamic changes of HBV DNAs in serum and peripheral mononuclear cells (PBMCs) in patients after lamivudine therapy are not clear, especially in PBMCs.

PBMCs contain various kinds of active immune cells. The activities of immune cells affect directly the results and efficacy of antiviral therapy^[4,5]. Few studies are available on the dynamic changes of HBV DNA in serum and PBMCs. The aim of this study was to investigate the inhibition of HBV DNA in serum and PBMCs in patients after LAM therapy.

MATERIALS AND METHODS

Patients and materials

A total of seventy-two patients with chronic hepatitis B were from Out-patient and In-patient Departments of our hospital during February 2003-February 2004. There were 50 males and 22 females aged 18-60 years (average 32.4 years). Diagnosis of hepatitis B was made according to the revised standard of the diagnosis established at the Tenth National Symposium on Viral Hepatitis in Xi'an in

Table 1 Change of HBV DNA in serum and PBMC of chronic hepatitis B patients after lamivudine treatment *n* (%)

Group	HBVDNA in serum				HBVDNA in PBMC

2000^[6]. All patients were confirmed to have the following conditions: above 16 years of age, normal or abnormal ALT, positive HbsAg and HBeAg in serum, negative anti-HCV, anti-HDV and anti-HEV in serum, positive HBV DNA in serum and PBMCs.

Methods

Seventy-two patients with chronic hepatitis B were randomly divided into two groups: lamivudine treatment group (*n* = 42) receiving 100 mg lamivudine daily for 48 wk, control group (*n* = 30) receiving routine medication with vitamin C and inosine, *etc.* All samples were prepared and stored at -20°C for further examination. HBV DNA in serum and PBMCs was detected after 4, 12, 24 and 48 wk of treatment.

Quantitative determination of HBA DNA in serum and PBMCs

HBV DNA in serum was detected by fluorescence quantitative PCR assay, strictly according to the manufacturer's instructions (Da An Gene Institute, Shenzhen, No: 20030041).

Lymphocyte separation medium (Second Reagent Factory of Shanghai, No. 200304) was used to separate PBMCs. After isolation, the cells were washed three times with PBS containing 1% brine. The cells were diluted to 1 × 10⁶ /mL with RPMI before detection.

Cellular DNA was extracted according to NaI method. Briefly, 100 μL 1 × 10⁶/mL cell suspension and 200 μL NaI were well mixed, inverted for 20 s, then mixed with 400 μL chloroform/iso-amy alcohol (24:1) and spun by centrifugation at 10 000 r/min for 12 min. Three hundred microlitre supernatant was mixed with 200 μL pure dimethyl carbinol, spun by centrifugation for 12 min at 14 000 r/min. Supernatant was collected and mixed with 1 mL 70% ethanol, the DNA was precipitated at -20°C.

HBV DNA in PBMCs was also detected by fluorescence quantitative PCR assay. The reaction conditions were: pre-denaturation at 93°C for 3 min, followed by 40 cycles of denaturation at 93°C for 45 s, extension at 55°C for 60 s and a final extension at 93°C for 30 s, at 55°C for 60 s. The reference graph was drawn according to standard content by a computer. The amount of HBV DNA was calculated. During PCR, a strict control was performed. All results were negative.

Statistical analysis

Statistical analysis was carried out by chi square test and *t*-test. *P* < 0.05 was considered statistically significant.

Figure 1 Content of HBV DNA in serum and PBMC of chronic hepatitis B patients after lamivudine treatment.

RESULTS

The content of HBV DNA in serum and PBMC was decreased after lamivudine treatment (Table 1, Figure 1).

DISCUSSION

Lamivudine is a HBV polymerase inhibitor and acts on HBV replication both *in vitro* and *in vivo*. It has been shown that lamivudine can suppress HBV replication, decrease transaminase levels and improve liver histology^[7-10]. However, the main goal of treatment in chronic hepatitis B is to eliminate or persistently inhibit the replication of HBV. After long-term application of lamivudine, antiviral resistance may occur due to HBV polymerase mutation, manifested as increased HBV DNA and serum transaminase, suggesting that the content of HBV DNA can be used to evaluate the efficacy of antiviral therapy. Lamivudine is not able to eliminate HBV ccc DNA in hepatocytes^[11], which is the main reason for HBV DNA rebound after withdrawal. Studies have shown that patients with hepatitis B usually accompany disorder of immune function caused by immunological injury^[12-25]. PBMCs contain various immune active cells, and play a significant role in immune responses during antiviral therapy. It has been shown that HBV infection may exist in PBMCs^[4,26,27]. When PBMCs are infected with HBV, they not only affect the function of immunity, but also weaken the efficacy of antiviral drugs. Therefore, the dynamic change of HBV DNA in PBMCs may be a reliable index for curative antiviral efficacy.

In our study, lamivudine had remarkable inhibitory effects on HBV DNA both in serum and in PBMCs. When the treatment time was prolonged, the negative rate of HBV DNA in serum and PBMCs was gradually increased. The eliminate effect of lamivudine on HBV DNA in

PBMCs was lower than that in serum. The negative rate of HBV DNA in serum was 90.48%, but only 59.52% in PBMCs after lamivudine treatment. HBV DNA was positive in 17 cases of chronic hepatitis B after 48 wk of treatment, which may be associated with the fact that mutations occurred in HBV after LAM therapy^[28], HBV DNA in PBMCs interferes with the immune activity of cells after HBV integrates with PBMCs, and decreases the contents of Ig, C₃, TNF and activity of NK cells as well as the ratio of CD4⁺/CD8⁺^[4,5,29]. Therefore, the function of cell-mediated immunity and humoral immunity are reduced and affect the curative effect of lamivudine.

In conclusion, HBV DNA exists in PBMCs even after 48 wk of lamivudine treatment. The presence of HBV DNA in PBMCs may infect hepatocytes again and cause the relapse of hepatitis.

Abstract

AIM: To characterize the intestinal transport and mechanism of metformin in rats and to investigate whether or not metformin is a substrate for P-glycoprotein (P-gp).

METHODS: The effective intestinal permeability of metformin was investigated using single-pass intestinal perfusion (SPIP) technique in male Wistar rats. SPIP was performed in three isolated intestinal segments (duodenum, jejunum and ileum) at the same concentration of metformin (50 $\mu\text{g/mL}$) to test if the intestinal transport of metformin exhibited site-dependent changes, and in a same isolated intestinal segment (duodenal segment) at three different concentrations of metformin (10, 50, 200 $\mu\text{g/mL}$) to test if the intestinal transport of metformin exhibited concentration-dependent changes. Besides, P-gp inhibitor verapamil (400 $\mu\text{g/mL}$) was co-perfused with metformin (50 $\mu\text{g/mL}$) in the duodenum segment to find out if the intestinal absorption of metformin was affected by P-gp exiting along the gastrointestinal track. Stability studies were conducted to ensure that the loss of metformin could be attributed to intestinal absorption.

RESULTS: The effective permeability values (P_{eff}) of metformin in the jejunum and ileum at 50 $\mu\text{g/mL}$ were significantly lower than those in the duodenum at the same concentration. Besides, P_{eff} values in the duodenum at high concentration (200 $\mu\text{g/mL}$) were found to be significantly lower than those at low and medium concentrations (10 and 50 $\mu\text{g/mL}$). Moreover the co-perfusion with verapamil did not increase the P_{eff} value of metformin at 50 $\mu\text{g/mL}$ in the duodenum.

CONCLUSION: Metformin could be absorbed from the whole intestine, with the main absorption site at duodenum. This concentration-dependent permeability behavior in the duodenum indicates that metformin is transported by both passive and active carrier-mediated saturable mechanism. The P_{eff} value can not be increased by co-perfusion with verapamil, indicating that absorption of metformin is not efficiently transported by P-gp in the gut wall. Furthermore metformin is neither a substrate nor an inducer of P-gp. Based on the P_{eff} values obtained in the present study and using established relationships, the human fraction dose absorbed for metformin is estimated to be 74%-90% along human intestine.

INTRODUCTION

Metformin (dimethylbiguanide), N,N-dimethylimidodicarbonimidic diamide (Figure 1) is an oral antihyperglycaemic agent used in the management of non-insulin-dependent diabetes mellitus (NIDDM). It reduces blood glucose levels predominantly by improving hepatic and peripheral tissue sensitivity to insulin without affecting the secretion of this hormone. Metformin also appears to have potentially beneficial effects on serum lipid levels and fibrinolytic activity, although the long-term clinical implications of these effects are unclear^[1]. Gastrointestinal absorption of metformin is incomplete, 20%-30% of an oral dose is recovered in the faeces^[2]. Absorption is estimated to be complete within 6 h of administration and is presumably confined to the upper part of the intestine^[2,3]. Metformin is poorly absorbed from the stomach and the delivery process highly correlated with the rate-limiting factor for metformin absorption from the duodenum, while the whole intestine is necessary for sufficient absorption of drugs^[3]. Proportionately more drugs are absorbed after 0.5 g dose than 1.5 g dose, possibly because of the involvement of an active, saturable absorption process^[3]. In clinical practice,

metformin is an effective antihyperglycaemic agent with additional beneficial effects on metabolic and fibrinolytic variables, both of which can be used as monotherapy or in combination with other antihyperglycaemic agents^[1].

The SPIP technique is performed in anesthetized rats whereby a section of intestine is isolated and perfused with a solution of the compound of interest. In the SPIP experimental procedure modifications can be made to the flow rate, length of perfused intestine, and concentration of the compound of interest thus giving the investigator exquisite control of the factors influencing the intestinal absorption of a chemical. In the most basic SPIP protocol the compound of interest is monitored in the perfusate only but not in the blood. Loss of compound, as determined by the difference between the inlet and outlet concentrations, is attributed to absorption but only after preliminary studies rule out other possible factors. The preliminary studies may consist of stability studies in the buffer (unperfused and blank perfused buffed) and homogenates of the intestine.

In vivo rat studies have also been performed in an attempt to study the role of intestinal P-gp in drug absorption and metabolism. P-gp, a plasma membrane protein of about 170 kDa, has been demonstrated in many normal tissues, including intestinal cells^[4,5]. P-gp in the gut wall acts as an efflux transporter of certain drugs and studies in several species including the rat indicate that P-gp may play an important role in limiting drug absorption^[6,7]. P-gp, a member of the ATP-binding cassette transporter superfamily (ABCB1) and is located on the apical membrane of intestinal enterocytes where it can actively efflux drugs from the cells back into the intestinal lumen^[8]. An increasing number of drugs, including HIV protease inhibitors like indinavir, zidovudine, saquinavir and anti-cancer drugs like paclitaxel, docetaxel, etc, have been reported to be substrates for P-gp^[9]. Verapamil, a P-gp substrate, is a competitive inhibitor of intestine P-gp in the rat^[10], and is used as a tool for P-gp inhibition^[10].

The aim of this study was to characterize and classify the intestinal permeability of metformin in rats using SPIP model, and to predict the intestinal absorption mechanism of metformin in humans as well as to investigate whether metformin is a substrate for P-gp.

MATERIALS AND METHODS

Instruments

The high performance liquid chromatography (HPLC) system consisting of a Shimadzu LC-6A auto solvent delivery module pump was purchased from (Shimadzu, Kyoto, Japan). Gilson 118 UV spectrophotometric detector, SCL-6A system controller, CTO-6A column oven, CKChrom chromatograph data system, syringe pump (BT01-YZ1515-B) were produced of Tianjin Xieda Electronic Co. Ltd (Tianjin, China). Homogenizer was from Shanghai Jinda Biochemical Instrument Factory (Shanghai, China). Heating operating table was from Shanghai No.1 Medication Store (Shanghai, China). Analytical balance (TG328A) and electronic balance (JA2003) were obtained from Shanghai Balance Instrument Factory (Shanghai, China). High speed table centrifuge (TGL-16) was purchased from Shanghai

Figure 1 Structure of metformin (dimethylbiguanide).

No.6 Medical Instruments Factory (Shanghai, China). Constant temperature water bath chamber was a produced of Beijing Xicheng Medical Instruments Factory (Beijing, China).

Drugs and reagents

Metformin (purity: 99.5%) and verapamil (purity: 99.5%) were produced by Department of Pharmaceutical Preparation, Tianjin Institute of Pharmaceutical Research (Tianjin, China). Doxofylline was produced by Research Center for New Drug Evaluation, Tianjin Institute of Pharmaceutical Research (Tianjin, China). Urethane was purchased from Beijing Chemical Engineering Plant (Beijing, China). Phenol red and ammonium acetate (analytical grade) were purchased from Tianjin Chemical Reagent No.1 Plant (Tianjin, China). Ion pair reagent, 1-octanesulfonic acid sodium salt (IPR-B₈, 0.25 mol/L) was purchased from Tianjin Chemical Reagent No.2 Plant (Tianjin, China). Methanol (HPLC grade) was purchased from Tianjin Concoct Chemical Reagent Company (Tianjin, China).

Animals

Male Wistar rats weighting 180-230 g were purchased from Center of Experimental Animals, Tianjin Institute of Pharmaceutical Research (Certificate No. 20050110), Tianjin, China. Animals were acclimated for at least 5 d before the experiments and housed in cage (5 each) under constant temperature (22 ± 2°C) with free access to food and drinking water. Animals were fasted overnight before use either in the SPIP study or for harvesting intestinal tissue to prepare homogenate preparation.

Perfusion solution

Krebs-Ringe buffer solution^[11] (K-R buffer solution containing 7.8 g NaCl, 0.35 g KCl, 1.37 g NaHCO₃, 0.02 g MgCl₂, 0.22 g NaH₂PO₄ and glucose in 1.48 g/1000 mL purified water) was used as blank perfusion solution. Phenol red (20 µg/mL) and doxofylline (20 µg/mL) were added to perfusion solution as non-absorbable marker and internal standard, respectively. Perfusion solution containing 10 µg/mL, 50 µg/mL, and 200 µg/mL metformin respectively, 20 µg/mL phenol red and 20 µg/mL doxofylline was used. In addition, 400 µg/mL verapamil was added to perfusion solution containing 50 µg/mL metformin to achieve solution containing P-gp inhibitors.

Collection of rat small intestinal fluid and Preparation of homogenates

After an overnight fast, animals were anesthetized with an intraperitoneal (i.p.) injection of urethane (0.7 mL/100 g). Upon verification of the loss of pain reflex, a midline abdominal incision of 3-4 cm was made and a 10-15 cm intestinal segment of interest (duodenum, jejunum and

ileum) was isolated and cannulated at both ends with plastic tubing. The segment was first rinsed with 37°C saline to clear the segment, then blank K-R buffer solution (without drug) was pumped into the segment at a constant flow rate of 0.2 mL/min. Blank perfused solution was collected at the outlet and used to prepare metformin solution (10, 50, 200 µg/mL) with doxofylline (20 µg/mL) for stability studies of metformin.

To prepare intestinal homogenates, animals were anesthetized as the above procedure, a 10-15 cm intestinal segment of interest (duodenum, jejunum and ileum) was isolated and removed. The excised intestinal segment was washed with ice-cold buffer and the mucosa was removed from the intestine by scraping the intestine. The intestinal mucosa was weighed and then homogenized with enough ice-cold blank K-R buffer solution to make a 20% w/v homogenate using a homogenizer. The homogenate was then centrifuged for the resultant supernatant, which was used to prepare metformin solution (10, 50, 200 µg/mL) with doxofylline (20 µg/mL) for stability studies of metformin.

Single pass intestinal perfusion experiment

SPIP studies were performed using established methods as previously described^[12,13]. Male Wistar rats weighing 180 g to 230 g were fasted overnight before the perfusion experiment with free access to tap water only. The rats were anesthetized with i.p. injection of urethane (0.7 mL/100 g) and placed on a heating operating table to maintain a body temperature of 37°C. Upon verification of the loss of pain reflex the abdomen was opened by a 3-4 cm midline longitudinal incision of and a 10-15 cm intestinal segment (duodenum, jejunum and ileum) was isolated and cannulated at both ends with plastic tubing. The segment was first rinsed with 37°C saline to clear the segment, and approximately 10 cm of the inlet tubing was placed inside the abdominal cavity to achieve an inlet perfusion solution at 37°C. Drops of saline were added onto the surgical area, which was then covered with wet pledget to avoid loss of fluid. The experiment was initiated by rapidly filling the segment with perfusion solution and the time was set zero with the immediate start of the perfusion. The perfusion rate was 0.2 mL/min. After approximately 30 min, when steady-state was achieved, the outlet perfused samples were collected on ice at 15 min intervals up to 105 min. Samples were frozen immediately and stored at -20°C. At the end of the experiment, the perfused intestinal segment was measured without stretching.

Effects of drug concentration and different intestinal site on intestinal absorption

Thirty rats were divided into 6 groups ($n = 5$) in the present study. SPIP was performed in different intestinal segments (duodenal, jejunal and ileal segment) to test if the intestinal absorption of metformin could exhibit the characteristics of intestinal site dependence. Each intestinal segment was isolated as follows: duodenum segment beginning from pylorus, jejunum segment beginning from 25 cm away from pylorus, while ileum segment the beginning at the site 20 cm upwards caecum. The above seg-

ments were perfused with solution containing 50 µg/mL metformin and 20 µg/mL phenol red. The experimental operation was carried out as described above.

Perfusion solutions of different drug concentrations were perfused to investigate the intestinal absorption mechanism of metformin. Duodenum segment was selected as the perfused segment, perfusion solutions containing 10, 50, 200 µg/mL metformin as well as 20 µg/mL phenol red were perfused to test if the permeability values exhibit concentration-dependent changes.

Effects of P-gp on intestinal absorption

Duodenum segment was selected for perfusion, 400 µg/mL verapamil was added to the perfusion solution (containing 50 µg/mL metformin and 20 µg/mL phenol red) as an inhibitor of P-gp exiting along the gastrointestinal track, then the changes of metformin absorption were determined to find out if the intestinal absorption of metformin was affected by P-gp exiting along the gastrointestinal track.

Sample analysis

The absorption and stability of samples were analyzed by the HPLC system at UV 250 nm with the oven temperature at 40°C. Analytes were separated on a DiamonsilTM ODS C₁₈ column (5 µm, 200 mm × 4.6 mm I.D.). The mobile phase was made up of methanol: 20 mmol/L NH₄AC (containing 1% 0.25 mol/L IPR-B₈) = 30:70 (V:V). The flow rate was 1.0 mL/min. Doxofylline (20 µg/mL) was used as an internal standard. Retention time for metformin, doxofylline, phenol red was 5.1 min, 7.2 min and 11.6 min respectively. All sample peaks were well separated (Figure 2).

Data analysis

Calculations were based on outlet perfusate steady-state concentrations achieved after approximate 30 min. The steady-state intestinal effective permeability (P_{eff} , cm/s) was calculated according to a parallel tube model^[14-16]:

$$P_{eff} = [-Q_{in} \cdot \ln (C_{out}/C_{in})] / A \quad (1)$$

Where Q_{in} is the perfusion flow rate (0.2 mL/min), A is the mass transfer surface area within the intestinal segment assumed to be the area of a cylinder ($2\pi rL$) with the length (L) (measured after 45 min) and radius (r) of $0.18 \text{ cm}^{[15,17]}$, C_{in} and C_{out} are the inlet and fluid-transport-corrected outlet solution concentrations, respectively. The latter was corrected by multiplying the inlet concentration with $[\text{phenol red}]_{in}/[\text{phenol red}]_{out}$.

Standard curve

Metformin stock solution (5, 10, 20, 50, 100, 200 µL) of and phenol red stock solution (10, 20, 30, 40, 50, 60 µL) were precisely drawn, then diluted to 1 mL with K-R buffer solution to make corresponding solutions containing metformin and phenol red 5 and 10, 10, 20, 30, 40, 50, 60 µg/mL phenol red, respectively. The solutions were then injected for determination of calibration curve. The regression curve for metformin and phenol was $Y = -0.00634 + 0.00599X$ ($r = 0.9998$) and $Y = -0.00814 + 0.00870$ ($r = 0.9995$), respectively, indicating good linear correlations.

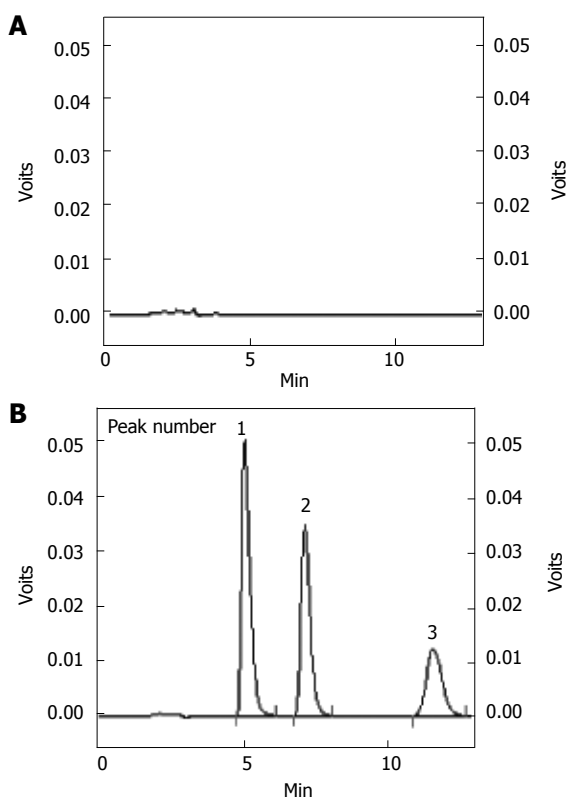

Figure 2 Representative chromatograms of blank (A) and *in situ* perfusion (B) samples containing metformin, doxofylline and phenol red (1: metformin; 2: doxofylline; 3: phenol red).

Accuracy and precision

The intraday and interday precision as well as the accuracy were determined with quality control samples, and five replicates each were analyzed on three consecutive days. Three concentrations were chosen from the high medium and low range of the standard curve (10, 50, 200 $\mu\text{g/mL}$ for metformin and 20, 40, 60 $\mu\text{g/mL}$ for phenol red). Precision was expressed as the relative standard deviation (RSD%). Accuracy was expressed as the mean relative error (RE%). A precision (RSD%) less than or equal to 15% and a accuracy (RE%) less than or equal to 15% were accepted. The data are summarized in Table 1.

Recovery

The absolute recovery was determined at three concentrations (10, 50, 200 $\mu\text{g/mL}$ for metformin, and 20, 40, 60 $\mu\text{g/mL}$ for phenol red) ($n = 6$ at each concentration). Results showed that the absolute recovery of metformin at these three concentrations ranged from $97.6 \pm 3.73\%$ to $101.6 \pm 3.14\%$, with RSD% less than 3.83%.

Stability studies

The stability study consisted of stability studies in the K-R buffer solutions (unperfused and blank perfused) as well as in homogenates of the intestine. The stability of metformin was based on the decrease of the parent compound after 2 h incubation in 37°C water bath as quantitated by HPLC. The stability was determined at concentration of 50 $\mu\text{g/mL}$ metformin, and 40 $\mu\text{g/mL}$ phenol red, $100.8 \pm 0.74\%$ and $108.1 \pm 3.22\%$ metformin

Table 1 Accuracy and precision data for assays of metformin and phenol red in perfused solution

Concentration ($\mu\text{g/mL}$)	Intra-d ($n = 5$)		Inter-d ($n = 5$)	
	Accuracy Mean RE %	Precision CV %	Accuracy Mean RE %	Precision CV %
Metformin				
10	-0.9	3.2	-3.5	4.2
50	1.5	1	6.8	6.3
200	0.9	2.1	10.5	0.7
Phenol red				
20	-2.4	3.8	7.8	6.4
40	-1.4	2.1	6.6	6.1
60	1.6	3.1	14.4	3.3

remained after perfusion with unperfused and perfused blank K-R buffer for 2 h. For the perfusion with intestinal homogenate, 2 h incubation at least $87.5 \pm 0.69\%$ metformin remained in the homogenate ($101.9\% \pm 1.74\%$, $87.5\% \pm 0.69\%$ and $90.0\% \pm 1.75\%$ for duodenal, jejunal, ileal homogenate, respectively). Results demonstrated that in the stability study, metformin was sufficiently stable ($> 80\%$ remaining) for the duration of the SPIP experiment (90 min) in K-R buffer solution, perfused K-R buffer solution and intestinal homogenates.

Statistical analysis

The results reported were expressed as means \pm SD. The statistical difference between treatment groups was evaluated using analysis of variance (ANOVA) and the identification of significance was carried out with LSD *post hoc* test. $P < 0.05$ was considered statistically different.

RESULTS

Intestinal permeability of metformin was determined in rat intestine segments (duodenum, jejunum and ileum) using *in situ* single-pass perfusion technique and the samples were analyzed by the proposed method. Effective permeability values were calculated from the steady-state concentrations of compounds in the perfusate collected from the outlet. Steady-state was confirmed by the ratio of the outlet to inlet concentrations (corrected for water transport) *versus* time. Representative results are shown in Figure 3. The effective permeability values for each intestinal segment at each concentration are plotted in Figure 4.

Effects of drug concentration and different intestinal site on intestinal absorption

Intestinal absorption site dependent changes in permeability were found in the jejunum and ileum where the permeability at 50 $\mu\text{g/mL}$ of metformin [$(3.26 \pm 0.73) \times 10^5$ and $(2.96 \pm 0.36) \times 10^5$ cm/s, respectively] was significantly different from those in the duodenum at the same concentration [$(4.51 \pm 1.08) \times 10^5$ cm/s, $P < 0.05$]. Furthermore, concentration dependent changes in permeability were also found in the duodenum where the permeability at 200 $\mu\text{g/mL}$ of metformin [$(2.70 \pm 0.63) \times 10^5$ cm/s] was significantly different from that at 10 $\mu\text{g/mL}$ of metformin $(4.71 \pm 0.86) \times 10^5$ cm/s and 50 $\mu\text{g/mL}$ of metformin $(4.51 \pm 1.08) \times 10^5$ cm/s, $P < 0.05$.

Figure 3 Approach to steady-state for metformin existing in the intestinal perfusate ($n = 5$).

Effects of P-gp on intestinal absorption

The P-gp efflux inhibitor, verapamil did not affect the measured duodenum P_{eff} for metformin at 50 $\mu\text{g/mL}$. No significant increase in permeability was found after co-perfusion with verapamil (400 $\mu\text{g/mL}$) in duodenum [$(4.51 \pm 1.08) \times 10^{-5}$ cm/s for metformin at 50 $\mu\text{g/mL}$ and $4.53 \pm 1.75 \times 10^{-5}$ cm/s for co-perfusion with 400 $\mu\text{g/mL}$ verapamil].

DISCUSSION

Drugs can cross membranes either by passive processes or by mechanisms involving the active participation of components of the membrane. In the former the drug molecule usually penetrates by passive diffusion along a concentration gradient by virtue of its solubility in the lipid bilayer. The two most common ways for the absorption of drugs are passive transfer by diffusion across the liquid membranes and passive diffusion through the aqueous pores at the tight junctions between cells, which are referred to as transcellular and paracellular absorption, respectively. Transcellular absorption is the predominant pathway for more lipophilic molecules^[18]. In contrast, the paracellular route of absorption is limited to small, hydrophilic compounds^[19]. Active transport (carrier-mediated membrane transport) is characterized by selectivity, competitive inhibition by congeners, a requirement for energy, saturability, and movement against an electrochemical gradient. Intestinal transport of a compound commonly employs a combination of several mechanisms. The relative importance of each pathway depends on a variety of physicochemical and physiological conditions.

The intestinal permeability is the propensity of a compound to move across the epithelial barrier of the intestine. *In vitro* and *in situ* absorption models, such as *in situ* perfusion of rat intestine, Caco-2 cell monolayer model, and excised intestinal segments in the Ussing chamber, are commonly used to investigate transport mechanism, classify permeability and *in vivo* absorption of drugs in humans^[20,21]. Comparisons between human P_{eff} data and these preclinical permeability models showed that they could be used to investigate and classify passive transport with a high accuracy^[22]. Recently, a GI-transit-absorption model (GITA) has been developed to analyze and predict drug absorption, and there is some evidence that this model is

Figure 4 Effective permeability, P_{eff} (cm/s) of metformin using single-pass intestinal perfusion. For each region, P_{eff} of metformin was determined at 50 $\mu\text{g/mL}$. For duodenum segment, P_{eff} of metformin was determined at 10, 50, 200 $\mu\text{g/mL}$, as well as 50 $\mu\text{g/mL}$ with addition of verapamil. The data were presented as mean \pm SD ($n = 5$ in each group). ^a $P < 0.05$ vs 10 and 50 $\mu\text{g/mL}$ metformin in duodenum; ^c $P < 0.05$ vs 50 $\mu\text{g/mL}$ metformin in duodenum.

very useful for estimating the absorption kinetics of drugs with various characteristics as well as the human data^[23].

Among the various models, cell-based assays using Caco-2 and MDCK cell lines are commonly used to predict passive absorption and the results obtained are greatly affected by experimental parameters such as pH^[24]. In contrast, *in situ* approaches provide experimental conditions closer to what is encountered following oral administration, with a lower sensitivity to pH variations due to a preserved microclimate above the epithelial cells^[25,26]. These techniques maintain an intact blood supply to the intestine, and can be used to estimate the impact of clearance pathways, such as enzymes and transporters, that are present in the gut. Moreover, drug permeability^[27], expression of drug metabolizing enzymes and transporters have been shown to vary along the intestinal tract^[28-30], which can be investigated using intestinal perfusion of the various regions. In addition, it was recently reported that oral drug absorption in rats and humans is very similar^[31]. Thus, it is likely that the intestinal perfusion conducted in rats may give a better prediction of the fraction of oral dose absorbed in humans than in *in vitro* models.

The SPIP procedure assumes that loss of drug during the perfusion is due to permeation of the intestine. Therefore, determination of the non-absorptive loss of perfused drug is required. Results of preliminary studies have confirmed that the loss of metformin in the SPIP study could be attributed to the intestinal absorption, and the confidence of the calculated permeabilities is high. The intestinal effective permeability represents a direct measurement of the local absorption rate and reflects the transport velocity across the epithelial barrier, expressed as centimeter per second^[32]. In the present study, SPIP was performed in three different intestinal segments to test if the intestinal absorption of metformin exhibited site-dependent changes. The results indicated that metformin could be absorbed along the whole intestine with the main absorption site at duodenum, contributing to the drug absorption. Further comparison of permeability values among high, medium and low concentrations in the duodenal segment demonstrated a concentration-dependent

change, exhibiting a decrease in permeability at the highest drug concentration. The result suggested that intestinal absorption of metformin was *via* passive and transcellular mechanism involving an active saturable process, or *via* a membrane transport protein in the gut wall, especially in the duodenum.

The present study also demonstrated that metformin could not be used as a substrate for rat intestinal P-gp because permeability values of metformin in the duodenum segment at 50 µg/mL were not increased by co-perfusion of the P-gp inhibitor verapamil, suggesting that metformin cannot be efficiently transported by P-gp in the gut wall, however, a saturable process may be involved in the intestinal transport of metformin. Since the SPIP experimental protocol cannot completely elucidate transport mechanism (i.e. inability to conduct directional transport studies), further studies with cultured cells or isolated tissue are necessary to identify the particular reason for the concentration dependent changes in permeability. Such studies would permit determination of both influx and efflux permeabilities. Experiments with cells transfected with the gene coding for a particular transport would further identify the specific protein involved in the carrier-mediated process.

Effective intestinal permeability estimated from *in situ* perfused rat intestine has been shown to correlate well with the extent of *in vivo* absorption in humans after oral administration of carrier-mediated absorbed drugs^[33]. It was recently reported that special care must be taken for drugs with a carrier-mediated transport mechanism^[22]. Furthermore, although *in situ* perfusion technique is time consuming, it provides a greater correlation with intestinal absorption in humans than Caco-2 and MDCK cell lines. Thus human intestinal permeability values of metformin may be predicted from permeability values obtained in this rat SPIP experiment according to^[16]:

$$P_{eff,man} = 3.6 \cdot P_{eff,rat} + 0.03 \cdot 10^{-4} \quad (2)$$

Based on the predicted permeability value in humans, the fraction absorbed in humans (fa_{man}) can further be predicted from rats for carrier-mediated absorbed drugs by^[34]:

$$fa_{man} = 1 - e^{-[2 \cdot P_{eff,man} \cdot t_{res} / r \cdot 2.8]} \quad (3)$$

Where t_{res} is the average small intestine transit time, r is radius in humans (assumed to be 3h and 1.75 cm, respectively).

Using equation (3) and the lowest permeability value of metformin obtained in this study (2.70×10^{-5} cm/s in the duodenum at 50 µg/mL of metformin), the permeability value of metformin in humans was estimated to be 1.0×10^{-5} cm/s. Then applying equation to metformin for the lowest permeability value in humans in this study gave an estimated fa_{man} of 74%, while for the highest one gave an estimated fa_{man} of 90%, which is in accordance with the previously reported values^[2,3].

The successful development of oral drug delivery formulations requires characterization of the intestinal absorption. Before the preparation for oral administration of extended-release and controlled-release system and targeting drug release system in gastrointestinal track, characteristics of drug absorption and transfer in the gastrointestinal track should be carefully studied and well understood. In general, appropriate candidates for extended-

release and controlled-release preparations are molecules that have poor colonic absorption but are characterized by better absorption properties at the upper parts of the gastrointestinal tract^[16]. Results of the present study showed that metformin could be absorbed in the whole human intestine, with the main absorption site at duodenum. However, it was reported that absorption of metformin in human intestine is incomplete, 20%-30% of an oral dose can be recovered in the faeces. Furthermore, it has been reported that oral absorption of the drug is slower than that of elimination^[35]. Therefore special care should be paid to the drug content and drug administration times (maybe 2 times/d) when preparing extended-release and controlled-release formulations in order to maintain the effective blood concentration. The common side effects of metformin therapy could be concluded as gastrointestinal symptoms, such as abdominal discomfort, nausea, and diarrhea that especially occur during the initial weeks of treatment^[36]. Employing of extended-release technique could reduce the direct drug stimulation to the gastrointestinal tract, and may reduce the above gastrointestinal symptoms due to the lower peak exposure of intestinal tissue to the drug.

In conclusion, intestinal permeability of metformin is concentration- and site- dependent. Fraction of the oral dose absorbed after oral administration is 74%-90% along the whole human intestine. Intestinal absorption of metformin may be *via* passive and transcellular mechanism involving an active, saturable process, or *via* a membrane transport protein in the gut wall, especially in the duodenum. The observed intestinal permeability values obtained in the SPIP model fit well the pattern observed in previous permeability studies for other structural different drugs in rat intestine.

Abstract

AIM: To study the inhibitory effects of Fuzheng Yiliuyin (Decoction for Suppressing Tumors by Strengthening the Body Resistance) in combination with chemotherapeutics on human gastric carcinoma cell strain.

METHODS: Fuzheng Yiliuyin (ZY) combined with various kinds of chemotherapeutics was put into two kinds of cultivated human gastric carcinoma cell strains, then its inhibitory effects on human gastric carcinoma cell strains were determined by the MTT method. Flow cytometer was used to assay the apoptosis rate, and the ultrastructure of gastric carcinoma cells was observed under transmission electron microscope.

RESULTS: Obvious apoptosis was seen in gastric carcinoma cells after treatment with ZY for 72 h. ZY and chemical drugs had synergistic inhibition effects on the cultivated gastric carcinoma cells, but the effects were different on various cell strains. The inhibitory effects of ZY could be strengthened by cytotoxic action and apoptosis. ZY combined with fluorouracil, etoposide and cisplatin (EFP) chemotherapeutics had better inhibitory effects on SGC-7901, while ZY combined with EFP or with DDP chemotherapeutics had better inhibitory effects than other drugs on MGC-803.

CONCLUSION: ZY induces apoptosis and inhibits the growth of gastric carcinoma cells. ZY has the synergistic function of chemotherapeutics.

Key words: Human gastric carcinoma cell strain; Traditional Chinese medicine; Chemotherapeutics

INTRODUCTION

Fuzheng Yiliuyin (ZY) has been used for 30 years to treat gastric carcinoma in our clinic. ZY is prepared from eleven herbs: milkvetch root, bighead atractylodes rhizome, Chinese Thorowax root, common Burreed rhizome, Zedoary, Radix Notoginseng, Dandelion, spreading Hedyotis herb, Agrimony, Tamariskoid spikemoss herb and Glycyrrhizia. Most of these herbs can inhibit cell proliferation, induce apoptosis and have anti-cancer effects^[1-4]. *In vitro* experiment has confirmed that Fuzheng Yiliuyin is effective in inhibiting proliferation of gastric cancer cells and induces apoptosis^[5]. Further double-blind placebo-controlled trial of chemotherapy plus Fuzheng Yiliuyin/placebo in advanced stage gastric cancer showed that ZY has anti-gastric cancer effects with lower side effects^[6]. Traditional Chinese medicines TCM could increase the effects and decrease the side effects of chemotherapeutics. However, whether TCM can increase all of the therapeutic effects of chemotherapeutics and whether the mechanism is the same remain unclear.

MATERIALS AND METHODS

Patients

The human gastric mucinous adenocarcinoma cell line (MGC-803) with lower differentiation was obtained from the Center of Molecular Biology of Xi'an Jiaotong University, China. The human gastric adenocarcinoma cell line (SGC-7901) with lower metastasis was obtained from Xijing Hospital of the Fourth Military Medical University, China. Fuzheng Yiliuyin (ZY) extract contains 2 g/L crude herbs, which was produced by Xi'an Jiaotong University. Fluorouracil (5-FU, Shanghai Pharmaceutical Factory), etoposide (Vp-16 Lianyungang Pharmaceutical Factory), cisplatin (DDP, Dezhou Pharmaceutical Factory), adriamycin (Pharmacia and Upjohn), annexin-V-FITC and PI (Roche), EDTA and MTT (Sigma) were used in the study.

Cell culture

Cells were cultured in RPMI1640 medium (pH 7.2-7.4)

containing 100mL/L foetal calf serum (FCS), penicillin and streptomycin at 37°C in a humidified (95%) incubator containing 95% air and (50mL/L) 5% CO₂. Cells were routinely sub-cultured using 2.5 g/L trypsin/ethylenedinitrile tetra-acetic acid (EDTA) solution.

MTT assay for determination of cell growth

Cell proliferation was determined by counting viable cells over time using trypan blue exclusion as the basis of viability. The logarithmically growing SGC-7901 and MGC-803 cells were plated at a density of 5×10^7 cells/L per well into a 96-well plate. After 24 h, the cells were treated with 1mg/L ZY in combination with 5-Fu, Vp-16, ADM, DDP, EFP and EAP, respectively for 24, 48, and 72 h. Control wells were treated with RMP11640 medium alone. Then 20 μ L MTT (5 g/L) was added to each well and incubated for an additional 4 h. After the culture media were discarded, 0.15 mL DMSO was added and vibrated for 10 min. The absorbance was measured at 570 nm using a Model 550-microplate reader. The inhibitory rates (IR) were calculated according to the following formula:

IR (%) = (1-absorbance of the treated wells)/(absorbance of the control wells) \times 100%.

Flow cytometry of apoptosis by annexin-V and PI double-staining

At the end of treatment, the cells were harvested by trypsin-EDTA solution to produce single cell suspension. Annexin-V and PI double staining kit (Roche) were used to assess apoptosis. The cells were analyzed by flow cytometry. Early apoptotic cells were localized in the lower right quadrant of a dot-plot graph using annexin-V-fluorescein and PI.

Cell morphology observation

The SGC-7901 and MGC-803 cells were separately incubated with 1mg/L ZY for 72 h. The culture medium was discarded, the cells were collected by gently scraping and washed three times in ice-cold PBS, then fixed with a solution of 2% formaldehyde and 3% glutaraldehyde in 0.1 mol/L sodium cacodylate buffer (pH 7.4) for 1 h. The fixed cells were washed three times in cacodylate buffer (pH 7.2) containing 0.2 mol/L sucrose, fixed with 1% osmic acid in 0.3 mol/L cacodylate buffer, dehydrated in

a graded series of acetone, and embedded in epoxy resin. Ultrathin sections were cut, stained with uranyl acetate and lead citrate, and assessed by electron microscopy

Statistical analysis

Data were expressed as mean \pm SD. Analysis of data was performed using one-way ANOVA. $P < 0.05$ was considered statistically significant.

RESULTS

SGC-7901 and MGC-803 cells were treated with various chemotherapeutics. Cell viability was determined by MTT assay. ZY increased the inhibitory effects of various chemotherapeutics on both kinds of cells in a time-dependent manner. ZY in combination with EFP had a better effect on SGC-7901 cells, while ZY in combination with DDP and EFP had a better effect on MGC-803 cells ($P < 0.05$).

After SGC-7901 and MGC-803 cells were exposed to ZY in combination with various chemotherapeutics for 72 h, annexin-V and PI double-staining FCM analysis showed that the apoptosis rates of SGC-7901 and MGC-803 cells were quite different after treated with different drugs. ZY increased anticancer effects of chemotherapeutics by directly enhancing the toxic effects or by inducing apoptosis (Table 2).

In order to confirm the cell apoptosis induced by treatment with ZY, the morphological changes of apoptosis were evaluated by transmission electron microscopy. Changes were observed in SGC-7901 cells (Figure 1A) and MGC-803 cells (Figure 1B) after treated with ZY, such as blebbing and loss of microvilli, vacuolation in cytoplasm, condensation of cytoplasm and nuclei, and fragmented

chromatin, which provided further evidence for the induction of apoptosis as a consequence of ZY treatment.

DISCUSSION

Gastric cancer is a common malignant tumor of the alimentary tract and its incidence is among the three leading kinds of neoplasm in different regions of China^[7,8]. Conventional treatments for advanced gastric cancer including extended resection, radiotherapy and chemotherapy have little influence on the improvement of patients' survival. Combinations such as FAMTX, ELF, EAP and EFP, produce an overall response rate of about 20% to 50%^[9-12]. Though combination chemotherapy for local advanced gastric cancer is effective, it is often associated with severe side effects, including fatal outcome.

Traditional Chinese herbal medicines can enhance the efficacy and reduce the toxicity of chemotherapy and radiotherapy by improving anticancer host defense mechanism and inducing apoptosis^[13-19]. The use of Chinese herbal medicine in combination with radiotherapy or chemotherapy is a better procedure in the treatment of advanced cancer.

This study showed that Chinese herbal medicines could increase the effects of chemotherapy on gastric cancer, but the cytostatic effect of it is different between different differentiation cells. This is why the same Chinese herbal medicine in combination with the same chemotherapy is effective in some patients and less effective in other patients. Though combined chemotherapeutic agents may show a better sensitivity than a single agent, and various drugs show various effects on various alimentary tract tumors^[20]. In this study, ZY in combination with a single chemotherapeutic agent or with several chemotherapies had the similar inhibitory effects on the same cells, suggesting that individual therapy should be performed based on the type and differentiation degree of tumors. Individual chemosensitivity is essential to chemotherapy for gastric cancer^[21].

Apoptosis plays a critical role in tumor initiation, progression, as well as in cancer therapy^[22]. In the present study, we investigated the inhibitory effects of ZY plus chemotherapy on gastric carcinoma SGC-7901 and MGC-803 cells. ZY caused not only cellular necrosis but also induced apoptosis and inhibited the proliferation of gastric cancer cells, indicating that TCM in combination with chemotherapy can induce apoptosis. In conclusion, ZY can be used in treatment of gastric cancer.

Abstract

AIM: To analyze the clinical characteristics of Chinese hereditary nonpolyposis colorectal cancer (HNPCC) families and to screen the germline mutations of human mismatch repair genes hMLH1 and hMSH2 in the probands.

METHODS: Thirty-one independent Chinese HNPCC families were collected in Zhejiang Province. All of them met Chinese HNPCC criteria. Clinical data about patient gender, site of colorectal cancer, age of onset, history of multiple colorectal cancer, associated extracolonic cancer were recorded. PCR and denaturing high performance liquid chromatography (DHPLC) were employed to screen the mutations. Sequencing analysis was used to find out the exact mutation site and characteristics of the samples showing abnormal DHPLC profiles.

RESULTS: One hundred and thirty-six malignant neoplasms were found in 107 patients including 14 multiple cancers. One hundred and six of the 136 neoplasms (77.9%) were diagnosed as colorectal cancer, with an average age of onset at 48.57 ± 29.00 years. Gastric cancer was the most common extracolonic cancer (10.3%) in these families. Twenty-three different sequence variations in hMLH1 and hMSH2 genes were detected in these 17 families. Fifteen sequence variations were located in the exons, including 5 SNPs, 3 silent mutations, 3 missense mutations, 2 nonsense mutations and 2 frameshift mutations. The latter seven mutations seemed to be pathogenic.

CONCLUSION: Germline mutations of hMLH1 and hMSH2 genes are identified in about one-third HNPCC kindreds fulfilling Chinese HNPCC criteria. Chinese HNPCC families have some particular clinical characteristics, such

as a left-sided predominance, less synchronous or metachronous colorectal cancer, and frequent occurrence of gastric cancer.

INTRODUCTION

Hereditary nonpolyposis colorectal cancer (HNPCC) is an autosomal dominantly-inherited cancer susceptibility syndrome. It is estimated that HNPCC may account for 5%-10% of the total colorectal cancers (CRC) worldwide^[1]. Clinically, HNPCC families are diagnosed based on the Amsterdam criteria. Although the Amsterdam criteria unify the diagnosis of HNPCC worldwide, they are too rigid to exclude extracolonic cancers associated with HNPCC. New criteria and guidelines have been proposed, such as the Japanese criteria, suspected HNPCC criteria. Based on the suspected HNPCC criteria and the specific characteristics of the tumor spectrum in Chinese population, the Chinese Hereditary Colorectal Cancer Collaboration has established the criteria for Chinese HNPCC families^[2].

Six genes (hMSH2, hMLH1, hPMS1, hPMS2, hMSH6/GTBP and hMLH3) involved in DNA mismatch repair have been proven to be closely related with the development of HNPCC. hMLH1 and hMSH2 genes are thought to be the main genes responsible for HNPCC, because more than 90% detected germline mutations in HNPCC families are located in these two genes^[3]. Denaturing high-performance liquid chromatography (DHPLC) is a mutation pre-screening method^[4]. The major advantage of DHPLC is the low cost and the high speed of analysis. Therefore, in this study, we analyzed the clinical characteristics of our 31 Chinese HNPCC families registered in our cancer institute, and screened the germline mutations of hMLH1 and hMSH2 genes by DHPLC and DNA sequencing.

MATERIALS AND METHODS

Clinical data

Thirty-one families involved in this study fulfilling the Chinese HNPCC criteria were collected in Zhejiang Province. Detailed familial and medical histories were obtained through an interview with the probands, a home visit to extended family members and an extensive review of medical records if available. Peripheral blood samples were collected from all participants after formal written consent was signed. Eligible HNPCC families were registered and family members were followed up intensively. All patients were reviewed by telephone or by outpatient visit at regular intervals. Data concerning sex, site of CRC, age of diagnosis, history of synchronous and/or metachronous CRC, instance of extracolonic cancers, and histopathology of tumors were documented and thoroughly verified.

Genomic DNA preparation and PCR

Genomic DNA was extracted using the QIAamp DNA isolation kit (Qiagen, Valencia, CA) according to the manufacturer's recommendations. PCR was performed using 100 ng of genomic DNA as template. A 25 μ L reaction mixture containing 10–20 pmol of each primer, 1.5 U of Taq DNA polymerase (Transgenomics, UK) with a final concentration of 2 mmol/L Mg^{2+} and 0.2 mmol/L of dNTPs was used. PCR conditions were as follows: an initial denaturing at 95°C for 5 min, followed by 40 cycles at 95°C for 30 s, at 55–60°C for 30 s, at 72°C for 40 s, and a final extension at 72°C for 10 min. A total of 35 sets of primers including 19 sets for hMLH1 gene and 16 sets for hMSH2 gene were used^[15].

DHPLC analysis

DHPLC analysis was carried out on an automated HPLC device equipped with a DNA separation column (WAVE: Transgenomic, San Jose, CA, USA) as previously described^[6].

DNA sequencing

PCR products displaying abnormal DHPLC peak were purified with microconcentrator filters (Amicon, Beverly, MA) and sequenced with a Bioasia-1524-030/3730 DNA sequencer. All mutations were sequenced in both directions.

RESULTS

Clinical characteristics of HNPCC families and probands

A total of 31 kindreds meeting the Chinese HNPCC criteria or the Amsterdam criteria were studied. One hundred and thirty six malignant neoplasms were found in 107 patients (14 multiple cancers), including 106 CRCs, 14 gastric cancers, 3 esophageal cancers, 2 lung cancers, 2 cervical cancers, 2 leukemia, 1 breast cancer, 1 ovarian cancer, 1 oral cancer, 1 thyroid cancer, 1 hepatic cancer, 1 urinary cancer, 1 malignant histiocytosis. CRC accounted for 77.9% (106/136) of the cancers. Nine multiple colorectal tumors and 5 colorectal tumors were associated with extracolonic cancer, accounting for 8.5% and 4.5% of the total CRCs, respectively. Of the 106 CRCs, 18 were located in the

right-sided colon, 8 in the transverse colon, 15 in the left-sided colon, 25 in the rectum and 40 in unidentified site. Left-sided colon cancers constituted of 60.6% (40/66) of all CRCs. Individuals suffering from gastric cancer accounted for 10.3% (14/136) of total patients. The average age of malignant neoplasm onset in all the patients was 48.82 ± 13.32 years and the ratio of males to females was 1.7:1. The average age of CRC patients was 48.57 ± 29.00 years. All predispositions in kindreds were followed up.

Mutations of hMLH1 and hMSH2 genes

A total of 23 abnormal peak profiles were found in 31 probands from 31 families. Finally, 17 probands were identified with 23 base variations by sequencing analysis, of which 7 base substitutions were located in the hMLH1 gene (6 in the exons, 1 in the intron) while the other 16 base substitutions were located in the hMSH2 gene (9 in exons, 7 in introns). Of the fifteen base substitutions in coding sequences, five were proven to be polymorphisms (SNPs), while the other ten were proven to be mutations, including 3 missense mutations (samples H4, H11 and H12), 2 nonsense mutations (samples H20 and H27), 2 frameshift mutations (samples H24 and H29), and 3 silent mutations (samples H5, H16 and H28). The detailed information is shown in Table 1 and Figure 1.

DISCUSSION

HNPCC is characterized by dominant right colon localization, early age of onset, high prevalence of synchronous and metachronous tumors, and certain extracolonic cancers^[14]. In our study, patients with Chinese HNPCC developed CRC at an average age of 48.57 ± 29.00 years. As compared to the onset of sporadic colorectal malignancies at the age approximately 60 years, the onset of HNPCC was much earlier, similar to that in Western countries. In the present study, synchronous and metachronous colorectal cancers only accounted for 8.5% of all CRCs, lower than those in Western countries. The reason is still unclear. Left-sided colorectal cancers accounted for 60.6% (40/66) of all CRCs. This result might be due to the high incidence of left-sided colon cancer (including rectal cancer) in Chinese population. Gastric cancer was the most frequent extracolonic cancer in our 31 families, while endometrial cancer was the most common in Western countries. The reason might be due to the high incidence of gastric cancer in Chinese population. Liu *et al.*^[15] have reported similar results found in their cohort of Chinese HNPCC families. These characteristics might truly reflect the specific clinical phenotype of Chinese HNPCC.

In this study, we screened mutations of the hMLH1 and hMSH2 genes in 31 Chinese HNPCC families by DHPLC and PCR as well as DNA sequencing. Twenty-three sequence abnormalities were detected in 17 probands, 15 in exons and 8 in introns. Base variants identified were compared with those described in the human gene mutation database (HGMD) (<http://www.uwcm.ac.uk/uwcm/mg/hgmd0.html>). Seven of the 15 sequence abnormalities including 3 missense mutations (H4, H11, H12), 2 nonsense mutations (H20, H27), and 2 frameshift mutations (H24, H29) in coding regions of the hMLH1

and hMSH2 genes might probably affect the protein functions. Detailed information of these mutations is listed in Table 1. Among them, mutations of H4, H11 and H20 have been reported before^[8,9,12], while the other four mutations of H12, H27, H24 and H29 are novel. The mutation rate was 22.6% (7/31). Nearly half of the mutations were missense mutations. Three (H5, H16, H28) of the fifteen sequence abnormalities in coding sequences are novel silent mutations in exons 1, 7, 5 of the hMSH2 gene, respectively. The last five (H3, H7, H16, H21 and H22) of

the fifteen sequence abnormalities in coding sequences are known as SNPs^[7,10,11,13].

The missense mutation detected in sample H4 located at codon 67 in exon 2 of the hMLH1 gene, has been reported as a pathological mutation^[8]. The missense mutation detected in sample H11 located at codon 629 in exon 12 of the hMSH2 gene has also been reported^[9]. In sample H12, a novel missense mutation at codon 839 in exon 15 of the hMSH2 gene was first discovered in our study, which is located in the Muts V structural motif

(peptides 619-854) of the hMSH2 gene and leads to amino acid change from histidine to arginine. In order to determine the significance of this mutation, 100 blood samples from cancer-free donors were tested under the same conditions and none of the 100 normal samples harbored the same base change as sample H12, suggesting that this base change is pathologic.

The nonsense mutation detected in sample H20 altered nucleotide 2250 (genomic DNA) from C to G at codon 750 in exon 19 of the hMLH1 gene, resulting in a stop codon instead of tyrosine, forming a truncated protein of MutL losing 6 peptides from 751 residue to 756 residue. This nonsense mutation has been reported by Syngal *et al.*^[12]. The other nonsense mutation in sample H27 altered nucleotide 2292 (genomic DNA) from G to A at codon 764 in exon 11 of the hMSH2 gene, leading to the substitution of a stop codon TGA for tryptophan condon TGG, forming a truncated protein of MutC structural motif (peptides 619-854) losing 170 peptides from 765 residue to 934 residue, suggesting that these nonsense mutations may have a causative effect on cancer predisposition and further studies are needed to examine their co-segregation with the phenotype.

Two frameshift mutations detected in samples H24 and H29 have not been reported previously. In sample H24, the base A deleted at codon 555 in exon 11 of the hMSH2 gene led to a stop codon at codon 556. While in sample H29, the GT deleted at codon 531 in exon 14 of the hMLH1 gene led to a stop codon at codon 555. Both mutations produced truncated proteins with insufficient function.

Of the 23 base variants, 8 were located in intronic regions. Five of these 8 variants have been previously reported and known as SNPs (<http://www.ncbi.nlm.nih.gov/>), the significance of the other 3 remains uncertain.

DHPLC is an elegant, new method for mutation detection. It detects heteroduplex formation in renatured PCR fragments possessing heterozygous sequence variations, and has been applied successfully to mutation screening of various genes^[3]. In the past few years, we have searched successfully for mutations in hMLH1 and hMSH2 genes in 29 HNPCC families and 34 suspected HNPCC families with PCR-SSCP and DNA sequencing methods^[16]. However, SSCP is inefficient in detecting mutations and misses 20% of point and frameshift mutations. Though DNA sequencing is supposed to be a screening method with a high sensitivity, it is time consuming and expensive. It was reported that the sensitivity of DHPLC for screening mutations of the hMLH1 and hMSH2 genes can reach 97% without false negatives^[6]. Furthermore, the system is highly automatic, the running time per sample averages only 7 min. Because of these advantages of DHPLC, it enables a broad screening of HNPCC families for human mismatch repair gene alterations in routine analysis.

Abstract

AIM: To study the influence of high-frequency electric surgical knives on healing of abdominal incision.

METHODS: Two hundred and forty white rats were divided into 10^0 , 10^2 , 10^5 , and 10^8 groups and rat models of abdominal operation were induced by using electric surgical knives and common lancets respectively. Then they were respectively given hypodermic injections of normal saline and 0.2 mL quantitative mixture of *Escherichia coli*, *Staphylococcus aureus* and *Pseudomonas aeruginosa* at a concentration of 10^2 , 10^5 and 10^8 . On the basis of the animal experiment, 220 patients undergoing abdominal operations (above type II) were randomly allocated into one of following three groups: electric knife (EK, 93 cases), electro-coagulation (EC, 55 cases) and control (72 cases). High-frequency electric surgical knives were used to dissect abdominal tissues and electro-coagulation for hemostasis in EK group. Common lancets and electro-coagulation were applied in EC group. Common lancets and tying silk suture were used in the controls.

RESULTS: In all the groups except group 10^0 , infection rate of incisional wounds made by electric surgical knives were remarkably higher than that with common lancets. Furthermore, there were significant differences in groups 10^2 , 10^5 , and 10^8 ($P < 0.05$), but not in group 10^0 ($P > 0.05$) between EK and EC groups. Clinical studies showed a delayed wound healing in 16 cases (17.20%) in EK, 11 cases (16.36%) in EC and 2 cases (2.86%)

INTRODUCTION

The high-frequency electric surgical knife is one of the common instruments in surgical operations. It has many advantages such as easy operation and good hemostatic effect, *etc.* In our clinical practice we found, however, the poor healing rates as well as high infection rate of incision made by electric knife (EK) were remarkably increasing. In order to approach the influence of high-frequency electric surgical knives on healing of the abdominal incisions, we carried out animal experiments with white rats from May to Dec 1999, and also conducted clinical trials on 220 patients undergoing abdominal operations (above level II) from Dec 1999 to Sept 2001. Our study shows that high-frequency electric knives may remarkably delay abdominal incision healing.

MATERIALS AND METHODS

Animal grouping

Experimental animals of Wistar white rats, weighing 150-180 g, were divided into experimental group (EG)

and control group (CG) at random, 30 each. Every group was subdivided into 10^2 , 10^5 , 10^8 groups according to the number of vaccinated bacteria, and 10^0 group using normal saline instead of vaccinated bacteria.

Preparation of bacteria solution

Standard strain sources: Based on WHO recommendation, frozen, dry and pure *Escherichia coli* ATCC (25 922), *Staphylococcus aureus* ATCC (25 923) and *Pseudomonas aeruginosa* ATCC (27 853) were supplied by the Clinical Trial Center of Ministry of Health.

Bacteria suspension solution preparation: The standard strains were vaccinated into plating culture of goat's blood, cultured at 35°C for 24 h to obtain the bacteria suspension solution with a concentration of 0.5 U (equal to 10^8 cfu/mL), then the bacteria solutions were made into 10^5 cfu/mL and 10^2 cfu/mL bacteria suspension solution for stock use.

Quantitative culture of bacteria suspension solutions: Ten microliters of the 10^2 cfu/mL bacteria solution were subjected to culture by pour plate method. The results showed that *Escherichia coli* was 130 cfu/mL, *Staphylococcus aureus* was 125 cfu/mL, and *Pseudomonas aeruginosa* was 110 cfu/mL. The 3 kinds of standard bacteria strain suspension solutions were mixed at equal amount, the colonies were counted, and its bacteria content was 12.67 cfu/mL. Thus bacteria content of 10^2 group was 24.33 cfu/0.2 mL (actual bacteria content was about 0.24×10^2).

One microliter of 10^5 cfu/mL bacteria solution was taken for pour culture. The results showed that *Escherichia coli* was 14 500 cfu/mL, *Staphylococcus aureus* was 115 000 cfu/mL, and *Pseudomonas aeruginosa* was 95 000 cfu/mL. The 3 kinds of standard bacteria strains were mixed at equal quantity, and the bacteria content was 224 500 cfu/mL. Therefore, bacteria content of 10^5 group was 44 900 cfu/0.2 mL (actual bacteria content was about 4.49×10^4).

The 10^8 cfu/mL bacteria solution was diluted to 1/50 of its concentration, and 1 μ L of it was taken for pour culture, the colonies were counted after 24 hours. The results showed that *Escherichia coli* was 130 000 000 cfu/mL, *Staphylococcus aureus* 125 000 000 cfu/mL, and *Pseudomonas aeruginosa* 115 000 000 cfu/mL. The 3 kinds of standard bacteria strains were mixed at equal quantity, and the bacteria content was 123 333 333 cfu/mL. Therefore, bacteria content of 10^8 group was 41 111 111 cfu/0.2 mL (actual bacteria content was about 4.11×10^7).

Experimental procedures

After the animals were anesthetized by ether, the experimental groups were operated with EK through midline incision of abdomen, while the control group with common surgical knives. The No 4 silk thread was used to suture peritoneum. According to the group division, 0.2 mL of the mixed bacteria solution was injected subcutaneously. The skin was sutured, and animals were marked and raised in different cages.

Observational parameters

Criteria for incisional healing: According to Surgery^[1]. The healing is classified as A: first-grade healing, B: second-grade healing, and C: third-grade healing.

Table 1 Comparison of operative incision of 3 groups

Group	n	Type I incision n (%)	Type II incision n (%)	Type III incision n (%)
EK	93	6 (6.45)	83 (89.23)	4 (4.30)
EC	55	3 (5.45)	50 (90.91)	2 (3.64)
Control	72	5 (6.94)	63 (87.50)	4 (5.56)

Grading of incisional infection: Non-infection (Grade I): presence of some granulation tissues in the section. Slight infection (Grade II): presence of a few neutrophil diffuse infiltration, the inflammatory area is smaller than 10% of the section. Moderate infection (Grade III): presence of much neutrophil infiltration, the inflammatory area is between 10% to 30% of the section. Severe infection (Grade IV): presence of severe neutrophil infiltration, the inflammatory area is larger than 30%.

Criterion for grease liquefaction: All those that have bad incision healings and meet the following descriptions could be diagnosed as grease liquefaction: (a) Incision has serum-like solution on the surface of incision. (b) Fat drops are observed with naked eyes or microscopy. (c) No purulent secretion is found. (d) Redness and swelling around the incision. (e) No growth in bacteria cultural medium.

Clinical studies

Patient grouping: A total of 220 patients were randomly divided into EK group, EC (electric coagulation) group, and common surgical knives group (control group). EK group consisted of 93 cases, including 57 males, 36 females, with age ranging from 21 to 80 (average 53.70) years. Fifty-seven underwent biliary system operation, 17 colorectal operation, 8 gastric operation, 5 portal hypertension cutout operation, 3 pancreatic operation, 3 respectively splenectomy, resection of small intestine and intestinal tuberculosis operation. EC group consisted of 55 cases, including 30 males, 25 females, with age ranging from 28 to 67 (average 51.54) years. The patients underwent biliary system operation (including one case for subtotal gastrectomy) (30 cases), gastric operation (11 cases), colorectal operation (4 cases), appendicitis exploratory laparotomy (3 cases), small intestine operation and portal hypertension cutout operation (2 cases each), enterolysis, pancreatic operation and liver operation (1 case each). Control group consisted of 72 cases (38 males, 34 females), with age ranging from 22 to 78 (average 55.09) years. Patients underwent biliary system operation (40 cases), gastric operation (10 cases), colorectal operation (7 cases), small intestine operation (5 cases), portal hypertension cutout operation and appendicitis exploratory laparotomy (3 cases each), abdominal mass operation (2 cases), hepatorrhesis with hepatorrhaphy and splenectomy (1 case each).

There were no remarkable differences in sex, age, and types of operative incision among all 3 groups. Table 1 shows the comparison of types of operative incision.

Surgical operation methods: The ways of preoperative preparation and operative disinfection and dressing in the 3 groups were the same. Operative incisions were mostly transrectus incisions, with a few other incisions. EK group

Table 2 Infection of incisional sites for the experimental animals

Group	n	EG's incision healing			Infection rate (%)	n	CG's incision healing			Infection rate (%)
		A	B	C			A	B	C	
10 ⁰	30	23	2	5	23.33	30	28	0	2	6.60
10 ²	27	17	3	7	37.04	30	26	1	3	13.33
10 ⁵	30	15	5	10	50.00	29	22	3	4	24.14
10 ⁸	30	11	4	15	63.33	30	19	2	9	36.67

used EK to resect tissues, and EC for hemostasis. EC group used common surgical knives to dissect tissues, and EC for hemostasis. Control group used common surgical knives, and silk thread suturing for hemostasis. Antibiotics were routinely used, and dressings were changed to observe the healing state of the incisions on the 3rd and 7th d after operation.

Instruments

EK group and EC group used GD350-D high-frequency electric surgical knives, made by Shanghai Hutong Electric Instrument Factory. Power of electric current was set at 40 W. Control group used common surgical knives.

Statistical analysis

Statistical analysis used chi-square test (χ^2). $P < 0.05$ was taken as significant.

RESULTS

Results of the animal experiments

Four white rats died of anesthesia accidents. The other 236 rats were put to death by cut-cord operation. On the 8th post-operative day, infection of incision sites was recorded, and then the 1 cm tissues around the original incision site were fusiformly excised for pathological examinations.

The comparison of incisional sites infection due to different density bacteria between the EG and CG are shown in Table 2.

Statistically significant differences in 10², 10⁵, and 10⁸ groups ($\chi^2 = 4.31, 4.22, 4.27$, respectively $P < 0.05$), but not in Group 10⁰ ($\chi^2 = 3.28, P > 0.05$) were observed.

The comparison of pathological infection of incision due to different density bacteria is shown in Table 3.

Statistically significant differences in groups 10², 10⁵ and 10⁸ ($\chi^2 = 4.05, 4.23, 5.08$, respectively $P < 0.05$), but not in group 10⁰ ($\chi^2 = 0.27, P > 0.05$) were observed.

All the above results showed there were differences in the infection rate based on either experimental observation or pathological examinations. However, both of them indicated that the bacterial contamination would increase the operative infection rate of EK, while the aseptic operation showed no significant difference.

Clinical study results

Second grade or 3rd grade healing (cacoethic healing) accounted for 16 cases (17.20%) in EK; 11 cases (16.36%) in EC, and 2 cases (2.86%) in the control. A significant difference between EK and the control was observed ($\chi^2 = 8.57, P < 0.05$). Furthermore, significant differences

Table 3 Pathological examination results of experimental animals

Group	n	EG				Infection rate(%)	n	CG				Infection rate(%)
		I	II	III	IV			I	II	III	IV	
10 ⁰	30	14	4	9	3	23.33	30	16	7	4	3	6.60
10 ²	27	5	5	10	7	37.04	30	13	5	5	7	13.33
10 ⁵	30	6	7	6	11	80.00	29	13	3	6	7	55.17
10 ⁸	30	5	5	8	12	83.33	30	13	3	5	9	56.67

were found between EC and the control ($\chi^2 = 5.66, P < 0.05$), but not between EK and EC groups ($\chi^2 = 0.017, P > 0.05$).

DISCUSSION

Common reasons for postoperative incisional site infection in laparotomy

Postoperative incisional site infection is a common complication in laparotomy. There are various reasons for infections, for example, without tight hemostasis on operative incisions, incisional contamination, and less strict aseptic operation. In spite of use of large doses of broad-spectrum antibiotics, this problem still has not been satisfactorily solved.

In 1917s, a French doctor Doyen invented EK^[2]. Since then, surgeons have been in favor of wide use of EK, merely because EK can make hemostasis quick and satisfactory, save the operative time and decrease bleeding during operation. In recent years, EK is more and more widely used in surgical operations. Because of unlimited and incorrect use of it, the injury of tissues is worsened and postoperative complications are increasing. Our experiment also testified this. In addition to incision site infection, there are also some grease liquefaction^[3] and abdominal incision deliscence, which are called delayed incision healing.

Early in the 1970s, Link *et al*^[2] proposed that EK could delay incision healing. The histological reports showed that the injury of electrocauterized tissue was worsened and the incisional site infection rate was increased. Studies by Soballe^[4] and Kumagai^[5] also indicated that EK could decrease the threshold of the infection in abdominal incisions.

Our animal experiments demonstrated that in each subgroup, the infection rate of incisional wounds made with EK was remarkably higher than that in the control group. There were significant differences in groups 10², 10⁵ and 10⁸ ($\chi^2 = 4.31, 4.22, 4.27$, respectively $P < 0.05$), except for group 10⁰ ($\chi^2 = 3.28, P > 0.05$). Since experimental pathological examination results were the same as experimental observational results, it indicated that EK could increase the infection rate of non-sterilized incisions, but not increase the infection rate of aseptic incisions.

Although clinical data were controversial on this issue, our current study demonstrated that there was a significant difference between EK and the control ($\chi^2 = 8.57, P < 0.01$). In addition, significant differences were observed between EC and the control ($\chi^2 = 5.66, P < 0.05$), but not between EK and EC ($\chi^2 = 0.017, P > 0.05$). It was proved

that EK may delay abdominal incision healing, while EC may not. Therefore, we suggest avoiding use of EK, and recommend use of common surgical knives when opening abdomen, and tying or EC for hemostasis.

Reasons for increased rate of incision cacoethic healing by EK

Local hyperthermy: When the temperature is higher than 45°C to 50°C, it can cause tissues and cells to denature; when the temperature is higher than 60°C, it can cause tissue necrosis. As the local temperature caused by EK can reach 200°C to 1000°C, if tissue is burnt under a big power again and again, a large number of histiocytes can be destroyed, which can cause incision wound hydrops and cacoethic healing.

Local tissue ischemia: When EK is being used, electric current and thermal energy are dispersed radiatively along the incisive margin, thereby causing denaturation and vascular occlusion in tissues on both sides of the incisive margins, and also the disturbances of local blood supply, thus affecting incisional healing. How *et al*^[2] have proved that tissues without blood vessels are more likely to be infected than those that have blood vessels.

Condition favorable for bacteria growth: The high temperature of EK can destroy the histiocytes, and lipocytes are more sensitive to thermal energy. A great amount of lipocytes destruction which can cause grease efflux, and coagulation tissues are good culture media for bacteria. Bacterial infection can cause incisional infection. That is why EK may increase the infection rate of non-sterilized incisions while has little effect on aseptic incisions.

Local hyperosmotic state: When the lipocytes are destroyed, micromolecular material makes the incisions in the hyperosmotic state, which accelerates subcutaneous hydrops, leading to incisions cacoethic healing.

Suggestions on application of EK

In our view, we should strictly follow the indications for use of EK. For complicated operations or operations of serious patients, such as reoperated patients, malignant tumor, in order to avoid excessive blood loss of patients,

save operative time, we should limitedly use EK. In another word, when opening abdomen, EC should be preferable to electrotomy and the electric current should be under control while using EC for hemostasis. When using electrotomy and EC in abdominal cavity operation, we also should control electric current to decrease tissue destruction, and the incision cacoethic healing rate. However, Kuzon^[6] failed to find any significant difference in the rate of the incisional complication between the high electric current volume and low electric current volume. Another point to be mentioned is, use of gauze before the operation is finished also has some positive effect on preventing incision liquefaction by getting rid of lipid and adipose tissues.

There are various causes for the infection of abdominal incision. Therefore, we should strictly follow the aseptic operating principle in the operation, protect incisions, avoid bacteria contamination, and make tight suturing for hemostasis. Meanwhile, prophylactic use of antibiotics in preoperative and postoperative periods is an effective way to decrease the infection rate of incisions.

Abstract

AIM: To search for new antiviral agents from traditional Chinese medicine, specifically anti-enteroviruses agents.

METHODS: The aqueous extracts (AE) of more than 100 traditionally used medicinal plants in China were evaluated for their *in vitro* anti-Coxsackie virus B3 activities with a MTT-based colorimetric assay.

RESULTS: The test for AE of 16 plants exhibited anti-Coxsackie virus B3 activities at different magnitudes of potency. They can inhibit three steps (inactivation, adsorption and replication) during the infection. Among the 16 plants, *Sargentodoxa cuneata* (Oliv.) Rehd. et Wils., *Sophora tonkinensis* Gapnep., *Paeonia veitchii* Lynch, *Spatholobus suberectus* Dunn. and *Cyrtomium fortunei* J. sm. also have activity against other enterovirus, including Coxsackie virus B5, Polio virus I, Echo virus 9 and Echo virus 29. Cell cytotoxic assay demonstrated that all tested AE had CC₅₀ values higher than their EC₅₀ values.

CONCLUSION: The sixteen traditionally used medicinal plants in China possessed antiviral activity, and some of them merit further investigations.

INTRODUCTION

Human enteroviruses, the largest genus of the *Picornaviridae* family, are of great medical and economic importance causing a variety of clinical syndromes and diseases. Enterovirus can cause any of the syndromes and, vice versa, any syndrome or disease could be the result of infection by the enterovirus. Coxsackieviruses, part of the enterovirus genus, can cause severe diseases of the heart, liver, eyes and pancreas, as well as acute infections of the central nervous system. Nowadays, Coxsackieviruses B are the major etiological agents of human myocarditis, causing between 25% and 35% of cases for which a cause is found^[1]. Transition from acute myocarditis to dilated cardiomyopathy has been suspected^[2]. So far, dilated cardiomyopathy is one of the major reasons for cardiac transplantation. Coxsackieviral RNA in the myocardium can be a marker of a poor clinical outcome and might influence prognosis after heart transplantation^[3]. Enteroviruses and Coxsackieviruses in particular, have been implicated in several chronic illnesses including juvenile onset diabetes mellitus, chronic fatigue syndrome, dermatomyositis and polymyositis, congenital hydrocephalus and amyotrophic lateral sclerosis^[4-6]. Until recently, there were no enterovirus-specific drugs available for clinical use^[7]. A great number of picornavirus replication inhibitors *in vitro* have been described but just few of them have shown effectiveness *in vivo*^[8], and none has been approved for clinical use yet. Etiological therapy for enteroviral diseases still remains elusive. The main reason for that is the fast development of drug-resistant and even drug-dependent mutants^[9,10]. Use of synergistic combinations of antivirals might be one of the possible efficient approaches to overcome the disadvantages of monotherapy. The same or greater effect could be achieved at lower concentrations than those required if drugs were to be used alone. Combined chemotherapy may also restrict the emergence of resistance to either or both of the partners in the combination. Also, research on the antiviral effect of combinations of picornavirus inhibitors might contribute to the better understanding of their mode of action and, in general, the mechanism of picornavirus replication. Currently, there is no specific antiviral therapy to treat or prevent enterovirus disease. Thus, new and more effective antiviral agents for future therapy in enterovirus infection are desired.

The development of a new antiviral drug is a difficult task taking into account the poor selective toxicity and fast selection of resistant viral variants with the existing

drugs. Frequencies of viral resistance to antiviral drugs are increasing and the difficulty of virus latency remains unsolved.

The screening of plants as a possible source of antiviral agents has led to the discovery of potent inhibitors of *in vitro* viral growth^[11-17] and the use of the ethnopharmacological approach enhances the probability of identifying new bioactive plant compounds^[18,19].

Plants have long been used as remedies against infection diseases. Many plant preparations have been used externally as disinfectants and antiseptics for wounds and pimples, as antidiarrhoeics and in the treatment of respiratory diseases. Nowadays, these are still used by rural populations. Plants considered useful against infectious diseases are interesting to test with regard to different etiological agents (viral, bacterial, fungus).

In our continuous efforts to search for novel antiviral agents from traditional medicinal plants, more than one hundred traditionally used medicinal plants in China were extracted with water and investigated for their *in vitro* anti-enterovirus activities. This is the first report on screening traditionally used medical plants against enterovirus.

MATERIALS AND METHODS

Preparation of the extracts

All traditionally used medicinal plants were purchased from Darentang Pharmaceutical Co. Ltd, a famous local traditional Chinese medicine provider in Tianjin city of China. All plant materials were air dried, ground and powdered. Hot water extracts of the traditionally used medicinal plants were prepared according to the procedures as described bellows: different medicinal plant materials (20 g) were boiled with 1000 mL of distilled water for 2 h. The aqueous was collected and the residual was extracted again with another 1000 mL of distilled water. The resulting aqueous extracts were collected, combined, filtered by gauze, concentrated under reduced pressure and lyophilized to dry. The AE extracts were dissolved in sterile distilled water.

Cells and virus

Vero E6 was used as target cells for virus infection. Cells were cultivated using RPMI-1640 supplemented with 10% fetal bovine serum (FBS), 100 units/mL penicillin G, 100 µg/mL streptomycin. In the antiviral assay, the medium was supplemented with 2% FBS and the above mentioned antibiotics. All cell culture reagents and media were purchased from Gibco BRL (Grand Island, New York).

Polio virus I was obtained from the American Type Culture Collection (ATCC), Rockville, USA. Cocksackie virus B3 and Cocksackie virus B5 were provided by Professor X.M. Li (Medical University of Tianjin, Tianjin, China). Echo virus 9 and Echo virus 29 were provided by the Chinese Type Culture Collection (CTCC), Wuhan, China. All virus strains were kept in our laboratory. All viruses were prepared and quantitated on Vero E6 cells and stored in small aliquots at -70°C until use.

Titration of viruses

Vero E6 cells were seeded in 96-wells culture plates at a

density of 10^4 cells/well and then incubated at 37°C in a humidified atmosphere containing 5 mL/L CO₂ for 24 h. A serial dilutions of virus stocks were prepared and cells were infected with the dilution of virus. After an additional 72 h of incubation, the cytopathic effect was recorded. The 50% tissue culture infective dose (TCID₅₀) per mL was calculated as described previously by Reed and Muench^[20].

Antiviral assay using MTT method

The antiviral activity of AE extracts was evaluated by the MTT method based in the color change which occurred following the reduction of 3-[4, 5-dimethylthiazol-2-yl]-2, 5-diphenyltetrazolium bromide (MTT) by mitochondrial enzymes^[21]. Vero E6 cells, treated by trypsin, were seeded in 96-well culture plates with a volume of 200 µL/well and a concentration of 10^5 cells/mL. After 24 h incubation, 100 µL of 100 TCID₅₀ of Cocksackie virus B3 was added, and the infected cells were incubated for another 2 h. Tested compound (200 µL) at different concentrations was then added to culture wells in triplicate. After further incubation at 37°C with 5 mL/L CO₂ for 72 h, MTT was added. The culture was incubated for four hours to allow the production of formazan and the absorbance at 492 nm was measured using a 96-well plate ELISA reader (Multiskan EX, Labsystems).

Viral inhibition rate was calculated as follows: $[(OD_{tv} - OD_{cv}) / (OD_{cd} - OD_{cv})] \times 100\%$.

OD_{tv}, OD_{cv} and OD_{cd} indicate the absorbance of the test compounds with virus infected cells, the absorbance of the virus control and the absorbance of the cell control, respectively. The 50% effectiveness concentration (EC₅₀) was defined as the concentration that achieved 50% cyto-protection against virus infection.

To confirm the results obtained with the MTT assay, the monolayers were also observed microscopically for estimating CPE (i.e. rounding and other marked morphologic changes with respect to control cells).

In addition to the post-incubation method of virus inhibition assay, pre-treatment (adding 2 h before virus infection) and co-treatment (adding at the same time of virus infection) of AE extracts were also attempted in the same protocol as mentioned above except the variation in the time of addition of AE extracts.

Cell cytotoxic effect

The cell cytotoxic effect of tested compounds toward Vero E6 cells was evaluated by MTT-based method. It was performed according to the procedures as described above with no virus added. Cell cytotoxic effect of each tested compound was calculated by the following formula: Percent of cell cytotoxic effect = $[1 - (OD_t / OD_s)] \times 100\%$.

OD_t and OD_s indicate the absorbance of the test substances and the solvent control, respectively. The 50% cell cytotoxic concentration (CC₅₀) of tested compounds was calculated according to Chiang *et al.*^[22,23].

Statistical analysis

Data were calculated for three separate experiments. The selectivity index (SI) was calculated as the ratio of CC₅₀ to EC₅₀. The Student's unpaired *t*-test was used to calculate

P values of difference of means between control and the tested samples on the inhibition of virus replication. Difference of sample between tested viruses with a *P* value less than 0.05 was considered statistically significant.

RESULTS

Anti-Coxsackie virus B3 activity of traditionally used medicinal plants in China

Aqueous extracts from 151 traditionally used medicinal plants were studied to detect the activities against Coxsackie virus B3, including effect on viral replication; effect on viral adsorption and subsequent replication and *in vitro* viral inactivation. The results showed that aqueous extracts of 16 used medicinal plants in China exhibited *in vitro* anti-Coxsackie virus B3 during the three different antiviral assays (Table 1). The antiviral activity against Coxsackie virus B3 by estimating cytopathic effect. Among the 16 medicinal plants, all exhibited strong anti-Coxsackie virus B3 activity on *in vitro* viral inactivation. But the extracts from *Sargentodoxa Cuneata* (Oliv.) Rehd.et Wils., *Sophora tonkinensis* Gapnep., *Paeonia veitchii* Lynch., *Paeonia lactiflora* Pall., *Ephedra Sinica* stapf, *Spatholobus suberectus* Dunn. and *Cyrtomium fortunei* J. sm. appeared to possess the strongest anti-Coxsackie virus B3 activity on viral replication; and the extract from *Cyrtomium fortunei* J. sm., *Sargentodoxa Cuneata* (Oliv.) Rehd.et Wils., and *Spatholobus*

suberectus Dunn. can strongly inhibited the adsorption of Coxsackie virus B3 to the cell.

EC₅₀ and selectivity index of five traditionally used medicinal plants against other enterovirus

Table 2 shows EC₅₀ of AE extract of five medicinal plants. Overall, all AE extract showed CC₅₀ higher than their EC₅₀. These observations indicated that the antiviral activity of AE extracts was not a result of their cytotoxic effect toward cells. The CC₅₀ values ranged from 125 to 500 mg/L.

With the EC₅₀ and CC₅₀ data, the selectivity index (SI) was calculated by dividing CC₅₀ by EC₅₀. The SI for the anti-Coxsackie virus B3 assay ranged from 3.9 to 9.8, and 1.6 to 17.2 for the anti-Coxsackie virus B5 assay. For anti-Echo virus 9, Echo virus 29 and Polio virus I assays, the SI ranged from 11.5 to 39.1, 3.8 to 17.7 and 3.7 to 11.6, respectively.

DISCUSSION

Medicinal plants have been traditionally used for different kinds of ailments including infectious diseases. Some of them are reported to exhibited antiviral activity in literature^[15,18]. According to Cragg's report, approximately 60% of anti-tumor and anti-infective agents that are commercially available or in the late stages of clinical trials today are of natural product origin^[24]. There is therefore,

no doubt that traditional medicinal plants can serve as a potential resource in the development of new antiviral agents in the future. Since current chemotherapy agents for enterovirus infections are either insufficient in quantity or limited in efficiency, there is thus a need to search for new and more effective antiviral agents for future therapy in enterovirus infections.

Among the 151 tested medicinal plants, five of them were found to exhibited a broad spectrum of anti-enterovirus activity. These five medicinal plants were *Sargentodoxa cuneata* (Oliv.) Rehd. et Wils, *Sophora tonkinensis* Gapnep., *Spatholobus suberectus* Dunn., *Paeonia veitchii* Lynch. and *Cyrtomium fortunei* J. sm. In China, they were not used to treat the virus infection. *Sargentodoxa Cuneata* (Oliv.) Rehd. et Wils is the dried vine stem of *Sargentodoxa cuneata* (Oliv.) Rehd. et Wils. (Fam. Lardizabalaceae), traditionally used to remove toxic heat, to promote blood circulation, and to relieve rheumatic conditions. *Sophora tonkinensis* Gapnep. is the dried root and rhizome of *Sophora tonkinensis* Gapnep. (Fam. Leguminosae), used to remove toxic heat, promote the subsidence of swelling, and soothe the sore throat. *Spatholobus suberectus* Dunn. is the dried stem of *Spatholobus suberectus* Dunn (Fam. Leguminosae), used to enrich the blood, to activate blood circulation, and to remove obstruction of the channels and collaterals. *Paeonia veitchii* Lynch. is the dried root of *paeonia lactiflora* Pall. or *Peaonia veitchii* Lynch (Fam. Ranunculaceae), used to remove heat from blood, to eliminate blood stasis, and to relieve pain. *Dryopteris crassirhizoma* Nakai is the dried rhizome of *Dryopteris crassirhizoma* Nakai (Fam. Aspidiaceae), used to remove toxic heat, to expel parasites, and to stop bleeding. Our studies revealed that the five medicinal plants suppressed five entroviruses at different magnitudes of potency. Among them, the aqueous extracts of *Sargentodoxa cuneata* (Oliv.) Rehd. et Wils showed the strongest antiviral activity to all five viruses and noteworthy SI value (SI > 4.0). The SI of five medicinal plants to five viruses values from 1.6 to 39.1 suggested a promising future for these extracts as antiviral products. It is important to emphasize there has been no a novel drug for enteroviruses diseases.

Anti-enteroviruses of aqueous extracts of these five plants against five enteroviruses *in vitro* have been demonstrated. It is not known, however, what these results signify for *in vivo* effectiveness. The results obtained in this preliminary screening justify continuing with the purification of crude extracts and isolation of active compounds for improving their potential as antiviral drugs and/or finding of new lead molecules.

Abstract

AIM: To record calcium and potassium currents in acutely isolated smooth muscle cells of mesenteric arterial branches in rats.

METHODS: Smooth muscle cells were freshly isolated by collagenase digest and mechanical trituration with polished pipettes. Patch clamp technique in whole-cell mode was employed to record calcium and potassium currents.

RESULTS: The procedure dissociated smooth muscle cells without impairing the electrophysiological characteristics of the cells. The voltage-gated Ca^{2+} and potassium currents were successfully recorded using whole-cell patch clamp configuration.

CONCLUSION: The method dissociates smooth muscle cells from rat mesenteric arterial branches. Voltage-gated channel currents can be recorded in this preparation.

INTRODUCTION

Ca^{2+} and K^{+} channels, two components that form action potential, are especially important for the regulation of cell excitability because they depolarize and repolarize excit-

able cells in response to depolarizing events. Voltage-gated K^{+} channels are implicated in governing cell excitability^[1] and setting resting potential^[2]. Studies have shown that molecular mechanisms, including protein phosphorylation, gene expression, muscle contraction and neurotransmitter release, are regulated by Ca^{2+} channels^[3]. Patch clamp technique is a powerful tool for studying the electrophysiological properties of biological membranes. Although some methods for patch clamp using freshly isolated smooth muscle cells have been described^[4], these methods need multiple enzymes^[5] or complex procedure^[6]. An improved method was described in the present study for the fast and reliable isolation of smooth muscle cells of mesenteric arterial branches by single collagenase digest and mechanical trituration. The present study was to establish the method of whole-cell recordings of calcium and potassium currents in acutely isolated smooth muscle cells. It can be used to observe the effects of drugs and some gastrointestinal tract disease on ion channels of smooth muscle cells of gastrointestinal tract.

MATERIALS AND METHODS

Solution and drugs

The Krebs-Ringer solution containing 120.7 mmol/L NaCl, 5.9 mmol/L KCl, 15.5 mmol/L NaHCO_3 , 1.2 mmol/L NaH_2PO_4 , 1.2 mmol/L MgCl_2 , 2.5 mmol/L CaCl_2 and 11.5 mmol/L glucose was used in this study with its pH adjusted to 7.4. The Ca^{2+} -free physiological saline solution (PSS) containing 150 mmol/L NaCl, 5 mmol/L KCl, 1 mmol/L MgCl_2 , 10 mmol/L HEPES, and 10 mmol/L glucose was also used in the study. The pH was adjusted to 7.4 with Tris-base. For recording Ca^{2+} currents, the cells were continuously perfused with the extracellular solution containing 140 mmol/L TeacCl, 5 mmol/L BaCl_2 , 10 mmol/L HEPES, 10 mmol/L glucose. The pH was adjusted to 7.4 with Tris-base. Recording pipettes were filled with the following intracellular solution containing 130 mmol/L CsCl, 10 mmol/L EGTA, 3 mmol/L MgATP, 0.3 mmol/L NaGTP, 10 mmol/L HEPES, 10 mmol/L glucose. The pH was adjusted to 7.2 with CsOH. For recording potassium currents, the cells were continuously perfused with HEPES-buffered physiological containing 150 mmol/L NaCl, 5 mmol/L KCl, 1 mmol/L MgCl_2 , 2 mmol/L CaCl_2 , 10 mmol/L HEPES, 10 mmol/L glucose. The pH was adjusted to 7.4 with Tris-base. The voltage dependent Ca^{2+} channels were blocked by using 0.2 mmol/L CdCl_2 . Intracellular solution containing 140 mmol/L KCl, 10 mmol/L

EGTA, 3 mmol/L MgATP, 10 mmol/L HEPES, and 10 mmol/L glucose. The pH was adjusted to 7.2 with Tris base. The internal recording solution was filtered through a Millipore 0.2 μm syringe filter before use and frozen till the experiment. Both external and internal solutions were of analytical grade. DTT, TTX, EGTA, MgATP, Na_2GTP , HEPES, CsCl, TealCl, collagenase and bovine serum albumin were obtained from Sigma.

Preparation of cells

Animals were provided by the Experimental Animal Center of Medical College of Xi'an Jiaotong University. All procedures were carried out in accordance with the United States Public Health Services Guide for Care and Use of Laboratory Animals and approved by the Institutional Animal Care and Use Committee of Xi'an Jiaotong University. The smooth muscle cells were freshly dispersed as described previously^[7]. Briefly, male Sprague-Dawley adult rats weighing 120-150 g were anesthetized with ether. The mesenteric arterial branches were dissected. The connective tissue and the endothelium were carefully removed under microscope (XTZ-E, Shanghai Shangguang Microscope Co., Shanghai, China) and the smooth muscle was cut into 1-2 mmol/L sections. The tissues were preincubated with oxygenated Ca^{2+} -free PSS for 40 min at 18-22°C, then incubated in oxygenated Ca^{2+} -free PSS containing 0.3% collagenase I, 0.3% bovine serum albumin, and 6 mg DTT for 25-30 min at 32°C. The tissues were washed three times with oxygenated Ca^{2+} -free PSS, and then gently agitated with a blunt-tipped glass pipette until the solution became cloudy. The debris was then removed with a fine 200 μm nylon mesh. The cell suspension was stored at 4°C and used within 5 h after cell harvesting.

Electrophysiological recordings

The smooth muscle cells were transferred to a recording chamber mounted on an inverted microscope (DMIRB, Leica, Germany) for 15 min. Only spindle-shaped cells were selected for experimentation. Electrophysiological recordings were performed with standard whole cell voltage-clamp technique^[8]. Recording pipettes were made from borosilicate glass capillaries using a puller (model p-97, Sutter Instrument, Novato, CA) and heat-polished to allow gigaohm seal formation. The resistance of the recording pipettes filled with internal recording solution was 3-6 M Ω in bath solution. The junction potential between the patch pipettes and bath solution was nullified immediately before G Ω seal formation. Cell capacitances were read from the potentiometer to set transient capacitance to zero. This value was used to calculate the cell size. After pipette and cell transient capacitance were compensated with the appropriate controls on the amplifier, the membrane was ruptured with gentle suction to obtain the whole cell voltage-clamp configuration. Series resistance was routinely compensated by 60%-70% and monitored periodically. Voltage-gated Ca^{2+} currents and delayed rectifier potassium currents (I_{KD}) were recorded as previously described^[9]. Electrophysiological recordings were performed at room temperature (22-25°C).

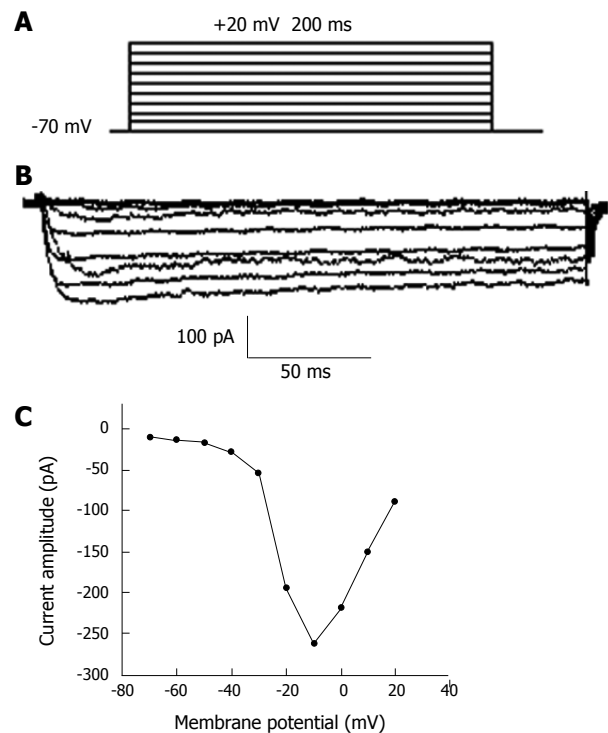

Figure 1 Voltage-gated calcium currents. **A:** Pulse protocols for recording voltage-gated Ca^{2+} current; **B:** Raw traces of calcium currents elicited in a freshly isolated smooth muscle cell; **C:** Current-voltage relation of calcium currents with isolated smooth muscle cells.

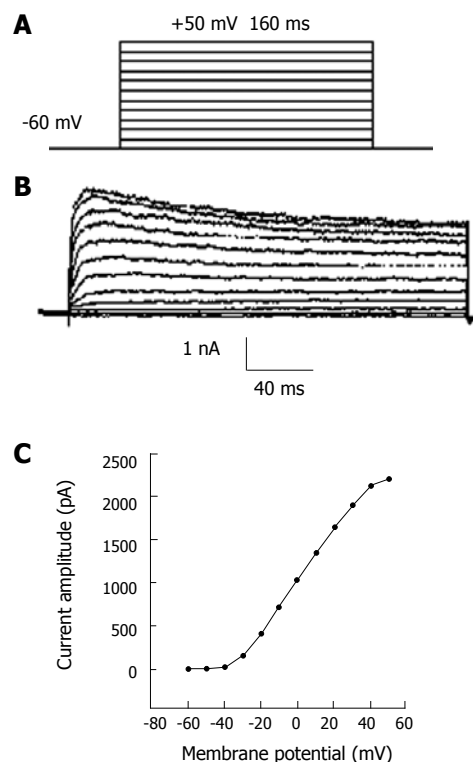

Figure 2 Delayed rectifier potassium currents. **A:** Pulse protocols for recording K^+ current; **B:** Raw traces of K^+ currents elicited in a freshly isolated smooth muscle cell; **C:** Current-voltage relation (I-V curve) of K^+ currents with isolated smooth muscle cells.

Statistical analysis

All data were analyzed by pCLAMP CLAMPFIT proce-

dures (Axon Instrument, USA). Current-voltage relations of voltage-gated channels were plotted by Origin 6.0 software (Microcal Software, USA).

RESULTS

Voltage-gated calcium currents

Voltage-gated Ca^{2+} currents were elicited by 200 ms depolarizing potential from -70 mV to +20 mV with an increment of 10 mV. At 5 s intervals, a holding potential was -70 mV (Figure 1A). The example of raw Ca^{2+} current traces for isolated smooth muscle cell is shown in Figure 1B. No significant inward current was observed until the depolarizing step reached -40 mV. Currents reached maximum amplitude at approximately -10 mV in each case, and became small with stronger depolarization. The current amplitude in dependence of the potential could be shown as an I-V curve (Figure 1C). The maximal current peak amplitude of the curve was -228.64 pA.

Delayed rectifier potassium current

I_{K} was elicited by 160 ms depolarizing pulses (-60 mV to +50 mV) at 2 s intervals, from a holding potential of -60 mV (Figure 2A). Figure 2B shows a series of raw current traces evoked. The outward currents showed a slow activation and inactivation during depolarizing pulses, and increased with increasing test potentials. The currents were sensitive to TeaCl , a potassium current blocker. The currents recorded under the condition were outward delayed rectifier potassium currents. Current-voltage (I-V) curve of I_{K} was obtained by plotting the currents evoked against test pulse (Figure 2C). The maximal current peak amplitude of the curve was 2216.75 pA.

DISCUSSION

Theoretically, isolation with enzyme irreversibly digests the protein-including ion channels in cell membrane, which could not be excluded with our method. Compared with methods reported previously^[5,6], the present methods have the following advantages. The isolating process is simple, fast and easy to manipulate using a single enzyme instead of several enzymes. The yield of the freshly isolated smooth muscle cells with high quality is increased markedly, leading to a $\text{G}\Omega$ seal. The activity and dose of enzyme could influence the cells' quality and quantity. Excessive enzyme destroys the normal structure of cells and causes swelling of cells. The membranes of the remanent

living neurons are easy to break before $\text{G}\Omega$ seal easily, which is the key to successful patch clamp experiments. On the other hand, the enzyme is not enough to disrupt the connection between cells. When pipetted, the sections are difficult to disperse. Incubation of sections is beneficial to their recovery. Careful and slow trituration of tissue sections is necessary and air bubble should be avoided to prevent cell damage.

In conclusion, Ca^{2+} and K^{+} channel currents can be successfully recorded in acutely isolated smooth muscle cells. Our method can dissociate smooth muscle cells from rat mesenteric arterial branches, and is a powerful tool for functional analysis at the level of individual smooth muscle cells.

ACKNOWLEDGMENTS

Instrument for patch clamp was provided by the Key Laboratory of Environment and Genes Related to Diseases (Xi'an Jiaotong University), Ministry of Education.

Abstract

Acute liver failure (ALF) is a medical emergency requiring immediate evaluation for liver transplantation. We describe an unusual case of a patient who presented with ascites, jaundice, and encephalopathy and was found to have ALF due to natural killer (NK)-like T cell leukemia/lymphoma. The key immunophenotype was CD2+, CD3+, CD7+, CD56+. This diagnosis, which was based on findings in the peripheral blood and ascitic fluid, was confirmed with liver biopsy, and was a contraindication to liver transplantation. A review of the literature shows that hematologic malignancies are an uncommon cause of fulminant hepatic failure, and that NK-like T-cell leukemia/lymphoma is a relatively recently recognized entity which is characteristically CD3+ and CD56+. This case demonstrates that liver biopsy is essential in diagnosing unusual causes of acute liver failure, and that infiltration of the liver with NK-like T-cell lymphoma/leukemia can cause acute liver failure.

INTRODUCTION

Acute liver failure (ALF) is a medical emergency,

and while liver transplantation can be life saving, it is imperative to perform a thorough evaluation to screen for potential contraindications^[1]. We describe an unusual case of a patient who developed ALF due to natural killer (NK)-like T-cell leukemia/lymphoma, a diagnosis with important implications, as it is a contraindication to liver transplantation. While a review of the literature shows that previously published case series have found this rare subtype of T-cell malignancy to involve the liver, we believe that this is the first report of it presenting as ALF.

CASE REPORT

A previously healthy 63 year-old man was admitted for three mo of fatigue, one mo of increasing abdominal girth and peripheral edema, two weeks of jaundice, and one week of confusion. He noted recent fevers, anorexia, weight loss, and day-night reversal. He had never received a blood transfusion or used intravenous or intranasal drugs. He had no tattoos or recent travel. He did not take prescription or over-the-counter medications, or nutritional or herbal supplements. He admitted using alcohol heavily in the past, but had been sober for more than 10 years. His family corroborated this information. There was no family history of liver disease.

On physical examination he was jaundiced and had findings consistent with hepatic encephalopathy including slurred speech and asterixis. He had moderate ascites, peripheral edema, and scattered spider angiomas. The liver was normal in size, but splenomegaly was detected.

Routine laboratory tests revealed hyponatremia, hypoalbuminemia, hyperbilirubinemia, thrombocytopenia, and prolonged prothrombin time not due to vitamin K deficiency (Table 1). The white blood cell count was $5.1 \times 10^9/L$ with atypical lymphocytes comprising 53% of the differential (Figure 1). Other diagnostic testing found a negative toxicology screen, 90% iron saturation, negative serologies for hepatitis A virus, hepatitis B virus, hepatitis C virus, human immunodeficiency virus, and human T-cell lymphotropic virus (HTLV) types I and II. Serologies were also negative for anti-nuclear antibodies, anti-smooth muscle antibodies, and anti-mitochondrial antibodies. Serum protein electrophoresis, alpha-1 anti-trypsin levels, ceruloplasmin levels, and alpha-fetoprotein were normal. Serum ammonia level was not measured. Abdominal ultrasound showed a normal liver size with heterogeneous echotexture, splenomegaly, and patent vasculature. Head CT scan excluded mass lesions and infiltrating disease.

Table 1 Laboratory results

Test	Result (normal range)
Sodium	128 mmol/L (135-145)
Creatinine	1.1 mg/dL (0.8-1.4)
AST (SGOT)	85 U/L (19-55)
ALT (SGPT)	40 U/L (19-72)
Total bilirubin	8.4 mg/dL (0.0-1.2)
Direct bilirubin	7.1 mg/dL (0.0-0.4)
Alkaline phosphatase	138 U/L (38-126)
GGT	80 U/L (13-68)
Serum albumin	1.7 g/dL (3.5-5.0)
Ascitic fluid albumin	0.5 g/dL (unspec)
White blood cell count	$5.1 \times 10^9/L$ (4.5-11)
neutrophils (%)	47
monocytes (%)	0
lymphocytes (%)	53 with atypical forms present
eosinophils (%)	0
Hematocrit (%)	33.3 (41-53)
Platelet count	$31 \times 10^9/L$ (150-440)
Prothrombin time	20 s (11-14)
International normalized ratio (INR)	1.7

Diagnostic paracentesis at a site in the left-lower-quadrant demonstrated a serum albumin-ascites gradient of 12 g/L, 12 475 red blood cells (RBCs)/mm³ and 1875 white blood cells (WBCs)/mm³ with a differential of 1% neutrophils, 4% monocytes and 95% lymphocytes. Because the lymphocytes were described as atypical with mitotic figures, a repeat paracentesis was performed at a right-lower-quadrant site. This revealed 1550 RBCs/mm³ and 250 WBCs/mm³ with the same differential and atypical cells. A sample of the ascitic fluid was sent for cytology (Figure 2). The peripheral blood flow cytometric immunophenotypes were as follows: CD2+, CD3+, CD7+, CD56+, CD4-, CD5-, CD8-, CD57-, and CD16-. A bone marrow biopsy revealed the same findings. Cytogenetic analysis of the bone marrow aspirate revealed the following karyotypes: 43, X, -Y, add (4) (q35), -5, dic (6;19) (q23; q13.4), -10, -11, -13, -14, -16, -18, add(22)(p11), +6 mars.

Since the patient's coagulopathy prohibited percutaneous liver biopsy, transjugular liver biopsy was performed for definitive diagnosis. There was no evidence of cirrhosis, but there was diffuse hepatic infiltration by a malignant lymphoid population (Figures 3A and 3B) which was immunohistochemically stained as follows: CD3+, CD20-, Epstein-Barr virus (EBV)-, granzyme B+, T1A-1+, and TdT-. The paraffin block of the liver biopsy was analyzed for a T-cell receptor (TCR) gamma gene rearrangement by polymerase chain reaction, and there was no evidence of a clonal TCR gamma gene rearrangement.

The patient was diagnosed with NK-like T-cell lymphoma/leukemia as the cause of liver failure on hospital d 4. This was deemed a contraindication to transplantation. His course was complicated on d 3 by bleeding duodenal ulcers amenable to standard endoscopic treatment. On d 4-6, high-dose methylprednisolone failed to induce remission, and his hepatic synthetic function and mental status worsened. On d 10 and 11, a salvage regimen

Figure 1 Peripheral blood smear-high power (1000 ×) view of atypically large lymphoid cells with blastic chromatin and abundant cytoplasm containing fine azurophilic granules.

Figure 2 Ascites cell-block- high power (600 ×) view of large lymphocytes with molding, convoluted nuclear membranes, dense chromatin, and abundant cytoplasm. Features are supportive of possible T-cell morphology.

Figure 3 Liver biopsy-low power (200 ×) view of the liver parenchyma infiltrated by a malignant lymphoid population composed of intermediate-sized to large atypical lymphocytes (A) and liver biopsy-high power (1000 ×) view of the liver parenchyma showing intermediate-sized to large atypical lymphocytes with very irregular nuclear contours and dense nuclear chromatin (B).

of gemcitabine was unsuccessful in inducing remission. On d 12, neutropenia, fever, and hypotension developed, and the patient's jaundice and encephalopathy progressed. The patient expired on hospital d 12.

DISCUSSION

The diagnosis of acute liver failure is a medical emergency because mortality is high without liver transplantation^[1]. However, thorough evaluation is mandatory to exclude contraindications to liver transplantation such as

underlying malignancy^[1,2].

Hematologic malignancies often incidentally involve the liver, but they uncommonly present as acute liver failure^[3,4]. When they do so, however, they carry a poor prognosis^[5]. Acute leukemias, Hodgkin's disease, non-Hodgkin's lymphoma, and transformation of chronic leukemias have all been noted in case reports or case series to present as hepatic failure^[5-20]. Infiltration of the liver and subsequent hepatic dysfunction specifically by T-cell leukemias and lymphomas are more unusual, though it has been reported in both the pediatric^[21,22] and adult patients^[23-29].

Natural killer cells, typically identified morphologically as large granular lymphocytes, are recognized for their role in cell-mediated immunity^[30]. They have characteristic immunophenotypes (CD3-, CD56+) which distinguish them from T cells (CD3+, CD56-). Other markers such as CD8 and the additional so-called NK-cell antigens (CD16 and CD57) are variably present^[31-32]. Over the past two decades, it has been noted that NK cells undergo clonal expansion and malignant transformation^[33]. This is believed to be a rare event, accounting for only a small fraction of all T-cell malignancies, which themselves are thought to comprise approximately just 15% of all non-Hodgkin's lymphoma^[31,34]. NK-cell leukemia/lymphomas are categorized as either immature (and more aggressive) or mature (with an indolent course), and more commonly affect the nasopharynx and sinuses though they have also been reported to involve the skin, mucosa of the gastrointestinal (GI) tract, testes, kidneys, and orbit^[31,35]. They are seen more frequently in Asia, Mexico, and South America, ostensibly due to associations with EBV and HTLV^[36-38]. Of note, while they are commonly associated with hepatosplenomegaly they have not been reported to present with acute liver failure^[31,39-41].

In contrast to NK cells, NK-like T-cells expressing features of both T cells and NK cells, are defined by a CD3+, CD56+ immunophenotypes, and tend not to be associated with EBV^[31]. The first reports of NK-like T-cell leukemias and lymphomas^[42,43] have described presentations including typical "B" symptoms such as fever, chills, night sweats and weight loss, as well as lymphadenopathy and splenomegaly. Disease involves the spleen, blood, marrow, GI tract, lung, kidneys, and liver, but none of the patients presented with frank liver dysfunction. In most instances, the disease is aggressive and rapidly fatal, regardless of treatment regimen. A large series identified 49 Chinese patients with extra-nasal CD56+ disease, 34 of whom are also CD3+^[38]. Of the 5 patients with liver involvement, all had reactive hemophagocytic syndrome but none presented with hepatic failure. Of the 29 patients with follow-up information available, 24 died in a median time of 3.5 mo. A recent phenotypic analysis of 408 Japanese cases of peripheral T/NK cell lymphoma had not described any with liver failure^[44].

In this paper we present the clinical course, immunophenotype, and cytogenetics of what we believe to be the first reported case of a patient with acute liver failure due to NK-like T-cell leukemia/lymphoma. This has implications beyond the rarity of this particular patient's condition. Because this patient had a history of alcohol consumption, his liver disease might have been

ascribed to alcoholic hepatitis from a relapse of alcohol use. However this case illustrates the importance of fully analyzing unexpected findings. The atypical lymphocytes seen on the peripheral smear and in the ascitic fluid cell count differential were not attributed to a reactive process. Rather, they led to the transjugular liver biopsy which is essential in making the diagnosis, and underscores the role of and importance of liver biopsy when the etiology of liver failure is unknown.

In conclusion, a hematologic malignancy infiltrating the liver, although rare, is a contraindication to liver transplantation. It is mandatory to exclude such processes in the correct clinical context. In our case, liver biopsy allowed prompt diagnosis and recognition of NK-like T-cell leukemia/lymphoma as the cause of acute liver failure.

Abstract

Situs inversus abdominus with rotational anomaly of the intestines is an extremely rare condition. Although intestinal malrotation has been recognized as a cause of obstruction in infants and children and may be complicated by intestinal ischaemia, it is very rare in adults. When it occurs in the adult patient, it may present acutely as bowel obstruction or intestinal ischaemia or chronically as vague intermittent abdominal pain. Herein, we present an acute presentation of a case of situs inversus abdominus and intestinal malrotation with Ladd's band leading to infarction of the intestine in a 32 year old woman.

INTRODUCTION

Situs inversus abdominus is an extremely rare condition when it occurs in adults. It may present with vague abdominal pain or with intestinal obstruction or with intestinal ischaemia. We describe a patient with situs inversus abdominus who presented to us acutely with intestinal ischaemia.

CASE REPORT

A 32-year-old woman presented to our emergency

department with severe cramping and generalized abdominal pain of 2 d duration. This cramping pain occurred every 2 to 3 h and was 30 to 40 min in duration. She vomited several times which was bilious in nature. Her last bowel movement was 2 d prior, and it was described as normal. Her past medical history included mitral valvuloplasty for rheumatic heart disease. She had also developed cardiac cirrhosis secondary to rheumatic heart disease. There was no history of previous abdominal surgery and denied alcohol or tobacco use.

On physical examination, the patient's vital signs were pulse 90, blood pressure 126/67, temperature 37°C, and respiratory rate was 16. The abdomen was not distended. She exhibited no peritoneal signs; however, mild diffuse tenderness to deep palpation was appreciated. Normal bowel sounds were present on auscultation. Her rectal examination was normal. Haemoglobin, white blood cell count, basic biochemistry panel and arterial blood gases were all within normal values. Abdominal X-rays did not reveal any features of obstruction. Chest radiography did not reveal any signs of perforation of a hollow viscus. A prompt computed tomography (CT) scan of the abdomen was performed which demonstrated situs inversus abdominus and free air intraperitoneally suggesting perforation of a hollow viscus (Figure 1). She was taken to theatre urgently for a laparotomy, which revealed malrotation of the intestines with complete situs inversus. The entire small bowel was found to be of doubtful viability and there was a presence of Ladd's band running from the ileocaecal valve to the duodenojejunal flexure around which the small bowel had rotated (Figure 2). The Ladd's band was divided which improved the perfusion of the bowel to a reasonable extent and a decision was made to pack the wound and have a second look laparotomy in the next 12 h. Postoperatively she was nursed in the intensive care unit where she developed endotoxic shock and multiple organ failure. At the second laparotomy, the entire small and the large bowel were infarcted which was deemed incompatible with life. A decision was made to close the abdomen and the patient died in the next few hours in the intensive care unit.

DISCUSSION

Situs inversus abdominus (SIA) is an uncommon anomaly with an incidence varying from 1 in 4000 to 1 in 20000 live births^[1]. Acute surgical emergencies complicating SIA are extremely rare in the adult and very few cases are reported in the English literature^[2,3]. Situs inversus was

Figure 1 CT Scan imaging showing (A) situs inversus (note liver on the left and stomach on the right side) and (B) free intraperitoneal air.

first described by Aristotle in animals and by Fabricius in humans^[4]. Congenital anomalies of intestinal rotation are often seen in infants and children; however, they are uncommon in adults. Approximately 85% of malrotation cases present in the first 2 wk of life^[5].

A brief knowledge of intestinal embryology is necessary in order to understand the rotation of the intestine and its anomalies. The embryo's gut is in the form of a straight tube at the fourth week of intra-uterine life. Approximately during the fifth week, a vascular pedicle develops and the gut can be divided into foregut, midgut, and hindgut. The superior mesenteric artery supplies blood to the midgut. The midgut is defined by a rapidly enlarging loop with the superior mesenteric artery running out to its apex. The cephalad portion of the loop gives rise to the first six metres of small intestine, and the remainder of the loop forms the distal small bowel and colon up to the splenic flexure. Intestinal rotation primarily involves the midgut. The rotation of intestinal development has been divided into 3 stages. Stage I occurs in wk 5 to 10. It includes extrusion of the midgut into the extra-embryonic cavity, a 90° anti-clockwise rotation, and return of the midgut into the fetal abdomen. Stage II occurs in week 11 and involves further anti-clockwise rotation within the abdominal cavity completing a 270° rotation. This rotation brings the duodenal "C" loop behind the superior mesenteric artery with the ascending colon to the right, the transverse colon above, and descending colon to the left. Stage III involves fusion and anchoring of the mesentery. The caecum descends, and the ascending and descending colon attach to the posterior abdominal wall.

Intestinal anomalies can be classified by the stage of

Figure 2 Schematic intraoperative findings show the presence of Ladd's band with small bowel ischaemia.

their occurrence^[6]. Stage I anomalies include omphaloceles caused by failure of the gut to return to the abdomen. Stage II anomalies include nonrotation, malrotation, and reversed rotation. Stage III anomalies include an unattached duodenum, mobile caecum, and an unattached small bowel mesentery.

Many remain asymptomatic through life and the anomaly is discovered only at autopsy. Some may present with chronic and unexplained abdominal discomfort, and even fewer may report acute episodes of agonizing abdominal pain. Symptoms can arise from acute or chronic intestinal obstruction that may be caused by the presence of abnormal peritoneal bands (Ladd's bands) or a volvulus.

Malrotation of the colon is estimated to occur in 0.2% to 0.5% of the adults and is significant clinically in only a small portion of them. There are no typical set of symptoms that are diagnostic of this clinical problem. The location of the pain may vary from epigastric to left upper quadrant. Often occurs postprandially and may last several minutes up to 1 h. Patients are frequently followed for a long period before undergoing surgery. The difficulty of diagnosis lies in both the absence of specific physical findings and the low adult frequency. Symptoms in the adult patient are often mistaken for irritable bowel syndrome, peptic ulcer disease, biliary and pancreatic disease, and psychiatric disorders^[7].

The diagnosis of rotational anomaly can be made by radiographic studies^[8]. In the absence of volvulus, a plain x-ray of the abdomen is of little diagnostic value. The absence of caecal gas shadow or the localization of small intestinal loops predominately in the right side should arouse the suspicion of malrotation^[9]. Malrotation can be diagnosed on CT by the anatomic location of a right-sided small bowel, a left-sided colon and an abnormal relationship of the superior mesenteric vessels. Nichols and Li described the abnormal position of the superior mesenteric vein (SMV) wherein the SMV was situated to the left of the superior mesenteric artery (SMA) instead of to the right on CT scan in patients with malrotation^[10].

The classic treatment for incomplete intestinal rotation is the Ladd procedure, which entails mobilization of the right colon, division of Ladd's bands and mobilization of the duodenum, division of adhesions around the SMA to broaden the mesenteric base, and an appendectomy. This

procedure was originally described by Ladd^[11].

In conclusion, adult presentation of situs inversus abdominus with intestinal malrotation is a difficult diagnosis because of the rare incidence of the disorder. These patients often present with chronic abdominal pain or with ischaemia as exemplified by our case. Diagnosis requires a high index of suspicion.

Abstract

Metastatic tumors of the gastrointestinal tract are rare. We describe a case of gastric metastasis due to primary lung cancer, revealed by an upper gastrointestinal endoscopy (UGIE). Haematogenous metastases to the stomach are a rare event. To our knowledge, only 55 cases have been described in the international literature. In these patients, the prognosis is very poor. We report herein a case of gastric metastasis by lung small cell carcinoma, with a review of the literature about this rare entity.

INTRODUCTION

Metastatic tumors of the gastrointestinal tract are rare^[1]. In most cases, the diagnosis is possible only at autopsy. To our best of knowledge, only 55 cases have been described in international literature so far^[2].

CASE REPORT

We describe a case of gastric metastasis due to primary lung cancer revealed by an upper gastrointestinal endoscopy (UGIE). In March 2005, a 63-year-old

Caucasian male was referred to our department because of fever (38°C), weight loss (5 kg in few months), epigastric pain, and constipation. He had an accidental chest trauma associated to right rib fractures 3 years back. He was a smoker of 20 cigarettes per day. At admission to our department, his general conditions were poor. Lymphadenopathy (> 3 cm) in the left scalenic region, and liver enlargement were evident. A mild anaemia (Hb 110 g/L), low platelet count ($40 \times 10^9/L$), and a marked increase of lactic dehydrogenase (LDH > 1000 U/L) were the most important blood biochemical alterations. A chest x-ray revealed a lung mass (> 5 cm in diameter) in the upper left hilar region. Multiple 1-3 cm secondary liver lesions scattered in both lobes, and with a typical "bull's eye" appearance were revealed by ultrasonography. An UGIE showed a 1.5-cm raised area, depressed on the tip with recent signs of haemorrhage in the gastric corpus, which was histologically identified as the metastasis of an undifferentiated small cell carcinoma (Figure 1). A total body computed tomography (CT) confirmed a left lung neoplasm associated to an infiltration of the left pulmonary artery, left upper bronchus stenosis, bulk mediastinal lymphadenopathies (> 3 cm), and bilateral pleural effusions. Liver secondaries were confirmed and multiple brain metastases were localised in the left parietal lobe and, bilaterally, in the occipital lobes. A total body bone scan showed diffuse bone involvement. A bronchoscopy and percutaneous biopsy of the left supraclavicular lymph node confirmed the diagnosis of diffuse poorly differentiated primary lung small cell cancer (Figure 2). The patient was provided only with a supportive care, considering his poor condition. He died one month later.

DISCUSSION

Haematogenous metastases to the stomach is a rare event^[3]. The most frequent tumors involved in secondary gastric sites are melanoma, breast, and lung cancer. Most patients with gastrointestinal metastases are asymptomatic^[1]. At autopsy, gastric metastases are present in 14% of all patients with lung cancer^[4]. Lung small cell carcinoma has a high incidence of vascular invasion^[3] and the gastric submucosal layer is always involved, followed by the mucosa, muscularis propria, and serosa^[5]. Complete inclusion of the metastasis within the gastric wall may be a sign of a primary tumor of another origin^[5].

Abdominal pain is the most frequent (80% of the cases) symptom in the symptomatic patient. Kadakia

Figure 1 Middle view of small cell among gastric glands (x 20).

Figure 2 Diffuse positivity for synaptophysin (avidin-biotin-peroxidase complex method x 40).

et al^[1] also reported iron-deficiency anaemia and acute upper GI bleeding. Severe upper gastrointestinal bleeding, hypovolemic shock, and stomach perforation may be the cause of death of the patient. Differential diagnosis with lymphoma, ectopic pancreas, carcinoid tumor, eosinophilic granuloma, Kaposi's sarcoma and gastric ulcer is important^[3]. Gastric metastatic lesions have a particular endoscopic aspect, appearing as "volcano-like" or umbilicated on the tip^[3] (Figure 3). These lesions may present with three different appearances^[3]: (1) multiple nodules of variable size with a central ulcer; (2) submucosal, raised, and ulcerated at the tip and defined as "volcano-like"; and (3) raised areas without a central ulcer. In few cases, the lesions appear as polyps or raised plaques^[3]. It has been reported a high percentage of gastric metastases in the fundus and cardias^[4], but in our experience, the lesions are present in the gastric corpus region, which is in agreement with Kadakia *et al*^[1].

Figure 3 Typical endoscopic aspect of "volcano-like" lesion, suggestive of gastric metastatic lesion.

Hamatake *et al*^[6] described a rare case of solitary gastric metastasis from the lower left lung. This was a poorly differentiated adenocarcinoma diagnosed during UGIE for UGI bleeding, which resolved after gastrectomy and left lobectomy.

It is important to identify these lesions in order to prevent serious complications, such as gastrointestinal bleeding, viscus perforation, or gastric outlet obstruction^[4]. An upper gastrointestinal endoscopy should be recommended before starting chemotherapy^[5], as confirmed by Suzaki *et al*^[7] who described a case of gastric perforation during systemic chemotherapy for lung neoplasm due to metastasis^[7].

<http://www.wjgnet.com/1007-9327/12/4098.asp>

INTRODUCTION

Adjustable gastric banding is an established procedure for the treatment of obesity. Early complications associated with gastric banding included per operative bleeding, infection, and pneumonia. Late complications relate to the band or to the port system. The former include displacement, with resultant valve or pouch enlargement; gastric perforation; and band penetration. Port-associated complications include infection, disconnection, or

migration. These late complications usually are corrected by surgery^[1-9]. Penetration of a gastric band into the stomach lumen is a rare late complication. In almost all cases, a penetrated band must be removed surgically but, under certain circumstances, endoscopic intervention can be attempted. We here report a case of endoscopic management of intragastric penetrated adjustable gastric band.

CASE REPORT

A 47-year-old man with morbid obesity (weight: 113 kg, body mass index 43.1 kg/m²) underwent open implanted adjustable gastric band (November 1997). The post-interventional follow up showed a good weight loss (weight 96.6 kg). Ten months later (September 25, 1998) because of the patient was found to have unexplained weight gains (weight 108 kg), filling volume in the band was increased to 2.5 mL. This was, however, ineffective (weight 110 kg), and because of the patient reported the possibility to have complete and plentiful meals a port disconnection was suspected. The port was replaced under local anesthesia. On November 2001, the patient was found to have once again weight gains (weight 117 kg) because of a recurrent port disconnection. A new port was implanted under local anesthesia and a filling volume in the band was progressively increased to 3 mL. On August 2002 (weight 93.5 kg), the patient experienced a sub-cutaneous abscess at site of port implantation, due to port-associated infection. An upper GI endoscopy was unremarkable and because of the infection was unresponsive to antibiotics, the port was removed and re-implanted. However, a recurrent port-associated infection was diagnosed 1 mo later and the patient was scheduled to receive a monthly upper endoscopy because of the risk of penetration of the gastric band into the gastric lumen. Six months later (February 2003; 62 mo after the banding procedure) endoscopy demonstrated a partial penetration of the gastric band into the gastric lumen (Figure 1). Because of the patient was asymptomatic at that time, it was decided to await the complete intragastric band migration for an endoscopic attempt to remove the gastric band. Gastroscopy 13 mo later (March 2004), revealed almost total penetration of the band; only a small tissue bridge held the device to the gastric wall. With almost complete penetration of the band, an endoscopic approach was

Figure 1 Endoscopic appearance of intra-gastric migration of band.

Figure 2 Endoscopic retrieval of the gastric band.

felt to be safe and feasible. An endoscopic attempt to remove the gastric band was therefore performed with surgical standby. The tissue bridge was injected with a dilute solution of epinephrine (1:10 000) and the tissue bridge then was resected step by step by using a needle-knife papillotome. After severing the tissue bridge, the band remained attached to the port system. Most of the silicone tube connecting the injection port with the gastric band was resected and the attached port was removed. The rest of the tube slipped into the stomach, the band lying freely within the gastric lumen. The band was cut by the means of the CBC360 AMI gastric banding cutter (C.J.Medical. Haddenham, Buckinghamshire, England) and finally retrieved endoscopically by using a polypectomy snare (Figure 2). The connecting tube was removed through little cutaneous incision. The post-interventional course was uneventful. A gastrografin swallow done postoperatively ruled out a leak, and patient was discharged 3 d later.

DISCUSSION

Penetration of a gastric band into the stomach lumen is a rare late complication^[2-9]. The suggested primary etiologic factor for the band penetration is pressure applied to the gastric wall. External pressure is applied either through chronic overfilling of the band or the inclusion of too much gastric wall at operation. Internal pressure is applied as a result of ingestion of excessively large food boluses early after operation. Another suggested factor is a rejection reaction against the silicon gastric band with subsequent circumferential fibrous contraction^[3,9]. The main symptoms that suggest dislocation or penetration of a gastric band are weight gain and epigastric pain or port-associated infection. The diagnosis is established by endoscopy or x-ray study. Because barium contrast radiography provides additional information on other complications of gastric banding, such as band slippage or pouch dilatation, this imaging study should be performed initially. Nonetheless, the final diagnosis of band migration is established by endoscopy^[4,5]. In almost all cases, a penetrated band must be removed surgically, and to our knowledge,

there are only two published case reports of endoscopic management of a penetrated gastric band^[10,11]. Whether a penetrated gastric band can be managed endoscopically depends on the degree of penetration. The risk of gastric perforation after endoscopic management is higher in patients with a small or a partial penetration of the band. Thus, the optimal candidate for endoscopic therapy should have an almost complete penetration of the band. In this group of patients, the risk of an iatrogenic perforation is relatively small. As demonstrated by the present case, endoscopic management of a penetrated gastric band is feasible under certain circumstances, specifically nearly complete penetration of the band into the stomach. The favorable course of the case described here demonstrates that adjustable gastric bands in the process of migration need not be removed surgically in patients who are asymptomatic. Complete migration can be awaited and the gastric band retrieved less invasively. Compared with operative removal, the procedure described above is expected to have fewer complications.

Abstract

We here report a case of a 51-year-old man with lung metastasis from esophageal carcinoma that was initially treated by combination chemotherapy consisting of fluorouracil and nedaplatin. Because metastatic disease disappeared, salvage esophagectomy was performed. Although chest wall recurrence developed at the thoracotomy wound, prolonged survival of 48 months was achieved by local tumor resection and additional chemotherapy. This combination chemotherapy is regarded as a promising and considerable treatment for metastatic esophageal carcinoma.

INTRODUCTION

It has been reported that 18% of patients with newly

diagnosed esophageal carcinoma have distant metastatic disease at presentation, in which the lung is the third most common site and accounts for 20% of metastasis cases^[1]. The prognosis of these patients is extremely poor and the urgent establishment of effective treatment is essential. We here describe a successful treatment for esophageal carcinoma with lung metastasis by induction chemotherapy followed by salvage esophagectomy.

CASE REPORT

A 51-year-old man complained of dysphagia for over two months. Endoscopy and a computed tomography (CT) scan of the chest performed in an affiliated hospital showed a circumferential tumor in the middle thoracic esophagus with bilateral multiple pulmonary nodules. He was referred to our hospital for further examination and treatment, and admitted on May 24, 2000. On physical examination, lymph nodes were palpable in the left supraclavicular fossa. Laboratory data including tumor markers were all within normal limits. A chest X-ray showed multiple small nodules in the bilateral lung. A barium meal study revealed an ulcerative tumor, 20 cm in length, mainly located in the middle and lower thoracic esophagus extending to the upper thoracic esophagus (Figure 1A). Endoscopy disclosed a protruding tumor 25 cm distal from the dental arch followed by a circumferential ulcerative tumor between 30 cm and 38 cm distal from the dental arch. A biopsy specimen histologically proved that it was a moderately differentiated squamous cell carcinoma. A CT scan of the neck through the abdomen demonstrated bilateral supraclavicular lymph node swelling and a total of 8 small nodules in the bilateral lung up to 1 cm in size with clear boundary (Figure 2A). Based on these findings, he was diagnosed with unresectable thoracic esophageal carcinoma with metastases to non-regional lymph nodes and lung, classified as stage IVB according to the TNM classification of the International Union Against Cancer (UICC)^[2]. With his written informed consent, he was registered with the Japan Clinical Oncology Group (JCOG) Trial (JCOG 9905), which was a phase II study of nedaplatin (NDP) and 5-fluorouracil (5-FU) in metastatic squamous cell carcinoma of the esophagus. Each course of chemotherapy consisted of 140 mg of NDP on d 1 and 1250 mg of 5-FU with continuous infusion on d 1-5.

Figure 1 A barium meal study before (A) and after (B) chemotherapy. More than 50 % decrease in total tumor size was demonstrated during chemotherapy, defined as partial response according to the guidelines of the Japanese Society for Esophageal Diseases^[3].

Figure 2 A chest computed tomography scan before (A) and after (B) chemotherapy. Complete disappearance of the multiple nodules in the bilateral lung was revealed during chemotherapy, defined as complete response^[3].

Figure 3 Resected specimen showing a 78 mm × 60 mm superficially invasive tumor (A) and histological examination showing foci of poorly-differentiated squamous cell carcinoma scattered in the submucosal layer (B) (HE, X 20).

Courses were repeated every 4 wk, and a total of 4 courses were performed. Hematological and non-hematological toxicities that developed during chemotherapy were grade 1 leukocytopenia and grade 3 anorexia, nausea, and stomatitis, respectively, as judged by the Common Toxicity Criteria of the National Cancer Institute (NCI-CTC) Version 2.0. After the completion of the 4th course of this combined chemotherapy, a CT scan revealed that multiple nodules in the bilateral lung disappeared (Figure 2B). No lymph node swelling was seen on the CT scan. On barium meal study, an irregular and slightly stenotic lesion, only 4 cm in length, was demonstrated in the middle thoracic esophagus (Figure 1B). A residual esophageal tumor was, however, endoscopically apparent as a slightly depressed lesion with a Lugol unstained area, which was histologically confirmed. Salvage esophagectomy was taken into consideration because the combined chemotherapy downstaged the patient's condition to that of a resectable disease.

On November 20, 2000, the patient underwent extended radical esophagectomy with a three-field lymphadenectomy, and reconstruction with a retrosternal gastric roll. No metastatic lesion was macroscopically found in the right lung during surgery. The resected specimen showed that the superficially invasive tumor was 78 mm × 60 mm in size (Figure 3A). Histological examination from the resected specimen showed foci of poorly-differentiated squamous cell carcinoma scattered in the submucosal layer (Figure 3B). No metastatic node was histologically identified. The histopathological response to chemotherapy was classified as grade 2 (moderately effective) according to the

guidelines of the Japanese Society for Esophageal Diseases^[3]. Consequently, R0 resection, according to the residual tumor classification of the UICC-TNM classification, was carried out^[2].

The patient had an uneventful postoperative course and was discharged 26 d after surgery. He was followed up at our outpatient department without any additional adjuvant therapy.

Chest wall recurrence probably due to tumor cell implantation developed at the thoracotomy wound nine months after esophagectomy. Because no other recurrence was detected, tumor resection was performed for local control. R1 resection was confirmed, as positive involvement of poorly-differentiated squamous cell carcinoma with the external surface of the resected specimen was histologically proved. Thereafter, the patient received two cycles of additional combined chemotherapy consisting of NDP and 5-FU, and was alive and well with no evidence of recurrence 48 mo after the second surgery.

DISCUSSION

The prognosis of patients with stage IVB esophageal carcinoma is extremely dismal. The 5-year survival rate of such patients after esophagectomy reported by the Japanese Society for Esophageal Diseases is 5.5%^[4]. The stage IVB disease comprises distinct two subgroups: one with distant organ metastasis and the other with non-regional nodal metastasis^[2]. Because esophagectomy has been mainly performed in the latter, overall survival of the disease is supposed to be even worse. Kato *et al*^[5] reported that the

3-year survival rate for esophageal cancer patients with distant organ metastasis is only 0.3%. Patients with distant organ metastasis are usually in poor condition at the time of presentation and receive only palliative treatment, radical treatment is selected only for patients in relatively good condition.

Surgery should be taken into consideration when complete resection of both primary and metastatic tumors is possible. In many cases, however, complete resection is impossible because multiple metastatic tumors are often detected in one or more organs. Although there are some reports on successful resection of esophageal carcinoma combined with liver metastasis^[6,7] or adrenal metastasis^[8], these cases seem to be exceptional.

Chemoradiotherapy is often performed in patients with non-regional nodal metastasis by extending the irradiation field^[9,10]. Nakada *et al.*^[11] reported that complete regression of esophageal cancer with concomitant liver metastasis and a long-term survival of 38 mo is achieved by concurrent chemoradiotherapy including metastatic lesions in the irradiation field. Except for these unusual cases, chemoradiotherapy is regarded as locoregional treatment in principle and should not be radical treatment for patients with distant organ metastasis.

Systemic chemotherapy is still widely accepted as a standard treatment for patients with distant organ metastasis. It is well known that squamous cell carcinoma of the esophagus is responsive to chemotherapy. Tumor reduction by at least 50% may occur in 35%-55% of patients with metastatic disease who receive cisplatin (CDDP)-based combination chemotherapy^[12]. Although chemotherapy can palliate symptoms in many patients, the response to chemotherapy typically lasts no longer than a few months and the median survival time of these patients is less than one year. To our knowledge, there is no other case in which an esophageal cancer patient with stage IV disease is down-staged by systemic chemotherapy, undergoes salvage esophagectomy for the residual esophageal tumor, and survives more than 4 years.

NDP is a second-generation platinum complex that has a characteristic property of being approximately 10 times as soluble in water as CDDP. Therefore, NDP is considered to have more pronounced activity against solid tumors and less nephrotoxicity and gastrointestinal toxicity than CDDP^[13]. A phase II study for metastatic squamous cell carcinoma of the esophagus using a combination of NDP and 5-FU has been conducted as a JCOG trial (JCOG 9905) in expectation of preferable anti-tumor effects and toxicities compared with that of CDDP and 5-FU^[14]. As a result, the overall response rate is 39.5% and 33.3% in

metastatic lung disease^[14]. Based on these results and the current case, combined chemotherapy consisting NDP and 5-FU is regarded as a promising and considerable treatment for metastatic squamous cell carcinoma of the esophagus.

Abstract

Preoperative images of acute appendiceal diverticulitis are rarely reported because of the difficulty of distinguishing appendiceal diverticulitis from other iliocecal diseases like acute appendicitis or cecal diverticulitis. We report a case of preoperatively diagnosed acute appendiceal diverticulitis. A 30-year-old female with a presumptive diagnosis of acute appendicitis from history and physical examination was admitted to our hospital. Ultrasound sonography showed inflamed appendiceal diverticula and inflammatory changes of the surrounding tissue. The swollen appendix was detected but its findings were slightly different from those of typical acute appendicitis in the following points. One difference was the thickened wall of the appendix, the other difference was the presence of air in the appendix. The patient underwent appendectomy and the pathological specimen revealed inflammatory changes of diverticula within the appendix.

INTRODUCTION

Acute appendiceal diverticulitis is an uncommon clinical entity. Some patients treated for presumed acute appendicitis have acute vermiform appendiceal diverticulitis. Almost all acute appendiceal diverticulitis are found after appendectomy because history and physical findings of appendiceal diverticulitis closely resemble those of acute appendicitis. The preoperative images are not so effective

in detecting an appendiceal diverticulum. Here, we report a case of acute appendiceal diverticulitis diagnosed preoperatively by ultrasound sonography.

CASE REPORT

A 30 year-old female was admitted to our hospital for abdominal pain, slight fever and mild anorexia. The present episode of abdominal pain began four days before admission. At first, she felt epigastralgia and by the time she arrived at the hospital the pain shifted to the right lower abdomen. Physical examination showed a body temperature of 37.4°C and localized tenderness in the right lower quadrant of abdomen. No rebound tenderness was observed. Laboratory studies demonstrated a white blood cell count of $11.0 \times 10^9/L$. Abdominal roentgenogram showed no remarkable abnormality except for a small amount of intestinal gas. Abdominal ultrasound sonography, with a 7-MHz linear-array transducer (GE LOGIC 7), demonstrated an enlarged swollen appendix with a cross section diameter of 10 mm and multiple hypoechoic small lateral pouch-like projections (Figure 1). The surrounding was enclosed by pouch like projections in the hyperechoic lesion which was thought to be caused by inflammatory changes of the mesoappendix. Wall thickening of appendix was more prominent than that seen in typical appendicitis (Figure 2). We made a diagnosis of acute appendiceal diverticulitis. The patient underwent an emergent appendectomy. The resected appendix was 14 cm long and 1.0 cm in diameter with multiple diverticula. One of the diverticula was surrounded by inflammatory tissue (Figure 3). Microscopic study revealed a pseudodiverticulum with inflammation in its wall and mesoappendix. She had an uneventful recovery and was discharged two days after surgery.

DISCUSSION

Appendiceal diverticulum is an uncommon clinical entity, with an incidence of 0.2%-1.5% in surgical pathologic specimens^[1]. Its preoperative images have been rarely reported. Place *et al*^[2] have reported abdominal CT findings of appendiceal diverticulitis but they could not distinguish it from cecal diverticulitis preoperatively. Macheiner *et al*^[3] have also reported sonographic features of diverticulitis of the appendix vermiformis. According to their reports, a hypoechoic, inflamed diverticulum is surrounded by echogenic fatty tissue. This description is the same as our sonographic findings of acute appendiceal diverticulitis.

Figure 1 Longitudinal view of the appendix. A hyperechoic mass (arrowheads) including hypoechoic lateral pouch like lesion (arrow) is observed. Hypo lesion is appendiceal diverticula, and hyperechoic mass is inflamed adipose tissue (= mesoappendix).

Figure 2 Cross section of acute appendiceal diverticulitis (A) in the present case and acute suppurative appendicitis (B) in another case. Layer structure (A: arrowheads) was found in appendiceal diverticulitis because of all inflamed layers, and inside echogenic (A: arrow) which means containing air. Multiple lateral hypoechoic projections (= diverticula) were observed. In comparison, an echogenic ring (B: arrowheads) was observed in acute appendicitis showing mucosal and submucosal inflammation, and an echo free space filled with inflammatory fluid inside it.

Other than these findings, we found different appendiceal features of acute appendiceal diverticulitis from those of

Figure 3 Multiple diverticuloses in the resected appendix (arrows) and peri-appendiceal inflammation (= diverticulitis) in 5 cm from the tip (arrowheads).

typical acute appendicitis (Figure 2). In typical suppurative acute appendicitis, edematous mucosa is observed as a cross-sectional ring of strong echo and inside it there is an echo free space filled with fluid. In comparison, the appendix wall layers are thickened and echogenic in appendiceal diverticulitis because of air in it. These findings strongly support that the main inflammation is in the appendiceal wall itself rather than in the actual appendix.

Diverticular disease of the appendix has four variations^[4], namely appendiceal diverticula without inflammation, acute appendicitis with diverticula, acute appendiceal diverticulitis with acute appendicitis, and acute diverticulitis. The fourth variation is true acute appendiceal diverticulitis as the case presented here. Its sonographic features resemble those of colonic diverticulitis rather than acute appendicitis except for the enlarged appendix. We suggest that sonographic study is useful for the early diagnosis of acute appendiceal diverticulitis.

Abstract

Small bowel stenosis is a serious complication of intestinal anisakiosis. The aim of this report is to investigate whether severe stenosis of the small intestine can be conservatively managed. We treated two patients with severe stenosis of the small intestine caused by anisakiosis. Surgical intervention was eventually performed on the 23rd and 35th in the hospital, respectively. Histopathological examination of the resected specimens revealed that the intestinal wall had been completely damaged by the inflammatory reaction of anisakiosis, and that the damage was irreversible, thereby suggesting that laparotomy is needed in cases of severe small bowel stenosis caused by intestinal anisakiosis, even if a long period of conservative treatment for the intestinal anisakiosis allowed the patient to pass successfully through the acute phase.

Matsuo S, Azuma T, Susumu S, Yamaguchi S, Obata S, Hayashi T. Small bowel anisakiosis: A report of two cases. *World J Gastroenterol* 2006; 12(25): 4106-4108

<http://www.wjgnet.com/1007-9327/12/4106.asp>

INTRODUCTION

Gastrointestinal anisakiosis, caused by an infection through the ingestion of *Anisakis* sp. larvae in raw or insufficiently cooked fish, commonly occurs in the stomach. Small bowel anisakiosis is rarely seen^[1-10]. It has been reported that anisakiosis is usually a self-limiting disease process

cured by conservative management for 1-2 wk after the onset of the symptoms^[5,8,9]. We herein present two cases of small intestinal anisakiosis which were treated surgically after long period of conservative management. We also discuss whether patients with severe small bowel stenosis, who have successfully passed through the acute phase of intestinal anisakiosis, can be conservatively managed.

CASE REPORTS

Case 1

A 59-year-old male was admitted on January 30, 2001 to our hospital, with complaints of mild urticaria, left-sided abdominal pain, and nausea. Four days before admission, the patient had eaten mackerel. Upon admission, abdominal CT showed a mild dilatation of the small intestine with ascites; small bowel edema and thickening of the intestinal wall were not detected. Beginning the day after admission, the patient received conservative medical treatment for acute pancreatitis, a diagnosis based on the serum amylase level of 1666 IU/L (normal range: 130-400). No evidence of eosinophilia was present. Abdominal pain continued after normalization of the serum amylase level. The titer of serum IgG antibodies for *Anisakis* sp. was 2.30 (normal range < 1.5). An upper gastrointestinal (UGI) series by Gastrografin[®] showed a narrow segment (20 cm in length) of the small intestine and revealed a dilatation on the oral side of the intestine (Figure 1). Kerckring's folds disappeared completely in the narrow segment. Laparotomy was performed on the 35th post-admission day because the stenosis of the small intestine had not improved at all. Hence, the affected segment of the ileum was resected that measured 50 cm in length. Histopathological examination of the resected specimens revealed ulceration with infiltration of inflammatory cells in all layers of the intestinal wall. The structure of the wall was completely destroyed (Figure 2). The postoperative course was uneventful.

Case 2

A 62-old-male was admitted on November 19, 2004 to our hospital, with complaints of upper abdominal pain, nausea, and vomiting. Four days before admission, the patient had eaten sashimi and salted salmon. Abdominal CT demonstrated a remarkable thickening of the jejunal wall with ascites (Figure 3). An upper gastrointestinal series showed a narrow segment of the jejunum (20 cm in length) and revealed a dilatation on the oral side of the intestine (Figure 4). Kerckring's folds were visible. The titer of serum IgE-specific antibodies for *Anisakis* sp. was

Figure 1 UGI series showing a narrow segment of the small intestine with the disappearance of Kerckring's folds.

Figure 4 UGI series showing a narrow segment of the small intestine with the preservation of Kerckring's folds.

Figure 2 Resected specimens revealed histologically a complete destruction of the jejunal wall (D). P: Preserved wall of the intestine with an infiltration of inflammatory cells.

Figure 5 Resected specimens revealed histologically a perforated ulceration (U) with an infiltration of inflammatory cells. D: Destructive wall of the intestine.

Figure 3 CT showing a remarkable thickening of the intestinal wall.

14.3 (normal range < 0.34). Laparotomy was performed on the 23rd post-admission day because conservative therapy had not been effective. The affected segment of the jejunum was resected that measured 80 cm in length. Histopathological examination of the resected specimens revealed a perforated ulceration with infiltration of inflammatory cells in all layers of the intestinal wall and the formation of granulation tissue. The structure of the intestinal wall was completely destroyed, similar to Case 1 (Figure 5). The postoperative course was uneventful.

DISCUSSION

Anisakiosis, previously called anisakiasis, is the formal

terminology for the disease associated only with the genus *Anisakis*^[11]. In Japan, where raw fish is traditionally eaten in the diet, anisakiosis has been a public health problem^[12]. In Japan, most commonly reported anisakiosis is gastric anisakiosis. By contrast, in Italy and Spain, it has been reported that the disease has manifested as lesions in the small intestine in the majority of cases, but we are aware that the number of reported cases in these two countries does not reflect the frequency of anisakiosis there^[13,14].

In our diagnosis of gastrointestinal anisakiosis for the patients who manifested acute abdominal pain, raw fish ingestion prior to their admission was the most important aspect of their clinical history. Our patients had a history of ingesting raw fish. A positive result on a serological test has been shown to be helpful in diagnosis^[15]. In addition, imaging modalities, such as US and CT, have been reported to be useful^[2,8]. Typical CT findings include a relatively long segment of the symmetric wall thickening with luminal narrowing and diffuse contrast enhancement on the involved segment^[8]. A long segmental stenosis found in UGI series of our cases was similar to the CT findings.

For surgeons, small bowel stenosis would be one of the abdominal complications in patients with intestinal anisakiosis. Some reports argue that an early surgical approach should be avoided in cases where a small bowel obstruction suggests the possibility of intestinal anisakiosis^[8,13]. We would like to consider whether severe stenosis of the small intestine can be conservatively managed despite the fact that anisakiosis is reported to be a self-limiting disease. In our two patients, surgical intervention was eventually performed on the 23rd and 35th post-admission days, respectively. To our knowledge, there have been no reports of a long period of conservative

treatment of intestinal anisakiasis with severe small bowel stenosis in patients who successfully passed through the acute phase. When the intestinal wall has been completely damaged by the inflammatory reaction of anisakiasis, the change is irreversible. Our results indicate that laparotomy should be recommended for patients with severe long segmental stenosis caused by intestinal anisakiasis when the condition does not improve within 1-2 wk after conservative treatment.

In conclusion, surgeons should consider early laparotomy in the cases of patients with severe intestinal stenosis resulting from anisakiasis.

Abstract

A middle aged, non-addict male presented with right upper abdominal pain and swelling with respiratory distress. Examination revealed central cyanosis, bipedal pitting edema with prominent epigastric and back veins. Liver was enlarged, tender, spanned 20 cm without any splenomegaly or ascites. Other systems were clinically normal. Laboratory investigations showed polymorphonuclear leucocytosis with slightly deranged liver function. Abdominal ultrasonography showed an abscess in the right lobe of the liver with compressed inferior vena cava (IVC), middle and left hepatic veins. Arterial blood gas (ABG) documented hypoxia with orthodeoxia and air-contrast echocardiography was suggestive of an intrapulmonary shunt. A diagnosis of hepato-pulmonary syndrome (HPS) was made with near normal liver function secondary to amebic liver abscess. It reversed completely following successful treatment of the liver abscess.

INTRODUCTION

Hepato-pulmonary syndrome (HPS) is a dreaded

complication of liver disease. It consists of the triad of hepatic dysfunction and/or portal hypertension, intrapulmonary vascular dilatation, and gas exchange abnormalities (PaO₂ < 70 mmHg or alveolo-arterial gradient > 20 mmHg). HPS occurs mostly in cirrhotic patients but it has also been reported in cases of non-cirrhotic portal hypertension with minimal hepatic dysfunction. Liver transplantation is the only therapeutic option of proven benefit. We present a case where a large amebic liver abscess gave rise to transient portal hypertension due to Budd-Chiari Syndrome (BCS). The hemodynamic alteration led to development of HPS with minimal hepatic dysfunction and it reversed completely after successful treatment of the abscess.

CASE REPORT

A 38-year old non-addict male presented with right upper abdominal pain and progressively increasing right upper quadrant swelling for the last 3 mo. Along with it he also noticed swelling of both feet for 2 mo and respiratory distress for last 7 d. The abdominal pain was dull aching in character. There was no definite history of radiation or any aggravating or relieving factors. The patient denied any history of nausea, vomiting, and altered bladder or bowel habits. The bipedal edema was not associated with any facial puffiness, palpitation, chest pain or oliguria. His respiratory distress was progressively increasing and was not relieved on upright posture. He also noticed yellowish discoloration of his eyes and urine along with occasional low grade fever and weight loss. His past, personal and family history was non-contributory.

General examination revealed mild pallor, icterus, and bipedal pitting edema along with the presence of central cyanosis. The patient was febrile (oral temperature 39.2°C) with a respiratory rate of 28/min. The umbilicus was central, inverted with a single prominent epigastric and back vein. The venous flow was below upwards. Liver was enlarged, firm and tender with a sharp margin and smooth surface. The hepatic span was 20 cm and there was no audible bruit or rub. He did not have splenomegaly or ascites. The chest was dull on percussion below 4th intercostal space (ICS) along midclavicular line (MCL), below 6th ICS along midaxillary line (MAL) and below 8th ICS along infrascapular region on the right side, without any mediastinal shift. Auscultation revealed diminished breath sounds with diminished vocal resonance over the above region without any added sounds.

Figure 1 Chest X-ray showing elevated right dome of diaphragm.

Figure 2 Abscess in right lobe of liver with compressed IVC and non-visualized middle and left hepatic veins.

Examination of the other systems was within normal limits.

A complete blood count showed hemoglobin 11.5 mg% and total leucocyte count of 11 200/cmm with polymorphonuclear leucocytosis. The liver function test revealed bilirubin of 4.5 mg/dL (direct: 3.1 mg/dL), AST: 65 U/L, ALT: 70 U/L, ALP: 350 U/L, protein: 7.1 g/dL (Alb: 3.7 mg/dL), P-time: 15.8 s (control 13 s); other biochemical parameters were unremarkable. Chest X-ray was normal except for an elevated right dome of diaphragm (Figure 1). Ultrasonography of the abdomen unmasked an abscess in right lobe of liver (13 cm × 14 cm), with mild ascites. The portal vein was 15.5 mm with normal splenic size. The IVC was compressed and the middle and left hepatic veins were not visualized (Figure 2). Doppler study showed absent phasic variation in above veins.

The viral markers were negative and an upper GI endoscopy was unrevealing. Bacterial culture of the anchovy sauce pus on CT guided aspiration was negative.

Arterial blood gas analysis was performed with the patient both in supine position and after standing upright for 5 min. It showed hypoxemia with orthodeoxia, along with an increased alveolo-arterial gradient [Supine PaO₂: 70 mmHg; Standing PaO₂ (after 5 min): 59 mmHg; Standing A-a O₂ gradient: 46 mmHg]. The hypoxia was partially corrected on 100% oxygen inhalation.

We performed an air contrast echocardiography. Ten milliliters of normal saline were agitated in two 10-mL syringes connected through a 3-way stopcock, and it was then injected through a 20 gauge right superior extremity intravenous line. Micro bubbles were detected immediately in the right sided cardiac chambers on apical 4-chamber view of 2-dimensional transthoracic echocardiography. Delayed visualization of micro bubbles in the left heart chamber (i.e., after 3 cardiac contractions following visualization of micro bubbles in the right heart chamber) was suggestive of intrapulmonary “right to left” shunting. Normally no bubbles should be detected in the left heart chambers even after 3 injections of agitated normal saline. If it is visible within 3 cardiac contractions it suggests intracardiac shunting. In our case micro bubbles were visible in the left heart chambers after 5 cardiac contractions. Chest radiography, electrocardiography, and echocardiography were performed to exclude primary pulmonary or cardiac pathology.

Hence, we diagnosed it as a case of HPS occurring as a rare complication of amoebic liver abscess due to transient portal hypertension with near normal liver function. The patient was put on tube drainage with intravenous metronidazole. The pig-tail catheter was removed after the drainage volume decreased and the IVC was fully decompressed. A repeat ABG after 8 wk showed normalization of both hypoxia and orthodeoxia (Supine PaO₂: 94 mmHg, Standing PaO₂: 91 mmHg, Standing A-a O₂ gradient: 9 mmHg).

DISCUSSION

Amoebic liver abscess is common in this part of the world. Development of BCS due to amoebic liver abscess though uncommon, has been previously reported^[1,2]. HPS is a specific entity identified in the recent past. Although many data have emerged, questions remain unanswered regarding its natural history and pathogenesis. Hepatic dysfunction appears to be the usual setting in which it occurs. Prevalence of HPS in cirrhotic patients ranges from 5% to 29%^[3,4]. However, there have been anecdotal reports of HPS in patients with portal hypertension, without evidence of hepatic dysfunction (e.g., congenital hepatic fibrosis^[5], nodular hyperplasia^[6], Budd-Chiari syndrome^[7]). HPS also has been reported in cases of non-cirrhotic portal hypertension^[8], where hepatocellular dysfunction is minimal.

In our case hepatic dysfunction was minimal but transient portal hypertension was evidenced by prominent epigastric vein and ultrasonographic documentation of dilated portal vein (15.5 mm). Development of HPS in this short period (3 mo) is unusual but has been reported^[2]. Portal hypertension plays an important role in the pathogenesis of HPS, probably by increased NO production^[9]. Hemodynamic alteration in BCS leads to increased sinusoidal pressure and increased shear stress. The activation of NO release, by shear stress, from endothelial cells through a specific G protein-mediated signaling pathway may be an important factor^[10]. HPS can be reversed by cavoplasty in cases of BCS due to inferior vena cava obstruction^[2]. In our case decompression of IVC by drainage of the abscess led to the reversal of HPS. Thus, the above mentioned mechanisms might form the

basis of development of intrapulmonary vascular dilatation as a result of elevated portal pressure, irrespective of the associated hepatic functional status.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published by
The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology

Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
<http://www.wjgnet.com>
Telephone: +86-10-85381901
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations,

institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

Key words

Please list 6-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P*<0.05, ^b*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, ^c*P*<0.05 and ^d*P*<0.01 are used. Third series of *P* values can be expressed as ^e*P*<0.05 and ^f*P*<0.01. Other notes in tables or under illustrations should be expressed as ¹*F*, ²*F*, ³*F*; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included.

Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 \pm 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂ not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjnet.com/wjg/help/15.doc>

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used

abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please download CAF from <http://www.wjgnet.com/wjg/help/9.doc>.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to *WJG* all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The *WJG* requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1) direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3) supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The *WJG* does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to *WJG* if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

COPY EDITOR FOR THIS ISSUE: Gianfranco Alpini, Professor

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*), a leading international journal in gastroenterology and hepatology, has an established reputation for publishing first class research on esophageal cancer, gastric cancer, liver cancer, viral hepatitis, colorectal cancer, and *Helicobacter pylori* infection, providing a forum for both clinicians and scientists, and has been indexed and abstracted in *Index Medicus*, MEDLINE, PubMed, Chemical Abstracts, EMBASE, Abstracts Journals, Nature Clinical Practice Gastroenterology and Hepatology, CAB Abstracts and Global Health. *WJG* is a weekly journal published by The *WJG* Press. The publication date is on 7th, 14th, 21st, and 28th every month. The *WJG* is supported by The National Natural Science Foundation of China, No. 30224801 and No.30424812, which was founded with a name of *China National Journal of New Gastroenterology* on October 1, 1995, and renamed as *WJG* on January 25, 1998.

Abstract

Short bowel syndrome (SBS) refers to the malabsorption of nutrients, water, and essential vitamins as a result of disease or surgical removal of parts of the small intestine. The most common reasons for removing part of the small intestine are due to surgical intervention for the treatment of either Crohn's disease or necrotizing enterocolitis. Intestinal adaptation following resection may take weeks to months to be achieved, thus nutritional support requires a variety of therapeutic measures, which include parenteral nutrition. Improper nutrition management can leave the SBS patient malnourished and/or dehydrated, which can be life threatening. The development of therapeutic strategies that reduce both the complications and medical costs associated with SBS/long-term parenteral nutrition while enhancing the intestinal adaptive response would be valuable.

Currently, therapeutic options available for the treatment of SBS are limited. There are many potential stimulators of intestinal adaptation including peptide hormones, growth factors, and neuronally-derived components. Glucagon-like peptide-2 (GLP-2) is one potential treatment for gastrointestinal disorders associated with insufficient mucosal function. A significant body of evidence demonstrates that GLP-2 is a trophic hormone that plays an important role in controlling intestinal adaptation. Recent data from clinical trials demonstrate that GLP-2 is safe, well-tolerated, and promotes intestinal growth in SBS patients. However, the mechanism of action and the localization of the glucagon-like peptide-2 receptor (GLP-2R) remains an enigma. This review summarizes the role of a number of mucosal-derived factors that might be involved with intestinal adaptation processes; however, this discussion

primarily examines the physiology, mechanism of action, and utility of GLP-2 in the regulation of intestinal mucosal growth.

INTRODUCTION

Advances in surgical and medical care have made it possible for those with massive small bowel resections to survive. Unfortunately, a loss of greater than 50% of the small intestine often results in short bowel syndrome (SBS)^[1-4]. SBS is characterized by the inefficient absorption of nutrients and fluids resulting in severe diarrhea, dehydration, electrolyte imbalances, nutrient deficiencies, weight loss, and frequently, a long-term dependence on parenteral nutrition^[4-6]. In the pediatric population, total parenteral nutrition (TPN) maintenance-associated complications frequently result in sepsis, secondary liver failure, and high morbidity^[5,7,8]. The development of therapeutic strategies that could reduce the consequences of SBS and long-term parenteral nutrition while enhancing the intestinal adaptive response would be valuable.

Numerous non-nutritional factors are potential stimulators of intestinal adaptation including peptide hormones, growth factors, and neuronally-derived components^[9]. Some of the growth factors that have been shown to stimulate intestinal growth include glucagon-like peptide-2 (GLP-2), epidermal growth factor (EGF), growth hormone (GH), insulin-like growth factor-1 (IGF-1), neurotensin (NT), intestinal trefoil factor (ITF), transforming growth factor (TGF- α ; TGF- β), and

Table 1 Growth factors as potential stimulators of intestinal adaptation

Growth factor	Amino acids /MW	Mucosal growth factors and SBS	
		Main source	GI receptor localization
GLP-2	33 aa/3.8 kDa	Ileal and colonic EE L-cells, pancreatic α cells	GLP-2R; EE cells, myenteric/submucosal neurons of ENS
EGF	53 aa/6.4 kDa	Submandibular gland, duodenal Brunner's gland, epithelial and Paneth cells	EGFR/HER/Erbb, HER2/Neu/Erbb2, HER3/Erbb3, HER4/Erbb4
KGF (FGF-7)	194 aa/2.5 kDa	Fibroblast-like stromal cells in epithelial tissue	KGFR; a/bFGFR epithelial cells
Hb-EGF	86 aa/22 kDa	Smooth muscle cells	Activate all as listed for the EGFR
GH	191 aa/22 kDa	Liver	CRF type-1, PRL-R
TGF- α	50-53 aa/6.2-6.4 kDa	Epithelial cells	Activate all as listed for the EGFR
NT	13 aa/?	Ileum/colon >> proximal SB, EE N-cells	NTR1
PYY	36 aa/42 kDa	Ileal and colonic EE L-cells	Y1-R; EE cells, myenteric/submucosal neurons of ENS
GRP	14 aa/?	Neuroendocrine cells in the ENS, fibroblasts	GRPR antrum, upper GI tract
CCK	8, 33 aa/39 kDa	Duodenal EE I-cells	CCK _A >> CCK _B upper GI tissue myenteric/submucosal neurons of ENS
Gastrin	17 aa/21 kDa	Gastric antrum G-cells	CCK _B >> CCK _A
	34 aa/40 kDa	Pancreatic D-cells	upper GI tissue
IGF-I/II	I-70 aa/7.6 kDa,	Proximal SB >> distal, liver,	IGF-IR and IGF-IIR
	II-67 aa/7.4 kDa	Fibroblasts	epithelial cells, glial cells, fibroblasts

Many of these factors include peptide hormones, growth factors, and neurovascular components. SB, small bowel; ENS, enteric nervous system; EE, enteroendocrine; GLP-2, glucagon-like peptide-2; EGF, epidermal growth factor; Hb-EGF, heparin-binding EGF; KGF, keratinocyte growth factor (FGF-7); FGF, fibroblast growth factor; GH, growth hormone; CRF-1, cytokine-related family type-1 (JAK-STAT pathway); PRL, prolactin (subgroup of the CRF-1 superfamily); TGF- α , transforming growth factor- α ; NT, neurotensin; PYY, peptide tyrosine tyrosine; GRP, gastrin-releasing peptide; CCK, cholecystokinin; IGF-I/II, insulin-like growth factor I/II.

fibroblast growth factor (FGF)^[10]. Table 1 lists some of the mucosa-derived humoral factors that have been shown to promote intestinal adaptation following intestinal resection.

GLP-2 is a potential therapy currently under consideration for the treatment of gastrointestinal disorders that are associated with insufficient mucosal function. Evidence from both animal studies and clinical trials demonstrate that GLP-2 is a trophic hormone that plays an important role in the regulation of intestinal adaptation^[11]. Under normal conditions, GLP-2 is secreted into the circulation in response to the ingestion of a mixed meal^[12-15], particularly following one that contains carbohydrates, fatty acids, and fiber^[16-18]. These studies have shown that following nutrient-induced release or exogenous administration, GLP-2 is involved in the regulation of cell proliferation, apoptosis, nutrient absorption, motility, as well as epithelial and intestinal permeability^[15,19-25].

Initial pilot Phase II trials in SBS patients treated with teduglutide, a GLP-2 analog, observed that there were modest increases in fluid and nutrient absorption. Based upon the positive results of this trial, Phase III studies in adults with SBS were initiated. Subsequently, a recent article in *GUT* shows that teduglutide, using various dosing modalities over a 21 d experimental period, was safe, well tolerated, and promoted intestinal growth in SBS patients having either an end jejunostomy or a colon in continuity^[26]. Moreover, teduglutide therapy in these SBS patients resulted in a significant increase in small intestinal villus height, crypt depth, and mitotic index. The authors state that the most significant clinical benefits of teduglutide in treating SBS patients were the reduction of intestinal wet weight excretion and in improving wet

weight absorption^[26]. There are several other clinical trials underway that are examining potential therapeutics for the treatment of SBS, unfortunately, Zorbitive® (hGH, glutamine) remains the only option presently available for prescriptive use.

This review summarizes the current understanding of a number of growth factors and their role in the treatment of SBS. As it is unlikely that there is just one specific growth factor responsible for maintaining mucosal growth, an important consideration is that there is likely some degree of regulation, transactivation, and crosstalk, between established stimulators of mucosal growth (i.e. epidermal growth factor, insulin-like growth factor-I, polyamines, GLP-2). Thus an understanding of the collective influence of these promoters of intestinal adaptation should not be dismissed. However, the primary focus of this discussion is to examine the physiology, mechanism of action, and utility of GLP-2 in the regulation of intestinal mucosal growth.

Discovery of GLP-2

The first indication that GLP-2 was trophic to the bowel was the observation that patients with glucagonomas had significantly elevated circulating enteroglucagon levels that was secondarily associated with intestinal mucosal hyperplasia^[27,28]. The correlations between serum enteroglucagon levels and mucosal growth of the small intestine provided further evidence for the trophic effects of GLP-2^[27]. A major breakthrough came in 1996 when it was shown that injection of proglucagon-producing tumors into nude mice resulted in significant mucosal hyperplasia^[29]. Isolation of the various components of these proglucagon-producing tumors revealed that GLP-2 was the trophic factor responsible for the increased

mucosal growth.

Additional evidence for intestinotrophic properties of GLP-2 came from studies in rats and mice in which GLP-2 administration induced intestinal hypertrophy i.e., significant increases in protein and DNA content, villus height, and bowel weight^[21,25,30,31]. Moreover, GLP-2 treatment reduced mucosal atrophy associated with TPN administration and augmented the adaptive growth response following massive small bowel resection^[19-21,32]. Our studies showed that in parenterally maintained animals (no luminal nutrition), infusion with GLP-2 stimulated intestinal adaptation following small bowel resection^[18]. Without the infusion of GLP-2, intestinal adaptation did not occur. Similarly, the immunoneutralization of endogenous circulatory GLP-2 reduced the intestinal post-resection adaptive response in rats and rabbits^[33].

What is GLP-2?

GLP-2 is a member of the PACAP (Pituitary adenylate cyclase activating peptide)/Glucagon superfamily that includes the enteroglucagon/proglucagon-derived peptides (PGDP) that are produced in the L-cells of the small intestinal and colonic mucosa. The L-cells have been identified as the cellular origin of enteroglucagon (Figure 1)^[24,34,35]. In 1983, the full sequence of hamster proglucagon, and later that year, the human sequence, were published revealing the sequences of GLP-1 and GLP-2^[36,37]. GLP-2 is described as glucagon-like as it shares approximately 50% sequence homology with glucagon^[37]. Sequencing of GLP-2 from human and pig intestine has confirmed the structure of GLP-2 as a 33 amino acid peptide that contains alanine at position 2 of the N-terminus (making it easily degraded by exopeptidases) and ends with a carboxy-terminal Asp residue^[45]. GLP-2 and the other PGDPs are derived following the proteolytic cleavage and other enzymatic modifications of proglucagon in the organelles of the pancreatic α -cells and intestinal L-cells^[38,39]. Interestingly, GLP-2 and the other products of post-translational processing (glicentin, GLP-1, oxyntomodulin) are produced in the intestinal L-cells, while glucagon and the major proglucagon fragment (MPGF) are produced in the α -cells of the pancreas^[40]. They are formed from the same precursor molecule and therefore must be secreted in parallel. Differential expression of prohormone convertase (PC), the enzyme responsible for cleaving proglucagon into various hormonal products in the different cells, accounts for the different products. The PC2 enzyme, which has a greater abundance in the pancreatic α -cells, preferentially produces glucagon as its end product^[41-43]. On the other hand, the PC1/3 enzyme, which is found in greater abundance in the intestinal L-cell, predominantly generates the glucagon-like peptides (GLP-1/2)^[41]. Therefore, the differential processing of proglucagon in pancreatic α -cells by PC2, and by PC1/3 in the intestinal L-cell, might generate two unique hormonal products from the same precursor with each having a different physiological effect^[43].

Initially, the GLP-2 sequence was identified in all mammalian cDNA, but not in other species. This led researchers to theorize that GLP-2 was a late evolutionary addition. Subsequent studies have demonstrated that fish,

Figure 1 Potential pathways involved in the production, release, activity, and sites of action of GLP-2. GLP-2 produced by the L-cell is induced following the ingestion of a meal and can be induced either by direct stimulation of the L-cell, or potentially following the release of upstream neuronal /hormonal agonists. The GLP-2R has been localized to components of the enteric nervous system (ENS) and to regions of the brain, thus the growth-promoting effects associated with GLP-2 may involve interactions with the brain-gut axis. Potentially the ENS / vagal interface might be responsible for the early release of GLP-2.

chickens, and lizards generate GLP-2 in the gut as a result of tissue-specific alternative RNA splicing of proglucagon RNA transcript^[44].

Site of GLP-2 production

The distal regions of the small bowel and/or the large intestine are necessary for GLP-2 production. This was demonstrated in a study in which patients with SBS, without a colon in continuity, had significant reductions in their post-prandial circulatory GLP-2. Subjects that had 140 cm or less of small bowel, with colon in continuity, exhibited a significant increase in their serum GLP-2 levels^[46,47]. Conversely, fasting and post-prandial serum GLP-2 levels were elevated in SBS patients (colon intact, no ileum) compared with sex- and age-matched controls^[46]. The locale of the GLP-2-containing tissue in the human intestine is debatable, though it was recently reported that the number of immunoreactive GLP-2 cells increase in a proximal to distal distribution in normal colonic tissue^[48].

However, there is debate as to the contribution of different regions of the bowel to total GLP-2 production. A 90% intestinal resection, leaving only 10 cm of distal ileum, results in a significant elevation in serum GLP-2 levels in the rat^[15]. These elevations in circulatory GLP-2 correlate with several measurable parameters of intestinal adaptation^[18]. As the remainder of the small bowel had been removed, this suggests that the distal ileum and/or the colon are the major sites of the L-cells, the cells responsible for the production of GLP-2 (Figure 1). Others describe that in the rat, TNBS (trinitrobenzene sulphonic acid) -induced ileitis resulted in no change in the number of GLP-2 immunoreactive cells in the ileum, yet colonic GLP-2 immunoreactivity was increased (personal communication, Jennifer O'Hara and Dr. K.A. Sharkey).

Interestingly, in a rat SBS model in which only 20 cm of jejunum was anastomosed directly to the ascending colon^[49] (i.e., removal of 80% of the distal small bowel

Figure 2 An experimental rat model of SBS-induces changes in circulatory GLP-2 levels. The distal regions of the small bowel and/or the large intestine are necessary for GLP-2 production. In these experiments, the entire proximal small bowel was removed; therefore the distal ileum and/or the colon are likely the cells responsible for the production of GLP-2 as all other bowel tissue had been removed. Resected = 90% intestinal resection leaving a 10 cm ileal remnant. CEC = cecetomy + removal of all but 20 cm of jejunum. The remnant jejunum was anastomosed to the ascending colon. ^a*P* < 0.05 vs cecetomized animals; ^c*P* < 0.05 vs 90% proximal resected animals that were enterally-fed (10 cm remnant ileum).

including the ileum and cecum), circulatory GLP-2 levels were significantly increased in comparison to both controls and the 90% resection animals with ileum intact (Figure 2). This strongly suggests that the colon is an important source of GLP-2. These findings emphasize the importance of determining if the increase in serum GLP-2 levels are the result of either an increase in the L-cell population, or alternatively, as a consequence of augmented GLP-2 production by the L-cells. Our ongoing experiments suggest, at least in this rat model of SBS, that increased GLP-2 production is the result of an increase in the colonic L-cell population (unpublished observations).

GLP-2 receptor and activity

Currently, the localization of the glucagon-like-2 receptor (GLP-2R) remains an enigma. Conflicting data in the literature report the GLP-2R to be located on enteroendocrine cells^[50], on non-epithelial elements such as neuronal cells^[51], and subepithelial myofibroblasts (Figure 1)^[52]. Moreover, the localization of the GLP-2R in the bowel might be region-specific. In a recent study by Orskov *et al*, GLP-2 receptors were found throughout the small and large bowel in humans, mice, marmoset, and rat^[52]. Furthermore, the intestinal region that had the greatest GLP-2R immunoreactivity was the proximal small bowel. These data were confirmed by both immunohistochemistry and *in situ* hybridization that showed that the GLP-2R was localized to cells lying beneath the basal membrane of enterocytes^[52].

The specific GLP-2 receptor has been isolated, sequenced, and found to be expressed in both the gut and in the hypothalamus (Figure 1)^[53]. GLP-2 binds to a 7 transmembrane (7-TM) G protein-coupled receptor that is comprised of 550 amino acids. In humans, the expression of the GLP-2R is localized to specific enteroendocrine cells in the stomach as well as the small and large bowel^[53-55]. Currently there have been only two human cervical carcinoma cell lines, including HeLa cells, in which GLP-2R mRNA transcripts have been detected^[56]: the majority of the signal pathway determinations have been carried out in cells transfected with the GLP-2R^[55]. The

Figure 3 A: GLP-2 stimulation of the G_s-Coupled Receptor induced cell proliferation. The proposed GLP-2 /GLP-2R signaling pathway as characterized in cells that were transfected with the GLP-2R. See section on GLP-2 receptor-activity for description (pages 11-12); B: GLP-2 stimulation of the G_{αi}-Coupled Receptor induced cell proliferation. Possible trafficking pathways triggered by GLP-2 in cells that tested negative for the characterized GLP-2R. Potentially, GLP-2 induces divergent signaling pathways which results in an increase in the rate of cell proliferation. See section on GLP-2 receptor-activity for description (pages 11-12).

enteroendocrine cells that do express the GLP-2R have also been found to express other gut hormones such as glucagon-like peptide-1, glucose dependent insulinotropic peptide, peptide YY, and serotonin^[50]. PACAP and VIP share the same VPAC₁ receptor with equal affinity^[34], thus it might be possible that other members of this family also share receptors.

There are a number of unanswered questions regarding the signaling mechanism involved in how GLP-2 stimulates mucosal growth. The initial studies on intracellular trafficking was done entirely in cell lines (BHK /COS) that had been transfected with the characterized GLP-2R^[55,57]. These data showed that GLP-2/GLP-2R signaling involved classic G protein-coupled G_{αs} activation of adenylyl cyclase (AC), increased cAMP and PKA accumulation, and eventually ELK-1/c-fos/c-jun gene activation and increased cell proliferation (Figure 3A). Conversely, in epithelial cell lines devoid of the GLP-2R (as confirmed by both Western blot analysis and by the absence of mRNA transcripts), GLP-2 administration was still capable

of increasing cell proliferation^[56,58,59]. Thymidine uptake as a measure of an increased proliferation was significantly inhibited following pre-incubation with pertussis toxin ($G\alpha_i$ inhibitor) or MAPK blockade, implying that $G\alpha_i$ or EGFR/TyrK trafficking pathways are involved (Figure 3B). These studies also revealed that, in comparison with the transfected cell lines in which increases in cAMP correlated with augmented growth, there was a significant correlation between increased cell proliferation and decreased cAMP accumulation.

Furthermore, the possibility that there are multiple signaling mechanisms for GLP-2 is suggested by recent observations regarding the divergent effects of GLP-2 administration on epithelial cell proliferation. These effects were dependent on both the cell line and the dose of GLP-2 administered. Two independent studies demonstrated that administration of GLP-2 results in the inhibition of proliferation of non-transformed small intestinal epithelial cell lines (IEC-6, IEC-18), while increasing proliferation of cancer-derived human colonic epithelial cell lines (Caco-2, Colo 320)^[59,60]. Moreover, there can be divergent effects of GLP-2 on epithelial cell migration, as GLP-2 significantly increased migration in the small intestine-derived IEC-6/IEC-18 cells, but had no effect on epithelial cell migration in the colonic Caco-2 or the Colo 320 cells^[60].

An article recently published in *Science* may have uncovered another important component of the GLP-2 signaling pathway^[61]. It is established that the intestinal epithelium undergoes constant renewal along the crypt-villus axis and that the β -catenin/T cell factor (TCF) transduction pathway is involved in these proliferation/differentiation events^[62-64]. These data reveal that GLP-2 treatment of mice increases β -catenin levels suggesting that β -catenin might be a downstream mediator of GLP-2-induced crypt cell proliferation. In addition, the expression of a cDNA encoding human R-spondin1 (hRSpo1) in KI chimeras led to a substantial increase in the diameter, length, and weight of the small intestine, diffuse thickening of the mucosa, and crypt epithelial hyperplasia^[61]. Their data showed that the administration of hRSpo1 potently affects proliferation of the intestinal epithelium through activation of β -catenin; the activation of this pathway by hRSpo1 indicates that the effect might be directly stimulated by receptor-mediated binding. It is interesting that the expression of hRSpo1 in human intestinal enteroendocrine cells, consistent with the role of this protein as a crypt cell mitogen, is similarly localized to the expression of GLP-2^[61]. This is certainly an exciting find in regards to mapping out potential signaling pathways involved in GLP-2-induced intestinal growth.

Collectively, this dichotomy suggests that there are divergent signaling pathways involved in how GLP-2 stimulates cell proliferation. Secondly, it begs the question: are other uncharacterized GLP-2R's or transactivation signaling mechanisms involved in the intestinotrophic effect of GLP-2 other than that initially described by Munroe *et al.*^[53]?

GLP-2 interactions with the ENS/CNS

There is evidence that the GLP-2R is expressed on both

Figure 4 GLP-2 stimulation of the enteric nervous system. GLP-2 binds to 7-TM G protein-coupled receptors localized to components of the ENS. This results in a conformational change in the GLP-2R that eventually activates c-fos expression via the $G\alpha_s$, AC, c-AMP pathway. This suggests that a rise in circulatory GLP-2 levels might stimulate the GLP-2R leading to an increased stimulation of the myenteric and/or submucosal neurons. Potentially the trophic effects on the gut mucosa associated with GLP-2 are the result of a second downstream mediator, either a neurotransmitter or direct innervation that is activated upon GLP-2's initial stimulation of the ENS localized GLP-2R.

murine enteric neurons and cerebral cortex astrocytes^[51,65]. Bjerknes and Cheng showed by *in situ* hybridization that the GLP-2R is located on nonepithelial elements of the enteric nervous system. These results were further verified by reverse-transcriptase polymerase chain reaction (RT-PCR) for the GLP-2R mRNA^[51]. Moreover, the GLP-2R was located on neurons and not on glial cells. These experiments demonstrate that GLP-2 is capable of inducing *c-Fos* activity in enteric neurons in as little as 7 min, and achieved maximal expression by 15 min. After 90 min, the increase in GLP-2-induced neuronal *c-Fos* activity was followed by increased *c-Fos* activity in the crypt cells of the jejunum and colon. These observations suggest that GLP-2 stimulates the GLP-2R leading to an increased *c-Fos* expression in myenteric neurons (Figure 4), which is secondarily followed by both an increase in *c-Fos* expression in the crypt cells and the stimulation of columnar crypt cell growth. Tetrodotoxin (TTX) pre-treatment abolished *c-Fos* expression in the crypt cells revealing that GLP-2 signaling in the bowel might be dependent on a transduction pathway requiring enteric neurons^[51]. Potentially the intestinotrophic property associated with GLP-2 involves a second downstream mediator that is released upon GLP-2's initial stimulation of the ENS (Figure 4).

The GLP-2R is also localized to regions of the hindbrain^[66]. The dorsal medial hypothalamus (DMH) contains a dense plexus of GLP-2 immunoreactive fibers that express GLP-2 receptor mRNA (Figure 1). Though

research regarding GLP-2's involvement in neuronal activation is still in its infancy, it is interesting that GLP-2's effects on enteric /vagal pathways are remarkably similar to those characterized for cholecystokinin^[67,68]. This possibility has led to discussions regarding GLP-2 as a factor involved in the regulation of feeding. There is evidence that GLP-2 administration can inhibit feed intake^[66,69,70] however, other investigators report no effect on appetite or energy intake at physiological concentrations of GLP-2^[71]. This area of GLP-2 physiology requires further investigation.

These observations suggest a novel pathway of GLP-2 action as perhaps either a meal-stimulated endogenous release of GLP-2 from the L-cell, or potentially, the therapeutic administration of GLP-2, could activate enteric neuronal activity, resulting secondarily in the release of downstream mediators capable of inducing crypt cell proliferation (Figure 4). Currently, no studies have been published in which the expression of the GLP-2R in the human enteric nervous system was examined.

GLP-2 receptor antagonists

An obstacle when examining mechanistic pathways involved in GLP-2-induced small bowel adaptation is the lack of effective GLP-2R antagonists. One possibility would be to use the primary degradation product (GLP-2³⁻³³) to see if the interaction with the GLP-2R could reduce the adaptive response to intestinal resection. These results might be difficult to interpret as the treatment of mice with either GLP-2¹⁻³³ or GLP-2³⁻³³ induces significant growth in both the small and large bowel, though the growth response induced by the degradation product is reduced^[72]. Furthermore, functional studies and binding data indicate that GLP-2³⁻³³ acts as both a partial agonist and as a partial antagonist on the GLP-2R^[72]. However, there is recent data that demonstrates GLP-2³⁻³³ antagonizes the growth-promoting activities of GLP-2¹⁻³³ *in vitro* and *ex vivo*^[73]. Shin *et al* suggest that endogenous GLP-2¹⁻³³ regulates the intestinal growth-promoting response via modulation of crypt-cell proliferation and villus apoptosis^[73]. Collectively, these findings do not support the use of GLP-2³⁻³³ as a full antagonist of the GLP-2 receptor.

GLP-2 inactivation and metabolism

As mentioned earlier in this review, GLP-2¹⁻³³ contains the amino acid alanine at position 2 thereby making it susceptible to degradation by the exopeptidase dipeptidyl peptidase IV (DPP-IV)^[74]. For excellent reviews on the structural and functional properties of DPP-IV, see Mentlein or Lambair^[75,76]. The primary metabolism of GLP-2¹⁻³³ by DPP-IV, which cleaves off two N-terminal amino acids, results in the formation of GLP-2³⁻³³, a potential receptor antagonist /agonist^[72,73]. The elimination half-life of intact GLP-2¹⁻³³ in humans is 7 min, whereas that of cleaved GLP-2³⁻³³ is 27 min^[14], thus the cleavage of the NH₂ terminal may potentially disrupt the signal transduction pathway and reduce GLP-2's biological effectiveness. The administration of GLP-2 to DPP-IV deficient rats results in higher GLP-2¹⁻³³ serum levels which correlate with a significant increase in small intestinal weight^[74,77]. Similar increases in intestinal hypertrophy also

occur in rats and mice administered a synthetic DPP-IV resistant GLP-2 analog (ALX-0600)^[31,74] suggesting that the inactivation of GLP-2¹⁻³³ by DPP-IV is a crucial limiting factor regarding GLP-2's trophic effect on the gut mucosa. In humans, the replacement of alanine in position 2 of the GLP-2 peptide with glycine, has been shown to extend the half life from approximately 7 min, as for GLP-2, to 0.9-2.3 h.^[26] Thus, DPP-IV resistant GLP-2 analogues might be useful therapeutically to help improve mucosal regeneration.

In contrast, there is evidence that DPP-IV may not be the only factor important in the degradation of GLP-2^[78]. Geier *et al* did not detect an observable role for DPP-IV in the regulation of GLP-2 in DPP-IV^{-/-} mice, as there were no measurable differences in GLP-2 levels or plasma DPP-IV-like activity between DPP-IV^{+/+} and DPP-IV^{-/-} mice. Although DPP-IV^{-/-} mice lack the *DPP-IV* gene, they do possess the genes for FAP, DP8, and DP9, and might have sufficient dipeptidyl peptidase levels to regulate GLP-2 cleavage. Moreover, the mice lacking the *DPP-IV* gene do not have either intrinsic resistance, or an enhanced rate of repair, in DSS-induced colitis. The authors concluded that residual dipeptidyl peptidase levels in the DPP-IV^{-/-} mice results in insufficient GLP-2¹⁻³³ bioavailability to protect these mice from DSS (dextran sodium sulfate) -induced damage. The association between GLP-2 and DPP-IV family members will require further study.

Plasma concentrations of GLP-2 are not only influenced by the rate of secretion, but by the elimination or clearance rate. The kidney is important in the clearance of GLP-2 as there are increased circulatory levels in patients with renal failure^[79,80]. In addition, experimental nephrectomy results in delayed clearance and increased circulating levels of GLP-2 in rats^[81]. The increase in circulatory GLP-2 levels following nephrectomy is not surprising as it has been shown that the kidney is the site of greatest DPP-IV activity^[75].

GLP-2 and intestinal inflammation

The treatment of animals with GLP-2 reduces harmful symptoms of inflammation associated with colitis as well as the mortality and the severity of both indomethacin and TNBS-induced enteritis^[35,82,83]. Moreover, studies within our lab reveal that GLP-2 ameliorates inflammatory parameters associated with TNBS-induced ileitis (Gastroenterology abstract, T1530, 2005). These reductions in inflammation (decreased myeloperoxidase activity, interleukin-1 β , and inducible nitric oxide synthase protein in mucosal tissue) 5 d post-TNBS occurred whether the GLP-2 was given simultaneously with TNBS, or 2 d post-TNBS injection. Others have observed that GLP-2 treatment initiated following chemotherapy enhances intestinal recovery^[84]. A second report also showed the benefits of GLP-2 treatment as a preventative against cancer therapy-induced mucosal damage^[85]. Teduglutide, a GLP-2 analog, given daily prior to whole body gamma-irradiation significantly increased crypt stem cell survival in mice when compared with vehicle-treated controls, though the protective effect was only observed when teduglutide was given prior to irradiation^[85]. Collectively, these reports indicate that GLP-2 might be a useful therapeutic strategy in

the treatment of diseases associated with intestinal inflammation.

There are conflicting reports regarding the effect of intestinal inflammation on GLP-2 production, particularly on the site of GLP-2 production. Intuitively, any situation that depletes the GLP-2-producing L-cells could potentially reduce the ability of GLP-2 to repair the mucosa. This could be the case in Crohn's/colitis patients as inflammation of the intestine likely disrupts the L-cells. In a mouse-model of T-cell-induced inflammatory bowel disease (IBD), the amount of GLP-2 was significantly reduced in the colon^[86], however, others report that TNBS-induced ileitis results in an increase in colonic GLP-2 immunoreactivity. (O'Hara and Sharkey, personal communications). Regarding the latter, perhaps an increase in local and circulatory GLP-2 is the result of IBD-induced diarrhea, thus increasing the nutrient load in the distal bowel, a well-described potent stimulus for inducing GLP-2 production^[12,15,17]. Though speculative, perhaps increased growth and nutrient absorption in the proximal small intestine as a result of increased GLP-2 production would be successful in ameliorating inflammatory processes. Conversely, Schmidt *et al* found that both the fasting and meal-induced plasma levels of GLP-2 were not different between healthy controls and IBD patients^[87]. This report suggests that L-cell secretion of GLP-2 is not altered in IBD. The discrepancies between these observations could be the result of model/species difference, or site-specific effects of inflammation in the bowel.

While GLP-2 is the most prominent enterotrophic peptide, there are a number of hormones that might be involved in the regulation of mucosal growth. These are briefly discussed as it is likely that processes involved in intestinal adaptation are regulated by a complex array of hormones, neuropeptides, and cytokines. A number of mucosal growth factors that might be useful for the treatment of short bowel syndrome are listed in Table 1.

Insulin-like growth factor-I

Another growth factor that might have a potential role in enhancing mucosal growth is insulin-like growth factor-I (IGF-I). IGF-I is produced mainly in the liver, but it is also synthesized locally in the gut^[88]. There is evidence that IGF-I stimulates intestinal growth under experimental conditions of TPN therapy, intestinal resection, and radiation therapy^[89]. In addition, the over-expression of the gene encoding for IGF-I is associated with increased small bowel length, small bowel weight, and crypt cell proliferation^[90]. Conversely, others report that ileal IGF-I levels remain unchanged following intestinal resection^[90,91].

Most of the circulating IGF-I is bound to IGF-binding proteins (IGFBPs) that potentially protect IGF-I from degradation thereby modulating the activity of IGF-I^[92,93]. IGFBPs are capable of controlling the availability of circulating IGF-I to target tissues and are thus key components in the GH-IGF-I somatotrophic axis. In humans, six IGFBPs have been identified and shown to modulate IGF-I actions differently^[94]. Serum levels, jejunal tissue protein, and mRNA levels of IGF-I are reduced following small bowel resection^[95]. One possibility

is that there is a significant decrease in IGFBP-3 mRNA following intestinal resection, thus this rapid decrease in the IGFBP-3 could increase IGF-I bioavailability resulting in an enhanced adaptive response^[96].

In SBS rats maintained on parenteral nutrition, IGF-I infusions induced jejunal hyperplasia and normalized ion transport^[97]. Thus acute IGF-I treatments might prove to be beneficial in easing the transition from parental to enteral feeds thereby avoiding some of the long-term dilemmas associated with TPN therapy^[98]. However, there is no significant evidence of serum or tissue concentration fluctuation of IGF-I following intestinal resection, therefore its utility as a treatment for SBS remains unclear.

Epidermal growth factor

Most of the EGF family of peptides (transforming growth factor- α , amphiregulin, heparin-binding EGF, epiregulin, betacellulin, neuregulin, neuregulin-2) are trophic to the gastrointestinal tract as they both stimulate crypt cell proliferation and suppress apoptosis^[99]. There is evidence that EGF administration at the time of small bowel resection enhances the adaptive response. This appears to be accomplished by inducing mucosal hyperplasia and increasing nutrient absorption, while reducing intestinal permeability, weight loss, and apoptosis^[49,100,101]. It is important to note that EGF therapy is most effective for intestinal adaptation when it is administered early following resection^[102]. Very few studies have examined serum EGF levels following small bowel resection. Shin *et al* showed that small bowel resection does not change serum EGF levels, yet there was an increase in salivary and a decrease in urinary excretion of EGF^[103]. Ileal epidermal growth factor receptor (EGFR) levels were significantly increased suggesting that the increased salivary EGF (significant endogenous source of EGF), enhanced EGF-R expression, and reduced urinary excretion of EGF, leads to an increase in ileal utilization of EGF following resection. Compared with control mice, the removal of the submandibular glands significantly attenuated the increase in villus height, total protein, and DNA content of the small bowel following massive small bowel resection^[104].

It has also been suggested that intestinal adaptation following resection requires a functional EGFR^[105]. Selective inhibition of the EGFR with an orogastric EGFR inhibitor (ZD1839, 50 mg/kg per day) results in impaired intestinal adaptation after small bowel resection^[106,107]. There is also an impaired adaptive response to intestinal resection in waved-2 mice-mice that are predisposed to a naturally occurring mutation that results in a reduction in EGFR protein tyrosine kinase activity. *In vitro* studies demonstrate that serum from intestinal resection mice or rats is capable of stimulating a proliferative response in rat intestinal epithelial cells (IEC)^[108]. This uncharacterized factor released into the serum of 7 d resected rats significantly increased EGF-R protein expression. Additionally, the proliferative response in IEC's was abolished following the addition of a specific EGFR inhibitor. It would be intriguing to explore if there is cross talk between GLP-2, which is significantly increased following intestinal resection, and the EGFR signaling pathway. The basis for this speculation was

discussed earlier and is depicted in Figure 3B.

PACAP and VIP

All but one of the members of the PACAP/glucagon superfamily, GIP, have been found as protein and/or mRNA in the brain and are thus classified as neuropeptides^[34]. For an excellent review of this family of peptides, see Sherwood *et al*^[34]. All of these peptides are found in the gut and signal through 7-TM G-protein coupled receptors. In humans, the present members include PACAP, glucagon, glucagon-like peptide-1, growth hormone releasing hormone, vasoactive intestinal peptide (VIP), secretin, glucose-dependent insulinotropic peptide (GIP), and GLP-2^[34]. Both VIP and PACAP have a widespread distribution and are known to affect neural, circulatory, gastrointestinal, endocrine, and immune systems. There is evidence that VIP and PACAP administration reduces apoptosis and promotes the survival of neural cells by inducing *bcl-2* activity. Increased *bcl-2* activity is associated with an inhibition of caspase-3 activity and decreased cytoplasmic cytochrome C release^[34]. Moreover, the BH4 domain of the pro-survival protein *bcl-2* both binds to the C-terminus of Apaf-1 on caspase-9, thus inhibiting caspase-induced apoptosis, as well as directly or indirectly preventing the release of cytochrome C from the mitochondria^[109,110]. Similar results were attained following the activation of GLP-2R signaling by GLP-2 administration in transfected cells treated with cyclohexamide or irinotecan. These data show that there was an inhibition of apoptosis, reduced caspase activation, and decreased mitochondrial cytochrome C release^[57,84]. An additional parallel of these peptides is revealed following recent studies suggesting that GLP-2 is a vasodilator^[111,112]. PACAP and VIP are both established as potent vasodilators^[34].

At physiological concentrations, VIP and GLP-2 are both ineffective in stimulating cell growth directly in cell culture. Perhaps the intact ENS might need to be activated first as VIP receptors, and likely GLP-2 receptors, are located on enteric neurons^[34,51]. It would be interesting to examine the growth-promoting potential of the ENS on epithelial cells *in vivo*.

There are conflicting results regarding plasma and tissue levels of VIP following small bowel resection and in studies examining SBS. These differences may be species-specific as following intestinal resection, dogs and pigs have a significant reduction in VIP levels, whereas in humans, there is either an elevation or no change in plasma VIP levels^[113-116]. There is no evidence that VIP and PACAP administration is directly trophic for the small bowel thus a role for VIP in small bowel resection in the rat has not been described.

Peptide YY and Cholecystokinin

Further study is required when looking at the relationship of other co-localized mediators that are released from the L-cell. Peptide tyrosine tyrosine (PYY) is a 36 amino acid gastrointestinal peptide present in endocrine L-cells of the ileal, colonic, and rectal mucosa^[117-121]. PYY is co-localized to some degree with GLP-1/GLP-2 in the L-cells^[122,123],

moreover, it generates many of the physiological actions that are also attributed to GLP-2. There are data that both GLP-2 and PYY: slow gastric emptying and intestinal transit; production rates in rats and humans are increased following intestinal resection, production rates are influenced by luminal nutrients in the hindgut; release might be influenced by a proximal gut hormone or perhaps a neuroendocrine mechanism^[51,124-133]. In support of the latter, our results examining postprandial GLP-2 release^[15], together with reports of the meal-stimulated PYY response^[133], demonstrate that there are significant increases in the serum levels of both peptides in less than 15 min. Intestinal transit times are not that rapid, thus these early increases probably are not attributable to luminal nutrients in the distal intestine. Neuroendocrine factor induction of the early release of PYY was described in a study by Greeley *et al*^[121]. They administered a meal to dogs and then diverted the entire meal out of the proximal intestine via the creation of a stoma. Thus, there was no possibility of nutrient stimulation of PYY containing L-cells in the distal gut. Interestingly, there was still significant increase in plasma PYY levels. In these same dogs, the removal of the ileum, colon, and rectum, resulted in no increase in plasma PYY levels in response to a meal. These findings replicate a human study previously discussed in this paper, but instead of PYY, GLP-2 levels in patients that received a colectomy were significantly reduced^[47]. This is certainly supportive of either a blood-borne hormone or a neural pathway in the generation of the early release of PYY and most assuredly, GLP-2. Furthermore, we have observed that rats with 20 cm of jejunum diverted out an abdominal stoma (i.e. no possibility of meal contents directly contacting the distal bowel) still had a significant increase in post-prandial GLP-2 levels-unpublished data-(Figure 5).

Several proximal gut hormones that are rapidly secreted following the ingestion of a meal have been tested (i.e., gastrin, glucose dependent insulinotropic peptide, secretin, neurotensin) and found to be ineffective in stimulating an increase in PYY^[121]. Currently, no published literature has shown that these can stimulate GLP-2 release. One potential agonist, cholecystokinin (CCK), induces a dose-dependent release of PYY, and this CCK-induced PYY release, can be blocked by a CCK antagonist^[121]. As CCK induces PYY production from L-cells, and having established that PYY and GLP-2 are co-localized, potentially, CCK might also be a foregut hormone responsible for stimulating the early release of GLP-2. It would be worthwhile to examine whether CCK also triggers GLP-2 secretion.

PYY administration has not shown that it is trophic to the gastrointestinal tract directly and it is unlikely that it is involved in the adaptive response following intestinal resection, though a reduction in intestinal transit may secondarily generate increased intestinal growth. These areas have not been explored. Both GLP-2 and PYY are inactivated by dipeptyl peptidases^[73,76], thus additional studies of SBS should explore the relationship between serum and intestinal tissue levels of GLP-2, PYY, and DPP-IV.

Polyamines

Polyamines are present in prokaryotes, plants and animals. The polyamines putrescine and its derivatives spermidine and spermine are found in nearly all cells of higher eukaryotes^[134,135]. The major role of polyamines in most cell types is to stimulate cell proliferation and thus is considered essential for life^[135,136]. The inhibition of polyamine biosynthesis blocks cell growth^[136,137]. The increase in intracellular polyamine levels and in the activity of ornithine decarboxylase (ODC), one of the rate-limiting enzymes in the strictly controlled polyamine biosynthetic pathway^[138], are associated with rapid growth rates^[139,140]. ODC activity in the rat small intestinal mucosa is increased following small bowel resection^[134,138], parasitic or enteropathogenic bacteria-induced small intestinal inflammation or colitis^[141,142], ischemia reperfusion^[143], and following partial obstruction of the lumen. All of these instances are associated with an increase in mucosal growth. Of clinical relevance, mucosal ODC activity in the colon and rectum has been reported to be significantly higher in both ulcerative colitis and Crohn's disease patients^[144]. In addition, evidence shows that polyamines are protective of DNA during the S-phase of the growth cycle^[135,145] and in part may explain the protective effects of GLP-2 following the administration of chemotherapeutic agents.

There is a rise in plasma enteroglucagon levels that precedes the activation of ODC^[143]. Thus it could be speculated that an increase in GLP-2 might initiate the activation of ODC leading to the repair of injured intestinal mucosa. If so, it would not be unreasonable for the growth promoting and protective role of GLP-2 in the small bowel to act through an ODC-dependent formation of polyamines. Considering that the trophic effects of many growth-promoting gut hormones are blocked following ODC or polyamine synthesis inhibition^[134,138], it would not be surprising if this pathway is involved as a downstream effector of GLP-2 induced intestinal growth.

Intestinal carcinogenesis

A great deal of attention has focused on the potential for cancerous growth attributable as a side effect following the application of growth factors. Recent results cautioning restraint regarding the utility of GLP-2 was indicated as GLP-2, and to a greater degree, a GLP-2 analog, promoted an increase in the growth of mucosal neoplasms in mice pre-induced to form colonic tumours^[146]. Furthermore, there was a significant increase in tumour load in the mice treated with either GLP-2, or the synthetic Gly2-GLP-2 analogue. There is also evidence that GLP-2R mRNA transcripts can be detected in two human cervical carcinoma cell lines^[56]. But does the application of growth factors such as GLP-2 or EGF always trigger neoplastic growth? Could the application of growth factors prevent the development of intestinal neoplasms? Perhaps the primary factor involved in neoplastic growth is not necessarily the addition of the growth factor, but rather a dysfunction in downstream receptor (i.e., mutation) or signal transduction pathways. For example, there is evidence that mutations in cytoplasmic signaling elements involved in the EGFR signaling cascade result in an

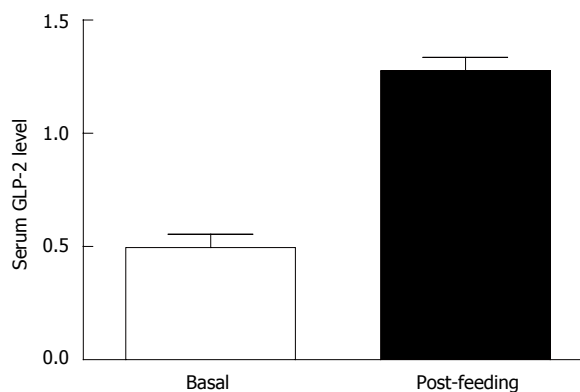

Figure 5 Neural or humoral mechanism involvement in the early release of GLP-2. The delivery of a meal significantly increases serum GLP-2 levels in rats with discontinuous small bowel (ANOVA, $P < 0.007$). The disruption of the continuity of the bowel (stoma creation) did not inhibit the initial nutrient-stimulated GLP-2 response. Thus, GLP-2 production is increased at least in part by neural and/or hormonal mechanisms. Serum GLP-2 levels reported as ng/mL.

alteration in signal transduction events that lead to changes in the downregulation/internalization of the EGFR^[147]. Perhaps what occurs in established oncogenic cells is that a mutation in an element of the signaling cascade prevents GLP-2- or EGF-induced receptor downregulation. This theory is supported by recent work that shows that an oncogenic form of c-Cbl/c-Cbl, which stabilizes and ubiquitinates the cytoplasmic region of the EGFR, is able to prevent EGF-induced EGFR down regulation thus bypassing degradative pathways^[148]. The consequences of this mutation are a bypass of receptor internalization and desensitization processes, an induction in the over expression of the EGFR, and finally, aberrant cell growth. A downstream defect in trafficking could potentially be the primary cause of neoplastic, abnormal cell growth, not necessarily the application of the growth factor.

In the case of the promotion of tumour size in mice following GLP-2 treatment as noted by Thulesen *et al.*, or potentially as in the CaCO-2, T84, HeLa cells^[56,58,59], what has occurred is that dysfunctional receptors and/or signal transduction pathways are already present within/on these cell types. As with any neoplastic condition, the application of growth factors is always a risk. Potentially the application of growth factors prior to the development of gastrointestinal neoplasms, such as during the early stages of Crohn's disease or ulcerative colitis, would be beneficial in halting the progress of prolonged inflammation. It is well established that prolonged intestinal inflammation often secondarily leads to the development of mutations, cell dysfunction, and carcinogenic growth.

CONCLUSIONS

The trophic effect of GLP-2 on the intestine demonstrates that it is possible to modify or accelerate the process of intestinal adaptation, which would potentially make GLP-2 useful for the treatment of short bowel syndrome. Evidence shows that increases in GLP-2 production following intestinal resection are significantly correlated with intestinal adaptation. The association between an increase in nutrient malabsorption and GLP-2 production

following intestinal resection has led to speculations that GLP-2 may act to control the nutrient absorptive capacity within the bowel. The increased availability of circulatory GLP-2 might then stimulate proximal mucosal growth resulting in enhanced nutrient absorptive capacity in the remaining intestinal remnant. Moreover, GLP-2 administration maintains epithelial barrier function and increases both crypt cell proliferation and weight gain in the absence of enteral nutrients. This supports the further development of GLP-2 as a therapeutic strategy that could enhance intestinal adaptation and reduce the consequences of parenteral feeding.

Although significant progress has been made towards elucidating the mechanisms mediating the trophic effects of GLP-2, several formidable challenges lie ahead. The biological and signaling role of the GLP-2R has not been fully defined, thus the mechanistic pathway(s) by which GLP-2 induces adaptive change in the small bowel presently remain elusive. Data showing that GLP-2 administration significantly increases cell proliferation in the absence of the characterized GLP-2R strongly suggest that GLP-2's trophic effect might also include activation of either an uncharacterized GLP-2R or the transactivation of other receptor/signaling paradigms. Another key goal should be in determining the mechanism involved in the early release of GLP-2 following a meal or in malabsorptive states. Lastly, an emergent area of interest is the potential of GLP-2 to induce stimulation of the ENS as an intermediate in the regulation of intestinal growth. Regardless, there is a very significant and biologically important effect of GLP-2 on intestinal function and whole animal physiology that strongly supports further research into the use of GLP-2 as a therapy. The future use of GLP-2 therapy for the treatment of intestinal disorders is an enticing prospect; however, the promise of these initial results must be tempered as we await confirmatory data from clinical trials.

ACKNOWLEDGMENTS

In addition to the contribution by the co-authors, GR Martin is very grateful to Joseph Davison, Wallace MacNaughton, Keith Sharkey, and John Wallace for all their enthusiasm, guidance, and wisdom passed down over the past several years.

<http://www.wjgnet.com/1007-9327/12/4130.asp>

Abstract

AIM: To investigate whether alphastatin could inhibit human gastric cancer growth and furthermore whether sphingosine kinase (SPK) activity is involved in this process.

METHODS: Using migration assay, MTT assay and Matrigel assay, the effect of alphastatin on vascular endothelial cells (ECs) was evaluated *in vitro*. SPK and endothelial differentiation gene (EDG)-1, -3, -5 mRNAs were detected by reverse transcription-polymerase chain reaction (RT-PCR). SPK activity assay was used to evaluate the effect of alphastatin on ECs. Matrigel plug assay in nude mice was used to investigate the effect of alphastatin on angiogenesis *in vivo*. Female nude mice were subcutaneously implanted with human gastric cancer cells (BGC823) for the tumor xenografts studies. Micro vessel density was analyzed in Factor VIII-stained tumor sections by the immunohistochemical SP method.

RESULTS: *In vitro*, alphastatin inhibited the migration and tube formation of ECs, but had no effect on proliferation of ECs. RT-PCR analysis demonstrated that ECs expressed SPK and EDG-1, -3, -5 mRNAs. *In vivo*, alphastatin sufficiently suppressed neovascularization of the tumor in the nude mice. Daily administration of alphastatin produced significant tumor growth suppression. Immunohistochemical studies of tumor tissues revealed decreased micro vessel density in alphastatin-treated animals as compared with controls.

CONCLUSION: Downregulating ECs SPK activity may be one of the mechanisms that alphastatin inhibits gastric cancer angiogenesis. Alphastatin might be a useful and relatively nontoxic adjuvant therapy in the treatment of gastric cancer.

INTRODUCTION

Angiogenesis, the development of new blood vessels from pre-existing endothelium is a critical process in many physiological and pathological conditions including embryonic development, organ regeneration, chronic inflammation and solid tumor growth. The process of formation of new blood vessels is complex and involves several discrete steps, such as ECs spreading, migration, proliferation and morphological differentiation of endothelial cells to form tubes. In the last three decades, considerable research has demonstrated that tumor growth and metastasis requires angiogenesis, and micro vascular endothelial cells recruited by the tumor have become an important second target in cancer therapy^[1-3]. This is the major reason why angiogenesis has attracted recent attention in the field of pharmacological research. The key for the development of such an angiostatic therapy is to develop useful angiogenesis inhibitors. A number of research groups have shown that various substances are effective in the inhibition of angiogenesis and/or in the treatment of angiogenic diseases like cancer at the experimental animal model level. Various angiostatic factors such as endostatin, angiostatin and thrombospondin have been identified and can block various steps in the tumor angiogenesis pathway. The application of these antiangiogenic agents for cancer treatment is being evaluated through clinical trials and many new angiogenesis inhibitors were reported^[4-6]. In previous studies, it was reported that alphastatin (24 amino acids) derived from the amino terminus of human fibrinogen could inhibit the growth of murine colonic adenocarcinoma. Significant reduction in tumor volume was found from the fifth day of administration and maintained for 12 d of intraperitoneal injection^[7]. S1P, formed through activation of SPK activity,

is a bioactive sphingolipid metabolite abundantly stored in platelets. Recently, S1P has been targeted for its potential roles in angiogenesis. It may stimulate DNA synthesis and chemotactic motility of ECs, and also induce tube formation of ECs on Matrigel. Further investigation indicated that S1P predominantly induces angiogenesis via endothelial differentiation gene (EDG), a family of Gi protein-coupled receptor. Activation of EDG receptors triggers several signaling pathways by pertussis toxin (PTX)-sensitive Gi protein. Moreover the signaling pathways activated by S1P have been extensively studied in various cell types. All of these proved that S1P may be a novel mechanism during angiogenesis.

In the present study, we attempt to extend the previous study to observe whether alphastatin inhibits human gastric cancer growth. Importantly, we first report that alphastatin suppress angiogenesis through downregulating ECs SPK activity and reducing ECs S1P level.

MATERIALS AND METHODS

Materials

Human umbilical vein ECs (HUVECs) and human gastric cancer cells (BGC823) were obtained commercially from ATCC. High glucose Dulbecco's modified Eagle's medium (DMEM) and bovine serum albumin (BSA, 1 g/L) were obtained from Sigma chemicals (St. Louis Mo, USA). Growth factor reduced (GFR) Matrigel was purchased from Becton Dickinson (San Jose, Calif, USA). Alphastatin was synthesized by New England Biolabs (Beverly, MA) using standard peptide synthesis techniques and purified to more than 95% using high performance liquid chromatography (HPLC). Hepatocyte growth factor (HGF) was purchased from Peprotech EC Ltd. Transwell plate was purchased from Corning Costar (Cambridge, MA).

Endothelial cells migration assay

HUVECs and BGC823 cells were cultured in DMEM containing 100 mL/L FBS and 10 g/L penicillin-streptomycin in a 50 mL/L CO₂ incubator at 37°C. Assessment of ECs migration was performed as recently described with minor modifications^[8]. HUVECs were dispersed into homogeneous single cell suspensions after trypsinization. These cells were extensively washed with DMEM containing 1 g/L acid-free BSA and resuspended in the same medium. HUVECs (10⁵) were dispersed onto the upper chamber of Transwell compartment with 8 µm pore size filter. The cells were allowed to adhere for 1 h at 37°C. The medium in the lower chamber was removed and replaced by migration medium containing HGF, HGF plus alphastatin or medium alone. Migration was allowed to proceed for 4 h at 37°C. The remaining cells attached to the upper surface of the filters were carefully removed with cotton swabs. Migrated cells were stained with crystal violet and finally examined by light microscopy. The numbers of migrated cells in at least 10 consecutive fields were evaluated and the average was calculated. Data were expressed as the mean ± SD of the number of migrated cells per field in 5 separate experiments.

Endothelial cells proliferation

HUVECs proliferation was assayed as described previously^[9] using standard MTT assay. Alphastatin was dissolved in PBS and diluted in DMEM medium. Cells were incubated in their complete medium containing 100 mL/L FBS, the complete medium plus alphastatin or the starvation medium without FBS. The cells were seeded into 96-well micro titer plates at 5 × 10⁴ cells/L in the presence of various concentrations of alphastatin for 24, 48, 72, and 96 h. At each time point, a quarter volume of MTT solution (2 g MTT/L phosphate-buffered saline) was added to each well and each plate was incubated for 4 h at 37°C resulting in an insoluble purple formazan product formation. The medium was aspirated and the precipitates dissolved in 100 µL of dimethyl sulfoxide (DMSO) buffered at PH 10.5. Absorbance at 490 nm was determined using R450 microplate reader (Bio-Rad, USA). Each sample was assayed in five duplicates and repeated at least three times. In order to validate the cytotoxicity of alphastatin, the cells were seeded at a density of 5 × 10⁴ cells per well in full growth medium in the absence or presence of alphastatin. After 24 h, the data was collected using CellTiter 96[®] AQueous One Solution Reagent Kit (Promega, USA).

Endothelial cells tube formation on Matrigel

Endothelial tube formation on Matrigel was conducted as described previously^[10]. Matrigel (10 g/L per well) at 4°C was added to a twenty-four-well plates and then allowed to polymerize at 37°C for 1 h. HUVECs (5 × 10⁴ cells) were seeded on Matrigel in 1 ml of growth medium and various concentrations of alphastatin. The plates were incubated at 37°C for 18 h. All conditions were triply performed. The formation of tube-like structures by HUVECs was analyzed by fluorescence microscope at × 100 magnification and the total area of tubular structures in five random microscopic fields per well was analyzed using Image tools package 3.0.

Reverse transcription polymerase chain reaction (RT-PCR)

After treated with various dose of alphastatin, total RNA was obtained from HUVECs using the Trizol Reagent kit (Invetrogen, USA). Two µg of total RNA was converted to cDNA by treatment with 100 units of reverse transcriptase and 0.5 µg of oligo-dT primer in 50 mmol/L Tris-HCl (pH 8.3), 75 mmol/L KCl, 3 mmol/L MgCl₂, 0.1 mol/L DTT and 1 mmol/L dNTP at 42°C for 1 h. The reaction was terminated by heating at 70°C for 15 min. Two µL of the cDNA mix was used for enzymatic amplification. Polymerase chain reaction was performed in 50 mmol/L KCl, 10 mmol/L Tris-HCl (pH 8.3), 1.5 mmol/L MgCl₂, 0.2 mmol/L dNTP, 2.5 units of Ex Taq DNA polymerase and 0.1 µmol/L for each of primers such as SPK, EDG-1, EDG-3 and EDG-5. The reaction mixture was repeated for 35 cycles, as heated at 95°C for 45 s, annealed at 57°C for 30 s and extended at 72°C for 60 s. The primers used were 5'ATGCACGAGG TGGTGAACG3' (sense) and 5'GGAGGCAGGTGTCTTGG AAC3' (antisense) for the SPK (426 bp); 5'CCGCAAGAACATTTCCAAG (sense) and 5'ACCCACCAACACCCGACAC (antisense) for EDG-1 (608 bp); 5'CCTGC GGGAGCATTA CCA

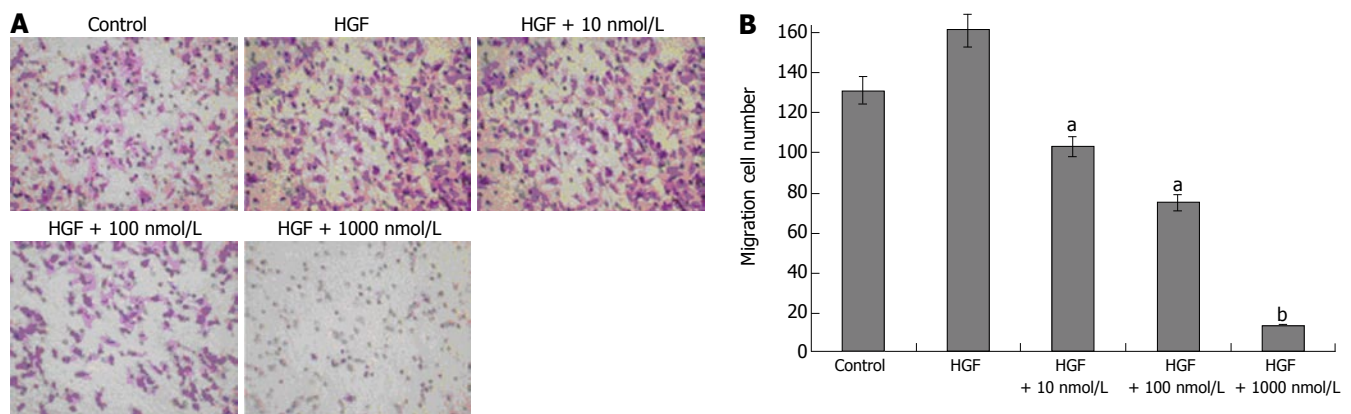

Figure 1 Alphastatin inhibit HUVECs migration induced by HGF (crystal violet stain, $\times 100$). All data shown as mean \pm SD. ^a $P < 0.05$; ^b $P < 0.01$ vs control group.

(sense) and 5'CACCTTACGGCTGCTGGAC (antisense) for EDG-3 (637 bp); 5'AAGTTCCACTCGGCAATGTAC (sense) and 5'GCAGC CAGCAGACGA TAAA (antisense) for EDG-5 (556 bp).

Measurement of sphingosine kinase activity

After various treatments, HUVECs were washed twice with PBS and harvested by scraping in 0.1 mol/L Tris-HCl buffer (pH 7.4) containing 200 mL/L (v/v) glycerol, 1 mmol/L mercaptoethanol, 1 mmol/L EDTA, 1mmol/L Na_3VO_4 , 15 mmol/L NaF, 10 mg/L leupeptin and aprotinin, 1 mmol/L phenylmethylsulfonyl fluoride and 0.5 mmol/L 4-deoxy pyridoxine. Cells were lysed by freezing and thawing. Cytosolic fractions were prepared by centrifugation at 12000 g for 30 min. One hundred and eighty milliliters of cytosol was incubated with 10 μL of sphingosine (1 mmol/L, dissolved in 50 g/L Triton X-100), 10 μL [γ -³²P] ATP (20 mmol/L) containing MgCl_2 (200 mmol/L) for 15 min. Sphingosine kinase activity was measured as previously described^[11-13].

In vivo Matrigel plug assay

Matrigel plug assay was performed as previously described^[14]. Briefly, nude mice were injected subcutaneously with 0.5 mL Matrigel. The injected Matrigel rapidly formed a single solid gel plug. After 7 d, the mice were euthanasia killed and Matrigel plug were removed. It was fixed with 50 g/L formaldehyde phosphate buffer saline and embedded in paraffin. The slides were routinely cut and stained with hematoxylin & eosin (HE). Capillaries were defined as tubular structures containing red blood cells.

Tumor cells implantation and pathology

The in-house and governmental animal protection committees approved all of the experiments and the animals were cared according to the guidelines for laboratory animals established by the Chinese government. Female athymic mice (Balb/c, nu/nu, 8 wk of age; weighing about 20 g) were maintained under clean room conditions in sterile rodent micro isolated cages. Animals received sterile rodent chow and water *ad libitum*. Human gastric cancer cells (BGC 823) were injected subcutaneously (SQ) into the right hind limb (2×10^6 cells in 100 μL of PBS). Tumor cell grew for 8 d until the tumor block established. Animals were ran-

domized for therapy when tumor volume reached 120-160 mm^3 . Tumor volume was determined three times weekly by direct measurement with calipers and was calculated by the formula "Volume (V) = length \times width² \times 0.52". Animals were intraperitoneally daily injected with alphastatin (0.25 mg or 2.5 mg/kg per day in 7 mice respectively) or PBS (control in 7 mice). The observations were terminated for ethical reasons when the tumor volume became large compared with the animal size. Tumor for histological analysis was harvested from three animals at d 12 after the start of antiangiogenic therapy. At the end of observation, tumor tissues were fixed in buffered formalin and were embedded in paraffin. Tissue slices (5 μm) were cut and stained with HE. To assess the tumor angiogenesis, immunohistochemical staining was performed using the anti-mouse Factor-VIII monoclonal antibody. Tumor angiogenesis was quantified by counting the number of positively stained microvessels in 10 randomly chosen fields at $\times 400$ magnifications.

Statistical analysis

The data were presented as mean \pm SD and analyzed by a statistical software of SPSS 10.0 for Windows program using Student's *t*-test and the analysis of variance (ANOVA). Significant differences were considered when $P < 0.05$.

RESULTS

Vascular endothelial cell migration and proliferation

Vascular endothelial cell migration is critical for tumor angiogenesis. To determine the effects of alphastatin on migration of HUVECs induced by chemoattractant media (HGF), we counted the number of cells that had migrated to the bottom of the Transwell membrane. Alphastatin significantly inhibited HUVECs migration in response to HGF in a dose-dependent manner (103 ± 4 and 75 ± 3 vs 131 ± 4 , $P < 0.05$; 13 ± 1 vs 131 ± 4 , $P < 0.01$, Figure 1). Alphastatin had no effect on cell proliferation even up to 2000 nmol/L for 96 h (Figure 2). The cytotoxicity of alphastatin was assessed and no detectable cytotoxic effect at those doses was found *in vitro* (data not shown).

Tube formation by HUVECs

When HUVECs were placed on growth factor-reduced

Figure 2 Alphastatin has no effect on HUVECs proliferation.

Matrigel surface, they formed a branching and anastomosing network of capillary like tubules with multicentric junctions over 18 h. Alphastatin inhibited the formation of tubular networks induced by PMA (25 $\mu\text{g/L}$) on Matrigel in a dose-dependent manner (Figure 3). A remarkable inhibition of tube formation was observed in the presence of 100 nmol/L ($1508.96 \pm 29.89 \mu\text{m}^2$ vs $2150 \pm 31.05 \mu\text{m}^2$, $P < 0.05$). At the same size field, there was longer distance between tubes and less tubules at alphastatin-treated group. Tube formation was quantitatively estimated by measuring the area covered by the tube network using the image analysis program.

SPK mRNA, EDG-1, EDG-3, and EDG-5 expression

Before measurement of SPK activity, RT-PCR was carried out using specific primers for SPK, EDG-1, EDG-3 and EDG-5 to assure expression of them in HUVECs. It was revealed that SPK, EDG-1, EDG-3 and EDG-5 were expressed in HUVECs (Figure 4). Whether alphastatin could change HUVECs SPK activity is a mystery. HUVECs were starved overnight in serum-free medium before the addition of alphastatin. Then, these cells were stimulated with various concentration of alphastatin for different times. Alphastatin could downregulate SPK in a dose-dependent manner. When HUVECs were treated with alphastatin at a concentration of 100 nmol/L, the cellular SPK activity reached a minimum value at 6 h (Figure 5). These data showed that alphastatin leads to downregulation of SPK through stimulation of HUVECs.

New capillaries formation

Matrigel was injected into nude mice with or without alphastatin. Reduction in the number of blood vessels was observed at 100 nmol/L alphastatin group (Figure 6). Sections of experimental tumors were stained with antimouse Factor-VIII antibody.

Microvessel density was less in alphastatin-treated group than in PBS group (Figure 7).

Gastric cancer growth in nude mice

For tumor growth quantification, we used the human BGC823 gastric cancer cell lines. After injecting tumor cells, tumors were allowed to grow until the block established (10 d). Then mice were randomized and divided into control group (PBS: $n = 7$) and therapy group

Figure 3 Alphastatin inhibit HUVECs tubule formation in response to PMA. All data shown as mean \pm SD. ^a $P < 0.05$ vs control group.

Figure 4 Expression of SPK, EDG-1, EDG-3, EDG-5 in HUVECs.

(alphastatin: $n = 7$). The tumor in control group steadily grew up to a final tumor volume of $1771 \pm 262 \text{ mm}^3$ over the same period as the therapy group. However, the growth rate of the tumor in the therapy group was significantly reduced between d 18 and d 26 ($P < 0.05$ and $P < 0.01$, Figure 8), and a final tumor volume was only $1145 \pm 114 \text{ mm}^3$ and $612 \pm 173 \text{ mm}^3$ respectively. Moreover, alphastatin injection appeared to be well tolerated *in vivo*

and had no significant effect on animal body mass and general condition.

DISCUSSION

Previous studies show that alphastatin is a potent antiangiogenic agent^[7]. However, little is known about whether it has any effect on human derived tumors and what mechanism related to the antiangiogenic activity of alphastatin. In the present study, we therefore tried to solve the question above. Gastric cancer is one of the

most common malignancies in Asia. However, so far there is no effective therapeutic measure for this highly malignant disease. Recent studies have demonstrated that angiogenesis is a prerequisite for development and growth of different tumors^[15-18]. Anti-angiogenic targeting of the neovasculation within tumors is considered one of the most promising strategies in the search for novel antineoplastic therapies^[19]. Strategies for anti-angiogenic drugs were described as follows: (1) interference with endothelial cell migration and proliferation; (2) interference with endothelial cell tubule formation and (3)

Figure 8 Animals injected with alphastatin exhibited a significantly reduced tumor volume. All data shown as mean \pm SD. ^a $P < 0.05$; ^b $P < 0.01$ vs PBS group.

interference with some factors involved in angiogenesis pathway^[20-25]. The present study shows that alphastatin inhibits angiogenesis *in vitro* and *in vivo*. Furthermore, for the first time we described that alphastatin could suppress human gastric cancer growth in nude mice through downregulating vascular endothelial cell SPK activity. In migration assay, we chose HGF as chemoattractant media because it is a multifunctional factor regulating cell growth, motility and migration for a variety of cell types including endothelial cell, epithelial cell and hepatocyte. Its effect of chemotaxis is greater than vascular endothelial growth factor (VEGF). Duan *et al* showed that HGF/c-Met activates SPK *via* ERK1/2 and PI3K pathways. SPK activation plays an important regulatory role in HGF-induced migration of endothelial cells^[26]. Lee *et al* showed that S1P strongly induces the formation of tube network of HUVECs which has the characteristics of strong intercellular interaction and sustained survival of large population of cells on Matrigel^[11]. These morphological changes of HUVECs may occur mainly through binding of S1P with EDG-1. In addition, S1P in part and indirectly stimulates HUVECs proliferation through direct secretion of angiogenic factors, because an increase in the expression of VEGF mRNA was detected within 24 h after treatment of HUVECs with S1P^[27-29]. In the present study, alphastatin inhibited the migration and tube formation of HUVECs, but no significant effect on cell proliferation even up to 2000 nmol/L. It was in SPK activity assay shown that alphastatin down regulated HUVECs SPK activity and reduced cellular S1P production. From the data above, it could be concluded that alphastatin inhibited the process of angiogenesis through interference with HUVECs SPK activity.

In the *in vivo* Matrigel plug assay, there was only granuloma formation without significant neovasculature in alphastatin group. Therefore, the antiangiogenic action of alphastatin *in vivo* may be due to its inhibitory effects on endothelial cells stimulated by VEGF as shown in the present study^[5]. In our tumor model, the BGC823 tumors continued to grow over the 12-d injection period, whereas nude mice injected daily with alphastatin demonstrated significant reduction in tumor volume from

d 8 of administration and this was maintained for 14 d of injection. The inhibition was in a dose-dependent manner. Immunohistochemical studies of tumor tissues revealed decreased microvessel density in alphastatin-treated animals as compared with control group. It is also likely that alphastatin down regulated SPK activity and reduced endothelial cell S1P production, resulted in inhibition of angiogenesis.

In conclusion, our current studies provide evidence for anti-angiogenic activities of alphastatin. It induced human gastric cancer vascular growth ceasing *in vivo*, inhibited tube formation on Matrigel and disrupted HUVECs migration. More importantly, the inhibition of angiogenesis was through down regulating HUVECs SPK activity and this may be a novel mechanism that alphastatin exerts antiangiogenic activity. All of these findings hint that, as a new anti-angiogenic agent, alphastatin might be a prototype anti-tumor drug.

Abstract

AIM: To investigate the effects of inositol hexaphosphate (IP₆) on proliferation of HT-29 human colon carcinoma cell line.

METHODS: Cells were exposed to various concentrations (0, 1.8, 3.3, 5.0, 8.0, 13.0 mmol/L) of IP₆ for a certain period of time. Its effect on growth of HT-29 cells was measured by MTT assay. The expressions of cell cycle regulators treated with IP₆ for 2 d were detected by immunocytochemistry.

RESULTS: IP₆ inhibited the HT-29 cell growth in a dose- and time-dependent manner. Analysis of cell cycle regulator expression revealed that IP₆ reduced the abnormal expression of P53 and PCNA and induced the expression of P21.

CONCLUSION: IP₆ has potent inhibitory effect on proliferation of HT-29 cells by modulating the expression of special cell cycle regulators.

INTRODUCTION

Colorectal cancer is the second most frequent cancer in Western countries^[1], and the third leading cause of cancer deaths in the United States^[2]. In China, the mortality

rate of colorectal cancer is the fourth to sixth leading cause of cancer deaths^[3]. Epidemiological studies have shown that high fiber foods, such as fruits, vegetables, whole grains and cereals, may protect against colorectal cancer^[4-8]. Animal studies have shown that wheat bran has protective effect against colorectal cancer^[9-14], which is attributed mostly to its high fiber content. Interestingly, many of the proposed protective mechanisms of wheat bran fiber, such as decreased transit time^[15], increased bulk^[16] and fermentation^[17], are analogous to those of inositol hexaphosphate (IP₆ or phytic acid), which is a major fiber-associated component of wheat bran^[18]. In some epidemiological studies, colorectal cancer-protective effect of fiber foods rich in IP₆, such as wheat bran has been observed^[18], indicating that IP₆ may protect against colorectal cancer.

IP₆ is a naturally occurring polyphosphorylated carbohydrate, found in plants, particularly in cereals and legumes (0.4%-6.4%)^[19]. It consists of a myo-inositol ring with six dihydrogen phosphate groups, assuming a chair conformation in dilute solution^[20]. This unique structure empowers IP₆ with a chelating capacity of binding to polyvalent (both mono and divalent) cations. Some of these metal ions such as magnesium and zinc play an important role in stimulation of cellular proliferation^[21]. This molecule is related to human health as an anti-nutrient. However, during the last decades it has been shown that IP₆ is also widely distributed in animal cells and tissues at substantial levels^[22,23]. Especially, a strong anti-cancer activity of IP₆ has been demonstrated both *in vivo* and *in vitro*^[24]. IP₆ exerts its anti-cancer activity by entering into cellular inositol hexaphosphate pool and affecting common cellular signal transduction pathways^[24,25], but its mechanisms of action are still not completely understood.

This study was to examine the effect of IP₆ on growth of HT-29 human colon carcinoma cell line. The expressions of cell cycle regulators were assessed after IP₆ treatment.

MATERIALS AND METHODS

Chemicals

IP₆ (a dodecasodium salt from rice) and 3- (4, 5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium (MTT) were purchased from Sigma (St Louis, MO, USA). DMEM/Ham F12 culture medium, fetal bovine serum and trypsin were from Gibco BRL (Grand Island, NY, USA). Rabbit polyclonal antibody to human P53, mouse monoclonal antibodies to human P21, PCNA and SP

histostain-plus kits were obtained from Santa Cruz Biotechnology (Santa Cruz, CA, USA).

Cell lines, culture conditions and IP₆ treatment

The HT-29 human colon carcinoma cell line was obtained from Xiehe Medical University (Beijing, China). Cells were grown in DMEM/Ham F12 medium supplemented with 10% fetal bovine serum, penicillin (100 U/mL) and streptomycin (100 g/L) under standard culture conditions (37°C, 950 mL/L humidified air and 50 mL/L CO₂). A stock solution of 100 mmol/L IP₆ in distilled water was freshly prepared each time before use, the pH was neutralized with NaOH and sterilized by passing through a 0.22 µmol/L membrane filter. Dilutions of 1.8, 3.3, 5.0, 8.0, 13.0 mmol/L in DMEM/Ham F12 medium were prepared from stock solution immediately before use. The DMEM/Ham F12 medium with equal volume of distilled water served as negative control.

MTT assay

Cell number was determined by colorimetric MTT assay^[24]. MTT was dissolved in PBS at 5 g/L, filter-sterilized, diluted in the DMEM/Ham F12 medium, giving a final concentration of 1.0 g/L. For growth assay, cells were plated in 96-well microtiter plates (Costar, Cambridge, MA, USA) at a density of 2×10^3 cells/well of 100 µL media. One of the IP₆ treatments was that cells were exposed to 1.8-13.0 mmol/L IP₆ for 6 h, 12 h, or 24 h, after which IP₆ was removed and cells were grown in media without IP₆. This treatment was given every other day and continued for 6 d. The other IP₆ treatment was that cells were treated with various concentrations of IP₆ continuously for 6 d, during which culture media were changed with fresh media every other day. At the indicated time the media were removed, 50 µL of MTT was added, and the incubation was continued for 4 h at 37°C. Individual cell viability was assessed by visualization of intracellular blue crystal formation by light microscopy. The precipitated formazan was dissolved with 150 µL of DMSO, and the absorbance was determined at 490 nm with a microplate autoreader (EL311sx, Bio-Tek Instruments, Inc., Winooski, VT). Cell growth assay was repeated three times.

Immunocytochemistry

Immunocytochemical staining for P53, P21 and PCNA was carried out by the standard streptavidin-peroxidase-biotin technique (SP technique) using SP kit. Cells were treated with 1.8-13.0 mmol/L IP₆ for 2 d and collected by a brief trypsinization and plated on slides. The cells were fixed in acetone at -20°C for 5 min. The endogenous peroxidase activity was quenched in a 3% solution of hydrogen peroxide for 15 min and blocked for 10 min. Cells were immunostained with monoclonal antibody (dilutions: P21 1:50, PCNA 1:80) and P53 polyclonal antibody (dilutions: 1:50) for 1 h at 37°C. After three further washes with PBS, a second biotinylated goat anti-rabbit or rabbit anti-mouse antibody was applied for 1 h at room temperature and then streptavidin conjugated to peroxidase was added. Following extensive washes with PBS, 3, 3'-diaminobenzidine was used for color development, and hematoxylin was used for

Table 1 P53 expression in IP₆-treated HT-29 cells (mean ± SD)

Concentration of IP ₆ (mmol/L)	Absorbance value
Control	0.6772 ± 0.0095
1.8	0.6161 ± 0.0203
3.3	0.5996 ± 0.0205
5.0	0.6067 ± 0.0130
8.0	0.5871 ± 0.0159
13.0	0.5817 ± 0.0158

counterstaining. The negative controls were performed by substituting the primary antibody with PBS. Hematoxylin-stained cells were examined under light microscope and photographed. Cells not counterstained were measured by VIDAS2.1 image analysis system for absorbance because hematoxylin staining could affect the image-analysis results. Three highly magnified visual fields which were not overlapped were randomly selected to measure the absorbance of each field. The mean absorbance was calculated.

Statistical analysis

The experimental results were repeated three times and expressed as mean ± SD. Statistical analysis was carried out using one-way ANOVA. $P < 0.05$ was considered statistically significant. Statistical analyses were performed using SPSS 11.5 (SPSS Inc, Chicago, IL, USA).

RESULTS

Effect of IP₆ on the growth of HT-29 cells

Continuous treatment with IP₆ inhibited the proliferation of HT-29 cells (Figure 1A). The absorbance value for each IP₆ group was lower than that of control group. At the same time point, the absorbance value decreased with increasing IP₆ concentration. The absorbance values for the 8.0 mmol/L and 13.0 mmol/L IP₆ groups decreased on d 6 ($P < 0.05$). The effects of discontinuous treatment with IP₆ on the growth of HT-29 cells are shown in Figures 1B-1D. The treatment with IP₆ for 24 h inhibited the cell growth. But neither 6 h nor 12 h treatment showed dose- or time-dependent inhibition effects though the absorbance value for each IP₆ group was lower than that for control group.

Effects of IP₆ on the expression of P53, P21 and PCNA

Compared to the control, the expression of P53 protein in HT-29 cells was decreased after 2 d of IP₆ treatment at different concentrations ($P < 0.05$) (Table 1 and Figure 2A, Figure 2B).

Compared to the control, treatment of HT-29 cells with IP₆ at various concentrations for 2 d increased the expression of P21 ($P < 0.05$) (Table 2 and Figure 2C, Figure 2D).

Compared to the control, the expression of PCNA decreased after treated with IP₆ at different concentrations for 2 d ($P < 0.05$) (Table 3 and Figure 2E, Figure 2F).

The absorbance values assayed by MTT after IP₆ treatment for different periods of time are listed in Tables 4, 5, 6, and 7.

Figure 1 MTT assay showing the effect of IP₆ on the growth of HT-29 cells after treated for 0 (A), 6 (B), 12 (C), 24 h (D).

DISCUSSION

Uncontrolled proliferation is one of the most important characteristics of malignant cells due to the aberrations of cell cycle regulators such as mutation, activation or inactivation of genes. Identification of cell cycle regulator specificity of anti-tumor drugs is essential to understand the mechanisms of their action.

MTT assay in this study showed that the growth of HT-29 cells was inhibited after continuous IP₆ treatment for 2-6 d ($P < 0.05$). The effect enhanced with increasing IP₆ concentration and prolonged treatment time, suggesting that the inhibition effects of IP₆ are dose- and time-dependent.

To confirm our data we used another proliferating marker, proliferating cell nuclear antigen (PCNA) which is

essential for both DNA replication and repair^[26]. During DNA replication, PCNA forms a ring structure clamping the synthesized DNA to the DNA polymerases δ and ϵ to ensure continuation of the replication process^[27,28]. In case of DNA damage, PCNA binds to the over-expressed P21^{waf1/cip1} leading to inhibition of PCNA-dependent replication, but it does not affect the DNA repair function attained by PCNA^[29]. Thus, PCNA is expressed in both cycling and non-cycling cells^[30]. Immunocytochemistry in this study showed that IP₆-treated cells reduced PCNA expression compared with control cells ($P < 0.05$), although the dose-dependent inhibition was not obvious, which was in agreement to the low proliferation rate observed in MTT assay, indicating that IP₆ inhibits proliferation of HT-29 cells.

Figure 2 Expression of p53 (A, B), p21 (C, D) and PCNA (E, F) in untreated control and IP₆-treated cells. The slides were counterstained with hematoxylin (× 400, × 100, × 400, respectively).

Since IP₆ inhibits cell growth, we studied the regulators of cell cycle. P53, a tumor suppressor protein, is a nuclear transcription factor that controls cell cycle progression^[31,32], and plays a role in G1/S check point of cell cycle allowing the repair of damaged DNA^[33,34]. Mutations and deletions of the tumor suppressor gene p53 have been identified in about 50% of colorectal carcinomas and are associated with poor prognosis due to its weaker ability to inhibit cell proliferation. The half-life of wild-type P53 is very short and difficult to detect, while the mutant P53 protein has a much longer half life and can be examined by conventional immunohistochemical technology^[35]. Rodrigues NR *et al*^[36]

showed that over-expression of p53 is synonymous with mutation and HT-29 cells have mutations in codon 273 of the p53 gene, so HT-29 cells overproduce mutant p53 antigen. In our study, the immunocytochemical results showed that in IP₆-treated cells the abnormal expression of P53 protein decreased compared to control (*P* < 0.05), indicating that IP₆ reduces the expression of mutant P53 protein. It was reported that treatment of HT-29 cells with IP₆ increases the level of wild-type P53^[37]. In the present study, P53 polyclonal antibody was not specified for wild P53 but responded to many antigenic determinants, including mutant P53, indicating that IP₆ up-regulates

the expression of wild-type P53 and down-regulates the expression of mutant P53 to control cell cycle check-point and prevent progression of cells to the DNA synthesis phase (S phase) of the cell cycle. But the exact mechanism by which IP₆ affects p53 is not clear and needs further study.

P21^{waf1/cip1} is an inhibitor of cyclin dependent kinases (CDKS) that are required for the cells to enter the S-phase of the cell cycle^[38]. The gene encoding P21^{waf1/cip1} is transcriptionally regulated by the protein product of the gene p53. Over-expression of P21^{waf1/cip1} is growth inhibitory, possibly by inhibiting the activity of cyclin/CDK complex^[39] which binds to the C-terminal domain of PCNA. The resulting P21-PCNA complex blocks the ability of PCNA to process DNA polymerase in DNA replication. Thus P21^{waf1/cip1} may act as a tumor suppressor because of its role in growth control^[39,40]. In the present study, the expression of P21 was increased after IP₆ treatment for 2 d ($P < 0.05$). After counterstaining with hematoxylin, untreated cells were stained purple while IP₆-treated cells were stained yellow, indicating that expression of P21 is higher in IP₆-treated cells. High-expression of P21^{waf1/cip1} leads to decreased nuclear expression of PCNA, which is in agreement with our results.

In summary, IP₆ remarkably inhibits proliferation of HT-29 human colon carcinoma cell line. IP₆ exerts its inhibitory effect in part by affecting special cell cycle regulators and reduces over-expression of mutant P53 and stimulates expression of wild-type P53 and P21^{waf1/cip1}. P21^{waf1/cip1} binds to PCNA, thus preventing PCNA-dependent cellular proliferation. In our immunocytochemical experiments, cells grew very slowly and were not adhered in media with high IP₆ dose, fell off and died very soon. The effect of 13.0 mmol/L IP₆ on expression of genes was less than that of 8.0 mmol/L IP₆, partly due to the rapid death of cells in 13.0 mmol/L IP₆, indicating that that IP₆ has no significant effect on the expression of genes. Furthermore, neither significant dose-dependent effect of IP₆ was observed on the expressions of cell cycle regulators nor obvious correlation among these indexes was found, possibly owing to the short period of IP₆ treatment (only 2 d), suggesting that the effects of IP₆ on gene expressions are relatively weak.

The present study is merely a preliminary investigation of IP₆ on colon cancer. The results are also limited although the effects of IP₆ can be seen. Additional research is needed to explore the mechanisms of IP₆ in cell proliferation and differentiation, apoptosis, and potential therapeutic value of IP₆.

prognosis, whereas patients who had deletion showed favorable prognosis (mean: 51.7 wk vs 124.82 wk, $P = 0.012$). Multivariate Cox regression analysis revealed that amplification of D21S1893, D21S1890 and *TFF*, blood vessel invasion, and staging were associated with poor prognosis.

CONCLUSION: D21S1893-D21S1890 region may harbor candidate genes especially *TFF* and serine protease family, which might be involved in tumor invasion and metastasis contributing to poor survival. The amplification in this region may be used as a prognostic marker in the treatment of CCA patients.

Abstract

AIM: To determine allelic imbalance on chromosomal region 21q22-qter including trefoil factor family genes (*TFF*) in cholangiocarcinoma (CCA) patients and analyze the correlation between allelic imbalances and clinicopathological parameters.

METHODS: Quantitative PCR amplification was performed on four microsatellite markers and trefoil factor family genes (*TFF1*, *TFF2*, and *TFF3*) using a standard curve and SYBR Green I dye method. The relative copy number was determined by DNA copy number of tested locus to reference locus. The relative copy number was interpreted as deletion or amplification by comparison with normal reference range. Associations between allelic imbalance and clinicopathological parameters of CCA patients were evaluated by χ^2 -tests. Kaplan-Meier method was used to analyze survival.

RESULTS: The frequencies of amplification at D21S1890, D21S1893, and *TFF3* were 32.5%, 30.0%, and 28.7%, respectively. Patients who had amplification at regions covering D21S1893, D21S1890, and *TFF* showed poor

INTRODUCTION

Cholangiocarcinoma (CCA) or intrahepatic bile duct cancer (ICC) is a malignant tumor in the biliary tree peripheral to the bifurcation of the right and left hepatic duct^[1,2]. Incidence rates of ICC vary substantially worldwide, reflecting the distribution of local geographic risk factors, in addition to genetic differences among various populations. In Western countries, the disease is rare, however, it is highly frequent in Southeast Asia, especially in Khon Kaen, Northeast Thailand. Truncated age-standardized incidence of CCA at ages > 35 years varied by three fold between districts, from 93.8 to 317.6 per 100 000 population^[3]. In Western countries, primary sclerosing cholangitis is the commonest known predisposing condition for this cancer. Eight percent to 40% of CCA have been reported in patients with primary

sclerosing cholangitis^[4]. Several clinical studies and animal model experimental studies suggest that the interaction between chemical carcinogens, especially nitrosamines and *Opisthorcis viverrini* infestation may play an important role in the development of CCA in Thailand^[5-7]. Thus, either the chemical carcinogen nitrosamine or liver fluke infection alone does not produce cancer. Food derived exogenous and *in situ* nitrosamine formation may lead to DNA alkylation and also deamination in predisposed and inflamed tissues. Furthermore, chronic irritation caused by the fluke results in hyperplasia and adenomatous change of bile duct epithelium^[6]. The DNA damaged biliary epithelium may then be transformed to malignant CCA^[7-9]. To date, the molecular basis of carcinogenesis and pathogenesis of cholangiocarcinoma is still unclear.

Allelic imbalance at specific genomic loci is an important step in the molecular genetic analysis of human cancers. Allelic imbalance at chromosome 21, especially region 21q22-qter, was found in several types of human cancers such as gastric cancer, breast cancer, ovarian clear cell adenocarcinoma, and primary colorectal cancer^[10-13]. Furthermore, chromosome 21q22.3 harbors a cluster of trefoil factor family (*TFF*) genes consisting of *TFF1*, *TFF2*, and *TFF3*^[14]. *TFF* functions include mucus stabilization and stimulation of normal epithelial cell restitution during wound repair through mitogenic and antiapoptotic activities. However, *TFF* peptides are overexpressed in several human solid tumors such as prostate, esophagus, breast, and pancreas and also function as tumor progression factor^[15-18]. Prolonged inflammation caused by parasitic infection frequently occurs in liver fluke related CCA. *TFF* and its neighborhood located at 21q22 may be involved in tumor development and progression. Moreover, our data on comparative genomic hybridization (CGH) in CCA showed the alteration of DNA copy number at 21q22-qter at 28%.

Taken these data together, the chromosomal region 21q22-qter may harbor candidate genes, which are involved in carcinogenesis and pathogenesis of CCA. Therefore, this study attempted to determine allelic imbalance on chromosomal region 21q22-qter including *TFF* genes to define affected sites for candidate genes which are involved in molecular carcinogenesis and pathogenesis of CCA. The associations between allelic imbalance and clinicopathological parameters were also determined.

MATERIALS AND METHODS

Samples and DNA preparation

This project was approved by the Ethical Committee of Khon Kaen University. Informed consents were obtained from patients who were willing to participate in the project. Frozen liver tissues were obtained from 80 CCA patients undergoing surgical resection at Srinagarind Hospital, Faculty of Medicine, Khon Kaen University, Thailand. CCA cases were diagnosed by physicians according to clinical finding, laboratory investigation and histological examination. Neural, blood vessel and lymphatic invasion were assessed by standard method^[19]. The clinicopathological data such as age, gender, histological type, and TNM stage^[20] were evaluated by reviewing the medical charts and pathology records. DNA was prepared from frozen liver tissues containing 80% of tumor cells by using a PuregeneTM DNA purification system (Gentra System, USA) according to manufacturer's instructions. In addition, DNA was prepared from placental tissue collected from a normal labor (postpartum) woman and used for setting a standard curve. Normal leukocyte DNA derived from 50 healthy donors was prepared into 14 pooled normal DNA and generated for normal reference range.

Quantitative PCR assay

Quantitative PCR amplification was performed on a Rotor Gene 2000 Real-time Amplification (Corbett Research, Australia) using four microsatellite markers (telomere-D21S1890-D21S1893-D21S1255-D21S1253-centromere) and trefoil factor family genes (*TFF1*, *TFF2*, and *TFF3*) covering chromosomal region 21q21-qter. Reference primers were chosen in the region of the housekeeping genes that usually are not altered alteration in CCA, *β-actin* and glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*). Primer sequences were obtained from the Genome Data Base. Locations of selected oligonucleotides and their sequences are shown in Table 1. PCR reaction was performed in a 25 μL reaction mixture containing 50 mmol/L KCl, 10 mmol/L Tris HCl pH 8.3, 100 μmol/L each of deoxynucleoside triphosphate (dNTP), 2.5 mmol/L MgCl₂ or 3.0 mmol/L (D21S1253, *TFF1*, and *β-actin*), 1.25 μL SYBR[®] Green I dye solution (Amresco, USA) (1:10 000 in DMSO), and 10 μmol/L or 5 μmol/L (D21S1253 and

D21S1255) or 15 $\mu\text{mol/L}$ (D21S1890) of each primer with 1.5 units or 2.0 units (D21S1253, D21S1255, and *GAPDH*) of *Taq* DNA polymerase. The PCR was performed at 95°C for 5 min followed by 95°C for 15 s, 45°C -60°C for 15 s and 72°C for 15 s for 35 cycles with an additional cycle of 72°C for 10 min.

Quantitative PCR amplification was performed using a standard curve and SYBR Green I dye method as described previously^[21]. The standard curve for each primer was generated using serial dilutions of placental DNA. The standard curve was constructed in each PCR run and the copy numbers of genes in each sample were interpolated using these standard curves. Placental DNA with known concentration was used for precision control. A coefficient of variation (CV) of each sample was determined based on triplicate test. The sample with a CV higher than 15% was re-tested. DNA copy number of each locus was calculated based on triplicate determination and duplicate PCR run.

Analysis of allelic imbalance

The relative copy number was determined by DNA copy number of tested locus to DNA copy number of reference locus. The DNA copy numbers of reference loci consisting of β -actin and *GAPDH* were averaged before calculation. The normal reference range was generated from the relative copy numbers of 14 pooled normal leukocyte DNA of 7 markers ($n = 98$). If the relative copy number of sample calculated differed significantly from normal reference range (mean \pm 2SD), the sample was verified as loss or gain. The relative copy number was interpreted as loss when the ratio was less than mean -2SD of normal reference range. On the other hand, the relative copy number was interpreted as gain when the ratio was more than mean + 2SD of normal reference range.

Statistical analysis

Associations between allelic imbalance and clinicopathological parameters of 80 CCA patients were evaluated by means of the χ^2 -tests. Survival curves for patients with allelic imbalance versus those without were calculated using the Kaplan-Meier method. Only 69 cases were available for follow-up. Six patients were lost for follow-up and five cases were perioperative death (patients who died within 4 wk after surgery). Differences in survival between these two groups were assessed by the log-rank test. Cox proportional hazards model was used in univariate and multivariate analysis. $P < 0.05$ was considered statistically significant.

RESULTS

Allelic imbalance on chromosomal region 21q22-qter

The normal reference range generated from relative copy numbers of pooled normal leukocyte DNA was 0.54-1.34 with 95% confidence interval (mean \pm 2SD). Allelic imbalance of 7 loci showed percentages of amplification at D21S1890 (32.5%), D21S1893 (30.0%), *TFF3* (28.8%), D21S1253 (26.3%), D21S1255 (23.8%), *TFF1* (22.5%), and *TFF2* (7.5%) and of deletion at *TFF3* (3.8%), D21S1255 (2.5%), *TFF2* (2.5%), and D21S1890 (1.3%).

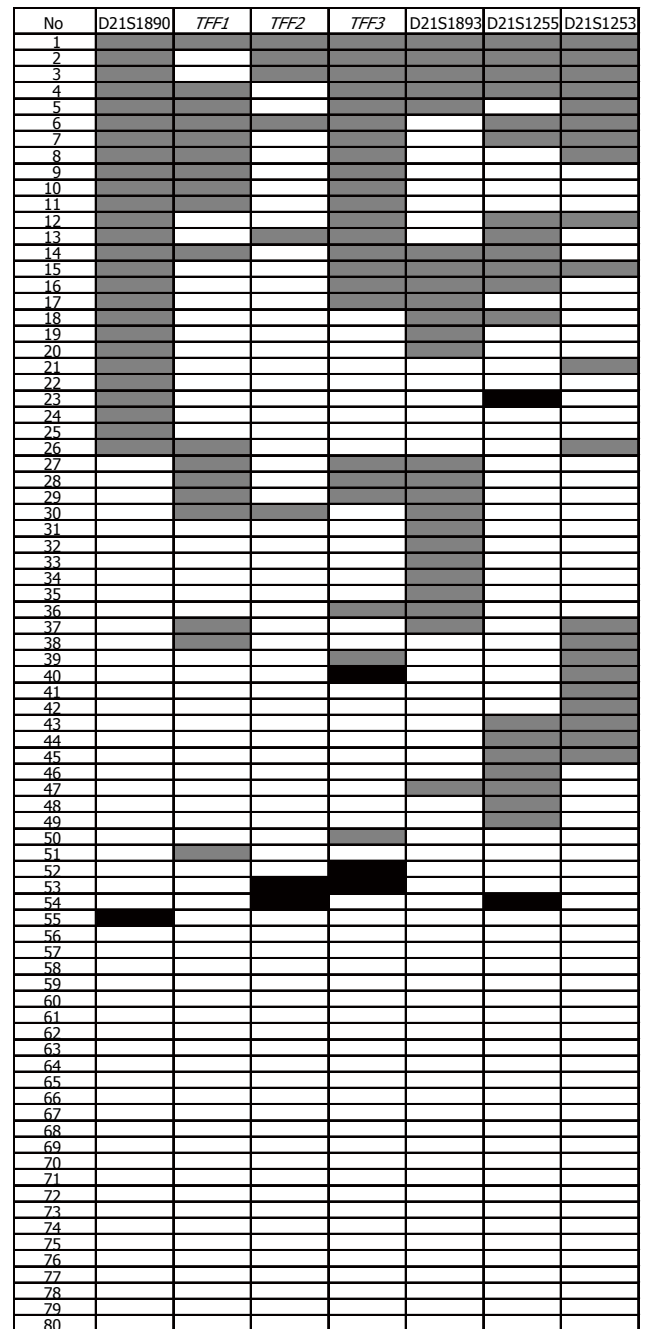

Figure 1 Fine mapping of allelic imbalance on chromosomal region 21q22-qter. D21S1890 is located at telomeric end while D21S1253 is located toward centromeric end. There are two common amplification regions at D21S1890 and the region between D21S1893 and *TFF3*.

The relative copy number of amplification of these loci ranged between 1.35-4.24 and of deletion between 0.39-0.52. Fine mapping of these regions is shown in Figure 1. Two regions of common amplification were D21S1890 and the region between D21S1893 and *TFF3*.

Associations between allelic imbalance and clinicopathological parameters of patients

The associations between allelic imbalance and clinicopathological parameters of patients were analyzed. The result showed no differences in age, sex, histological type, invasion (blood vessel, lymphatic, and nerve), and survival time between patients with and without

allelic imbalance in almost all loci ($P > 0.050$). However, significant difference was observed in histological type at loci covering D21S1893 through D21S1890 including *TFF* ($P = 0.023$). Deletion at D21S1893, D21S1890, and *TFF* found in a papillary type was higher than that in a non-papillary one (Table 2). Furthermore, patients who had deletion in this region tended to show non-invasion of blood vessel ($P = 0.052$) (Table 2). Kaplan-Meier survival curves demonstrated that patients who had amplification at D21S1893, D21S1890, and *TFF* showed poor prognosis, whereas patients who had deletion at D21S1893, D21S1890, and *TFF* showed favorable prognosis ($P = 0.012$) (Figure 2). Multivariate analysis showed significant effects of amplification at D21S1893, D21S1890, and *TFF*, blood vessel invasion, and staging on prognosis (Table 3).

DISCUSSION

Many techniques have been used to detect genetic alterations. The real-time qPCR technique is an alternative method to determine allelic imbalance because most allelic imbalances also result in changes of relative copy numbers. In our study, allelic imbalance determined by qPCR using SYBR Green I system showed CV less than 15%, suggesting good consistency and reliability^[21]. The house keeping genes, *β-actin* and *GAPDH*, were used as reference loci in

**Figure 2** The association between survival time and allelic imbalance on loci D21S1893, D21S1890 and *TFF* was analyzed by Kaplan-Meier. The patients who had amplification at D21S1893, D21S1890 and *TFF* showed poor prognosis, whereas patients who had deletion at D21S1893, D21S1890 and *TFF* showed favorable prognosis.

our study. To assess the validity of these reference genes, we determined the copy number ratios of *β-actin*/*GAPDH* in 14 pooled normal leukocytes and 80 CCA samples. The observed ratios measured from normal DNA ($1.01 \pm 0.14SD$) and tumor DNA ($1.06 \pm 0.15SD$) were similar ($P = 0.271$) and both were significantly equal to 1, thus, confirming their validity as appropriate reference genes in our work.

Our finding of allelic imbalance on chromosomal region 21q22-qter in CCA patients showed predominant amplifications at markers D21S1890 (32.5%) and D21S1893 (30%). This region has length about 3.5 Mb in physical map distance and contains about 25 identified genes. Trefoil factor family (*TFF1*, *TFF2*, and *TFF3*) and serine protease family (*TMPRSS2* and *TMPRSS3*) are candidate genes located in this region and have a potential tumor progression activity. In this study, all CCA tissues were obtained from patients who were residents of north-eastern region of Thailand where liver fluke infection remains highly endemic. Increased gene amplification at chromosome 21q22.3 especially *TFF* genes in liver fluke related CCA may result from healing process of inflamed tissues. Normally, TFF peptides are involved in the normal mucosal defense and epithelial restitution in cell injury. However, in chronic inflammation, the overproduction of TFF peptides may result in tumor progression. TFF peptides might exert beneficial effects during the early step of mucosal injury and inflammation and subsequently undesirable effects during chronic inflammation and neoplastic progression. TFF peptides function as a tumor progression factor by increasing cell scattering, invasion, survival and angiogenesis^[22-25]. *TFF3* stimulates cell motility by inducing a rapid phosphorylation of β -catenin, which is associated with perturbation of the functional integrity of E-cadherin/catenin system. The promotion of cell motility in association with epidermal growth factor receptor (EGFR) leads to the enhancement of tumor cell invasion and metastasis^[26,27]. However, exogenous TFF peptides

alone are not sufficient to induce the invasive phenotype in premalignant human colonic adenoma cells PC/AA/C1 and kidney MDCK epithelial cells, but require the priming and permissive action of src and RhoA to exert their proinvasive activity^[22]. These observations suggest that trefoil peptides elicit a coordinated cellular response enabling cell migration without triggering the programmed cell death response usually precipitated by cell detachment from a stationary anchored state. TFF1 protects cells from anoikis, chemical-, or Bad-induced apoptosis by reducing caspase-3, caspase-6, caspase-8, and caspase-9 activities^[25]. TFF3 may act as anti-apoptosis by preventing p53-dependent and p53-independent apoptosis pathways^[28]. The anti-apoptotic effects of TFF3 are associated with activation of the PI3K-Akt signaling pathway. Thus, TFF functions as an anti-apoptosis factor, resulting in an increase in number of survived cancer cells through proliferation *via* Ras/MEK/MAP kinase signaling transduction pathway. Angiogenic activity of TFF is comparable to that induced by vascular endothelial growth factor (VEGF), leptin, and transforming growth factor- α . Stimulation of angiogenesis by TFF1 in the chick chorioallantoic membrane (CAM) assay was COX-2- and EGFR-dependent, but independent

of the VEGF receptor KDR/flk-1 and the thromboxane A2 receptor (TXA-2-R). These results implicate a role of TFF in the formation of new blood vessels during normal and pathophysiological processes linked to wound healing, inflammation, and cancer progression^[23].

Transmembrane protease, serine 2 (*TMPRSS2*) and transmembrane protease, serine 3 (*TMPRSS3*) are members of serine protease family. Proteases have been increasingly recognized as important factors in the pathophysiology of tumorous diseases. Members of the endopeptidases, such as serine protease family, mediate the proteolytic degradation of the extracellular matrix, which is an indispensable step in tumor invasion and metastasis^[29]. *TMPRSS2* was highly expressed in prostate cancer and correlated with the metastatic potential and involved in microvascular endothelial cell reorganization and capillary morphogenesis^[30,31]. *TMPRSS3* is strongly expressed in a subset of pancreatic cancer and various other cancer tissues, and its expression correlates with the metastatic potential of the clonal SUT-2 pancreatic cancer cell lines^[32]. The data suggested that both *TMPRSS2* and *TMPRSS3* may be important for the processes involved in metastasis, invasion, and angiogenesis in tumor cells. Our study showed high amplifications of markers D21S1893 and D21S1890, suggesting that existence of candidate genes might be involved in pathogenesis of CCA. The data regarding the involvement of serine protease and *TFF* in aggressive feature and metastasis supported our finding that amplifications of candidate genes at regions D21S1893, D21S1890, and *TFF* were found in poor prognostic CCA patients. Clinical data of CCA patients supported our hypothesis that TFF stimulated cell motility via E-cadherin/catenin and APC complexes and promoted tumor cell survival by anti-apoptosis, while serine protease mediated vascular endothelial invasion and angiogenesis leading to poor survival in CCA patients. Although the differences in genetic alterations between liver fluke related and non-liver fluke related CCA have been observed previously^[33,34], the conclusion regarding the difference between these two groups in allelic imbalance on chromosome 21q22 cannot be drawn.

As far as we know, allelic imbalance on the chromosomal region 21q22-qter including *TFF* in CCA patients is first reported by our group. The protein expression and functions of *TMPRSS2*, *TMPRSS3*, and *TFF* related to cancer invasion and metastasis in liver fluke related CCA patients require further study. The application of allelic imbalance on D21S1893, D21S1890, and *TFF* may be of value as a prognostic marker and a selection for CCA patient treatment.

Abstract

AIM: To study the effect of bilirubin on the oxidative liver status and the activity and expression of heme oxygenase-1 (HO-1) in rat liver injury induced by prehepatic portal hypertension.

METHODS: Wistar male rats, weighing 200-250 g, were divided at random into two groups: one group with prehepatic portal hypertension (PH) induced by regulated prehepatic portal vein ligation (PPVL) and the other group corresponded to sham operated rats. Portal pressure, oxidative stress parameters, antioxidant enzymes, HO-1 activity and expression and hepatic sinusoidal vasodilatation were measured.

RESULTS: In PPVL rats oxidative stress was evidenced by a marked increase in thiobarbituric acid reactive substances (TBARS) content and a decrease in reduced glutathione (GSH) levels. The activities of liver antioxidant enzymes, superoxide dismutase (SOD), catalase (CAT) and glutathione peroxidase (GSH-Px) were also diminished while activity and expression of HO-1 were enhanced. Administration of bilirubin (5 µmol/kg body weight) 24 h before the end of the experiment entirely prevented all these effects. Pretreatment with Sn-protoporphyrin IX (Sn-PPIX) (100 µg/kg body weight, i.p.), a potent inhibitor of HO, completely abolished the oxidative stress and provoked a slight decrease in liver GSH levels as well as an increase in lipid peroxidation. Besides, carbon monoxide, another heme catabolic product, induced a significant increase in sinusoidal hepatic areas in PPVL group. Pretreatment of PPVL rats with Sn-PPIX

INTRODUCTION

Portal hypertension (PH) constitutes a major complication in chronic liver diseases including cirrhosis. It is associated with a hyperdynamic splanchnic circulation in response to the resistance of portal blood flow to reach the liver. This complication is associated with collateralization of the portal system, leading to the development of varix at various locations in the upper gastrointestinal tract^[1].

Oxidative stress is the result of excessive generation of reactive oxygen species (ROS), depletion of intracellular antioxidant defences or a combination of both, leading to an imbalance in the redox status of the cell. Reactive oxygen species induce cell, tissue or organ damage and ROS have been proposed as a major factor responsible for several diseases, and have been implicated in portal hypertension^[2].

ROS occur in tissues and may damage DNA, proteins, carbohydrates, and lipids. These potentially deleterious reactions are controlled by a system of antioxidant defences, which eliminate pro-oxidants and scavenge free radicals. Various intracellular compounds such as glutathione, and antioxidant enzymes including catalase (CAT), superoxide dismutase (SOD), and glutathione peroxidase (GSH-Px)^[3] provide protection against oxidation. Heme oxygenase (HO) is the key microsomal enzyme in heme degradation to carbon monoxide (CO), iron and biliverdin, the latter being converted into bilirubin by the cytosolic biliverdin reductase^[4,5]. Heme oxygenase, the rate limiting enzyme in heme degradation pathway, is induced in animal tissues, particularly in liver by many factors including its own

substrate heme, several heme-proteins, heavy metals, UVA radiation, hypoxia, hyperoxia and others^[6-9]. Induction of HO is entirely prevented by administration of several antioxidants such as α -tocopherol and allopurinol^[9]. In recent years good evidence has been accumulated showing that bilirubin can act as a highly effective antioxidant and free radical scavenger, and it has been proposed that it can play a physiological and key role as an endogenous protective agent against oxidant mediated injury^[10-14].

Antioxidant effects suggest that oxidant species play a major part in the induction of HO either directly or by GSH depletion^[9,10,15]. An increase in HO activity will enhance bilirubin formation and because unconjugated bilirubin is an efficient scavenger of ROS, its increase would be the cellular response to oxidative stress^[10,12-14]. Besides, similar to nitric oxide, CO derived from heme oxygenase reaction also acts as a neurotransmitter and regulator of vascular tone^[16].

Of the two known mammal liver HO isoenzymes, HO-1 and HO-2^[17], only HO-1 is inducible, herewith we will only refer to HO-1.

The aim of this work was to investigate the effect of HO-1 overexpression in rat livers with prehepatic portal hypertension.

MATERIALS AND METHODS

Animals and surgical procedures

Wistar male rats (200-250 g) were housed separately and acclimatised before use under conditions of controlled temperature ($25 \pm 2^\circ\text{C}$) and illumination (12 h light/dark cycle). Rats were fed with standard rat chow and water *ad libitum*. After 1 wk of acclimatisation, rats were randomised and separated into two groups: (1) Sham operated ($n = 24$) and (2) Prehepatic portal vein ligated rats ($n = 24$) (PPVL). Portal hypertension was induced by a calibrated portal vein stenosis according to the procedure of Chojkier *et al*^[18]. In brief, rats were anaesthetised with sodium pentobarbital (50 mg/kg body weight, i.p.) and then a midline abdominal incision was made. The portal vein was located and isolated from the surrounding tissues. A ligature of 3-0 silk was placed around the vein and snugly tied it to a 20 gauge blunt end needle placed along side the portal vein. The needle was subsequently removed to yield a calibrated stenosis of the portal vein. Sham rats underwent an identical procedure except that portal vein was isolated but not stenosed. Fourteen days after the operation rats of group 2 developed portal hypertension. Then, one day before the experiment, portal hypertensive and Sham rats were divided into three subgroups. One of each subgroup received one bolus injection of bilirubin (5 $\mu\text{mol/kg}$ body weight, i.p.) or one bolus injection of Sn-protoporphyrin IX (Sn-PPIX; 100 $\mu\text{mol/kg}$ body weight, i.p.). Then, six groups of animals were used ($n = 8$): Sham group (Sham), PPVL, Sham pretreated with bilirubin group (Sham + bilirubin), PPVL pretreated with bilirubin group (PPVL + bilirubin), sham pretreated with Sn-PPIX group (Sham + Sn-PPIX) and PPVL pretreated with Sn-PPIX group (PPVL + Sn-PPIX). Bilirubin and Sn-PPIX were prepared as follows: solutions in 0.1 mol/L NaOH were freshly prepared before administration, adjusted to pH 7.4 with

phosphate buffer and diluted with saline. In each subgroup portal pressure was measured immediately before the sacrifice. Fourteen days after the corresponding operation and before sacrifice, the rats were anaesthetised with sodium pentobarbital (50 mg/kg), intraperitoneally (i.p.). Portal pressure was measured through a needle placed in the splenic pulp, and maintained in place by cyanoacrylate gel. The needle was cannulated to a polyethylene catheter (50) filled with a heparinized saline solution (25 U/mL) and connected to a Statham Gould P23ID pressure transducer (Statham, Hato Rey, Puerto Rico) coupled to a Grass 79D polygraph (Grass Instruments, Quincy, MA). Animals were treated in accordance with guidelines established by the Animal Care and Use Committee of the Argentine Association of Specialists in Laboratory Animals (AADEALC), and were in accordance with the Guide to the Care and Use of Experimental Animals published by the Argentine Council on Animal Care.

Enzyme preparations and assays

Rats were anaesthetised with sodium pentobarbital (50 mg/kg body weight, i.p.) and killed 14 d after surgery. Livers were excised and perfused "in situ" with ice-cold saline solution (0.9% NaCl), then excised and homogenised in a Potter-Elvehjem homogenizer using different solutions. For heme oxygenase assay the homogenate was prepared using 4 vol of ice-cold 0.25 mol/L sucrose solution containing 1 mmol/L phenylmethyl sulfonyl fluoride, 0.2 mmol/L EDTA and 50 mmol/L potassium phosphate buffer (pH 7.4). Homogenates were centrifuged at 20000 g for 20 min and supernatant fractions centrifuged at 150000 g for 90 min. The microsomal pellet obtained was washed and resuspended in 20 mmol/L potassium phosphate buffer (pH 7.4), containing 135 mmol/L KCl, 1 mmol/L phenyl-methylsulfonyl fluoride and 0.2 mmol/L EDTA to a protein concentration of 10 mg/mL. Microsomal HO-1 was obtained as described elsewhere^[17]. The 150000 g supernatants obtained from the microsomal preparation were fractionated by addition of ammonium sulfate (AS), and the 40%-60% AS fraction dissolved in 10 mmol potassium phosphate buffer (pH 7.4) and dialyzed against the same buffer using this preparation as biliverdin reductase. Heme oxygenase activity was determined as described elsewhere^[10]. The standard incubation mixture in a final volume of 200 μL contained 10 μmol potassium phosphate buffer (pH 7.4), 60 nmol NADPH, 50 μL HO-1 (0.5 mg protein), 50 μL biliverdin reductase (0.42 mg protein), and 200 nmol hemin. Incubations were carried out at 37°C for 30 min. Activity was determined by measuring bilirubin formation, which was calculated as the difference in absorbance measured at 455 and 520 nm, employing an ϵ value of $50 \text{ mM}^{-1} \text{ cm}^{-1}$ ($\text{viS}_{\text{max}} 455 \text{ nm}$)^[11]. CAT, SOD and GSH-Px activities were determined spectrophotometrically in liver homogenates prepared in a medium consisting of 140 mmol/L KCl and 25 mmol/L potassium phosphate buffer (pH 7.4), and centrifuged at 600 g for 10 min. The supernatant, a suspension of preserved organelles, was used as homogenate. Catalase activity was determined by measuring the decrease in absorbance at 240 nm^[19] glutathione peroxidase activity following NADPH oxidation at 340 nm^[20], and superoxide dismutase

activity by inhibition of adrenochrome formation rate at 480 nm^[21]. One unit in the SOD assay is defined as the amount of enzymatic protein required to inhibit 50% of epinephrine auto-oxidation.

Lipid peroxidation

Lipid peroxidation in liver was determined by measuring the rate of production of thiobarbituric acid reactive substances (TBARS), expressed as malondialdehyde equivalents^[22]. One volume of homogenate was mixed with 0.5 volume TCA (15% w/v) and centrifuged at 2000 g for 10 min. The supernatant (1 mL) was mixed with 0.5 mL thiobarbituric acid (0.7% w/v) and boiled for 10 min. After cooling, sample absorbance was read spectrophotometrically at 535 nm. Malondialdehyde concentration was calculated using an ϵ value of $1.56 \times 10^5 \text{ M}^{-1}\text{cm}^{-1}$.

Endogenous hepatic GSH content

Total glutathione (GSH plus GSSG) was determined in liver homogenates after precipitation with 2% perchloric, and using yeast-glutathione reductase, 5, 5' dithio-bis-(2-nitrobenzoic acid) (DTNB) and NADPH and reading at 340 nm. GSSG was determined by the same method in the presence of 2-vinylpyridine. GSH was calculated from the difference between total glutathione and GSSG^[23].

Western-blot analysis of HO-1 expression

Samples of homogenate obtained for HO-1 activity assays were also analyzed by Western immunoblot technique as previously described^[24]. An amount of protein (50 μg) from homogenates of control and treated rats was run in sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis using a 12% acylamide resolving gel (Mini Protean II System, BioRad, Hertz, UK). Separated proteins were transferred to nitrocellulose membranes and non-specific binding of antibodies was blocked with 3% non-fat dried milk in PBS, pH 7.4 for 1 h at room temperature. Membranes were then probed with polyclonal goat anti-HO-1 antibody (Santa Cruz, BioTech, California)(1:300 dilution in Tris-buffered saline, pH 7.4) overnight at 4°C. Immune complexes were detected using donkey anti goat secondary antibody (1:1500) (Santa Cruz, BioTech, California), and were visualized using ECL reagent (Amersham, Pharmacia). Intensity of bands was analyzed with Gel-Pro[®] analyzer 3.1 version, Media Cybernetics.

Microscopy and image analysis

Hepatic tissue was fixed in buffered formalin and stained with routine techniques (HE, Reticulin and Masson's trichomic) for light microscopy. For high resolution optic microscopy (HROM) tissue was fixed in 3% glutaraldehyde buffered with sodium cacodylate, embedded in epoxy and stained with toluidine blue. Images from light microscopy were captured and digitised (Cap view) and standardised (PhotoShop 7.0); then the selected sinusoidal areas of the pericentral vein areas were extracted with auto level function. Threshold in red images were obtained through Scion Image B4.02 analyser. Selected areas for quantification were measured as pixels per area (square inches). Standard referenced area utilized was 8.33 square inches^[25].

Table 1 Effect of different treatments on portal pressure (mean \pm SE)

Treatment	Portal pressure (PP) (mmHg)
Sham	7.9 \pm 0.6 ^b
PPVL	14.4 \pm 1.9
Sham + bilirubin	7.6 \pm 0.9 ^b
Sham + Sn-PPIX +	7.3 \pm 0.7 ^b
PPVL + Bilirubin	14.0 \pm 1.8
PPVL + Sn-PPIX	13.8 \pm 1.6

^b $P < 0.001$ between sham groups and PPVL, PPVL + Bilirubin and PPVL + Sn-PPIX groups, according to Neuman-Keuls' test.

Figure 1 Effect of PPVL and bilirubin on lipid peroxidation. Rats were treated as described in Methods. Values are the means of three different experiments using three rats each time, and bars indicate SE. ^a $P < 0.05$ vs sham.

Protein determination

Protein concentration was measured following Lowry *et al.*^[26] using bovine serum albumin as standard.

Statistical analysis

Results are expressed as mean \pm SE. Data were analysed statistically by factorial analysis of variance (ANOVA) and followed by the Neuman-Keuls' test for comparison of means. Differences were considered significant at $P < 0.05$.

RESULTS

Portal pressure measurement

The portal pressure results are shown in Table 1. Differences between Sham *vs* PPVL rats at d 14 without and with bilirubin and Sn-PPIX were significant ($P < 0.001$). No differences were found either in Sham or in PPVL animals when they were treated with bilirubin and Sn-PPIX.

Oxidative stress generation

Reactive oxygen species are responsible for peroxidative cell damage. TBARS were 150% increased in PPVL rat livers (Figure 1).

GSH is a leading substrate for enzymatic antioxidant functions and is also a known radical scavenger. Therefore, if PPVL treatment induced the formation of ROS, it could be expected that GSH levels be affected. It can be

Figure 2 Effect of PPVL and bilirubin on GSH liver content. Rats were treated as described in Methods. Values are the means of three different experiments using three rats each time, and bars indicate SE. ^a*P* < 0.05 vs sham.

Table 2 Effect of PPVL and bilirubin on antioxidant enzyme activities (mean ± SE)

Group	Catalase (pmol/mg protein)	Total superoxide dismutase (U/mg protein) ¹	Glutathione peroxidase (U/mg protein) ²
Sham	10.5 ± 1.1 ^a	9.0 ± 0.2 ^b	0.129 ± 0.004 ^a
PPVL	6.5 ± 0.5	4.5 ± 0.1	0.100 ± 0.004
Sham + Bilirubin	10.7 ± 0.9 ^a	9.3 ± 0.1 ^b	0.132 ± 0.006 ^a
PPVL + Bilirubin	9.4 ± 0.9 ^a	8.9 ± 0.2 ^b	0.131 ± 0.004 ^a

Enzymatic activities were assayed as described in the text. ¹One unit of SOD activity is defined as the amount of enzyme required to inhibit 50% of the epinephrine autooxidation. ²One unit of the enzyme represents the decrease of 1 mmol of NADPH/min under the assay conditions. ^a*P* < 0.05 between Catalase and Glutathione Peroxidase of Sham groups, PPVL + Bilirubin and PPVL group, ^b*P* < 0.01 between Superoxide Dismutase of group of Sham groups, PPVL + Bilirubin and PPVL group and PPVL group according to Neuman-Keuls' test.

seen in Figure 2 that in the liver of PPVL animals GSH concentration was about 50% decreased when compared to Sham group. When rats were pretreated with bilirubin both TBARS and GSH levels were equal to Sham animals (Figures 1 and 2).

Enzymatic defence system

Table 2 shows the activities of CAT, SOD and GSH-Px in the liver of Sham and PPVL animals pretreated with bilirubin as well as in both groups without bilirubin. These enzymes were significantly inhibited (CAT 38%, SOD 50% and GSH-Px 23%) in PPVL rats. Pretreatment with bilirubin had no effect in Sham animals, but in PPVL rats the inhibition of antioxidant enzymes was totally prevented.

Heme oxygenase activity and expression

As it is shown in Figure 3, PPVL treatment increased liver HO-1 activity by 80%. Bilirubin pretreatment did not have any effect in Sham rats, but it completely prevented HO-1 induction provoked by PPVL. As occurred with HO-1 activity, a similar increment in HO-1 expression was obtained in liver of PPVL rats (Figure 4A and B).

Previous results using acute intoxication with different drugs demonstrated that as a consequence of ROS pro-

Figure 3 Effect of PPVL and bilirubin on HO-1 activity. Rats were treated as described in Methods. One unit of HO-1 is defined as the amount of enzyme producing 1 nmol of bilirubin per 30 min under the standard incubation conditions. Values are the means of three different experiments using three rats each time, and bars indicate SE. ^a*P* < 0.05 vs sham.

Figure 4 Western blot analysis of HO-1 expression in PPVL rat liver (A). Densitometry was done to quantify HO-1 protein expression (B). The blot is representative of 3 blots with a total of 4-5 samples/group between the 3 blots. *P* < 0.01 sham vs PPVL group.

duction, liver GSH levels rapidly decreased and then HO-1 was induced. It was also observed that HO-1 induction appeared to occur once the ROS was increased and the antioxidant defence system decreased. Bilirubin action as a protective agent against oxidative stress suggests that inhibition of HO-1 could enhance even more the oxidative stress induced by PPVL model. Therefore, the effect of Sn-PPIX, a strong inhibitor of HO-1 was assayed 24 h before the end of the experiment. Table 3 shows that a single administration of Sn-PPIX decreased to half HO-1 activity in Sham rats. PPVL animals pretreated with the inhibitor of HO-1 (Sn-PPIX), slightly decreased hepatic GSH levels (20%) and significantly increased TBARS production (70%) over the values obtained by PPVL treatment.

Effect of CO on hepatic sinusoidal vasodilatation

As it is shown in Table 4 and Figure 5, CO produced a significant increase in the sinusoidal hepatic areas of PPVL rats when compared to sham animals. Pretreatment of

Table 3 Effect of Sn-PPIX administration on the HO-1 induction and on TBARS and GSH contents in PPVL rat livers (mean \pm SE)

Treatment	HO-1 (U/mg protein) ¹	TBARS (nmol/min per mg protein)	GSH content (μ mol/g liver)
Sham	0.50 \pm 0.01 ^b	0.10 \pm 0.01 ^d	7.5 \pm 0.2 ^d
PPVL	0.90 \pm 0.02	0.25 \pm 0.01	3.7 \pm 0.1
Sham + Sn-PPIX	0.25 \pm 0.01	0.11 \pm 0.01 ^d	7.2 \pm 0.3 ^d
PPVL + Sn-PPIX	0.48 \pm 0.04	0.32 \pm 0.02	2.3 \pm 0.2

Sn-PPIX was administered as described in Materials and Methods. Sham animals were injected with saline solution. Enzymatic activity was assayed as described in the text. ¹One unit of the enzyme forms 1 nmol of bilirubin/30 min under assay conditions. Different letters within columns indicate significant differences according to Neuman-Keuls' test. Differences in HO-1 were of ^b $P < 0.01$ between Sham group and PPVL, Sham + Sn-PPIX groups. Differences in TBARS and in GSH content were of ^d $P < 0.01$ between Sham groups and PPVL groups.

Table 4 Effect of different treatments on vasodilatation of hepatic sinusoids (mean \pm SE)

Treatment	Sinusoidal area
Sham ($n = 258$)	3.64 \pm 0.08
PPVL ($n = 245$)	4.20 \pm 0.02 ^b
Sham + Sn-PPIX ($n = 257$)	3.45 \pm 0.01
PPVL + Sn-PPIX ($n = 249$)	3.48 \pm 0.04

The selected area for quantification was measured as pixels per area (square inch). The area standard used was 8.33 square inch. ^b $P < 0.01$ between PPVL and the other three groups, according to Neuman-Keuls' test.

PPVL animals with Sn-PPIX totally prevented this effect and similar values to Sham group were obtained (Table 4). Groups Sham and PPVL + Sn-PPIX showed normal histological features when focusing on sinusoidal space (similar Figure 5A), while group PPVL showed sinusoidal dilation (Figure 5B).

DISCUSSION

Aerobic organisms are continuously exposed to oxygen, which renders them prone to damage generated by ROS. There are a number of cellular mechanisms to protect the cell from oxidative stress. Antioxidant enzymes such as CAT, SOD and GSH-Px play critical roles in oxidative stress protection by converting ROS into less harmful products^[27]. Recently, HO-1 and its product bilirubin have gained attention in cytoprotection against oxidant mediated injury^[10-14,28,29].

Our results showed that the administration of bilirubin in rats decreased PPVL-induced lipid peroxidation, restored GSH content and activity of the antioxidant enzymatic system to normal levels. These results open possibilities for considering the use of bilirubin as an efficient antioxidant and free radical scavenger (Figures 1 and 2, Table 2).

Bilirubin administration totally prevented the decrease of antioxidant enzyme activities and induction of HO-1 activity provoked by PPVL (Table 2, Figure 3). These findings are in agreement with our own previous reports

Figure 5 Hepatic centrolobular zone of Sham operated rats (A). Sinusoidal area spread normal histological features (HE, 100 x magnification). Hepatic centrolobular zone corresponding to PPVL group (B). Sinusoidal area is increased (arrows) (Reticulin, enhanced image, 40 x magnification).

on the protective effect of bilirubin against oxidative stress caused by different physical and chemical agents^[28].

Administration of Sn-PPIX, a known competitive inhibitor of HO-1 expectedly decreased HO-1 activity (Table 3). When the inhibitor was given to PPVL rats, HO-1 activity remained at control levels, but an increase in TBARS content and a decrease in GSH levels were observed (Table 3).

CO is, like nitric oxide, an endogenous compound that activates guanylate cyclase^[30], leading to the generation of cyclic guanosine monophosphate, which in turn mediates various physiological functions, and excessive production of CO, a consequence of HO-1 overexpression, could play an important role in modulating vascular tone under different pathological situations^[16,31]. Besides, it has been demonstrated that administration of zinc protoporphyrin IX, a strong inhibitor of heme oxygenase, elicits a marked increase in the vascular resistance as a consequence of sinusoidal constriction^[32]. These results are in agreement with the effects observed in PPVL rats pretreated with Sn-PPIX (Table 4, Figure 5). Increased production of CO, as a consequence of HO-1 induction, may be beneficial in some pathological situations, including hypertension^[33], but can also be detrimental in other disease conditions^[34]. For instance, in PH it would be detrimental because an increased production of CO in splanchnic organs may contribute to the development and maintenance of the splanchnic hyperdynamic circulation associated with the PH syndrome. But at this point, we can also speculate that an enhanced release of the vasodilator CO may contribute to the modulation of hepatic blood flow.

It has been demonstrated that HO-1 is induced in

splanchnic organs of PH rats^[35-37], and it was also reported that patients with portal hypertensive diseases had significantly greater the activity and expression of liver HO-1 than those from normal individuals^[38]. HO-1 activity in the liver is not related to systemic vascular resistance; however this organ may show high activity of HO due to that reticuloendothelial cell-rich tissues are involved in the removal of senescent erythrocytes and plasmatic hemoglobin from the circulation.

The precise mechanisms whereby HO-1 expression is induced in PH rats are still unknown, but the results here obtained lead us to believe that this induction was provoked as a consequence of oxidative stress generation. Besides, it is noteworthy that HO-1 is transcriptionally activated by several chemical and physical factors that may be increased during PH^[1], including cytokines, endotoxin and shear stress^[39]. For these reasons, in the present study we suggest a beneficial role of HO-1 overexpression in a rat model of prehepatic portal hypertension.

In this study, no differences in portal pressure were observed in PPVL rats when compared this group with PPVL + Bilirubin and PPVL + Sn-PPIX groups. This fact could be explained by the persistence of some amount of portal systemic shunting and by the hepatic blood resistance that was not modified despite the pericentral sinusoidal dilation documented here.

In conclusion, our data suggest that ROS generation by portal hypertension situation alter heme degradation. They also evidenced that the cell possesses an inducible pathway against oxidative stress finally leading to increased bilirubin formation, which then exerts its antioxidant protective action. These results shed light on the response of heme degradation to PPVL-induced oxidative stress, and further support the involvement of bilirubin as a physiological protective agent against PPVL-induced oxidative cell injury. The potential use of bilirubin as an antioxidant in combination with other antioxidants or with conventional treatments, as a new therapeutic approach for portal hypertensive patients, can be considered.

Abstract

AIM: To investigate the role of IFN- γ inducible protein-10 (IP-10) and regulated upon activation, normal T cell expressed and secreted (RANTES) protein in acute pancreatic allograft rejection in rats.

METHODS: An experimental pancreas transplantation model was established using diabetic SD rats as the recipient, induced by applying streptozocin (STZ). Pancreas transplantation was performed with a physiologic method of portal venous and enteric drainage. Rats were divided into two groups, isograft group (group A, $n = 24$) and allograft group (group B, $n = 24$) in which either healthy SD rats or Wistar rats served as donors, respectively. Twelve diabetic or healthy SD rats were used as controls. At d 1, 4, 7, and 10 post transplantation, serum IP-10 and RANTES were assessed by ELISA and their expression in the allografts was determined by immunohistochemistry.

RESULTS: In group B (allograft group), the development of acute rejection was significantly correlated with increased serum concentration and tissue expression of IP-10 and RANTES, with a peak level at d 7 post transplantation. In contrast, there was no obvious change before and after transplantation in group A (isograft group).

CONCLUSION: Our study suggests a possible role of IP-10 and RANTES in acute rejection and early monitoring of chemokines may be helpful in predicting the outcome of pancreas transplantation.

INTRODUCTION

In the past several decades, great success has been made in the transplantation field. However, the acute rejection is still a tremendous obstacle to the development of the transplantation. Acute allograft rejection is a complex process comprising interrelated series of events, such as the recognition of the allograft antigen, the activation and proliferation of the leukocytes, the migration of the leukocytes to the allograft. In the pathogenic process, several kinds of inflammatory molecules are required, such as proinflammatory cytokines, adherence molecules and chemokines. The chemokines are a large family of "chemoattractant cytokines", including IFN- γ inducible protein-10 (IP-10), regulated upon activation, normal T cell expressed and secreted (RANTES), Mig, etc. They play a critical role in directing leukocytes to the allograft and in amplifying intragraft inflammation during rejection^[1,2]. In the past years it has become evident that individual proinflammatory chemokines (such as IP-10, RANTES) are indispensable in the rejection process of heart transplantation, kidney transplantation, and lung transplantation, compared to other chemokines^[3-5]. However the roles of chemokines in pancreas transplantation are still not well known and pancreas transplantation has its own speciality that differs from other organ transplantations. For example, it is well known that pancreatic grafts are very susceptible to allograft rejection because of the strong immunogenicity of pancreas itself^[6]. To assess the changes of chemokines IP-10 and RANTES in the acute rejection of pancreas transplantation, we established the pancreas transplantation model in rats firstly, using a physiologic method of portal

venous and enteric drainage^[7], and then evaluated the severity of rejection, detected the concentration of serum RANTES and IP-10 using ELISA kits, and examined the expressive position and intensity of IP-10 and RANTES in the allograft pancreas.

MATERIALS AND METHODS

Animal preparation

The diabetic rats were induced firstly by single intravenous injection of streptozocin (STZ; Sigma, USA) at a dose of 50 mg/kg of body weight, when the closed flock male SD rats weighing 250-280 g were chosen (offered by the Experimental Animal Center of Jiangsu Province, China). After the STZ injection, the nonfasting blood glucose and urine glucose of the rats were assayed before the inducement and measured on alternate day. Only rats with nonfasting blood glucose exceeding 16.8 mmol/L and the strong positive reaction of the urine glucose were selected as recipients. The closed flock male Wistar rats (offered by the Silaike Co. Ltd, Shanghai, China) and healthy SD rats weighing 220-250 g served as donors. The donors and recipients were matched under the condition that the weights of the recipients were more than that of donors by about 30 g.

Grouping of experimental rats

Rats were divided into two groups, isograft group (group A, $n = 24$) and allograft group (group B, $n = 24$), in which either healthy SD rats or Wistar rats served as donors, respectively. Twelve diabetic or healthy SD rats were used as controls.

Surgical procedure and collection of specimen

A physiologic method for pancreas transplantation was adopted, in which the vein was reconstructed by end-to-side anastomosis between the donor portal vein and the recipient superior mesenteric vein, and arterial reconstruction was carried out by end-to-side anastomosis of the donor to the recipient abdominal aorta, and enteric drainage was performed by a side-to-side anastomosis between the duodenum of donors and that of recipients. The level of the recipient's blood glucose below 11.2 mmol/L at 1 d post operation was regarded as successful transplantation. The recipients were sacrificed at 1, 4, 7, 10 d ($n = 6$ animals/time point) after transplantation. The 12 rats in control groups were killed at the beginning of the experiment. Blood samples were collected and placed quietly for clotting for 2 h at room temperature before centrifuging for 30 min at $1000 \times g$, then the serum was pipetted immediately and stored at -70°C . After representative portions of pancreas grafts were removed, some of them were immediately snap-frozen in liquid nitrogen for immunohistology and the rest were fixed in 10% formalin for histopathological examination.

Histopathology examination

The samples of pancreas grafts were fixed, dehydrated, embedded, sliced, and stained with hematoxylin and eosin following the routine proposal. The classification of acute rejection was stated according to the Nakhleh

Table 1 Classification of acute rejection in allograft group post transplantation

	Grade I	Grade II	Grade III	Grade IV
1 d	5	1		
4 d		4	2	
7 d			5	1
10 d				6

Nakhleh Classification Criterion, Grade I: no rejection present, Grade II: mild lymphoplasmacellular infiltration or endothelialitis, Grade III: moderate lymphoplasmacellular infiltration or arteritis/vasculitis, Grade IV: severe lymphoplasmacellular infiltration or fibrinoid necrosis.

Classification Criterion^[8].

Determination of serum IP-10 and RANTES

ELISA kits (TPI INC., USA) were used for the determination of serum IP-10 and RANTES, and the procedure was strictly according to the protocol recommended by the manufacturers. The results were expressed as the quantity per mL serum.

Immunohistology

For immunohistology, 10 μm frozen sections of pancreas were prepared, fixed in acetone for 10 min, dried in the airy place, and incubated with goat polyclonal IP-10 antibodies and rabbit polyclonal RANTES antibodies respectively. Then, the sections were incubated with rabbit anti-goat IgG and goat anti-rabbit IgG respectively. All the reagents were offered by Santa Cruz Co, USA. The cells stained clearly were regarded as positive ones. According to the percentage of positive cells in the whole infiltrating immune cells, the results of immunohistology were expressed in four grades: negative (the rate of positive cells $< 5\%$), mild positive (the rate of positive cells $> 5\%$ and $< 25\%$), moderate positive (the rate of positive cells $> 25\%$ and $< 50\%$), strong positive (the rate of positive cells $> 50\%$).

Statistical analysis

The concentration of serum IP-10 and RANTES were expressed as mean \pm SD. The significance of differences was tested using either *t*-test for means of two samples or analysis of Variance and *q*-test for means of multiple samples. $P < 0.05$ was considered as significant.

RESULTS

Classification of acute rejection

The acute rejection was classified according to the criterion stated by Nakhleh. In this study, a mild edema appeared around the islet and the acinus 1 d post transplantation both in the allograft and isograft groups. The edema disappeared and no evident rejection was found at 4, 7, and 10 d after the operations in the isograft group, though evident rejection appeared in the allograft group (Table 1).

Changes of serum IP-10 and RANTES

In the allograft group, serum IP-10 concentration was elevated significantly since 4 d and peaked at 7 d after the

Table 2 Concentration of serum IP-10 in isograft, allograft and control groups (ng/L)

	1 d	4 d	7 d	10 d
Isograft group	40.88 ± 10.76	36.74 ± 10.33	38.13 ± 12.73	31.83 ± 7.55
Allograft group	43.34 ± 15.29	66.26 ± 11.08 ^a	83.28 ± 16.44 ^a	70.08 ± 17.65 ^a
Control group	28.76 ± 7.41			

^a $P < 0.05$ vs control group.

operations, compared to the control group ($P < 0.05$). However, no significant difference was found between the isograft group and the control group at the four corresponding phases. The tendency of serum RANTES was similar to that of IP-10, only showing a sharp increase at 1 d after the transplantation in the isograft group ($P <$

**Figure 3** IP-10 immunohistochemical staining of pancreas allografts. Moderate expression was observed at 4 d post transplantation (× 200).**Figure 4** RANTES immunohistochemical staining of pancreas allografts. Moderate expression was observed at 4 d post transplantation (× 200).

0.05) compared with the control group (Tables 2 and 3).

Expression of IP-10 and RANTES in the pancreas grafts

There were no detectable expressions of IP-10 and RANTES protein in the normal pancreas. Mild expression was observed at 1 d after the operation both in the allografts and isografts (Figures 1 and 2). At 4 d after the transplantation, expression of IP-10 and RANTES appeared moderately in the allografts (Figures 3 and 4), whereas their expression could not be detected in the isografts. At 7 d after the operation, the positive expression was strongest in the allografts (Figures 5 and 6). Besides, they were expressed in different places. IP-10 was gathered around the vessels; RANTES was clearly expressed in the lymphocytes in interstitial tissues and concentrated in the narrow space between the inflammatory and normal tissues.

DISCUSSION

Acute rejection is a very complicated process, in which the cellular and humoral immune mechanisms are involved. In the process of acute rejection, the cellular immune reaction is of primary importance^[9]. The circulating lymphocytes firstly adhere to the vessel endothelium, then penetrate the vessel wall, cross the interstitial tissue, migrate into the graft, and finally destroy the graft^[10]. In these processes, the chemokines are indispensable.

Figure 5 IP-10 immunohistochemical staining of pancreas allografts. Strong positive expression was observed at 7 d post transplantation ($\times 200$).

Figure 6 RANTES immunohistochemical staining of pancreas allografts. Strong positive expression was observed at 7 d post transplantation ($\times 200$).

Chemokines accelerate the migration and activation of the leucocytes and lymphocytes through the interaction between the chemokines and their receptors, and play a key role in recruitment of inflammatory cells into an organ transplant^[11].

Chemokines are a group of 8-11 kDa proteins, owning four conservative tyrosines in their primary sequence. According to the positional relation between the first tyrosine and the second one, the family are divided into four subfamilies, namely, CXC subfamily, CC subfamily, C subfamily and CX3C subfamily^[12].

IP-10 is one of CXC subfamily, mainly coming from activated fibroblasts, monocytes, endothelial cells and T cells^[13]. By the interaction between IP-10 and its receptor (CXCR3), IP-10 function in the recruitment of activated Th1 cells specifically and amplify the Th1 reaction. It has been reported that IP-10 and CXCR3 were detected in the allograft in the lung and heart transplantation, and the quantities of IP-10 and CXCR3 are positively related with the severity of rejection response^[14]. The latest study performed by Kanmaz *et al*^[15] showed an important correlation between urinary excretion of IP-10 and acute rejection in baboon kidney transplantation and indicated that urinary IP-10 might be a more accurate predictive parameter than serum creatinine to monitor the occurrence of acute rejection of renal transplant.

RANTES belongs to the CC subfamily, produced and secreted by the CD8⁺ T cells, endothelial cells, and fibroblasts, directing the recruitment of T cells, monocytes, eosinophils to the local tissue^[16]. It has been confirmed that RANTES is closely related to the pathogenesis of rejection in heart, lung, kidney transplantation, *etc.* Mulligan *et al*^[2] found that the protein of RANTES was detectable 6-8 d after the heart transplantation in mice in heterogeneous group. However, the results were opposite in the homogeneous heart transplantation. Sekine *et al*^[17] reported that the mRNA of RANTES was closely positively correlated with the number of infiltrating monocytes, using the models of lung transplantation. Similar results were also obtained in liver transplantation^[18]. Some experiments have succeeded in prolonging the functional time of the allografts by inhibiting the interaction between the chemokines and their receptors. Hancock *et al*^[19] reported that the survival phase was elon-

gated, provided that the IP-10 knockout mice served as the donors. Yun *et al*^[20] demonstrated that the use of Met-RANTES, the specific antagonist to RANTES, could alleviate the infiltration of CD4⁺ and CD8⁺ lymphocytes and attenuate allograft rejection in mice. It seems that IP-10 and RANTES play a pivotal role in the rejection of organ transplantation.

In our experiments, there was no detection of IP-10 and RANTES protein in the normal pancreas. In the isograft group, the proteins of IP-10 and RANTES were detected weakly at 1 d, and restored to the normal level since 4 d post transplantation. In the allograft group, the expression of IP-10 and RANTES protein were also upregulated in the primary phase of acute rejection, and then developed with the severity of the rejection reaction. The trend of serum IP-10 and RANTES was the same as that in the graft. It seems that the detection of IP-10 and RANTES benefits the early diagnosis of acute rejection.

We also noticed that the expressing loci and pattern of IP-10 and RANTES was obviously different. IP-10 was gathered around the vessels; meanwhile, RANTES was clearly expressed in the lymphocytes in the interstitial tissues and crowded in the narrow space between the inflammatory and normal tissues. This result perhaps demonstrated that IP-10 and RANTES play different roles in the acute rejection. IP-10 is a key molecule in directing the lymphocytes to penetrate the endothelium and migrate across the tissue. RANTES, produced by the cells in the inflammatory tissues, can be recognized and bound with its receptors on the surface of passage macrophage, T cells. The activated T cells unregulated the expression of RANTES, and more inflammatory cells were attracted into the graft. The process was cycled and amplified and the inflammation aggravated.

In summary, IP-10 and RANTES play a critical role in the acute rejection after pancreas transplantation. Further research will help the understanding of the pathogenesis of acute rejection. IP-10 and RANTES will be a tool for the early diagnosis and a target for the therapy of acute rejection.

Abstract

AIM: To investigate the clinicopathological features of gastrointestinal stromal tumor (GIST) and to study the reference indexes for malignancy.

METHODS: Fifty-two cases of primary GIST were distinguished from a group of gastrointestinal mesenchymal tumors using a panel of antibodies such as CD117 and CD34 by immunohistochemical SP method. Their biological behaviors were analyzed using the expression of p21WAF1 and Bax in 52 cases of GIST.

RESULTS: Grossly, the tumor size was between 1.5 cm and 13 cm (mean: 5.5 cm). Focal areas of hemorrhage, necrosis, or small cyst formation could be seen. Microscopically, the tumor was composed of spindle cells (20 cases), epithelioid cells (20 cases) and mixed cells (12 cases). Immunohistochemically, CD117 and CD34 showed diffuse strong positive expressions, the positive rates were 98.1% and 92.3%. SMA, S-100, NSE, NF and MBP showed focal positive expressions, the positive rates were 48.1%, 28.8%, 25%, 21.2% and 42.3% respectively. Vimentins were all positive desmin and CgA were all negative. In normal adult stomach and intestine, the immunoreactive staining for CD117 and CD34 showed immunoreactive interstitial cells of Cajal in myenteric neuroplexus. Among the 52 cases of GIST, 27 were positive for p21WAF1 (51.9%), 29 for Bax (55.8%). The expression of p21WAF1 and Bax had no significant difference with the localization, size, histological subtype of GIST, but had a significant difference with the histological grade ($P = 0.000$, respectively). p21WAF1 expression had a positive correlation to Bax expression ($r = 0.461$, $P = 0.001$, $\kappa = 0.459$).

CONCLUSION: GIST has complicated arrangements and various cell types. Positivity of CD117 and CD34 is the most valuable factor in diagnosing GIST. Expression

of p21WAF1 and Bax plays an important role in potential malignancy and malignancy rather than in benign GIST. p21WAF1 and Bax may be used as the markers in the assessment of GIST malignant potential.

INTRODUCTION

Gastrointestinal stromal tumor (GIST) is the most common mesenchymal tumor in the digestive tract^[1]. Mutational activation of *c-kit* has been found to be associated with the pathogenesis of GIST^[2], CD117 positivity is the most valuable marker in diagnosing GIST. But the biological behaviors of GIST are difficult to predict^[3], some metastasize whereas others remain asymptomatic for years^[4]. In this study, we detected CD117, CD34, SMA, S-100, NSE, NF, MBP, vimentin, desmin, CgA, p21WAF1 and Bax using immunohistochemical staining method to explore the expression of p21WAF1 and Bax and its correlation to clinicopathologic characteristics of GIST.

MATERIALS AND METHODS

Specimens

Fifty-two cases of GIST were selected from the Department of Pathology, First Hospital of Harbin Medical University in 2001 to 2004. The slides stained with hematoxylin and eosin were reviewed. Based on the diagnostic criteria proposed by Haber *et al*^[5], among the 52 cases of GIST, 20 were cases of benign GIST, 12 and 20 were cases of potentially malignant and malignant GIST respectively. Age ranged 34-78 years (mean: 54.3 years).

Immunohistochemistry

Resected specimens were fixed in 40 g/L formaldehyde and embedded in paraffin. Four- μ m thick sections were dewaxed, rehydrated in graded alcohols, and processed

Table 1 Primary antibody used for immunohistochemical study

Antibody	Clone	Dilution	Pretreatment
CD117	polyclonal	instant	Microwave
CD34	QBEnd/10	instant	Microwave
SMA	1A ₄	instant	None
Vimentin	V9	instant	None
Desmin	ZC18	instant	None
S-100	4C4.9	instant	None
NSE	E27	instant	None
NF	DA2/FNP7	instant	Microwave
MBP	polyclonal	instant	None
CgA	LK2H10	instant	Microwave
p21WAF1	4D10	1:25	Microwave
Bax	2D2	1:50	Microwave

using immunohistochemical SP method. All antibodies were purchased from Beijing Zhongshan Biotechnology CO. LTD (Table 1). Tissues positive for all the purchased antibodies were used as positive controls, sections prepared with PBS instead of the primary antibody were used as negative controls. When the number of positive cells was < 10%, 10%-50%, or > 50%, the immunoreactivity for p21WAF1 and Bax was scored as 1 +, 2 +, 3 +, respectively. When the number of positive cells was ≤ 50% and > 50%, the immunoreactivity for other antibodies was scored as 1 +, 2 +, and 3 +, respectively.

Statistical analysis

Statistical analyses were performed using SPSS 11.5 software. Pearson χ^2 test, Fisher's exact test, Spearman rank correlation test and Kappa test were used when appropriate. $P < 0.05$ was considered statistically significant.

RESULTS

Grossing findings

The tumor size was 1.5-13 cm (mean: 5.5 cm). Tumors were generally round or oval in shape with pink-white and firm well-circumscribed and cut surface. Focal areas of hemorrhage, necrosis, or small cyst formation could be seen. Submucosal or subserosal tumors sometimes extended into the gastrointestinal lumen, leading to ulceration in mucosa.

Light microscopic findings

Among the 52 cases of GIST, spindle cell type was found in 20, epithelioid cell type in 20 (Figure 1A) and mixed type in 12. The tumor cells arranged in interlacing fascicles or formed whirls. The tumor cells were spindle, oval or round in shape, sometimes signet-ring like cells could be observed with a clear cytoplasm (Figure 1B). Hemorrhage and/or necrosis and/or hyaline degeneration (Figure 1C) could be found in some cases. Mucosal or serosal invasion (Figure 1D) sometimes could be seen in some malignant GISTs.

Table 2 Relation between p21WAF1, Bax expression and clinicopathological features

Items		<i>n</i>	p21WAF1			Bax

p21WAF1	<i>n</i>	Bax		<i>r</i>	<i>P</i>
		+	-		
+	27	21	6	0.461	0.001
-	25	8	17		

Immunohistochemical findings

CD117 and CD34 showed diffuse positive expressions, the positive rates were 98.1% (Figure 2A) and 92.3%. SMA, S-100, NSE, NF and MBP showed focal positive expressions, the positive rates were 48.1%, 28.8%, 25%, 21.2% and 42.3%, respectively. Vimentins were all positive while desmin and CgA were all negative. In normal adult stomach and intestine, the immunoreactive staining for CD117 and CD34 showed immunoreactive interstitial cells of Cajal in myenteric neuroplexus (Figure 2B). Among the 52 cases of GIST, 27 were positive for p21WAF1 (51.9%, Figure 2C), 29 for Bax (55.8%, Figure 2D).

According to the χ^2 test, the expression of p21WAF1 and Bax had no significant differences in the localization, size, and histological subtype of GIST, but there was a significant difference in the histological grade ($P = 0.000$, Table 2). There was a significant difference between benign and potentially malignant or malignant GISTs, but the difference in p21WAF1 and Bax expression between potentially malignant and malignant GISTs was not significant. According to Spearman rank correlation test and Kappa test, p21WAF1 expression had a positive correlation to Bax expression ($r = 0.461$, $P = 0.001$, $\kappa = 0.459$, Table 3).

DISCUSSION

In 1983, Mazur and Clark^[6] first introduced the vague term 'gastrointestinal stromal tumor'. Under light microscope,

Figure 1 Epithelioid cells (A), signet-ring like cells (B), hyaline degeneration (C), and mucosal invasion (D) in GISTs.

Figure 2 Expressions of CD117 (A), CD34 (B), p21WAF1 (C), and Bax (D) in GIST.

the morphology of stromal tumors looks sometimes like a leiomyoma, sometimes like a Schwannoma^[7]. Most gastrointestinal mesenchymal tumours, previously classified as leiomyomas, schwannomas or leiomyosarcomas, are today classified as GISTs on the basis of molecular and immunohistological features^[8]. GIST derives from the interstitial cells of Cajal (ICC), or from a common precursor of ICC and smooth muscle cells of the digestive

tract^[9]. Immunoperoxidase staining can show both c-kit and CD34-positive cells surrounding the Auerbach ganglia plexus in the gastrointestinal tract^[10]. The great majority of GISTs occur in the stomach (60%-70%) and small intestine (25%-35%)^[11]. In this study, 46.1% GISTs occurred in stomach and 23.1% in small intestine. In addition, the tumors arose in the esophagus, mesentery. The 52 cases of GISTs were subclassified as spindle or

epithelioid type stromal tumors based on the predominant pattern^[12]. Among them, spindle cell type was found in 20, epithelioid cell type in 20 and mixed type in 12.

To make a diagnosis of GISTs, immunohistochemical staining of the CD117 and CD34 is required, because they can characteristically express CD34 and CD117^[13]. In this study, CD117 and CD34 showed diffuse positive expressions, the positive rates were 98.1% and 92.3%. Eighteen cases with focal immunoreactivity for SMA were diagnosed as GISTs with smooth muscle differentiation. S-100, NSE, NF and MBP showed focal positive expressions, which could be used as the diagnostic criteria of GISTs with nerve differentiation.

As a sensitive and specific marker of GIST, *c-kit* seems to be a useful antibody in diagnosis and differential diagnosis of GIST, but it may not be used as a prognostic index^[14]. Coagulative necrosis, mitotic activity over 10/50HPF, high cellularity with obvious pleomorphism are also helpful parameters for diagnosis of malignancy aside from metastasis and invasion. Adhesion over 5 cm in diameter and mitotic activity over 5/50HPF but less than 10/50HPF might be the potentially malignant parameters^[15]. But the effective and reproducible diagnostic parameters for differentiating benign from malignant gastrointestinal stromal tumors (GISTs) are still not clear^[16].

p21WAF1 is a cyclin-dependent kinase inhibitor (CDKI) which contributes to the regulation of cell cycle progression by controlling CDK activity and induces a G1 arrest^[17,18]. Thus, it is a tumor suppressor gene and likely plays an important role in tumor development. Moreover, reduced expression of p21WAF1 has been reported to have a prognostic value in several human malignancies^[19]. Pindzola *et al*^[18] reported that malignant gastrointestinal stromal tumor expresses p21WAF1/CIP1. In this study, p21WAF1 expression was not associated with the localization, size and histological subtype of GISTs, except for the tumor grade showing a higher frequency of p21WAF1 expression in potential malignancy and malignancy than that in benign GISTs (75%, 85% and 5%, respectively), indicating that p21WAF1 expression plays an important role in potential malignancy and malignancy rather than in benign GISTs. However, there was no statistical significance between potentially malignant and malignant GISTs, suggesting that overexpression of p21WAF1 is associated with increasing malignant potential, and that p21WAF1 overexpression may be another useful marker in the assessment of the malignant potential in GIST.

The Bcl-2 protein family plays an important role in the regulation of apoptosis. This family contains both proapoptotic members (Bax, Bid, Bad, and Bak) and antiapoptotic members (Bcl-2 and Bcl-xl^[20]). Overexpression of Bax protein increases apoptosis^[21]. Previous studies have shown that Bax expression might be involved in differentiation/histological types of colorectal cancer^[22]. Chao *et al*^[23] reported that in endometrial carcinoma, the positive rate of Bax overexpression increases correspondingly with increase in histological grade. Although apoptosis is associated with the tumor grade of various carcinomas, little is understood about the association of apoptosis in mesenchymal tumors^[24].

Noguchi *et al*^[25] reported that there is no statistically significant difference in Bax expression between benign and malignant tumors. In our study, Bax expression was associated with tumor grade showing a higher frequency of Bax expression in potential malignancy and malignancy than in benign GISTs (91.7%, 80%, 10%, respectively), suggesting that Bax expression plays an important role in potential malignancy and malignancy rather than in benign GISTs. However, there was no statistical significance between potential malignancy and malignancy, suggesting that overexpression of Bax is associated with increasing malignant potential. Thus Bax overexpression may be another useful marker in assessment of the malignant potential in GISTs.

Yang *et al*^[26] reported that p21WAF1/CIP1 could inhibit proliferation and induce apoptosis of hepatocellular carcinoma cells, and that inhibition of VSMC growth by overexpression of human p21 gene is accompanied with induction of apoptosis. These results suggest that regulation of cell cycle by p21 may be closely linked to programmed cell death /apoptosis in human vascular smooth muscle cells^[27], but a number of recent studies have pointed out that in addition to being an inhibitor of cell proliferation, p21WAF1 acts as an inhibitor of apoptosis^[28,29]. In our study, a positive correlation was found between p21WAF1 and Bax ($r = 0.461$, $\kappa = 0.459$), demonstrating that p21WAF1 is closely linked to Bax. In conclusion, p21 gene induces apoptosis by increasing Bax expression and plays an important role in potential malignant and malignant GISTs. Moreover, other factors besides p21WAF1 may regulate Bax.

Abstract

AIM: To investigate the effect of donor splenocyte infusion combined with cyclosporine A (CsA) on rejection of rat small bowel transplantation (SBT).

METHODS: Male Sprague-Dawley (SD) rats and female Wistar rats weighing 230-270 g were used as donors and recipients respectively in the study. Heterotopic small bowel transplantation was performed. The rats were divided into three groups: group one receiving allotransplantation (SD→Wistar), group two receiving allotransplantation (SD→Wistar) + donor splenocyte infusion, group three receiving allotransplantation (SD→Wistar) + donor splenocyte infusion + CsA followed by CsA 10 mg/kg per day after transplantation, in which recipient Wistar rats were injected with 2×10^8 SD splenocytes 28 d before transplantation, and treated with CsA after transplantation. Finally, the specific DNA fragment of donor Y chromosome was detected in recipient peripheral blood and skin by PCR. The survival time after small bowel transplantation was observed. Gross and histopathological examinations were performed.

RESULTS: The survival time after small bowel transplantation was 7.1 ± 1.2 d in group 1, 18.4 ± 3.6 d in group 2 and 31.5 ± 3.1 d in group 3. The survival time was significant longer ($P < 0.01$) in group 3 than in groups 1 and 2. The gross and histopathological examination showed that the rejection degree in group 3 was lower than that in groups 1 and 2.

INTRODUCTION

Small bowel transplantation (SBT) has become an accepted therapy for intestinal diseases in patients who require total parenteral nutrition^[1,2]. Because of the rich lymphatic tissue in small bowel and its mesentery, the mesenteric lymph nodes and lymphatic plexus are transplanted along with the small bowel. Thus, small bowel transplantation has a more severe immune rejection compared with other organ transplantations^[3]. Immune rejection is the leading cause of failure in small bowel transplantation^[4-7]. Although the results of SBT have been dramatically improved during the past few years, the major impediment to success in SBT is still acute rejection (AR). The key steps toward a successful transplantation are therefore to attenuate immune reactions and to induce immune tolerance to grafts.

The spleen is an immunologically privileged organ. The incidence rate and degree of rejection after spleen transplantation are much lower than those of other solid organ transplantations. Splenocyte chimerism has been successful in inducing tolerance in acute and chronic rejection liver transplant models^[9]. Both in experimental study and in clinical practice, splenocytes (including lymphocytes, dendritic cells, Kupffer cells, etc) play an important role in immune tolerance induction. Although splenocyte chimerism can effectively decline the immune reactions in organ transplantation, but whether the administration of spleen cells to recipients has the same effect in SBT is uncertain. Some parameters were tested to confirm the anti-rejection effect of splenocyte infusion

combined with CsA on rat small bowel transplantation in this study.

MATERIALS AND METHODS

Animal preparation

Healthy inbred male Sprague-Dawley (SD) rats as donors, and inbred female Wistar rats as recipients, weighing 250 ± 20 g, provided by Medical Experiment Animal Center, Harbin Medical University, were housed in standard animal facilities, and fed with commercially available rat chow and tap water *ad libitum* for 1 wk before test to acclimatize to the laboratory. The donor and recipient were paired according to the similar body weight.

Rat small bowel transplantation

All procedures were performed under inhalation anesthesia with ether. The entire small bowel from the ligament of Treitz to the ileocecal valve was isolated with the superior mesenteric artery on a segment of aorta and portal vein^[14]. After donor systemic heparinization (300 U), the graft was perfused with 20 mL of cold lactated Ringer's solution *via* the aorta. The lumen was also washed in 20 mL of the same solution. In the recipient, end-to-side vascular anastomoses were performed between the graft aorta and recipient infra-renal aorta and between the graft portal vein and recipient inferior vena cava with 10-0 sutures using the standard microsurgical technique. The superior extremity of the transplanted small bowel was ligated and a distal small bowel stoma was performed on the left abdominal wall. Animals that died within 3 d were considered as technical failures and excluded from data collection^[10-12].

Spleen cell preparation

SD rats were sacrificed by decapitation. Spleens were collected and kept on ice in RPMI 1640 medium (Life Technologies, Grand Island, NY) supplemented with antibiotics (100 units/mL penicillin and 100 μ g/mL streptomycin). The spleens were disrupted in the medium by pressing spleen fragments between two glass slides. Cell suspensions were filtered through cotton gauze and washed three times with RPMI 1640 medium. Viable nucleated cells were counted and adjusted usually to 2.0×10^7 /mL.

Experimental groups and postoperative care

The rats were divided into three groups: group 1 as allotransplantation group (SD \rightarrow Wistar, $n = 10$), group 2 as allotransplantation (SD \rightarrow Wistar) + donor splenocyte infusion, group 3 as allotransplantation (SD \rightarrow Wistar) + donor splenocyte infusion + CsA, with CsA 10 mg/kg per day after transplantation, in which recipient Wistar rats were injected with 2×10^8 SD splenocytes 28 d before transplantation and treated with CsA after transplantation. Animals were fed with only sugar water (7 g/d) on d 1, rat chow and water on d 2 and thereafter. The rats' mental state, appetite, and ejection liquid of small bowel stoma were also observed.

Analysis of microchimerism

Microchimerism in peripheral blood and skin of Wistar rat recipients was assessed by PCR. Blood and skin were

collected, and genomic DNA was isolated from buffy coat with a DNA extract kit and from skin by the proteinase k-phenol-chloroform method. Microchimerism was detected by specific primers for the donor Y chromosome. PCR was performed with 100 ng of the DNA template, 18 pmol of forward (5'- CGT GGA GAG CGC AAG TT -3', p1) and reverse primers (5'- GTC GCT GTT TCT GCT GTA GTT A -3', p2). The primers were designed to distinguish donor DNA from recipient DNA, and yielded a visible PCR product of 154 bp with the donor DNA template under ethidium bromide fluorescence. The 50 μ L reaction contained 10 mmol/L Tris (pH 8.3), 50 mmol/L KCL, 1.5 mmol/L MgCl₂, 0.001% gelatin (Perkin- Elmer, Foster City, CA), 50 g/L BSA, 0.2 mmol/L dNTPs, and 1 unit of Amplitaq DNA polymerase (Perkin-Elmer). The cycling conditions were: at 94°C for 4 min, followed by 35 cycles at 94°C for 60 s, at 55°C for 60 s, at 72°C for 60 s and a final extension at 72°C for 8 min in a GeneAmp PCR System 2400 (Perkin Elmer). The products were separated on 1.5% agarose gel containing ethidium bromide.

Histopathological analyses

Rats' small bowel allografts were excised from stoma or by laparotomy and fixed in 10% formalin. The fixed tissue was paraffin embedded, and tissue sections were stained with hematoxylin and eosin (HE). Rejection was graded histologically according to the phase of acute intestinal rejection established by Rosemurgy *et al*^[13] and Sudan *et al*^[14]. The sections were graded for tissue injury using a scale of 0 (none) to 7 (severe) based on the following criteria: 0: normal mucosa; 1: development of subepithelial (Gruenhagen's) spaces at villus tips; 2: extension of the subepithelial space with moderate epithelial cell lifting from the lamina propria; 3: massive lifting down sides of villi, some denuded tips; 4: denuded villi, dilated capillaries; 5: disintegration of the lamina propria; 6: crypt layer injury; 7: transmucosal infarction. All histological analyses were performed in a blinded fashion to avoid bias.

Graft survival

All recipients were followed up by visual inspection and submitted to autopsy soon after they died. Graft survival time was defined as the time until death of recipient due to immune rejection.

Statistical analysis

All data were analyzed by Student's *t* test and expressed as mean \pm SD. *P* < 0.05 was considered significant and *P* < 0.01 very significant.

RESULTS

Gross observation

The rats awaked soon after operation. In allotransplantation group (group 1), the rats presented various degrees of lethargy, anorexia hair disorder, unresponsiveness to outside stimulation and body weight loss. Intestinal graft was pale. Intestinal lumina was enlarged with massive adhesion and gradually aggravated, accompanying mass purulent discharge. Intestinal perforation occurred in some severe cases. In allotransplantation + donor splenocyte

Figure 3 Histopathological findings in different groups after SBT. **A:** Few histopathological changes in the normal tissue (group 3); **B:** Intact villi and some infiltrates in allografts obtained from donor splenocyte recipients (group 2); **C:** Inflammatory infiltrates throughout the intestine and extensive apoptosis (arrows) and ulceration in the transplanted intestine (group 1).

Table 1 Survival time after small bowel transplantation in rats (mean \pm SD)

Group	<i>n</i>	Survival time (d)
group 1	10	7.1 \pm 1.2
group 2	10	18.4 \pm 3.6
group 3	10	31.5 \pm 3.1 ^b

^b*P* < 0.01 vs groups 1 and 2.

Table 2 Histologic grading of graft after small bowel transplantation in rats (mean \pm SD)

Group	<i>n</i>	Histologic grading
group 1	10	6.4 \pm 2.81
group 2	10	5.1 \pm 1.06
group 3	10	3.2 \pm 1.67 ^a

^a*P* < 0.05 vs groups 1 and 2.

infusion group (group 2), the rats were vigorous, sensitive to outside stimulation, and low-grade adhesion occurred 7 d after transplantation. In allotransplantation + donor splenocyte infusion + CsA group (Group 3), the rats were vigorous, and sensitive to outside stimulation, and low-grade adhesion occurred 6 d after transplantation (Figure 1).

Donor cell chimerism

Male donor cell chimerisms in recipients were determined by analyzing metaphase spreads for the presence of donor Y chromosomes. Y chromosomes were found in rats of the spleen cell infusion group but not in rats of allotransplantation group (Figure 2).

Survival time after transplantation

The survival time after small bowel transplantation was 7.1 \pm 1.2 d in group 1, 18.4 \pm 3.6 d in group 2, and 31.5 \pm 3.1 d in group 3. The survival time was significant longer (*P* < 0.01) in group 3 than in groups 1 and 2 (Table 1).

Histopathologic examination

Few histopathological changes and inflammatory infiltrate were detected in rats of group 3 (Figure 3A). After allotransplantation + splenocyte infusion treatment, some histopathological features of rejection were found, villi were intact but showed some blunting, crypts had no necrosis and lymphocyte infiltrate was minimal. A significant decrease in AR changes was observed in grafts of recipients treated with donor splenocyte infusion (Figure 3B). In group 1, severe rejection was characterized by complete villus flattening, epithelial apoptosis, and transmural cellular infiltrate (Figure 3C, Table 2).

DISCUSSION

In clinical practice, immune rejection induced by organ transplants necessitates the use of potent immunosuppressive drugs. However, excessive dosage of immunosuppressive agents may result in severe side effects, such

as hypertension, hepatic and/or renal toxicity. Moreover, prolonged usage of immunosuppressants often leads to severe infection and increased susceptibility to malignant tumors, thus critically affecting the health of recipients. It is therefore imperative to assess the protective effect of immune tolerance on organ transplantation. Recently, it has been reported that donor-derived multilineage hemopoietic cell microchimerism is a prerequisite for tolerance induction in organ allograft recipients^[15,16]. In an effort to augment the natural microchimerism that occurs following organ transplantation, adjunctive perioperative donor spleen cell infusion should be considered in conventionally immunosuppressed human organ transplant recipients^[17,18]. It was reported that donor spleen cell infusion can enhance liver allograft survival in humans^[19] because of the lack of recipient type antigen presenting cells (APC)^[20]. In our study, the survival time of the rats that received infusion of donor spleen cells combined with CsA was significantly longer compared to those that did not receive it.

The spleen is an immunologically privileged organ. The rejection incidence rate and degree of spleen transplantation are much lower than those of other solid organs. The spleen cell infusion can induce donor-specific transplantation tolerance and transient microchimerism. In our study, SD splenocyte chimerism was established in Wistar rats. SB grafts remained normal and were well vascularized. By contrast, the bowel of control animals showed AR.

The survival time was significant longer (31.5 ± 3.1 d *vs* 7.1 ± 1.2 d, $P < 0.01$) in group 3 than groups 1 and 2. The rejection degree in group 3 was lower than that in group 1. Rats in group 3 had better histological structures than rats in group 1 (3.2 ± 1.67 *vs* 6.4 ± 2.81 , $P < 0.05$), suggesting that donor spleen cell transfusion combined with cyclosporine A is a simple and practical method to suppress rejection of small bowel transplantation in clinical practice.

In conclusion, donor-specific tolerance induced by splenocyte chimerism prevents AR in an experimental model of highly immunogenic SB allografts. Central tolerance through splenocyte chimerism can be used to study the immune tolerance mechanisms. Further work is needed to reveal if chimerism is induced by spleen cell transfusion.

Abstract

AIM: To evaluate the long-term outcome and surgical indications of hepaticojejunostomy (HJ) for the treatment of hepatolithiasis.

METHODS: Three hundred and fourteen elective cases with hepatolithiasis but without biliary stricture or cystic dilatation treated in the past 10 years were reviewed retrospectively. The patients were divided into HJ group and T tube drainage group according to biliary drainage procedure. Furthermore, four subgroups were subdivided by hepatectomy as a balance factor, group A₁: hepatectomy+HJ; group A₂: choledochotomy+HJ; group B₁: hepatectomy + choledochotomy T tube drainage; group B₂: choledochotomy + T tube drainage. The stone residual rate, surgical efficacy and long-term outcome were compared among different procedures.

RESULTS: There was no surgical mortality among all patients. The total hospital mortality was 1.6%. The overall stone residual rate after surgical clearance was 25.9%. There was no statistical difference between HJ group and T tube drainage group in terms of stone residual rate after surgical clearance, however, after postoperative choledochoscopic lithotripsy, the total stone residual rate of T tube drainage group was significantly lower than that of HJ group (0.5% vs 16.7%, $P < 0.01$). Hepatectomy + choledochotomy tube drainage achieved the optimal therapeutic effect, only 8.2% patients suffered from an attack of cholangitis postoperatively, which was significantly lower than that of hepatectomy + HJ (8.2% vs 22.0%, $P = 0.034$). The major reason for postoperative cholangitis was stone residual in the HJ group (16/23, 70.0%), and stone recurrence in the T tube drainage group (34/35, 97.1%). The operative times were significantly prolonged in those undergoing HJ, and the operative morbidity of HJ was higher than those of T tube drainage.

CONCLUSION: The treatment result of HJ for hepatolithiasis is not satisfactory in this retrospective study due to high rate of stone residual and postoperative cholangitis. HJ could not drain residual stone effectively. HJ may hinder post-operative choledochoscopic lithotripsy, which is the optimal management for postoperative residual stone. The indications of HJ for hepatolithiasis should be strictly selected.

INTRODUCTION

Hepatolithiasis is a common disease in Southeast Asia and is especially prevalent in China^[1,2]. This disease features a high stone residual and recurrence and its long-term outcome is far from satisfactory. The principles for the treatment of hepatolithiasis are complete clearance of stones, eradication of the diseased bile duct (stricture) and atrophic liver tissue and reconstruction of satisfactory bile drainage. Biliary-enteric anastomosis which mostly includes choledochoduodenostomy (CD) and Roux-en-Y hepaticojejunostomy(HJ), is one of the most common procedures used for hepatolithiasis. Due to the sump syndrome and high risk of stasis following CD^[3,4], many authors prefer HJ to CD as the standard procedure for benign biliary diseases^[4-6]. In fact, we have used HJ instead of CD to reconstruct enteric biliary drainage for hepatolithiasis or bile duct stricture in our department since 1990.

In the cases of hepatolithiasis simultaneously with extrahepatic bile duct stricture or congenital cyst dilatation, because the diseased bile duct should be resected, HJ is the treatment of choice to reconstruct bile drainage. However, in the cases without bile duct stricture or cystic dilatation, whether HJ is suitable remains controversial^[7-9].

In the current study, we reviewed the cases with hepatolithiasis treated surgically in our department in the past 10 years retrospectively, and evaluated the outcome and surgical indications of HJ for the treatment of hepatolithiasis.

MATERIALS AND METHODS

Patients

A total of 425 consecutive patients with hepatolithiasis treated surgically at the Department of Hepaticobiliary Surgery, the First Affiliated Hospital, Sun Yet-san University from June 1992 to June 2002 were reviewed retrospectively. According to our study purpose, the following cases were excluded because of no alternative surgical procedures for their conditions at that time, respectively, (1) 21 cases of hepatolithiasis complicated with acute obstructive suppurative cholangitis, who underwent choledochotomy, stone extraction and T tube drainage emergently once the diagnosis was confirmed; (2) 21 cases of hepatolithiasis with congenital choledochal cyst or Caroli's disease, who underwent stone removal, cyst resection or hepatectomy and HJ; (3) 23 cases of hepatolithiasis with left or right hepatic ducts or their second branches stricture, who received diseased bile duct resection and (or) bile duct stricturoplasty and HJ; (4) 46 cases of hepatolithiasis complicated with cholangiocarcinoma were also excluded. The remaining 314 elective cases were enrolled in this study, including 122 men, and 192 women. The mean age of whole group was 48 years (range: 15-88).

Grouping

According to the different procedures of bile drainage, 314 patients were divided into HJ group ($n = 123$) and T tube drainage group ($n = 191$). Because some cases in these two groups underwent hepatectomy simultaneously, we used hepatectomy as a balance factor to subdivide these two groups into four subgroups, Group A₁: Hepatectomy + HJ ($n = 76$); group A₂: choledochotomy + HJ ($n = 47$); group B₁: hepatectomy + choledochotomy T tube drainage ($n = 85$); group B₂: choledochotomy + T tube drainage ($n = 106$). The rate of residual stone, operative complications and therapeutic outcomes were compared among these groups.

Procedure of HJ

The standard procedure of HJ was an end-to-side, mucosa-to-mucosa anastomosis of the intra- and (or) extra-hepatic duct with a Roux-en-Y jejunal loop measuring 40 to 60 cm in length. The anastomosis was sutured with absorbable material (Viracyl, 4-0, Johnson Ltd, USA) interruptedly. A rubber tube measuring 3.5-5 mm in diameter was placed through biliary-enteric anastomosis retrogradely for later cholangiography or choledochoscopic manipulation. This drainage tube was removed when no stone resided within the biliary tract proofed by a cholangiogram at postoperative d 14. If there was residual stone proofed by cholangiography, the drainage tube tract was left for 6 wk to allow subsequent choledochoscopic manipulation. The indications of HJ we used previously were (1) the diameter of the common bile duct was larger than 2 cm; (2) intrahepatic stone located bilaterally; (3) peripheral bile duct stone that could not be cleared during surgery.

Measurement of residual stone

The diagnosis of postoperative stone residual was based on the cholangiogram performed through the T tube and

transanastomotic drainage tube at postoperative d 14 or ultrasound findings. Once residual stone was found, choledochoscopic stone extraction or lithotripsy (four-direction fiber choledochoscopy, 3.5 mm in diameter, Olympus Co., Japan) was done 6 wk after operation. This was repeated at 1 wk interval until the residual stone was completely cleared, or as clear as possible.

Postoperative follow-up

Follow-up was performed by reviewing medical records and patient interviews or telephone interview. At the end of this study, totally 241 out of 309 completed the follow-up (period: 2-12 years, median 7.6), the other patients were lost. Cholangitis was considered when patient presented with right upper quadrant pain, chill, fever or jaundice.

Statistical analysis

Patients' database was established by SPSS 11.0 software. *t*-test, rank test (continuous data) and Fisher's exact test, Chi-square test (categorical data) were used. $P < 0.05$ was considered statistical difference.

RESULTS

Operative mortality and hospital death

There was no surgical mortality in this study. Five cases (1.6%) died of hepatic failure postoperatively during their hospital stay, including 1 case in subgroup A₁, 2 cases in subgroup A₂, and 2 cases in subgroup B₂.

Patients' clinical characteristics

Patients' demographic and clinical data are shown in Table 1. The number of patients who had previous bile surgery of subgroups A₁ and A₂ was greater than those of subgroups B₁ and B₂, respectively ($P < 0.05$). The history and operating times of patients in the subgroups A₁ and A₂ were longer than those in subgroups B₁ and B₂, respectively ($P < 0.05$); the amount of blood loss in subgroups A₁ and A₂ was larger than those in the subgroups B₁ and B₂ respectively ($P < 0.05$).

Postoperative stone residual

The diagnosis of postoperative stone residual was based on the cholangiogram and ultrasound findings postoperatively. The most common site of stone residual was the intrahepatic duct. The overall stone residual rate after surgical clearance in our series was 25.9% (Table 2). There was no significant difference of stone residual between the HJ group and the T tube drainage group (20.3% *vs* 28.3%, $P > 0.05$). The cases who underwent hepatectomy [group (A₁ + B₁)] had less stone residual than those who did not, [group (A₂ + B₂)] ($P < 0.05$).

Postoperative complications

The common postoperative complications are listed in Table 3. The complications in subgroup A₁ was more than that in subgroup A₂ ($\chi^2 = 4.324$, $P < 0.05$).

Management of residual stone

The treatment of choice for postoperative residual stone

HJ, hepaticojejunostomy; CBD, common bile duct. ^a*P* > 0.05 vs T tube drainage group.

was choledochoscopic lithotripsy through the T tube or the transanastomotic drainage tube route 6 wk after operation. Totally 54 cases had residual stones in the T tube drainage group, and 53 had their stones completely cleared by choledochoscopic lithotripsy after 1 to 6 sessions. Only 1 case was failed because his T tube withdrew simultaneously after discharge. However, only 5 cases whose residual stones could be successfully eliminated in HJ group, the other 20 cases failed because their fistula were unsuitable or difficult for the entry of choledochoscope, or the long Roux-en-Y loop hindered the technical manipulation. The overall stone residual rate of the T tube drainage group was significantly lower than the HJ group after choledochoscopic lithotripsy [0.5% (1/189) vs 16.7% (20/120), *P* < 0.01].

Postoperative cholangitis

Postoperative cholangitis presented by right upper quadrant pain, chill, fever and jaundice occurred at least once in 58 cases (Table 4). Five cases in the HJ group suffered from 4-6 episodes of cholangitis till the second operations were done. The main causes of cholangitis observed in our series were stricture of the biliary-enteric anastomosis (*n* = 3), stone residual (*n* = 16) or reflux of intestinal fluid (*n* = 1) in the HJ group, and stone recurrence (*n* = 34) or later

Table 3 Postoperative complications

Complications	Group A1 (<i>n</i> = 76)	Group A2 (<i>n</i> = 47)	Group B1 (<i>n</i> = 85)	Group B2 (<i>n</i> = 106)

development of bile stricture for chronic inflammation of bile duct in the T tube drainage group (Table 4).

DISCUSSION

Postoperative stone residual and recurrence still remain a

challenge in the treatment of hepatolithiasis. Though the systemic approaches have been used, the stone residual rate was over 30% in a nationwide survey of 4197 surgical hepatolithiasis cases in China^[2]. The overall stone residual rate after surgical clearance in our series was 25.9%. There was no significant difference between the HJ group and the T tube drainage group after surgical clearance. However, when hepatectomy as one of the treatments of choice was considered as a balance factor, we found that among patients who received hepatectomy the stone residual rate was significantly lower than those who did not. This finding is consistent with our previous report^[10] and other reports^[11-13].

Hepatolithiasis will cause bile duct stricture, liver parenchyma atrophy and chronic fibrosis due to repeated pyogenic cholangitis. These pathologic changes, especially bile duct stricture, may hinder stone extraction during surgery, even though the choledochoscopy was used. Hepatectomy provided the best therapeutic effect for completely removing the stone, the diseased bile duct (stricture ring) and atrophic liver parenchyma as well.

Postoperative choledochoscopic lithotripsy through the T tube or the bile duct drainage tube route is a potential remedial treatment for residual stone, as indicated by the T tube drainage group in this study. However, only 5 cases whose residual stone could be successfully removed by this method in the HJ group. Other cases with residual stone could not be removed due to the difficulty for choledochoscopy to access the bile duct through a long (40-60 cm) Roux-Y loop or because the tunnel was too small to enter for the choledochoscopy. After postoperative choledochoscopic lithotripsy, the overall stone residual in the T tube drainage group was markedly lower than that in the HJ group (0.5% *vs* 16.7%, $P < 0.01$). This indicates that HJ hinders postoperative choledochoscopic manipulation. For easy access to the biliary tract, hepaticocutaneous jejunostomy with a stoma after biliary surgery is recommended for the convenience of long-term treatment of stone residual or recurrence^[14]. However, hepaticocutaneous jejunostomy is not advocated for its possible complications related to fistula, infection, parastomal hernia, early stoma closure, and prolonged surgical procedure or hospitalization^[15].

Postoperative cholangitis is a critical factor to evaluate the long-term surgical result of this disease. Hwang *et al*^[16] reported that high risk factors related to cholangitis after initial surgery was bile duct stricture, residual stones, recurrent stones, and patients who were treated with nonhepatic resection. Our long-term follow-up (2-12 years, median 7.6) data demonstrated that patients who underwent hepatectomy with CBD exploration and T tube drainage had less attack of cholangitis, and the occurrence of cholangitis was significantly lower than those who underwent hepatectomy with HJ. Though the residual stones were nearly cleared in the T tube drainage group, and the immediate outcome was good, the occurrence of cholangitis was high. This was due to high recurrence of intrahepatic stone secondary to the bile duct stricture which was not treated during the initial surgery. The major reasons for postoperative cholangitis observed in our study were stone residual in the HJ group (16/23, 70.0%), and stone recurrence in the

T tube drainage group (34/35, 97.1%).

It was believed that the intrahepatic residual stone located in the peripheral bile duct would drain to Roux-Y loop through a large biliary-enteric anastomotic mouth simultaneously after surgery, therefore, residual stone would be cleared, and furthermore, HJ could prevent biliary-enteric regurgitation^[14,17]. To drain a residual stone, HJ is a popular procedure for hepatolithiasis, especially for the case with bilateral stones. Our data showed that the numbers of patients who had previous biliary surgery for hepatolithiasis were higher in the HJ group than that in the T tube drainage group. It suggests that HJ would be the final and optimal procedure for recurred or residual hepatolithiasis at that time. However, many clinical evidences showed that the intrahepatic residual stone could not drain to the Roux-Y loop completely and easily, especially for the stones located at the right posterior lobe and left lateral lobe of the liver. Rather they would accumulate continuously within the bile ducts, which was the main reason for the postoperative cholangitis episodes. This was also evidenced by the long-term follow-up data of the HJ group in this series. Actually, HJ can not completely block biliary-enteric regurgitation. The reflux cholangitis occurring in HJ performed for benign biliary diseases was 10%-15%^[18]. Besides the stone residual and bile duct stricture, postoperative cholangitis was also related to the decrease of motility of Roux-en-Y loop itself. Jejunal transection would lead to abnormal motility of the distal part of jejunum^[19,20]. Ducrotte *et al*^[21] reported that low motility of the Roux-en-Y loop presented by near-absence of phase III's activity, and an absence of response to meal was observed in recurrent cholangitis patients, and subsequently, microbes might colonize and overgrow in the loop. Later on they documented a similar result in asymptomatic patients undergoing HJ^[22].

HJ permanently eliminates the physiological preventive function of regurgitation by the papilla of Vater, which is a barrier between biliary tract and gastrointestinal tract, and subsequently, enteric biliary reflux and bacterial colonization of the biliary tract may occur^[23,24]. Furthermore, in a long-term large series study, Tocchi *et al* found that biliary tract may tend to develop malignancy following biliary-enteric bypass procedures for the benign biliary disease due to chronic inflammation of the bile duct^[25]. This indicates that bile duct cancer may be a long-term complication of biliary-enteric drainage.

On the other hand, our data also demonstrated that HJ prolonged the operation time and increased the risk of intraoperative bleeding and blood transfusion.

In conclusion, the overall long-term outcome of HJ for intrahepatic lithiasis was not satisfactory because of its high rate of stone residual and postoperative cholangitis in our study. HJ could not drain the residual stone effectively. Considering the shortcomings of HJ mentioned above, it is of critical importance to consider the surgical indications of HJ for hepatolithiasis. We advocate that HJ is needed only in the following conditions. (1) Hepatolithiasis complicated with extrahepatic ducts or its second branches stricture, which needs stricturoplasty and HJ. (2) Hepatolithiasis with congenital bile duct dilatation in which the dilated bile duct should be resected. (3) Dysfunction of the papilla of Vater, especially in the case of fibrotic

stricture of the papilla of Vater. Our results indicate that if intrahepatic stone could not be cleared during surgery, a T tube placement within the CBD rather than HJ would facilitate postoperative choledochoscopic lithotripsy.

Abstract

AIM: Pancreatic pseudocysts (PPC) as a complication of
pancreatitis are approached only in the case of abdomi-
nal pain, infection, bleeding, and compression onto the
gastrointestinal tract or biliary tree.

METHODS: From 02/01/2002 to 05/31/2004, all con-
secutive patients with symptomatic PPC who underwent
an interventional endoscopic approach were evaluated in
this pilot case-series study: Group (Gr.) I-Primary percu-
taneous (external), ultrasound-guided drainage. Gr. II-
Primary EUS-guided cystogastrostomy. Gr. III-EUS-guid-
ed cystogastrostomy including intracystic necrosectomy.

RESULTS: (=“follow up”: $n = 27$): Gr. I ($n = 9$; 33.3%):
No complaints ($n = 3$); change of an external into an inter-
nal drainage ($n = 4$); complications: (a) bleeding ($n = 1$)
followed by 3 d at ICU, discharge after 40 d; (b) septic
shock ($n = 1$) followed by ICU and several laparotomies
for programmed lavage and necrosectomy, death after 74 d.
Gr. II ($n = 13$; 48.1%): No complaints ($n = 11$); external
drainage ($n = 2$); complications/problems out of the 13
cases: 2nd separate pseudocyst ($n = 1$) with external
drainage (since no communication with primary internal
drainage); infection of the residual cyst ($n = 1$) + following
external drainage; spontaneous PPC perforation ($n = 1$) +
following closure of the opening of the cystogastrostomy
using clips and subsequently ICU for 2 d. Gr. III ($n = 5$;
18.5%): No complaints in all patients, in average two en-
doscopic procedures required (range, 2-6).

CONCLUSION: Interventional endoscopic management
of pancreatic pseudocysts is a reasonable alternative
treatment option with low invasiveness compared to sur-

INTRODUCTION

Pancreatic pseudocysts (PPC) are complications of
acute and chronic pancreatitis^[1-4], pancreatic trauma, and
pancreatic duct obstruction^[4]. For differential diagnosis,
PPC needs to be distinguished from cystic tumor lesions
of the pancreas. An examination with transabdominal
ultrasound and endoscopic ultrasonography (EUS) is
considered an initial step of the diagnostic and therapeutic
management. PPC are to be treated in the case of
subsequent infection, bleeding, and compression onto
the gastrointestinal tract or the biliary tree^[5]. Abdominal
pain is the predominating clinical sign. Fever and septic
symptoms are hints for infected PPC. The aim of the
study was to demonstrate (1) the differential treatment
strategies in PPC^[6], (2) the safety of an interventional
endoscopic approach of PPC as a reasonable alternative
and less invasive treatment option^[7,8], and (3) the outcome
and short-term follow-up results including problems and
complications^[7-9].

MATERIALS AND METHODS

From February 01, 2002 to May 31, 2004, all consecutive
patients with symptomatic PPC were enrolled in
this pilot case-series study. Patients underwent an
interventional approach in the case of abdominal pain,
fever, increase of C-reactive protein (CrP) above the
normal range, and compression onto the gastrointestinal
tract or the biliary tree caused by the PPC with

Table 1 Interventional endoscopic approach of PPC: Indications and methodological aspects of the 3 different treatment groups (see also "Patients and methods" section above)

GROUP	Title	n	Indication	Method
I	Primary, percutaneous, ultrasound-guided placement of a drainage	9	Septic symptoms & inhomogeneous cystic content with suspected infection of PPC revealed by transabdominal ultrasound & EUS	-Ultrasound-guided puncture of the PPC -Aspiration of 10-20 mL of cystic fluid/content -Laboratory analysis (amylase, lipase, CEA, Ca19-9) -Microbiologic investigation for microbial detection/growth -Placement of a 10-Fr. pigtail drainage (Endoflex, Voerde, Germany) -Rinsing with 20-50 mL NaCl/h (bolus) <i>via</i> the drainage -Administration of antibiotics (ceftriaxone [Rocephin®, Hoffmann-La Roche AG, Grenzach-Wyhlen, Germany] plus metronidazol [Clont®, Bayer Vital GmbH, Leverkusen, Germany]) over 7 d
II	Primary, EUS-guided cystogastrostomy	13	Echo-free PPC with no inner echos & no evidence of infection	-Puncture of the cyst with 19-G needle (Wilson-Cook [Cook Deutschland GmbH], Mönchengladbach, Germany) -Cytologic investigation of cystic fluid/content -Placement of a 8.5-Fr.-double pigtail catheter Endoflex, Voerde, Germany) -Administration of antibiotics (ceftriaxone [Rocephin®, Hoffmann-La Roche AG, Grenzach-Wyhlen, Germany]) over 3 d
III	EUS-guided cystogastrostomy with following necrosectomy	5	-Suspected sequester & necrosis within the PPC revealed by ultrasound -Persisting fever & septic symptoms after cystogastrostomy & EUS-guided placement of a drainage	-Introduction of a 0.035-Inch guide wire (MTW Endoskopie, Wesel, Germany) <i>via</i> needle in place -Opening of the PPC with needle knife (Erbe Elektromedizin GmbH, Leipzig, Germany) -Enlargement of the PPC opening with balloon dilatation (Boston Scientific Medizintechnik GmbH, Ratingen, Germany) -Endoscopy of the cystic cavity -Removal of the necroses with loop & Dormia's basket (MTW Endoskopie, Wesel, Germany, each) (min. 2x) -Microbiologic investigation for microbial detection/growth -Placement of a transgastrocystic 8.5-Fr.-double pigtail drainage (Endoflex, Voerde, Germany) -Removal of the pigtail catheter after 3-6 mo -Administration of antibiotics (ceftriaxone plus metronidazol) over 7 d

disturbance(s) of the gastrointestinal passage. Patients were subdivided into 3 groups as shown in Table 1.

A consent form was obtained from each patient enrolled in the study.

RESULTS

Overall, 27 consecutive patients with symptomatic PPC were enrolled in the study over the 28-mo study period. The following details comprise the outcome, subsequent therapeutic steps, and the follow-up data of the various treatment groups.

Group I (primary percutaneous, ultrasound-guided placement of a drainage): Nine patients of 27 (33.3%) underwent the approach of an external drainage of the PPC (Figure 1). In three patients, no further complaints were observed with no additional therapy. An internal drainage was placed in four patients (Figures 2 and 3). After the septic symptoms disappeared, the external drainage was replaced by an internal drainage (Figure 4). In the complication profile, there was one case of post-interventional bleeding with a subsequent 3-d stay at the ICU and discharge after a total of 40 d. In one case, septic shock occurred. The patient died after several open laparotomies for programmed lavages and necrectomy after a 74-d care at the ICU.

Group II (primary EUS-guided cystogastrostomy): By the mean of this approach, 13 of 27 patients (48.1%) were treated, aiming for the placement of an internal drainage for the PPC. In the vast majority of patients ($n = 11$),

Figure 1 EUS images of an infected pancreatic pseudocyst (abscess) prior (A) and after placement (B) of an external drainage.

no further complaints or signs were reported, and no intervention-related symptoms were observed. Therefore, no further therapy was required. In two patients, an additional external drainage was placed: In one of the two patients, additional PPC were found, which, though communicating with other PPC, were not drained by the internally (transgastrocystically) placed drain reaching the originally detected PPC. In the second patient, a subsequent infection of the residual PPC was diagnosed following the initially successful internal drainage. This required a temporary external drainage. Out of 13 patients, there was only one serious complication. During the endoscopic intervention, a spontaneous perforation of the PPC was observed. Therefore, the cystogastrostomy was closed endoscopically by the mean of clips, which resulted in no further complaints, signs and symptoms after a 2-d stay and monitoring at the ICU. Hereafter, the patient's

Figure 2 EUS-guided drainage of a pancreatic pseudocyst after previous external drainage: (A) EUS image; (B) Subsequent fluoroscopy control image of correct placement of the drainage.

Figure 3 Endoscopy-guided cystogastrostomy via guide wire (A) and placement of an internal drainage (B).

discharge became possible.

Group III (EUS-guided cystogastrostomy including necrosectomy): This approach was used successfully in 5 of 27 patients (18.5 %) (Figure 5). The postinterventional course of all patients was uneventful and they did not show any problems or complications. On average, two endoscopic procedures (range, 2-6) were required to achieve the intended aim.

All together, there were three serious complications out of 27 subjects who underwent an interventional endoscopic approach of their PPC resulting in a complication rate of 11.1%. However, one patient died post-interventionally (mortality, 3.7%) because of septic complications with the underlying necrotizing pancreatitis.

DISCUSSION

In this report, treatment results for a novel interventional endoscopic approach for PPC are described. According to the aim of the study, this approach is a reasonable initial option in the therapeutic spectrum and it can be considered an establishing, less invasive, feasible, safe, and effective treatment alternative in experienced hands compared with open surgery, showing acceptable outcome and follow-up results with regard to complication rate and mortality^[1-4,9-12]. The great advantage of this endoscopic approach is that it avoids the more severe trauma and invasiveness of a surgical intervention (no general

Figure 4 Endoscopic images: (A) EUS-guided puncture after previous external drainage; (B) Balloon dilatation via guide wire.

Figure 5 Endoscopic view: (A) After EUS-guided placement of an internal drainage (external drainage previously); (B) Into the pseudocystic cavity showing necroses; (C) Showing necrosectomy; (D) Through the transgastrocystic opening into the necrosectomized pseudocystic cavity.

anesthesia, no laparotomy, no risk for wound infection, less alteration of pulmonary and cardiac function, benefit for high-risk patients with a number of accompanying diseases or significant problems in their medical history). This endoscopic approach keeps the surgical intervention option still available in the case of unsuccessful outcome and follow-up. The endoscopic approach may provide comparable complication and mortality rates as shown for open cystogastrostomy or cystojejunostomy in a reasonably selected group of patients. However, the endoscopic approach has not changed but emphasizes the indications and principles^[6] for the interventional treatment of PPC as follows: (1) Only symptomatic PPC are to be treated^[6,12], (2) Basically, decision-making favors a forced interventional endoscopic approach together with an abdominal surgeon for surgical back-up^[6]. (3) EUS is the main tool for diagnostic and treatment of PPC^[3,4,6,10,13,14].

In particular, the novel aspect of the suggested approach is the less invasive character of this type of endoscopic intervention. The endoscopic approach

includes differential treatment options (primary percutaneous, ultrasound-guided placement of a drainage EUS-guided cystogastrostomy with or without subsequent necrosectomy) and a comparable outcome to open surgery as indicated by periinterventional morbidity and mortality.

The main complications and problems of the endoscopic procedure are subsequent infection of the cyst^[6-9], bleeding^[3,6-10], pancreatitis^[7,8], perforation^[9], colonic fistula^[15], failure of the drainage^[2], conversion^[1], PPC recurrence^[2,9,10,12], and even death. In our study, we observed only one bleeding, one perforation and one case of septic shock but none of the other possible complications. We showed a complication rate of 11.1% ($n = 3$), which is relatively low compared to De Palma *et al*^[7,8] who reported a complication rate of 24.5%. In our study, there was one death due to necrotizing pancreatitis possibly indicating an unsuitable case for the endoscopic procedure.

According to this study, we suggest the following algorithm (a modification of Vosoghi^[4] and Baillie^[6]): (1) Initially, a possible malignant tumor growth of the cystic lesion needs to be excluded by means of EUS^[6], laboratory analysis of cystic contents and cytologic investigation. In the case of an echogenic, thickened cystic wall and detectable Doppler signals within the cystic septum^[6], a malignant cystic tumor lesion can be suspected. The suspected diagnosis can be supported by cytologic investigation of cystic content detecting tumor cells. In addition, levels of tumor markers such as CEA and Ca19-9 can be analyzed in the cystic fluid. The sensitivity and specificity of Ca19-9 to predict malignant tumor growth in cystic lesions of the pancreas is approximately 80% (cut off point, 50 000 IU/mL). In the case of a malignant cystic tumor lesion, a surgical approach is obligatory. If there are no hints of malignancy, (2) ERCP follows to clarify whether the PPC communicates with the pancreatic duct^[6]. If yes, (3a) a transpapillary drainage needs to be implanted^[4,6-10]. Otherwise, (3b) a transgastrocystic, EUS-guided drainage is placed^[4,6-10]. If there are hints of an infected PPC or an abscess (echo-rich cystic content, necroses, sequester) revealed by transabdominal ultrasound, EUS, or clinical exam, primarily, (3c) an external (percutaneous) drainage of the PPC is to be favored^[2,4]. After placement of a drainage, rinsing the cyst over several days and administration of antibiotics can be initiated. Depending on the patient's clinical course (persisting PPC of the same size and configuration, persisting septic signs and symptoms, no falling inflammatory laboratory parameters) it has to be decided whether additionally, (3d) a necrosectomy^[6] or even (3e) surgical intervention is required^[4].

An interesting additional approach to consider is a laparoscopic endogastric pseudocyst gastrostomy, which combines less invasiveness, in particular, in large retrogastric PPC with the potential option of facilitated debridement of necrotic pancreas^[1,2].

In conclusion, interventional endoscopic management of pancreatic pseudocysts is a reasonable alternative treatment option considering: (1) surgical principles^[6] and (2) lower invasiveness.

Compared with surgical intervention there is a similar or even lower complication rate and mortality as shown by these study results. Subsequent follow-up investigations of the patients treated in this report, favoring again EUS, and studies with a higher value of evidence and larger case numbers are necessary to investigate treatment outcome and possible long-term consequences more appropriately^[2,11].

Abstract

AIM: To analyze the prevalence of the two commonest thrombophilic mutations, factor V Leiden and prothrombin G20210A, in patients with gastric cancer.

METHODS: One hundred and twenty-one patients with primary gastric carcinoma and 130 healthy subjects, comparable for age and sex, were investigated. Factor V Leiden was detected by using polymerase chain reaction and restriction enzyme digestion, and prothrombin G20210A gene mutation by allele-specific PCR.

RESULTS: Among the 121 cancer patients, factor V Leiden was found in 4 cases (GA genotype: 3.3%) and prothrombin G20210A in 10 cases (GA genotype: 8.3%). Of the 130 control subjects, factor V Leiden was detected in 6 cases (GA genotype: 4.6%) and prothrombin G20210A in 8 cases (GA genotype: 6.1%). No double heterozygous carriers of both mutations were found in either group. The prevalence of both factor V Leiden and prothrombin G20210A variant was not statistically different between the cancer patients and the healthy subjects.

CONCLUSION: Our study suggests that, in gastric cancer, the risk factors of thrombophilic cancer state are on acquired rather than on a genetic basis and that prothrombin G20210A does not seem to be a cofactor in gastric cancer pathogenesis.

INTRODUCTION

The pathogenesis of haemostatic disorders in cancer is complex and mainly on acquired basis. To date, little conclusive information is available in literature about the association of cancer hypercoagulability and inherited thrombophilia. The most common genetic defect in Caucasian population is factor V Leiden, a glutamine to arginine switch at amino-acid 506, due to G to A transition at nucleotide 1691 of coagulation factor V. This point mutation makes factor Va resistant to the proteolytic action of activated protein C so that activated factor V persists, rather than being inactivated. Another genetic defect is prothrombin G20210A polymorphism, a G to A transition at nucleotide 20210 in the 3'-untranslated region of the prothrombin gene, associated with elevated levels of prothrombin, which contributes to thrombotic risk by promoting enhanced thrombin generation.

Recently, Miller *et al*^[1] found an increased incidence of neoplasia of the digestive tract in men with persistent activation of the coagulation pathway. In addition, there is some evidence that prothrombin G20210A gene mutation may be involved in cancer development and/or progression. The prevalence of factor V Leiden and prothrombin G20210A gene polymorphism was analyzed in a cohort of 175 patients with gastrointestinal carcinoma and a significantly increased prevalence of prothrombin gene mutation in the patient group as compared to normal controls was detected^[2]. On the contrary, Paspatis *et al*^[3] demonstrated that the prevalence of both factor V Leiden and prothrombin G20210A in 74 colorectal cancer patients was found to be similar to that of 192 colonoscopically selected control subjects. To the best of our knowledge, no data regarding the prevalence of factor V Leiden and prothrombin G20210A in the subset of patients with gastric cancer are available in the literature. We, therefore, performed a prospective case-control study to analyze the

prevalence of factor V Leiden and prothrombin G20210A in patients with gastric cancer.

MATERIALS AND METHODS

One hundred and twenty-one consecutive patients (78 men, 43 women; mean age: 62 years, range: 51-76 years) with operable gastric carcinoma (TNM staging: T₁₋₃, N₀₋₂, M₀) and 130 healthy subjects, matched for age, sex and ethnic-background, were investigated for the presence of factor V Leiden and prothrombin G20210A gene mutation. All individuals were from central Italy, without any previous thrombotic event. Specifically, no control subject or cancer patient had a history of peptic ulcer or *H pylori* infection.

Genomic DNA was extracted from white blood cells according to standard procedures. Factor V Leiden was detected by using polymerase chain reaction and restriction enzyme digestion following the methods described by Bertina *et al*^[4]. Prothrombin G20210A gene mutation was detected by allele-specific PCR according to the methods described by Poort *et al*^[5].

Statistical analysis

Statistical analysis was performed using χ^2 test (with Yates correction).

RESULTS

Among the 121 cancer patients, factor V Leiden was found in 4 cases (GA genotype: 3.3%) and prothrombin G20210A variant in 10 cases (GA genotype: 8.3%). Among the 130 control subjects, factor V Leiden was detected in 6 cases (GA genotype: 4.6%) and prothrombin G20210A variant in 8 cases (GA genotype: 6.1%). No double heterozygous carriers of both mutations were found in both groups. The prevalence of both factor V Leiden and prothrombin G20210A was not statistically different between the cancer patients and the healthy subjects.

DISCUSSION

The present study suggests that, in gastric cancer patients, there is no increase in the prevalence of both fac-

tor V Leiden and prothrombin G20210A gene mutation. These data seem apparently in contrast with the results of Pihusch *et al*^[1], obtained in a cohort of patients with carcinoma of all the gastrointestinal tract (most patients with adenocarcinoma of the colon), and this could indicate a different, peculiar pathogenetic pathway of gastric carcinogenesis. To our knowledge, this is the first report about the prevalence of factor V Leiden and prothrombin G20210A in a cohort of gastric cancer patients. Moreover, the ethnic background of our subjects is different and this could partly explain our results. On the other hand, our data are in agreement with the findings by Paspatis *et al*^[2] who did not find a significant difference in the prevalence of the two prothrombotic polymorphisms in 74 colorectal cancer patients as compared to the controls. However, the limitation of our study is the low statistical power of our sample size.

In conclusion, our data strengthened the evidence that, in gastric cancer, the thrombophilic state is on acquired rather than on genetic basis and seem to suggest that the prothrombin G20210A is not involved in gastric cancer pathogenesis.

Pancreatic neoplasm; Mass-forming pancreatitis

D'Onofrio M, Zamboni G, Tognolini A, Malagò R, Faccioli N, Frulloni L, Pozzi Mucelli R. Mass-forming pancreatitis: Value of contrast-enhanced ultrasonography. *World J Gastroenterol* 2006; 12(26): 4181-4184

<http://www.wjgnet.com/1007-9327/12/4181.asp>

Abstract

AIM: To assess the utility of contrast-enhanced ultrasonography (CEUS) with a second-generation contrast medium in the differential diagnosis between mass-forming pancreatitis and pancreatic carcinoma.

METHODS: From our radio-pathology database, we retrieved all the patients affected by mass-forming pancreatitis or pancreatic carcinoma who underwent CEUS. We evaluated the results of CEUS in the study of the 173 pancreatic masses considering the possibilities of a differential diagnosis between mass-forming pancreatitis and pancreatic tumor by identifying the "parenchymographic" enhancement during the dynamic phase of CEUS, which was considered diagnostic for mass-forming pancreatitis.

RESULTS: At CEUS, 94% of the mass-forming pancreatitis showed intralesional parenchymography. CEUS allowed diagnosis of mass-forming pancreatitis with sensitivity of 88.6%, specificity of 97.8%, positive predictive value of 91.2%, negative predictive value of 97.1%, and overall accuracy of 96%. CEUS significantly increased the diagnostic confidence in the differential diagnosis between mass-forming pancreatitis and pancreatic carcinoma, with receiver operating characteristic curve areas from 0.557 ($P = 0.1608$) for baseline US to 0.956 ($P < 0.0001$) for CEUS.

CONCLUSION: CEUS allowed diagnosis of mass-forming pancreatitis with diagnostic accuracy of 96%. CEUS significantly increases the diagnostic confidence with respect to basal US in discerning mass-forming pancreatitis from pancreatic neoplasm.

Key words: Contrast-enhanced ultrasonography; Pancreatitis;

INTRODUCTION

Mass-forming pancreatitis usually arises in patients with a history of chronic pancreatitis^[1]. The main characteristic feature at pathology is progressive interstitial fibrosis with chronic inflammatory infiltrate. Differential diagnosis with a neoplastic disease may be difficult because mass-forming pancreatitis and pancreatic tumor may present with the same symptoms and signs^[2]. Autoimmune pancreatitis is a rare type of chronic pancreatitis which has been proposed as a separate clinical entity in 1995 and later defined^[3,4]. As opposed to the other forms of chronic pancreatitis, in the autoimmune form, the pancreas is increased in volume, usually in a diffuse way with the typical "sausage" look, and Wirsung duct is compressed by glandular parenchyma or string-like^[4]. At ultrasonography (US), mass-forming pancreatitis is often very similar to pancreatic carcinoma^[1,5], presenting in most cases as a hypoechoic mass in a limited sector of the gland, usually at the head, often with enlargement or lumpiness of the gland contour. Contrast-enhanced ultrasonography (CEUS), thanks to the real-time continuous visualization of blood perfusion of the pancreas and its masses, has been recently used in the evaluation of the vascularization of solid pancreatic lesions, with results superior to single-slice spiral CT^[6,7]. The CEUS features of autoimmune pancreatitis have also been evaluated^[8]. In this study, we aimed to assess the utility of CEUS with a second-generation contrast medium in the differential diagnosis between mass-forming pancreatitis and pancreatic carcinoma.

MATERIALS AND METHODS

From our radio-pathology database, we retrieved all the patients affected by mass-forming pancreatitis or pancreatic ductal adenocarcinoma who underwent CEUS at our Institution between January 2002 and January 2005. Our Institutional Review Board does not require any informed consent for retrospective studies. This study included 35

patients (26 males, 9 females, mean age 49.1 years) affected by mass-forming pancreatitis (19 chronic alcohol-related pancreatitis, 15 chronic autoimmune pancreatitis, 1 genetic pancreatitis) and 138 patients affected by pancreatic tumors (78 males, 60 females, mean age 62.4 years). A total of 173 pancreatic masses were enrolled. All the pancreatic masses underwent cytological or histological diagnosis. All the patients with cytological diagnosis of pancreatitis were followed up at least for one year. All CEUS examinations were performed by radiologists on a Sequoia 512 6.0 (Acuson, Mountain View, CA, USA) ultrasound system, with harmonic microbubble-specific imaging with low acoustic ultrasound pressure (2-4 MHz Coherent Contrast Imaging or Cadence Contrast Pulse Sequencing; Mechanical Index 0.2; 12-13 frames/s). A 2.4 mL bolus of a second-generation contrast medium, SonoVue® (Bracco, Milan, Italy), was intravenously injected, followed by a 5 mL bolus of saline solution. All CEUS examinations were performed by the same radiologist and recorded on videotape/VHS or magneto optical disk/MOD systems to have the possibility to immediately review the dynamic study. Insonation of the pancreatic lesion was continuous with dynamic observation of the shift from the unenhanced phase to the contrast-enhanced phase. The enhancement pattern of the lesions was compared to that of the adjacent normal parenchyma. Definition of the arterial phase is possible when observing hyperechogenicity of the aorta or other big perilesional arteries. The venous phase is defined when the splenomesenteric-portal tree becomes hyperechoic. The lesions were classified according to the lesional enhancement in the enhanced phases as hypovascular/hypoechoic (lesions almost without enhancement or with enhancement lower than that of the adjacent parenchyma), isovascular/isoechoic (lesions with slight continuous enhancement or enhancement similar to that of the adjacent parenchyma) and hypervascular/hyperechoic (lesions with bright enhancement or enhancement superior to that of the adjacent parenchyma). The presence of a slight continuous enhancement inside the pancreatic masses, isovascular with the adjacent pancreatic parenchyma, was defined as "parenchymographic enhancement". We evaluated the results of CEUS in the study of the 173 pancreatic masses considering the possibilities of a differential diagnosis between mass-forming pancreatitis and pancreatic tumor by identifying the parenchymographic enhancement during the dynamic phase of CEUS, which was considered diagnostic for mass-forming pancreatitis. The reports of all the CEUS examinations were reviewed retrospectively, but all the CEUS studies had been interpreted in a prospective manner by the attending radiologist and so utilized for the data analysis. The sensitivity, specificity, positive and negative predictive values and diagnostic accuracy of CEUS in the characterization of the pancreatic masses were then calculated. Moreover, to compare baseline US and CEUS, each mass-forming pancreatitis was evaluated at baseline US and at CEUS with a 3 level diagnostic score: 0 = absence of malignancy (isoechoic lesions); 1 = indeterminate (hyperechoic lesions); and 2 = presence of malignancy (hypoechoic lesions). Diagnostic confidences of baseline US and of CEUS in the characterization of mass-forming

Figure 1 Ductal adenocarcinoma. **A:** US showing slightly hypoechoic pancreatic head mass (asterisk); **B:** CEUS showing poor enhancement of the mass, appearing hypoechoic to the rest of pancreatic parenchyma in the contrast-enhanced phases.

pancreatitis were represented by means of the ROC (receiver operating characteristic) curves; diagnostic advantage of CEUS on baseline US was calculated by comparing the areas under the ROC curves obtained by using a computer software package (Analise-it; Analise-it-software, Leeds, England).

RESULTS

All the contrast-enhanced ultrasound examinations were technically adequate allowing the dynamic observation of the shift from the unenhanced to the contrast-enhanced arterial and venous phases.

Pancreatic tumors

Pancreatic carcinomas were hypoechoic to the adjacent parenchyma at CEUS during the dynamic phases in 91% (126/138) of the cases (Figure 1), while hyperechoic and isoechoic in 7% (9/138) and 2% (3/138) of the cases, respectively.

Mass-forming pancreatitis

Mass-forming pancreatitis involved diffusely the pancreatic parenchyma in 8.5% (10/35) of the cases, while 71.5% (25/35) of the cases were focally localized. Of the 25 focally localized cases, 16 were at the pancreatic head, 5 at the uncinate process and 4 at the pancreatic body. The main pancreatic duct was dilated in 10 cases, the common bile duct was dilated in 11, and dilation of both ducts was observed in 6 cases. Lesional calcifications were

Figure 2 Mass-forming chronic autoimmune pancreatitis. **A:** US showing hypoechoic head pancreatic mass (asterisk); **B:** CEUS showing parenchymographic enhancement of the pancreatic lesion in the head of the pancreas during the contrast-enhanced phases.

observed in 5 (14%) patients. One patient was positive for the SPINK-1 genetic marker. Five patients had significantly higher levels of serum tumoral markers (CA 125 in 1 and CA 19-9 in 4 cases). At CEUS, 94% of the mass-forming pancreatitis showed intralesional glandular parenchymography (Figure 2), while 6% of the mass-forming pancreatitis remained hypoechoic during the dynamic phase. CEUS allowed diagnosis of mass-forming pancreatitis, assuming isoechogenicity as significant for pancreatitis, with sensitivity of 88.6%, specificity of 97.8%, positive predictive value of 91.2%, negative predictive value of 97.1%, and overall accuracy of 96%. The presence of parenchymographic enhancement or hypoechogenicity in the examined pancreatic masses in the dynamic phases of CEUS significantly increased the diagnostic confidence in the differential diagnosis between mass-forming pancreatitis and pancreatic tumor, with receiver operating characteristic curve areas from 0.557 ($P = 0.1608$) for baseline US to 0.956 ($P < 0.0001$) for CEUS (Figure 3).

DISCUSSION

Mass-forming pancreatitis is caused by various etiopathogenetic factors. However, at least two distinct categories have been recognized: alcohol-induced and autoimmune-related^[9]. Differential diagnosis between mass-forming pancreatitis and pancreatic tumor is a crucial point for the correct management of patients affected by pancreatic masses. However, differential diagnosis can be difficult in

Figure 3 Receiver operating characteristic curves of baseline ultrasound and contrast-enhanced ultrasound in the characterization of 173 pancreatic masses, discerning between benignancy (pancreatitis) and malignancy (tumor).

clinical practice^[10,11]. In fact, mass-forming pancreatitis and pancreatic tumors may present with the same symptoms and signs^[2]. Several clinical and imaging features have been proposed to be helpful for the differential diagnosis. In case of mass-forming chronic pancreatitis, the presence of small calcifications in the lesion may suggest its inflammatory nature^[12], but is surely poorly specific. The identification of perfusion features similar to those of the normal pancreatic parenchyma (i.e., glandular parenchymography) is strongly suggestive of inflammatory mass, while ductal carcinomas typically display a low/absent enhancement due to the scirrhous content of this tumor. Contrast-enhanced ultrasonography (CEUS) has recently been used for pancreatic lesions study with good results^[6,13]. The CEUS finding consistent with an inflammatory origin of a pancreatic mass is the presence of a parenchymographic enhancement, defined as slight continuous enhancement inside the pancreatic mass with isovascularity to the adjacent pancreatic parenchyma. In this study, considering the presence of this sign, CEUS diagnosis of mass-forming pancreatitis was possible with sensitivity of 88.6%, specificity of 97.8%, positive predictive value of 91.2%, negative predictive value of 97.1% and an overall diagnostic accuracy of 96%. The intensity of this parenchymographic enhancement is surely related to the length of the underlying inflammatory process. It has been observed that the more the inflammatory process is chronic and long-standing, the less intense is the intralesional parenchymography, probably in relation to the entity of the associated fibrosis. As opposed to this, in mass-forming pancreatitis of more recent onset, the enhancement is usually more intense and prolonged^[5]. The characteristic findings of autoimmune pancreatitis have been well defined: increased levels of serum gammaglobulin or IgG; presence of autoantibodies; enlargement of the pancreas; diffusely irregular narrowing of the main pancreatic duct and occasional stenosis of the intrapancreatic bile duct; fibrotic changes with lymphocyte infiltration; absent or mild symptoms; rare pancreatic calcifications and cysts; occasional association with other autoimmune diseases and effective steroid therapy^[14]. Autoimmune pancreatitis is also reported to be characterized

by periductal flogosis, mainly sustained by lymphocytic infiltration, with evolution to fibrosis^[3,4]. The exact incidence and prevalence of this disease are not known, but previous studies have shown a male preponderance (ratio of 2:1) and a predominant involvement of the elderly age group^[15]. The association with other autoimmune diseases has been reported, although data about the exact incidence of this association are not available^[14]; the most commonly associated diseases are Sjogren syndrome, diabetes mellitus, inflammatory bowel disease (especially Crohn's disease), primary biliary cirrhosis, primary sclerosing cholangitis and systemic lupus erythematosus^[15,16]. Response to steroid therapy is reported in the literature, but dosage and duration of the therapy are not standardized. However, pancreatitis is the most common benign condition that mimics pancreatic neoplasm, and in recent experience at Johns Hopkins, lymphoplasmacytic sclerosing pancreatitis is the most common form of pancreatitis in patients who are subjected to pancreaticoduodenectomy for suspected neoplasm^[17]. Ultrasonographic features of autoimmune pancreatitis are very similar to those of focal pancreatitis, even though autoimmune pancreatitis may interest more frequently the entire gland or present a larger extension and ubiquitous localization. US findings are characteristic in the diffuse form when the entire gland is involved. Echogenicity is markedly reduced, gland volume is increased and Wirsung duct is compressed by glandular parenchyma. Focal autoimmune pancreatitis at the pancreatic head is often characterized by the sole dilation of the common bile duct^[8]. The vascularization of autoimmune pancreatitis can be demonstrated by CEUS, which shows most often a moderate or marked^[8] enhancement in the early contrast-enhanced phase, though inhomogeneous due to the thinning of the glandular vessels as the consequence of the thick lymphocytic infiltration and fibrosis. In our study, parenchymographic enhancement, defined as slight continuous enhancement inside the pancreatic masses with isovascularity to the adjacent pancreatic parenchyma, was shown in 94% of the mass-forming pancreatitis. These CEUS findings have been reported to be especially useful in the study of focal forms of autoimmune chronic pancreatitis, in which differential diagnosis with ductal carcinoma is a priority^[11]. The ability of EUS as well other imaging modalities to differentiate pancreatic cancer from pseudotumorous chronic pancreatitis is reported in literature^[18]. Our data suggests that contrast-enhanced ultrasonography should be used in the characterization of pancreatic masses as complementary to CT and MRI. The sensitivity of CEUS in the identification of inflammatory masses allows to propose to obtain a diagnosis with fine needle percutaneous cytology in pancreatic focal masses that show glandular parenchymography at the examination. However, our study is surely limited by the retrospective evaluation.

In conclusion, CEUS allows diagnosis of mass-forming pancreatitis with diagnostic accuracy of 96%. CEUS significantly increases the diagnostic confidence in respect to basal US in discerning mass-forming pancreatitis from pancreatic neoplasm.

Abstract

AIM: The aim of the study was to evaluate the predictive factors of survival in patients with locally advanced squamous cell esophageal carcinoma (LASCOC) treated with definitive chemoradiotherapy (CRT) regimen based on the 5FU/CDDP combination.

METHODS: All patients with LASCOC treated with a definitive CRT using the 5FU/CDDP combination between 1994 and 2000 were retrospectively included. Clinical complete response (CCR) to CRT was assessed by esophageal endoscopy and CT-scan 2 mo after CRT completion. Prognostic factors of survival were assessed using univariate and multivariate analysis by the Cox regression model.

RESULTS: A total of 116 patients were included in the study. A CCR to CRT was observed in 86/116 (74.1%). The median survival was 20 mo (range 2-114) and the 5-year survival was 9.4%. Median survival of responder patients to CRT was 25 mo (range 3-114) as compared to 9 mo (range 2-81) in non-responder patients ($P < 0.001$). In univariate analysis, survival was associated with CCR ($P < 0.001$), WHO performance status < 2 ($P = 0.01$), tumour length < 6 cm ($P = 0.045$) and weight loss $< 10\%$ was in limit of significance ($P = 0.053$). In multivariate analysis, survival was dependant to CCR ($P < 0.0001$), weight loss $< 10\%$ ($P = 0.034$) and WHO performance < 2 ($P = 0.046$).

CONCLUSION: Our results suggest that survival in patients with LASCOC treated with definitive CRT was correlated to CCR, weight loss and WHO performance status.

INTRODUCTION

Esophageal cancer is a frequent gastrointestinal malignancy with 32 332 new cases per year in Europe. In France, esophageal carcinoma is the third most frequent digestive tract cancer with approximately 5000 new cases per year^[1,2]. Approximately 50% of patients present a locally advanced esophageal carcinoma at diagnosis. To date, the incidence rate of adenocarcinoma is increasing but squamous cell carcinoma still remains the most frequent histological type in France^[1,2]. The definitive chemoradiotherapy (CRT) based on the Herskovic regimen is considered as the standard medical treatment in non operated patients with locally advanced esophageal carcinoma^[3,4]. Moreover, two phase III trials recently suggested that definitive CRT could be considered as an alternative treatment in patients with esophageal carcinoma^[5,6].

However, some questions remain unsolved as regards the CRT regimen optimisation. Moreover, although most studies included both patients with squamous cell and adenocarcinoma, it has been suggested to consider these two tumours separately for treatment as regards their different risk factors, carcinogenesis pathways and treatment response^[3-5,7-11]. Furthermore, the study of Rizk *et al* recently reported that long term prognosis in patients with esophageal carcinoma treated with preoperative CRT could be significantly different according to the histological type of tumour^[11]. However, few reported series have specifically focused on the long-term survival analysis in patients with squamous cell carcinoma treated with definitive CRT using the 5FU/CDDP combination^[12-20]. Moreover, most of these series included a limited number of patients or reported results with short follow-up^[13-20].

The aim of the present study was to assess the long-

term results and the predictive factors of survival in a large series of patients with a locally advanced squamous cell esophageal carcinoma (LASCOC) treated with a definitive CRT regimen based on the 5FU/CDDP chemotherapy (CT) combination. Furthermore, knowledge of these prognostic factors could be useful for the management of individual patients as well as a stratification variable for the design of future randomised trials.

MATERIALS AND METHODS

Patient population

All consecutive patients with a LASCOC referred between January 1994 and the 31st December 2000 were retrospectively included for the study. Patients were selected based on the following criteria: a histologically confirmed squamous cell carcinoma; a first-line treatment with a definitive CRT regimen using the 5FU/CDDP CT and concomitant external radiotherapy (RT). Patients were excluded if they had previous a history of carcinoma during the past three years and if they had synchronous distant metastasis. In our centres, the definitive CRT regimen based on the 5FU/CDDP combination was the first therapeutic option used in patients with LASCOC.

For each patient, we routinely recorded all baseline clinical and tumour characteristics including age, sex, World Health Organisation (WHO) performance status, dysphagia Atkinson score and weight loss at the beginning of treatment, median tumour length, esophageal tumour location, and tumour stage. Events and toxicity related to treatment were also included in the computer data base.

Tumour stage

The 1983 AJCC staging system was used in this study according to recently published recommendations^[21]. Tumour evaluation was based on oesophagoscopy, barium oesophagography, chest and abdominal computed tomography (CT-scan), endoscopic bronchoscopy and esophageal ultrasonography when feasible.

Treatment schedule

CRT regimen was based on the 5 FU/CDDP CT combination associated with an external RT. The RT was delivered either by a dose of 50 Gy (50 Gy/25 fractions per 5 wk) with concomitant CT courses delivered on wk 1 and 5, or either a dose of 60 Gy (20 Gy/10 fractions \times 3 courses separated by a 2-wk break) with concomitant CT courses delivered on wk 1, 5 and 9. The CT courses combined 5-FU (750 to 1000 mg/m² per day delivered by continuous infusion on 4 d) and CDDP (75 to 100 mg/m² delivered on 1 d). The target volume of RT was the macroscopic tumour and enlarged lymph nodes, if any, surrounded by 5 cm proximal and distal margins and a 2 cm radial margin. The target was extended to the inferior cervical area in cases of tumours located above the carina. The specified dose was delivered at the intersection of the central axis of the beams, according to international guidelines. The irradiation technique was applied in anterior and posterior opposed fields. At 40 Gy, the radiation portals were reduced to shield the spinal cord and encompass the primary tumour with a 2-3 cm craniocaudal

margin.

Evaluation of clinical response and toxicity to CRT

Patients were considered to have a clinical complete response (CCR) to CRT when no residual tumour was identified on endoscopy and when no metastatic disease occurrence was observed on CT-scan. This evaluation was performed 2 mo after CRT completion.

Toxicity related to the treatment was evaluated using the National Cancer Institute Common Toxicity Criteria (NCI-CTC, version 2.0). Toxicity was assessed in each patient at d 1 of each chemotherapy course. At each course, patients received the treatment when they exhibited a WHO performance status of 2 or less; satisfactory haematologic function (leucocytes count \geq 3000 mm⁻³, platelet count \geq 100000 mm⁻³) and good renal function (creatinine serum level \leq 100 micromole/L). Patients with major complication i.e. heart disease, pulmonary fibrosis, or active carcinoma at the other site were not eligible for treatment.

Follow-up

The follow-up was performed on clinical basis, endoscopy and CT scan. Histopathological confirmation of the recurrence was not routinely required. Follow-up was performed either until death or for the purpose of this study until October 2005.

Statistical analysis

Analysis was performed in October 2005 and was considered the cut-off date. Survival curves according to the putative prognostic factors were established using the Kaplan-Meier method and were compared with a log-rank test. The effects of clinical characteristics at baseline related to prognosis using univariate analysis were further evaluated in multivariate analysis using Cox regression model. A two-side *P*-value equal or less than 0.05 was considered to indicate statistical significance. Data from patients who had been lost to follow-up were censored at the time of last obtained information. The date of CRT initiation was the starting point for the analysis of overall survival. The date of CRT response evaluation was the starting point for the analysis of the disease free survival.

RESULTS

Patients characteristics

Between the first of January 1994 and the 31st December 2000, one hundred and sixteen consecutive patients were treated with a CRT based on the 5FU/CDDP CT combination. The majority of patients had a good performance status and the dysphagia score prior to CRT reflected their ability to eat a normal or semisolids diet for approximately 90% of these patients (Table 1). Among patients who were estimated with T1-T2 tumour on CT-scan, 14 were estimated to present with a T1-T2 N0 tumour. These latter patients were treated with a definitive CRT as regards age and/or comorbidities.

Safety and toxicity per patient

Significant toxicities per patient are shown in Table 2.

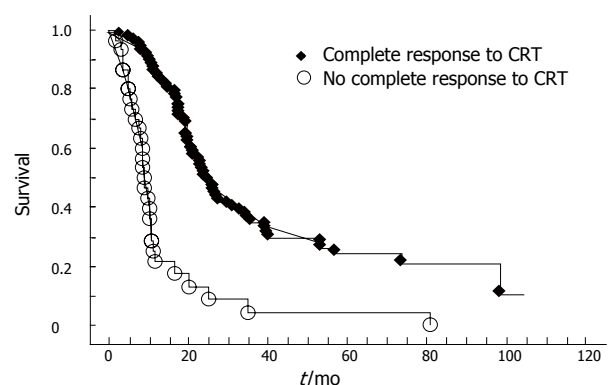

Figure 1 Survival according to response to CRT. The median overall survival of patients who had a complete clinical response (CCR) to the chemoradiotherapy (CRT) was 25 mo as compared to 9 mo in non-responder patients ($P < 0.001$).

There was no death related to CRT. Moreover, 75 patients (64.6%) experienced grade 3-4 toxicities and 112 (96.5%) patients achieved the planned concomitant CRT regimen. Dose modification to the planned CT regimen were required in 55 patients (47.4%) and 18 patients (15.5%) received at least one of their CT courses with a delay of more than 1 wk. The mean delivered radiation dose was 53.2 Gy.

During the CRT treatment, 18 patients (15.5%) required nutritional enteral feeding. In contrast, palliation of the dysphagia by endoscopic stenosis dilation was performed in 25 patients (21.6%). A self expandable metallic stent was inserted in 6 patients (5.1%) during CRT treatment.

Clinical complete response (CCR) to CRT

A total of 86/116 patients (74.1%) achieved a CCR to CRT. In the remaining 30 non-responder patients, a self expanding metallic stent was inserted in 12 for dysphagia palliation after completion of CRT, a CT treatment was initiated in 1 patient and salvage surgery was performed in 2 patients.

Patient outcome

In October 2005, 7/116 patients (6%) were still alive. The median follow-up of these surviving patients was 79 mo (range 56-104) and the median follow-up of the 11

patients who were lost to follow-up during the study was 45.1 mo (range 9-68).

The median overall survival was 20 mo (range 2-114) and the 2-years and 5-years survival rates were 39.6% and 9.4%, respectively. Moreover, the median overall survival of the 86 patients who had CCR to CRT was 25 mo (range 3-114) as compared to 9 mo (range 2-81) in non-responder patients ($P < 0.001$) (Figure 1). The median disease free survival of responder patients to CRT was 17 mo.

During the follow-up, 34 of responder patients (39.5%) experienced a local disease recurrence, 37 patients (43%) experienced metastatic disease and 19 of them experienced both of these recurrences.

Prognostic factors of survival

As regards univariate analysis (Table 3), survival was correlated to CCR to CRT ($P < 0.001$), WHO performance status < 2 ($P = 0.01$) and tumour length < 6 cm ($P = 0.045$). In contrast, weight loss $> 10\%$ at the start of CRT was in limit of statistical significance and was included in multivariate analysis ($P = 0.053$). In a Cox regression model (Table 3), the independent covariates significantly associated with survival were the CCR to CRT ($P < 0.0001$; Odds Ratio (OR): 0.121; IC95 = 0.06-0.24), the weight loss $< 10\%$ ($P = 0.034$; OR: 0.53; IC95 = 0.29-0.95) and a WHO performance status < 2 ($P = 0.046$; OR: 0.495; IC95 = 0.24-0.99).

DISCUSSION

To date, definitive CRT based on the 5FU/CDDP combination is considered as standard treatment in non operable patients with locally advanced esophageal carcinoma whatever the histological tumour phenotype^[3-5]. Some authors recently suggested that histological types of oesophagus tumour could be considered separately regarding their significant different treatment response and long term prognosis^[9-11]. Therefore, we performed a retrospective analysis of the long term outcome and predictive factors of survival in 116 patients with LASCOC treated with a definitive CRT using the 5FU/CDDP CT combination.

In our study, the 5-year survival was 9.4% and the median overall survival was 20 mo. We also found that responder patients to CRT had a significantly increased median survival as compared to non-responders patients (24 mo *vs* 9 mo; $P < 0.001$). This result was supported by the multivariate analysis which identified the CCR as an independent prognostic factor of survival. In definitive CRT series using the 5FU/CDDP combination, a survey of literature showed that median overall survival ranged from 17 to 26 mo and the 5-year survival rate from 20% to 30%^[12-20]. The 5-year survival rate in our study was slightly lower as compared to those reported in these series. This result could be explained by the patient selection bias in these prospective trials, whereas our retrospective study possibly reflected the outcome of non-selected patients with LASCOC treated with definitive RT.

The CCR to CRT was obtained in 75.9% of patients in our series. Moreover, a CCR was identified as an independent prognostic factor of long-term survival in our multivariate analysis. Although the prognostic significance of pathological complete response after preoperative CRT was well documented^[22-24], to our knowledge, there are no previous studies that have reported similar result in patients with LASCOC treated with definitive CRT using the 5FU/CDDP combination. In fact, the significant impact of CCR to CRT in long-term survival in patients treated with the same definitive CRT regimen was reported in series which included patients with mixed histological tumour types^[12,25,26]. Moreover, in the reported Ohtsu *et al* study focusing exclusively on patients with LASCOC, the CCR to CRT was identified as a predictive factor of the progression free survival but not for overall survival^[18]. In our study, 39.5% of responder patients to CRT had a local disease recurrence. In previous studies, local recurrences were reported to be as high as 38% to 48% after definitive CRT^[12,18]. Furthermore, a distant metastasis occurred in 43% of responder patients to CRT in our series. This result compared less favourably to other series including patients with squamous cell carcinoma treated with the same CT combination, where less than 30% of responder patients to CRT experienced a distant metastasis^[12,18]. The frequent use of additional CT in responder patients to CRT in these latter series could probably explain the difference in metastasis frequency. Indeed, only 44% of patients received additional CT after the CRT completion in our study.

Thus, our results suggest that further optimisations of

Table 3 Predictive factors of survival, univariate and multivariate analysis

the definitive CRT regimen are required for both local and systemic disease control improvement. To date, the 5FU/CDDP combination used in our study is still considered the standard for the CRT regimen. Evaluation of novel chemotherapy regimens which include new drugs such as irinotecan and new cancer therapies encompassing those directed against vascular growth factor and epidermal growth factor pathways may be usefully associated with RT to provide improved sustained CCR and therefore optimal long-term survival^[27-30]. Furthermore, CRT regimen optimisation should determine the optimal radiotherapy dose in order to achieve a sustained local disease control. In our study, patients received a mean dose of 52.1 Gy of external RT in the tumour bed, which was a similar dose as that used in the standard regimen described by Herskovic *et al*^[31]. Recently, Zhang *et al* reported, in a retrospective study, that patient who received a dose of RT more than 51 Gy had a statistically better local disease-free survival and overall survival as compared to patients treated with a dose of RT less than 51 Gy^[31]. Minsky *et al* specifically investigated dose escalation in RT. In this prospective study, patients were randomised in a CRT regimen using either 50.4 Gy of RT or 64.8 Gy of RT^[32]. However, the unexplained excess of death frequency (9%) which occurred prior to the dose escalation in patients treated in the 64.8 Gy arm did not permit a valid conclusion as regards the optimal dose of RT. In our study, no death due to CRT was observed. However, we found that 64.6% of patient experienced grade 3-4 toxicities, which was a similar result to that usually reported^[3,4]. As regards the new RT techniques including three dimensional CT planning with conformal beam, dose escalation in the definitive CRT regimen could be reconsidered. Further studies including these new RT techniques may be helpful to evaluate the optimal and safety dose of RT in patients with LASCOC.

Multivariate analysis identified the WHO performance status less than 2 as the second independent predictive factor of long-term survival in patients treated with definitive CRT for a LASCOC. The WHO performance status has been previously identified as prognostic factor in patients with esophageal cancer treated by radiotherapy alone or in patients with metastatic oesophago-gastric cancer in previous studies^[21,33]. Moreover, Polee *et al* also identified this variable as a prognostic factor of survival in

a meta-analysis performed in six prospective trials which included several CRT regimens and mixed histological type of esophageal tumour^[34]. However, to our knowledge, this result had never been previously reported in patients with LASCOC treated in curative intent with definitive CRT using the 5FU/CDDP combination. The WHO performance status evaluation provides useful information on the patient's general well-being indirectly reflecting the impact of the malignancy on the physiological individual condition. Although the evaluation of the WHO performance status seems to be subjective, our results showed that this variable was significantly correlated with survival. Moreover, weight loss before treatment starting was also identified as prognostic factor in our work. This variable was recently to be correlated with prognosis in a meta-analysis by Thomas *et al* in patient treated by definitive CRT for esophageal cancer^[30].

Interestingly, tumour characteristics were not identified as prognostic factors in our study. Indeed, the tumour diameter and the tumour length were only significant in univariate analysis. In surgical series, the extent of the tumour infiltration in the esophageal wall and the lymph node involvement were frequently closely correlated with survival^[23,24,35]. Although an underpowered significance could not be excluded in the analysis, our results could also reflect the limited accuracy of the usual staging evaluation including oesophagography, oesophagoscopy and thoraco-abdominal computed tomography used during the period of the study. However, these imaging modalities appear to be more accurate for the CRT response assessment as regards the significant link that was observed between the CCR and survival. The high rate of early disease recurrence in our study could reflect an overestimation of the CCR rate by modalities used in our study. Thus, the further use of endoscopic ultrasound and PET-FDG, may be helpful to provide better correlative data for initial tumour staging and for tumour response assessment^[36-38].

In conclusion, based on a large series of patients with LASCOC, our results suggest that survival of these patients treated with definitive CRT using the 5FU/performance status. These prognostic factors could be considered for the management of individual patients as well as a stratification variable for the design and interpretation of further randomised trials. However, as regards the retrospective design of our study, further prospective studies are necessary to investigate the impact of these prognostic factors.

Abstract

AIM: To evaluate the response to pegylated-interferon alpha 2a in chronic hepatitis C patients on chronic haemodialysis.

METHODS: Ten patients with chronic C hepatitis were enrolled in this study. All had increased aminotransferases for more than 6 mo, positive antiHCV antibodies and positive PCR HCV-RNA. We administered Peg-Interferon alpha 2a 180 μ g/wk for 48 wk. After 12 wk of treatment we evaluated the biochemical and early virological response (EVR). At the end of the treatment we evaluated the biochemical response and 24 wk after the end of the treatment we evaluated the sustained virological response (SVR). We monitored the side-effects during the treatment.

RESULTS: Two patients dropped out in the first 12 wk of treatment and 2 after the first 12 wk of treatment. After 12 wk of treatment, 7 out of 8 patients had biochemical response and EVR and 1 had biochemical response but persistent viremia. We had to reduce the dose of pegylated-interferon to 135 μ g/wk in 2 cases. Three out of 6 (50%) patients had SVR 24 wk after the end of the treatment. Intention-to-treat analysis showed that 3 out of 10 patients (30%) had SVR. Side-effects occurred in most of the patients (flu-like syndrome, thrombocytopenia or leucopenia), but they did not impose the discontinuation of treatment.

CONCLUSION: After 12 wk of treatment with Peg-Interferon alpha 2a (40 ku) in patients on chronic haemodialysis with chronic C hepatitis, EVR was obtained in 87.5% (7/8) of the cases. SVR was achieved in 50% of the cases (3/6 patients) that finished the 48 wk of treatment.

INTRODUCTION

Although constant efforts have been made to improve the outcome of hepatitis C patients, chronic infection with hepatitis C virus (HCV) remains a problem for hepatologists. The development of new therapeutic formulas (pegylation) and the introduction of ribavirin were major steps forward. However the problem is not entirely solved since the sustained virological response can be obtained in only half of HCV-infected patients. There are also the special groups of patients (with liver cirrhosis, with HIV coinfection, patients on chronic haemodialysis) in which the optimal antiviral treatment is still not established.

In patients on chronic haemodialysis, the number of individuals infected with HCV is rather high mostly due to nosocomial infection. The reported prevalence of HCV infection ranges from 8% to 20% in dialysis patients in developed countries^[1-5] and much higher in less developed countries^[6]. The prevalence of anti-HCV among dialysis patients was 43.9% in Saudi Arabia in 2001^[7], 30% in India in 2002^[8], and 41% in Turkey (2001)^[9]. In United States of America in 2000, 8.4% of haemodialysis patients were anti-HCV positive^[5]. The incidence of HCV infection is higher in patients undergoing dialysis at hospitals than in those undergoing haemodialysis or peritoneal dialysis at home.

The main mechanisms involved in nosocomial infection with HCV in haemodialysis patients are filter reuse, use of contaminated haemodialysis machines and contamination of medical staff's hands^[10]. It has been proven that the incidence of HCV infection in haemodialysis patients increases if the nurse does not change her gloves before injecting each patient^[11] and if HCV (+) patients undergo haemodialysis in the same room with HCV (-) patients^[12].

Other possible risk factors for transmission of the virus are sharing single vials to prepare drugs or infusions for different patients, distance less than one meter between chairs^[13], sharing a single heparin-saline solution ampoule in different patients^[14]. A large French multi-center study^[15] on 1323 haemodialyzed patients has shown an incidence of 0.4% new HCV infections per year, almost two thirds of them occurring in infected patients on dialysis during the same shift at the same unit.

Regardless of the route of infection, the evolution of HCV-infected patients on chronic haemodialysis is often severe. Martin *et al*^[16] showed that 24% of haemodialysis patients with positive anti-HCV Ab have liver cirrhosis and that there is no correlation between the severity of hepatic lesions and viral genotype, viral load or transaminase level. Hence we must treat chronic hepatitis C in haemodialysis patients, particularly in those on the waiting list for renal transplantation, because post-transplant immunosuppressive therapy can accelerate the natural course of the liver disease. Interferon-based therapy is not recommended in HCV positive patients after renal transplantation due to a significant risk of graft loss and a low rate of clearance of the virus^[17,18]. Also ribavirin monotherapy for renal transplant recipients positive for anti-HCV is associated with improvement in liver enzymes but not significant change of HCV RNA^[19]. On the other hand, Kamar *et al*^[20] showed that treatment of HCV positive haemodialysis patients with interferon α could induce complete and sustained clearance of the virus in almost 29% of them, without any relapses after renal transplantation despite subsequent immunosuppressive treatment.

Another problem of the treatment for HCV-infected patients on dialysis is the contraindication of ribavirin, due to the risk of deep and long-lasting haemolytic anaemia^[21].

Due to these characteristics of this special group of patients and the promising results of our previous study using standard interferon in haemodialysis patients^[22], we decided to evaluate the effect of pegylated-interferon in patients with chronic hepatitis C on dialysis.

MATERIALS AND METHODS

We included 10 haemodialysis patients in our study (4 males and 6 females, mean age 40.2 years). Written informed consent to participate in this study was obtained from all of them. All had increased aminotransferases for more than 6 mo, anti-HCV antibodies (Elisa III) and positive PCR HCV-RNA. The viral load at admission and after 12 wk of treatment (EVR) was determined by the classical polymerase chain reaction (Roche) with a detection limit of 600 UI/mL. The viral load 24 wk after the end of treatment (SVR) was determined by real-time PCR (Abbott) with a detection limit of 23 UI/mL. None of the patients presented with clinical, biological, endoscopic or ultrasound signs of liver cirrhosis. We did not perform liver biopsy because of the increased risk of bleeding in haemodialysis patients.

All patients were treated with pegylated-interferon alpha 2a (180 μ g/wk) for 48 wk. We evaluated the biochemical response every month and the virological response after 12

wk of treatment (early virological response-EVR) and 24 wk after the end of treatment.

We monitored the side effects during the treatment. At the end of the treatment we evaluated the biochemical response of our patients (number of patients with normal transaminases) and the sustained virological response (SVR) 24 wk after the end of the treatment (72 wk from the beginning of the treatment) by determining the virological load.

RESULTS

The 10 patients studied are listed in Table 1. At the beginning of the study the virological load was low in 2 patients (< 10 kIU/mL), moderate in 5 patients (10-500 kIU/mL), and high in 3 patients (> 500 kIU/mL). Two patients were excluded from the study. One patient was excluded because of lack of compliance and 1 patient discontinued the treatment due to complications after surgery (sepsis).

We determined the biochemical and virological response (PCR RNA HCV) in the 8 patients who continued the treatment after 12 wk of therapy. Of these patients, 7 (87.5%) had biochemical response (normal transaminases) as well as virological response (viral load < 0.6 kIU/mL), 1 (12.5%) had biochemical response (normal transaminases) but persistent viremia. We continued the treatment with pegylated-interferon alpha 2a for 48 wk. During this period one patient died of cerebral haemorrhage caused by arterial hypertension after 16 wk of therapy (the patient having normal prothrombin time and only mild thrombocytopenia-104 000 platelets/mL) and one patient was excluded from the study due to lack of compliance after 28 wk of therapy.

The total number of patients who finished the 48-wk treatment was 6 (60%). All of them had biochemical response at the end of treatment (normal transaminases). Three out of 6 patients (50%) had sustained virological response (SVR) 24 wk after the end of the treatment. The intention-to-treat analysis showed that 3 out of 10 patients (30%) had sustained virological response 24 wk after the end of the treatment.

All patients had minor flue-like symptoms, 4 had mild thrombocytopenia ($Tr < 150\,000/\text{mm}^3$) and 2 had moderate thrombocytopenia ($Tr < 100\,000/\text{mm}^3$), 4 had transitory mild leucopenia ($L < 4000/\text{mm}^3$). In the 6th mo of therapy one of the patients developed sepsis secondary to central venous catheter infection. During this period the patient had elevated transaminases. Unfortunately, this patient abandoned the treatment one month later.

We modified the dose of pegylated-interferon in 2 patients. In one we reduced it to 135 μ g/wk for 1 mo (because of the thrombocytopenia and haemorrhagic complications-metroragia, epistaxis, prolonged bleeding of the fistula), then 180 μ g/wk was administered again. In the second patient the dose reduction to 135 μ g/wk was initiated in the 4th mo of therapy until the end of 48-wk treatment.

We did not stop the treatment in any patient due to severe side effects of pegylated-interferon.

Table 1 Demographic data of haemodialysis patients treated with pegylated interferon

No.	Patient	Sex	Age	Duration of treatment wk	Stop of because treatment of	Initial viral load (UI/mL)	Viral load at wk 12 (UI/mL)	Viral load at wk 72 (UI/mL)
1	B.L.	F	42	48		4090	< 600	< 23
2	C.A.	M	34	48		84 760	< 600	45
3	B.V.	M	45	48		252 000	< 600	263 300
4	L.D.	F	40	6	Non compliance	8000	-	-
5	B.L.	F	44	48		157 000	< 600	< 23

10	P.C.	M	51	28	Non compliance	> 1 000 000	< 600	-

DISCUSSION

Many clinical trials have focused on the treatment of chronic hepatitis C patients on chronic haemodialysis with standard interferon, because ribavirin is not recommended. Some studies have used ribavirin at low doses (170-300 mg/d) together with standard interferon^[23]. The results are encouraging but a careful monitoring of anaemia is mandatory. When anaemia occurs it is corrected with high doses of erythropoietin. On the other hand, post-transplant treatment of chronic C hepatitis with interferon is not recommended because it can induce graft rejection (15.4%-63.6% of cases)^[24]. Also, post-transplant monotherapy with ribavirin or amantadine has been proven inefficient^[24].

Fabrizi *et al*^[6] have found a mean SVR of 37% and a mean dropout rate of 17% in chronic hepatitis C patients on dialysis after interferon monotherapy. Our experience in treatment of these patients with standard interferon showed that sustained biochemical response is 46.1% and sustained virological response (HCV-RNA) is 38.4% respectively 6 mo after interferon treatment^[22].

The promising results of monotherapy with standard interferon in chronic haemodialysis patients with chronic hepatitis C^[22,25-27] have shown that viral clearance occurs in 27%^[27] to 64%^[26] of patients after 12 mo of treatment with standard interferon.

In patients on chronic haemodialysis, the combined treatment with interferon and ribavirin is difficult to manage because haemolysis is induced by ribavirin. There are studies in which ribavirin is administrated at low doses (170-300 mg/d), the results are remarkable but anaemia should be carefully monitored^[23].

The second therapeutic option for patients on chronic haemodialysis with chronic C hepatitis is to use pegylated interferon. In most of the studies performed in patients with chronic C hepatitis and normal renal function, the response rate doubled when the patients switched from standard interferon to pegylated-interferon. Some 3 rd phase studies have been performed in Greece, Mexico, Great Britain and USA to evaluate the sustained virological response after treatment with pegylated interferon alpha 2a in patients on chronic haemodialysis.

Martin *et al*^[28] demonstrated that the absorption, distribution and total clearance of pegylated-interferon alpha 2a (40 ku) are not very different from those in

patients with normal renal function, and that the tolerability of pegylated-interferon alpha 2a and the adverse effects in patients on chronic haemodialysis are similar with those in patients without renal impairment. In our group the side effects were quite the same with those in "normal" patients with chronic hepatitis C treated with pegylated-interferon.

We reduced the dose of pegylated-interferon to 135 µg/wk in 2 cases (in one patient only for one month and in another until the end point of treatment). Various authors have recommended a dose of 180 or 135 µg/wk of pegylated-interferon alpha 2a in patients on chronic haemodialysis. We prefer to start with 180 µg/wk in order to reduce the dosage if severe side effects occur. We reduced the dosage in 2 patients due to thrombocytopenia and bleeding.

Data on the patients on haemodialysis treated with pegylated-interferon alpha 2b are rather discouraging. A study by Russo *et al*^[29] on the HCV-infected patients on haemodialysis treated with pegylated-interferon alpha-2b showed that a poor tolerance is associated with substantial side effects. Also, a case report by Potthoff *et al*^[30] showed that IFN-alpha 2b three times a week after haemodialysis seems to be better tolerated than pegylated-interferon-alpha 2b once a week. A randomized study performed by Mahmoud *et al*^[31] in pretransplant haemodialysis patients with chronic hepatitis C treated with standard interferon alpha 2b, showed that IFN-treated patients have significantly better post-transplant hepatic functions and significantly lower rates of chronic allograft nephropathy. Further studies are needed to find out which type of interferon is better tolerated and has better results for the treatment of haemodialyzed patients with chronic hepatitis C.

Since there are more and more encouraging results of treatment with interferon in patients on chronic haemodialysis with chronic hepatitis C, it is likely that very soon all these patients can benefit from antiviral therapy (standard interferon alone or in combination with ribavirin, or pegylated-interferon).

After 12 wk of treatment with Peg-Interferon alpha 2a (40 ku) in patients on chronic haemodialysis with chronic C hepatitis, the early virological response (EVR) (HCV-RNA absent by PCR) was obtained in 87.5% (7/8) of the cases. All the patients that finished the 48 wk of treatment had normal transaminases (biochemical response) (6/6). We had to reduce the dose of Peg-Interferon in only 2 cases. Even if side effects occurred in most of the patients

(flue-like syndrome, thrombocytopenia or leucopenia) they did not impose the discontinuation of treatment. The sustained virological response at 6 mo after the end of the therapy was achieved in 50% of the cases (3/6 patients) that finished the course of 48 wk of treatment.

Abstract

AIM: To investigate human telomerase reverse transcriptase (hTERT) mRNA in the serum of cholangiocarcinoma patients.

METHODS: The serum of thirty three cholangiocarcinoma patients, forty one benign biliary tract disease patients and ten healthy volunteers were collected and analyzed for the expression of hTERT mRNA by real-time reverse transcriptase-polymerase chain reaction (RT-PCR). We then examined the correlation between values of serum hTERT mRNA and the pathological staging of cholangiocarcinoma.

RESULTS: hTERT mRNA was detected in 28 of 33 (84.85%) of serum obtained from cholangiocarcinoma patients and 9 of 41 (21.9%) of serum obtained from benign biliary tract disease patients. hTERT mRNA was not detected in any serum obtained from healthy volunteers. on the other hand the common tumor marker, CA19-9 was detected in 20 of 33 (60.6%) of serum obtained from cholangiocarcinoma patients and 8 of 41 (19.5%) of serum obtained from benign biliary tract disease patients. However, no correlation was found between the present of serum hTERT mRNA and tumor staging.

CONCLUSION: These results indicate that the detection of circulating hTERT mRNA was identified in almost all cholangiocarcinoma patients. It offers a novel tumor marker, which can be used as a complementary study for

INTRODUCTION

Cholangiocarcinoma is the cancer arising from cholangiocyte, the epithelial cells lining the intrahepatic and extrahepatic bile ducts. It is one of the most common liver cancers in the population of Northeast Thailand and responsible for approximately one in five cancer-related deaths among Thai patients^[1]. Three-year survival rates of 40%-60% have been reported only in a few number of patients resected for cure^[2]. Diagnosis of cholangiocarcinoma is often difficult. It requires multiple complementary studies including evaluation of clinical symptoms, imaging, and tumor markers. Tissue biopsy and cytology have poor sensitivity and are positive only in about 30% of cases of cholangiocarcinoma. Recently, the percentages of positive serum obtained from the common marker (CA19-9) are only less than 70%^[3]. In addition, CA19-9 can be elevated in cholestasis in the absence of malignancy, and following liver injury. Thus, their accuracy for the diagnosis of cholangiocarcinoma is limited. It is necessary to find novel markers to use in diagnosis and treatment.

The human telomerase, which composed of two subunits including telomerase RNA template (hTR) and telomerase transcriptase protein (hTERT), functions as a reverse transcriptase enzyme in the process of telomere synthesis^[4]. Telomerase activity was detected in 85%-100% of cancer patients whereas normal somatic cells have low or undetectable^[4,5]. In addition, previous results demonstrated that circulating tumor-related RNA

including telomerase is frequently found in the plasma and serum of cancer patients^[6-8].

Consequently, telomerase activity is possibly used as a common molecular tumor marker in the serum. Previous studies also found a good correlation between the telomerase activity and the expression of hTERT subunit. The aim of this study is to test the usefulness of hTERT mRNA detection in the serum of cholangiocarcinoma patients by using real-time reverse transcriptase polymerase chain reaction.

MATERIALS AND METHODS

Cell lines

The human cholangiocarcinoma cell line HuCCA1 (kindly provided by Prof. Sirisinha, Department of Microbiology, Mahidol University) and RMCCA1 (established from Department of Surgery, Rajavithi Hospital) were grown in Ham's F12 medium supplemented with 100 mL/L fetal bovine serum at 37°C in a 5% (50 mL/L) CO₂ humidified atmosphere.

Patients and sample preparation

Thirty-nine informed and consenting patients undergoing surgery for cholangiocarcinoma at the Rajavithi Hospital, Thailand, between July 2003 and April 2006 were included in this study. Tumor samples were collected at the time of surgery and histopathologically characterized to confirm the diagnosis. Pathological data, including tumor staging was also collected. Fifty patients undergoing surgery for benign biliary tract disease were included in this study. Ten normal subjects were studied as negative controls.

Sample Collection

Blood was collected prior to surgery in plain tubes for serum sampling. After clotting, tubes were centrifuged at 1000 r/min for 15 min at room temperature, and serum was collected. This was followed by a second 15-min centrifugation at 1000 r/min to remove cellular debris. Serum samples were aliquoted and stored at -70°C until use. Serum CA19-9 level was measured in Clinical Laboratory of Rajavithi Hospital. The cut-off level was 100 IU/mL.

RNA Extraction

RNA from cell lines and serum was extracted using a commercially available kit (High Pure RNA Kit; Roche Diagnostics GmbH, Mannheim, Germany), according to the manufacturer's instructions. Only fresh or once-freeze thawed serum was used.

Real time RT-PCR for hTERT mRNA

Quantitative detection of hTERT mRNA was performed with the TeloTAGGG hTERT Quantification Kit (Roche Diagnostics GmbH, Mannheim, Germany), using the LightCycler system (Roche Diagnostics, Mannheim, Germany) for real-time PCR according to the manufacturer's instructions. For the reaction mixtures, 2 µL of hTERT reaction mix, 0.1 µL of reverse transcriptase, 2 µL of hTERT or PBGD mix, 13.9 µL of H₂O and 2 µL of standard RNA template or RNA from

Table 1 The patient demographic data and blood chemistry data

	Benign biliary tract disease	Cholangio-carcinoma	Healthy volunteers
Sex (Male:Female)	21:20	19:14	6:4
Age (year), (median)	53.68 (22-82)	56.40 (35-85)	49.50 (26-60)
SGOT (IU/dL)	105.32 ± 52.26	112.52 ± 44.54	30.20 ± 12.20
SGPT (IU/dL)	96.04 ± 45.42	73.41 ± 44.30	28.50 ± 9.22
Total Bilirubin (mg/dL) ^a	3.8 ± 2.21	12.8 ± 5.24	1.05 ± 0.25
Alkaline Phosphatase (U/dL) ^a	309 ± 67.53	550 ± 24.44	98 ± 10.60

^a*P* < 0.005.

serum samples was prepared. The reaction conditions were reverse transcription at 60°C for 10 min, followed by initial denaturation at 95°C for 30 s and 40 cycles of denaturation at 95°C for 0.5 s, annealing at 60°C for 10 s, and extension at 72°C for 10 s, respectively. The standard curve was established by determination of the five standards hTERT mRNA provided by the kit. The samples were normalized on the basis of the content of PBGD. Serum samples with more than 150 copies of PBGD suggesting an appropriate quality of RNA were used for the analysis of telomerase. Serum samples in which hTERT mRNA were detected were assigned to the hTERT-positive group.

Statistical analysis

Values were expressed as mean ± SD. Mean values were measured by the Student's *t* test. Correlations between serum hTERT mRNA and stage of cholangiocarcinoma were assessed using the chi-square test (χ^2). Sensitivity, specificity, positive predictive value, and negative predictive value were measured. *P* < 0.05 was considered as statistically significant.

RESULTS

Detection of hTERT mRNA in cholangiocarcinoma cells

The expression of hTERT mRNA in two cholangiocarcinoma cell lines (HuCCA1 and RMCCA1) was investigated. Quantitative real-time RT-PCR demonstrated definite expression of hTERT mRNA in both cholangiocarcinoma cell lines (Figure 1). This evidence confirmed the existence of telomerase activity in cholangiocarcinoma. Therefore, we attempted to detect the circulating hTERT mRNA in the serum of cholangiocarcinoma patients.

Detection of serum hTERT mRNA

Thirty-nine patients who were confirmed diagnosis as cholangiocarcinoma, fifty benign biliary tract disease patients and ten healthy volunteers were included in this study. Their serum was collected and extracted for total RNA. Only RNA samples, that could be detected by the expression of porphobilinogen deaminase (PBGD) as a housekeeping gene were included in this study. The thirty-three serum samples from cholangiocarcinoma patients, fortyone serum samples from benign biliary tract disease patients and ten serum samples from healthy volunteers detected for PBGD were as-

Figure 1 Continuously monitoring the development of signals in parallel standards and samples results in a series of amplification curves. The amplification of a 198 bp fragment of the generated hTERT cDNA was identified. (A: Signal from RMCCA1; B: Signal from HuCCA1; C, D: Signals from serum of cholangiocarcinoma patients; E, F: Signals from serum of benign biliary tract patients).

sayed for the expression of hTERT mRNA (Figure 1). The patients' demographic data was demonstrated in Table 1. There were no differences in sex, age, serum SGOT and serum SGPT between benign and cancer patients. However, total bilirubin and alkaline phosphatase were significantly high in cancer groups.

Serum hTERT mRNA was recognized in 28 of 33 cholangiocarcinoma patients (84.85%) and 9 of 41 benign biliary tract disease patients (21.9%). However, serum hTERT mRNA was not detected in any healthy volunteers. The efficiency of serum hTERT was compared with the serum CA19-9 as shown in Table 2. Serum hTERT was higher in sensitivity for detection of cholangiocarcinoma than serum CA19-9.

Detection of serum hTERT mRNA in relation to tumor stage

We also evaluated for the association between serum hTERT mRNA and the histopathological staging of cholangiocarcinoma in the surgical specimens resected from these patients. The result showed that serum hTERT mRNA could be detected in all stages of cholangiocarcinoma patients. However, it did not correlate with the staging of cholangiocarcinoma (Table 3).

DISCUSSION

Eukaryotic chromosomal ends consist of repeating DNA sequences (TTAAGG) termed telomeres. An enzyme that adds telomeric repeats onto chromosomal ends is telomerase. This enzyme is composed of two subunits; hTR and hTERT^[4]. Accordingly, both hTR and hTERT are necessary for telomerase activity, yet the catalytic activity of the enzyme is generally regulated through the presence and activity of hTERT. Therefore, the detection of hTERT mRNA is a guarantee for the present of telomerase activity^[8]. In most somatic cells in which telomerase activity is undetectable, telomeric sequences are lost with each cell division because of the end-replication problem. Unlike healthy cells, most malignant human cells are capable of escaping senescence and sustaining infinite proliferation through the activation of telomerase to

Table 2 Comparative analysis of serum hTERT mRNA and serum CA19-9 in diagnosis of cholangiocarcinoma

	Serum hTERT (%)	Serum CA19-9 (%)
Sensitivity	84.85	60.6
Specificity	78.05	80.49
Positive predictive value	75.68	71.43
Negative predictive value	86.49	71.74
False Negative	13.51	28.26
False Positive	24.32	28.6

Tumor stages	Serum hTERT positive	mRNA negative
Stage I	2	1
Stage II	17	3
Stage III	9	1

stabilize their telomere length^[4,8-12].

Traditionally, telomerase activity has been assessed based on a biochemical primer extension assay, the inefficiency and low sensitivity of which, together with the low amounts of telomerase activity, greatly limit the application of the assay in primary human tumors^[9]. Therefore, the detection of hTERT by real-time RT-PCR was used in this study. This assay determined the expression of telomerase by measuring the amount of the mRNA encoding its catalytic subunit hTERT. The relative telomerase expression levels were determined by comparing them to the expression levels of the housekeeping gene porphobilinogen deaminase (PBGD). hTERT-encoding mRNA from the serum was reverse transcribed and 198 bp fragments of the generated cDNA was amplified with specific primers in a one step RT-PCR reaction. The amplicon was detected by fluorescent emission using a specific pair of hybridization probes. In a separate RT-PCR, mRNA encoding for porphobilinogen deaminase (PBGD) was processed. The reaction product served as both a control for RT-PCR performance and as a reference for relative quantification.

Our study showed that hTERT mRNA was detected in almost all of the cholangiocarcinoma patients (84.85% of cases). However, in benign biliary tract disease patients, hTERT mRNA was also detectable (21.9% of cases). According to the previous report, telomerase activity has been reported in normal lymphocytes^[8-12]. This result suggested the contamination of lymphocytes in the serum specimens. Comparison with the common tumor marker, CA19-9 was detected in only 60.60% of cases. This data suggested that hTERT mRNA should be a candidate tumor marker in cancer patients.

hTERT mRNA is not specifically detected in serum of cholangiocarcinoma patients but it was also significantly found in several types of cancers such as breast cancer, malignant melanoma and thyroid cancer^[8]. Certainly, we have detected hTERT mRNA in the serum of five patients with hepatocellular carcinoma and three patients with pancreatic cancers (data not shown). This indicates that the

detection of circulating extracellular tumor-derived mRNA is not confined to any one cancer type, but may actually be a relatively ubiquitous finding across a broad range of cancers. However, no relationship was found between the expression of hTERT mRNA and clinicopathological findings. According with previous study, the presence of hTERT was unrelated to tumor size, tumor grade or the presence of nodal metastasis^[12]. These results suggest that the detection circulating hTERT mRNA does not predict prognosis in cholangiocarcinoma.

In conclusion, hTERT might serve as a tumor marker, which early identified circulating specific RNA originating from tumor cells. However, further examinations using more cholangiocarcinoma cases are necessary to evaluate the usefulness of this marker.

Abstract

AIM: To compare the efficacy of enzymatic detergent with chlorhexidine for gastroscope bacterial decontamination.

METHODS: A prospective randomized controlled study was undertaken to evaluate the ability of these 2 agents to achieve high level disinfection in a gastroscope. A total of 260 samples were collected from 5 different gastroscopes. Manual cleaning was done for 10 min with these 2 agents separately ($n = 130$ each). Then all specimens underwent 2% glutaraldehyde soaking for 20 min. After 70% alcohol was rinsed, sterile normal saline was flushed into each gastroscope channel and 40 mL of sample was collected. The sample was sent for aerobic bacterial culture after membrane was filtered. A colony count greater than 200 cfu/mL was considered significant.

RESULTS: The positive culture rate was 4.6% in the enzymatic detergent arm and 3.1% in the chlorhexidine arm. *Pseudomonas* species were the main organism detected from both groups (60%). Multiple organisms were found from 4 specimens (enzymatic detergent arm = 1, chlorhexidine arm = 3).

CONCLUSION: The contamination rate of both types of cleaning solution is equivalent.

INTRODUCTION

The endoscope is a complex, reusable device that requires reprocessing before being used in subsequent patients. Generally, a high-level of disinfection is required for reprocessing endoscopes^[1-2]. To date, all published incidents of pathogen transmission related to gastrointestinal (GI) endoscopy are associated with failure to follow established cleaning and disinfection/sterilization guidelines or with the use of defective equipments^[3-5].

Guidelines for reprocessing flexible gastrointestinal endoscopes have been recommended by several professional organizations^[6-10]. However, different professional organizations do not have similar recommended practices^[6-9]. Cleaning solutions are one of the different factors. In USA, multi-society guidelines for reprocessing flexible gastrointestinal endoscopes recommend to use enzymatic detergent as an initial endoscopic cleaning agent^[1]. However, different countries select different agents for this purpose. Chlorhexidine is one of the popular solutions that have been accepted for endoscope cleaning in Thailand. Unfortunately, there are some reports on bacterial transmission from this standard endoscope reprocessing practice^[7]. Bacterial biofilm is known to interfere with the cleaning efficacy of chlorhexidine. Biofilms consist of colonies of organisms forming structures to maximize growth potential. The ability of bacteria to form biofilms is an important factor in the pathogenesis of endoscopy-related infections, particularly as biofilms interfere with disinfection. Strategies aimed at decreasing biofilm formation and viability play an important role in endoscope disinfection because biofilms adhere to the internal channels of endoscopes^[4,7].

Recently, many professional organizations have accepted enzymatic detergent for endoscope cleaning^[1,7,9,11]. However, there is no randomized controlled study to demonstrate the efficacy of this agent for scope cleaning over chlorhexidine. Hence, the aim of this study was to evaluate the cleaning ability of these 2 agents combined with a standard disinfectant like glutaraldehyde to achieve high level disinfection for gastroscope cleaning.

MATERIALS AND METHODS

A prospective randomized controlled study was undertaken to evaluate the cleaning capacity of gastroscopereprocessing by 3E-ZYME (Medisafe UK Limited, Hartfordshire, UK) and hexene (Osoth Inter Laboratoreis, Chonburi, Thailand). All specimens were collected at the Gastroenterology Unit, King Chulalongkorn Memorial Hospital between July 2004 and October 2004. A total of 260 samples were collected from 5 different gastroscopes. These samples were divided into two groups by stratified randomization and block of 4. Group 1 ($n = 130$) received enzymatic detergent during endoscope cleaning, and group 2 ($n = 130$) received chlorhexidine detergent during endoscope cleaning.

The 3E-ZYME is a non-foaming, triple enzymatic detergent and designed for use in endoscope processing. It has a neutral pH formulation and is safe for instruments when used as directed. The directions indicate that 3E-ZYME should be diluted 3-7 milliliters (mL) to every liter (L) of warm (40°C-60°C) water and that the devices should be immersed for 1 min. In the other group, hexene was used as the conventional cleaning detergent. Hexene is an aqueous solution of 4% (weight/volume) chlorhexidine gluconate. In the present study, hexene was diluted from 25 mL to 5 L with filtered water, and the endoscopes were also immersed for 10 min.

Gastroscopereprocessing was performed in accordance with recognized standards for infection control and endoscope reprocessing. All personnel were well trained to comply with the protocol. The protocol for gastroscopereprocessing in the present study is shown in Table 1. Endoscope was randomly selected to be cleaned by one of the two cleaning agents. After gastroscopereprocessing was completely performed, a sample was collected by the flush method (injecting sterile water from the top of accessory channel of the endoscope and subsequently, the sample was collected from the distal tip of the endoscope). All samples were sent for aerobic bacterial cultures using a membrane filtering. Anaerobic bacterial, fungal and viral cultures were not performed due to insufficient information regarding the effect of bacterial biofilm over these organisms.

For quantitative culture, membrane filter method was performed in this study (limit of detection, 1 cfu/specimen). All inoculated plates were incubated aerobically at 37°C for 24-48 h before the number of colonies was counted. Culture results were variably reported as colony counts per milliliter. A colony count greater than 200 cfu/mL was considered significant.

Chulalongkorn University Institutional Board Review approved and supported all ethical issues related to this study. Descriptive statistics were expressed as n (%). Statistical analysis was performed by chi-square or Fisher's exact test. $P < 0.05$ was considered statistically significant. Data were analyzed with the Statistic of Package for Social Sciences (SPSS 11.5) program (Chicago, IL, USA).

RESULTS

All the five gastroscopes were equally distributed in the

Table 1 Steps for gastroscopereprocessing in the present study

Gastroscopereprocessing

Cleaning After completion of the cleaning procedure, the inserted tube was wiped with a wet cloth and soaked in detergent solution (chlorhexidine or 3E-ZYME). Detergent solution was suctioned through the biopsy channel until the solution was visibly clean.

While the scope was submerged, mechanical cleaning was performed by washing all debris from the exterior. All removable parts were separately cleaned. A soft cleaning brush was used to clean all accessible channels. Manual cleansing was done for 10 min.

The scope was removed from the detergent solution and then submerged in 5 L of filtered water. An all-channel irrigator was used to flush water through it.

Leak testing of the scope was performed.

Disinfection After manual cleaning, the gastroscopereprocessed high-level disinfection in a container using 2% glutaraldehyde with a 20-min soak time.

The scope was removed from 2% glutaraldehyde and then submerged in 5 L of filtered water. An all-channel irrigator was used to flush water through it.

Rinsing and Drying The suction/biopsy channel was rinsed with 70% alcohol 20 mL and dried for 5 min.

The suction/biopsy channel was sampled using the flush method.

2 groups (Table 2). The rates of bacterial contamination (> 200 cfu/mL) in both groups are shown in Table 3. The positive culture rate was 4.6% from the enzymatic detergent group and 3.1% from the chlorhexidine group. This was not statistically significant ($P = 0.747$).

Overall, the rate of bacterial contamination was 3.85% (10/260 samples). The incidences and types of organisms during study period are shown in Table 4. The most common organism was *Pseudomonas* (60%) in group 1 ($n = 4$, 3.1%) and group 2 ($n = 5$, 3.8%) (Table 3). Other organisms included *Klebsiella* species (13.33%), *Enterobacter* species (6.66%), *Acinetobacter baumannii*

(6.66%), *Staphylococcus coagulase negative* (6.66%) and *Staphylococcus aureus* (6.66%).

DISCUSSION

Ensuring safety in patients undergoing endoscopy, proper endoscope reprocessing is required. According to Spaulding classification of disinfection of medical and surgical instruments, flexible GI endoscope reprocessing is categorized as semicritical level since endoscopy has no involvement with tissue penetration^[12]. The reprocessing of endoscopes is susceptible to multiple errors, as it is a multi-step process relying on both human and material for reprocessing. The reprocessing involves meticulous manual cleaning and rinsing. This step is followed by high-level disinfection with liquid chemical germicide. Chlorhexidine is commonly used to decontaminate an endoscope prior to high level disinfection. However, recent reports from the Center of Disease Control and Prevention suggested that a significant number of infections are transmitted during endoscopic procedures after reprocessing these scopes under both manual and automated cleanings^[7]. Detailed analysis of these cases has identified either a breakdown in the cleaning process or a damage by equipment as the causative factor^[6,13]. It is possible that bacterial biofilm contributes to the failure of adequate endoscope reprocessing in certain instances. Vickery *et al*^[14] showed that bacterial biofilm is an important factor in endoscope contamination, and that routine cleaning procedures do not remove biofilm reliably from endoscope channels. Generally, biofilm consisting of bacteria enclosed in a matrix of exopolysaccharide (EPS) can form on many medical devices such as catheters and endoscopes. Chemical cleaning methods by agents like chlorhexidine are often ineffective because biofilm has a strong resistance to these biocides. Biofilm removal by physical methods such as ultrasound and mechanical cleaning is reasonably effective but it is difficult to supervise in practice.

To solve this problem, agents that can be used to remove the bacterial biofilm during the process of endoscope cleaning are desirable. The efficacy of enzymatic cleaning agents to reduce the bacterial load and biofilm in laboratory setting has been studied recently^[15]. In addition, the ASGE and the SHEA have recently endorsed enzymatic detergents in reprocessing endoscopes and reusable accessories^[1].

Enzymatic detergents generally containing various combinations of protease, lipase and amylase, require a minimum contact time to enable them to adequately remove the bacterial biofilm^[16]. To date, there has been no report on the bacterial decontamination rate of these enzymatic detergents for endoscope reprocessing.

The bacterial concentration cultured from an endoscope after decontamination is an important factor in determining the risk of transmission from an endoscope to a patient. At present there is no standard bacterial concentration above which the endoscope is considered contaminated. We used the AAMI^[17,18] guidelines established for hemodialysis water, < 200 cfu/mL.

In our series, the overall rate of bacterial contamination above the cut off level from enzymatic detergent and

Table 4 Incidence and types of organisms during study period

Type of organism	Enzymatic detergent (samples, n)	Chlorhexidine (samples, n)	Total, n (%)
<i>Pseudomonas aeruginosa</i>	4	5	9 (60)
<i>Klebsiella</i> species	1	1	2 (13.3)
<i>Enterobacter</i> species	1	0	1 (6.7)
<i>Acinetobacter baumannii</i>	0	1	1 (6.7)
<i>Staphylococcus coagulase negative</i>	1	0	1 (6.7)
<i>Staphylococcus aureus</i>	0	1	1 (6.7)
Total	7	8	15 (100)

chlorhexidine was very low (3.85%). This is significantly different from previous studies that mainly used non-enzymatic cleaning agents which demonstrated a contamination rate as high as 24%^[1,5]. The majority of bacteria identified in this study were Gram-negative bacilli. *Pseudomonas aeruginosa* was the most common species. This is similar to other published series^[19,20]. Though we did not observe any adverse clinical outcomes in the patients exposed to the contaminated endoscopes, the primary goals of this study were not to address this question.

A group from Walter Reed Army Medical Center reported that their surveillance of bacterial culture result from GI endoscopes is as high as 14.5% and that more than half of positive cultures are obtained from therapeutic scopes that were used during emergency procedure, which might be attributed to faulty mechanical cleaning by non-nursing personnel after emergent procedures^[5]. Furthermore, adherence to the standard guideline for endoscope reprocessing can result in a low rate of disease transmission^[1].

In conclusion, 4% chlorhexidine is not worse than enzymatic detergent for endoscope decontamination. Both of them have a very low rate of significant positive bacterial cultures. Further investigations on the effectiveness of the enzymatic agent on decontamination of other organisms apart from aerobic bacteria are required.

Abstract

AIM: To study the effect of a one-year lamivudine regimen in patients with chronic hepatitis B.

METHODS: Medical records of HBeAg negative hepatitis B patients who attended a hepatitis clinic in Tehran between March 2002-March 2004 were evaluated. The patients received 100 mg lamivudine tablets once daily for at least 12 mo. Liver enzymes and complete blood count were checked at baseline and the end of treatment (12th mo) and 6 mo after discontinuation of treatment.

RESULTS: Of all patients, 24 were excluded. Of 71 patients left, 58 (81.7%) were men. Mean age of the patients was 38 ± 14 years. Mean level of ALT in serum was 1437 ± 205 nkat/L at baseline with a significant reduction at the end of treatment to a mean level of 723 ± 92 nkat/L ($P = 0.002$). In 38 patients (53.5%), the ALT level was normal after one-year treatment. Five patients (7.3%) relapsed (biochemically) within 6 mo after discontinuing lamivudine therapy (the patients with good end of treatment response). Mean level of AST in serum was 1060 ± 105 nkat/L at baseline which decreased significantly to 652 ± 75 nkat/L at the end of treatment ($P = 0.002$).

CONCLUSION: Over half (53.5%) of chronic hepatitis B patients with HBeAg negative have normal liver enzyme level at 12-mo lamivudine therapy.

INTRODUCTION

Chronic hepatitis B is a pandemic disease which has been under constant focus because it has long-term serious complications such as hepatic cirrhosis and hepatocellular carcinoma, while it is a preventable condition. About 350 million people have the condition all around the world with 200 000 patients living in Iran^[1]. Length of drug therapy, frequency of recurrences after primary remission, cost of drug regimen and resistance to treatment have led investigators to look for the best and most cost-effective therapeutic regimens for chronic hepatitis B in numerous studies throughout the world. A study in Canada estimated the annual cost of medical care for a patient with chronic hepatitis as high as \$2191 while a cirrhotic patient's medical care costs summed up to an estimated \$11 228 each year^[2].

The objectives of treatment in chronic hepatitis B patients are suppression of viral replication as well as reduction in hepatic inflammation. Lamivudine is a nucleoside analogue which prevents the viral DNA synthesis. Markers such as HBeAg, liver enzymes especially ALT and HBV DNA are used for monitoring patients' response to treatment. Many studies assessed the effectiveness of a number of different therapeutic regimens in different community contexts^[3,4]. In the present study, we investigated the effect of a one-year lamivudine regimen in HBeAg negative patients with chronic hepatitis B who attended a hepatitis clinic in Tehran.

MATERIALS AND METHODS

Patients

Ninety-five medical records of HBeAg negative hepatitis B patients who were registered in a hepatitis clinic in Tehran during March 2002 to March 2004 were evaluated; these patients had positive HBsAg, positive HBeAb, negative HBeAg and sustained or intermittent increased ALT for more than 6 mo. Serum HBV DNA loads were measured by quantitative real-time PCR with primers that amplify

Table 1 Frequency of response and serum liver enzymes during 12-mo treatment of HBeAg negative patients with lamivudine (*n* = 71)

	Baseline	3 mo		6 mo		12 mo	
		Mean	Frequency of response	Mean	Frequency of response	Mean	Frequency of response
ALT (nkat/L)	1437 ± 205	1060 ± 122	65 (91.5%)	813 ± 160	61 (85.9%)	723 ± 92	38 (53.5%)
AST (nkat/L)	1060 ± 105	960 ± 77	68 (95.7%)	770 ± 88	63 (88.7%)	652 ± 75	36 (50.1%)

P = 0.002 for ALT between baseline and 12 mo treatment levels; *P* = 0.002 for AST between baseline and 12 mo treatment levels.

a highly conserved region of the surface gene^[5] and with a detection system that employed molecular beacon technology^[6]. The assay was calibrated using international HBV standards and a plasmid control containing a full-length cloned copy of HBV ayw. The assay has a 7 log₁₀ linear response, with a lower limit of detection of 2×10^5 copies/L and an intraassay coefficient of variability of 15%. All patients with a serum ALT level of more than 2 times of upper normal limit, serum HBV DNA more than 10^5 copies/mL with histopathologic features in liver biopsy consistent with chronic hepatitis (\geq F2) in the Knodell score, [also known as the histologic activity index (HAI)], were included. Those who had evidence of other liver diseases such as hepatitis C, autoimmune liver diseases, non alcoholic fatty liver disease (NAFLD) and non alcoholic steatohepatitis (NASH) in sonography and liver biopsy, and biliary tract diseases, thyroid diseases were excluded. Also, all cases of non-compliance with therapy were excluded.

Methods

Lamivudine was prescribed at a dosage of 100 mg daily. All patients had used the drug for at least 12 mo. Liver enzymes (AST, ALT), complete blood cell counts were checked and recorded at baseline, mo 3 and 6 of treatment, the end of one year treatment and 6 mo after discontinuation of treatment. Forty-two patients had detected serum HBV DNA loads at the end of treatment for their own interest in evaluation of some virological responses.

Statistical analysis

The data were analyzed by SPSS and paired *t* test was used to compare the variables before and after treatment. *P* < 0.05 was taken as significant.

RESULTS

Of all medical records, 24 were withdrawn from the study: 16 patients did not take the prescribed drug correctly, and 8 patients had a follow-up period of less than 6 mo. Of 71 patients left, 58 were men. Mean age of the patients was 38 ± 14 years. The youngest patient was 12 years old while the oldest was 71. Mean weight of patients was 68 ± 14 kg. The lowest weight was 38 kg while the highest was 115 kg. Biochemical markers are as follows: Mean level of hemoglobin was 144 ± 17 g/L with lowest value of 109 g/L and highest value of 175 g/L. Mean white blood cells count was $(6.39 \pm 2.2) \times 10^9$ /L with lowest count of 3.1×10^9 /L and highest count of 11.6×10^9 /L. Mean prothrombin time was 14.3 ± 4.5 s at baseline with

Table 2 Liver serum markers after 3 and 6 mo of termination of one-year regimen in patients who responded to treatment (*n* = 38)

	12 mo Mean	After 3 mo		After 6 mo	
		Mean	Frequency of normal level	Mean	Frequency of normal level
ALT (nkat/L)	538 ± 90	688 ± 157	28 (73.7%)	902 ± 238	25 (65.8%)
AST (nkat/L)	447 ± 122	677 ± 143	32 (84.2%)	803 ± 210	28 (73.7%)

P < 0.04 between 12 mo of and after 6 mo cessation of treatment for ALT, *P* < 0.03 between 12 mo of and after 6 mo cessation of treatment for AST.

shortest time of 11 s and longest time of 46 s. Mean platelet count was $(199.9 \pm 9.03) \times 10^9$ /L. Of all patients, 20 (28.2%) were diagnosed by clinical manifestation while a major proportion of patients (32%-45.0%) were diagnosed incidentally by routine examination on the blood they donated. Only 7 patients were diagnosed through screening and checkups.

In terms of probable routes of transmission, 43.7% had a history of dental procedure, 15.5% had a tattoo and 12.7% underwent a surgical procedure. Of all patients, 44 (62%) had no family history of hepatic disease. Those who had a positive family history had a sibling with the condition, while 4 mothers and 8 fathers had the condition.

A biopsy was taken from 37 patients before the treatment. The biopsy samples were reported based on Knodell score. Of these samples, 73% had a score of less than 6. The liver enzyme levels before, during and after treatment with lamivudine were compared. As shown in Table 1, mean level of ALT in serum was 1437 ± 205 nkat/L at baseline with a significant reduction after treatment to a mean level of 723 ± 92 nkat/L (*P* = 0.002). In 53.5% of patients the ALT level was normal after one-year treatment. Mean level of AST in serum was 1060 ± 105 nkat/L at baseline which decreased significantly to 652 ± 75 nkat/L after treatment (*P* = 0.002). Of 38 (53.5%) patients who responded to treatment, 28 (73.7%) and 25 (65.8%) patients had normal ALT levels after 3 and 6 mo of termination of one-year regimen, respectively. There was no significant elevation of ALT and AST after 3 mo of cessation of treatment compared to 12 mo of treatment, while there was a significant difference between ALT and AST level at 6 mo after termination of and 12 mo of treatment (*P* < 0.04 and *P* < 0.03, respectively, Table 2). At the end of treatment, HBV DNAs were measured in 42 cases and was negative in 24 cases.

Mild adverse events were seen in 12 patients including fatigue in five patients, headache in three, myalgia in two, decreased appetite in two, but there were no reports of therapy discontinuation.

DISCUSSION

The major proportion of the patients were men and the age distribution of sample can be regarded as an adult population. The probable routes of transmission in order of frequency were a history of dental procedure, having a tattoo and a history of surgical procedure, which is consistent with other studies^[7,8]. However, to confirm these results, studies to evaluate the precise role of these risk factors in the transmission of hepatitis B are needed. It is clear that the risk of transmission of hepatitis *via* these procedures has not been evaluated completely in our study. The most frequent event leading to diagnosis was blood donation, which is consistent with other studies^[9]. The most significant factor under focus in our study was the changes in serum levels of liver enzyme especially ALT after treatment by lamivudine. As presented earlier the reduction in serum level of ALK, AST, and ALT were significant at 12 mo of therapy.

In a 3-year retrospective study in the United States, the therapeutic response markers of 119 patients were analyzed. The results showed that 61% of patients had a normal ALT level after treatment. The ALT serum level at baseline was not a significant predictor for response to therapy by lamivudine^[10]. Similar results were reported by a Chinese study on 129 patients with chronic hepatitis. In the current study 60.3% of patients completing a one-year lamivudine treatment had a normal ALT level while the ALT level was normal in only 24.5% of controls at 12 mo. The difference was significant^[11]. A recent study in Pakistan showed that a course of one-year lamivudine treatment was associated with significant reduction in ALT serum level, the treatment was more effective in patients with HBeAg at baseline^[12]. In another study in Austria, 72% of the intervention group had normal ALT level while 29% of controls had normal ALT level^[13]. Most studies of one-year lamivudine treatment for patients with chronic hepatitis B showed a reduction of liver enzyme to normal level at 12 mo^[14-18]. In our study, 53.5% of patients had normal liver enzyme level at 12 mo of lamivudine therapy, which is slightly lower than that of other studies.

In patients whose enzyme level was not normal after lamivudine treatment (50% of patients), it is likely that a resistant mutant is present which warrants further study for confirmation.

<http://www.wjgnet.com/1007-9327/12/4206.asp>

Abstract

AIM: To compare two different *H pylori* stool antigen tests as noninvasive diagnostic methods.

METHODS: The study population consisted of 22 upper gastrointestinal system bleeding patients. Urea breath test (UBT), rapid urease test (RUT) and histopathological examination were applied to all patients. Stool specimens from these patients were examined by rapid STRİP!HpSA and one step simple *H pylori* antigen cassette test for the detection of *H pylori* antigens.

RESULTS: For these 22 patients, 15 (68.2%) were diagnosed as positive and seven (31.8%) were diagnosed negative for *H pylori* infection by the gold standard methods. Whereas 10 (45.5%) were positive and 12 (54.5%) were diagnosed negative by the rapid STRİP!HpSA test. The sensitivity, specificity, positive and negative predictive values were 60%, 86%, 90% and 50%, respectively. When compared to the gold standard methods, these differences were not significant. However, six patients (27.3%) were positive, and 16 (72.7%) were negative by the simple *H pylori* stool antigen cassette test. The sensitivity, specificity, positive and negative predictive values were 33%, 86%, 83% and 38%, respectively. Compared to the gold standard methods, the simple *H pylori* stool antigen cassette test results were significantly different ($P = 0.012$).

CONCLUSION: Rapid STRİP!HpSA test could be used as a routine diagnostic tool in the microbiology laboratory for assessing clinical significance and eradication control of *H pylori* in upper gastrointestinal system bleeding patients.

INTRODUCTION

H pylori is a microaerophilic gram-negative spiral shaped bacterium^[1-3]. It is recognized as the major cause of gastritis, gastric and duodenal ulcers, gastric adenocarcinoma and mucosa-associated lymphoid tissue (MALT) lymphoma, however little is known about its role in functional dyspepsia^[4,5]. *H pylori* colonizes the gastric mucosa and attaches to the gastric epithelial cells^[6]. The prevalence of *H pylori* infection is 70%-90% in developing countries and 25%-50% in developed countries^[2,7]. Person-to-person spread is the most probable mode of transmission. Faecal-oral and oral-oral transmissions have been reported^[8]. Chronic *H pylori* infections of the stomach are increasingly recognized as a major risk factor for the development of gastroduodenal disease. *H pylori* can be detected by noninvasive and invasive methods, the latter requiring endoscopy. Noninvasive testing for *H pylori* can be done by measuring exhaled ¹³C urea breath test (UBT), by serology, by stool antigen tests, by a simple stool PCR and by analyzing body materials such as saliva and urine^[2,9]. Although histopathology and culture of the organism, which are not easily and routinely performed, is considered the gold standard for the diagnosis of *H pylori* infection, we need rapid, accurate and reliable noninvasive methods^[2].

In the case of upper gastrointestinal bleeding which is a major cause of morbidity, mortality and medical care costs, peptic ulcer is the most frequent source of bleeding in these patients. Treatment of *H pylori* infection is more effective than antisecretory non-eradicating therapy in preventing recurrent upper gastrointestinal bleeding from peptic ulcer. Consequently, all patients with peptic ulcer

bleeding should be tested for *H pylori*, and eradication therapy should be prescribed to infected patients^[10].

In the presence of upper gastrointestinal bleeding, the diagnosis of *H pylori* infection may be compromised. The UBT is responsible for a high number of false negative results when it is used to diagnose *H pylori* in patients with upper gastrointestinal bleeding. Coagulation disorders or anticoagulation may prevent a biopsy being taken. The UBT may not be feasible in patients on artificial respiration, or in the presence of impaired consciousness or acute abdominal disease. Therefore, it is suggested that noninvasive methods, such as serology or UBT, be used to identify *H pylori* infection in these patients. In some cases, the indication for *H pylori* eradication therapy is based only on a serological test. Serology alone, however, is a rather inaccurate diagnosis method^[10-12]. An ideal noninvasive test for *H pylori* infection should be safe and acceptable to patients, inexpensive and easy to perform, and with a high degree of sensitivity and specificity^[13].

The diagnostic role of HpSA test and simple *H pylori* antigen cassette test in patients with upper gastrointestinal bleeding remains unclear. Only a few reports have discussed the results of the HpSA test and simple *H pylori* antigen cassette test in these patients^[10-12,14]. The aim of this study was to evaluate diagnostic accuracy of stool antigen tests of rapid STRIP!HpSA and simple *H pylori* antigen cassette test other than HpSA in patients with upper gastrointestinal bleeding. We also compared two different *H pylori* stool antigen tests as noninvasive diagnostic methods with UBT, RUT and histopathology as gold standard methods.

MATERIALS AND METHODS

Patients

The study population consisted of 22 upper gastrointestinal system bleeding patients (13 males, 9 females; mean age, 58 \pm 18 years; age range, 20 to 86 years) between September 2004 and January 2005. UBT (Infai, Germany), rapid urease test (RUT) and histopathological examination were applied to all patients.

The diagnosis of *H pylori* was defined as positive for UBT alone or for histopathology and (or) RUT results defined as gold standards. A patient was classified as *H pylori* negative when UBT and (or) histopathological examination and urease test were both negative.

Endoscopy and biopsy sampling

Two antrum and two corpus biopsy specimens were taken from each patient undergoing upper endoscopy from the same location in the stomach: one from the antrum and the corpus. One of these was used for the rapid urease test and the other two were immediately fixed and transported in 10% phosphate-buffered formalin solution for histopathologic examination.

Histopathologic examination of biopsy specimens

Paraffin-embedded gastric biopsy specimens were routinely processed. Haematoxylin-eosin, Alcian blue and Giemsa stains were used for morphologic examination

of *Helicobacter*-like organisms (HLO) and updated Sydney system was used^[15]. Histopathology was performed by a specialized pathologist.

Stool specimens

Stool specimens from these patients were collected and were kept at -20°C until used. They were examined by rapid STRIP!HpSA (Meridian Bioscience Europe) and one step simple *H pylori* antigen cassette test (Linear Chemicals, S.L. Spain) for the detection of *H pylori* antigens. Both tests were performed in accordance with the manufacturer's specifications.

Stool antigen tests

Rapid STRIP!HpSA (Meridian Bioscience Europe) is a rapid immunoassay using a monoclonal anti-*H pylori* antibody on a strip for the detection of *H pylori* infections in stool specimens. The strip is introduced in a tube containing diluted patient samples and the appearance of a pink-red line in the reading area indicates a positive result after 5 min of incubation at room temperature. A positive test result is evaluated according to the blue band (control line), a distinguishable pink-red band (test line) also appears across the white central zone of the reaction strip. Any pink-red line, even very weak, must be considered as a positive result. By contrast, the sample is considered negative when only one blue coloured band (control line) appears across the white central area of the reaction strip.

Simple *H pylori* antigen cassette test (Linear Chemicals, S.L. Spain) is a rapid immunochromatographic test using a single monoclonal antibody. A diluted fecal sample is placed in an immunochromatographic support and the result is read after 5 min. A positive test will display a red line in the reading area next to a blue control line. Even a minimal trace of a red line was considered positive. By contrast, the sample is considered negative when only the control blue line develops. If no line appears in the reading area the test is considered null^[14,16].

RESULTS

The diagnosis of *H pylori* was defined as positive for UBT alone or for histopathology and (or) RUT results defined by gold standard methods. A patient was classified as *H pylori* negative when histopathological examination and urease test were both negative.

For those 22 patients, 15 (68.2%) were diagnosed as positive and seven (31.8%) negative for *H pylori* infection by the gold standard methods. Meanwhile, 10 (45.5%) were positive and 12 (54.5%) were negative by the rapid STRIP!HpSA test. The sensitivity, specificity, positive and negative predictive values were 60%, 86%, 90% and 50%, respectively. When compared to the gold standard methods, these differences were not statistically significant. However, six patients (27.3%) were positive, and 16 (72.7%) were negative by the simple *H pylori* stool antigen cassette test. The sensitivity, specificity, positive and negative predictive values were 33%, 86%, 83% and 38%, respectively. Compared to the results by the gold standard methods, the simple *H pylori* stool antigen cassette test

Table 1 Results of invasive and noninvasive methods for diagnosis of *H pylori* infection in patients with gastric bleeding

	Positive <i>n</i> (%)	Negative <i>n</i> (%)	False positive <i>n</i> (%)	False negative <i>n</i> (%)
Urea breath test	12 (54.54)	10 (45.45)	2 (9.09)	2 (9.09)
Rapid urease test and/or histopathology	15 (68.18)	7 (31.82)	-	-
Rapid STRIP!HpSA stool antigen test	10 (45.45)	12 (54.54)	1 (4.54)	6 (27.27)
Simple <i>H pylori</i> stool antigen cassette test	6 (27.27)	16 (72.73)	1 (4.54)	10 (45.45)

results were statistically different ($P = 0.012$) (Table 1).

DISCUSSION

Many studies have described the use of ELISA-based HpSA stool antigen kits with either polyclonal or monoclonal antibodies, for diagnosis of *H pylori* infections. In this study we evaluated the diagnostic accuracy of two non-ELISA-based kits, rapid STRIP!HpSA and simple *H pylori* antigen cassette, in patients with upper gastrointestinal bleeding.

Meridian Bioscience, Inc. introduced the concept of detecting *H pylori* antigens in stool specimens, with a microtiter based immunoassay, in 1997. Primer Platinum HpSA, after extensive evaluation, was accepted as an accurate tool for non-invasive *H pylori* infection diagnosis^[17-19]. Recent official European Guidelines recommend the use of either stool antigen or urea breath test for diagnosis and confirmation of eradication four weeks after the end of the treatment^[20].

To our knowledge, three recent studies have evaluated the HpSA test in the presence of gastrointestinal bleeding: Gisbert *et al* ($n = 34$ hospitalized patients; sensitivity of polyclonal ELISA, monoclonal ELISA and monoclonal immunochromatographic test was 74%, 94%, 60%, respectively), Lin *et al* ($n = 93$ patients with bleeding peptic ulcers and 59 patients with nonbleeding peptic ulcers; sensitivity 82% and specificity 68%) and Peitz *et al* ($n = 114$ patients; the sensitivity 84% and specificity 90%)^[10-12].

In another study, Erzin *et al* compared two different stool antigen tests for the primary diagnosis of *H pylori* infection in Turkish patients with dyspepsia. A total of 151 patients who were referred to the endoscopy unit were included. They used FemtoLab *H pylori* enzyme immunoassay and Premier Platinum. The sensitivity and specificity of the monoclonal FemtoLab *H pylori* were 93% and 90% respectively, and of the polyclonal Premier Platinum HpSA were 84% and 67%, respectively. They concluded that Femtolab *H pylori* was an excellent tool for primary diagnosis of *H pylori* in Turkish patients with dyspepsia^[21].

Still in another study, Kato *et al* compared rapid lateral flow stool antigen immunoassay (LFI) and stool antigen enzyme immunoassay (EIA) for the diagnosis of *H pylori* infection in children. One hundred and eighty-two children and adolescents were studied. The sensitivity, specificity and accuracy of the LFI method were 90.6%, 95.8% and

94% respectively and for the EIA method, sensitivity, specificity and accuracy were 96.8%, 99.2% and 98.3%, respectively^[22].

Islam *et al* assessed the performance of the HpSA for the diagnosis of *H pylori* infection and confirming post-therapy eradication compared to generally well accepted clinical reference standard. HpSA was used for the 127 patients. The sensitivity and specificity of HpSA were 67% and 100%, respectively. As a result, HpSA was found to be a reasonably useful diagnostic test for *H pylori*. The HpSA may prove to be useful for the primary care physicians as part of the test-and-treat strategy for dyspepsia, but this may need further study^[23].

Ito *et al* investigated the clinical usefulness of HpSA test for the evaluation of the success of eradication therapy by comparing it with the UBT. A total of 105 patients with *H pylori* infection were enrolled in that study. The diagnostic accuracy of the UBT and the HpSA test was 94.3% and 97.1%, respectively. As a result, HpSA is a very useful and non-invasive diagnostic tool for the evaluation of eradication therapy of *H pylori*. A combination of the HpSA test and the UBT is very practical in the clinical evaluation of eradication therapy of *H pylori*^[24].

Manes *et al* compared the accuracy of HpSA, FemtoLab and UBT in the assessment of eradication of *H pylori* infection 4-8 wk after the completion of antibiotic treatment. Three hundred and forty-six patients were studied. The sensitivity and specificity of HpSA were 73.4% and 97.8%, respectively. The sensitivity and specificity of FemtoLab were 88.3% and 97.8%, respectively. They concluded that both the new stool antigen tests, although less accurate, may represent valuable alternatives to UBT since they were cheap and easy to perform and did not need the use of expensive isotope ratio mass spectrometers. Thus, due to its high level of sensitivity, the new monoclonal stool test could be preferred for the post-eradication setting of *H pylori* infection^[25].

Five recent studies done by Shaikh *et al* ($n = 86$ children; sensitivity 76% and specificity 61%), Raguza *et al* (133 children; sensitivity 94.6% and specificity 96.6%), de Carvalho Costa Cardinali *et al* (161 children; sensitivity 96.9% and specificity 100%), van Doorn *et al* (106 children; sensitivity 100% and specificity 92%) and Elitsur *et al* (121 children; sensitivity 67% and specificity 99%) evaluated the HpSA test in asymptomatic children with *H pylori* infection compared to other methods. It was demonstrated that the commercial polyclonal HpSA test can not replace histopathologic findings as the best standard for the diagnosis of *H pylori* infection in children^[26-30].

Syam *et al* evaluated the HpSA for the detection of *H pylori* infection in 63 dyspeptic patients. The sensitivity and specificity of HpSA were 66.7% and 78.9%, respectively. They concluded that HpSA stool test may be useful for the primary diagnosis of *H pylori* infection in peptic ulcer^[31].

Arikan *et al* conducted a prospective study to examine the reliability of the HpSA test. The HpSA test had a 91% sensitivity and 83% specificity. HpSA test proved to be as reliable as pathological examination for confirming the existence of *H pylori* in humans. Thus, the HpSA test was a useful method for detecting *H pylori* in patients for whom

endoscopy was not indicated^[32].

Lopez *et al* compared the efficacy of several non-invasive methods and assessed comparative reliability of the stool tests. Eighty-six patients were applied FemtoLab, HpSA and Simple *H pylori* tests. The sensitivity and specificity of HpSA were 58% and 96%, respectively and the sensitivity and specificity of simple *H pylori* were 61% and 78%, respectively. According to the results, they suggested that UBT was the most reliable diagnostic examination for determining *H pylori* status in patients with chronic renal failure on dialysis because stool tests showed heterogeneous results^[14].

Inelmen *et al* evaluated the accuracy of HpSA in the diagnosis of *H pylori* infection in 85 elderly patients affected by medication. Among 56 patients who were not taking PPIs, the sensitivity and specificity of the HpSA test were 76% and 93%, respectively. Among 29 patients who had received pharmacological therapy with PPIs, the sensitivity and specificity of HpSA test were, respectively, 82% and 83%. They concluded that HpSA was a useful test in elderly people. The test was easy, simple to perform and non-invasive^[13].

Chisholm *et al* conducted a comparative evaluation of the performances of Premier Platinum HpSA ELISA, Amplified IDEIA HpStAR ELISA and ImmunoCard STAT!HpSA kits. ImmunoCard STAT!HpSA was demonstrated easier to perform than ELISA and was more sensitive than the HpSA kit. Compared with the IDEIA HpStAR kit, the ImmunoCard test was less sensitive (87.8% versus 95.9%, respectively) and specific (89.4% versus 100.0%, respectively). The Amplified IDEIA HpStAR kit was the most sensitive and specific of the three tests and it was available for pre-treatment, noninvasive detection of *H pylori* in stool samples in an English adult dyspeptic population^[33].

Previously we studied forty adult Turkish dyspeptic patients. Two antrum and corpus biopsies were taken from each patient and RUT and histopathology were applied to all patients as gold standard methods for the diagnosis of *H pylori* infection. Stool specimens were examined by polyclonal Premier Platinum HpSA and simple *H pylori* cassette test before and after the eradication therapy. When we compared with gold standard methods, the diagnostic accuracy of Premier Platinum HpSA and simple *H pylori* cassette tests were 75% and 87.5%, respectively.

In that study the HpSA test was polyclonal test but we wanted to compare it with the available monoclonal Simple *H pylori* cassette test^[34]. The new Rapid STRIP!HpSA test was also used in this group of patients (unpublished data). As no results have been published to date on the rapid STRIP!HpSA test and the simple *H pylori* stool antigen cassette test, we undertook the present study. The simple *H pylori* stool antigen cassette test, although easy to use, gave a sensitivity that was too low (33%) for the reliable diagnosis of *H pylori* infection. However, the rapid STRIP!HpSA test, which was also convenient to use, was more sensitive (60%). We conclude that because it is a monoclonal test, rapid STRIP!HpSA, can be used as a routine diagnostic tool in the microbiology laboratory for assessing clinical significance and eradication control of *H pylori* in upper gastrointestinal bleeding patients.

Abstract

AIM: To review the experience of a major medical teaching center with diagnostic and therapeutic colonoscopies and to assess the incidence and management of related colonic perforations.

METHODS: All colonoscopies performed between January 1994 and December 2001 were studied. Data on patients, colonoscopic reports and procedure-related complications were collected from the departmental computerized database. The medical records of the patients with post procedural colonic perforation were reviewed.

RESULTS: A total of 12 067 colonoscopies were performed during the 8 years of the study. Seven colonoscopic perforations (4 females, 3 males) were diagnosed (0.058%). Five occurred during diagnostic and two during therapeutic colonoscopy. Six were suspected during or immediately after colonoscopy. All except one had signs of diffuse tenderness and underwent immediate operation with primary repair done in 4 patients. No deaths were reported.

CONCLUSION: Perforation rate during colonoscopy is low. Nevertheless, it is a serious complication and its early recognition and treatment are essential to optimize outcome. In patients with diffuse peritonitis early operative intervention makes primary repair a safe option.

INTRODUCTION

Since first introduction in 1969^[1] flexible colonoscopy has been accepted as the best method for the diagnosis, treatment and follow-up of colorectal pathologies. Nevertheless, being an invasive procedure it harbors major risks of bleeding, perforation and even death^[2-4]. The incidence of perforation is 0.2% to 0.4% for diagnostic colonoscopy and 0.3% to 1.0% with polypectomy^[2,5,6]. Recent large series have reported lower perforation rates of 0.002% to 0.19%^[7-10]. The aim of the present study was to review the experience of a major university affiliated medical center with colonoscopy and to assess the incidence of perforations and their management.

MATERIALS AND METHODS

A total of 12067 colonoscopies were performed between January 1994 and December 2001. Data on patients undergoing colonoscopy was entered into a computerized database and included demographic patient information and detailed colonoscopic reports. A retrospective review of the medical records of all patients diagnosed with colonic perforation after colonoscopy was performed. The following parameters were analyzed: patient age and sex, background disease, laboratory work-up, indication to endoscopy, interval from the procedure to the diagnosis of perforation, clinical presentation, location, management, and outcome of the perforation.

RESULTS

Of 12 067 colonoscopies performed, seven were associated with colonic perforation. There were 4 women and 3 men with a mean age of 70 years (range 31-80) (Table 1). The procedure was done on an outpatient basis in all cases. Five perforations occurred during diagnostic colonoscopy, one during polypectomy and one during electrocoagulation of an arteriovenous malformation. Six perforations were

identified during the procedure or immediately thereafter, and one patient who had a cecal polyp coagulated with hot biopsy forceps, was diagnosed about 24 h after the procedure. In 3 patients perforation was suspected when a hole in the intestinal wall was noted. All the patients had severe abdominal pain and distention. Plain abdominal roentgenograms performed in all 7 patients showed free intraperitoneal air in 4, retroperitoneum in 2 and no abnormalities in one patient.

Six patients had, on examination, diffuse abdominal tenderness and underwent immediate operation. All five perforations that occurred during diagnostic colonoscopy were found to be in the sigmoid colon, and repair was achieved mostly by debridement and primary suture of the perforated site. The postoperative period was uneventful. One patient was treated nonoperatively with intravenous fluids, antibiotics and intestinal rest and was placed under close clinical observation. He was afebrile and had localized abdominal tenderness with no peritoneal signs or leukocytosis. The patient who was diagnosed and operated on about 24 h post colonoscopy had a wound infection. Median hospital stay of the operated group was 8 d (range 4-15). The patient who was treated nonoperatively was hospitalized for 13 d. There were no deaths.

DISCUSSION

Colonic perforation occurs rarely during colonoscopy but it is still considered a major complication^[2-4]. During the 8-year period reviewed, there was a combined diagnostic and therapeutic colonoscopic perforation rate of 0.058%. This rate is lower than that in most of the published series^[7-10]. The management of colonoscopic perforations may be conservative or surgical, and should be selective. The choice of treatment depends on the mechanism and size of the perforation, adequacy of bowel preparation, timing of diagnosis, the patient's clinical condition and the primary colonic pathology^[9-16]. Table 1 summarizes some reports evaluating the incidence and management of colonoscopic perforations. The low morbidity rate in our series is probably attributed to the combination of supportive treatment and early surgical intervention, which resulted in no intraperitoneal contamination in 4 out of 5 patients, and therefore primary repair could be completed safely. Early surgical exploration in all patients with peritoneal irritation or free air on abdominal X-ray is recommended by other authors as well^[10,17,18]. Farley *et al*^[10] reported on 43 perforations among 57 028 colonoscopies (0.075%). Forty-two were treated by emergency laparotomy. Most patients underwent primary repair or limited resection with anastomosis. The authors concluded that in order to minimize morbidity and mortality prompt operative intervention is the best strategy in most patients. Dafnis *et al*^[18] reported on 8 perforations in 6066 colonoscopies (0.13%). All patients underwent surgery. Most perforations were repaired by primary closure, and the postoperative course was uneventful in all patients.

Perforations occurring during diagnostic colonoscopy are due to direct mechanical penetration with the instrument tip, sharp flexion of the colonoscope, high pressure applied when a loop is formed or barotrauma

¹Three of 11 patients failed medical treatment and required surgery; ²Two patients were treated after colonoscopy performed elsewhere; ³Includes only colonoscopic polypectomies.

as a result of aggressive gas insufflation^[19,20]. The most common underlying cause in the present study was direct mechanical injury of the colonic wall by the colonoscope. It occurred in patients with diverticular disease or a strictured, severely diseased colonic segment. These risk factors are in accordance with those noted in the literature^[21,22]. Perforations during therapeutic colonoscopy occur as a result of similar mechanisms, as well as from thermal or electrical injury, as in two cases in the present study^[11,12]. The most frequent site of perforation was the sigmoid colon, as in other studies^[10,13,18,23,24]. This may be explained by its anatomical characteristics of frequent redundancy or narrowing from diverticular disease or adhesions after previous pelvic operations^[25].

In conclusion, although the rate of perforation during colonoscopy is low, it is a serious complication and its early recognition and treatment are essential to optimize outcome. Surgery is mandatory in all patients with generalized peritoneal irritation. Early operative intervention makes primary repair a good and safe option, with low morbidity and mortality, unless there is a colonic pathology that necessitates resection. Selected patients with localized peritoneal irritation can be managed nonoperatively.

Abstract

AIM: To observe the dynamic changes of liver microcirculation *in vivo* after arterial embolization with degradable starch microspheres (DSM).

METHODS: DSM were injected into the proper hepatic artery through a silastic tube inserted retrogradely in gastroduodenal artery (GDA) of SD rats. Fluorescent microscopy was used to evaluate the dynamic changes of blood flow through the terminal portal venules (TPVs), sinusoids and terminal hepatic venules (THVs). The movements of DSM debris were also recorded. Six hours after injection of DSM, percentages of THVs with completely stagnant blood flow were recorded.

RESULTS: Two phases of blood flow change were recorded. In phase one: after intra-arterial injection of DSM, slow or stagnant blood flow was immediately recorded in TPVs, sinusoids and THVs. This change was reversible, and blood flow resumed completely. In phase two: after phase one, blood flow in TPVs changed again and three patterns of blood flow were recorded. Six hours after DSM injection, 36.9% \pm 9.2% of THVs were found with completely stagnant blood flow.

CONCLUSION: DSM can stop the microcirculatory blood flow in some areas of liver parenchyma. Liver parenchyma supplied by arteries with larger A-P shunt is considered at a higher risk of total microcirculatory blood stagnation after injection of DSM through hepatic artery.

INTRODUCTION

It has been accepted that transarterial chemoembolization (TACE) is an effective method to treat the unresectable hepatocellular carcinoma (HCC). With the characteristics of long retention time in the tumor tissue, iodinated poppyseed oil (Lipiodol) has been frequently used as the embolization material in clinical practice^[1-4]. Animal experiments demonstrated that after injection of iodized oil into the hepatic artery, small Lipiodol drops could be found in the terminal portal venules (TPVs), which was assumed passing through the pathway of arterial-portal anastomosis such as the peribiliary plexus^[5-7]. When Lipiodol drops flow into the sinusoids, they can severely occlude the blood flow, cause the stagnation of local microcirculation, and further lead to ischemic liver parenchyma injury^[8,9]. Super-selective technique with microcatheter and guidewires has been considered as a safe and effective way to treat HCC. Under some conditions in which liver function is severely damaged or blood supply of HCC is so complex that it is impossible to super-select the tumor feeding arteries, TACE is developed. Degradable starch microspheres (DSM), a temporary artery embolizer has been increasingly used as an alternative to Lipiodol in some particular situations^[10-12]. It has also been suggested that, when the tumor feeding artery cannot be super-selected by microcatheter and guidewire, one-shot injection of DSM before TACE can be regarded as a practical method to protect the tumor free liver tissue from the injury caused by Lipiodol inflow following TAE. To fully understand its effects on liver microcirculation, we injected DSM through proper hepatic artery of rats, and the dynamic changes of liver microcirculation were evaluated by *in vivo* fluorescent microscopic observations.

MATERIALS AND METHODS

Animal model

Ten Sprague-Dawley rats weighing 300 to 450 g were used in compliance with the regulations and the Guide for the Care and Use of Laboratory Animals. The animals were

fed with standard food pellets and tap water *ad libitum*. They were deprived of food but obtained free access to water for 12 h before the experiments. Anesthesia was performed by intra-peritoneal injection of 50 mg/kg sodium pentobarbital. The left femoral vein was cannulated with a 1F silastic tube (Natsume Corp. Tokyo, Japan) for additional anesthesia and liquid transfusion during the procedure. After a midline abdominal incision, the liver was carefully retracted to expose the gastroduodenal artery (GDA), which was catheterized by another 1F silastic tube (Natsume Corp., Tokyo, Japan) with its tip placed before the bifurcation that leads to the proper hepatic artery. The left lobe of liver was gently exteriorized and positioned over the window of the microscope stage. The liver parenchyma was covered with a small piece of plastic wrap; its surface was constantly irrigated with Ringer's solution at the body temperature.

Fluorescence microscopy

The exteriorized left liver lobe was transilluminated with monochromatic light generated by a prism monochromator equipped with a xenon lamp. Microscopic images of the microvasculatures were obtained with objective lenses (magnification, $\times 10$, $\times 20$) and an ocular lens (magnification, $\times 10$). DSM (Yakult Honsha Co., Ltd., Tokyo, Japan) 12 mg in 0.2 mL was prepared in a 1 mL syringe and the solution was made uniform before injection. After infusion of 1 g/L fluorescent sodium 0.1 mL into the cannulated GDA, DSM was injected gently in one minute. The *in vivo*

Figure 2 After infusion of fluorescent sodium from the GDA to proper hepatic artery, blood flow from TPVs to THVs through sinusoids can be clearly visualized.

microscopic images of the following procedure were recorded on videotapes.

In vivo evaluation

For each rat, areas with best visualization were selected for evaluation. Six hours later, 1 g/L fluorescent sodium 0.1 mL was infused through the cannulated left femoral vein to check the whole surface of liver lobe for a complete confirmation of the liver microcirculation. One hundred THVs were randomly selected during the horizontal and vertical movements of the microscope. THVs with completely stopped blood flow were statistically counted.

Statistical analysis

Data analysis was performed employing the Statistical Package for the Social Sciences Version 12.0 for Windows (SPSS[®] Inc., Chicago IL, USA). Results of the descriptive statistical analysis were presented as mean \pm SD.

RESULTS

Clear images of the liver microcirculation (TPVs, sinusoids, and THVs) could be seen under *in vivo* fluorescent microscope (Figure 1). Blood flow from one TPV was drained through the sinusoids into several THVs; similarly, one particular THV provided venular drainage for several TPVs. Hepatic arterioles, the other afferent vessels in the liver, usually could not be visualized (Figure 2).

Blood flow in TPVs after DSM injection

Blood flow through TPVs demonstrated an immediate response after DSM injection. The speed of blood flow dropped dramatically at once. In 2.0 ± 0.8 min (Max 3 min), the blood flow in the observed area completely stopped. After that, blood flow through TPVs resumed gradually; 12.7 ± 2.1 min (Max 15 min) after injection of the DSM, blood flow through TPVs completely recovered (Table 1). No evidence of DSM or its disaggregated debris could be recorded within this time interval. For convenient explanation, we named this period as "phase one", and the

Figure 3 A: Small debris can enter sinusoids through TPV (arrow); B: The same TPV as image 3, debris of DSM continuously enter sinusoids through TPV, blood flow in TPV is intermittent but not stagnant.

Figure 4 Percentage of the completely stagnant THVs 6 h after DSM injection in 10 rats. The minimal percentage is 22%, and the maximal is 53%.

blood flow changes afterward as “phase two”. In phase two, three different types of blood flow changes in TPVs could be recorded.

Type one: The speed of blood flow slowed down again, and then completely stopped. This phenomenon could be found as early as 25 min after DSM injection and last for the whole procedure. The TPVs could never resume their blood flow during the observational period. DSM or its debris could be hardly found in TPVs in this type.

Type two: The speed of blood flow in TPVs decreased at different level, either slightly striking or some times intermittent, however the stagnation was not recorded during the whole observation time. Numerous small pieces of debris with irregular shapes could be found to flow through and drain into the distal sinusoids (Figure 3A and B).

Type three: In particular areas, TPVs kept a constant flow after phase one. The blood flow did not change during the whole procedure. DSM or its debris could not be recorded in these TPVs.

Blood flow in sinusoids and THVs

The blood flow through sinusoids and THVs followed the changes of TPVs in phase one. They also demonstrated a dramatic decrease of blood flow speed after DSM injection. Some even completely stopped. Nevertheless, it could be fully recovered.

During the following period, three kinds of blood flow, similar to that of the TPVs could also be recorded in sinusoids and THVs, ie, completely stagnant blood flow, intermittent and slow flow, normal flow.

DSM debris in the hepatic microvasculature

Twenty minutes (the earliest time) after injection of DSM, small pieces of debris could be found in some sinusoids. Some of the debris, with a relatively small size, could directly pass through the sinusoids and flow into THVs. Some debris, with larger size, could occlude the corresponding sinusoids. This occlusion was temporary; recanalization could be achieved by opening of collaterals or further distal movement of the disaggregated debris. The number of DSM debris reached a peak value 1 h after DSM injection. No DSM particles with the original size and shape could be found in sinusoids and THVs. Numerous disaggregated debris with small diameter entered the THVs.

Hepatic microcirculation after DSM injection

Six hours after DSM injection, the brightness of the liver surface was not uniform after infusion of fluorescent sodium through the femoral vein, suggesting the heterogeneous nature of the liver blood flow. Areas with completely stagnant blood flow in TPVs, THVs and sinusoids could be found sparsely distributed among the areas with normal or sluggish blood flow. Approximately $36.9\% \pm 9.2\%$ of randomly selected THVs were found with completely stagnant blood flow (Figure 4).

DISCUSSION

DSM is a kind of embolization material that can temporarily occlude the vessels. The degradation of

DSM is considered to be caused by a combination of the chemical effects of amylase and the striking force of the vortexial arterial flow. Hepatic arterial perfusion is essential for an optimal sinusoidal function because it maintains transsinusoidal pressure^[13]. After intra-artery injection of DSM, immediately slow down or even stop of the blood flow in TPVs, sinusoids, and THVs could be found. It is considered that a sudden reduction of arterial blood flow is caused by numerous DSM casts embolization. The blocked blood flow could soon be resumed due to a compensatory increase of portal blood flow as a buffer response. This can explain the phenomenon of phase one which happened after the DSM injection. After a complete recovery of blood flow in phase one, presinusoidal A-P shunt^[14-16] should be the reason for the appearance of three types of blood flow in phase two. We have found in our previous study that after intra-arterial injection of DSM, various sizes of DSM casts are formed inside the arterioles which can block the arterial blood flow. The proximal end of DSM casts will disaggregate under the pumping force of vortexial arterial blood flow. Debris with different sizes will be discharged at the proximal end and further occlude the branch of the original artery. We presume that A-P shunts have various size, some larger debris of the disaggregated DSM can pass through larger A-P shunts and reach the portal side that is proximal to TPVs. Debris accumulated at the portal side form a number of emboli. These emboli, if big enough, will completely shut the portal blood flow to distal TPVs and be harder to disaggregate because the pumping force of portal blood stream is much weaker than that of the arterial one. This means, at certain areas of liver parenchyma, both arterial and portal blood flows are stopped by DSM casts and the debris emboli. Few debris could be found in the distal TPVs because the proximal portion of TPVs was completely occluded by the debris emboli. This explains the type one phenomenon. For some small A-P shunt, only small-sized debris can pass through; and these smaller debris could partially occlude portal branch and was easily to be pushed distally. Some could reach TPVs and flow through sinusoids to THVs. This caused type two phenomenon. As for the type three phenomenon, it is considered that no debris of DSM entered portal site through A-P shunt.

After entering sinusoids, debris could occlude sinusoids. For a single sinusoid, the blood flow can be resumed either by further disaggregation of the debris or by opening of the small collaterals. Small DSM debris, when passing through sinusoid, will flow freely into THVs. Six hours after injection of DSM, we found 22%-53% (mean: 36.9% \pm 9.2%) of THVs with totally stagnant blood flow. That means all sinusoids draining blood to these THVs had been stagnant in blood flow. The corresponding liver parenchyma received no fresh blood supply during this time. The cause of stagnant blood flow in sinusoids surrounding THVs is presumed at the presinusoidal level. We assume that the occlusion site was the presinusoidal portal vein with relatively larger diameter. After arterial embolization by DSM casts, the more bigger debris of DSM entered this portion through larger A-P shunt and accumulation of these debris formed intravascular

emboli. Weak pumping force of portal blood flow could not disaggregate these emboli, and the amylase could take effects more slowly because little fresh blood flow could reach those emboli. With all those factors, the emboli could maintain stable during a fairly long period of time. Thus, a simultaneous blockade of the arterial and portal blood flow could lead to a completely stagnant blood flow in distal sinusoids. Because the amylase in blood flow will chemically disaggregate the DSM and its debris, whether the TPVs, sinusoids and THVs can resume their blood flow later needs to be further studied.

It is preliminarily confirmed in this study that DSM, with its degradation products, can enter portal vein through hepatic arterial injection. It can completely stop the microcirculatory blood flow in some areas of liver parenchyma. A-P shunt is considered to be a determining factor during the procedure. Liver parenchyma supplied by arteries with larger A-P shunt is presumed to have higher risk of total microcirculatory blood stagnation after injection of DSM through hepatic artery. Whether the use of DSM can provide protective effects during TACE awaits further evaluation.

Abstract

AIM: To investigate the clinical significance and presence of mutations in the surface (S) and overlapping polymerase gene of hepatitis B patients with coexisting HBsAg and anti-HBs.

METHODS: Twenty-three patients with chronic hepatitis B were studied. Of the 23 patients, 11 were both positive for hepatitis B virus (HBV) surface antigen (HBsAg) and antibody to HBV surface antigen (anti-HBs), 12 were negative for anti-HBs while positive for HBsAg. DNA was extracted from 200 μ L serum of the patients. Nucleotide of the surface and overlapping polymerase gene from HBV-infected patients was amplified by PCR, and the PCR products were sequenced.

RESULTS: Forty-one mutations were found within the surface gene protein of HBV in 15 patients (10 with coexisting HBsAg and anti-HBs). Six (14.6%) out of 41 mutations were located at "α" determinant region in 5 patients (4 positive for HBsAg and anti-HBs). Eleven mutations (26.8%) occurred in the downstream or upstream of "α" determinant region. Lamivudine (LMV)-selected mutations were found in three patients who developed anti-HBs, which occurred in amino acid positions (196, 198, 199) of the surface protein and in YMDD motif (M204I/V) of the polymerase protein simultaneously. Presence of these mutations did not relate to changes in ALT and HBV DNA levels.

CONCLUSION: Besides mutations in the "α" determinant region, mutations at downstream or upstream of the "α" determinant region may contribute to the development of anti-HBs. These mutations do not block the replicating competency of HBV in the presence of high titer of anti-HBs.

INTRODUCTION

Hepatitis B virus (HBV) infection leads to a wide spectrum of liver diseases, including acute self-limited infection, asymptomatic carrier state, fulminant and chronic hepatitis, which could result in life-threatening sequelae, such as liver cirrhosis and hepatocellular carcinoma^[1]. In acute self-limited infection, clearance of HBV is associated with seroconversion from HBsAg to anti-HBs due to the coordination of humoral and cellular immune response^[2,3]. However, this condition is very rare in chronic infection patients, especially in patients infected at birth, partly because of inadequate humoral and cellular immunity of the host^[4]. Furthermore, the prevalence of HBV mutations that could escape from humoral and cellular immunity may result in persistent virus infection.

The S gene of HBV has three open reading frames (ORF), including preS1, preS2 and S region. The surface gene contains a neutralizing epitope named "α" determinant region located at the condon positions 124-147. Mutations in this region could alter the antigenicity of HBsAg, causing failure of anti-HBs to neutralize HBsAg and escaping from the host's immune system, resulting in active viral replication and liver disease^[5,6]. It is reported that mutations of some epitopes located at downstream of the "α" determinant region may also affect the neutralization domain^[7]. The surface gene overlaps with the catalytic domains of polymerase^[7]. Thus, mutations in the surface gene have an effect on the polymerase gene while the polymerase gene mutations also impact the surface gene^[8,9].

The present study was to analyze the prevalence of mutations in the surface and polymerase gene of HBV in patients with coexisting anti-HBs and HBsAg.

MATERIALS AND METHODS

Patients

Sera were obtained from 23 Chinese patients with chronic HBV infection. Presence of HBsAg, anti-HBs, hepatitis e antigen (HBeAg), antibody to HBeAg (anti-HBeAg) was detected by commercially available kits according to the instructions. All patients were positive for HBsAg. Of the 23 patients, 11 were positive for anti-HBs (No. 1 to 11) and 20 were positive for HBeAg. Fifteen out of the 23 patients had elevated alanine aminotransferases (ALT) levels. Virological and biochemical parameters of 8 patients positive for anti-HBs and HBsAg at the time of HBV sequence analysis were analyzed. No patients had a history of HBV vaccination or hyper immune globulin therapy. Three patients positive for HBsAg and anti-HBs had a history of lamivudine (LMV) therapy for more than 1 year. All patients were negative for antibody to hepatitis C virus. Sera were stored at -20°C for DNA extraction.

Primer synthesis

For polymerase chain reaction (PCR), primers were synthesized according to the published sequences. Sequences of the primers for amplifying the surface gene of HBV are as follows: HBV S1: 5'-TTACAGGCGGGGTTTTC-3' (nt 197, sense); HBV S2: 5'-AAGGGACTCAAGATG-3' (nt 789, anti-sense). Primers of HBV P1, 5'-GTATTCCTCCATCCATCATCC-3' (nt 599, sense) and HBV P2, 5'-CAAGGCAGGATAGCCACATT-3' (nt 1033, anti-sense) were used for amplification of polymerase gene of HBV.

PCR amplification

DNA was extracted from 200 µL serum using a blood DNA kit (Omega, USA). Two microlitres of DNA template and 1 µL of each of the primers, 2 µL of 10 × dNTP and 0.5 U of Taq DNA polymerase (Promega, US) were used in a volume of 50 µL for PCR. After denaturation at 94°C for 5 min, the reaction for amplification of the surface gene with primers HBV S1 and HBV S2 was carried out at 94°C for 30 s, at 56°C for 1 min, and at 72°C for 1 min for 35 cycles, and a final extension at 72°C for 10 min. The reaction with primers HBV P1 and HBV P2 for amplifying the polymerase gene was performed at 94°C for 30 s, at 56°C for 30 min, at 72°C for 1 min for 35 cycles, and a final extension at 72°C for 10 min.

Sequencing of PCR products

The PCR products were purified by centrifugation. Direct sequence of the gene was determined using Taq Dye-Deoxy terminator sequencing kits. Sequencing reactions were analyzed on an automated DNA sequencer (model 377, ABI100, Applied Biosystem). Deduced amino acid sequences were compared with the reported consensus sequence of genotype C, subtype adw, HBV clone (PAK66, PIWK146). Mutations were determined as sequence difference from the consensus sequence.

The nucleotide sequence data presented in this paper could be found in the DDBJ/EMBL/GeneBank nucleotide sequence databases with the access numbers AB014381,

Table 1 Clinical data of two groups of patients

Clinical factors	Groups		P
	Positive anti-HBs	Negative anti-HBs	
Age in years	40.3 ± 13.2	42.5 ± 14.7	0.7672
Sex, M/F	5/6	7/5	0.6531
Patients with HbsAg, n (%)	11 (100)	12 (100)	
Patients with HbeAg, n (%)	9 (81.8)	11 (91.7)	
Patients with anti-HBe, n (%)	1 (9.1)	0 (0)	
ALT in IU/L	65.9 ± 30.5	98.9 ± 42.0	0.6541
HBV-DNA (log)	7.0 ± 1.60	6.87 ± 0.9	0.5263
Number of amino acid residues			
mutations in S gene, n (%)	34/41 (82.9)	7/41 (17.1)	

Fisher's exact test was used for the categorized data; two-tailed Student's *t* test was used for ALT levels, age and HBV DNA levels (log, copies mL⁻¹).

AB033554, AY812744, AY812743, AY800249, AY123424, AF100309.

Statistical analysis

Two-tailed Student's *t* test was used to assess the difference in ALT levels, age, HBV DNA levels between the two groups of patients. Fisher's exact test was used for the analysis of difference in mutations between the two groups. *P* < 0.05 was considered statistically significant.

RESULTS

Comparison of the clinical features between the two groups of patients is shown in Table 1. There was no significant difference in ALT levels, age, HBV DNA levels between the two groups (*P* > 0.05). The relevant biochemical and virological parameters of 8 patients (No.1 to 6, No.8 and 10) are shown in Table 2.

Nucleotide and deduced amino acid sequences of surface region and polymerase gene of HBV were performed in 23 patients. Comparison with the published HBV sequence showed that 21 (91.3%) out of 23 patients were infected with genotype C, 1 with genotype B and 1 with genotype D.15 (65.2%). Of the 23 patients who developed amino acid mutations in the surface gene protein, 10 were positive for anti-HBs and 5 were negative for anti-HBs. Mutations at the "α" determinant region were observed in 5 patients (5/15, 33.3%) (Figure 1). Forty-one mutations were found at 27 amino acid positions within the surface gene of HBV, and 34 mutations (82.9%, 34/41) were presented in the patients with coexisting HBsAg and anti-HBs. Six (14.6%) out of 41 mutations were located at the "α" determinant region, and 4 mutations were presented in the first loop (positions 124-137), the others were in the second loop (positions 139-147, S143T, G145R). Six mutations at amino acid residues 40 (N40S) and 47 (T47V, T47K, T47R) coincident with HLA class I-restricted (CTL) epitope^[10] were observed in 5 patients, 11 mutations (26.8%) occurred in 6 patients within the major hydrophilic regions of upstream and downstream of the "α" determinant region (amino acid positions 99-169), 6 mutations at 3 amino acid positions (196, 198 and 199) associated with LMV-selected

13	-	L	-	-	-	M	-	-

mutation were observed in 5 patients.

Because the S gene overlaps with the major catalytic domain of the polymerase gene, the mutations near the YMDD motif of the polymerase gene were studied. Eight mutations within amino acid residues 518-569 of the polymerase gene were observed at 4 positions (V173L, L180M, M204I/V, S223A) in 5 patients. Three patients who received long term LMV therapy and developed anti-HBs at the time of sequencing, had YMDD mutations (M204I/V) in polymerase gene and the S gene mutations at amino acid positions 196, 198 and 199 (Table 3).

Five out of 15 (33.3%) patients who had amino acid mutations did not develop anti-HBs, while T131N, L162Q, W196L mutations in the S gene and L180M mutation in polymerase gene were simultaneously observed in only one of these patients.

DISCUSSION

HBV is the most common etiologic agent of chronic and often fetal liver diseases world wide. HBV variants present during natural infection or anti-virus therapy, and contribute to disease persistence. The S gene of HBV is crucial for binding and infectivity, and "α" determinant of the surface gene may form a target of humoral neutralizing antibody. Mutations in the region affect the binding of anti-HBs to corresponding HBsAg^[5], produce escape from the neutralizing antibody, result in persistent infection and replication of HBV, even the relatively high titer anti-HBs develops.

In the present study, 15 patients had amino acid

mutations in the surface gene of HBV, and 10 of them were positive for anti-HBs. Forty-one mutations were found in 23 patients, and 34 (82.9%) mutations were presented in the patients with coexisting HBsAg and anti-HBs. only 6 mutations within the "α" determinant region were observed in 5 patients (4 for anti-HBs positive). Passive or active immune therapy may develop the escape mutation^[11,12], which has a point mutation from guanosine to adenosine at nucleotide 587 (condon 145, G145R). Mutation of G145R, however, was only seen in 1 patient in our study, and it may be the reason why no patient in our cohort received active or passive hepatitis B immunization. The data suggest that mutation within the "α" determinant region may play an important role in the presence of anti-HBs. A recent study showed that mutation in the "α" determinant region contributes to the most therapy failure, but there are still some therapy failures associated with mutations in the major hydrophilic region of the surface gene located at downstream or upstream of the "α" determinant (positions 99-169)^[13]. In the present study, 26.8% mutations were observed in the above mention region, suggesting that these mutations also change the antigenicity of HBsAg and contribute to the development of anti-HBs. One patient who had amino acid mutation (T131N) in the "α" determinant region did not develop anti-HBs. It may be due to the relatively lower sensitive assays because it was reported that anti-HBs complexed with HBsAg could be detected in nearly all patients with chronic hepatitis B when tested by a highly sensitive immunoassay^[14].

Lamivudine-selected mutations in the S gene of HBV have been demonstrated by sequencing HBV isolated from the serum of patients treated with long-term LMV^[15,16]. In addition, LMV-selected mutations within the HBsAg protein downstream of the "α" determinant (I195M, W196S and M198I) lead to a decrease in the antigenicity of the protein and binding to the anti-HBs antibodies, therefore poorly inhibiting their interaction with wild-type HBsAg^[17]. In our study, the change of methionine to isoleucine (rtM204I) or valine (rtM204V) was found in the YMDD motif of the polymerase gene protein in three patients who received long-term LMV therapy. These patients also had W196L/W196F or W199C mutations within the surface gene protein of HBV simultaneously.

The surface gene of HBV also includes the putative

Figure 1 Amino acid mutations in the surface gene of HBV. Positions of mutation in deduced amino acid residues are indicated by vertical line below the surface protein of HBV. The consensus sequences of A, B and D different from those of genotype C are listed in parentheses. Dashes mean residues identical to these reference residues. Patients 1 to 11 were positive for HBsAg and anti-HBs, the others were negative for anti-HBs.

HLA class I-restricted cytotoxic T lymphocyte (CTL) epitopes^[2]. Because the putative CTL epitope mutations result in epitope inactivation and T cell receptor antagonism^[18], mutant virus could evade cellular immunity and lead to persistent infection^[19,20]. In the patients studied here, 6 mutations at amino acid residues 40 and 47 were observed in 1 and 5 patients, respectively, and 5 of them were positive for anti-HBs. These patients had relatively high HBV DNA level. Three of them had elevated ALT levels. This result is similar to the report from Taiwan, which revealed a high frequency of mutations at amino acid positions 40 and 47 of the surface gene in patients with chronic hepatitis B, suggesting that these mutations change CTL recognition and contribute to chronic infection in some patients^[10].

In fact, patients positive for anti-HBs have more amino acid mutations, especially mutations in the crucial region of the surface gene associated significantly with the presence of anti-HBs. But presence of these mutations is not related to clinical features, ALT levels, HBV DNA levels and the presence of HBeAg, suggesting that these mutations may not alter the replicating competency of HBV although highly titer of anti-HBs develops. It is possible that these mutants may secrete into the serum via trans-complementation of intact protein in hepatocytes. The biochemical and virological follow-up parameters of 8 patients (No.1 to 6, No.8 and 10) showed that only 2 patients had persistent anti-HBs positive condition during the whole 4 year follow-up period, indicating that anti-HBs can be detected in chronic hepatitis B patients.

In conclusion, the presence of mutations in the “α” determinant of surface gene is not high in patients with coexisting anti-HBs and HBsAg. The mutations at the major hydrophilic region of the surface gene contribute to the development of anti-HBs in these patients and produce escape from the neutralizing antibody, and lead to

persistent infection. Long-term LMV therapy could induce YMDD mutation in the polymerase gene and surface gene of HBV.

Abstract

AIM: To investigate clinical characteristics and therapy of pancreatic encephalopathy (PE) and Wernicke encephalopathy (WE).

METHODS: In a retrospective study of 596 patients with acute pancreatitis (AP), patients with PE were compared to those with WE in regards to history, clinical manifestation, diagnosis, treatment and outcome.

RESULTS: There were 93 patients with severe acute pancreatitis (SAP). Encephalopathies were discovered in 10 patients (1.7%). Six patients with PE all developed in SAP (6.5%), and three of them died (3% of SAP, 50% of PE). Four patients with WE developed in AP (0.7%), and two of them died (0.3% of AP, 50% of WE). Two patients with WE were treated with parenteral thiamine and survived. Global confusions were seen in all patients with encephalopathy. Ocular abnormalities were found. Conjugate gaze palsies were seen in 1 of 6 (16.7%) patients with PE. Of 4 patients with WE, one (25%) had conjugate gaze palsies, two (50%) had horizontal nystagmus, three (75%) had diplopia, and one (25%) had myosis. Ataxia was not seen in all patients. None of patients with WE presented with the classic clinical triad. CSF examinations for 2 patients with WE showed lightly-increased proteins and glucose. CT and MRI of the brain had no evidence of characteristic abnormalities.

CONCLUSION: PE occurs in early or reiteration stage of SAP, and WE in restoration stage of SAP/AP. Ocular abnormalities are the hallmarks of WE, and horizontal nystagmus is common. It is difficult to diagnose earlier an encephalopathy as PE or WE, as well as differentiate one from the other. Long fasting, hyperemesis and total parenteral nutrition (TPN) without thiamine are main causes of thiamine deficiency in the course of pancreatitis.

INTRODUCTION

Pancreatic encephalopathy (PE) is an uncommon complication of acute pancreatitis (AP). PE, which is one of multiple organ dysfunction syndrome (MODS), generally occurs in early stage of severe acute pancreatitis (SAP) and has a high mortality of 57%^[1]. But in the last or restoration stage of AP, neurological complications are mostly Wernicke encephalopathy (WE) which results from long fasting, hyperemesis and total parenteral nutrition (TPN) without thiamine (vitamin B1, Vit B1). A large dose of Vit B1 is certainly effective for WE. However, it is difficult to diagnose earlier an encephalopathy as PE or WE, as well as differentiate one from the other. Recent studies^[2] have shown that WE is poorly recognized by clinicians, even when features of the classic triad of symptoms are evident. Recognition of the progressive nature of the disease is critical because the mortality rate is as high as 10% to 20%^[3-5], and treatment may correct all abnormalities. This study demonstrates many of the common clinical characteristics of WE and the diagnostic dilemma physicians encounter when confronted with WE. By reviewing our clinical experience, we can learn many lessons which are beneficial for physicians, not just those who care for patients with PE.

MATERIALS AND METHODS

Patients and methods

A retrospective study was conducted on 596 patients with AP hospitalized at China PLA General Hospital over a 10-year period from Jun 1993 to Dec 2003. There were 93 patients with SAP. A chart was reviewed containing the following demographic and clinical data: age, sex, clinical

Table 1 Manifestation and outcome of patients with encephalopathy

No.	Sex	Age (yr)	Primary disease	Manifestation of encephalopathy	Diagnosis	Treatment/Outcome
1	M	29	SAP with ARDS.	4 th d of onset, restlessness, haziness, delirium. Pathological sign negative.	PE	Diazepam, haloperidol. Recovery
2	F	51	SAP	At onset, haziness, delirium.	PE	Recovery
3	M	41	SAP with ALI.	4 th d of onset, restlessness, sleepiness, haziness.	PE	Recovery
4	M	34	SAP with pseudocyst bleeding	SAP for 3 mo, 3 rd d after pseudocyst operation, hallucination, delirium, conjugate gaze palsies, coma, suspected Kernig sign. Diffused pancreatic necroses.	PE	Death
5	F	42	SAP with ALI and shock	9 th d of onset, delirium, unconsciousness.	PE	Death
6	M	31	SAP with ARF and ARDS.	33 rd d after onset, restlessness, hebetude, unconsciousness, delirium.	PE	Death
7	F	37	Recovery Phase of AP	Protracted vomiting. No supplement of VitB ₁ . 36 th d after onset, diplopia, tinnitus, apathy, dizziness, horizontal nystagmus. CSF negative, MRI negative.	WE	VitB ₁ , B ₁₂ im. Recovery after 4 d
8	M	48	Recovery Phase of SAP, with ALI and pseudocyst	45 th d of onset, diplopia, sleepiness, haziness, horizontal nystagmus, spatial disorientation, decreased tendon reflex.	WE. Once suspected PE	Fasting for 51 d, no VitB ₁ in TPN for 44 d. Recovery after 4-day's administration of VitB ₁
9	M	37	Acute recurrent pancreatitis with pseudocyst	Long fasting, no supplement of VitB ₁ . Nausea, vomiting, dizziness, hypomnesia, alalia, diplopia, amentia, coma. Conjugate gaze palsies, active tendon reflex, ankle clonus positive. CSF: total cells 134, WBC 2; glucose, protein increased lightly. MRI: suspected focus of brain stem.	WE. Once suspected PE and encephalitis	Dexamethasone ineffective. Administration of VitB ₁ , 400 mg/d. Death
10	F	40	Recovery phase of AP	42 nd d after onset, vomiting, dizziness, alalia, trance, amentia, sleeplessness, hyperspasmia, coma. Myosis, decreased tendon reflex. Pathological signs negative. CSF: protein positive; total cells 180, WBC 0; glucose, protein increased lightly.	WE. Once suspected viral encephalitis	Dexamethasone, acyclovir ineffective. Respirator. Death

ALI: acute lung injury; ARF: acute renal failure; ARDS: acute respiratory distress syndrome; CSF: cerebrospinal fluid; TPN: total parenteral nutrition.

signs, history, imaging, treatment, hospital course and outcome. Patients with PE were then compared to those with WE in regards to history, clinical manifestation, diagnosis, treatment, and outcome.

RESULTS

Encephalopathy was discovered in 10 patients (1.7%), including 6 males and 4 females with a mean age of 39.0 years (from 29 to 51 years old). Six patients with PE all developed from SAP (6.5%); three patients died (3% of SAP, 50% of PE). Four patients with WE developed from AP (0.7%); two patients died (0.3% of AP, 50% of WE). Two patients with WE were treated with parenteral Vit B1 and survived. PE occurred in early or reiteration stage of SAP, and WE in restoration stage of SAP/AP.

The clinical features were also reviewed in all patients (Table 1). Global confusions were seen in all patients with encephalopathy. Ocular abnormalities were also found. Conjugate gaze palsies were seen in 1 of 6 (16.7%) patients with PE. Of 4 patients with WE, 1 (25%) was seen conjugate gaze palsies, 2 (50%) horizontal nystagmus, 3 (75%) diplopia, and 1 (25%) myosis. Ataxia was not seen in any of the patients. None of the patients with WE presented with the classic clinical triad. CSF examination was performed on 1 patient with PE and showed negative, whereas it was done on 2 patients with WE and showed lightly-increased proteins and glucose. Of the 10 patients, 5 had CT scan of the brain and none had evidence of characteristic abnormalities. MRI was performed on 2 patients with WE and only 1 had some suspected changes of brain stem. Long fasting, protracted vomiting and TPN without Vit B1 supplement were main causes of Vit B1

deficiency, which crucially resulted in WE.

DISCUSSION

PE, first described by Lowell in 1923, refers to the abnormalities of mental status in patients with AP. Abnormalities of mental status, such as spatial disorientation, trance, agitation with delusion and hallucination, were defined as PE by Rothermich^[6,7]. In China, PE had a high mortality of 57%^[1], and main causes of death were shock, MODS, renal failure and ketoacidosis. At present pathogenesis of PE is unclear yet, and most scholars think that it is related to phospholipase A (PLA) activation, hypovolemia, multiple organ failure, electrolyte disturbance and cytokine effect in the course of AP^[8]. In recent years, it has been gradually known that PLA in pancreatitis is not only the primary factor causing pancreatic necrosis, but also crucial substance resulting in PE^[9]. Johnson *et al*^[10] reported a male patient with AP. Cerebral fat embolism was established as the cause of his death. They thought that PE might be due to hypoxia secondary to pulmonary fat embolism, cerebral fat embolism, or the complicating syndromes of disseminated intravascular coagulation or hyperosmolality.

PLA2 damages structural phospholipid of brain cell membrane; platelet activating factor (PAF) increases intracerebral vascular permeability with brain edema and demyelination of grey and white matter. PE is primarily due to the demyelination of the cerebral grey and white matter caused by PLA2, which can induce increased vascular permeability. The intravascular osmotic pressure decreases and the brain becomes more vulnerable to transudation, and finally brain edema is resulted^[11].

With proper treatment, the recovery in patients aged

below 40 is uneventful. Those older than 60 especially those with a previous history of cerebral infarction may have some sequela^[11]. Ruggieri *et al*^[12] presented a patient of 43-year-old man who, after an acute episode of pancreatitis, experienced five relapses, with alternating focal signs. The patient had improved, but cognitive impairment persisted after a 7-year follow-up.

A report^[13] of Boon *et al* showed the usefulness of MRI in the diagnosis of this disorder. Patchy white matter signal abnormalities, resembling plaques seen in multiple sclerosis, might reflect the lesions that were found in the cerebral white matter of post-mortem confirmed patients.

Estrada *et al*^[7] conducted a prospective study on 17 patients with AP. PE was discovered in 6 patients (35%). A direct relationship was found to exist between the PE condition and an increase in CSF-lipase, and electroencephalographic changes were nonspecific. The encephalopathy did not affect the course of AP, and showed no relationship to type of treatments involved. Whereas the severity of AP was not related to the presence or absence of encephalopathy.

Our study revealed that PE occurred in early or reiteration stage of SAP and had a global confusional state for 2-7 d. Some patients had ocular abnormalities. There was no specific therapy for PE. Treatment of AP was the key to prevention and therapy of PE.

The clinical trial of Qian *et al*^[14] revealed that recombinant human growth hormone (rhGH) had a therapeutic effect for patients with early PE; rhGH combined with somatostatin might reduce occurrence of PE. However, the mechanism is unclear yet.

WE is an uncommon neurological disorder characterized by a triad of ocular abnormalities, ataxia, and global confusional state. In 1881, Carl Wernicke initially described punctate hemorrhages affecting grey matter around the third and fourth ventricle and aqueduct of Sylvius and designated it "polioencephalitis hemorrhagica superioris"^[15]. Experimental and clinical studies have demonstrated that WE results from a deficiency of thiamine (vit B1), an essential coenzyme in intermediate carbohydrate metabolism^[16,17].

The mortality rate ranges from 10% to 20%. At autopsy, patients may have pin-point hemorrhages in the mamillary bodies, hypothalamus, and paraventricular regions of the thalamus, around the aqueduct and beneath the floor of the fourth ventricle^[3-5]. A retrospective study of Ogershok *et al* showed similar pathological lesions at autopsy^[2].

Although WE is thought to be a disease that occurs primarily in the alcoholic population, Lindboe's autopsy study revealed 12 (23%) of 52 patients in nonalcoholic population^[4]. Some of the nonalcoholic conditions associated with this disorder include prolonged intravenous feeding, hyperemesis gravidarum, anorexia nervosa, refeeding after starvation, thyrotoxicosis, regional enteritis, malabsorption syndromes, hemodialysis, peritoneal dialysis, uremia, HIV, malignancy, and gastroplasty with postoperative vomiting^[15,18,19].

WE is a life-threatening condition that is avoidable by early recognition and administration of thiamine. Recognition of this disorder remains difficult because very few patients actually present with the classic signs of nystagmus, ataxia, and global confusion. To deal with this diagnostic

problem for chronic alcoholics, new operational criteria were published in 1997. The diagnosis criteria require 2 of the following 4 signs: dietary deficiencies, oculomotor abnormalities, cerebellar dysfunction, and either an altered mental state or mild memory impairment^[20]. Harper *et al*^[3] indicated that only about 16% had this classic triad, and 19% had no clinical signs. On Harper's review of both clinical and pathology studies, a wide range of the presentation with these signs was revealed. Ocular signs were present in 29% to 93%, ataxia in 23% to 70%, and mental changes in 82% to 90%.

In fact, none of the CT studies helps clinicians with the diagnosis. MRI can reveal areas of signal change in the paraventricular regions of the thalamus and in the paraventricular regions of the midbrain with this disorder. Dilation of the third ventricle and atrophy of the mamillary bodies can also be seen. MRI is helpful in confirming the diagnosis of WE; however, the absence of abnormalities does not exclude the diagnosis. The sensitivity of MRI is 53%, whereas the specificity is 93%^[21-24].

WE is a medical emergency and treatment consists of hospital admission and administration of intravenous thiamine. The clinical response after administering thiamine is usually striking and rapid enough to be virtually diagnostic^[3]. As few as 2 mg of thiamine may be enough to reverse the ocular symptoms (which generally begin to improve in 1-6 h), however, initial doses of at least 100 mg are usually administered. Ataxia and acute confusional state may resolve dramatically, although improvement may not be noted for days or months. We suggest starting thiamine prior to treatment with IV glucose solutions, and continuing until the patient resumes a normal diet. Magnesium is an indispensable cofactor in thiamine-dependent metabolism. In hypomagnesemic states, normal function of thiamine pyrophosphate, the active coenzyme containing thiamine, does not occur. Consequently, the final step in treating WE is correcting magnesium deficiency. The prognosis of WE depends on the stage of disease and prompt institution of thiamine^[15,16].

Our study revealed that WE continued to be a rare but life-threatening condition often overlooked in the course of AP. WE occurred in restoration stage of SAP/AP. Ocular abnormalities were the hallmarks of WE, and horizontal nystagmus was common. Long fasting, hyperemesis and TPN without Vit B1 in the course of AP were main causes of Vit B1 deficiency. Two patients with WE were treated with parenteral Vit B1 and survived; two patients once misdiagnosed as PE or cephalitis.

Chen *et al*^[1] analyzed 185 patients with AP complicated with encephalopathy. They thought that encephalopathy appearing in the early course of AP was PE. PE had a high mortality of 57%. WE appeared in the late course of AP (> 2 wk or in recovery period), and had a mortality of 33% (26/78). The difference between the two groups was significant ($P < 0.01$). Supplement of thiamine in time resulted in lower mortality in WE. Therefore, they suggested that patients who have been on fasting for a long time (more than 10 d) should be given thiamine intramuscularly in case WE occurs.

Winslet *et al*^[25] reported a young obese female with AP complicated by pseudocyst formation and intermittent

gastric outlet obstruction, who had been maintained on high-calorie enteral feeds, developed a sudden onset of confusion and ophthalmoplegia associated with papilloedema and retinal haemorrhages. A possible diagnosis of WE was made. The patient was treated with parenteral thiamine, and survived. The authors suggested that any patient with suspicious or unusual neurological symptoms and signs associated with possible malnutrition, hyperemesis or malabsorption should be given intravenous thiamine without delay to avoid the potential morbidity and mortality associated with undiagnosed WE.

In summary, it is difficult to diagnose earlier PE and WE complicating AP. In case differential diagnosis of PE and WE is baffled, Vit B1 diagnostic treatment may be useful: patients' condition of WE is supposed to improve after injected Vit B1 (100 mg/d) therapy for 1-3 d. If a patient, in the course of pancreatitis, has suspicious or unusual neurological symptoms and signs, a possible diagnosis of encephalopathy should be made, and the patient should be given intravenous thiamine without delay to avoid the potential morbidity and mortality associated with undiagnosed WE.

Abstract

AIM: To investigate the distribution of beta-catenin in nuclei or membrane/cytoplasm of gastric carcinoma cells, the relationship between E-cadherin gene methylation and its expression, and the role of beta-catenin and E-cadherin as potential molecular markers in predicting tumor infiltration.

METHODS: Twenty-nine cases of gastric carcinoma, classified as diffuse and intestinal variants, were selected for study. Nuclear and cytoplasmic proteins were purified and beta-catenin content was detected by ELISA. DNA methylation of E-cadherin/CDH1 gene promoter was studied by methylation-specific PCR and compared with E-cadherin expression detected by immunohistochemistry.

RESULTS: In 27 cases of gastric carcinoma, the ratio of beta-catenin content between nuclei and membrane/cytoplasm was correlated with the T-classification ($r = 0.392$, $P = 0.043$). The significance was present between T2 and T3 groups. No correlation was detected between diffuse and intestinal variants in terms of their beta-catenin distribution. In 21 cases of diffuse variants of gastric carcinoma, there was a difference in E-cadherin expression between CDH1 gene-methylated group and non-methylated group (29 % vs 71 %, $P = 0.027$). No correlation between CDH1 gene methylation and T-classification was found, neither was the significance between E-cadherin expression and tumor infiltration grade.

CONCLUSION: Comparative analysis of nuclear and membrane/cytoplasmic beta-catenin can predict local tumor infiltration. E-cadherin/CDH1 gene methylation is an important cause for its gene silence in diffuse

INTRODUCTION

Gastric carcinoma is highly malignant and usually results in a poor outcome. Until now there is no satisfactory tumor marker for predicting its evolution. E-cadherin, a trans-membrane glycoprotein of 120 KD which is expressed in normal epithelium, may play an important role both in cell-cell adhesion and in tumor invasion and metastasis. The low expression of E-cadherin may favor the dissociation of carcinoma cells from one another for their invading out of basal membrane. Though mutation and allelic loss have been confirmed as major mechanisms for E-cadherin (CDH1) gene inactivation in many malignancies^[1], it has been recently reported that CDH1 promoter methylation could be frequently detected in gastric carcinoma^[2]. Still it is controversial whether DNA methylation is the main cause for E-cadherin/CDH1 gene silence. As a copartner of E-cadherin, beta-catenin is critical for intercellular adhesion in membrane and cytoplasm of cells, it also plays a role as a transcription activating protein in nuclei^[3]. The nuclear accumulation of beta-catenin may stimulate gastric epithelium proliferation^[4], nevertheless the effect of beta-catenin on tumor infiltration in gastric carcinoma is waiting to be more precisely studied by quantitative analysis. The aim of the present study was to investigate the relationship between E-cadherin gene methylation and its expression, the distribution of beta-catenin in nuclei and cytoplasm in gastric carcinoma, and the role of beta-catenin and E-cadherin as potential molecular markers in predicting tumor infiltration.

MATERIALS AND METHODS

Patients and tumor samples

Tissue blocks were obtained from the Department of Digestive Disease, Shanghai Ruijing Hospital and the Department of Pathology, Shanghai No.2 Hospital, involving 29 cases of gastric carcinoma operated from 2002 to 2003, of which 21 were diffuse variants and 8 were intestinal variants, together with 5 paraneoplastic non-tumor gastric tissues. The samples were freshly frozen at -70°C for DNA and protein extraction. Also the samples were fixed in 40 g/L formalin buffer then paraffin-embedded routinely for immunohistochemistry. T-classification revealed that 3 cases were T1, 5 T2, 18 T3 and 3 T4.

ELISA for nuclear/cytoplasmic beta-catenin

Nuclear and cytoplasmic protein was isolated for beta-catenin analysis. Frozen tumor tissue (1.0 cm × 1.0 cm × 1.0 cm) from each case was cut into minimal sections and homogenized manually for 5 min at 4°C with 700 µL cytoplasmic lysis buffer (0.15 mol/L NaCl, 10 mmol/L HEPES, 1mmol/L EDTA, 6 mL/L NP-40). Membrane and cytoplasmic lysis were checked by microscopic examination. The nuclei were collected by centrifuging for 5 min at 1 300 r/min at 4°C, then vigorously homogenized for 30 min at 4°C with 500 µL nuclear lysis buffer (0.4 mol/L NaCl, 20 mmol/L HEPES, 0.2 mmol/L EDTA, 0.5 mmol/L PMSF, 250 mL/L glycerol, 1.2 mmol/L MgCl₂, 0.5 mmol/L DTT, 0.5 mg/L leupeptin, 0.5 mg/L aprotinin, 0.5 mg/L pepstatin). The protein in nuclear or cytoplasmic solution was tested by Coomassie reagents following the manufacturer's instructions (Coomassie Plus-200 protein assay reagent, No-23238, Hyclone-PIERCE, USA).

Nuclear or cytoplasmic content of beta-catenin was analyzed by ELISA. The proteins were immobilized onto 96-well microtiter plates at 4°C, and washed with PBS-0.5 mL/L Tween 20. Monoclonal mouse antibody (anti-beta-catenin, M-0545, Antibody Diagnostica Company, USA) was applied in 1:25 dilution of PBS-0.5 mL/L Tween 20 at 37°C for 1h. After being washed, the wells were incubated with AKP-conjugated secondary antibody and then washed again and 1mg/mL pNPP was added. Absorbance of eluted dye was measured at A312nm. Negative controls were performed by replacing primary antibody with PBS-0.5 mL/L Tween 20.

Methylation-specific PCR (MSP) for E-cadherin/CDH1 gene

For each sample, the frozen gastric tissue (0.5 cm × 0.5 cm × 0.5 cm) was cut into minimal sections and incubated with proteinase K (20 g/L) at 55°C for 24 h. The DNA was extracted by standard phenol/chloroform technique.

DNA samples (100 µL) were incubated in 0.2 mol/L NaOH at 37°C for 10 min, then modified with sodium bisulfite solution following the manufacturer's instructions (CpGenome DNA modification kit, S7820, Ingergen Company). The modified DNA was amplified with E-cadherin/CDH1 gene-specific primers as follow: methylated-specific primer set: sense 5'-GGTGAATTTTGTAGTTAATTAGCCGGTAC-3' and antisense 5'-CATAACTAACCG AAAACGCCG-3', yielding a

product of 204 bp; unmethylated-specific primer set: sense 5'-GGTAGGTGAATTTTGTAGTTAATTAGTGGTA-3' and antisense 5'-ACCCATAACTAACCAAAAACACCA-3', yielding a product of 211 bp^[5]. The PCR mixture (50 µL in total) contained 1 × buffer (SABC Biochemical) with 1.5 mmol/L MgCl₂, 0.2 mmol dNTPs, 0.2 µmol of each primer, and 4 µL of DNA sample. PCR conditions were 10 min at 94°C, after which 3U of Taq DNA polymerase (SABC Biochemical) was added, and 35 cycles at 94°C for 50 s, at 57°C for 40 s, at 72°C for 90 s, and a final extension at 72°C for 5 min. The positive control was performed on DNA from normal gastric tissue by using unmethylated-specific primers, and the negative control was prepared on PCR mixture without primers. The PCR products were migrated by electrophoresis on 20 g/L agarose gel, with 100 bp DNA ladder as a DNA marker.

Immunohistochemistry (IHC) for E-cadherin expression

Formalin-fixed paraffin-embedded tissue sections (4 µm thick) were deparaffinized in xylene for 10 min, and rehydrated through graded alcohols to water. Antigen retrieval was performed by microwave of tissue sections in 10 mmol/L sodium citrate buffer (pH 6.0) for 15 min at 750 W. Endogenous peroxidase activity was blocked with 3 mL/L hydrogen peroxide. Primary antibody (anti-E-cadherin, mouse monoclonal antibody, Antibody Diagnostica Company, USA) was applied at 1:25 dilution and incubated for 1 h at room temperature. The slides were washed in PBS for 15 min, and secondary incubations were carried out by using anti-mouse antibody-polymerized dextran-HRP complex (ADI Two-Step System, Antibody Diagnostica Company, USA) for 30 min. Immunoreactivity was visualized with 3,3'-diaminobenzidine tetrahydrochloride (DAB), and counterstained with hematoxylin. The brown-stained color in cell membrane by DAB was defined as positive reactivity. Negative controls were performed by replacing primary antibody with PBS. The DAB staining in nuclei or cytoplasm was considered as negative.

The expression of E-cadherin was considered as positive when at least 10% of tumor cells were colored by DAB^[6]. In quantitative evaluation, 5 microscopic fields were analyzed on each tissue slide. The percentage of positive cells (300 to 900 tumor cells counted for each sample) was classified as grade 1 (11%-25%), grade 2 (26%-50%), grade 3 (51%-75%) and grade 4 (more than 75%).

Statistical analysis

Fisher's exact probability test was used to evaluate the relation between E-cadherin/CDH1 gene methylation and its expression. Correlations among the E-cadherin protein, the ratio of beta-catenin content between nuclei and membrane/cytoplasm, the tumor infiltration grading and the Lauren's typing were evaluated by method of Spearman (statistical software: SAS 6.12).

RESULTS

ELISA for nuclear/cytoplasmic beta-catenin

Twenty-seven cases of gastric carcinoma were successfully analyzed for beta-catenin distribution. The ratio of beta-catenin content between nuclei and membrane/cytoplasm

Figure 1 Ratio of beta-catenin content between nuclei and membrane/cytoplasm in different groups of gastric carcinoma according to the T-classification levels.

was correlated with the T-classification ($r = 0.392$, $P = 0.043$). The significance was present between T2 and T3 groups (Figure 1). There was no relation between diffuse variant and intestinal variant in terms of their beta-catenin distribution in tumor cells.

Methylation-specific PCR for E-cadherin/CDH1 gene

In 29 cases of gastric carcinoma, CDH1 gene promoter methylation was identified in 13 cases (45%) (Figure 2), of which 7 cases were histologically diffuse variants (33%), 6 cases intestinal variants (75%). All 3 T1 cases were found to be positive for CDH1 gene methylation, so did 1 of 5 T2 cases, 7 of 18 T3 cases and 2 of 3 T4 cases. There was no difference in diffuse and intestinal variants for their CDH1 gene methylation, and no correlation between CDH1 gene methylation and T-classification was found. The CDH1 gene methylation was also identified in 3 specimens of paraneoplastic non-tumor gastric tissues.

Immunohistochemistry for E-cadherin expression

E-cadherin expression was detected in 18 of 29 gastric carcinoma cases (62%) (Figure 3), of them 12 cases were diffuse variants (57%) and 6 cases intestinal variants (75%). Two of 3 T1 cases, 2 of 5 T2 cases, 11 of 18 T3 cases and all 3 T4 cases were found to be positive for E-cadherin expression.

Of the 13 gastric carcinoma cases which were identified for CDH1 gene methylation, E-cadherin expression was found in 2 of 7 diffuse variants and 5 of 6 intestinal variants. In 21 cases of diffuse variants, there was a difference in E-cadherin expression between CDH1 gene-methylated group and non-methylated group (29% *vs* 71%, $P = 0.027$). No significance between E-cadherin expression and T-classification was found, neither was the relation between diffuse variant and intestinal variant for their E-cadherin expression.

DISCUSSION

Our previous study demonstrated that E-cadherin and beta-catenin are co-expressed in gastric carcinoma^[7]. The regulation at their transcriptional levels seems to be independently controlled by different mechanisms^[8]. Beta-catenin is a bifunctional protein, location in nuclear or cytoplasm/membrane is critical for its activity as an adhesive factor or proto-oncoprotein. In nuclei, beta-catenin plays a role as a target of the wnt signaling pathway in stimulat-

Figure 2 Methylation-specific PCR (MSP) analysis of E-cadherin/CDH1 gene in gastric carcinoma. Sodium bisulfite-modified DNA samples were subjected to PCR with specific primers. Existence of methylation was demonstrated by the presence of PCR product (204 bp) rendered by methylated specific primers. M: methylated-specific primer sets; U: unmethylated-specific primer sets.

Figure 3 Immunohistochemical analysis of E-cadherin expression in gastric carcinoma (DAB × 400). Positive reaction was assessed as membrane reactivity.

ing cell proliferation through activation of cyclin D1^[9] and c-myc gene^[10]. The nuclear translocation of beta-catenin depends on its stabilization and the P13K signaling pathway. The latter may be activated by EB virus infection^[11], which is also thought to be an important cause for E-cadherin/CDH1 gene methylation^[12].

The nuclear accumulation of beta-catenin seems to be helpful, regarding tumor infiltration in gastric^[13] and colorectal carcinoma^[14], but this accumulation could also be found in early neoplasia or even in non-tumor metaplasia^[4], and beta-catenin expression at cell level does not appear to change from normal to carcinoma epithelium^[15]. Our results indicated that the evaluation of both nuclear and membrane/cytoplasmic beta-catenin expression might have a prognostic implication and a potential diagnostic value for gastric carcinoma. In the present study, we found a significant variation of beta-catenin distribution from T2 to T3 grade, suggesting that beta-catenin plays an important role in tumor infiltration in gastric smooth muscle. The possible mechanism may be that beta-catenin could regulate the matrix metalloproteinase activity in degradation of extracellular matrix components^[16], and this regulation is mainly focused on local infiltration rather than metastasis^[17].

E-cadherin is an indispensable protein for cell adhesion in normal epithelium. Loss of its function is propitious to tumor invasion. For silence of the E-cadherin/CDH1 gene in gastric carcinoma, recent studies showed that not only the changes of DNA sequence but also the epigenetic

modification^[18,19] such as DNA methylation, may play an important role in the loss of E-cadherin expression.

DNA methylation has attracted great attention recently, as many tumor suppresser genes contain CpG-rich promoters called CpG islands, which are normally unmethylated. Silence of these genes may occur in association with the aberrant hypermethylation of their promoter regions. It has been reported that E-cadherin/CDH1 gene is frequently methylated in colorectal and gastric carcinoma, but its endogenetic changes such as mutation are rare^[12,20]. An *in vitro* study demonstrated that the E-cadherin expression, associated with the cell metamorphosis, could be induced by demethylation drugs^[21]. These studies indicate that DNA methylation may be a possible mechanism for E-cadherin/CDH1 gene silence in human gastric carcinoma.

In the present study, 45% of gastric carcinomas were positive for E-cadherin/CDH1 gene methylation, which corresponds to the result of previous study^[22]. We showed that E-cadherin expression was negatively correlated with its gene methylation in diffuse variants, indicating that DNA methylation may diminish E-cadherin expression and thus favor the devastating activity of the tumor. The data reported here do not provide evidence of correlation between CDH1 gene methylation and tumor infiltration, but are in agreement with the hypothesis that methylation status of CDH1 promoter may be an early event in gastric carcinogenesis^[15].

In conclusion, comparative analysis of nuclear and membrane/cytoplasmic beta-catenin can predict tumor infiltration in gastric wall, and the E-cadherin/CDH1 gene methylation is an important cause for its gene silence in diffuse variant gastric carcinomas. Analysis for detecting distribution of beta-catenin protein and methylation state of E-cadherin/CDH1 gene helps to understand the dynamic process of oncogenesis.

ACKNOWLEDGMENTS

The authors thank Dr. Jian-Min Tang (Department of Pathology, Shanghai No.2 Hospital) for his collaboration in acquiring the tumor samples and Professors Yan-Fei Zhao and Xing-Xu Du and Dr. Jian-Guo Dong for their kindly supports.

Abstract

AIM: To investigate the effect of Tetrandrine (Tet) on LPS-induced NF- κ B activation and cell injury in pancreatic acinar cells and to explore the mechanism of Tetrandrine preventing LPS-induced acinar cell injury.

METHODS: Male rat pancreatic acinar cells were isolated by collagenase digestion, then exposed to LPS (10 mg/L), Tet (50 μ mol/L, 100 μ mol/L) or normal media. At different time point (30 min, 1 h, 4 h, 10 h) after treatment with the agents, cell viability was determined by MTT, the product and nuclear translocation of subunit p65 of NF- κ B was visualized by immunofluorescence staining and nuclear protein was extracted to perform EMSA which was used to assay the NF- κ B binding activity.

RESULTS: LPS induced cell damage directly in a time dependent manner and Tet attenuated LPS-induced cell damage (50 μ mol/L, $P < 0.05$; 100 μ mol/L, $P < 0.01$). NF- κ B p65 immunofluorescence staining in cytoplasm increased and began showing its nuclear translocation within 30 min and the peak was shown at 1 h of LPS 10 mg/L treatment. NF- κ B DNA binding activity showed the same alteration pattern as p65 immunofluorescence staining. In Tet group, the immunofluorescence staining in cytoplasm and nuclear translocation of NF- κ B were inhibited significantly.

CONCLUSION: NF- κ B activation is an important early event that may contribute to inflammatory responses and cell injury in pancreatic acinar cells. Tet possesses the protective effect on LPS-induced acinar cell injury by inhibiting NF- κ B activation.

INTRODUCTION

Many animal and clinical studies have shown that once the progress of acute pancreatitis is initiated, common inflammatory responses are involved. There is a local inflammatory reaction at the site of injury; if marked, this leads to a systematic inflammatory response syndrome (SIRS), and this systemic response is ultimately responsible for the majority of the mortality^[1,2]. Lipopolysaccharides (LPS) have been found in the plasma of patients suffering from severe pancreatitis at an early stage of the disease and inflammatory changes resembling acute pancreatitis were described after administration of LPS to several animal species^[3,4].

The transcription factor nuclear factor- κ B (NF- κ B) is a key regulator of cytokine induction. NF- κ B represents a family of proteins sharing the Rel homology domain, which bind to DNA as homo- or heterodimers, and activate a multitude of cellular early and stress-related response genes, such as the genes for cytokines, adhesion molecules^[5]. NF- κ B exists in an inactive form in the cytoplasm of most cells where it binds to an inhibiting protein, I κ B. Many stimuli activate NF- κ B, including cytokines, LPS and oxidative stress. Stimuli trigger the translocation of NF- κ B from cytosol to nucleus where NF- κ B binds to its consensus sequence on the promoter-enhancer region of different genes and regulates transcription of specific genes^[6]. Recently, some experimental results suggested that the cholecystokinin (CCK) analogue cerulein induced the rapid activation of NF- κ B both *in vivo* and in cultured acinar cells *in vitro* and activation of NF- κ B preceded pancreatic injury and inflammation^[7]. Early blockage of NF- κ B activation improved the survival of rats with taurocholate pancreatitis^[8].

In our previous study^[9,10], we have found that LPS could directly induce the calcium overload, NF- κ B activation and cell injury in isolated rat pancreatic acinar cell. Furthermore, NF- κ B activation could be attenuated by EGTA, a calcium chelater. Based on these results, we speculate that calcium disorder might take part in the NF- κ B activation in isolated rat pancreatic acinar cell and calcium channel blocker (CCB) may be useful for the treatment of acute pancreatitis by influencing NF- κ B activation in pancreatic acinar cells.

Tetrandrine (Tet), is a main component of fourstamen stephania root which belongs to traditional Chinese drug and one of natural non-specific CCBs. Tet possesses complicated pharmacological effects and has been used in the therapy of many kinds of disease, such as hypertension, arrhythmia, hepatic fibrosis, *etc*^[11]. In former *in vivo* experiments^[12,13], we have observed that Tet could improve the pathological alteration of pancreas and lung and decrease the mortality of rats with acute taurocholate pancreatitis. In an attempt to further explore the mechanism of Tet in the treatment of AP, we adopted isolated pancreatic acinar cells and examined whether Tet possesses the protective effect on LPS-induced acinar cell injury by inhibiting NF- κ B activation.

MATERIALS AND METHODS

Animals and materials

Male Sprague-Dawley rats (200–250 g) obtained from Experimental Animal Center of Chinese Academy of Sciences (Grade SPF II Certificate No. SYXK 2002-0023) were fasted for 12 h. *Escherichia coli* LPS (WE coli 055: B5) and MTT were purchased from Sigma Co, USA. Tetrandrine was provided by Pharmacology Department of 2nd Medical University of PLA. NF- κ B gel shift assay system kits were provided by Promega Co, USA. [γ -³²P] ATP was purchased from Shanghai Isotope Company. Antibody against NF- κ B p65 was obtained from Santa Cruz Biotechnology Co, CA. Fluorescein isothiocyanate (FITC)-conjugated goat-anti-rabbit antibody was purchased from KPL Company, USA. All other chemicals were supplied from local source at the highest purity available. Hepes buffer salt solution (HBSS) (in mmol/L): NaCl 118, KCl 4.7, CaCl₂ 2.5, MgCl₂ 1.13, NaH₂PO₄ · 2H₂O 1.0, D-glucose 5.5, HEPES 10, bovine serum albumin 2 g/L, minimum essence medium 2%, L-glutamine 2.0, soybean trypsin inhibitor 0.1 g/L, pH adjusted to 7.4 with NaOH 4 mmol/L.

Preparation of isolated pancreatic acinar cells

Pancreatic acinar cells were isolated from male SD rats by collagenase digestion^[14]. In brief, after the rat was anesthetized, the pancreas was quickly removed and parenchyma was minced into small fragments and incubated in 10-mL standard buffer containing collagenase V (90 kU/L) at 37°C, and the pancreatic fragments were digested again by collagenase under a shaking condition for 20 min in an incubator. After collagenase digestion, tissue was gently pipetted. Dispersed acini were filtered through a 150- μ m nylon mesh, centrifuged 3 times each for 3 min at 100 × g, resuspended with culture media (in HBSS, replacing bovine serum albumin 2 g/L with 10%

heat-activated bovine serum) and incubated with 95% O₂, and 5% CO₂.

Cell culture and treatment

Pancreatic acinar cells were planted in 24 and 96 well plates at 37°C in a CO₂ (50 mL/L) incubator and cultured for 4 h, then exposed to different content of media (10 mg/L LPS, 50 μ mol/L Tet and 100 μ mol/L Tet or culture media as control) for 30 min, 1 h, 4 h and 10 h respectively.

MTT assay

An MTT assay was employed to assess the viable cell number quantitatively. Briefly, 100 μ L of cell suspension (1×10^4 cells) was seeded into 96-well tissue-culture plates. Cells were treated with LPS (10 mg/L), or normal media. Cells in Tet group were treated with 50 μ mol/L or 100 μ mol/L Tet for 15 min before stimulated by LPS. After treatment with these agents for indicated period, 10 μ L MTT (terminal concentration 0.5 g/L) was added into each well, and incubated for 4 h. The formazan crystals were produced by viable cells and dissolved by Me₂SO, and the optical density (OD) of the solution was measured at 490 nm of wavelength. Cell viability was directly proportional to OD value. The viable cell number was expressed as a percentage relative to control cells, measured as $100\% \times OD_{490, \text{treated}} / OD_{490, \text{control}}$ (at 0 h timepoint).

NF- κ B immunofluorescence studies

The pancreatic acinar cells that were seeded onto 24-well plates and treated as described above respectively for indicated period were used for immunofluorescence staining. First, the glass slips were pretreated with 0.1% poly-lysine and cell suspensions were incubated at room temperature for 60 min. The cells were then fixed in freshly prepared 4% phosphate-buffered paraformaldehyde for 20 min at 4°C. Then they underwent permeabilization with the addition of phosphate-buffered 0.1% Triton X-100 (wt/vol) for 5 min at room temperature and then incubated in PBS containing 1% bovine serum albumin (wt/vol, blocking solution) for 30 min, also at room temperature. Incubation of the cells was done with either rabbit anti-rat NF- κ B p65 polyclonal antibodies (1:100 dilution in blocking solution) or with blocking solution alone as negative control for 1 h at room temperature. This was followed by incubation with goat anti-rabbit antibodies (1:100 dilution in blocking solution) conjugated to FITC for 45 min at room temperature. Finally, the slips were mounted and sealed for examination under a confocal microscope.

Electrophoretic mobility shift assay (EMSA) for determination of NF- κ B activity

After treatment with stimuli for the above indicated period, pancreatic acinar cells were collected to extract nuclear protein for further examination of the activity of NF- κ B by EMSA.

Nuclear protein extraction: Nuclear protein extracts were prepared according to Steinle *et al*^[6] with the following modifications. Pancreatic acinar cells (4×10^6) were collected, washed twice with cold phosphate-buffered sa-

Figure 1 Protective effect of Tet on LPS-induced cell damage in pancreatic acinar cells. Pancreatic acinar cells were treated with LPS 10 mg/L, Tet 50 μ mol/L or Tet 100 μ mol/L for 1, 4, and 10 h. Results are expressed as percentage of control values (without LPS treatment) at 0 h time-point ($n = 3$). Mean \pm SD. ^a $P < 0.05$, ^b $P < 0.01$ vs LPS group at the same time-point. ^c $P < 0.05$, ^d $P < 0.01$ vs control group at the same time-point.

line (PBS), homogenized in 1.5% citrate, then centrifuged at 4000 g for 15 min at 4°C, at which point the supernatant was removed. Then 0.3 mL of 0.25 mol/L sucrose-citrate was added into the pellet and mixed to create a nucleic suspension, which was pipetted and paved on the surface of 1.2 mL 0.88 mol/L sucrose-citrate in a tube and centrifuged at 2000 g for 10 min. The resulting pellet was washed twice in 0.05 mol/L Tris-HCl (pH 7.5)-0.15 mol/L NaCl and centrifuged at 2000 g for 10 min at 4°C. After removing the supernatant, an equal volume of KMTD (0.3 mmol/L KCl, 1 mmol/L MgCl₂, 10 mmol/L Tris-HCl (pH 8.0) and 1 mmol/L DTT) was mixed into the pellet and incubated for 1 h. During the incubation, the samples were shaken drastically every 15 min. After incubation, the suspension was centrifuged at 15000 g for 15 min at 4°C. Aliquots of the nuclear protein extracts from supernatant were stored at -70°C. Protein content of the extracts was determined using Lowry method with bovine serum albumin as the standard.

EMSA: Activity of NF- κ B was examined by EMSA^[15]. The NF- κ B oligonucleotide contains DNA binding sites for NF- κ B transcription factors. The double-stranded DNA probe sequence is 5'AGT TGA GGG GAC TTT CCC AGG C 3' and antisense 3'TCA ACT CCC CTG AAA GGG TCC G 5' (the binding site is underlined). The 3.5 pmol of the appropriate consensus oligonucleotide was end-labeled with [γ -³²P] ATP using T₄ polynucleotide kinase. The ³²P-labeled double stranded oligonucleotide was used as a specific probe. For the competition assay, the unrelated oligonucleotide, AP₂ consensus oligonucleotide which lacked κ B binding site, was used as a non-specific probe. Nuclear proteins extracted from Hela cell were used as positive control. The nuclear extract equivalent to 5 μ g protein was incubated with radiolabeled probe in reaction buffer, and then the mixture was subjected to electrophoresis on 7% acrylamide (wt/vol) gel at 250 V in 0.5 \times TBE buffer for 2 h. After being dried, the gel was exposed to X ray film at -70°C for 48 h.

Statistical analysis

Each n refers to the number of separated experiment. The

quantitative data were expressed as mean \pm SD and compared using unpaired t -test. The significant differences of incidence of nuclear translocation of NF- κ B p65 between LPS group and Tet-pretreated group were analyzed by Chi-square test. $P < 0.05$ was considered significant.

RESULTS

Tet attenuated LPS-induced cell damage

The viable cell number exposed to LPS 10 mg/L decreased with the increase of stimulating time and the difference was significant ($P < 0.05$), compared with control at the same time point. Compared with LPS group, cell mortality in the group pretreated with Tet at 50 μ mol/L or 100 μ mol/L decreased significantly at each time point (50 μ mol/L, $P < 0.05$, 100 μ mol/L, $P < 0.01$, Figure 1). It suggests that LPS induced cell damage in a time-dependent manner and Tet could attenuate LPS-induced cell damage.

Tet abrogated LPS-induced NF- κ B product and nuclear translocation in pancreatic acinar cells

To monitor its activity at a cellular level, NF- κ B p65 antibody was used to recognize the product and nuclear translocation signal of the p65. Active p65 level in cytoplasm and its nuclear translocation in pancreatic acinar cells were monitored by immunofluorescence visualization. The cells untreated with LPS showed a slight exclusive cytoplasmic fluorescence pattern (Figure 2B). In contrast, cytoplasmic fluorescence in pancreatic acinar cells treated with LPS 10 mg/L for 1 h and 4 h increased significantly (Figure 2C and 2D). P65 nuclear translocation was seen in $> 60\%$ of pancreatic acinar cells incubated with LPS for 30 min and nuclear staining further increased and reached the peak after 1 h of treatment in the LPS group (nuclear translocation ratio $> 90\%$). In the Tet-pretreated group, the pancreatic acinar cells were pretreated with Tet for 15 min and then stimulated with 10 mg/L LPS for 30 min, 1 h and 4 h. Cytoplasmic fluorescence in pancreatic acinar cells was impaired (Figure 2E and 2F) and P65 nuclear translocation was little seen, compared with that in the LPS group ($P < 0.05$ or $P < 0.01$, Table 1).

Figure 2 Tet prevented LPS-induced nuclear translocation of p65 in isolated pancreatic acinar cells. P65 was visualized by indirect immunofluorescence staining using rabbit anti-p65 polyclonal antibodies (1:100) which only recognized NF- κ B p65. Goat anti-rabbit antibodies (1:100) conjugated to FITC was performed, and visualized under a confocal microscope. Nuclear p65 was observed at 1 h (C), 4 h (D) after treatment with LPS (10 mg/L) but not in saline-treated controls at 1 h (B), nor in negative control (A). Nuclear localization of p65 and the fluorescence in cytoplasm were markedly reduced by Tet 100 μ mol/L at 1 (E), 4 h (F), compared with that of LPS group at the same time (Original magnification \times 400).

Figure 3 **A:** Effect of LPS on NF- κ B activity in pancreatic acinar cell. Lane 1: control; Lane 2: treated with LPS 10 mg/L for 1 h; Lane 3: treated with LPS 10 mg/L for 1 h + cold NF- κ B probe; Lane 4: treated with LPS 10 mg/L for 1 h + labeled AP₂ probe; **B:** The time course of LPS-induced NF- κ B activity in pancreatic acinar cell. NF- κ B activity in pancreatic acinar cell stimulated by LPS 10 mg/L for indicated periods of time. Lane 1: 0 min; Lane 2: 30 min; Lane 3: 1 h; Lane 4: 4 h; Lane 5: 10 h; **C:** Effect of Tet on LPS-induced NF- κ B activity in pancreatic acinar cell. Lane 1: control; Lane 2: treated with Tet 100 μ mol/L for 1 h; Lane 3: treated with LPS 10 mg/L for 1 h; Lane 4: treated with LPS 10 mg/L + Tet 100 μ mol/L for 1 h; Lane 5: treated with LPS 10 mg/L for 4 h; Lane 6: treated with LPS 10 mg/L + Tet 100 μ mol/L for 4 h.

Tet interfered with LPS-induced NF- κ B activation:

EMSA was performed to detect the binding activity of NF- κ B in different group. Pancreatic acinar cells were incubated with LPS or Tet and nuclear extracts were prepared and incubated with a ³²P-labeled DNA oligo-nucleotide containing the recognition site of NF- κ B. The specificity of the shift bands was verified by competition assays: The shift bands were suppressed by the incubation with cold NF- κ B probe and not influenced by non-specific competition with labeled AP₂ probe (Figure 3A). Very little NF- κ B binding activity was detected under the unstimulated condition and LPS induced NF- κ B binding activity increased in a time dependent manner and NF- κ B binding activity was maximal at 1 h after incubation of LPS in 10 mg/L (Figure 3B).

The effect of Tet on LPS-induced NF- κ B activation was assessed in pancreatic acinar cells. It was found that in the presence of Tet 100 μ mol/L, the optical density and

Table 1 Effect of Tet on LPS-induced nuclear translocation of NF- κ B p65 in pancreatic acinar cells

Group	Ratio of nuclear translocation (%)		
	30 min	1 h	4 h
LPS 10 mg/L	60.9	90.5	44.7
Tet 50 μ mol/L + LPS	34.7 ^a	34.5 ^b	18.9 ^b
Tet 100 μ mol/L + LPS	28.6 ^b	32.1 ^b	17.3 ^b

Pancreatic acinar cells were pretreated with 50 μ mol/L or 100 μ mol/L Tet for 15 min and then stimulated with 10 mg/L LPS for 30 min, 1 h and 4 h. In the Tet-pretreated group, cytoplasmic fluorescence in pancreatic acinar cells was impaired (Figure 2E and 2F) and P65 nuclear translocation was little seen, compared with that in the LPS group. ^a*P* < 0.05, ^b*P* < 0.01 vs LPS group at the same time-point.

volume of NF- κ B shift band markedly decreased than that of LPS group at the same time (Figure 3C).

DISCUSSION

Lipopolysaccharide (LPS, endotoxin) of the gram negative bacteria outer wall plays a central role in the pathophysiology of the sepsis syndrome^[3]. Many experiments demonstrated it is related to the pathogenesis of acute pancreatitis^[4,15,16].

LPS induces NF- κ B activation in many cells, such as canine tracheal smooth muscle cells, primary rat microglia or monocyte of humans^[17-19]. In our previous study^[9], we have found that LPS induced the increase of NF- κ B binding activity by EMSA and p65 subunit of NF- κ B translocation to nuclei by immunofluorescence. However, it is unknown whether there is a more primary factor which precedes the LPS-induced NF- κ B activation. Our other study^[10] revealed that the first alteration measured after exposing pancreatic acinar cells to LPS system was an increase in the $[Ca^{2+}]_i$ which appeared within several hundreds of second. The increase in $[Ca^{2+}]_i$ preceded all the other pathological events in the progress of LPS-induced pancreatic acinar cells damage. Intracellular calcium overload exerted an important effect on LPS-induced pancreatic acinar cells damage and egtazic acid, a Ca^{2+} chelate could attenuate the damage by inhibiting Ca^{2+} influx. The result suggested that the disorder of calcium homeostasis in pancreatic acinar cells was an important mediator of LPS-induced cell damage. Tando *et al* observed that caerulein-induced NF- κ B/Rel activation requires both Ca^{2+} and protein kinase C as messenger^[5]. We adopted calcium channel blocker (CCB) to observe its effects on the NF- κ B activation and viability of isolated rat pancreatic acinar cell.

In our present study, we found that LPS was able to induce the damage in intact pancreatic acinar cells directly at 1 h and the mortality of cell increased with the increase of concentration and stimulating time of LPS. The increase of NF- κ B activity preceded the pathological alteration in the progress of LPS-induced pancreatic acinar cells damage. Moreover, a typical CCB, Tet could abrogate LPS-induced NF- κ B nuclear translocation, interfere with the DNA binding activity of NF- κ B and attenuate cell damage of pancreatic acinar cells. The results show that NF- κ B activation is an important early event that may contribute to inflammatory response and cell injury in pancreatic acinar cells and Tet possesses the protective effect on LPS-induced acinar cell injury by inhibiting NF- κ B activation. These findings will be helpful to explain the mechanism of Tet in the treatment of AP at the biological level.

Abstract

AIM: To investigate the correlation between expression of CD58 and severity of hepatitis B.

METHODS: The level of soluble CD58 (sCD58) in serum of patients with hepatitis B was detected by enzyme-linked immunosorbent assay. The level of expression of membrane CD58 molecule in PBMC was detected by direct immunofluorescence. The levels of serumal TBIL, DBIL, IBIL, ALT and AST were detected by the automated biochemistry analyzer as well.

RESULTS: The levels of sCD58 in serum and membrane CD58 molecule in PBMC of patients with hepatitis B were significantly higher than that in normal controls ($P < 0.05$). Level of CD58 was related to the levels of serumal TBIL, DBIL, IBIL, ALT and AST.

CONCLUSION: The level of CD58 molecule (in both serum and PBMC form) of patients with hepatitis B is related to the degree of liver damage.

INTRODUCTION

Hepatitis B is caused by Hepatitis B virus (HBV), but the

pathogenesis of hepatitis B is not well understood. HBV infects human liver cells but has no direct cytopathic effect on these cells. Therefore, it is unlikely that direct viral cytotoxicity is the primary cause of pathology in vivo. Several studies have suggested that hepatitis B may be mediated in part by immunopathologic mechanisms. As one of the intercellular adhesion molecules, CD58 provided co-stimulatory signals for the activation of T lymphocyte, it plays an important role in promoting the adhesion of T cells to targeted cells^[1-3]. In this study, we used double antibody sandwich ELISA and direct immunofluorescence to analyze the levels of sCD58 in serum and the expression of CD58 on the surface of PBMC of patients with hepatitis B, and compared with those levels of healthy controls to evaluate the role of CD58 in the pathogenesis of hepatitis B.

MATERIALS AND METHODS

Sample collection and processing

Forty-three patients with hepatitis B are selected from outpatients and inpatients of the Department of Infectious Diseases of First Hospital of Xi'an Jiaotong University and Second Hospital of Xi'an Jiaotong University. The patients were divided into four groups, namely mild chronic hepatitis B group ($n = 12$), moderate chronic hepatitis B group ($n = 11$), severe chronic hepatitis B group ($n = 10$) and severe hepatitis B group ($n = 10$). Eleven healthy persons were taken as normal control group. The diagnostic code for Hepatitis B which edited by 5th Chinese Academic committee of Infection Disease and Parasite in 2000 was used as the classification criteria.

Detection of the sCD58 in serum

The serum samples were diluted 1:50 with assay buffer (5 μ L sample + 245 μ L assay buffer), and then the levels of sCD58 in the diluted samples were detected by use of double antibody sandwich ELISA following the kit instructions (Australia Science Laboratory company). The standard wells were designated by the instruction as well. The OD value of each well of the samples and the sCD58 standards was read out on an EL311 autoplater reader (BIO-TEK Instruments, American) with a test wavelength of 450 nm and a reference wavelength of 620 nm; hence the optimal concentration of sCD58 could be determined. Blank wells were used as background control.

Detection of membrane CD58 in PBMC

One ml of PBMC sample was mixed with 10 μ L of

Figure 1 Content of CD58 in serum.

Figure 2 Content of membrane CD58 molecule in mild chronic hepatitis B.

Figure 3 Content of membrane CD58 molecule in moderate chronic hepatitis B.

Figure 4 Content of membrane CD58 molecule in severe chronic hepatitis B.

mouse anti-human CD58 antibody marked by fluorescence FITC (American Southern Biotech), incubated in the dark at room temperature, washed twice with PBS, and centrifuged at 2500 r/min before abandoning supernatant. One ml of PBS-formaldehyde was added to fix cells, and CD58 positive cells were detected by using FACS Calibur flow cytometer.

Detection of the liver function

One mL serum sample was used to test the levels of TBIL, DBIL, IBIL, ALT and AST by the CHEMIX-180 automated biochemistry analyzer (Japanese SYSMEX Corporation).

Statistical Analysis

The significance among different groups was examined by one-way analysis of variance followed by two-sample Student's *t*-test. Differences between groups were considered significant if probability value of $P < 0.05$ were obtained. The data were presented by means \pm SD.

RESULTS

Content of sCD58 in serum

The levels of sCD58 of patient with HBV infection were significantly higher than that of normal control ($P < 0.05$); and the difference among the groups were significant ($P < 0.05$) (Figure 1).

Content of membrane CD58 molecule

The results showed that the level of membrane CD58 molecule in PBMC of patients with HBV infection was significantly higher than that of the normal group and the differences among the groups were significant ($P < 0.05$). The levels of membrane CD58 molecule increased significantly in an order from light chronic hepatitis B, medium group, severe group and severe hepatitis B. The membrane CD58 molecule in PBMC might relate to the severity of the disease (Figures 2-5, Table 1).

DISCUSSION

CD58 is also called lymphocyte function associated antigen-3 (LFA-3)^[4-6], which belongs to the CD2 family. As an important co-stimulating molecule, CD58 plays an important role in promoting the adhesion of T cells to targeted cells, and enhancing the recognition and sensitivity of T lymphocyte to the superantigen^[7-9]. CD58 promotes hyperplasia and activation of T cell^[1,2], promotes T cells soak inflammatory parts and takes part in signal transmission of T cells. Combined with CD2 molecules on the surface of NK cells, CD58 increases the adhesion between NK cells and target cells, activates NK cells^[10,11], and increases the toxin of the cells^[12,13]. After integrating

Figure 5 Content of membrane CD58 molecule in severe hepatitis B.

with activated T cells, CD58 and CD2 facilitate interferon γ and IL-2 mRNA record and translate, differentiate CD4⁺T to Th1 and further initiate the immune response of the cell^[3,14]. Some researchers proved that integrated with matching cells, CD58 may boost the ability of activated T cells and NK cells^[15,16].

Our experiment showed that the levels of sCD58 in serum and membrane CD58 molecule in PBMC of patients with HBV infection were significantly higher than that of the normal group. The levels of CD58 varied from different groups of patients with hepatitis B, correlated to the severity of the disease. The results also showed that the percentage of CD58⁺ cell of patients with hepatitis B might be related with TBIL, DBIL, IBIL, ALT and AST, which prove the expression of CD58 is closely correlated with the liver damage. According to the results of the research, the increased levels of sCD58 molecule in serum and membrane CD58 molecule in PBMC of patients with hepatitis B could enhance the adhesion of APC and T cells to identify antigen^[17,18]. This study proved that the combination of CD58 and CD2 activated T cells was similar to the way of TCR/CD3. This might lead to a series of responses in the cells, including the increase of the concentration of Ca²⁺, the activation of PKC, several lipid genes in the resting cells such as IL-2 and IFN- γ being recorded and the transformation of T cells from G0 stage to S stage. The T cells activated by integration of CD58 and CD2 would increase the record and translate of IL-2 and IFN- γ mRNA, and then differentiate into Th1 which would enhance the cell immune response. Combined

with CD2 molecules on the surface of NK cells, CD58 could activate NK cells and increase the cytotoxic effect^[19]. And this would contribute to the organisms to eliminate HBV. The cytotoxic effect of the immune cells might be implemented by releasing PF or inducing apoptosis of CD95 cells^[20].

In summary, this study showed that the sCD58 in serum and membrane CD58 molecule in PBMC of the patients with hepatitis B is related to the severity of the disease and the liver damage. CD58 might enhance the elimination of viruses through activating T and NK cells and promoting cell immune response. However, this would also lead to the damage of liver cells.

Abstract

AIM: To investigate the significance of angiopoietins, Tie2 and vascular endothelial growth factor (VEGF) expression in the angiogenesis and progress of hepatocellular carcinoma (HCC).

METHODS: Fresh surgically resected specimens of HCC and noncancerous liver (NCL) tissue from 38 patients with HCC were obtained, and expression of angiopoietin-1 (Ang-1), angiopoietin-2 (Ang-2), Tie2, and VEGF messenger RNA (mRNA) was examined by real-time quantitative reverse transcription-polymerase chain reaction (RT-PCR). Expression pattern of each gene in HCC and NCL tissue specimens was compared and the potential role and interaction in angiogenesis of HCC were analyzed. Genes' expression level and its relationship with tumor's clinicopathological parameters were also investigated. Immunohistochemical staining of CD34 was performed to determine the microvessel density (MVD) and Ang-2/Ang-1 ratio was calculated. Relationships between Ang-2/Ang-1 ratio, VEGF and MVD and clinicopathological features were also tested so as to evaluate their significance in the progression of HCC.

RESULTS: Ang-2 and VEGF mRNAs in HCC were significantly higher than those in NCL tissue ($P < 0.05$), whereas the Ang-1 and Tie2 mRNAs showed no statistical significance ($P > 0.05$), though slightly lower level of Ang-1 mRNA in HCC was observed. Ang-2/Ang-1 ratio and VEGF were both positively correlated to MVD. The Ang-2/Ang-1 ratio, Ang-2 and VEGF were all associated with tumor's clinicopathological parameters ($P < 0.05$) except for histological grades ($P > 0.05$). Ang-1 and Tie2 levels in different clinicopathological groups were not significantly different ($P > 0.05$).

CONCLUSION: Dominant Ang-2 expression against

Ang-1 through Tie2 receptor in the presence of VEGF plays a critical role in initiating early neovascularization and transformation of noncancerous liver to hepatocellular carcinoma. Its consequently constant operation in formed HCC induces further angiogenesis and progression of HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most malignant tumors in the tropics and the Far East, including China. It is the fourth most common cause of cancer death and accounts for 53% of all liver cancer deaths worldwide^[1]. HCC is also a hypervascular carcinoma. It is believed that angiogenesis contributes to its malignant biological characteristics such as invasion and high rates of recurrence and metastasis^[2-4]. Angiogenesis is a neovascularization process during which endothelial cells of the pre-existing capillaries proliferate and migrate to form new vascular tips or so-called "vascular sprouts" or "endothelial buds"^[5]. The growth, invasion and metastasis of malignant tumors depend on the process of angiogenesis. There is evidence that solid tumors do not grow beyond 2-3 mm³ in volume when vascular sprouts are blocked^[6].

Angiogenesis is a very complicated network which is closely regulated by many angiogenic factors. Vascular endothelial growth factor (VEGF) and angiopoietin are the two most important regulators. The latter is a novel family of angiogenic factors including Ang-1, Ang-2, Ang-3, and Ang-4, which have been isolated and identified as a group of ligands of the tyrosine kinase Tie2 receptor^[7,8]. Ang-1 and Ang-2 have been reported as the most potent regulators for neovascularization^[9] and are the activator and an-

tagonist of Tie2 receptor, where binding of Ang-1 causes autophosphorylation of Tie2 whereas Ang-2 binding suppresses the autophosphorylation^[9,10]. It was reported that proper regulation of tyrosine kinase Tie2 is absolutely required for normal vascular development, apparently by regulating vascular remodeling and maturation^[11]. Ang-1 helps to maintain and stabilize maturation vessels by promoting interaction between endothelial cells and support cells, such as pericytes. Knockout mice deficient in Ang-1 develop severe vascular defect and die in uterus, similar to Tie2 deficient mice^[12]. Ang-2 acts as an alternative ligand for Tie2 and binds to Tie2 with similar affinity, but competitively antagonizes Ang-1 effects with blockage of Tie2 phosphorylation and activation. Functionally, transgenic mice over-expressing Ang-2 show even more severe vascular defects as the Ang-1 or Tie2 deficient mice^[13]. In the presence of VEGF, vessel destabilization caused by Ang-2 has been hypothesized to induce angiogenic response, whereas in the absence of VEGF, Ang-2 leads to vessel regression^[13,14].

Although the exact role of angiopoietin/Tie2 system remains enigmatic, there is evidence that this system in the presence of VEGF is important for the initiation of angiogenesis and vascular sprouting in tumors^[15]. It was recently reported that VEGF and angiopoietin/Tie2 system play a key role in the transformation of normal lung to non-small cell lung carcinoma^[16]. However, their exact role in the initiation and development of HCC is still unclear. In this study, we investigated the expression of Ang-1, Ang-2, Tie2 and VEGF by real-time quantitative reverse transcription-polymerase chain reaction (RT-PCR). Thirty-eight specimens of HCC and noncancerous liver (NCL) tissues were examined in an attempt to definite their role.

MATERIALS AND METHODS

Patients and specimens

Fresh surgically resected specimens of HCC and noncancerous liver tissue were obtained from 38 patients with HCC who underwent partial hepatectomy in the Department of General Surgery of Zhongnan Hospital, Wuhan University (Wuhan, China) from 2003 to 2005. Demographic data of all patients are shown in Table 1. Thirty-four patients suffered from hepatitis and liver cirrhosis at different extent. Diagnosis of all patients was confirmed by histological examination after operation, and the noncancerous liver tissue was resected. Fully informed consent was obtained from all patients, and the study was performed in accordance with the guidelines of the Helsinki Declaration of 1975 amended in 1983. Those who accepted any therapy or accompanied any other severe complications and those with metastatic liver tumor were excluded. Some samples were frozen in liquid nitrogen immediately after resection and the remaining were fixed in 10% formalin, embedded in paraffin and stained with hematoxylin-eosin for pathological examination. Histological grade was classified according to the criteria of Edmondson and Steiner.

Real-time semiquantitative RT-PCR assay

Total RNA was extracted with Trizol reagent (Promega,

USA) following the manufacturer's instructions and quantitated by absorbance analysis at 260 nm. First-strand cDNA was synthesized using first standard buffer, dNTP mixture containing each deoxynucleotide triphosphate base dithiothreitol and moloney murine leukemia virus RT (GIBCO, BRIL) as previously described^[17]. Four-fold dilution of the products was used for PCR in a Rotor-Gene2000 real-time PCR machine (Corbett Research, Australia). Primers of each gene are shown in Table 2 as previously described^[10]. Glyceraldehyde-3-phosphate dehydrogenase (G3PDH) was used as an internal standard. Reverse transcription was performed at 50°C for 30 min. The samples were subjected to PCR analysis using the following cycling parameters: at 95°C for 10 min, then at 95°C for 15 s and at 60°C for 1 min for 40 cycles. Negative controls (cDNA-free solutions) were included in each reaction. Standard reaction curve was analyzed by Rotor-Gene 5.0 (Corbett Research)

Figure 1 Expression of Ang-1, Ang-2, Tie2 and VEGF in HCC and NCL. HCC: hepatocellular carcinoma; NCL: noncancerous liver tissue. ^a $P < 0.05$ vs NCL.

software and relative quantity according to standard reaction curve (R_v) was calculated according to the formula $R_v = R_{\text{Gene}}/R_{\text{G3PDH}}$ by computer.

Immunohistochemical assessment of vessel density

Paraffin-embedded tissues were sectioned (4 μm). The slides were deparaffined as usual, washed with tris buffered saline (TBS), and then incubated with 10% normal goat serum (Zhongshan Bio. CA). The sections were incubated with appropriately diluted (1:10) rat anti-human CD34 monoclonal antibody (Santa Cruz Biotechnology, CA) for 24 h at 4°C. Primary antibody was removed and washed with TBS, goat-anti-rat IgG peroxidase (Zhongshan Bio. CA) was then added. Finally the slices were stained as usual with haematoxylin and washed with distilled water. Quantification of blood vessels was carried out as previously described^[18]. Any brown-stained endothelial cell cluster distinct from adjacent microvessels, tumor cells, or other stromal cells was considered as a single countable microvessel. The most vascular areas of tumors were identified on a low-power field ($\times 100$), and vessels were counted in five high-power fields ($\times 200$). The data were presented as mean \pm SD. The process was performed by special pathologists in a blind manner.

Statistical analysis

Data were analyzed for significance with unpaired t test

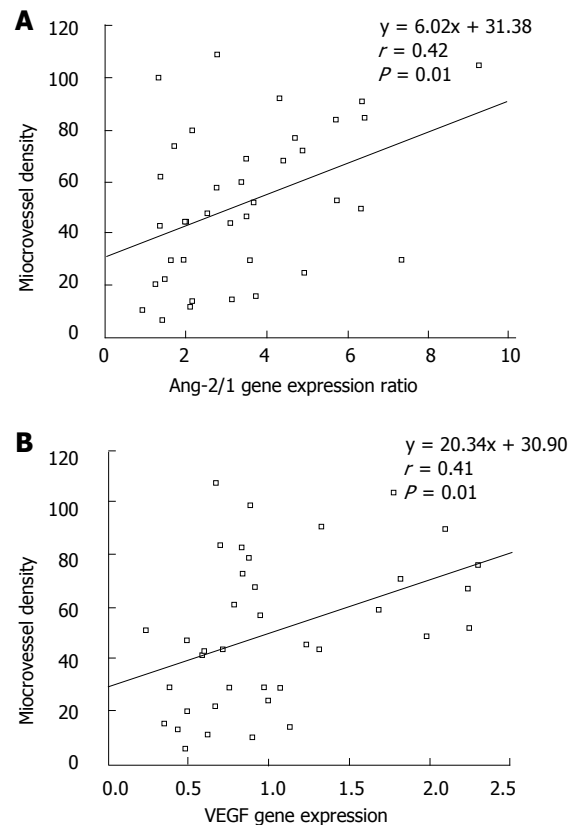

Figure 2 Relationship between Ang-2/Ang-1 ratio and microvessel density (A) and between vascular endothelial growth factor (VEGF) and microvessel density (B).

and ANOVA test. Statistical software SPSS 11.5 was used in the analysis. $P < 0.05$ was considered statistically significant.

RESULTS

Expression of Ang-1, Ang-2, Tie2 and VEGF in NCL and HCC

The expression of Ang-2 and VEGF mRNA was significantly higher in HCC than in the NCL tissue ($P < 0.05$), but the Ang-1 and Tie2 mRNA showed no statistical significance ($P > 0.05$), though slightly lower level of Ang-1 in HCC was observed (Figure 1).

Correlation between Ang-2/Ang-1 ratio, VEGF and MVD

The expression of CD34 in NCL tissue was poor or even negative, but strong in HCC. Microvessel counting revealed that MVD was higher in HCC than in NCL. Because the balance between Ang-1 and Ang-2 mainly defines Tie2 signal, we determined the ratio of Ang-2 to Ang-1 and evaluated its correlation with MVD. VEGF was also involved. The Ang-2/Ang-1 ratio in HCC was positively related to MVD ($P = 0.01$, $r = 0.42$) and VEGF ($P = 0.01$, $r = 0.41$) (Figure 2).

Relationship between gene expression pattern and clinicopathological parameters

The values of Ang-1, Ang-2, Tie2, VEGF and Ang-2/Ang-1 ratio were classified according to HCC clinicopathological parameters including tumor size, tumor capsule, portal vein invasion, distal metastasis and histological

Table 3 Relation between gene expression pattern and clinicopathological parameters (mean \pm SD)

Clinical parameters	Ang-2	Ang-1	Ang-2/1	Tie2	VEGF
Tumor size (cm)					
< 5 (<i>n</i> = 10)	0.267 \pm 0.113	0.148 \pm 0.089	2.175 \pm 1.025	1.686 \pm 0.550	0.552 \pm 0.205
\geq 5 (<i>n</i> = 28)	0.748 \pm 0.422	0.212 \pm 0.082	3.880 \pm 2.067	1.570 \pm 0.990	1.213 \pm 0.537

Portal vein invasion					
positive (<i>n</i> = 11)	1.152 \pm 0.376	0.232 \pm 0.053	5.096 \pm 1.691	1.880 \pm 1.494	1.791 \pm 0.423
negative (<i>n</i> = 27)	0.405 \pm 0.163	0.180 \pm 0.092	2.753 \pm 1.631	1.488 \pm 0.500	0.732 \pm 0.254
Metastasis					
positive (<i>n</i> = 6)	1.320 \pm 0.366	0.235 \pm 0.061	5.912 \pm 1.847	2.262 \pm 1.734	2.007 \pm 0.214
negative (<i>n</i> = 32)	0.490 \pm 0.271	0.187 \pm 0.088	2.967 \pm 1.600	1.148 \pm 0.619	0.857 \pm 0.415
Tumor capsule					
positive (<i>n</i> = 13)	0.308 \pm 0.135	0.178 \pm 0.112	2.078 \pm 0.887	1.733 \pm 0.424	0.579 \pm 0.198
negative (<i>n</i> = 25)	0.783 \pm 0.429	0.203 \pm 0.068	4.135 \pm 1.998	1.529 \pm 1.056	1.278 \pm 0.558

grades. Ang-2, VEGF and Ang-2/Ang-1 ratio were all associated with the above clinicopathological parameters ($P < 0.05$) except for histological grades ($P > 0.05$), whereas Ang-1 and Tie2 showed no relation with any of the clinicopathological parameters ($P > 0.05$) (Table 3).

DISCUSSION

VEGF and angiopoietin are two of the most important regulators for neovascularization. The former is the most potent angiogenic factor that promotes endothelial proliferation and increases vascular permeability by binding to its specific receptors in endothelial cells such as Flt-1, KDR/Flk-1 and Flt-4^[19]. Animal models and *in vitro* experiments have shown that Ang-1, Ang-2 and Tie2 in association with VEGF constitute a system that regulates vascular quiescence and endothelial plasticity, through which a balanced state of vascular maturity and development of complex vascular networks can be achieved^[20]. In the current study we investigated the expression of Ang-1, Ang-2, Tie2 and VEGF mRNA in HCC and noncancerous liver in an attempt to definite their exact role in carcinogenesis and progression of HCC *via* angiogenesis. To avoid possible influence of indefinite borderline carcinoma invasion, the noncancerous liver tissue was obtained from HCC position as far as possible during surgery. Ang-2, as an actively angiogenic factor in the presence of VEGF, is little expressed in physiological condition but highly expressed in several actively neovascularized organs such as endometrium, ovary, placenta *etc*^[9,20-22]. This factor is up-regulated in many carcinomas, such as gastric, ovarian, colorectal and breast cancer, *etc*^[23-26]. In this study, Ang-2 mRNA was significantly up-regulated in HCC compared with the non-tumorous liver tissue, which is consistent with previous reports^[2,27] and has been regarded as a contributor to recurrence, metastasis and poor prognosis of HCC. Besides, high expression of Ang-2 and low expression Ang-1 were found in HCC in comparison with NCL, indicating that they play a key role in the carcinogenesis and progression of HCC *via* angiogenesis. Tumorous angiogenesis is very

different from the physiological process^[28]. During this procession, vascular quiescence and stabilization are mediated by Ang-1, Ang-2 and Tie2 system. Therefore, the pathologic state of imbalanced Ang-2/Ang-1 ratio in the presence of VEGF plays a critical role in the transformation of noncancerous liver to liver cancer by initiating early neovascularization. Vajkoczy *et al*^[29] reported that tumors in their very early stage are initiated by host vessels via VEGF, VEGF receptor-2 and Ang-2. Wong *et al*^[16] also reported that angiopoietins, tie2 and VEGF are differentially expressed in the transformation of normal lung to non-small cell lung carcinomas.

CD34 protein, an endothelial-specific marker, was immunohistochemically stained and MVD was determined in HCC in our study. Ang-2/Ang-1 ratio was calculated and statistical analysis showed that Ang-2/1 ratio was positively correlated to MVD, and VEGF, but such relation was not found between Ang-1, Tie2 and MVD. Ang-2/Ang-1 ratio, Ang-2 and VEGF are all associated with tumor's clinicopathological characteristics such as tumor size, tumor capsule, portal vein invasion and metastasis, indicating that VEGF and angiopoietin/Tie2 system contributes greatly to the progress of HCC by modulating angiogenesis. Continuous growth of carcinoma induces hypoxia and necrosis in central portion, thus reversely up-regulating VEGF^[30]. In the presence of Ang-2, tumor and invasion angiogenesis are greatly accelerated. A study^[31] on C6 glioma showed that Ang-2 expresses strongly whereas VEGF expresses poorly when the tumor reaches 1mm in diameter, and when the tumor reaches more than 2 mm in diameter necrosis occurs in the central portion, both Ang-2 and VEGF are strongly expressed which induces intensive angiogenesis. Interestingly, in the current study Ang-1, Ang-2, Tie2, VEGF and Ang-2/Ang-1 ratio were all not statistically associated with histological grades of HCC, which is similar to a previous report on ovarian cancer^[32].

In conclusion, expression of Ang-2 against Ang-1 through the Tie2 receptor in the presence of VEGF plays a critical role in initiating early neovascularization and in-

duces transformation of noncancerous liver to HCC. The consequently constant immature neovascularization in HCC further promotes angiogenesis and progression of tumors.

Abstract

AIM: To investigate genetic instability of gene BRCA1 at locus D17S855, and their relationship with clinicopathological characteristics of gastric cancer in Chinese population.

METHODS: Microsatellite instability (MSI) and loss of heterozygosity (LOH) of gene BRCA1 at locus D17S855 were compared between 37 samples of gastric cancer and corresponding non-cancerous gastric tissue.

RESULTS: MSI at locus D17S855 was positive in 7 of 37 samples of gastric cancer (18.95%). MSI had a close relationship with TNM staging but no relation with lymph node metastasis, histological type or tumor differentiation. MSI positive frequency in TNM I + II (31.58%, 6/19) was much higher than that in TNM III + IV (5.56%, 1/18), ($P < 0.05$). LOH positive rate was 18.92% (7/37). LOH had no relationship to histological type, tumor differentiation or lymph node metastasis, but LOH positive rate in TNM III + IV was 33.33% (6/18), much higher than that in TNM I + II (5.26%, 1/19), ($P < 0.05$). BRCA1 protein was expressed in 14 of 37 samples of gastric cancer. The positive rates of BRCA1 protein in TNM I + II and TNM III + IV were 57.89% and 16.67%, respectively, ($P < 0.05$). The positive rate of BRCA1 protein was 77.78% in high differentiation samples, 30.77% in middle differentiation and 12.50% in lower differentiation samples, ($P < 0.05$).

CONCLUSION: MSI of BRCA1 gene could be used as a molecular marker in early phases of sporadic gastric cancer in Chinese population. LOH occurs at later period of gastric cancer, therefore, it could be used as prognostic factor.

INTRODUCTION

Gastric cancer is one of the most common cancers worldwide, and growing evidence suggests that accumulation of multiple alterations such as activation of proto-oncogenes and inactivation of tumor suppressor genes is responsible for the development and progression of gastric cancer. Genetic instability of oncogenes such as microsatellite instability (MSI) and loss of heterozygosity (LOH) is probably associated with mutations in genes responsible for tumor-genesis, and they play important roles in tumor clinical pathology^[1-4]. The studies of MSI and LOH of gastric cancer have been focused on genetic instability of P53, P16 and FHIT, but studies of gene BRCA1 gene are very few. The gene BRCA1 is located in the chromosomal region 17q21. Many studies have reported that BRCA1 is a tumor suppressor gene of breast and ovarian tumors, but only few studies have been done on Chinese gastric cancer^[5-7]. The present study was undertaken to investigate MSI and LOH of gene BRCA1 at locus D17S855 in Chinese gastric cancer, their influence on the expression of BRCA1 protein, and their relationship with clinical pathological characteristics of gastric cancer.

MATERIALS AND METHODS

Tumor samples and DNA extraction

A total of 37 formalin-fixed, paraffin-embedded tumor samples and corresponding non-tumor samples from the same sporadic gastric patients were collected. These samples included 30 cases of tubular adenocarcinoma and 7 cases of mucoid adenocarcinoma. All the samples were sectioned into 10 μ m sections, and tumor samples contained at least 90% tumor cells. Genomic DNAs

from tumor and normal components were extracted by proteinase K and phenol-chloroform extraction methods.

Polymerase Chain Reaction (PCR)

Primers of D17S855 locus were: 5'-GGA TGG CCT TTT AGA AAG TGG- 3' and 5'-ACA CAG ACT TGT CCT ACT GCC -3' (Bioasia Shanghai)^[8]. Polymerase chain reaction (PCR) was carried out in 50 μ L reaction mixtures containing 1.0 mmol/L MgCl₂, 10 \times Buffer 5 μ L, 200 μ mol/L dNTP, Taq polymerase 2 units and primers 50 μ mol/L. PCR was carried out for one cycle of 94°C for 4 min followed by 35 cycles of 94°C for 1 min, 60°C for 1 min, 72°C for 1 min, followed by a final extension for 10 min at 72°C. The PCR productions were detected by 2% agarose gel containing ethidium bromide, underwent electrophoresis for 30 min at 15 V/cm, and were examined under ultraviolet light.

Single strand conformation polymorphism analysis of MSI and LOH

The PCR production and an equal volume of denaturing stop solution (98% deionised formamide, 0.05% bromophenol blue and 0.05% xylene cyanol) were heated for 10 min and then were rapidly cooled on ice. Electrophoresis was carried out on 8% polyacrylamide gels at 100 V for 4 h. After electrophoresis, the gels were ordinarily silver-stained. To detect MSI and LOH, the PCR productions of normal and tumor DNA from the same patients were run in adjacent lanes. MSI was positive as either tumor samples added an allele band or moved as compared with normal tissue. LOH was positive as tumor samples lacked an allele band as compared with normal tissue.

Immunohistochemistry staining

Immunohistochemistry for BRCA1 protein was performed on 5 μ m sections from paraffin-embedded tumor tissue which was dewaxed in xylene and dehydrated in a graded ethanol series. The sections were immersed in 3% hydrogen peroxidase for 10 min to block endogenous peroxidase activity, and then rinsed in water. Thereafter, the sections were heated in a microwave for 5 min at 100°C to retrieve antigen. The sections were incubated with primary antibody BRCA1 (Santa Cruz Biotechnology, USA), then the sections were allowed to react by standard Envision method using secondary antibody (DAKO, Denmark). The binding was visualized by DAB, and then the samples were counterstained with hematoxylin.

Imaging analysis and data collection

After immunohistochemistry staining, sections were analyzed by Leica-Qwin computer imaging techniques. We selected twenty continuous high microscopical views that did not overlap. Then we tested the gray-value of background and named as GA. The gray-value of BRCA1 positive granules was named as G_a and area density of BRCA1 positive cells in the view area was named as A_{Aa}. We used Excel function to compute the value of PU (positive unit) which represented expression intensity of

Figure 1 Polyacrylamide gel electrophoresis (PAGE) of BRCA1 gene at D17S855 locus Compared with normal tissue (1N), MSI was positive as added an allele band (↑) in tumor tissue (1C). Compared with normal tissue (2N), LOH was positive as lacked an allele band (↑) in tumor tissue (2C).

BRCA1 protein in gastric cancer cell. The highest gray value was 255 in Leica-Qwin system.

Statistical analysis

Statistical analysis was performed using analysis of variance (AVONA) and *t*-test. A *P* value of < 0.05 was considered significant difference.

$$PU = \frac{G_a - G_A}{(1 - A_{Aa}) \times 255} \times 100$$

RESULTS

Single strand conformation polymorphism analysis (PCR-SSCP) of MSI and LOH

In our experiment, 37 paired normal/tumor DNAs were successfully amplified by PCR method, and were tested by 8% polyacrylamide gels. MSI was positive as added an allele band in tumor tissue as compared with normal tissue; LOH was positive as lacked an allele band in tumor tissue as compared with normal tissue (Figure 1).

Of locus D17S855 at gene BRCA1, the positive frequency of MSI in 37 cases of gastric cancer was 18.92% (7/37) (Table 1). MSI of BRCA1 gene was significantly correlated with clinical TNM staging and degree of tumor differentiation; however, there was no significant difference between MSI-positive and MSI-negative cases in tumor histological type or lymph node metastasis. In tumor node metastasis (TNM) staging, the positive frequency of MSI in stage TNM I + II (31.58%) was more than that in stage TNM III + IV (5.56, *P* < 0.05), and the frequency of LOH-positive of 37 cases of gastric cancer was 18.92% (7/37) (Table 2). LOH of BRCA1 gene was significantly correlated with clinical TNM staging; however, there was no significant difference between LOH-positive and LOH-negative cases in tumor histological type, tumor differentiation degree or lymph node metastasis. In tumor node metastasis (TNM) staging, the positive frequency of LOH in stage TNM III + IV (33.33%) was higher than that in stage TNM I + II (5.26%, *P* < 0.05).

Table 1 Relationship between hereditary instability of BRCA1 gene at locus D17S855 and clinicopathological parameters of gastric cancer

Clinicopathological parameters	Case (n)	MSI positive rates (%)	LOH positive rates (%)	BRCA1 positive rates (%)	BRCA1 expression (PU Mean \pm S)
Histology	37	7 (18.92%)	7 (18.92%)	14 (37.84%)	33.56 \pm 2.23
Tubuladenoma	30	6 (20.00%)	6 (20.00%)	12 (40.00%)	32.87 \pm 2.93
High differentiation	9	4 (44.44%) 1 (7.69%)	1 (11.11%)	7 (77.78%) ^a	34.03 \pm 1.79
Middle differentiation	13	1 (12.50%)	1 (7.69%)	4 (30.77%)	33.49 \pm 2.34
Low differentiation	8	1 (14.29%)	4 (50.00%)	1 (12.50%)	33.58 \pm 1.67
Mucoadenoma	7		1 (14.29%)	2 (28.57%)	32.87 \pm 2.59
Lymph metastasis					
No	17	5 (29.41%)	1 (5.88%)	9 (52.94%)	34.75 \pm 1.78

Figure 2 The expression of BRCA1 protein in gastric cancer. The brown-yellow granules of BRCA1 protein were mostly located in nucleolus. The cytoplasm and membrane of cells were also stained (HE stained \uparrow). $\times 100$.

Immunohistochemistry analysis of BRCA1 protein

The expression of BRCA1 protein in gastric cancer was the brown-yellow granules, mostly located in nucleolus, and cytoplasm and membrane of cells were also stained (Figure 2). The frequency of BRCA1 protein-positive in 37 cases of gastric cancer was 37.84% (14/37) (Table 2). Expression of BRCA1 protein was significantly correlated with clinical TNM staging and tumor differentiation degree; however, expression of BRCA1 protein was not associated with tumor histological type or lymph node metastasis. The positive frequency of BRCA1 protein in TNM I + II (57.89%) was much higher than TNM III + IV stage (16.67%, $P < 0.05$), and BRCA1 positive-rate in well differentiation cases was higher than poor differentiation cases. The frequency of BRCA1 protein-positive decreased as tumor differentiation went down, 77.78% in high differentiation cases, 30.77% in middle differentiation cases, and 12.50% in low differentiation

Table 2 Relationship between MSI, LOH of BRCA1 gene at locus D17S855 and BRCA1 protein expression

Grouping	Cases	BRCA1 protein positive rates	BRCA1 expression (PU Mean \pm S)
MSI positive group	7	85.71% (6/7)	34.05 \pm 1.91
MSI negative group	30	26.67% (8/30) ^a	32.59 \pm 2.23
LOH positive group	7	28.57% (2/7)	32.87 \pm 2.35
LOH negative group	30	40.00% (12/30)	34.03 \pm 2.66

^a $P < 0.05$.

cases ($P < 0.05$). There was no difference in BRCA1 protein expression intensity analyzed by computer imaging.

DISCUSSION

In 1994, the breast-cancer susceptibility gene, BRCA1, was identified by positional cloning; subsequently, this gene has been the subject of intensive research effort. BRCA1, located on chromosome 17q21 and encoding a tumor suppressor gene that functions, in part, as a caretaker gene in preserving chromosomal stability, is composed of 22 coding exons distributed over 100 kb of genomic DNA^[3]. This gene encodes 1863 amino acids, and more than 200 different germline mutations associated with cancer susceptibility have been identified. Cell cycle checkpoints play an essential role in cell survival by preventing the propagation of DNA damage through cell cycle progression before DNA repair. Recent studies have demonstrated that both ATM and BRCA1 are required for effective S-phase and G2/M-phase checkpoints. Other work has indicated that BRCA1 regulates G2/M DNA damage induced checkpoints through its ability to activate Chk1 kinase and thereby induce signaling cascades downstream of Chk1. BRCA1 functions as a co-activator of p53-mediated gene transcription. Other studies have shown that overexpression of BRCA1 results in the transcriptional activation of GADD45 in a p53-dependent manner. As GADD45 has been implicated in G2/M checkpoints, BRCA1 may in part activate G2/M checkpoints by induction of GADD45 protein^[3,9,10].

The association of the BRCA1 gene with susceptibility to breast and ovarian cancer has been strongly demonstrated, and locus D17S855 was found as one of the best candidate loci to detect tumor suppressor genes^[10]. Mori *et al* found that BRCA1 might play an important role in the development of esophagus cancer with high frequent LOH^[9]. Therefore, locus D17S855 was used in this experiment to detect MSI and LOH in gastric cancer of Chinese population.

In this study, the frequency of MSI-positive in 37 cases of gastric cancer was 18.92%. MSI of BRCA1 gene was significantly correlated with clinical TNM staging and tumor differentiation degree; however, there was no significant difference between MSI-positive and MSI-negative cases in tumor histological type or lymph node metastasis. TNM staging represents the prognosis of tumor, and we found in the experiment that the frequency

of MSI in stage TNM I+ II was more than that in stage TNM III + IV. Therefore, as far as gene BRCA1 is concerned, high frequency of MSI endowed with a good prognosis. Furthermore, the positive frequency of MSI decreased as tumor differentiation went down, tumor differentiation correlated with the development and malignant degree of tumor. According to the experiment results, MSI of BRCA1 was an early period molecule marker of sporadic gastric cancer. Candusso *et al* found that LOH often occurred in the later stage of cancer, mostly with lymph metastasis^[10]. The positive frequency of LOH in 37 cases of gastric cancer in our study was 18.92%, and the positive frequency of LOH in stage TNM III + IV was higher than that in stage TNM I + II. The results suggested that LOH of BRCA1 gene might occur in the later stage of gastric cancer and could be a marker that predicts prognosis of gastric cancer.

The positive frequency of BRCA1 protein in MSI positive group was higher than MSI negative group, but there was no significant difference between LOH positive and negative groups. Expression of BRCA1 protein was significantly correlated with clinical TNM staging and tumor differentiation degree; however, expression of BRCA1 protein was not associated with tumor histological type or lymph node metastasis. The frequency of BRCA1 protein-positive decreased as tumor differentiation went down. All these data suggested that BRCA1 gene might restrain gastric cancer from developing further.

In conclusion, MSI of BRCA1 is an early event in development of sporadic gastric cancer in Chinese population and LOH of BRCA1 gene occurs in later stage, therefore BRCA1 gene might be a suppressor gene for gastric cancer.

Abstract

Von Meyenburg complexes are benign liver lesions consisting of adenomatous bile duct proliferates. We present two patients suffering from esophageal cancer accompanied by the occurrence of von Meyenburg complexes. Preoperative computerized tomography (CT) of the liver had not shown these lesions. In one of the patients, diffuse nodular manifestation was found in both liver lobes, mimicking diffuse hepatic metastases. Intraoperative frozen section revealed the benign nature of the lesions in both cases. The patients underwent esophageal resection without complications. To the best of our knowledge, the coincidence of von Meyenburg complexes and esophageal cancer has never been reported before. This uncommon entity should be taken into consideration as a differential diagnosis of liver lesions in malignancies. It underlines the importance of intraoperative frozen section for liver lesions of unknown origin.

INTRODUCTION

Von Meyenburg complexes are benign liver lesions con-

sisting of dilated bile duct structures with a surrounding fibrous stroma. Their incidence is age-dependent and they are observed about 1% in children and 5%-6% in adults^[1]. Usually, these lesions do not have any pathological value and are incidental findings in asymptomatic patients^[1]. However, a malignant transformation and association with cholangiocarcinomas have been discussed, but not yet proven^[2,3]. As von Meyenburg complexes are small lesions, they are usually not detected on radiological examinations, including ultrasound, CT and magnetic resonance imaging (MRI)^[4-7].

We present herein two cases of preoperatively undetected von Meyenburg complexes associated with primary esophageal cancer and review the present literature concerning these lesions.

CASE REPORT

Patient 1 is a 66-year-old male suffering from an esophageal squamous cell carcinoma. Preoperatively, distant metastases were excluded by abdominal ultrasound, chest X-ray and high resolution CT-imaging of the thorax and liver (Figure 1). Surgical therapy with abdomino-thoracic resection of the esophagus was indicated.

Intraoperatively, abdominal exploration revealed multiple white nodular lesions in both lobes of the liver. With a diameter of 2-3 mm, they had the macroscopic aspect of diffuse liver metastases (Figure 2). To confirm the diagnosis of metastases, which would have excluded the patient from further curative resection of the primary esophageal carcinoma, a frozen section was performed. Surprisingly, histology showed benign microhamartomas, so-called von Meyenburg complexes (Figure 3). Because of the benign nature of the lesions, esophageal resection was performed as planned. The postoperative course was uneventful, liver function was normal and the patient recovered quickly.

Patient 2 is a 47-year-old male also suffering from an esophageal squamous cell carcinoma. Comparable to patient 1, the preoperative liver CT scan showed no pathological findings except for liver steatosis and a small cyst in segment IV/VIII.

Intraoperatively, we additionally found a suspicious liver lesion of 5 mm size in segment III. In contrast to the case described above, this was a solitary lesion, with the macroscopic aspect of a metastasis. However, frozen section revealed a sclerotic von Meyenburg complex. Consequently, the operation was performed as planned. No further complications occurred in the postoperative course.

Figure 1 Preoperative CT scan (patient 1). No parenchymal inhomogeneity or focal lesions can be detected.

DISCUSSION

Esophageal cancer is an important cause of cancer death, with an incidence of about 8-10/100 000 and 13 300 deaths in the United States in 2004^[8]. About 35% of all patients already suffer from liver metastasis by the time of diagnosis of the primary tumor. Since patients are excluded from potentially curative resection of the tumor when metastases are present, the diagnosis of liver metastases plays a crucial role for further treatment. The prognosis of these patients is also highly dependant on the respectability of the tumor.

Distant metastases, especially liver metastasis, can be diagnosed by CT scan or MRI with high sensitivity and specificity^[6]. Sensitivities of these diagnostic means range between 74% and 85%^[9]. In these series, almost all false-negative results occurred when lesions were less than 1.5 cm in diameter. Therefore, non-invasive detection of small metastases can be difficult or even impossible.

When suspicious lesions are found by CT scan, further differentiation is possible by additional MRI imaging^[5]. Differential diagnosis of liver metastases includes benign liver lesions, including hemangiomas, adenomas, von Meyenburg complexes or infectious lesions e.g. miliary tuberculosis^[5].

Bile duct hamartomas (von Meyenburg complexes) of the liver are usually detected during laparotomy or autopsy as an incidental finding. Multilocular occurrence is possible although they are rarely spread throughout the whole liver, as it was observed in our first patient. They may be found in normal liver tissue, but also in association with Caroli's syndrome, congenital hepatic fibrosis (CHF) or autosomal dominant polycystic kidney disease (ADPKD)^[10]. Histology of von Meyenburg complexes consists of a variable number of dilated small bile ducts, embedded in a fibrous, sometimes hyalinizing stroma (Figure 3).

If detected by CT scan or MRI, von Meyenburg complexes appear as small intrahepatic cystoid lesions. The lesions are frequently located adjacent to the portal veins, although the lesions can also be located everywhere else^[5]. However, it remains difficult to differentiate between metastases and benign liver lesions. Moreover, small liver

Figure 2 Intraoperative aspects (patient 1). Multiple small nodules are present in both lobes of the liver, mimicking diffuse metastatic lesions.

Figure 3 Histologic staining of a von Meyenburg complex (patient 1).

lesions with a diameter of less than 1.5 cm are often not detected by CT or MRI^[9].

Since the treatment of metastatic disease is completely different from resectable esophageal cancer, liver lesions need to be identified and characterized as early as possible. In our presented patients, the preoperative staging did not reveal any liver metastases. This underlines the importance of exact diagnostic measures in cases of unexpected intraoperative findings. Besides intraoperative ultrasound of the liver, frozen section is the gold standard for further differentiation of liver lesions of unknown origin.

Von Meyenburg complexes are defined as innocuous lesions. However, there are about 10 reported cases of neoplastic transformation of von Meyenburg complexes resulting in cholangiocarcinomas^[2,3].

In conclusion, von Meyenburg complexes are an important differential diagnosis of hepatic metastases. As the existence of liver metastases is crucial for therapeutic decision making in malignant diseases, this differential diagnosis must be carefully clarified. Since von Meyenburg complexes are usually less than 5 mm in size, they can escape preoperative radiologic diagnostics. The macroscopic appearance of von Meyenburg complexes can mimic liver metastasis as demonstrated in our reported patients. This underlines the importance of intraoperative frozen sections to make the correct diagnosis.

Abstract

Autoimmune manifestations are common both in patients chronically infected by hepatitis C virus, and in patients transplanted for non-autoimmune diseases. A correlation between interferon based treatment and autoimmune diseases or the development of autoantibodies is well established in non-transplanted patients, but few data are available about transplanted patients. It is unclear whether interferon may increase the incidence of acute cellular rejection and there are few reports on the development of atypical autoimmune manifestations during post-liver transplantation interferon or pegylated interferon treatment. We describe a case of systemic lupus erythematosus following treatment with pegylated interferon alfa-2b in a transplanted patient with recurrence of chronic hepatitis C. Our experience suggest that pegylated interferon may induce autoimmune diseases in the immunosuppressed host, different from acute cellular rejection and call for a great attention to possible autoimmune disorders development during interferon based treatments in liver transplanted patients.

INTRODUCTION

Autoimmune manifestations are common in patients chronically infected by hepatitis C virus (HCV)^[1]. On the other hand, tissue autoantibodies are common in liver recipients transplanted for non autoimmune diseases and may be associated with negative graft outcome^[2,3]. The safety and efficacy of interferon (IFNs) and the newest pegylated interferons (Peg-IFNs) for the treatment of recurrent hepatitis C in transplanted patients are still debated^[4,5]. In particular, it is unclear whether IFN may increase the incidence of acute cellular rejection (ACR) and there are no reports on the development of atypical autoimmune manifestations during post-liver transplantation (LT) IFN or Peg-IFN treatment.

We report a case of severe autoimmune disease, different from ACR, during treatment with Peg-IFN alfa-2b in a transplanted patient with recurrence of chronic hepatitis C (CHC).

CASE REPORT

A 55-year-old man, underwent LT in March 2001 for HCV genotype 1 liver related cirrhosis. Acute immunosuppressive (IS) schedule was cyclosporine, azathioprine (AZA) and steroids. According to the Transplantation Unit IS protocol, AZA and steroids were stopped 3 wk and 1 year after LT, respectively. Screening tests for LT revealed the presence of cryoglobulins with a cryocrit of 8% and antinuclear antibodies (ANA) at low titre (1/160) with homogeneous pattern. After LT, clinical outcome was regular until January 2002, when the patient showed a persistent mild increase of transaminases (ALT 115 U/L and AST 103 U/L) with high viral load (17.5 MEq/mL, Versant HCV-RNA 3.0 bDNA, Bayer). Liver histology showed mildly active chronic hepatitis with severe fibrosis, presence of lymphocytes and macrovesicular steatosis, sug-

Figure 1 Liver histology before starting antiviral treatment.

Figure 2 Liver histology after stopping antiviral treatment.

gestive of HCV recurrence (Figure 1).

In October 2002 the patient started a cycle of Peg-IFN alfa-2b (1.1 mcg/kg per week) and Ribavirin (6.4 mg/kg per day). After 4 wk of treatment transaminases were normal. HCV-RNA showed a 2 log fall (0.01 MEq/mL) at wk 12; became undetectable by branched DNA, but still positive by polymerase chain reaction (TMA test, Versant HCV-RNA, Bayer) at wk 24 and finally negative by PCR at wk 36.

At wk 44 the patient presented migrant arthritis and the following biochemical parameters: normal transaminases, CyA 240 ng/mL, increased gamma-glutamyltransferase (γ GT), alkaline phosphatase (ALP) and bilirubin (384 U/L, 690 U/L and 1.69 mg/dL, respectively), gamma-globulins 30%, Waaler-Rose 1/1280, ANA 1/640 and anti-DNA positive. No vascular or biliary complications were revealed by ultrasound and computed tomography, nor any signs of infectious diseases were present. Suspicion of an immune mediated manifestation, prednisone 10 mg/d was started. However, despite the presence of signs of autoimmunity we decided to complete the Peg-IFN cycle in consideration of the fact that we were almost at the end of the planned 48 wk of treatment with the patient responding to Peg-IFN.

At wk 48 the patient was asymptomatic, transaminases and bilirubin were normal, HCV-RNA negative by PCR, while ALP and γ GT were decreased (ALP 350 U/L and γ GT 94 U/L). Peg-IFN was stopped and steroids were maintained.

One month later, the patient developed pleuro-pericardial effusion and ascites. Liver function tests (LFTs) were normal, HCV-RNA was negative (PCR) and CyA within the therapeutic range; ANA was very high (1/1280) as well as perinuclear anti-neutrophil cytoplasmic antibodies (pANCA) (1:320). Therefore, our patient developed a syndrome characterised by high titre autoantibodies, migrant arthritis and serositis. Following the current criteria, the diagnosis of systemic lupus erythematosus could have been made^[6,7]. Prednisone was increased to 15 mg/d and diuretics introduced, resulting in the remission of liquid effusions and a progressive reduction of autoantibodies (ANA 1:160 and pANCA negative). We did not increase further the prednisone dosage in consideration of the possibility of an HCV re-activation in an already immunosuppressed patient and because of the initial clinical remission of autoimmune manifestations.

In March 2004, four months later, the patient presented an important increase of all LFT (GOT 257 U/L, GPT

197 U/L, ALP 438 U/L, γ GT 356 U/L, total bilirubin 20.35 mg/dL, with direct bilirubin 17.20 mg/dL) with normal eosinophils, serum HCV-RNA positive at low titre (2.96 MEq/mL). CyA was close to the lower limit of the therapeutic range (100 ng/mL). Liver biopsy revealed the presence of interface hepatitis, numerous rosettes, cholangitis with ductular proliferation and bile duct regression (Figure 2). Histological findings were not suggestive for HCV recurrence and did not fulfil the standard criteria for acute or chronic rejection^[8]. Therefore, International Criteria for Autoimmune Hepatitis (AIH score)^[9] were applied, according to which the patient was categorized as positive for "probable AIH" (score + 11). Consequently, steroid treatment was increased and the patient was switched from cyclosporine to tacrolimus. Response to immunosuppressive treatment was slow but progressive until normalization of LFTs.

DISCUSSION

It is well known that treatment with IFN may cause autoimmune diseases or the development of autoantibodies in non transplanted patients^[10-13] while few data are available on transplanted ones. In particular, to the best of our knowledge, it has never been described the development of SLE after LT during interferon treatment. Only two cases of SLE have been described during IFN treatment in immunocompetent patients treated for HCV infection^[12]. In a series of 677 patients treated for HCV infection, 4% developed autoimmune diseases, the majority (62%) being represented by thyroid dysfunction; only 1 patient developed an SLE-like syndrome with an incidence of 0.15% in the study population^[14]. Alfa-IFN therapy has been moreover associated with the development of idiopathic thrombocytopenic purpura, myasthenia gravis, Addison's disease, diabetes, COELIAC disease, rheumatoid arthritis, primary biliary cirrhosis, polymyositis, psoriasis^[12,15-23].

Antiviral actions of alfa-IFN include the induction of several proteins, such as protein kinase (PKR) and 2',5'-oligoadenylate synthetase, important in viral dynamics^[24]. Moreover, IFNs induce the expression of MHC both on antigen presenting cells (APC) and hepatocytes, resulting in a virus-specific lysis of infected cells mediated by cytotoxic T-cell response^[25]. Thus, IFNs may lead to the development of autoimmune diseases by the up-regulation of MHC in both transplanted and non transplanted patients.

Moreover, the interaction of IFN activities in a particular pathway, such as in the immunosuppressed host, may lead to severe autoimmune manifestations that can compromise the graft survival. A relation between virological response and ACR was suggested in a recent study. Authors supposed that viral eradication improves microsomal function leading to a decrease of IS drugs levels^[4]. The same mechanism may play a role in the induction of other autoimmune diseases such as that occurred to our patient who developed an SLE. Furthermore, our patient was on treatment with calcineurin inhibitors that have been thought to predispose to autoimmunity by interfering with T cell maturation and developing autoaggressive T-cells clones^[26]. It is therefore possible that various mechanisms contribute to the development of autoimmune manifestations after liver transplantation.

In conclusion, the clinician should be aware of the possible development of autoimmune disorders, different from ACR, during interferon based treatment in LT patients, especially if signs of autoimmunity are present before starting IFN.

Abstract

Radiofrequency ablation (RFA) is an innovative technique used primarily for the palliative treatment of unresectable liver tumors. Its therapeutic indications however, have been expanded and now include various other organs and diseases. There is a paucity of data regarding technical details and complications of the use of RFA in the spleen. We report a case of partial splenectomy using radiofrequency ablation for splenic hydatid disease, complicated by an abscess formation.

INTRODUCTION

The spleen is an important component of the body's defenses against infection and the adverse consequences of its removal have become increasingly apparent over the last four to five decades. Death rates from overwhelming post splenectomy sepsis have been reported to be up to 600 times greater than those of the general population, with an estimated life time risk for post splenectomy sepsis of 5%. There is evidence that splenic reticuloendothelial function can be preserved by partial splenectomy, provided that at least 25% of splenic tissue is preserved^[1,2].

Partial splenectomy is not routinely practiced mainly because of the lack of vascular control to arrest bleeding^[3]. The most common indications included splenic trauma, staging and palliation of malignant diseases, inflammatory pseudotumors, hemangiomas, lipomas, hamartomas,

parasitic and non parasitic cysts and other benign conditions.

Radiofrequency ablation is a relatively new technique for local ablation of unresectable liver tumors^[4]. It has been successfully adapted as a treatment modality of primary and metastatic tumors of the liver, kidney, breast, and bone^[5]. Furthermore, the RF energy has been used successfully for the division of liver parenchyma^[6]. Very few clinical studies refer to the use of RF energy in the spleen. We report a case of partial splenectomy using RF energy complicated by an abscess formation.

CASE REPORT

A 52 year old man was admitted to our hospital with vague abdominal pain localized to the left upper quadrant of the abdomen. The patient's past medical history included an appendectomy performed 30 years ago and two operations for the removal of liver echinococcal cysts, performed 28 and 4 years ago. Physical examination and routine blood tests were unremarkable. The patient was found to be positive for anti-echinococcal antibodies, and thus two cycles of scolicedal agent were administered pre-operatively. The patient's radiographic work up, which included routine X-rays, an ultrasound and a computed tomography of the abdomen, revealed two hydatid cysts; one located at the lower splenic pole (9 cm × 10 cm × 8 cm) and the other located at the left pelvic floor (10 cm × 5 cm × 4 cm).

The patient underwent an exploratory laparotomy, through a midline incision. The abdominal cavity was entered with difficulty due to dense adhesions. The left colon was mobilized from the lateral abdominal wall, but the cyst was attached to the mesentery and subsequently its blood supply was sacrificed. Multiple erosions of the left colon were identified and subsequently a left colectomy and end colostomy were performed. The cyst was finally removed en block.

The spleen was surrounded by multiple dense adhesions and access to the splenic hilum was very difficult. However all the surrounding tissue was mobilized and pushed away from the cyst and the splenic pole. No vascular division took place. The cyst involved the lower pole parenchyma.

At this point division of the splenic parenchyma was decided in order to achieve en block removal of the hydatid cyst.

The Radionics Cooltip Radiofrequency System (Radionics/Tyco Hellas) was used to create a zone of desiccation between the cyst and the splenic

Figure 1 A zone of desiccation was created between the hydatid cyst and the splenic parenchyma using the RF electrode.

Figure 2 The splenic remnant after removal of the hydatid cyst and hemostasis using the radiofrequency energy.

parenchyma. A 3 cm Cooltip RF electrode was applied approximately 2 cm from the cyst wall and into the splenic parenchyma away from the hilum (Figure 1). The RF generator was turned on to the maximum power up to 140 W. Generator output, tissue impedance and electrode tip temperature were calculated, and measurement appeared on the generator's screen. Chilled saline was circulated by the perfusion pump through two coaxial cannulae in the probe during RF application to help prevent tissue boiling and cavitations immediately adjacent to the needle. The generator was activated to the maximum power and using the manual mode, the RF was applied until the impedance of the coagulated tissue reached a level twice as high as the initial measurement. Division of the splenic parenchyma was carried out using scissors. Residual bleeding was taken care of using RF again. The cyst was finally removed en block (Figure 2).

After copious irrigation and hemostasis the abdominal cavity was drained and closed in a standard fashion and the colostomy was matured. The pathology revealed macroscopically an intact hydatid cyst surrounded by approximately a 1 cm ring of coagulated splenic tissue.

For the first two post operative days, small amounts of dark bloody stained fluid was continuously flowing from the splenic bed drain. On the fourth postoperative day the patient became septic and he was transferred to the ICU in septic shock.

Figure 3 The splenic remnant was found to be infected with multiple microabscesses.

Urgent abdominal CT revealed the presence of atelectasis of the lower lobe of the left lung, with pleural effusion, gastric dilation and the presence of perisplenic abscess.

The patient was taken back to the operating room, and splenectomy was performed. The spleen was found to be infected and multiple abscesses surrounding the spleen were identified (Figure 3). The abdominal cavity was then washed out with copious amount of irrigation, and drains were placed again.

After 3 d in the Intensive Care Unit, the patient returned to the floor. Subsequently, the patient developed an enterocutaneous fistula, which was treated conservatively.

The pathology macroscopically revealed a splenic remnant that weighed 305 g and was 15 cm × 12 cm × 3 cm in size. A section of 1 cm of the parenchyma showed ash colored areas throughout the spleen, which became more prominent towards the lower pole.

Microscopically a zone of coagulative necrosis with deeper areas of liquefaction and hemorrhagic necrosis was identified. The rest of the spleen was characterized by changes in the architecture of the white pulp. The red pulp was characterized by intense dilation of the sinuses with infiltration of plasma cells and macrophages around the perivascular space throughout the spleen.

DISCUSSION

The incidence of septic complications, such as abscess formation, in RF assisted operations has been reported in various organs. In a recent review of 3670 patients

with liver tumors who underwent open, laparoscopic percutaneous or combined RFA the incidence of septic complications was 1.1%^[7]. Although there are no large series of RF assisted hepatectomies the reported incidence of an abscess formation after division of the liver parenchyma using RF energy remains low.

Septic complications resulting from the application of RF energy to the kidney, adrenals, breast and lungs have been documented to have an incidence of 1%. However all the reported studies have been conducted on a small series of patients^[5].

Predisposing factors for septic complications in RF assisted operations are diabetes mellitus, the existence of bilio-enteric anastomosis for the liver cases and a simultaneous “dirty” operation, like a colectomy, with the most common reported pathogen being the *Staphylococcus aureus*^[8].

In the presented case a colectomy was performed with a subsequent end colostomy due to multiple adhesions transforming a clean procedure into a “dirty one”. In our opinion, that may be a predisposing factor for a septic complication following RF assisted partial splenectomy, though this has not been investigated in the literature in most series, since most of the studies refer to RF as a single procedure.

Intraoperative cultures of the abscess material obtained during the operation, grew an enteric flora *Enterococcus Faecium*, sensitive to a broad spectrum of antibiotics.

Experimental studies^[9,10] have established the safety and efficiency of RF energy to splenic tissue. Quanda Liu *et al*^[11] reported the first clinical series of nine patients who underwent RFA for hypersplenism in patients with liver cirrhosis, with no mortality and no morbidity, other than hydrothorax. However, in this study, the spleen was ablated but not divided. To the best of our knowledge, no data exists regarding the application of the RF energy for partial splenectomy to the splenic parenchyma other than few case reports with zero reported morbidity^[3,12].

We report a case of partial splenectomy using RF energy for hydatid cyst removal complicated by a splenic abscess.

Based on our experience of RF assisted liver resections, we applied maximum RF energy to create a zone of desiccation on the splenic parenchyma. However, the application of RF energy to the spleen is in many ways different than that performed on the liver

parenchyma. Perhaps the double blood supply to the liver and subsequently the hit sink phenomenon, makes the liver parenchyma less sensitive to the RF energy than that of the spleen. In our case the pathology of the splenic remnant revealed changes throughout the splenic parenchyma probably due to excessive applied energy.

In conclusion, we believe that RF assisted partial splenectomy should be performed with the least possible RF energy to achieve hemostasis.

Abstract

With the occasion of a case of malignant melanoma of the gallbladder, which appeared to be primary, we have reviewed the literature and the result of this research was that primary melanoma of the gallbladder remains a questionable medical entity. Only few cases of both primary and metastatic gallbladder melanoma have been reported so far, and the only agreement is that surgery is the mainstay treatment. The role of adjuvant chemotherapy, hormonotherapy or immunotherapy for both primary and metastatic disease remains undefined.

<http://www.wjgnet.com/1007-9327/12/4259.asp>

INTRODUCTION

Having a biopsy specimen histologically proving melanoma of the gallbladder, it is difficult to determine whether it is a primary or secondary tumor. Even though gallbladder and this metastatic lesion comprises between 50%-66% of gallbladder metastasis^[1], the occurrence of metastasis in the gallbladder is rare and has only been reported in the literature exceptionally^[2-7]. Both primary melanoma in

the gallbladder and isolated metastasis to the gallbladder, are not common events. In fact, primary melanoma in the gallbladder is an extremely rare condition and its existence is still questioned by some. According to the literature, primary malignant melanoma in the gallbladder is a controversial issue, and it is still far from clear whether primary melanoma of this organ is a definite entity in itself. Herein, we present a patient in whom malignant melanoma developed initially in the gallbladder. There was no evidence of another acceptable primary site in postoperative investigation and no previous history could be obtained of a pigment cutaneous lesion, which had been treated or regressed.

CASE REPORT

A 38-year old woman presented with a 36-h history of right upper abdominal pain associated with nausea, vomiting and a temperature 38.6°C. Physical examination revealed the presence of severe tenderness in the right upper quadrant of the abdomen. The gallbladder was not palpable. The hematological tests showed an elevation of her white blood cell count (WBC) to 13800/mm³ with neutrophilia. Liver function studies were normal; these laboratory findings disclosed the following values (the normal reference range is given in parentheses): serum aspartate aminotransferase, 21 IU/L (< 30 IU/L); alanine aminotransferase, 19 IU/L (< 30 IU/L); serum alkaline phosphatase, 184 IU/L (100-320 IU/L); serum g-glutamyl transpeptidase, 30 IU/L (16-73 IU/L); and the serum bilirubin, 0.7 mg/dL (< 1 mg/dL). Ultrasound examination of the gallbladder did not demonstrate lithiasis but a polypoid mass without acoustic shadowing (Figure 1). The patient underwent open cholecystectomy. The specimen was opened and a polypoid mass measuring 1.5 cm × 2.0 cm of dark-yellow color was revealed. The postoperative course of the patient was uneventful, but the histological report indicated a melanoma of the gallbladder (Figures 2 and 3). In H&E stain the diagnosis of a primary melanoma was suspicious, confirmed by immunostaining (HMB-45). After that, a meticulous medical history, physical examination and imaging check did not reveal any other primary focus of the disease. No evidence of the disease was marked after six months in the periodical control, however, four months later the patient died from cerebral hemorrhage due to brain metastasis. Although the patient was informed of her disease, she refused any chemotherapy as well as

Figure 1 Ultrasound of melanoma of gallbladder.

Figure 2 Histological appearance of melanoma of gallbladder stained with HE. $\times 400$.

Figure 3 Neoplastic cells immunostained with anti-HMB-45 antibodies. $\times 400$.

the proposed transplenic immunostimulation^[8,9].

DISCUSSION

Theoretically, according to histogenesis, melanoblasts have not yet been demonstrated in organs of endodermal origin^[10] and as gallbladder is an endodermal derivative, it is unlikely that melanoma arises from this organ or other visceral structures. On the other hand, non neoplastic melanoblasts resulting from migration of melanin-producing cells from the neural crest to endodermal derivatives during embryologic development explains the presence of me-

lanocytes within their mucosa^[11-13] and supports the possibility of developing primary melanomas at these sites^[14]. Therefore, primary melanoma of the gallbladder is at least theoretically possible^[4,15]. Even though primary melanoma of the gallbladder remains a debatable clinical entity, reports on this subject continue to accrue. In 1907 the first primary melanoma of the gallbladder was described by *Wieting* and *Handt*^[16] and fifty years later *Walsh* reported the first histologically proven case of primary gallbladder melanoma^[17]. Since that time there have been additional reports of primary melanoma of the gallbladder^[12,15,18-20]. In fact, it is very difficult to differentiate primary from metastatic lesions based on histological features. *Mac Fadden et al*, compared primary and metastatic biliary melanomas and found that the two groups displayed remarkable similarity with regard to pathologic findings^[13]. To help in the differentiation between primary and metastatic melanoma of the gallbladder, according to the literature, the following clinical and pathological criteria should be fulfilled: (1) any other obvious primary site must be excluded by medical history and laboratory investigation, and (2) the tumor, either papillary or polypoid, must be solitary arising from the mucosa of the gallbladder and display junctional activity^[2-4]. Junctional activity, i.e. intraepithelial extension in the mucosa overlying the tumor is considered as significant finding in the diagnosis of the primary melanoma of mucosal surfaces^[11,21]. However, the presence of atypical melanocytes in the adjacent epithelium of invasive tumor does not necessarily define a primary tumor^[22]. Although the presence of "junctional changes" of the mucosa is still controversial, the presence of a solitary polypoid tumor within the lumen of the gallbladder accompanied by junctional activity within the tumor and the absence of an antecedent history of melanoma, or lack of another obvious primary site, are factors that suggest the gallbladder as the primary site of origin. Finally, even today, the establishment of primary histogenesis in these cases is contingent upon a detailed medical history of the patient, a thorough cutaneous and ophthalmic inspection and a radiologic control. However, there always exists the possibility that a regressed primary tumor is a hidden source of gallbladder melanoma. In regard to clinical presentation, involvement of the gallbladder rarely produces symptoms, which could explain the paucity of cases reported in the literature^[23], however, as it is usually reported including our case, acute cholecystitis without the presence of stone in the majority of cases was the initial clinical manifestation and the reason for emergency admission in the hospital. In contrast to gallbladder cancer, melanoma of the gallbladder does not seem to be associated to cholelithiasis. In 1999 *Dong et al*, after having reviewed the literature, found that gallstones appear to be only incidentally and namely in 21.1% of cases (4 of 19 patients) with primary lesions and 27.3% of cases (3 of 11 patients) with symptomatic metastatic disease and this was consistent with the results of their series^[24]. Several diagnostic modalities have been employed to investigate gallbladder lesions. Ultrasound is by far the most useful tool in this attempt. Upper ultrasound abdominal examinations are frequently requested in patients with thick high grade malignant melanoma or clinical suspicion of metastasis. Ultrasound may document metastatic lesions

within the gallbladder. However, polypoid lesions in the lumen of the gallbladder present a focal thickening of the gallbladder wall without acoustic shadowing, due to their lower density in relation with gallstones. As autopsy studies have confirmed the incidence of the gallbladder metastasis from malignant melanoma to be 15%, a careful review of the gallbladder is advocated when abdominal ultrasound examination is performed on patient with malignant melanoma. Ultrasound helps to distinguish between metastasis and benign polyps. The importance of size of the lesion is obvious as 94% of the benign lesions are less than 1 cm in diameter, whereas, 88% of malignant lesion are more than 1 cm^[25]. If the presence of vascular flow within the mass itself is documented, the usefulness of colour-flow Doppler ultrasonography is evident^[26]. Computed tomography is of some value especially in detecting metastatic disease.

Surgical excision is the treatment of choice of both primary and metastatic melanomas of gallbladder. During surgery a thorough search is needed in order to detect any possible abdominal metastasis, as the majority of gallbladder metastases are totally asymptomatic. Although in most cases these metastases are in the form of multiple serosal implants, there are intraluminal metastases involving the mucosa and this fact creates difficulties in detecting these metastases during surgery. Although the mainstay of treatment is surgical removal of the gallbladder, we believe that study of the clear role of adjuvant chemotherapy, hormoneotherapy or immunotherapy at increasing the survival rate is necessary. Basically, the presence of multiple metastases is an indication of systematic chemotherapy. Till today, the usefulness of adjuvant chemotherapy for both primary and metastatic melanomas remains to be clarified, as only one controlled trial has shown significant improvement in response rate mid survival with the combination dacarbazine and tamoxifen^[27]. Despite appropriate therapy, the diagnosis of either condition portends a poor prognosis with few patients surviving more than two years. Furthermore, according to *Langley*, the prognosis of metastatic melanoma is dismal and the average survival is 7 mo^[28].

In conclusion, firstly, the outlook of patients with gallbladder melanoma remains bleak and secondly, the existence of primary melanoma of the gallbladder is still questionable, and certainly will not be settled by this article.

Abstract

A rare case of multiple small bowel ruptures due to ischemic enteritis (ISE) is reported. The patient was admitted to the hospital with acute abdominal pain followed by bloody diarrhoeas. Preoperative colonoscopic findings were similar to those presented in Crohn's disease. Intraoperatively, ischemic lesions and multiple ruptures were localized at the jejunum and the proximal ileum. Histopathological examination of the resected bowel segment established the diagnosis of ISE. Although ISE is not common, concurred multiple ruptures of the small bowel is a rare but actual complication.

INTRODUCTION

Ischemic enteritis (ISE) is caused either by interruption or significant decrease of the arterial inflow to the small intestine. Most patients are elderly, i.e., over sixty years of age. Younger patients, however, especially those with diabetes, lupus erythematosus or sickle-cell anaemia, may also present with ISE. Definite diagnosis of ISE cannot be established before histopathological results are obtained. ISE seems to be a rapid, progressive disease resulting in a 95% mortality rate^[1]. We report a rare case of acute abdo-

men due to multiple ruptures of the small bowel. ISE was proved to be the cause of the ruptures.

CASE REPORT

A 62-year old male presented with a two-month history of abdominal pain, watery diarrhoeas and occasionally fresh intestinal bleeding. Colonoscopy revealed aphthous ulcers both in the ascending colon and in the cecum. A small bowel series showed "tile-paved" images with multiple ulcers in the ileum. Furthermore, gastroscopy revealed the presence of aphthous ulcers in both the stomach and the duodenum. These ulcers were similar to those found in the colon. Biopsy specimens were taken from the stomach, the ileum, the cecum and the rest of the colon. The diagnosis of Crohn's disease was suspected and anti-Crohn's drug therapy was started. The histopathology results 8 d later, however, excluded Crohn's disease and revealed signs of focal enteritis without inflammatory reaction in the submucosa. Ten days after the first admission, the patient presented again in the emergency department suffering from acute abdominal pain accompanied by diarrhoeas and moderate intestinal bleeding. Physical examination revealed acute abdomen and the plain abdominal X-rays showed free air under the diaphragm. CT scanning confirmed liquid and air accumulation in the abdominal cavity.

The patient underwent emergency laparotomy. Intraoperatively, more than twenty micro-perforations localized in the mesenteric surface of the small bowel were found extending from the end of the jejunum to the middle of the ileum. Intestinal resection (about 60 cm in length) followed by side-to-side anastomosis was performed. Four days later, the patient developed similar symptoms of acute abdomen. On reoperation, numerous micro-perforations in both the jejunum and the remaining ileum were found. An additional small bowel resection (about 80 cm in length) was performed, followed by jejunostomy.

On the third postoperative day the patient was operated on again due to the same symptoms. Multiple perforations were encountered once more in the remaining small bowel and an additional bowel resection (approximately 120 cm in length) was performed. Within three days the patient developed renal and hepatic failure and died 2 d later. Macroscopically, the intestinal lesions were characterized by mucosal ulceration of variable length along the resected segments of small bowel, progressing to full thickness necrosis of the intestinal wall. Histopathological examina-

tion revealed numerous scattered segments of acute necrotizing enteritis with annular strictures and relatively shallow ulcers.

DISCUSSION

Two types of ISE have been described in the literature: occlusive and non-occlusive. Embolism or thrombosis of the superior mesenteric artery are the causes of occlusion in 30% and 25% of the patients respectively. Thrombosis of the superior mesenteric vein is responsible for occlusion in 20% of the patients. Non-occlusive ISE occurs in the remaining patients (25%)^[2]. Although the embolus in superior mesenteric artery embolism is usually installed in the middle colic artery, small intestinal branches are also sometimes occluded. The jejunum is affected in 20% and the ileum in 45%-55% of the patients respectively^[3]. Thrombosis of the superior mesenteric artery or vein is considered to be idiopathic in the majority of patients. However, it can also be related to diseases such as portal hypertension, septicaemia, lack of antithrombin III, lack of protein C or S, as well as chronic contraceptive pills intake^[4].

Non-occlusive ISE is due to low blood flow because of cardiac insufficiency, acute myocardial infarction, arrhythmias, dissecting aneurysm of the aorta, septicaemia and diabetes mellitus as well. Decrease of blood flow up to 80% of its normal value occurs due to prolonged vasoconstriction of the mesenteric vessels^[2]. According to Feurle *et al*^[5], analogous to ischemic colitis, an entity of acute ischemic small bowel enteritis exists, so that mesenteric ischemia apparently can induce a clinical syndrome of "regional enteritis", as occurred in our patient.

Early symptoms (acute abdominal pain and bloody diarrhoeas) and late complications (intestinal necrosis, peritonitis, septicaemia and shock) in our patient, were similar to those presented in the literature^[6].

The accuracy of angiography in localizing the site of embolism or thrombosis of the superior mesenteric artery is more than 95%. Its main advantage is that the catheter may remain in the artery, so that vasodilatation substances can be properly given^[7]. Angiography was not performed in our case due to acute abdominal symptoms. These symptoms led the patient to emergency laparotomy. The accuracy of CT scans in diagnosing mesenteric artery or vein thrombosis is approximately 80%. For embolism the rate is 45%-55%^[8,9]. CT scans, however, fail to establish the diagnosis in the majority of ISE cases, and this happened

in our patient as well. ISE due to superior mesenteric artery embolism can be treated by arteriotomy and embolectomy. The patient should undergo an aorto-mesenteric bypass in the case of thrombosis of the superior mesenteric artery. In initial stages of superior mesenteric vein thrombosis conservative treatment with high doses of heparin is recommended. Unfortunately, in most cases the diagnosis is established during laparotomy, due to acute abdominal symptoms. This occurred in our patient as well^[10].

In conclusion, ischemic enteritis is an uncommon but usually fatal clinical condition. The disease may lead to haemorrhage, intestinal necrosis, multiple small bowel ruptures, peritonitis, septicaemia, shock and death. Immediate diagnosis and proper medical and surgical therapy are crucial for a good prognosis. Unfortunately, a definite diagnosis of the disease is usually established after histopathological results of the resected bowel segment have been obtained. Although the disease is not common, it should be considered in the differential diagnosis of acute abdomen, especially when acute abdominal pain is accompanied by diarrhoea and/or intestinal bleeding.

Abstract

Splenic arteriovenous fistula (SAVF) accounts for an unusual but well-documented treatable cause of portal hypertension^[1-4]. A case of a 50-year-old multiparous female who developed suddenly portal hypertension due to SAVF formation is presented. The patient suffered from repeated episodes of haematemesis and melaena during the past twelve days and thus was emergently admitted to hospital for management. Clinical and laboratory investigations established the diagnosis of portal hypertension in the absence of liver parenchymal disease. Endoscopy revealed multiple esophageal bleeding varices. Abdominal computed tomography (CT) and transfemoral celiac arteriography documented the presence of a tortuous and aneurysmatic splenic artery and premature filling of an enlarged splenic vein, findings highly suggestive of an SAVF. The aforementioned vascular abnormality was successfully treated with percutaneous transcatheter embolization. Neither recurrence nor other complications were observed.

Siablis D, Papathanassiou ZG, Karnabatidis D, Christeas N, Katsanos K, Vagianos C. Splenic arteriovenous fistula and sudden onset of portal hypertension as complications of a ruptured splenic artery aneurysm: Successful treatment with transcatheter arterial embolization. A case study and review of the literature. *World J Gastroenterol* 2006; 12(26): 4264-4266

INTRODUCTION

Splenic arteriovenous fistulas (SAVF) represent a rare pathological entity that should be suspected especially in cases of acute portal hypertension not related to chronic liver disease^[1-4]. They may be either asymptomatic or lead rapidly to the development of portal hypertension, with a clinical picture of gastro-intestinal bleeding, diarrhea, ascites or unfavorable heart failure due to hyperdynamic blood flow state^[1-4].

In this report an uncommon case of portal hypertension affecting a multiparous female is discussed. Rupture of a splenic artery aneurysm (SAA) into the splenic vein and formation of a fistulous tract between them consist the underlying pathology. The authors emphasize the positive impact of transcatheter arterial embolization as an effective alternative to surgical intervention in the management of such vascular malformations.

CASE REPORT

A 50-year-old female was referred to our institution for management of an intermittent but intense epigastric pain and a feeling of gastric fullness that were associated with repeated episodes of haematemesis and melaena during the past twelve days. No history of abdominal (accidental or iatrogenic) trauma was reported. On the other hand, it was notable the fact that the patient had delivered successfully four labors between the ages of 26-40 years old.

Upon admission the patient's abdomen was distended and tender. The liver was not palpable and no signs of jaundice were observed. Abdominal auscultation revealed a systolic bruit located at the left flank. Ascites was also depicted. Full blood cell count exhibited markedly decreased values of hematocrit and hemoglobin. Coagulation studies and liver and renal function tests were not affected. Serological markers of hepatitis A, B, C, D were negative and no antibodies were detected. Urgent endoscopy showed multiple bleeding esophageal varices. The stomach was

Figure 1 A: Post contrast CT scan reveals a tortuous and aneurysmatic splenic artery of maximum diameter of approximately 52 mm (short white arrow) associated with dilated vessels at the splenic hilum (long white arrow) and early opacification of the portal axis (long black arrow). In addition ascites is present as well (small triangle); B: Celiac angiogram confirms the presence of the splenic artery aneurysm (black arrow) in contiguity with the markedly dilated splenic vein and the premature and intense filling of the splenoportal trunk (black arrowhead and white arrows).

Figure 2 Selective transarterial catheterization (long black arrow) and embolization of the aneurysmal sac with numerous adequate metallic macrocoils (small black arrows) resulted in full occlusion of the sac and the fistulous tract enabling thus the reduction of the pressure in the splenoportal circulation.

found full of blood and the gastric mucosa was red irritated and edematous; findings consistent with mild portal gastritis. The endoscopic variceal ligation that immediately followed only controlled the bleeding temporarily.

Contrast enhanced CT scan of the upper abdomen demonstrated an aneurysmal dilated tortuous splenic artery of maximum diameter of 52 mm, an engorged splenic vein along with simultaneous opacification of the splenic vessels as well during the arterial phase (Figure 1A). Ascites was also confirmed. The aforementioned imaging features strongly supported the case of an SAA that was connected to the splenic vein through a fistula and caused an abrupt elevation of the portal pressure. Celiac and splenic arteriographies were carried out and showed a dilated splenic artery with a large aneurysm combined with premature portal and splenic vein filling and marked opacification of the splenoportal axis (Figure 1B).

The patient's condition remained unstable due to continuing bleeding and transcatheter embolization was scheduled. By using the transfemoral route the aneurysmal sac was accessed and subsequently detachment of adequate metallic macrocoils was performed resulting thus in full occlusion of the sac, cessation of the hyperkinetic portal flow and successful control of the gastro-intestinal bleeding (Figure 2).

The patient had an uncomplicated recovery and was discharged eight days later in stable clinical condition. At the time of this writing, 10 mo later the patient remains free of symptoms with no evidence of post-procedural recurrence or complications.

DISCUSSION

SAA was first described by Beaussier in 1770^[5]. According to autopsy studies its prevalence ranges from 0.01% to 10.4%. SAAs are found incidentally on 0.78% of angiograms and in 7.1% of patients with cirrhotic portal hypertension^[6]. Splenic artery accounts for the third most common abdominal vessel site that is affected by the aneurysmal disease after infra-renal aorta and iliac artery^[7,8].

Splenic artery aneurysm formation relies upon structural incompetence of the connective tissue of the arterial wall to secure the integrity of the vessel lumen^[5,6,8]. Associated risk factors include portal hypertension, connective tissue disorders, congenital abnormalities, trauma and infection^[6]. Unlike other true visceral aneurysms atherosclerosis does not play a leading role in splenic artery aneurysmal dilatation. They are most commonly encountered among females (female to male ratio: 4/1) especially the multipara^[6].

It has been postulated that increased visceral blood flow and gestational hormones during pregnancy alter pathologically the structure of the arterial wall by causing fragmentation of the elastic fibers of the media and loss of smooth muscle^[6,8]. As parity increases these factors have a cumulative effect predisposing thus to aneurysmal formation^[6]. Hence, the fact that this patient had four successful pregnancies can justify the progressive growth of a splenic artery aneurysm.

Splenic artery aneurysm may present as an incidental finding on imaging modalities or with abdominal pain^[6].

It has been also reported a lifetime risk of rupture of 2%-10% with an associated mortality of 25%^[9]. These rates increase remarkably among pregnant women whereas the estimated risk of rupture can reach up to 50% with related maternal and fetal mortality of 70% and 90% respectively^[6]. The rupture may take place either into the gastrointestinal tract and peritoneal cavity or into the splenic vein resulting in splenic arteriovenous fistula development.

Splenic arteriovenous fistulas represent an unusual clinical entity that was first reported by Wiegert in the 19th century^[1-4]. Their majority occurs more commonly after rupture of an SAA into the corresponding vein but their origin can be congenital, traumatic (iatrogenic or accidental) or even infectious^[1-4].

Despite the fact that SAVFs may stay free of symptoms for a long period of time, the hemodynamic changes that develop owing to the arteriovenous shunt may lead to a sudden increase of portal vein pressure. In contrast, chronic liver disease follows a more time-consuming process before ending in portal hypertension^[1].

The clinical profile of splenic arteriovenous fistula mainly consists of upper abdominal pain, gastro-intestinal bleeding and secretory diarrhea^[1-4]. These features are attributed to the abrupt increase of the mesenteric venous pressure^[1,3]. An abdominal bruit, usually of the "machinery" type, is often heard over the left flank^[1,3,4] and although its presence can raise a high index of clinical suspicion, it is encountered only in 30% of cases^[4].

Although abdominal ultrasound combined with the Color Doppler technology can document blood flow abnormalities, splenomegaly and exclude liver parenchymal disease, the established imaging modality in detecting SAVFs is selective celiac or splenic arteriography. The method localizes with accuracy the vascular abnormality and contributes greatly in the assessment of collateral flow pathways^[10]. It is mostly recommended in cases with sudden onset of portal hypertension, abdominal bruit and absence of chronic liver disease^[4]. The patient's medical history should be always taken into account.

On the basis of a well-established diagnosis immediate intervention is rendered mandatory in order to avoid unfavorable complications that will adversely affect prognosis. Splenic artery aneurysms should be promptly treated in high risk patients with symptomatic or expanding aneurysms, women of childbearing age and also patients undergoing liver transplantation^[5,11].

Traditionally surgical and or laparoscopic resection with or without splenectomy is employed in the treatment of SAAs^[5-7,9-12]. However, this patient carried a substantial surgical risk owing to the continuing variceal bleeding and the high possibility of aneurysmal rupture, during surgery, due to its size and the elevated pressure in the splenoportal axis. In addition, surgical approach of SAVFs presents often with technical difficulties and potential hazards of failure because of the distal site of the lesion and the formation of adhesions and numerous portal col-

laterals^[4]. As a result, endovascular techniques emerged as an alternative option. Aneurysmal exclusion using a stent graft was not considered as a feasible solution mostly due to the presence of the fistula and the tortuosity of the splenic artery. In this case successful control of the variceal bleeding and cessation of the hyperkinetic blood flow in the splenoportal axis were achieved by selective catheterization of the sac and detachment of adequate metallic coils that promote permanent thrombosis. Unlike surgical techniques transcatheter arterial embolization is a less invasive, relatively low-risk, rapid procedure that can be easily applied regardless of the location of the vascular malformation^[4,12]. It does not necessitate splenectomy avoiding thus immunologic deficits and a lifelong risk of sepsis^[13]. The aforementioned advantages of transcatheter arterial embolization over surgery support strongly its efficacy in treating safely patients with splenic artery aneurysm complicated with arteriovenous fistula^[4,12,13].

Abstract

Type I gastric carcinoid tumors result from hypergastrinemia in 1%-7% of patients with pernicious anemia. We diagnosed pernicious anemia in a 48-year-old female patient with complaint of fatigue for three months. She had no gastrointestinal symptoms. Endoscopic examination of the upper gastrointestinal tract revealed atrophic gastritis and a polypoid lesion in the corpus of 3-4 mm in size. Endoscopic polypectomy was performed. Histopathological examination of the specimen revealed positive chromogranin A and synaptophysin stainings compatible with the diagnosis of a carcinoid tumor. Serum gastrin level was increased, urinary 5-hydroxyindoleacetic acid was within the normal range. There was no other symptom, sign, or laboratory finding of a carcinoid syndrome in the patient. No metastasis was found with indium-111 octreotide scan, computed tomographies of abdomen and thorax. Type I gastric carcinoid tumors are only rarely solitary and patients with tumors < 1 cm in size may benefit from endoscopic polypectomy.

Kadikoylu G, Yavasoglu I, Yukselen V, Ozkara E, Bolaman Z. Treatment of solitary gastric carcinoid tumor by endoscopic polypectomy in a patient with pernicious anemia. *World J Gastroenterol* 2006; 12(26): 4267-4269

INTRODUCTION

Pernicious anemia is characterized by type A (autoimmune) atrophic gastritis, megaloblastic anemia, and neurological and psychiatric findings. It is the most common cause of cobalamin deficiency due to a loss of acid-secreting parietal cells in the gastric body and fundus^[1]. It is known that patients with pernicious anemia have a higher risk to develop gastrointestinal malignancies such as gastric adenocarcinoma and carcinoid tumors, or oesophageal squamous cell carcinoma^[1-4].

Gastric carcinoid tumors, which arise from hyperplasia of enterochromaffin-like (ECL) cells in the gastric mucosa, comprise 1%-3% of gastric neoplasms^[5-7]. Type I carcinoid tumors are associated with ECL cell hyperplasia, hypergastrinemia, achlorhydria, and chronic atrophic gastritis, with or without pernicious anemia^[8,9]. Type I carcinoid tumors are detected approximately in 1%-7% of the patients with pernicious anemia^[1,3,9,10]. Most of the gastric carcinoid tumors are multifocal, solitary tumors are rare^[3,11-14].

This report describes the treatment of a solitary gastric carcinoid tumor by endoscopic polypectomy in a patient with pernicious anemia.

CASE REPORT

A 48-year-old female patient who was suffering from fatigue for three months was admitted to the hospital. She had no gastrointestinal symptoms, and she negated alcohol abuse. Physical examination revealed pallor, jaundice, and atrophic glossitis. A grade-2 systolic ejection murmur was auscultated on the pulmonary area. Laboratory findings were a hemoglobin level of 59 g/L, a white blood cell count of 2400/mm³, a platelet count of 76 000/mm³, a mean erythrocyte volume of 99 fL, and a reticulocyte count of 2.5%. Peripheral blood smear examination revealed 42% neutrophils, 40% lymphocytes, 12% monocytes, 6% eosinophils, and 3% normoblasts. Moreover, macrocytosis, aniso-poikilocytosis, Howell-Jolly bodies, Cabot ring in erythrocytes, and hypersegmentation in neutrophils were observed. Bone marrow aspiration revealed erythroid hyperplasia (E/M ratio: 6/1), evident megaloblastic changes, and nucleo-

Figure 1 Megaloblastic changes in the bone marrow.

Figure 2 Polypoid appearance and atrophic gastritis at endoscopy.

Figure 3 Carcinoid tumor positive stained with hematoxylin-eosin A and synaptophysin (x 40).

Figure 4 Indium-111 octreotide scan of the patient.

cytoplasmic dissociation in normoblasts (Figure 1). While iron parameters were normal, the levels of vitamin B₁₂ and homocysteine were 62 ng/L (N: 200-900 ng/L) and 91 μ mol/L (N: 0-12 μ mol/L), respectively. Anti-parietal cell antibody was positive. The biochemical values were normal except those for lactate dehydrogenase 1635 IU/L, total bilirubin 44 mg/L, and indirect bilirubin 34 mg/L. Thyroid function tests were normal, too. By performing upper gastrointestinal tract endoscopy, atrophic gastritis in fundus and corpus and a polypoid lesion in the corpus of 3-4 mm in size were seen (Figure 2). *H. pylori* were not detected with rapid urease test. Endoscopic polypectomy was performed. By histopathological examination, a carcinoid tumor was diagnosed, mainly on the basis of positive stainings for chromogranin A and synaptophysin. *H. pylori* was negative (Figure 3). The levels of fasting serum gastrin and 24 h urinary 5-hydroxyindoleacetic acid were 2000 ng/L and 12.6 μ mol (N: 10.4-31.2 μ mol), respectively. Spiral computed tomographies of thorax and abdomen were normal. Indium-111 octreotide scan revealed a normal distribution of tracer activity (Figure 4). Electrocardiography, transthoracic Doppler echocardiography, chest X-ray, and gastric endoscopic ultrasonography were normal. Endoscopic re-examination of the stomach was performed and multiple biopsies were obtained from the polypectomy site. The second pathological examination failed to detect any remnant of the carcinoid tumor or neuroendocrine cell hyperplasia. Treatment with vitamin B₁₂ at a dose of 1000 μ g/d orally was started^[15]. After 6 mo follow-up, the patient was well, and her whole blood counts and the vitamin B₁₂ level were normal.

DISCUSSION

Type I gastric carcinoid tumors result from hypergastrinemia in patients with pernicious anemia. Hypergastrinemia is the result of achlorhydria and atrophic gastritis. Hypergastrinemia acts as a trophic factor for ECL cells, resulting in hyperplasia in gastric mucosa^[6,9-11,16,17]. Serum gastrin levels usually range from 740-4000 ng/L in those patients^[17]. Although most of those patients are asymptomatic, dyspepsia, pain, nausea, unexplained weight loss, gastrointestinal bleeding, or anemia may be seen^[11,13,17]. These carcinoid tumors are usually localized in the gastric fundus or corpus and are less than 2 cm in diameter. Often, they are multifocal. Nodal and hepatic metastasis occur in 2% of the patients^[3,11,12,14,17]. Solitary gastric carcinoid tumors that like our patient were reported infrequently^[11,13,14,17]. Type II gastric carcinoid tumors, a very rare type, occurs in patients with Zollinger-Ellison syndrome. Most of carcinoid tumors are associated with multiple endocrine neoplasia (MEN) type I. Hypergastrinemia and ECL cell hyperplasia are seen in type II gastric carcinoid tumors. They are multifocal, and their sizes are between 1-2 cm. Local lymph node metastasis can produce^[5,6,11]. Type III gastric carcinoid tumors are sporadic, they are not associated with hypergastrinemia, and, in contrast to types I and II, they are invasive large solitary tumors. Carcinoid tumors larger than 3 cm cause metastasis in 66%

of the patients while metastasis is detected in only 10% of patients with single tumors smaller than 1 cm^[11,17,18].

In our patient, pernicious anemia was diagnosed because of macrocytic anemia, megaloblastic changes in the bone marrow, a decreased vitamin B₁₂ level, an increased homocysteine level, and atrophic gastritis. The pathological examination of the polyp revealed a solitary gastric carcinoid tumor. Serum gastrin level was high, and urinary 5-hydroxyindoleacetic acid level was normal. There were not symptoms, signs, or laboratory findings of a carcinoid syndrome in our patient. Because of hypergastrinemia in the absence of a Zollinger-Ellison syndrome or MEN type I, the final diagnosis was type I gastric carcinoid tumor.

The best approach modality to the patients with type I gastric carcinoid tumors is endoscopic resection especially in tumors smaller than 1 cm^[17,19]. Antrectomy/total gastrectomy is recommended in cases with multiple tumors larger than 1 cm, and with abdominal symptoms such as unexplained weight loss, or aggravation of anemia^[6,17,19,20].

We performed endoscopic polypectomy and re-evaluated the patient endoscopically with repeated biopsies. Metastasis was not detected in computed tomographies, pathological examinations, and octreotide scan. Thus, antrectomy/total gastrectomy was not performed. Annual follow-up with endoscopy and computed tomography are planned for the patient. In pernicious anemia, the incidence of gastric carcinoid tumors is increasing as a result of the careful endoscopic and pathological examinations. Type I solitary gastric carcinoid tumors are infrequently detected solitary and endoscopic polypectomy may cure the patient if the tumor is smaller than 1 cm. A follow-up program should be scheduled for patients who underwent polypectomy for any metastasis.

Abstract

In this report, we present computed tomographic findings of colonic trichuriasis. The patient was a 75-year-old man who complained of abdominal pain, and weight loss. Diagnosis was achieved by colonoscopic biopsy. Abdominal computed tomography showed irregular and nodular thickening of the wall of the cecum and ascending colon. Although these findings are nonspecific, they may be one of the findings of trichuriasis. These findings, confirmed by pathologic analysis of the biopsied tissue and Kato-Katz parasitological stool flotation technique, revealed adult *Trichuris*. To our knowledge, this is the first report of colonic trichuriasis indicated by computed tomography.

INTRODUCTION

Trichuris trichiura (*T. trichiura*), a whipworm, is the third most common nematode worldwide after *Ascaris* and *Enterobius*^[1]. First described by Roederer in 1761, the whipworm is found primarily in tropical climates characterized by poor sanitation^[1]. Whipworm infection usually causes no clinical symptoms, although a severe infection can cause abdominal pain, diarrhea, constipation, weight loss, and anemia^[2-5].

In the patient described in this report, we identified irregular and nodular marked thickening of the wall of the cecum and ascending colon as a CT finding of trichuriasis. To our knowledge, this is the first report of colonic trichuriasis revealed by that modality. A follow-up CT scan showed that the colonic manifestations of trichuriasis had resolved six months after the conclusion of the medical treatment.

CASE REPORT

A 75-year-old man with suspected colon carcinoma was referred to our radiology unit for evaluation by computed tomography (CT). He complained of abdominal pain, constipation, and a weight loss of 5 kg in the prior two months. Physical examination revealed mild tenderness in the right lower abdomen. The patient's white blood cell count was $13.9 \times 10^9/L$ (reference intervals, $5-11 \times 10^9/L$) without eosinophilia. The results of other laboratory tests (including biochemical analysis) were within the normal range with the exception of moderate anemia (hemoglobin level, 90 g/L; reference intervals, 140-180 g/L).

CT scans were obtained using a four-channel MDCT scanner (Sensation 4; Siemens, Erlangen, Germany). A mixture of 1000 mL water and 40 mL contrast material was used for bowel opacification. Portal phase CT scans (2.5 mm collimation, 12.5 mm/0.5 s table speed) were acquired at 60 s after contrast material injection.

CT scan of the abdomen showed irregular and nodular marked thickening of the wall of the cecum and ascending colon (Figure 1A, B). Endoscopic examination revealed multiple ulcerated mucosal lesions in the ascending colon. The cecum could not be properly examined because of intestinal content. The results of pathologic analysis of the biopsied tissue, which was obtained colonoscopically from the ascending colon, revealed adult *Trichuris* and the signs of active colitis (Figure 2); these findings were confirmed by Kato-Katz parasitological stool flotation technique^[6]. The patient was subsequently treated with mebendazole 100 mg twice daily for 3 d. On follow-up at the end of the treatment clinical findings had resolved, and a repeat CT scan obtained 6 mo after the treatment revealed a colonic wall thickness within the normal range (Figure 3) and no *T. trichiura* eggs were seen in any stool specimens.

DISCUSSION

Trichuriasis is an intestinal infection found in human beings, which is caused by *T. trichiura*, more commonly known as whipworm because of its whip-like appearance.

Figure 1 Computed tomographic scans (A, B) of the abdomen. Note the irregular and nodular thickened wall of the cecum and the ascending colon (arrows).

Figure 2 Pathologic examination reveals transverse section of anterior portion of *Trichuris trichiura* (arrow) embedded in superficial colonic mucosa and free body part of *Trichuris trichiura* (arrowheads) extending into the lumen of the colon.

Figure 3 Computed tomographic scan obtained 6 mo after the treatment show a normal colonic wall thickness.

It is characterized by the invasion of the colonic mucosa by the adult *Trichuris* and produces minor inflammatory changes at the sites of localization. Trichuriasis remains a health problem in certain geographic areas. Infection is acquired by the ingestion of embryonated eggs from contaminated drinking water and food. The eggs hatch in the small intestine, and the larvae then enter the intestinal crypts^[1]. After a brief period of maturation, the larvae may migrate to the proximal colon, where they reside and over 1 to 3 mo mature into adults^[1,2,6,7]. The adult *T. trichiura* is a threadlike worm 30 to 50 mm in length. *T. trichiura* penetrates the intestinal mucosa and frequently triggers minor inflammatory changes in the cecum, appendix, and terminal ileum^[7]. Diagnosis is usually based on the identification of typical *T. trichiura* eggs in stool specimens^[6]. Adult whipworm is rarely seen during colonoscopy and colonoscopy can directly diagnose trichuriasis, confirming the threadlike form of worms with an attenuated end^[7-11]. Literature research revealed that imaging findings sometimes similar with a tumor of the colon because of tumor-like appearance of the granulomatous tissue reaction due to *T. trichiura*^[12].

A few reports have described the radiographic appearance of *T. trichiura* on double-contrast barium enema^[13]. Characteristic findings revealed by that modality have included multiple tiny target-shaped or pinwheel-shaped collections of barium that are associated with peculiar s-shaped filling defects thought to be consistent with the shape of the adult male *T. trichiura*^[13]. Colonic

wall thickening is a common and nonspecific finding that occurs in many other conditions such as infections, inflammatory bowel disease and carcinoma. However, knowledge of this entity is helpful for differential diagnosis in the endemic areas of trichuriasis.

We concluded that colonoscopy with biopsy is the gold standard for such disease like trichuriasis. Irregular and nodular thickening of the cecum and the ascending colon on CT scan may be one of the findings of trichuriasis. Although that finding is nonspecific, parasitic infections including trichuriasis should be considered as differential diagnoses, especially in areas in which such infection is endemic.

Abstract

Percutaneous liver biopsy is considered one of the most important diagnostic tools to evaluate diffuse liver diseases. Pseudoaneurysm of hepatic artery is an unusual complication after ultrasound-guided percutaneous liver biopsy. Delayed hemorrhage occurs much less frequently. We report a case of pseudoaneurysm of the hepatic artery of a 46-year-old man who was admitted for abdominal pain after 4 d of liver biopsy. The bleeding was controlled initially by angiographic embolization. However, recurrent bleeding could not be controlled by repeat angiography, and the patient died 4 d after admission from multiorgan failure. The admittedly rare possibility of delayed hemorrhage should be considered whenever a liver biopsy is performed.

Ren FY, Piao XX, Jin AL. Delayed hemorrhage from hepatic artery after ultrasound-guided percutaneous liver biopsy: A case report. *World J Gastroenterol* 2006; 12(26): 4273-4275

<http://www.wjgnet.com/1007-9327/12/4273.asp>

INTRODUCTION

Percutaneous liver biopsy is considered one of the most important diagnostic tools to evaluate diffuse liver diseases. The most common complication of percutaneous liver biopsy is bleeding. The major complication and mortality rates are about 2%-4% and 0.01%-0.33% respectively^[1]. Ultrasonography-guided percutaneous liver biopsy has been shown to increase the diagnostic yield and significantly decrease complications even on outpatients^[2-4].

The less common complication of delayed bleeding after percutaneous liver biopsy, has a higher mortality associated with late recognition^[5]. Pseudoaneurysms of the hepatic artery initially should be managed with angiographic embolization, reserving surgical intervention for failure of embolization^[6]. Here we report a case of fatal delayed hemorrhage from pseudoaneurysm of the hepatic artery after percutaneous liver biopsy. The diagnosis was confirmed by ultrasound and angiography.

CASE REPORT

A 46-year-old man with genotype 1b chronic hepatitis C virus (HCV) infection was evaluated for progressive fatigue and elevated aminotransferases. The hemoglobin, prothrombin time, bleeding time, and platelet count were normal. Abdominal ultrasound was normal and ultrasonography showed no focal hepatic lesion or evidence of cirrhosis. He received a liver biopsy to evaluate the pathologic change before interferon therapy. A percutaneous liver biopsy was conducted under ultrasonographic guidance with a 2.8-mm Menghini-type aspiration needle with one pass. Chronic hepatitis was diagnosed based on histopathological assessment according to a scoring system that includes semi-quantitative assessment of liver disease grading and staging^[7]. Laboratory data and liver biopsy revealed moderate activity (grade 2/4, stage 2/4). After liver biopsy, transient hypotension was noted during the first two hours of in-hospital observation and the patient was discharged 6 h later.

Four days later, the patient complained of right upper quadrant pain radiating to the right shoulder. The abdomen was soft with normal bowel sounds and mild right upper quadrant tenderness without rebound tenderness. The patient denied abdominal trauma. Laboratory results including white blood cell count (WBC): $5.5 \times 10^9/L$; platelet count (PCT): $204 \times 10^9/L$; hematocrit (HCT): 47%; prothrombin time international normalized ratio (INR): 1.0; aspartate aminotransferase (AST): 107 IU/L; alanine aminotransferase (ALT): 145 IU/L; total bilirubin (TBIL): 16 $\mu\text{mol/L}$; alkaline phosphatase (ALP): 128 IU/L; BUN and serum creatinine (CRE): were normal. His blood pressure (BP) was 19.3/11.3 kPa, and heart rate (HR) 69 beats/min. The diagnosis of pseudoaneurysm was established 4 d after the percutaneous liver biopsy by abdominal ultrasonography. The patient suddenly became hemodynamically unstable

Figure 1 Angiography of the right hepatic artery. Pseudoaneurysm (arrows) in the right hepatic artery branch.

Figure 2 Platinum coils (arrows) are seen filling the feeding branch. Angiography obtained after embolization of the branch leading to and from the pseudoaneurysm.

with an HR 135 beats/min and BP 10.7/5.3 kPa 13 h after admission, which was over 5 d after the percutaneous liver biopsy. The repeat HCT was 39%. The patient was resuscitated and underwent immediate angiography, which showed a pseudoaneurysm in the right hepatic artery branch (Figure 1). The pseudoaneurysm measured approximately 1.8 cm × 2.1 cm. The patient was treated with embolization performed by multiple straight of the right hepatic artery branch (Figure 2). The angiography was repeated 28 h after admission and revealed continued extravasation of blood from the right lateral subcapsular location. These demonstrated new areas of active arterial extravasation with possible complex laceration of the right hepatic lobe. The laboratory tests obtained 33 h after admission showed INR 2.1; ALT: 3970 IU/L; AST: 4910 IU/L; ALP: 290 IU/L; TBIL: 32 μ mol/L; albumin (ALB): 17 g/L, CRE: 230 μ mol/L; and BUN: 19 mol/L. Soon afterward, the patient received surgery, which revealed right hepatic lobe laceration with hemorrhage. After surgery, the patient's condition continued to deteriorate with a decreasing HCT. Repeated ultrasound of the liver revealed the interval development of multiple cystic lesions in the right hepatic lobe compatible with intrahepatic hematomas. No further surgical intervention was performed because of the diffuse nature of the bleeding. The patient died 4 d after admission from multiorgan failure.

DISCUSSION

Outpatient percutaneous liver biopsy is a common practice in the differential diagnosis and treatment of chronic liver disease. The major complication and mortality rates were about 2%-4% and 0.01%-0.33% respectively^[1]. According to the recent National Institutes of Health (NIH) Consensus Conference on the management of chronic hepatitis C, liver biopsy is recommended before therapy to assess the severity and activity of the liver disease^[18]. Treatment with interferon is recommended if the liver biopsy shows evidence of septal fibrosis and/or moderate-to-severe necroinflammatory changes. More recent view on the issue of performing a liver biopsy in hepatitis C patients advises to perform a liver biopsy in genotype 1 patients, but usefulness of histologic assessment in genotypes 2 or 3 is debated, since these patients have a very good virological response^[9]. At the best, liver biopsy is supported by a grade III recommendation^[9]. Early bleeding

within hours can result from intrahepatic hematoma or laceration of the liver capsule^[1]. Previous studies showed an overall complication rate of 0.28% and fatality rate of 0.03% among 189 085 liver biopsies^[10]. Other reports showed, there were 3 deaths (0.004%) in 68 276 and 19 deaths (0.052%) in 36 786 liver biopsies^[11]. Factors associated with an increased risk of hemorrhage included increasing age, number of biopsy passes and presence of malignancy in the liver^[1,12]. The risk of hemorrhage or complication^[13] was not related to the biopsy needle type or diameter of the needle^[14].

Pseudoaneurysms more commonly occur in patients who are post liver transplant or post cholecystectomy^[15,16]; only 11 pseudoaneurysms occur among 1211 patients undergoing multiple liver biopsies after liver transplantation, whereas only 2 (0.17%) cases were attributed to percutaneous liver biopsy^[17]. This case report demonstrated an unusual complication of hepatic artery pseudoaneurysm from percutaneous liver biopsy. The use of teep mattress sutures for initial control of bleeding is preferred^[18]. After percutaneous liver biopsy with liver diseases, most patients experiencing these events were asymptomatic, and angiographic defects were found in 61% of angiography performed within 1 wk but in 11% of angiography done after more than 1 wk^[16]. The present case showed that clinical features of pseudoaneurysms may range from asymptomatic to hemobilia to massive delayed fatal hemorrhage. Ultrasound with Doppler can be used to diagnose pseudoaneurysm and to evaluate portal blood flow. A celiac or selective hepatic angiography will demonstrate the actual location and size of the pseudoaneurysm^[16,19]. A few previous studies showed that embolization of a hepatic artery pseudoaneurysm had a success rate of 97%, and the occlusion of the more proximal hepatic artery caused by dissection or thrombosis may necessitate a direct percutaneous approach^[15]. Both transarterial and direct percutaneous accesses to pseudoaneurysms have also been successfully employed^[15]. However, direct embolization of the pseudoaneurysm, allowing patency of the hepatic artery, has also been reported^[15]. In this case, bleeding from pseudoaneurysm of the hepatic artery was controlled initially with embolization, but laboratory tests performed after embolization suggest that the patient apparently had ischemic hepatitis and continued to deteriorate from rebleeding. The patient died 4 d after admission from

multiorgan failure. Ischemic hepatitis or shock liver is defined as an extensive hepatocellular necrosis associated with a decrease in hepatic perfusion due to systemic hypotension. Serum aminotransferase levels (ALT and AST) increased rapidly after the ischemic episode and peaked within 1 to 3 d to at least 20 times the upper normal limit. After recovery, aminotransferases returned to near normal levels in 7-10 d of the initial insult^[20].

In conclusion, delayed fatal hemorrhage from pseudoaneurysm of hepatic artery is an unusual complication after percutaneous liver biopsy. Pseudoaneurysms should initially be managed with angiographic embolization^[6], and surgical intervention may be needed if embolization fails.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published by
The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
<http://www.wjgnet.com>
Telephone: +86-10-85381901
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations,

institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

Key words

Please list 6-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P*<0.05, ^b*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, ^c*P*<0.05 and ^d*P*<0.01 are used. Third series of *P* values can be expressed as ^e*P*<0.05 and ^f*P*<0.01. Other notes in tables or under illustrations should be expressed as ¹*F*, ²*F*, ³*F*; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included.

Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Patent (list all authors)

- 16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 \pm 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂ not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjnet.com/wjg/help/15.doc>

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used

abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please download CAF from <http://www.wjgnet.com/wjg/help/9.doc>.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to *WJG* all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The *WJG* requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1) direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3) supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The *WJG* does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to *WJG* if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

COPY EDITOR FOR THIS ISSUE: Dr. Patricia F Lalor

World Journal of Gastroenterology (*World J Gastroenterol* , *WJG*), a leading international journal in gastroenterology and hepatology, has an established reputation for publishing first class research on esophageal cancer, gastric cancer, liver cancer, viral hepatitis, colorectal cancer, and *Helicobacter pylori* infection, providing a forum for both clinicians and scientists, and has been indexed and abstracted in Current Contents/Clinical Medicine and Science Citation Index-Expanded, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, Nature Clinical Practice Gastroenterology and Hepatology, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993. *WJG* is a weekly journal published by The *WJG* Press. The publication date is on 7th, 14th, 21st, and 28th every month. The *WJG* is supported by The National Natural Science Foundation of China, No. 30224801 and No.30424812, which was founded with a name of *China National Journal of New Gastroenterology* on October 1,1995, and renamed as *WJG* on January 25, 1998.

Abstract

The gastrointestinal tract is lined by a simple epithelium that undergoes constant renewal involving cell division, differentiation and cell death. In addition, the epithelial lining separates the hostile processes of digestion and absorption that occur in the intestinal lumen from the aseptic environment of the internal milieu by defensive mechanisms that protect the epithelium from being breached. Central to these defensive processes is the synthesis of heme and its catabolism by heme oxygenase (HO). Dietary heme is also an important source of iron for the body which is taken up intact by the enterocyte. This review describes the recent literature on the diverse properties of heme/HO in the intestine tract. The roles of heme/HO in the regulation of the cell cycle/apoptosis, detoxification of xenobiotics, oxidative stress, inflammation, development of colon cancer, heme-iron absorption and intestinal motility are specifically examined.

INTRODUCTION

The lumen of the intestine mucosa is predominately

covered with epithelial cells called enterocytes which are responsible for the terminal digestion and absorption of nutrients. These cells have a limited lifespan before being replaced by cells derived from the crypt region^[1]. There is also evidence of apoptosis within the crypt, presumably in response to excess cellular proliferation, cytotoxicity or genomic damage^[2]. Surviving cells undergo apical migration, limited cell replication, commitment and differentiation^[1]. The process of differentiation is gradual, characterised by the accumulation of cell-specific products in the upper crypt region and attaining the mature phenotype in the lower to middle-villus region. Recent evidence indicates that heme is important in intestinal development as well as maintaining the mucosal barrier and protecting the body from invasion and the damaging consequences of ingested xenobiotics. However, heme in the colon may irritate the mucosa and derange the normal rates of proliferation/exfoliation, circumstances that raise the probability of colon cancer. Heme is also an important source of body iron and how it is absorbed by the enterocyte is considered in this article, as well as the role heme plays in intestinal motility. It needs to be recognised that an in depth focus on each of these components is outside the scope of this review, rather it is our intention to provide the general reader with evidence and interpretations supporting the markedly varied involvement of heme in intestinal function.

HEME BIOSYNTHESIS AND HEME OXYGENASE (HO) (EC 1.14.99.3)

Heme biosynthesis

Heme biosynthesis involves 8 enzymes, four localised to the cytoplasm and the others in the mitochondrial matrix^[3-5] and is regulated by the first enzyme in its synthesis aminolevulinic acid synthase^[6] (Figure 1A). Heme biosynthesis also requires iron, which in the intestinal crypt is derived from the plasma by the activity of the transferrin receptor operating in collaboration with the hemochromatosis protein (HFE)^[7] (Figure 1B). Although heme synthesis is highest in the crypt epithelium it continues along the length of the crypt-villus axis. As the cells leave the crypt region iron appears to be acquired from the diet since dietary iron deficiency reduces the heme content of villus enterocytes, and in villus cells transferrin receptor has 25% the activity of crypt epithelium^[8,9] (Figure 1B).

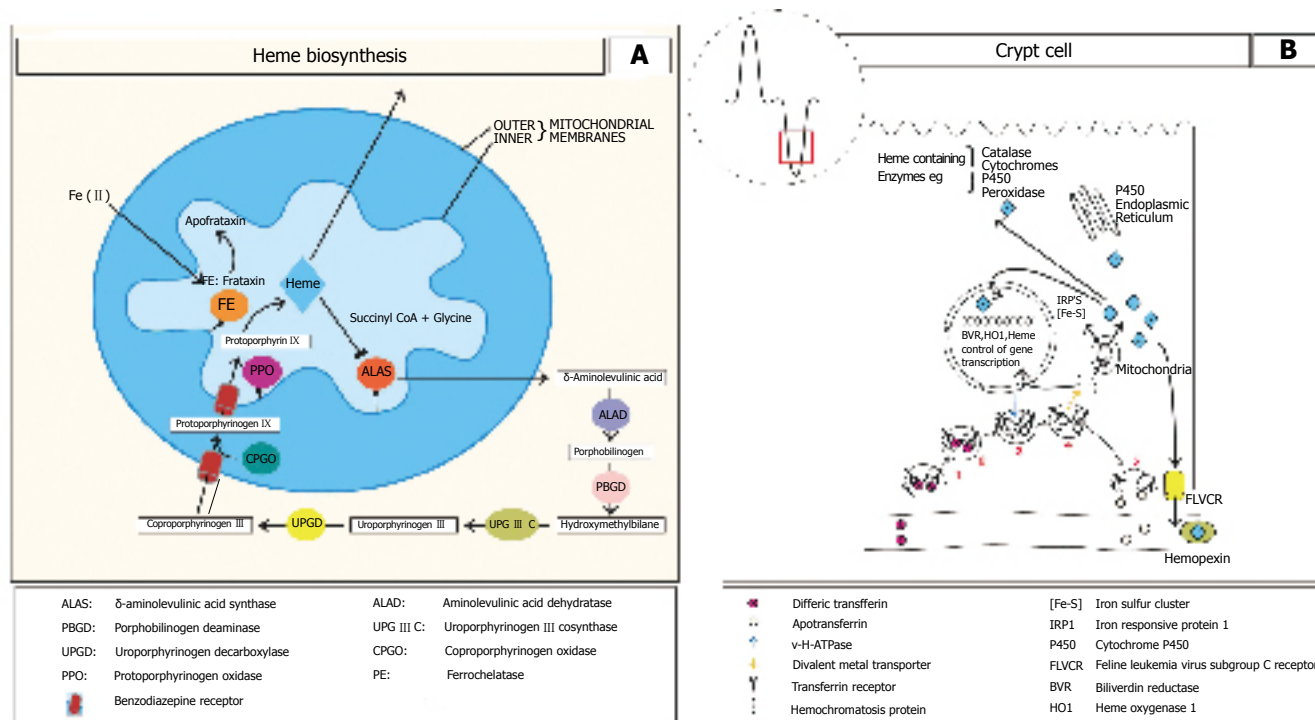

Figure 1 A: The heme biosynthetic pathway. Mitochondrial and cytosolic locations of the eight enzymes are shown circled and coloured. Commencing synthesis is ALAS on the inner mitochondrial membrane of the first intermediate as well as subsequent intermediates. Heme synthesis is regulated by heme at the level of ALAS via feedback repression. It has been suggested that frataxin may donate ferrous iron to protoporphyrin in the formation of heme; **B:** In the intestinal crypts the uptake of plasma transferrin-iron occurs by the transferrin receptor (TfR). In iron deficiency HFE complexes with TfR1 and to a much lesser extent with iron loading. (1) TfR binds to plasma diferric transferrin. (2) TfR is internalised by receptor mediated endocytosis. (3) In the cytoplasm a v-H-ATPase fuses with the endosome and acidifies it to release the iron from transferrin. Following ferrereduction Fe(II) is transported to the cytoplasm by a metal transporter. (4) possibly divalent metal transporter 1 (DMT1). The iron is then transported into the mitochondria where it is incorporated into heme. The mitochondria are also a major producer of iron sulphur clusters. (5) The transferrin receptor - apotransferrin complex then return to the cell membrane where at the neutral pH, apotransferrin dissociates. Heme, heme oxygenase and BVR may regulate gene transcription during enterocyte differentiation. FLVCR functions to export excess heme.

Function of HO

HO catalyses the mixed function oxidation of heme using cytochrome P-450, NADPH and molecular oxygen^[10-12]. HO functions in the oxidative cleavage of heme specifically at the α -methane bridge, resulting in the formation of biliverdin IX α which is rapidly reduced to bilirubin IX α by soluble biliverdin reductase (BVR). Since tissue BVR activity is 30-50 times greater than HO activity, this suggests that it is unlikely to limit heme breakdown, and that the rate limiting component is HO^[12]. Recently, the crystal structure of HO in complex with heme and biliverdin-iron has been solved^[13]. HO binds heme and oxygen between two helical folds with the proximal fold binding heme while the distal helix contains an oxygen binding site^[13].

Isoforms of HO

HO is expressed as two isoforms designated HO-1^[14] and HO-2^[14,15] which are products of different genes^[14]. HO-1 shares substantial homology with HO-2^[15]. The molecular mass of HO-1 is 32 kD, while HO-2 is 36 kD. HO-1 expression is induced by numerous factors, including oxidative stress, inflammation, cytokines, nitric oxide, prostaglandins, an elevated level of substrate^[16], iron deficiency^[17], metals including Cd, Co, Cr, Cu, Fe, Hg, Ni, Pd, Pt, Sn, Zn^[3,16,18,19], hyperoxia^[20] and UV light^[21]. The induction of HO-1 by hyperthermia has led to use of an alternate name, heat shock protein 32 (HSP-32)^[22]. Unlike

the inducible expression of HO-1, HO-2 expression is relatively constant.

HO and re-utilization of heme

HO-1 is mainly involved in the reutilization of heme-iron from hemoglobin and the expulsion of iron from tissue stores as evidenced by HO-1 knockout mice which develop anaemia because of progressive tissue iron retention particularly within macrophages^[23]. A previous study shows that less than 50% of endogenous hepatic heme degradation in rats is accounted for by HO-1 activity as evidenced by the generation of CO from heme^[24]. Therefore there appear two separate fates for catabolized heme-iron. Firstly a HO-1 dependent pathway, where iron from heme passes efficiently from the macrophage to the plasma, probably by the iron transporter ferroportin^[25], and secondly, a HO-1 independent pathway which results in retention of the freed iron.

HO and oxidative stress

HO-1 functions to diminish cellular oxidative stress because HO-1 reduces the levels of the pro-oxidant heme and produces the antioxidant bilirubin^[26]. Supporting this, humans deficient in HO-1^[27] and individuals with impaired transcription due to a microsatellite polymorphism in the HO-1 promoter region^[28,29] present with a phenotype similar to HO-1 knockout mice^[30]. Interestingly, HO-2 is unable to compensate for the loss of HO-1, probably

because its expression is restricted to a select group of cells or it is unable to be induced to the levels of activity required to produce the effects seen with HO-1 expression^[27-30]. HO-1 and intestinal oxidative stress is discussed in a later section.

INTESTINAL HEME BIOSYNTHESIS AND HEME OXYGENASE

Heme biosynthesis

The synthesis of heme and heme-containing proteins is crucial for intestinal function. These hemoproteins include electron carrying proteins such as cytochrome (CYP) P450 (see section on detoxification), mitochondrial localised cytochromes, the ferriredutase Dcytb^[31], catalase and peroxidases which catalyse the reaction of hydrogen peroxide (H₂O₂) to water and oxygen (see section on oxidative stress). In addition to biosynthesis, heme can also be acquired by the enterocyte *via* intestinal absorption. This will be discussed in detail below with respect to the intestine.

HO gene expression

In the human intestinal cell lines CaCo-2 and HT-29, internalisation of heme increased HO-1 expression, indicating that the heme responsive element in the promoter region of the HO-1 gene was accessible and functional^[32,33]. Duodenal HO-1 expression is also increased in iron deficiency^[17] and by conditions that lead to oxidative stress including heavy metals and inflammation (see below with respect to the intestine). Up-regulation of HO-1 gene expression *via* the estrogen receptor β ^[34], octreotide, a somatostatin analogue^[35] and glutamine^[36] has been established. HO-2 expression is constitutive and mainly confined to the enteric nervous system and interstitial cells of Cajal, although it is possible that HO-2 is expressed by enterocytes^[37]. This will be addressed later in this review.

Heme turnover along the crypt-villus axis

Heme turnover is the balance between heme synthesis and its destruction by heme oxygenase. It is subject to variation along the crypt-villus length, being highest in the crypt and least at the villus tip^[38]. Thus the crypt region has the highest activity of both heme biosynthesis and heme oxygenase activity. As the cells migrate the rate of heme synthesis decreases but destruction decreases to a lesser extent, therefore total heme content is highest at the villus enterocytes compared with crypt epithelium.

HO-1 and intestinal cell proliferation and differentiation in the crypts

Cell turnover and differentiation is a function of crypt epithelium. Similar to that seen in the crypt epithelium, HO-1 activity is highest in undifferentiated intestinal epithelial Caco-2 cells^[39]. This suggests that HO-1 and cell proliferation/apoptosis may be linked^[40]. Supporting this, inhibiting HO-1 activity reduced cell proliferation and increased cell death^[40,41]. Conversely, in the human intestinal cell line HT-29 cells induction of HO-1 activity reduced expression of the pro-apoptotic gene caspase-3

and inhibited apoptosis. This supports the idea that HO-1 activity is anti-apoptotic^[42]. It is possible that HO-1 mediates these effects indirectly on gene transcription *via* the activity of BVR (Figure 2).

HO/BVR in intestinal cell signalling

BVR (EC 1.3.1.24) must undergo auto-phosphorylation in order to convert biliverdin to bilirubin^[43]. This property of phosphorylation/dephosphorylation during the conversion of biliverdin to bilirubin is similar to that seen with signalling kinases. Recent evidence indicates that BVR functions as a serine/threonine kinase that operates in the insulin receptor/MAPK pathways^[44] and a transcription factor with a bZip domain involved in ATF-2/CREB and HO-1 regulation^[45]. These additional roles suggest that BVR may have a broader function in regulating cellular activity^[46]. Since BVR immunoreactivity is seen in nuclei of epithelium lining the GI tract, this suggests a possible role in the regulation of gene transcription^[47].

HO-1 acts as a guardian of the genome during differentiation

It is possible that HO-1 may modulate proliferation by scavenging and/or preventing the formation of reactive oxygen metabolites (ROM) and reactive nitrogenous metabolites (RNM), since ROM inhibit Caco-2 cell proliferation^[48] and stimulate apoptosis^[49]. This is particularly relevant to the intestinal crypt region where proliferation exists and the levels of antioxidant detoxifying enzymes such as superoxide dismutase, glutathione peroxidase, glutathione reductase and catalase are low^[50]. If this is true then HO-1 level in the crypt region may act in defence against oxidative stress to limit mutation of DNA. HO-1 may therefore be one guardian of the genome, limiting mutations of DNA and promoting deletion of aberrant cells (Figure 2).

Differentiation is likely to result in elimination of cellular heme

As discussed previously the production of heme for enzymes, electron transport and as substrate for activity of HO1 and BVR is likely to be finely balanced since excess heme leads to oxidative stress and subsequent cell damage. Therefore as differentiation concludes heme production must fall. This may be achieved through reduced heme biosynthesis, increased HO-1 activity or increased heme export. With respect to heme export, a human heme exporter with homology to Feline leukaemia virus, subgroup C receptor (FLVCR) has recently been identified which has a clear function in erythropoiesis at the CFU-E stage of development^[51]. Impairment of FLVCR leads to the loss of CFU-E cells and impairs erythroid differentiation by inducing apoptosis. FLVCR is also expressed by Caco-2 cells, suggesting that it may be involved in intestinal differentiation by reducing the cellular heme concentration as the cell differentiates^[51]. This would reduce the oxidative burden on the stem/progenitor cell and potentially limit genomic damage^[52]. Supporting the existence of the FLVCR in the intestine, Caco-2 cells internalised heme by an active transport process and transcytosed it from apical to basal surfaces^[53].

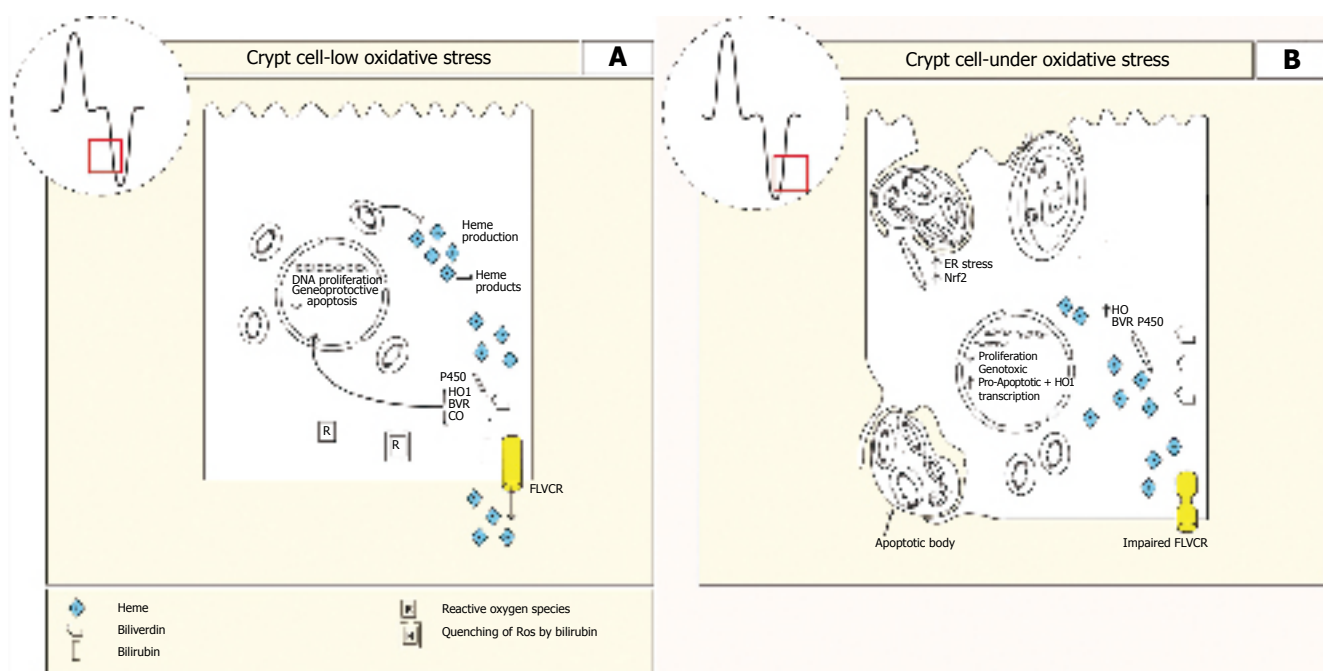

Figure 2 A: Epithelium of the crypt region is active in cell proliferation and differentiation. Heme production is required for the synthesis of heme containing enzymes. In these cells there are also high levels of heme oxygenase activity suggesting that heme breakdown is required for the production of bilirubin and carbon monoxide to maintain appropriate proliferation, differentiation and apoptosis. If the oxygen tension of the cell should increase or production of heme exceeds use, as would be seen as differentiation proceeds, then excess heme may be exported via FLVCR to limit oxidative stress. Increased oxidative stress may also be buffered by the antioxidant bilirubin; B: In the presence of increased oxidative stress caused by excess heme production, impaired FLVCR transport or increased oxygen tension, heme increases to levels that are genotoxic and the cell is predisposed to pro-apoptotic gene expression placing the cell into a death programme. Normal intestinal growth and differentiation would be impaired.

The converse was also true. Exposing the membranes to trypsin selectively increased the rate of uptake across the apical membrane only. Taken together these results raise the possibility that heme can be actively secreted from the cell in either direction possibly involving FLVCR (Figure 2).

HO activity along the length of the intestinal tract correlates with heme-iron absorption

HO activity is highest in the duodenum and lowest in the terminal ileum^[54-56]. This pattern of HO activity appears to correlate with the uptake of ingested xenobiotics and heme-iron absorption along the length of the intestinal tract (see below). In fact, treating rats with phenobarbital increased microsomal P450 enzyme activity, and absorption of iron from hemoglobin^[57]. Conversely, when an inhibitor of intestinal HO activity was given, intestinal heme-iron absorption decreased^[58] (see below).

HO and CYP450 activities in xenobiotic metabolism

The intestine makes an important contribution to the detoxification of many ingested xenobiotics (food additives, industrial chemicals, pesticides, plant toxins and pharmaceutical agents)^[59-61]. The heme containing P450 enzymes in particular the CYP3A superfamily are an integral component of xenobiotic detoxification. P450 levels are highest in the proximal duodenum, falling to lowest levels at the ileum^[62,63]. This correlates with the gradient of exposure to ingested xenobiotics. The highest activity of the P450 enzymes studied to date is the villus region^[64-67]. Interestingly, ingested xenobiotics induce greater CYP activity in the crypt epithelium compared with

villus enterocytes^[66]. Since the crypt cells do not absorb nutrients, this suggests that they passively absorb the drug or that the drug is actively absorbed by enterocytes and then taken up from the plasma by crypt cells. This interpretation is consistent with highest levels of heme biosynthesis in crypt epithelium.

Detoxification involves three phases, firstly the CYP450s and its mixed function oxidases adds a reactive group to the xenobiotic, secondly the molecule is made water soluble by conjugation to glucuronic acid, sulphates, glutathione or amino acids by UDP-glucuronosyltransferases [UGT], sulfotransferases [SULT] or glutathione *S*-transferases [GST], respectively, thirdly the metabolite is excreted from the enterocyte into the lumen by a transporter such as the ATP binding cassette transporters (ABC), P-glycoprotein^[59,62,63]. This "first pass" detoxification of xenobiotics is most active in the upper villus where absorption of nutrients and xenobiotics are greatest^[64-67].

To perform optimal detoxification the enterocyte must express appropriate levels of CYP450 and this is in part determined by heme turnover. Therefore for the enterocyte to express appropriate CYP450, adequate absorption of iron from the diet is required for heme synthesis along with conditions that limit HO-1 expression^[68-70]. If HO-1 activity is induced, for example by ingestion of environmental contaminants such as cadmium, organotin and heavy metals increased destruction of CYP will take place and first pass detoxification will be compromised. Similarly, iron deficiency reduces the ability to synthesise heme and therefore detoxify xenobiotics^[64,65,71]. This may

Figure 3 Left: Xenobiotics in the diet enter the enterocyte via facilitated diffusion or a specific transport process. Appropriate P450 expression on smooth endoplasmic reticulum (SER) enables first pass metabolism including phase I, and phase II metabolizing enzymes. Phase III multi drug resistance transporters (MDR) transport the conjugated-xenobiotic compound to the lumen or blood stream where increased hydrophilicity impairs re-entry into the enterocyte and leads to its elimination from the body directly. *De novo* synthesis of P450 occurs in the enterocytes and is dependent on appropriate levels of dietary iron. Right: In the presence of oxidative stress caused by high dietary intake of metals or compounds that induce heme oxygenase 1 (HO-1), heme containing P450 are broken down leading to increased entry of xenobiotics to the body. Dietary iron deficiency leads to reduced P450 activity and reduced detoxification capabilities.

therefore predispose an individual to cancer and ulceration of the colon^[72] (Figure 3).

HO and hyperbilirubinaemia

Several metalloporphyrins are competitive inhibitors of HO-1 activity because they have the capacity to interact with the heme binding site in HO-1, but are unable to activate the enzyme. This leads to a loss of heme degradation^[73-76]. This strategy has been used in the correction of human neonatal hyperbilirubinemia^[77-79]. Treatment with tin-protoporphyrin/mesoporphyrin, two structurally related heme analogues are effective in lowering serum bilirubin levels in many animals by competitively inhibiting HO^[73-79]. In addition, the use of short interfering RNAs targeting HO-1 mRNA expression has also been proposed to treat hyperbilirubinemia^[80]. Although there is a recognised loss of endogenous heme through the bile during metalloporphyrin administration^[81-83] that has been linked to an iron deficient state^[84], the iron deficiency has been shown to be readily reversible.

In the enterocyte, bilirubin is conjugated to glucuronic acid by bilirubin glucuronyl-transferase and excreted into the intestinal lumen^[85], or passed into the plasma where it non-covalently binds albumin and is transported to the liver, conjugated and excreted into the bile. However, early in perinatal life the luminal activity of secreted lysosomal-derived glucuronidase is high suggesting that enterocyte and biliary excreted conjugated-bilirubin can be deconjugated within the intestinal lumen enabling bilirubin to be reabsorbed *via* the enterohepatic circulation^[86]. This would contribute to neonatal hyperbilirubinemia.

Glutamine increases HO-1 expression

Glutamine is a major source of energy for the enterocyte and has been shown to promote intestinal growth and maintain intestinal integrity particularly when the intestine is heat stressed and starved^[36,87-91]. Glutamine stimulates intestinal proliferation and acts synergistically with epidermal growth factor to induce the mitogen-activated protein kinases and Jun nuclear receptor kinases. These in turn phosphorylate nuclear transcription factors such as AP-1 which activate transcription of target genes involved in cell proliferation and repair, including HO-1^[36,88]. Recently it was shown that glutamine stimulation of HO-1 expression was protective against endotoxic shock of the lower intestine^[90].

The inflammatory response and the role of HO-1

The epithelium lining the gastrointestinal tract presents a “mucosal barrier” to the migration of pathogens into the lamina propria that reside within the lumen of the gastrointestinal tract. In addition to the epithelium which is selectively permeable to nutrient absorption, the mucosal barrier comprises tight junctions that prevent migration of pathogens between cells. Breaching the mucosal barrier elicits an inflammatory response which first involves the innate immune system. Toll like receptors (TLR) expressed on the basolateral surface of enterocytes and the cell membrane of macrophages are activated^[92] and these in turn activate intracellular signalling pathways that induce NF- κ B dependent transcription of genes involved in the pro-inflammatory response such as cytokines, chemokines, immune receptors, nitric oxide synthase, prostaglandins and cell surface adhesion molecules^[93-95]. The pro-inflammatory mediators initially function to increase blood flow and edema. Concomitant with this, endothelial cell membranes express cell adhesion receptors including ICAM-1 that enable white blood cells to adhere and extravasate^[34]. The further release of pro-inflammatory chemokines (CINC-1, -3) may lead to hemostasis and organ failure^[34].

Inflammation is known to induce HO-1 gene expression and in turn its activity. The bilirubin and CO produced are thought to have restorative effects on impaired tissue function, in the case of bilirubin it is a potent anti-oxidant^[26,96-98]. There was increased oxidized bilirubin in the urine of patients following invasive surgery, supporting the idea that bilirubin acts as an antioxidant to scavenge reactive oxygen species^[97].

The second metabolite of HO-1 activity, CO has been shown to relax vascular smooth muscle by binding to the heme moiety of soluble guanyl cyclase (sGC). Activation of sGC increases blood flow to the site of intestinal injury^[99,100], inhibits platelet aggregation^[101], reduces microvascular fibrin accumulation^[102] and restricts leukostasis in postcapillary venules^[93,103]. Reduced leukostasis by CO is thought to occur *via* inhibition of the expression of the adhesion molecules, P-, E- selectins, and ICAM although some contribution by bilirubin is also thought responsible for the leukostasis^[104-106]. CO exerted additional cytoprotection by inhibiting components of the pro-inflammatory pathway including TNF- α , IL-1 β , IL-2,

Figure 4 **A:** The intestinal mucosal barrier is maintained by a series of lateral membrane specialisations near the apical pole of the epithelial cell. It comprises tight junctions, adherens junctions, desmosomes and gap junctions that prevent the movement of pathogens across the epithelial monolayer. Constitutive expression and activities of endothelial nitric oxide synthase (eNOS) and heme oxygenase 1 (HO-1) is important for maintaining adequate blood flow, anti-inflammatory, anti-thrombotic (-) and anti-apoptotic effects on endothelium, neutrophils, platelets, and enterocytes, respectively. HO-1 activity produces the antioxidant bilirubin to limit oxidative damage; **B:** The loss of mucosal integrity results in the translocation of pathogens and establishment of an inflammatory response by the following series of events. (1) Initiation of synthesis of proteases by bacteria erode tight junction complexes between epithelial cells. (2) Binding of bacterial motifs activates toll like receptors, initiating the NF- κ B pathway. (3) Increased expression of pro-inflammatory cytokines, chemokines and endothelial cell surface adhesion molecules. (4) Leukocytes extravasate and increased permeability of capillaries increases fluid accumulation (5) Phagocytic cells produce myeloperoxidase which combines with peroxide to form hypochlorous acid that damages pathogen and host systems alike. (6) Peroxide produced by enterocytes in combination with ferrous iron can produce superoxide anions that damage lipids, DNA and proteins. (7) NO is produced at high concentrations that combines with peroxide to form the pro-oxidant peroxynitrite. (8) Platelets also bind to the endothelial surface to induce hemostasis. (9) Presentation of antigens by dendritic cells via major histocompatibility class 1 to cytotoxic T-cells leads to antibody presentation and destruction of infected epithelial cells.

IL-6, interferon- γ and cyclo-oxygenase, while stimulating the anti-inflammatory cytokine IL-10^[42,107-114] (Figure 4).

The third metabolite resulting from HO-1 activity is Fe(II). If this reaches the labile iron pool it will induce oxidative stress by participating in Fenton and Haber Weiss driven reactions and this would exacerbate inflammation. However, this is avoided by sequestration by ferritin^[21].

Endothelial nitric oxide synthase (eNOS) maintains mucosal integrity

Nitric oxide synthase (NOS) is a heme-containing enzyme that converts L-arginine to nitric oxide (NO) and citrulline. Similar to CO, NO binds the heme moiety of guanylate cyclase to produce vascular smooth muscle relaxation. Under normal circumstances eNOS/NO is important in maintaining mucosal integrity by modulating intestinal blood supply. NO at low concentrations stimulates mucous production, electrolyte secretion and decreases pro-inflammatory responses of mast cells, neutrophils, platelets and endothelial cells^[115-117] (Figure 4A).

Induction of nitric oxide synthase (iNOS) damages mucosal integrity

During inflammation cytokines activate NF- κ B dependent gene expression of iNOS by intestinal epithelial cells, neutrophils and macrophages. This leads to production

of NO^[116-118] at considerably higher levels than by eNOS activity. At this concentration NO reacts with superoxide anions to form the cytotoxic reactive nitrogen metabolite, peroxynitrite^[119-123]. Although peroxynitrite destroys micro organisms, it also reversibly inhibits heme containing proteins including cytochrome C, catalase, cytochrome P-450 and cytoskeletal proteins^[120,122]. It was suggested that inhibition of iNOS during endotoxin-induced gut mucosal dysfunction was beneficial because mitochondrial oxidative metabolism was unimpaired^[119]. This leads to maintenance of mucosal barrier integrity that resists bacterial translocation^[124] (Figure 4B).

Collectively, these findings indicate that at low concentrations NO maintains mucosal integrity, but at high concentrations NO induces reactive nitrogen metabolites which impair intestinal function.

The role of HO-1 versus iNOS in intestinal inflammation

During intestinal inflammation HO-1 mRNA expression increases in response to the activity of NO^[125]. It is likely that this is due to increased transcription and stabilization of existing transcripts^[125]. In addition, induction of HO-1 in a human intestinal cell line resulted in the degradation of cytokine-induced NOS. This reduced the production of NO and therefore peroxynitrite^[124]. Heme was also shown to reduce the NOS mRNA^[124]. The inhibition of NOS

activity by HO-1 was lost when tin protoporphyrin was given, indicating the direct effect of HO-1 in regulating NOS activity^[126]. These findings are consistent with a role for HO-1 in limiting the deleterious effects of excessive iNOS by directly inhibiting its transcription, degrading existing NOS and scavenging excess ROM/RNM with bilirubin.

NUTRITION AND MECHANISM OF HEME-IRON ABSORPTION

In western civilisations, 40% of the average non-vegetarian person's total body iron is derived from heme products. However, iron from these substances only constitutes 15% of ingested iron^[127,128], suggesting that heme-iron is more efficiently absorbed than non-heme iron. This observation also explains why vegetarians are more prone to iron deficiency than meat eaters. Despite the importance of the contribution of heme to body iron stores, how it is absorbed is still poorly understood.

Mechanism of Heme-Iron Absorption

It is generally recognised that in omnivorous animals, heme is not transferred into the blood as an intact metalloporphyrin, instead absorption of iron from heme involves three steps (1) Uptake of luminal metalloporphyrin [Fe(II)-protoporphyrin-IX] by the enterocyte (2) catabolism within the enterocyte, combining of pools of ingested iron from non-heme and heme sources and (3) release of elemental iron to the bloodstream by the enterocyte^[129-133]. A large number of proteins are thought to be involved in the mechanism of heme iron absorption and these are tabulated along with their sites of expression and function (Table 1). Most of these proteins will be discussed individually in the following sections and is also summarised in Figure 5.

Worthington and co-workers used immunofluorescent methods to show that the uptake of a heme analog was temperature and time dependent, could be inhibited by heme competition and augmented by inhibitors of heme synthesis^[134]. It is likely that Worthington and co-workers identified a heme transport process by Caco-2 cells that may be a transporter and/or possibly a heme receptor.

Heme uptake by a heme transporter

Heme is taken into the enterocyte intact as evidenced by the recovery of ⁵⁹Fe-heme from the small intestinal mucosa following the gavage of radiolabelled hemoglobin^[130-133]. This process is energy dependent indicating an active process^[135]. The finding that absorption of iron from hemoglobin and hemoglobin were equivalent suggests that uptake of heme is independent of the redox state of the heme-iron^[136,137]. Alternatively there is an oxidoreductive mechanism on the cell surface that is capable of converting the iron redox state before internalization.

A microvillus membrane transporter that imports heme from the lumen into enterocytes of mice was recently characterised^[138]. This protein was expressed in the duodenum but not the ileum, consistent with expression at the site of highest heme-iron absorption. Heme carrier

Table 1 Proteins involved in intestinal heme-iron absorption along with their function, location and whether they are regulated by iron

Protein	Function	Location	Regulation by Fe
Heme receptor	Receptor for heme	?	Inversely
HCP1	Transporter of heme	AM → BC	Constant
FLVCR	Heme exporter	?	Unknown
Ferritin	Iron storage	C	Directly
DMT1	Fe(II) importer	AM+Lys	Inversely
Ferroportin	Fe(II) exporter	BL AM	Inversely
Hephaestin	Ferroxidase + ?	SN, BL	Constant
HO 1	Degradation of heme	C	Inversely
HO 2	Degradation of heme	SMC, EN	Constant
HFE	Regulator	TW	Inversely
TfR1	Tf:Fe endocytosis	BL, SN	Constant
Transferrin	Endosomal iron transport	C	Inverse

DMT1 = divalent metal transporter 1; HO = heme oxygenase; HCP1 = heme carrier protein 1; FLVCR = Feline leukaemia virus, subgroup C receptor; HFE = hemochromatosis protein; TfR1 = transferrin receptor 1; AM = apical membrane; BL = basolateral membrane; SN = supranuclear; LM = lateral membrane; Lys = Lysosomes; TW = terminal web; C = cytoplasm; BC = basal cytoplasm; SMC = smooth muscle cells, EN = enteric nerves; ? = putative; Tf:Fe = transferrin iron.

protein 1 (HCP1) encodes a protein with strong homology to bacterial tetracycline-resistance proteins, which are characterised as having 12 transmembrane domains and are members of the major facilitator superfamily^[138]. Functional characterisation of HCP1 using *Xenopus* oocytes revealed selectivity for the transport of heme but not tetracycline or non-heme iron. *In vitro* studies involving HCP1 siRNA and *in vivo* studies blocking HCP1 activity by antibodies indicated that the uptake of heme fell. HCP1 also required energy but the source of energy is presently unknown. Collectively, these findings indicate the first functional characterisation of a heme specific transporter.

Interestingly, during conditions known to increase non-heme iron absorption such as hypotransferranemia and iron deficiency, HCP1 mRNA expression remained constant although it was increased by hypoxia. Similarly, the extent of HCP1 protein expression remained constant with respect to the iron content of the enterocyte, although the protein translocated from the microvillus membrane to the basal cytoplasm during iron loading. The lack of increased expression of HCP1 by iron deficiency may in part explain the limited ability to increase heme-iron absorption. It may also indicate that HCP1 needs additional modulating proteins in order to regulate heme-iron absorption (Figure 5).

Heme uptake by a heme receptor

Previous studies have reported a 50% increase in heme binding to microvillus membrane preparations during iron deficiency, raising the possibility of a brush border localised heme receptor^[139-142]. This is based on the measurements of binding [¹⁴C]-heme to semi-purified brush border preparations^[139-142]. Subsequent solubilisation of the brush border microvillus membranes identified

the size of the heme binding substances, one with a molecular mass of about 250 kDa the other about 60 kDa. Displacement of the [^{14}C]-heme by unlabelled heme was seen with the 250 kDa complex, but not the about 60 kDa complex^[139-141], suggesting the larger peak represented a heme receptor complex, while the smaller peak was thought to be polymerised heme^[140]. Based on the capacity of the large complex to be saturated with heme and having an K_a of 10^{-6} to 10^{-7} mol/L this suggests that it is a relatively high affinity heme receptor.

In addition to the identification of a putative heme receptor in the intestine, others have identified a heme binding protein that is distinct from the hemopexin receptor^[143] with similar binding characteristics to the intestinal heme receptor. Since the heme binding protein and HCP1 have molecular weights of about 250 kDa and about 50 kDa, respectively, it is unlikely they are the same protein, unless HCP1 forms part of a larger complex. The finding that erythroleukaemic cells internalise heme coated latex beads^[144,145] and that trypsin treatment eliminates heme binding^[146,147] supports the existence of a heme receptor-mediated, endocytotic pathway. It therefore appears that there are at least two defined pathways involved in the uptake of heme into the enterocyte, one involving HCP1^[138] and the other a receptor-mediated endocytotic process^[139-142,144-147]. Despite considerable characterisation of the heme receptor almost thirty years ago there has been little progress made since (Figure 5).

Intracellular processing of heme

Morphological studies show that following ingestion of a heme-rich meal by rodents, heme was first seen along the microvillus membrane, then in tubulovesicular structures of the apical cytoplasm and finally in secondary lysosomes^[148,149]. Based on time course studies, DAB (3,3-Diaminobenzidine tetrahydrochloride) disappeared from lysosomes suggesting that heme was either transported from these structures or that it was degraded within them. In either case heme degradation involves HO activity but whether this is HO-1 or HO-2 is presently unknown.

Alcohol and heme-iron absorption

In rats treated with alcohol there was increased absorption of iron from heme as well as the entire hemoglobin complex where it was transported to the liver as a haptoglobin-hemoglobin complex^[150,151]. Thus, absorption of iron from hemoglobin also appears to contribute to the iron over loading caused by excessive alcohol consumption.

Limitations in iron absorption from heme

The intracellular sites where restrictions to the absorption of iron from heme occur have been studied in dogs given radiolabelled hemoglobin and then measuring the progression of radioactivity through mucosal compartments^[133]. The most likely sites where the rate of iron absorption was limited appears to be at the stage of heme breakdown and/or the release of iron from the cell. This might involve the steps where HO operates, where iron is released out of an intracellular compartment, or from the cell (see below).

Figure 5 Six steps in the uptake of heme by intestinal enterocytes. Heme taken up by heme carrier protein (HCP1) is internalised and broken down in the cytoplasm by HO-1 (1), by a HO-1 independent enzyme(s) (2), some is released intact back into the lumen (3) or plasma by FLVCR (4). Heme may also bind to a heme receptor and with HCP1 be internalised by receptor mediated endocytosis. The heme may be released to the cytoplasm by HCP1 (5), or the heme may be broken down in the lysosome and the released iron transported to the cytoplasm by the divalent metal transporter (DMT1) (6). The iron released from heme passes to the basal cytoplasm and is transported across the basal membrane by ferroportin in the ferrous state, oxidized to ferric-iron by hephaestin and transported in the plasma by transferrin.

Other proteins possibly involved in the transport of Fe(II) from heme

In view of the likely convergence of iron derived from sources of non-heme and heme iron what is known for non-heme iron is described.

Divalent Metal Transporter 1 (DMT1)

The Microcytic mouse (*mk*) and anaemic Belgrade rat (*b*) have an autosomal recessive inherited, hypochromic, microcytic anaemia associated with a well-characterised defect in the transferrin cycle in erythroid cells^[152], as well as a defective intestinal non heme-iron transport that is manifest at the site of uptake at the microvillus membrane^[153]. The similar phenotypes are explained by an identical mutation in DMT1 at G185R^[154,155]. Deletion of DMT1 also resulted in loss of iron transport by the intestine but not the liver or placenta^[156]. The finding that heme is broken down intracellularly and a portion of DMT1 is found inside the enterocyte could suggest that DMT1 is involved in heme-iron absorption. There is an absolute requirement for DMT1 in the uptake of iron by the intestine^[156], suggesting that intestinal absorption of iron from heme also requires DMT1 but this remains to be determined (Figure 5).

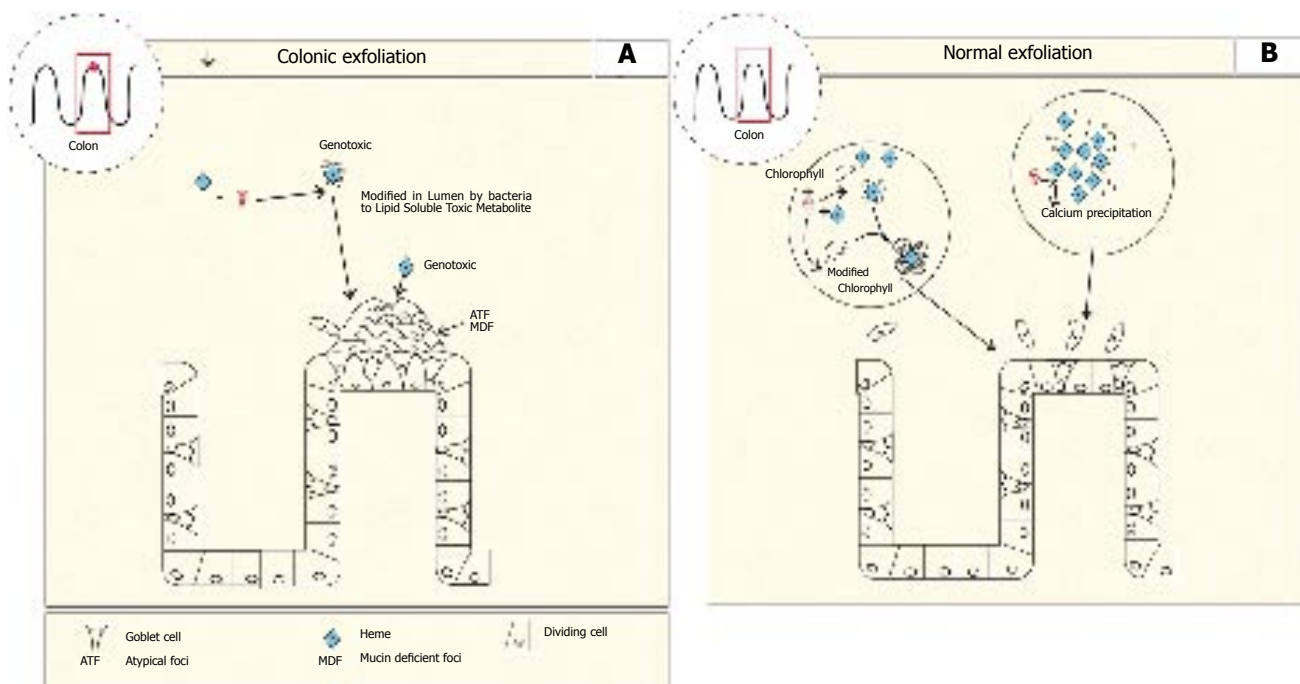

Figure 6 A: In the colon excess heme is metabolised into a lipid soluble heme metabolite possibly by commensal bacteria. Heme itself is also genotoxic. This results in the formation of aberrant atypical foci, that are mucin deficient (ATF, MDF). Apoptosis is inhibited which could lead to increased survival of mutant cells; **B:** In the presence of calcium or chlorophyll heme precipitates into biologically inactive compounds which inhibit the heme factor or binds the heme factor rendering it inert, respectively leading to normal colon growth.

Hemochromatosis protein (HFE)

Intestinal expressed HFE is recognised to regulate iron absorption *via* the uptake of transferrin bound iron by crypt cells. The finding that HFE is expressed along the terminal web of enterocytes during iron deficiency where it co-localised with DMT1, raises the possibility that HFE may function directly in iron absorption and this may include heme-iron^[157]. This is also supported by the finding that HFE expression is inversely proportional to iron absorption^[157]. If this is the case then HFE is positioned to interact with HCP1, the putative heme receptor and DMT1. Whether DMT1 and HFE work intracellularly (such as in lysosomes) at levels that cannot be detected by immunofluorescent microscopy remains to be determined.

Ferroportin

Basolateral transport of non-heme iron involves ferroportin/Ireg-1/MTP-1/SLC40A1, most often referred to as ferroportin^[25]. This is based on the study showing that over-expression of ferroportin in macrophages during erythrophagocytosis increased release of non-heme iron, but not heme^[158]. This observation is likely to apply to the enterocyte but this needs to be determined. Also selective deletion of ferroportin in mice resulted in non-heme iron accumulation within enterocytes^[159] which provides support for the hypothesis that ferroportin functions with non-heme iron (Figure 5).

Mammalian iron-ATPase

Baranano and co-workers have identified a microsomal membrane Fe(II) transporter from the spleen which presumably represents an iron transporter expressed by macrophages. It is induced by heme, and depends

on hydrolysable triphosphate, magnesium and temperature^[160]. It is proposed that following heme catabolism by macrophages, Fe(II) is shunted into the lumen of the endoplasmic reticulum. Others have found a similar transporter in liver microsomes^[161]. Whether this transporter functions in enterocytes remains to be determined.

HEME AND COLON CARCINOGENESIS

Although heme-iron is more bio-available than non-heme iron it has limited ability to be absorbed. Therefore, unabsorbed heme reaches the colon. Luminal heme is also derived from the blood *via* extravasation and from desquamation. Previous studies have shown that heme irritates the epithelium of the colon as evidenced by mild diarrhoea^[162,163]. It was shown that feeding heme but not non-heme iron to rats results in significant increased proliferation of colonic mucosa^[162]. In addition, the incidence of aberrant atypical foci (ATF) and mucin-depleted foci (MDF)^[164] increased as the heme content of the diet increased suggesting that heme is carcinogenic^[164,165]. In fact, it was demonstrated that heme was genotoxic in the human colon tumour cell line HT29^[166].

It has been shown that a heme breakdown product rather than heme or iron *per se* was responsible for the inflammation and ATF formation^[162,163]. In the colon some heme breakdown products are produced by the presence of colonic bacteria^[167], and it has been suggested the heme is converted to a cytotoxic factor, although it has not been fully characterised^[162,163]. Gene microarray analysis of 365 genes expressed by the colon revealed that feeding heme

down-regulated mucosal pentraxin 30-fold^[168,169]. Since pentraxin is involved in the recognition and clearance of dying cells, a process that is normally ongoing in the intestinal tract, downregulation of this gene by heme infers that apoptosis of colonic mucosal cells may be inhibited. If this is true then it might explain the increased carcinogenic potential if cells with mutated genomes cannot be eliminated^[168]. In support of this, De Vogel et al., showed that heme supplementation decreased colonic exfoliation^[170] (Figure 6).

The cytotoxic affect of heme on the colon was lost when the diet was supplemented with green vegetables^[170]. It was hypothesised that chlorophyll in green vegetables inhibited the formation of the heme factor by competing for solubilisation with heme in the large intestine. Alternatively, chlorophyll and heme could form a complex that blocks the site of covalent modification of the heme and reduces the formation of the heme factor^[170]. Calcium was also shown to protect against the effects of heme on colonic proliferation and normalising pentraxin expression, presumably because calcium precipitates heme, thereby preventing the formation of the soluble heme induced cytotoxic factor^[169,171,172]. This conclusion is consistent with the inhibitory effect that calcium has on heme bioavailability for its absorption in the small intestine^[171] (Figure 6A and B).

HEME AND HO-2 IN INTESTINAL MOTILITY

Peristaltic contractions are controlled by stellate shaped non-neuronal interstitial cells of Cajal (ICC) situated within the myenteric plexus (ICC-MY)^[173-177]. Clusters of spindle shaped bipolar ICC found throughout the circular and longitudinal muscle layers (ICC-DMP) generate pacemaker potentials spontaneously but these are modified by neural input^[177]. Adjacent to the submucosa and within the circular muscle layer ICC also appear to synapse with nerves (ICC-IM)^[174-177]. Loss of ICC leads to markedly impaired neurotransmission and typical gastrointestinal motor patterns indicating their importance in co-ordinating neural modulation of intestinal motility. In the small intestine ICC-MY appear important for pacemaker ICC but in other regions of the bowel this is regulated by ICC-IM.

The network is connected to the smooth muscle syncytium *via* either gap junctions or peg in socket junctions. These membrane specialisations provide a means of conducting pacemaker currents to intestinal smooth muscle^[174-177]. It is thought that pacemaker potentials originate from unitary potentials caused by the release of calcium from mitochondrial stores^[177,178] which in turn cause a rise in membrane potential generated by opening of Ca^{2+} permeable channels. The plateau component observed in pacemaker potentials is generated by opening Ca^{2+} activated Cl^- channels^[179]. Repolarisation involves removal of cytosolic Ca^{2+} to stores and K^+ transport *via* activated K^+ channels^[179]. The frequency of these events establishes the pacemaker potential of a particular region of the intestine. Muscle contraction will occur providing the membrane potential is capable of activating L-type

Ca^{2+} channels and depolarising the cell^[180]. The resulting increase in cytosolic Ca^{2+} levels is coupled to contraction. Contraction is limited by activation of large-conductance Ca^{2+} -activated K^+ channels and L-type Ca^{2+} inactivation^[180].

It has been shown that HO-2 but not HO-1 is present in all classes of ICC (-MY, -IM & -DMP), although HO-2 expression was greater in ICC-MY than in ICC-IM. Enteric neurons also express HO-2^[180-192]. In the gastric fundus and in particular mucosal epithelial cells, neurons of the submucosal and myenteric plexus and ICC co-express HO-2 and BVR indicating that these cells have the capacity to generate bilirubin^[47]. Since ICC have numerous mitochondria it is hypothesised they produce heme to serve as substrate for HO-2 activity and the CO produced may regulate membrane potential and in turn affect intestinal contraction^[186]. In the genetic absence of ICC and in HO-2 knockout mice the membrane potential of intestinal smooth muscle is depolarised compared with wild type controls^[174,185,188]. Studies have shown that the HO-2 mediated hyperpolarisation is probably due to the effect of CO on activation of K^+ currents in smooth muscle^[181,184], and that exogenous CO given to HO-2 knockout mice hyperpolarises the resting membrane potential^[191]. Supporting this, the membrane is more hyperpolarised near the submucosa and these cells have higher HO-2 activity and CO production than cells near the myenteric plexus where the membrane is more depolarised^[191]. Taken together it suggests that CO produced from ENS and ICC function in maintaining membrane potential and the gradient that exists along the longitudinal and across the circular musculature^[184,191]. It would be expected that increased CO production would result in a greater level of smooth muscle relaxation because the membrane potential is further away from threshold. The mechanism by which CO reduces the resting membrane potential is unclear^[188].

CONCLUSIONS

Within the intestine heme serves important roles in energy production, in enzymes involved in detoxification, in the generation of the second messenger gases NO and CO and the antioxidant bilirubin. The products of heme breakdown namely CO and bilirubin restrict oxidative stress, inflammation, and regulate the cell cycle and differentiation in the crypt region. Excess heme may also promote the development towards colon cancer. Dietary heme is an important source of iron for the body and the absorption of iron from heme differs from non-heme. The molecular mechanism operating in the early phases of absorption appears to involve a transporter although there is evidence of a receptor mediated process and numerous other proteins may function in heme-iron as in non-heme iron absorption. The ability of HO to perform these varied functions within the enterocyte probably depends on different compartments within the cell which are differentially accessed by heme and HO. Future studies will determine how heme-iron is absorbed and the mechanisms by which HO regulates the cell cycle and differentiation, limits the inflammatory process.

Abstract

AIM: To study the association between nitrite and nitrosamine intake and gastric cancer (GC), between meat and processed meat intake, GC and oesophageal cancer (OC), and between preserved fish, vegetable and smoked food intake and GC.

METHODS: In this article we reviewed all the published cohort and case-control studies from 1985-2005, and analyzed the relationship between nitrosamine and nitrite intake and the most important related food intake (meat and processed meat, preserved vegetables and fish, smoked foods and beer drinking) and GC or OC risk. Sixty-one studies, 11 cohorts and 50 case-control studies were included.

RESULTS: Evidence from case-control studies supported an association between nitrite and nitrosamine intake with GC but evidence was insufficient in relation to OC. A high proportion of case-control studies found a positive association with meat intake for both tumours (11 of 16 studies on GC and 11 of 18 studies on OC). A relatively large number of case-control studies showed quite consistent results supporting a positive association between processed meat intake and GC and OC risk (10 of 14 studies on GC and 8 of 9 studies on OC). Almost all the case-control studies found a positive and significant association between preserved fish, vegetable and smoked food intake and GC. The evidence regarding OC was more limited. Overall the evidence from cohort studies was insufficient or more inconsistent than that from case-control studies.

CONCLUSION: The available evidence supports a positive association between nitrite and nitrosamine intake and GC, between meat and processed meat intake and GC and OC, and between preserved fish, vegetable and smoked food intake and GC, but is not conclusive.

INTRODUCTION

Humans are exposed to a wide range of N-nitroso-compounds (NOCs) from diet, tobacco smoking, work place and drinking water^[1,2], which are the major source of exposure in the general population^[3]. Preformed exogenous nitrosamines are found mainly in cured meat products, smoked preserved foods, foods subjected to drying by additives such as malt in the production of beer and whiskey, pickled and salty preserved foods^[2]. Available data suggest that nitrosamines are found more frequently and at higher concentration in Asian foods than in Western foods^[4]. On the other hand, nitrosamines are formed endogenously from nitrate and nitrite. Although the levels have reduced during the last 20 years, sodium nitrites are still widely used as food preservatives in cured meat products. Nitrite is also formed in the human body from oral reduction of salivary nitrate. Vegetables and water are the main sources of nitrate intake. Nitrites are transformed into nitric oxide by gastric acid-catalysed formation, which acts as an nitrosating agent of amines and amides, as consequence of NOC^[2]. Under chronic inflammatory conditions, such as precancerous conditions of gastric cancer (GC) and oesophageal cancer (OC), nitrosating agents are overproduced^[1]. Studies in volunteers have shown that red meat intake has a consistent dose response in the endogenous formation of NOC measured in faecal samples, while white meat intake has no effect^[5].

So far, there is no conclusive epidemiological evidence that nitrosamines are carcinogenic to humans, although they produce a wide range of tumours in more than 40 animal species tested^[6]. Two important nitrosamines, namely N-nitrosodiethylamine (NDEA) and N-nitrosodimethylamine (NDMA), are classified as probably carcinogenic to humans (group 2A) by International Agency for Research on Cancer (IARC)^[7]. One previous comprehensive review on nutrition and cancer^[8] concluded that there is convincing evidence that the consumption of the Chinese salted-dry fish is causally associated with the risk of nasopharyngeal cancer with their nitrosamine content being the most plausible agent. Evidence of an increasing cancer risk due to N-nitrosamine and cured meat intake is considered insufficient for GC and possible for OC^[8]. A previous review of dietary nitrates, nitrites and NOC and risk of nasopharynx, oesophagus, stomach, pancreas, colorectal and brain cancer concluded that epidemiological evidence related to GC and other tumours remains inconclusive, although the strongest evidence pointed to an increased risk of nasopharyngeal and oesophageal cancer in subjects exposed to high dietary NOC levels^[9].

Several foods, such as processed meat and dried salted fish, which are sources of nitrites and/or nitrosamines, are also important sources of salt. Salt produces an inflammatory process leading to damage of the protective stomach mucosa and increases the risk of stomach cancer^[8]. *H. pylori* infection may be related to salt and NOC, in enhancing carcinogenesis after the epithelium is damaged^[8].

The aim of this article is to review and evaluate the available epidemiological evidence about the association between dietary exposure to preformed nitrosamine and related food intake and gastric and oesophageal cancer risk in humans.

MATERIALS AND METHODS

Inclusion criteria

Epidemiological studies (case-control or cohort studies) published between 1985 and 2005 evaluating the relationship between nitrosamines, NDMA, nitrites, food sources of exogenous and endogenous nitrosamines, and oesophageal or gastric cancer risk in males and females were included in the study. Experimental studies were not considered.

Search strategy

We conducted electronic searches in MEDLINE and CANCERLIT databases from 1985-2005. The search strategy included the following terms “oesophageal”, “gastrointestinal” “gastric”, “stomach”, “upper aero digestive tract”, “cancer”, “nitrosamines”, “NOC”, “NDMA”, “processed meat”, “meat”, “intake”, “salted fish”, “dietary patterns”, “nitrites” and “diet”. The search was supplemented with references included in recovered papers that were not identified in the electronic search. References contained in recent reviews of the literature were also consulted^[10].

Figure 1 Nitrites and nitrosamines intake and gastric or oesophageal cancer. *Without confidence intervals, but statistically significant. ¹Ndme; ²Nitrites; ³Nitrosamines.

Data extraction

The following information was gathered from the original publications: study data (author, journal, year, country); epidemiologic design including type of study, number of subjects, follow-up (years), number of cases/controls, type of controls; diet including type and quality of dietary assessment method, number and type of food items; results including the most fully adjusted odds ratio or rate ratios and 95% confidence intervals for the highest and lowest categories of compound/food intake used from each included article. Covariates included in the analysis were also evaluated.

Exposure definition and classification

Since information about gastric cancer and NOC and their precursors was heterogeneous, sources of exposure were classified into two groups: nitrosamines and nitrites; food sources of endogenous (red meat) and exogenous (processed meat, beer, pickled and dried vegetables, smoked fish or meat, salted and dried fish or meat) nitrosamines. The odds ratio for each study was plotted in the included Figures, using symbols whose size was proportional to the study size.

RESULTS

Study characteristics

A total of 75 publications potentially eligible for inclusion in this review, were identified. After a detailed examination, in which some papers with duplicate or inappropriate information were detected and excluded, 63 studies were finally selected^[11-71,78-80]. Of these, 52 studies were case-control studies and 11 were cohort studies. Most of them were carried-out in Asia (35%), Europe (30%), and USA (23%).

Dietary intake of nitrosamines or nitrites

Cohort studies: We found 2 cohort studies^[11,12] with information on GC and nitrites, nitrosamines or both (Figure 1). In relation to nitrites, one found a positive but not significant association^[12] while the other found

no association^[11]. Only one cohort study investigated the association between NDMA and GC and found no association^[11]. We did not find any cohort studies investigating the relationship between nitrosamine or nitrite intake and OC.

Case-control studies: We found 8 case-control studies with information on GC and nitrites, nitrosamines or both^[13-20] (Figure 1). Among the 7 studies on nitrites and GC^[13-17,19,20], 5 showed a positive association^[13,15-17,20] and 3 achieved statistical significance^[15-17]. Two of them^[15,16] were large studies, adjusting for all relevant confounding factors. In relation to nitrosamine intake and GC, among the 5 studies published^[14,17-20], 4 found a positive association which was statistically significant (SS) in 3 of them^[18-20]. We found only 2 case-control studies reporting results in relation to OC which showed no association with nitrite intake^[16] or no significantly positive association with nitrite and NDMA intake^[21] (Figure 1).

Dietary intake of food sources of exogenous and/or endogenous nitrosamines

Cohort studies: We found 8 cohort studies with results about GC risk and food sources of exogenous nitrosamines and/or foods that could enhance their endogenous formation^[22-28,43] (Figure 2). Only 3 studies reported results in relation to red meat intake. A positive and statistically significant association was observed with pork in one large study^[26] while no association was found in the other studies with few GC cases^[25,28]. In relation to high processed meat intake, 6 studies reported results^[22,23,26-28,43] but the association was positive and SS was found only in 2 studies^[22,28]. The largest study^[27] did not observe any association, but it was a study based on mortality cases with a relatively small number of food items included in the Food frequency questionnaires (FFQ). Salted, dried or preserved fish intake was associated (but not significantly) with GC risk only in one of the 5 cohort studies reporting results^[23-26,28], but in most of them the number of GC cases was too small. For pickled and dried vegetables, 3 studies found positive association but none of them achieved statistical significance^[23,25,26].

Figure 3 A: Meat intake and gastric cancer (case-control studies); (a) Meat intake: (a1) meat (a2) pork (a3) grilled meat (a4) mutton (a5) beef (a6) red meat; B: Processed meat and gastric cancer (case-control studies); * Without confidence intervals, but statistically significant; (b) Processed meat: (b1) salted meat (b2) processed meat (b3) bacon (b4) sausage (b5) cold cuts (b6) cured meat; C: Preserved fish, smoked foods, preserved vegetables and beer consumption and Gastric cancer (case-control studies); (c) Preserved fish: (c1) salted/dried fish (c2) salted fish (c3) processed fish (c4) dried fish (c5) preserved fish (d) Smoked foods: (d1) smoked meat (d2) smoked foods (d3) smoked/pickled (d4) smoked fish (e) Preserved vegetables: (e1) pickled vegetables (e2) dried vegetables (e3) salted vegetables (e4) preserved vegetables (f) Beer.

In the largest study^[26] the risk was borderline significant, but in the others the number of cases was too small. In relation to OC, (Figure 4A) we found 2 cohort studies^[29,30] reporting results associated with meat intake, which were positive and SS in one study^[29], while no association was observed regarding pickled vegetables.

Cases-control studies: We found 16 case-control studies

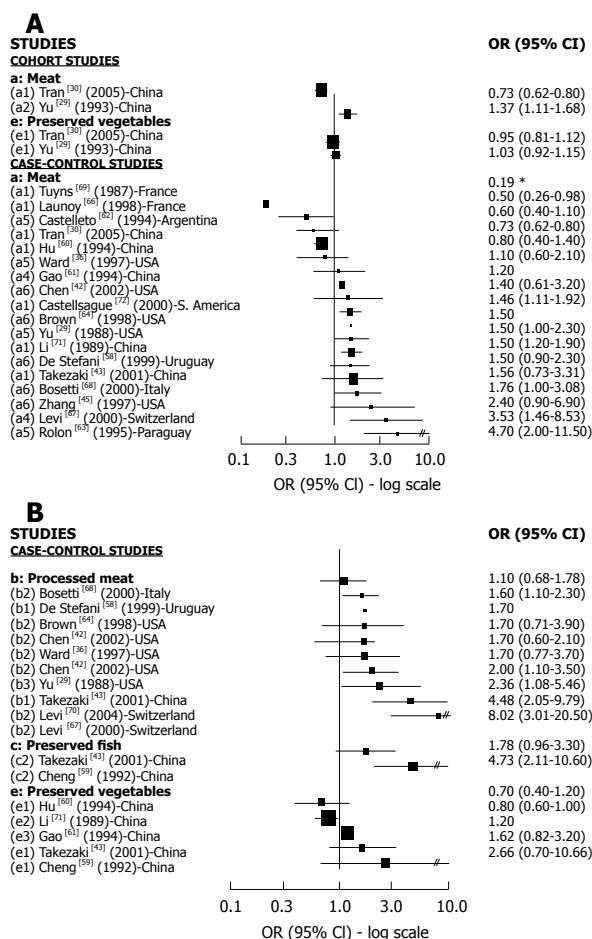

Figure 4 A: Meat and preserved vegetables and oesophageal cancer; * Without confidence intervals, but statistically significant; (a) Meat intake: (a1) meat (a2) pork (a3) grilled meat (a4) mutton (a5) beef (a6) read meat (e) Preserved vegetables: (e1) pickled vegetables (e2) dried vegetables (e3) salted vegetables (e4) preserved vegetables; **B:** Processed meat, preserved fish and preserved vegetables and oesophageal cancer (case-control and cohort studies); (b) Processed meat: (b1) salted meat (b2) processed meat (b3) bacon (c) Preserved fish: (e) Preserved vegetables: (e1) pickled vegetables (e2) dried vegetables (e3) salted vegetables.

(Figure 3A) reporting results between different types of meat intake (mutton, red meat, beef, fresh meat, grilled meat, pork) and GC risk^[31-40,42-45,51,54] and 11^[31,33,35-38,40,42-45] of them suggested a positive association with at least one type of meat intake and GC risk, which was statistically significant in 2 studies^[31,37] carried out in the USA. We found 14 publications^[18,33-37,42-46,48,49,55] with reported results on processed meat intake and GC risk (Figure 3B), and 12 of them^[18,33-37,42,45,46,48,49,55] showed a positive association while 4 were statistically significant^[37,45,48,49]. For dried/salted or preserved fish (Figure 3C), we found 7 studies^[32,34,38,40,41,43,56] reporting results, and 6 described a positive association with GC^[34,38,40,41,43,56] while 4 achieved statistical significance^[34,40,41,56]. Three studies published results about smoked food intake and GC risk^[17,31,65] and all of them showed a positive and significant association. For pickled and preserved vegetables, 5 of 6 studies^[41,43,44,52,53,57] showed a positive association with GC, which was statistically significant in all of them^[41,43,44,52,53]. Other food sources, such as beer^[31,49,50,52,78-80] were analyzed, but only one study showed a significant association with GC^[79].

Table 1 Overall quantification of epidemiological studies on nitrosamines and related food intake and gastric and oesophageal cancer risk

Smoked foods	3 (3) [3]			
Beer	7 (6) [1]			

SS: Statistically significant.

We found 18 case-control studies^[29,30,36,42,43,45,58,60-64,68,71,72] which published results on OC and different types of meat intake (Figure 4A). A positive association was observed in 11 of them^[29,42,43,45,58,63,64,66,67,70,71] and was SS in 6^[29,63,66,67,70,71]. For processed meat (Figure 4B), 8^[29,36,42,43,58,64,66,69] of 9 studies^[29,36,42,43,58,64,66,69] described a positive association with OC, which was SS in 5 studies^[29,43,58,67,69]. Only 2 studies^[43,59] publishing results on preserved fish intake and OC showed a positive association, being SS in one^[59]. The association between preserved vegetable intake and OC was reported in 5 studies^[43,59-61,70] and a positive but not significant association was observed in three of them^[43,59,61]. The two largest studies^[61,70] did not find any association.

DISCUSSION

Nitrite and nitrosamine intake

Although the evidence on nitrite and nitrosamine intake from cohort studies is limited (Table 1), results from case-control studies are quite consistent and support a positive relationship with GC. We did not find any results about the relation with OC from cohort studies and few case-control studies reported results, therefore a conclusion about the relationship between OC and nitrite and nitrosamine intake is impossible.

Meat intake

Only few cohort studies have reported results regarding the relationship between red meat intake and GC and OC, showing a positive association in 2 of 3 studies of GC and in 1 of 2 studies on OC. However, there are a large number of case-control studies presenting results on meat intake and GC and OC. Most of them have found a positive association (11 from 16 for GC and 11 from 18 for OC) particularly for OC, and in most of these studies the association is SS. Overall the evidence from case-control studies supports a positive association between meat intake and GC and OC. However, meat is a common substrate to endogenous formation of NOC and also a source of other carcinogenic compounds,

such as heterocyclic amines (HA) and polycyclic aromatic hydrocarbons (PAH) which should be taken into account.

Processed meat intake

Most of the relatively few cohort studies showing results on processed meat intake and GC risk have found no association between them. However, several of these studies considered only a small number of GC cases and food items. No cohort study has shown results on processed meat intake and OC. However a relatively large number of case-control studies have shown quite consistent results supporting a positive association between processed meat intake and GC and OC risk (10 of 14 studies on GC and 8 of 9 studies of OC), which were SS in most of them, particularly regarding OC.

Preserved fish intake

Regarding GC risk and preserved fish intake (particularly dried and salted), inconsistent results were found between case-control and cohort studies. While the case-control studies supported a positive association, the cohort studies did not, although most of them had a small number of cancer cases, and confidence intervals were wide. Therefore, further evidence is needed. No evidence is available from cohort studies in relation with OC and the few case-control studies showed a possible positive association.

Preserved vegetable intake

Results from case-control studies support a positive association between pickle and other preserved vegetable intake and GC risk. Almost all the studies have shown a positive and significant association. Cohort studies have also observed a positive but not significant association, although the number of cancer cases was small. Most of the studies were carried-out in Asian countries. To date, results on OC risk are inconsistent, but the number of studies is small.

Smoked food intake

Although the evidence is too limited for a definitive conclusion, it supports a positive association between smoked food intake and GC risk. No evidence exists for OC risk.

Beer drinking

So far the evidence is limited, but the majority of studies support a not significantly positive association with GC.

Limitation of evidence

Only 2 cohort^[11,12] and 9 case-control studies^[16,21,22-28] of 65 studies included in this review have published results on nitrite or nitrosamine intake in relation to GC or OC risk. This could be due to the absence of a complete food composition table for NOC content in foods^[72]. For the remainder, the estimation of dietary exposure to NOC and their precursors were done indirectly through foods identified as sources of them.

All the results could be affected by measurement

errors in the dietary intake, a common limitation of epidemiological studies. FFQ do not usually collect detailed and complete information about preservation and processing methods of all potential food sources of nitrosamines. In addition, the small number of food items usually included in the FFQ and/or lack of portion size information does not permit accurate estimation of nitrosamine and total food intake. The observed range of total food items in the FFQ varied between 22 and 81 in the studies used. Therefore, it could be expected that not all the studies have achieved an accurate assessment of the intake of these compounds. However, despite the fact that some studies have estimated adequately the exogenous intake of nitrosamines, none of them had information about endogenous NOC. It was reported that endogenous synthesis could contribute to 45%-75% of the total human exposure^[3]. However, recent studies carried out in humans have shown that endogenous NOC could be up 30-fold higher than exposure from dietary sources^[73-75], suggesting that we are actually measuring a small part of the total dietary human exposure to NOC, and therefore underestimating their effect.

In relation to possible factors that could modify the effect of NOC, few studies considered the intake of vitamin C or smoking habits. None of the studies on GC adjusted their results to consider *H pylori* infection. This is important because *H pylori* decreases the levels of vitamin C, a recognized inhibitor of endogenous nitrosamine formation^[76]. On the other hand, red meat is a source of iron which is considered an essential growth factor for *H pylori*^[77]. Therefore, some interaction with meat is expected. Finally, it is also important to take into account interactions with genes, particularly with polymorphisms of metabolic genes involved in the metabolism of NOC or DNA repair genes, which so far have been poorly studied.

Conclusions and future directions

At present, available epidemiological evidence from case-control studies on nitrite and nitrosamine intake supports a positive association with GC risk. The evidence in relation with OC is insufficient. There is quite consistent evidence from case-control studies about the positive association between meat and processed meat intake with both GC and OC risk. There is also quite consistent evidence from case-control studies about the positive association between preserved fish and preserved vegetable intake and GC risk, although results are more inconsistent in cohort studies. We have found a suggestive indication of a positive association between GC risk and smoked food intake. However, evidence about the effect of preserved fish and vegetable intake on OC risk is more limited, suggesting that there is no association between beer intake and GC although the evidence is still limited. Overall, more prospective cohort studies are needed to permit definitive conclusions, and should include a large number of cancer cases, dietary questionnaires with a large and detailed number of food items, good estimation of portion size, and control for all known confounding variables in a population with a wide range of food intake.

Evaluating the role of selected genotypes involved in

the metabolism of these chemical compounds and DNA repair potentially related to the risk of cancer, is also useful. On the other hand, taking into account that endogenous production seems to be the most important contributor to total NOC exposure, validated methodologies that allow an accurate assessment of production are needed. Therefore, measurement and quantification of DNA adducts of nitrosamines in humans may be the most direct way to assess both sources (exogenous and endogenous) and provide the best biomarker of exposure^[6].

In summary, prospective studies with long follow-up periods and validated methodologies quantifying all sources of exposure are needed to confirm the role of NOC in gastric and oesophageal carcinogenesis.

Abstract

AIM: To investigate the changes that occur in E-cadherin expression during the process of metastasis in colorectal cancer.

METHODS: E-cadherin expression was detected by immunohistochemistry and two indices of expression were calculated which reflected the level of expression and the locations (membrane and cytoplasm). Univariate and multivariate survival analyses were used to assess the value of these two E-cadherin indices as predictors of both disease-free (DFS) and disease-specific (DSS) survival.

RESULTS: E-cadherin membrane index (MI), but not cytoplasmic index (CI), was significantly higher in primary tumors than their metastases ($P = 0.0001$). Furthermore, both primary tumor MI and CI were higher among the patients who developed subsequent metastasis ($P = 0.022$ and $P = 0.007$, respectively). Interestingly, both indices were higher in liver metastase compared to other anatomic sites (MI, $P = 0.034$ and CI, $P = 0.022$). The CI of the primary tumors was a significant predictor of DFS ($P = 0.042$, univariate analysis), with a strong inverse correlation between CI and DFS ($P = 0.006$, multivariate analysis). Finally, the MI of primary tumor proved to be a significant independent predictor of DSS, with higher indices being associated with a more favorable outcome ($P = 0.016$).

CONCLUSION: Examination of E-cadherin expression and distribution in colorectal tumors can be extremely valuable in predicting disease recurrence. The observation that aberrant cytoplasmic expression of

INTRODUCTION

Colorectal cancer (CRC) is the second leading cause of cancer-related mortality in industrialized Western countries. The prognosis of CRC patients dramatically depends on the development of recurrence and/or metastasis. However, one of the major problems is the definition of reliable criteria for predicting recurrence and identifying the tumors that will respond to chemotherapy^[1,2].

The metastatic cascade starts with a breakdown of the epithelial integrity, which enables tumor cells to invade the surrounding stroma, penetrate either into blood or lymphatic vessels, and finally infiltrate into the appropriate target organs. Epithelial differentiation is critically dependent on maintenance of intact intercellular junctions by cell-cell adhesion molecules. Impairment of these junctions facilitates the invasion of epithelial cells, thus favoring the progression of carcinomas^[3]. There are several cell-cell adhesion molecules, including cadherins (E-, P-, N-cadherins), catenins (α , β , and γ catenins), and the CD44 family (standard and variants)^[4-6].

Of these cell-cell adhesion molecules, E-cadherin is normally located at the zonula adherens and is functionally necessary for epithelial integrity^[7,8]. Decreased levels of E-cadherin expression were reported in many immunohistochemical studies on epithelial malignancies^[9-11]. In some tumor types, including CRC, the loss of E-cadherin expression is associated with the loss

of tumor differentiation and is shown to be correlated with an increased likelihood of distant metastasis. These data suggest an important role of E-cadherin in tumor invasion and/or slowing down metastases^[12-14].

In the present study, we hope to extend these studies using immunohistochemistry to examine the levels of E-cadherin expression in primary tumors and their metastases from a series of 42 CRC patients. E-cadherin expression on the cell membrane and its cytoplasmic accumulation were assessed separately. Univariate and multivariate survival analyses were used to determine the potential predictive and prognostic value of E-cadherin expression in these patients.

MATERIALS AND METHODS

Patients, treatment and follow-up

A series of 42 patients were diagnosed and treated for Duke's B, C and D CRC at the Department of Oncology and Radiotherapy, Turku University Central Hospital and six other hospitals of the same hospital district between January 1996 and August 2003. The key clinical characteristics of the patients are summarized in Table 1. The patients were prospectively followed up until death or when they were seen alive for the last time, with a mean follow-up time of 32.3 mo (median 28.2) for the whole series in this study. At diagnosis, 30 patients had metastasis and the remaining patients developed metastatic diseases during follow-up. Disease-specific survival (DSS) and disease-free survival (DFS) were calculated based on the time from diagnosis to death (due to disease), and on the time from diagnosis to the appearance of metastatic diseases, respectively. In calculating the DSS, the patients who died from other or unknown causes were treated as censored cases.

Immunohistochemistry

Formalin-fixed, paraffin-embedded samples were available from all 42 primary tumors and their metastases. Paraffin blocks were cut on polylysine-coated microscopy slides for immunohistochemistry. The sections were deparaffinized in xylene, thrice for 10 min, then dehydrated in a descending series of ethanol (100%, 96%, 70%), followed by washes in TBS (0.05 mmol/L Tris-buffer physiological saline, pH 7.4-7.6), thrice for 5 min. Antigen retrieval was achieved by heating the samples without boiling in 10 mmol/L sodium citrate buffer, pH 6.0 (200 mL) in a microwave oven. This treatment was conducted twice for 7 min. The sections were washed in TBS buffer for 30 min. The endogenous peroxidase was blocked by 0.3% hydrogen peroxide in methanol for 20 min. The sections were washed in TBS for 15 min.

To inhibit non-specific binding, the samples were incubated in diluted normal horse serum (15 µL serum per 1 mL of TBS-buffer), in humid boxes for 30 min. The primary antibody was monoclonal mouse E-cadherin antibody (clone HECD-1, sub-class IgG₁, Zymed Laboratories, San Francisco, CA, USA), at a dilution of 1:300 from the stock. The dilution was based on dilution experiments. Bound primary antibody was visualized with

the avidin-biotin peroxidase technique (Vectastain ABC kit, Vector Laboratories, Burlingame, CA, USA). The antibody was diluted with 20 mmol/L TBS, pH 7.4 (10 mmol/L CaCl₂, 0.1% NaN₃ and 1% BSA). The sections were incubated in the diluted antibody and the negative controls in 1% BSA in TBS-buffer. The antibody and the 1% BSA incubations were done with 195 µL of the incubation fluid, which was enough to cover the whole section. The incubation took place in incubation boxes at 4°C overnight. After the incubation, the boxes containing sections were left at room temperature for 30 min. The incubation fluid (primary antibody or bovine albumin) was washed off with TBS-buffer (two washes). The secondary antibody (4.5 µL biotinylated anti-mouse antibody in 1 mL of 1% BSA) was pipetted onto the sections and incubated in the moist box for 30 min. The secondary antibody was washed in TBS buffer for 15 min. Vectastain ABC reagent was then used to stain the fixed secondary antibody. After 30 min of incubation, the sections were washed with TBS-buffer.

The final staining was done in diaminobenzidine tetrahydrochloride (DAB) solution (49 mL TBS-buffer, 34 mg imidazole, 17 µL 30% hydrogen peroxide and 1 mL 30% DAB), for 5 min. The slides were washed with distilled water, 70% ethanol for 1 min, then in distilled water. The nuclei were stained with Mayer's hematoxylin

for 30 s. Extra stain was washed with tap water. The slides were then transferred through ascending ethanol series, and xylene before mounting.

Evaluation of E-cadherin staining

The E-cadherin staining was evaluated by an observer blinded to the clinical data (AE) under regular light microscopy. Only the infiltrating part of the neoplasm was evaluated. Both the membranous and cytoplasmic staining were evaluated separately. For cell membrane staining, four categories were used (+++, ++, +, -), starting from equivalent to normal through to entirely negative^[10]. The cytoplasmic staining was also graded into four categories: (0) negative, no detectable staining, (1) weak, but still detectable staining, (2) moderate, clearly positive but still weak, and (3) heavy staining, intense. In calculating the staining index; membrane (MI) and cytoplasmic (CI), both the intensity of staining and the fraction of positively stained cells were taken into account, using the following formula:

$$I = 0*f_0 + 1*f_1 + 2*f_2 + 3*f_3$$

where, I is the staining index, f_0 - f_3 the fractions of the cells showing a defined level of staining intensity (from 0 to 3). Theoretically, the index could vary between 0 and 3^[15]. The reproducibility of the E-cadherin staining indices was tested twice by one of the observers (AE) analyzing the sections, after a few days (intra-observer variation).

Statistical analysis

Statistical analyses were made using SPSS® (SPSS, Inc., Chicago, USA) and STATA (Stata Corp., TX, USA) software packages (SPSS for Windows, version 12.0.1 and STATA/SE 8.2). Frequency tables were analyzed using the χ^2 test, and likelihood ratio (LR) or Fisher's exact test was used to assess the significance of the correlation between the categorical variables. Odds ratios and their 95% confidence intervals (95%CI) were calculated where appropriate by the exact method. Differences in the means of continuous variables were analyzed using non-parametric tests (Mann-Whitney or Kruskal-Wallis) for 2- and K-independent samples, respectively. Analysis of variance (ANOVA) was only used for deriving the mean values and their SD of each individual category. Bivariate correlation (Spearman rho) and scatter plots were used to check the correlations between the two continuous variables (MI, CI vs DFS, DSS), controlled by linear regression analysis (R and R^2) for linearity. Univariate survival (life-table) analysis for the outcome measure (DSS, DFS) was based on Cox's method (indices treated as continuous variables). Multivariate survival analysis was made using Cox's proportional hazards model in a backward stepwise manner with the log-likelihood ratio (L-R) significance test, and using the default values for enter and exclusion criteria. The assumption of proportional hazards was controlled by log-minus-log (LML) survival plots. In all tests, the values $P < 0.05$ were regarded statistically significant.

RESULTS

E-cadherin expression was assessed in all tumors (Figure 1).

Figure 1 Immunohistochemical staining patterns. **A:** Primary tumor showing high E-cadherin membranous and cytoplasmic indices (MI = 1.75, CI = 0.85); **B:** Metastatic disease showing low E-cadherin indices (MI = 0.40, CI = 0.25); **C:** Metastatic disease in the liver showing high E-cadherin indices (MI = 1.00, CI = 0.60); **D:** Metastatic disease in the colon showing low E-cadherin indices (MI = 0.35, CI = 0.25).

Figure 2 Comparison of E-cadherin indices in primary tumors and metastases.

The expression pattern of E-cadherin was predominantly membranous in normal colonic epithelium but this pattern was disturbed (diffuse cytoplasmic and membranous) in the tumor area.

E-cadherin indices in primary tumors and metastases are shown in Figure 2. Interestingly, MI was significantly higher in primary tumors compared with their metastases ($P = 0.0001$), whereas CI did not show such difference. Both membrane and cytoplasmic E-cadherin expression in the primary tumor was increased in patients who developed metastases ($P = 0.022$ and $P = 0.007$, respectively).

Among the metastatic lesions, MI and CI were related to the site of metastases as shown in Figure 3, both indices were higher in metastases of the liver than in those at other anatomic sites ($P = 0.034$ and $P = 0.022$, respectively).

E-cadherin CIs were significantly higher in the primary tumors from patients who were above the median age of 67.5 years compared with those who were below ($P = 0.044$). MI and CI did not significantly correlate with other clinical variables such as sex, tumor grade, tumor stage, etc.

The Cox model was used to analyze the power of E-cadherin indices as predictors of DFS and DSS, using univariate mode for each of the values separately, followed

Figure 3 Comparison of E-cadherin indices and site of metastases.

by the multivariate test of all index values entered in the model. In univariate analysis, only the CI in the primary tumors was a significant predictor of DFS, with OR of 3.25 (95%CI 1.04-10.13) ($P = 0.042$). When all indices were entered in the multivariate Cox model, the CI of the primary tumor retained its value as an independent predictor of DFS, with OR of 4.65 (95%CI 1.36-15.89), while the others dropped out from the model. Indeed, there was a strong inverse correlation between CI and DFS, as shown in the scatter plot (Figure 4), cytoplasmic expression in the primary tumor was significantly higher in patients with disease recurrence ($n = 26$) during the follow-up period than those without (R^2 linear = -0.126, and $r = 0.354$ in linear regression analysis, as well as in bivariate correlation) (Spearman rho = -0.418; $P = 0.006$). This independent predictive power of the CI was not confounded by lymph node status, tumor location, primary T, grade, or age (continuous or dichotomized). In fact, predictive power increased in the final model to OR 7.30 (95%CI 1.51-35.10) ($P = 0.013$).

In the analysis for DSS, none of the indices in either the primary tumor or the metastasis were significant predictors of DSS in the univariate mode. However, in the multivariate model, adjusted for all recorded variables, MI in the primary tumor proved to be a significant independent predictor of survival, in that the higher indices were associated with a more favorable outcome, OR 0.332 (95%CI 0.136-0.813) ($P = 0.016$). In scatter plot, R^2 linear was 0.058 and in linear regression, $r = 0.240$ (Spearman rho = 0.267, $P = 0.091$). None of the other variables in the model proved to be significant independent predictors of DSS.

DISCUSSION

Cancer metastasis occurs through various steps and many biological factors are involved in these processes^[16]. Among these, the adhesion molecules are closely involved in the development and growth of metastatic tumors^[17]. If the activity of adhesion molecules is decreased, cells tend to detach from their site of origin. Conversely, the reattachment of tumor cells at the sites of metastases is mediated by multiple adhesion molecules, including integrins, selectins and cadherins^[18].

Colorectal epithelial cells of the crypt normally exhibit strong membranous expression of E-cadherin at cell-cell borders. This reflects the normal localization of this

Figure 4 Association of recurrence with E-cadherin CI indices in metastases.

intercellular adhesion molecule^[19]. When we assessed the level and pattern of expression of E-cadherin in primary colorectal tumors and their metastases, membranous and cytoplasmic expression at both locations was consistent with the previous reports^[20-23]. Multiple mechanisms are known to cause abnormal E-cadherin expression, including mutations or deletions of the E-cadherin gene itself, mutations in the β -catenin gene, and transcriptional repression of the E-cadherin gene, e.g., by hypermethylation or chromatin rearrangements in the E-cadherin promoter region^[24,25]. It is not yet clear which of these are relevant in CRC. However, in this study, the presence of both membranous and cytoplasmic expression in some tumors suggests that the E-cadherin molecule is still capable of locating the membrane, but its abnormal presence in the cytoplasm may be due to other reasons.

In this study, primary tumors showed significantly higher membranous expression of E-cadherin compared with the metastases, while cytoplasmic expression did not differ between the two tumor groups. This may reflect the selection of cells with less E-cadherin expression as metastases are formed, or possibly the local environment of the organ in which the metastasis has been formed. Our findings suggest that the site of metastasis is associated with the distribution of E-cadherin expression. There were differences in E-cadherin expression (both CI and MI) among the metastatic lesions at different anatomic locations. Both MI and CI were significantly higher in metastatic lesions in the liver than in metastasis at other sites (Figure 3). Although these observations implicate several possible mechanisms, there is little data to draw any definitive conclusions; however, Bongiorno *et al* reported that cancer cells in thoracic neoplasms and in Barrett's esophagus lost their E-cadherin expression transiently during their dissemination, and then re-expressed this and other adhesion molecules at a distant metastatic site^[26]. This concept is indirectly supported by the present observations that MI was significantly higher in primary tumors than in their metastases, whereas CI did not show such a difference. Our findings justify the need to examine the expression of other adhesion molecules so as to investigate the possibility that circulating cancer cells with a distinct adhesion molecule pattern would be preferentially selected to deposit in the liver. Some debate

exists concerning the changes in the level of E-cadherin expression in the primary CRC and its metastasis. Gagliardi and co-workers compared 14 liver metastases with their corresponding primary tumors and found complete loss of membranous E-cadherin expression in 7/14 (50%) liver metastases of which 6/7 (86%) showed intense expression in the corresponding primary tumors^[19], while Ikeguchi and colleagues reported increased E-cadherin expression in up to 40% of the liver metastases compared with only 17% of the metastatic lymph nodes that were studied^[27]. Similarly, Mayer *et al* reported that in many gastric carcinomas, E-cadherin expression in metastatic lesions of the liver was indeed stronger than that in the primary tumors^[28].

When we looked at the patients with metastases at the time of diagnosis ($n = 30$), we found that CI was almost double in their primary tumors, suggesting that increased aberrant distribution of E-cadherin in the primary tumors may reflect an increased likelihood of metastasis formation. Furthermore, cytoplasmic expression in the primary tumors was significantly higher in patients with disease recurrence ($n = 26$) during the follow-up period than those without recurrence. The E-cadherin MI was very similar among those who had metastasis at onset and in those who developed recurrence during follow-up (1.13 *vs* 1.25, respectively). In addition, CI values in the primary tumors of patients who had primary metastasis (0.48) were very similar to those who had subsequent recurrence (0.54). In both cases, CI was always lower among those without primary metastasis and in those who did not develop recurrent disease, (0.27 and 0.22, respectively). These findings suggest that cytoplasmic (aberrant) E-cadherin expression more closely reflects the adverse biological behavior of CRC than does membranous (normal) expression.

In univariate analysis, the cytoplasmic E-cadherin index in primary tumors was a significant predictor of DFS, and CI retained its independent predictive power of DFS also in the multivariate model. In fact, its predictive power substantially increased in the final multivariate model. This effect is explained by the strong inverse correlation between CI levels and DFS (Figure 4). The CI did not predict DSS, however, in either univariate or multivariate model. Interestingly, the MI of the primary tumor proved to be a significant predictive factor in multivariate analysis (with OR and 95%CI far below 1.0), indicating that higher MI values are associated with more favorable disease outcome, suggesting that membranous (normal) E-cadherin expression may reflect a tumor that retains a more normal cell phenotype.

Certainly, our findings support the concept that aberrant (cytoplasmic) E-cadherin expression is a sign of adverse disease outcome in CRC. These results are consistent with the previous reports that loss of normal expression of E-cadherin is associated with poor prognosis in breast and colorectal carcinoma^[29,30]. The present study further confirms the power of E-cadherin indices as predictors of disease recurrence and progression.

This study found no significant correlation between E-cadherin indices and the various clinical variables recorded (sex, tumor grade, tumor stage, *etc*); however, this

is not surprising since other groups have also reported similar findings^[31].

Finally, the importance of distinguishing between membrane and cytoplasmic E-cadherin expression is emphasized by this study, because it seems to reflect different aspects of the behavior of CRC. Cytoplasmic expression more closely predicts disease recurrence and aberrant expression (downregulation) at the membrane seems to indicate a poorer prognosis. In both cellular locations, E-cadherin expression is reduced in metastasis as compared with the primary tumors. We can only speculate at the mechanisms of this change in expression, and it may be due to alterations in catenins, which link the cadherin molecules to the actin cytoskeleton. Similarly, the observed higher levels of E-cadherin expression (both MI and CI) in metastatic deposits in the liver than in other sites need further investigations.

To conclude, it is clear that examining E-cadherin expression and distribution in colorectal tumors is extremely valuable in predicting disease recurrence. The observation that aberrant cytoplasmic expression of E-cadherin can predict disease recurrence is obviously of great importance for both the patient and the clinician, and affects significantly decisions concerning the therapy and management of the patients.

CONCLUSION: The results indicate that the mechanism of T cell hyporesponsiveness to HBcAg includes activation of HBcAg-induced regulatory T cells in contrast to an increase in T_H2-committed cells in response to HBsAg.

Abstract

AIM: To study the mechanisms of hyporesponsiveness of HBV-specific CD4⁺ T cells by testing T_H1 and T_H2 commitment and regulatory T cells.

METHODS: Nine patients with chronic hepatitis B were enrolled. Peripheral blood mononuclear cells were stimulated with HBcAg or HBsAg to evaluate their potential to commit to T_H1 and T_H2 differentiation. HBcAg-specific activity of regulatory T cells was evaluated by staining with antibodies to CD4, CD25, CTLA-4 and interleukin-10. The role of regulatory T cells was further assessed by treatment with anti-interleukin-10 antibody and depletion of CD4⁺CD25⁺ cells.

RESULTS: Level of mRNAs for T-bet, IL-12R β2 and IL-4 was significantly lower in the patients than in healthy subjects with HBcAg stimulation. Although populations of CD4⁺CD25^{high}CTLA-4⁺ T cells were not different between the patients and healthy subjects, IL-10 secreting cells were found in CD4⁺ cells and CD4⁺CD25⁺ cells in the patients in response to HBcAg, and they were not found in cells which were stimulated with HBsAg. Addition of anti-IL-10 antibody recovered the amount of HBcAg-specific T_H1 antibody compared with control antibody ($P < 0.01$, $0.34\% \pm 0.12\%$ vs $0.15\% \pm 0.04\%$). Deletion of CD4⁺CD25⁺ T cells increased the amount of HBcAg-specific T_H1 antibody when compared with lymphocytes reconstituted using regulatory T cells ($P < 0.01$, $0.03\% \pm 0.02\%$ vs $0.18\% \pm 0.05\%$).

INTRODUCTION

Hepatitis B virus (HBV) is a noncytotoxic DNA virus which causes chronic hepatitis and hepatocellular carcinoma as well as acute hepatitis^[1]. HBV now affects more than 300 million people worldwide^[2] and in approximately 5% of adults and 95% of neonates who become infected with HBV, persistent infection develops.

It has been shown that cytotoxic T lymphocytes (CTLs) play a central role in the control of virus infection^[3]. In addition, CD4⁺ T cells provide help for both CTLs and B-cell responses^[4]. Hyporesponsiveness of HBV-specific T cells in peripheral blood has been shown in patients with chronic HBV infection^[5]. Recently, lamivudine treatment in chronic hepatitis B has been reported to restore both CD4⁺ T cells and CTL hyporesponsiveness following the decline of serum levels of HBV DNA and HBsAg^[6,7]. However, previous reports have indicated that HBV-specific T cells restored by lamivudine treatment are insufficient to completely suppress HBV replication^[8,9]. In our previous study, we observed a defect in recovery of HBcAg-specific T_H1 cells despite restoration of CTLs, although they showed limited functions^[10,11]. Since type 1 helper T (T_H1) cells are believed essential for immunity against intracellular pathogens^[12], more detailed study of HBV-specific CD4⁺ cells is needed in order to understand the mechanisms of persistent infection in CHB.

Increasing evidence has suggested that both cytokine

balance including interferon- γ (IFN- γ) and interleukin-4 (IL-4) and direct signaling through the T cell receptor is important for T_H1 and T_H2 commitment^[13]. The critical transcription factors for commitment of T cells to the T_H1 or T_H2 pathway are T-bet or GATA-3 respectively^[14-16]. Whether various antigens derived from the HBV genome affect expression of these factors is unknown. It is important to understand how cytokine balance and antigen types could affect T_H1/T_H2 commitment in chronic hepatitis B.

There have also been reports about the possible induction of anergy by regulatory T cells (T_{reg} cells), that constitutively express CD25 (the IL-2 receptor α -chain) in the physiological state^[17-19]. In humans, this T_{reg} population, as defined by CD4⁺CD25⁺CTLA-4⁺ expression, constitutes 5% to 10% of peripheral CD4⁺ T cells and has a broad repertoire that recognizes various self and nonself antigens. It has been indicated that T_{reg} cells have several different mechanisms for suppressing various kinds of immune cells^[20,21]. The important mechanisms are cell to cell contact and secretion of cytokines including IL-10 and transforming growth factor- β (TGF- β)^[22-26]. Antigens derived from HBV might induce T_{reg} cells to escape from immunological pressure as reported in persistent infection of EB virus, hepatitis C virus and HIV-1^[24,26,27].

In this study we examined the mechanisms of hyporesponsiveness of HBV-specific CD4⁺ T cells by evaluating the T_H1/T_H2 commitment and activity of T_{reg} cells.

MATERIALS AND METHODS

Study design

Nine patients with chronic hepatitis B (CHB) were enrolled in this study (Table 1). The patients had more than 5.0 log genome equivalent (LGE /mL; Chugai Pharmaceutical Co., Tokyo, Japan) of serum HBV DNA and had elevated alanine aminotransferase (ALT) values (normal range < 40 IU/L) for more than 6 mo prior to the study. Six patients were seropositive for HBeAg and three patients were seropositive for anti-HBe. All the patients were negative for antibodies to hepatitis C virus (HCV) and did not have liver diseases due to other causes, such as alcohol, drug, congestive heart failure and autoimmune disease. For control subjects, ten healthy HBsAg-vaccinated subjects were included.

Permission for the study was obtained from the Ethical committee at Tohoku University School of Medicine. Written informed consent was obtained from all the subjects enrolled in this study. The study comprised 6 mo of monitoring before obtaining peripheral blood with assessments at 1, 2, 4, and 6 mo. At each assessment, patients were evaluated for serum HBV DNA, HBeAg, anti-HBe, blood chemistry and hematology. HBsAg, anti-HBs, total and IgM anti-HBc, HBeAg, anti-HBe, and anti-HCV were determined by commercial enzyme immunoassay kits (Abbott Laboratories, Chicago, IL). Serum levels of HBV DNA were measured by transcription mediated amplification-hybridization protection assay (lower limit of detection: 3.7 LGE/mL).

Table 1 Summary of clinical characteristics of patients with chronic hepatitis B enrolled in the study

Case	Age (yr)	Gender	ALT (IU/L)	HBeAg (Cutoff index)	Anti-HBe (Inhibition %)	HBV DNA (LGE/mL)	HBV Genotype
1	55	M	78	67	< 0.5	5.8	C
2	36	M	183	100	< 0.5	7.6	ND
3	31	M	50	66.9	< 0.5	7.6	C
4	42	M	141	100	< 0.5	6.8	C
5	27	M	77	75.7	< 0.5	7.6	C
6	42	F	42	93.8	< 0.5	7.0	C
7	32	M	70	< 0.5	100	6.2	C
8	29	M	81	< 0.5	86.9	5.3	C
9	58	M	117	0.7	100	7.3	C

The values for serum levels of ALT, HBeAg, anti-HBe, HBV DNA and HBV genotypes were determined at the time of blood sampling. Abbreviations: M, male; F, female; LGE/mL, log genome equivalent /mL; ND, not determined.

Reagents

IL-10 and IFN- γ secretion assay kits were purchased from Miltenyi Biotec (Bergisch Gladbach, Germany). Monoclonal antibodies to human CTLA-4 (APC-labeled), CD4 (PerCP-labeled), CD3 (FITC-labeled), CD25 (FITC-labeled), IL-10 (No Azide / Low Endotoxin) and isotype-matched control antibodies were purchased from BD Biosciences Pharmingen (San Diego, CA). HBsAg and HBeAg were obtained from Biodesign International (Saco, MA).

Cell culture

Peripheral blood mononuclear cells (PBMCs) isolated from heparinized blood by Ficoll-Hypaque density gradient centrifugation were resuspended in RPMI 1640 supplemented with 8% human AB serum (Nabi, Miami, FL; complete medium) and were cultured in a 96-well plate at a concentration of 1×10^7 cells/mL in complete medium in the presence of HBsAg (29 μ g/mL) or HBeAg (10 μ g/mL) for 24 h. Thereafter, CD4⁺ cells (4×10^5 cells) were separated from the stimulated PBMCs using anti-CD4-coated magnetic beads (Dynabeads M-450 CD4, DYNAL, Oslo, Finland) for quantification of mRNAs.

Quantified real time PCR

Total cellular RNA was extracted from CD4⁺ cells using an RNeasy Mini Kit (Qiagen, Valencia, CA) according to the manufacture's instruction. Contaminating small DNA was removed by DNase I digestion using an RNase-free DNase system (Qiagen). Subsequently, total RNA was reverse-transcribed to single strand cDNA using random hexamers. In brief, the amount of extracted RNA was measured by NanoDrop ND-1000 (NanoDrop Technologies, Rockland, DE). After mixing with random primers and DEPC water, 1 μ g RNA was further mixed with $5 \times$ first strand buffer, dNTP mixture and 0.1 mol/L DTT. After preincubation (25°C, 10 min), M-MLV RT (Takara, Tokyo, Japan) and ribonuclease inhibitor were added and samples were incubated further for 60-min at 37°C. Realtime PCR was performed on an ABI PRISM 7700 Sequence Detector (Perkin-Elmer Applied Biosystems, Foster City, CA) using predeveloped TaqMan Assay Reagents (Perkin-Elmer

Applied Biosystems) according to the manufacturer's protocol^[28]. The commercially available primers and probe for the amplification of T-bet (ID Hs00203436), IFN- γ (ID Hs00174143), GATA-3 (ID Hs00231122), IL-4 (ID Hs00174122), FOXP3 (ID Hs00203958) and GAPDH were purchased from Perkin-Elmer Applied Biosystems. Amplification of IL-12R β 2 was performed as previously described^[29].

IL-10 and IFN-gamma secretion assay

Purified PBMCs were stimulated at 1×10^7 cells/mL in complete medium with or without HBcAg (10 μ g/mL) for 9 h at 37°C. Cells were washed by adding 2 mL of cold buffer and resuspended in 90 μ L of cold medium. After the addition of 10 μ L of IL-10- or IFN-gamma-capture Reagent, cells were incubated for 5 min on ice. Thereafter, cells were diluted with 1 mL of warm medium (37°C) and further incubated in a closed tube for 45 min at 37°C under slow continuous rotation. Cells were washed and IL-10- or IFN- γ -secreting cells were stained by adding 10 μ L of IL-10- or IFN- γ -Detection Antibody (PE-conjugated) together with anti-CD4-PerCP and anti-CD25-FITC. In some experiments, FITC fluorescence was amplified by FASER kit-FITC (Miltenyi Biotec). Selected samples were stained with anti-CD14-FITC, anti-CD3-PerCP, anti-HLA-DR-APC (BD Biosciences). Cells were analyzed by FACSCalibur.

To assess the effects of IL-10 on the HBcAg-specific IFN- γ production by CD4⁺ T cells, PBMCs were stimulated at 1×10^7 cells/mL in complete medium with or without HBcAg (10 μ g/mL) and with or without anti-human IL-10 monoclonal antibody at the indicated concentration for 9 h at 37°C. Cells were then used for IFN- γ -secretion assay and analyzed by FACSCalibur.

Intracellular and surface CTLA-4 staining

In order to analyze the expression of total CTLA-4 in CD4⁺CD25⁺ cells, cells were fixed and permeabilized using BD cytofix/cytoperm solution (BD Bioscience) after cell surface markers including CTLA-4 were stained. Subsequently, intracellular CTLA-4 was stained and the cells were analyzed by FACSCalibur^[30].

Depletion of T_{reg} cells

By using the CD4⁺CD25⁺ Regulatory T Cell Isolation Kit (Miltenyi Biotec), three fractions of lymphocytes were obtained; lymphocytes depleted of CD4⁺ cells (fraction 1), purified CD4⁺CD25⁺ lymphocytes (fraction 2) and purified CD4⁺CD25⁺ cells (fraction 3). To test the effect of CD4⁺CD25⁺ cells on HBcAg-specific IFN- γ production, 2 sets of lymphocyte preparations were reconstituted. The first set, designated as T_{reg}⁺, was the mixture of all three fractions and contained 5%-7% CD4⁺CD25⁺ cells. The second set, designated as T_{reg}⁻, was the mixture of fractions 1 and 2, and contained 0.5% (mean) of CD4⁺CD25⁺ cells.

Statistical analysis

Differences in the amounts of cytokines produced were analyzed by oneway ANOVA between patients with CHB and healthy controls. The frequencies of cytokine-secreting cells were analyzed by Mann-Whitney U test.

Both tests were run using SPSS ver. 10. A level of $P < 0.05$ was considered as being statistically significant.

RESULTS

Expression of mRNA relating to T_H1/T_H2 commitment in CD4⁺ cells

In CHB patients, HBcAg significantly suppressed the expression of mRNAs for T-bet ($P < 0.01$), IL-12R β 2 ($P < 0.05$) and IL-4 ($P < 0.05$) compared with those of healthy volunteers (Figure 1A). In addition, the expression levels of mRNAs for IFN- γ and GATA-3 were below 1.0 in response to HBcAg stimulation (Figure 1A). On the other hand, HBsAg induced the upregulation of GATA-3 mRNA compared with healthy volunteers ($P < 0.01$) while the expression level of T_H1 related mRNA (T-bet, IFN- γ , and IL-12R β 2) remained unchanged (Figure 1B).

IL-10 secreting cells in response to HBcAg were enriched in CD4⁺CD25⁺ lymphocytes

Involvement of the suppressive cytokine IL-10 in suppression of T_H1-commitment of HBcAg-stimulated cells was evaluated by enumeration of IL-10-secreting cells. Since the cells secreting IL-10 were mostly found in the CD3⁺ population, cells were further studied by staining with antibodies to CD4 and CD25. A population of IL-10-secreting CD4⁺ T cells was readily detectable in patients with CHB (Figure 2A) and these IL-10 secreting cells in CD4⁺ T cells showed CD25^{high} expression (Figure 2B), while there were no such responding cells in healthy subjects (Figure 2C). In addition, when the cells were stimulated with HBsAg, no IL-10 producing CD4⁺CD25^{high} cells were detected (Figure 2D). The percentage of HBcAg-specific IL-10 secreting CD4⁺ cells in all patients with CHB was $0.10\% \pm 0.04\%$ (mean \pm standard deviation), and the population was more prominent in CD4⁺CD25^{high} cells (Figure 3). Our next question was whether T_{reg} cells increased in number or were induced by HBcAg stimulation. Therefore, the population of CD4⁺CD25^{high}CTLA-4⁺ T cells was compared between CHB patients and healthy subjects (Figure 4A). However, no statistical difference in the population with this phenotype was found between normal subjects and CHB patients (Figure 4B).

Recovery of IFN- γ -secreting cells by the addition of anti-IL-10 antibody

Low response of HBcAg-specific T_H1 cells defined by IFN-gamma-secreting CD4⁺ T cells in response to HBcAg stimulation was indicated by the lack of statistical difference in that population between patients with CHB and normal subjects (Figure 5A). To further assess the role of IL-10 in the suppression of T_H1 responses to HBcAg stimulation, the effect of anti-IL-10 antibody on T_H1 response was evaluated by addition of anti-IL-10 cultures. The population of CD4⁺ T cells was comparable when cultured with and without anti-IL-10 antibody (Figure 5B). In the presence of anti-IL-10 antibody, the population of IFN- γ -secreting CD4⁺ T lymphocytes in response to HBcAg significantly increased (2.3-fold, $0.34\% \pm 0.12\%$; mean \pm SD of 9 cases) compared to culture with a control

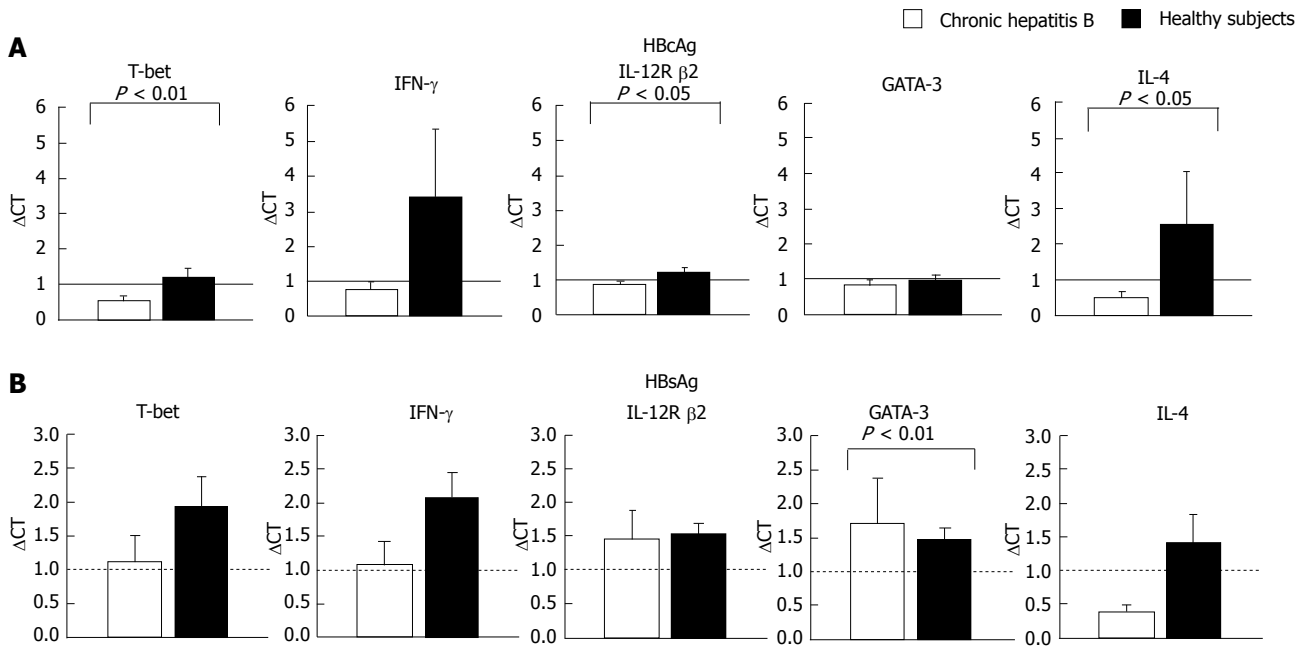

Figure 1 Comparison of levels of mRNAs for T-bet and GATA-3 after stimulation with HBsAg and HBCAg with mRNAs for IFN- γ , IL-10 and IL-4. Total cellular RNA was extracted from CD4⁺ T cells after the stimulation of PBMCs with HBCAg (10 μ g/mL) or HBsAg (29 μ g/mL) for 24 h. **A:** HBCAg stimulation; **B:** HBsAg stimulation. Levels of mRNA for T-bet, GATA-3, IFN- γ , IL-12R $\beta 2$ and IL-4 were quantified by TaqMan PCR. GAPDH was used as an internal control. Relative amount of target mRNA was calculated using comparative CT method. The expression level of mRNAs of the non-stimulated sample in each subject is represented as 1.0 and relative amount of target mRNA in a stimulated sample was calculated using the as following formula: relative amount = $2^{-\Delta\Delta CT}$, where $\Delta\Delta CT$ was given by subtracting ΔCT (non-stimulated cells) from ΔCT (stimulated cells). The ΔCT value was determined by subtracting the GAPDH C_T value from the target C_T value. The validation experiments were performed in advance for all the target mRNAs to demonstrate that efficiency of each target and GAPDH are approximately equal.

Figure 2 FACS analysis of HBCAg-specific production of IL-10 in patients with hepatitis B. Cellular source of HBCAg-specific production of IL-10 was identified by staining for IL-10-secretion (PE-labeled), anti-CD3-PerCP, anti-CD4-PerCP and anti-CD25-FITC. Representative dot plots of IL-10-secreting CD4⁺ T cells in a patient with CHB (**A**) and IL-10-secreting CD4⁺CD25^{high} T cells in a patient with CHB (**B**). For the control, IL-10-secreting cells in a healthy subject with HBCAg stimulation (**C**) and in a patient with CHB with HBsAg stimulation (**D**) were also shown. Numbers shown in the dot plots indicate percentage of the cells in the quadrant region.

Figure 3 Increased populations of HBcAg-specific IL-10-producing CD4⁺ or CD4⁺CD25^{high} T cells in patients with chronic hepatitis B. Population of IL-10 secreting cells in CD4⁺ T cells and in CD4⁺CD25⁺ T cells was evaluated in patients with CHB. Frequencies of HBcAg-specific IL-10 secreting cells were calculated by subtracting percentage in non-stimulated samples from percentage in HBcAg-stimulated samples. Upper limits of normal subjects (mean \pm 2SD of 5 subjects) were shown by straight lines in the plots (0.14% for CD4⁺CD25⁺ cells and 0.027% for CD4⁺ cells). A FITC faser kit (BD Bioscience Pharmingen) was used in some experiments of ease separation of positive events by enhancing fluorescence intensity.

Figure 4 Comparison of CD4⁺CD25^{high} T cell population between patients with hepatitis B and healthy subjects. The cells that express CD4, CD25^{high} and CTLA-4 were identified by flow cytometry. Representative dot plots of an *ex vivo* sample of a patient with CHB is shown (A), numbers shown in the dot plot indicates percentage of cells in the quadrant lesion. Percentage of CD4⁺CD25⁺ T cells was shown for patients with CHB and healthy subjects (B).

Figure 5 Addition of neutralizing anti-IL-10 antibody restores HBcAg-specific production of IFN- γ by CD4⁺ in patients with hepatitis B. PBMCs obtained from 5 patients with CHB and 7 healthy subjects were stimulated with HBcAg (10 μ g/mL) for 9 h and thereafter cells were stained for IFN- γ -secretion (PE) and anti-CD4-PerCP to determine the population of HBcAg-specific T_H1 being identified as IFN- γ ⁺ cells in CD4⁺ T cells (A). Anti-IL-10 neutralizing antibody or isotype-matched control antibody were added to the culture during stimulation with HBcAg. The addition of anti-IL-10 antibody did not affect the percentage of CD4⁺ T cells (B). In culture with anti-IL-10 antibody, numbers of HBcAg-specific T_H1 were significantly higher than those in culture with a control antibody (C).

antibody (0.15% \pm 0.04 %, $P < 0.01$, Figure 5C).

T_{reg} depletion restores the response of IFN- γ -secreting CD4⁺ T cells to HBcAg

Similar to the effect of anti-IL-10 antibody, depletion of T_{reg} induced the recovery of HBcAg-specific T_H1 response. T_{reg} were depleted by a CD4⁺CD25⁺ T cell separation kit (Figure 6A) and the cultures were reconstituted by mixing separated fractions. T_{reg}⁻ culture contained 0.5% (mean) of CD4⁺CD25⁺ cells on average, while T_{reg}⁺ culture contained 3.5% of CD4⁺CD25⁺ cells on average (Figure 6B). The number of IFN- γ -secreting CD4⁺ cells in response to HBcAg significantly increased in T_{reg}⁻ culture by 6-fold (0.03% \pm 0.02%, mean \pm SD of 9 cases) compared with that in T_{reg}⁺ culture (0.18% \pm 0.05%, $P < 0.01$, Figure 6C).

Expression level of FOXP-3 and CTLA-4 was analyzed in 3 separate fractions to verify that CD4⁺CD25⁺ cells exhibited typical characteristics of T_{reg} cells. Fraction 3 (CD4⁺CD25⁺) expressed higher FOXP-3 than fraction 2 (CD4⁺CD25⁻) by 3.7 fold and fraction 1 (CD4⁻) by 7.8 fold. The percentage of total CTLA-4 expression in fraction 1, fraction 2 and fraction 3 was 0.45%, 2.71% and 32.71% respectively.

DISCUSSION

The response of T cells to HBcAg has been reported to contribute to the resolution and seroconversion of HBV infection in chronic hepatitis B^[31]. However, in the previous study we were unable to detect the recovery

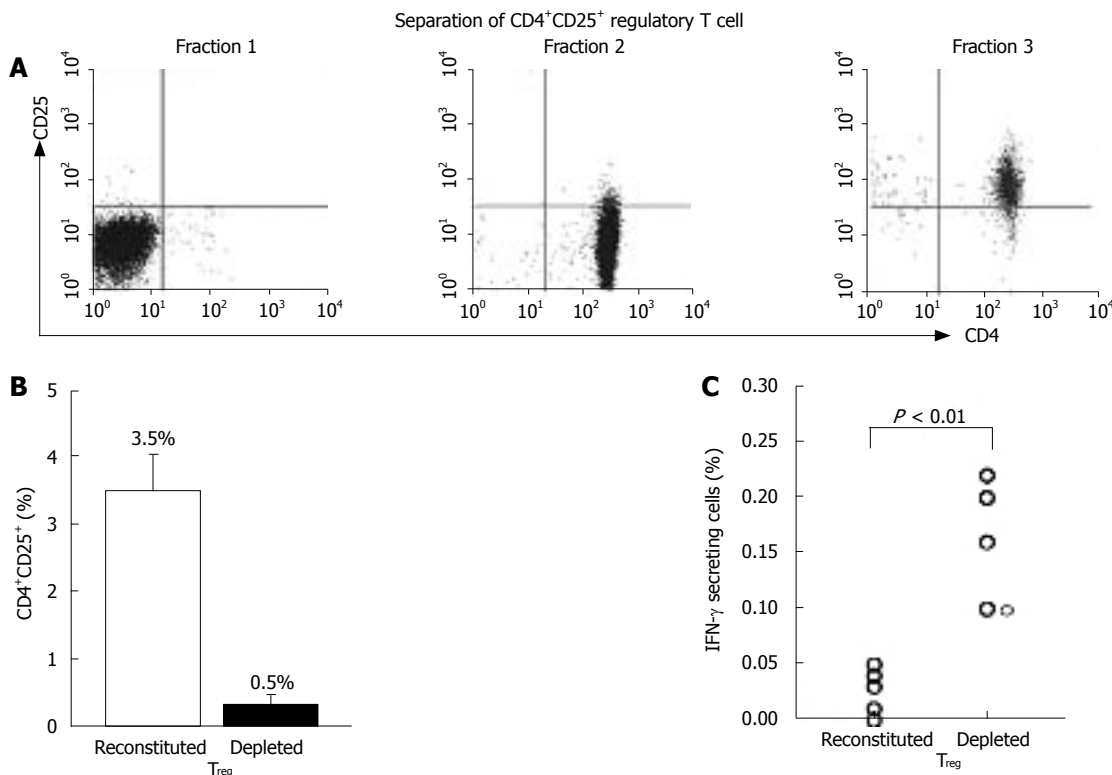

Figure 6 Depletion of CD4⁺CD25⁺ T cells from PBMCs increases HBcAg-specific production of IFN-γ in patients with hepatitis B. Using the differential expression of CD4 and CD25, cells were separated into 3 fractions; fraction 1 consisted of CD4⁺ cells, fraction 2 consisted of CD4⁺CD25⁺ cells and fraction 3 consisted of CD4⁻CD25⁺ cells (A). Thereafter, 2 sets of lymphocyte preparations were reconstituted by remixing fractions 1, 2 and 3 or by remixing fractions 1 and 2 (B). They were stimulated with HBcAg to finally stain a CD4⁺IFN-γ⁺ population (C).

of HBcAg-specific T_H1 despite the substantial increase in HBV-specific CTLs in patients receiving lamivudine therapy^[11]. The results raised a question about the profound suppression of CD4⁺ T cell response to HBV in patients with chronic hepatitis B. The current results showed that polarization of CD4⁺ T cells was suppressed when the cells were stimulated with HBcAg in patients with chronic hepatitis B. The mechanisms underlying this suppression of CD4⁺ T cells were through suppression of either direction to T_H1 or T_H2 by HBcAg stimulation, while HBsAg stimulation favored T_H2 deviation in chronic hepatitis C.

It may be possible that T_{reg} cells are one of the mediators of the suppression of T_H1 response to HBcAg as suggested by the results of an increased population of IL-10-secreting CD4⁺CD25^{high} cells. This indicates the presence of an inducible T_{reg} population which is specific for HBcAg and produces IL-10, as well as a natural T_{reg} population in patients with CHB. However, the role of HBcAg is controversial, since it can induce IL-18, a monokine that stimulates T lymphocytes and macrophages to produce IFN-γ, in both healthy subjects and patients with chronic hepatitis B^[32], and cause an increase in IL-10-producing T lymphocytes and monocytes *in vitro*^[33]. Our data indicate lack of HBcAg-specific T_H1 response in CHB patients, although the results of IL-18 are not available. Our study was conducted on a small scale with 9 patients and the hyporesponsiveness of HBV-specific T cells should be investigated in studies with larger populations.

T_{reg} cells may be a common feature of immune sup-

pression in chronic viral infection. In HIV infection, appearance of T_{reg} in peripheral blood has been shown to have a suppressive role in CTL development against HIV antigen^[34]. In patients with chronic hepatitis C, the evolution of inducible T_{reg} cells specific for HCV antigens has been reported^[35] and the presence of CD8⁺ T_{reg} cells homing to suppress local inflammation in the liver has also been reported in HCV infection^[36]. Thus T_{reg} cells may have diverse effects during chronic viral infection; suppression of cellular immune response to eliminate the virus and the suppression of unfavorable tissue damage by the cellular immune response to the virus^[37]. In addition, there has been a report of different clinical features in patients with chronic hepatitis C, namely a higher prevalence of cryoglobulinemia in patients with lower T_{reg} cells^[38]. Although natural T_{reg} population may also contribute to the suppression of CD4⁺ T cell response from the results of CD4⁺CD25⁺-depletion, the population of CD4⁺CD25^{high} T cells *ex vivo* was not different between normal subjects (5.73% ± 1.87%) and patients with chronic hepatitis B (4.73% ± 1.15%) similar to the results of Franzese *et al*^[39], while Stoop *et al* have reported the increased T_{reg} population in peripheral blood of patients with CHB^[40]. The change in T_{reg} population and its contribution to pathogenesis needs to be evaluated by comparing various HBV diseases.

Manipulation of activity of T_{reg} cells specific for HBcAg may become one of the potent options in future therapy. An immunomodulating approach, which is indicated by successful use of GITR (glucocorticoid-

induced TNF- α receptors) to suppress activity of T_{reg} cells^[41], may become beneficial in patients with CHB.

In summary, this report demonstrates underlying mechanisms of suppression of immune responses to HBcAg in chronic HBV infection. A therapeutic approach to the molecules or cell types involved in these mechanisms may contribute to the improvement of prognosis in patients with chronic hepatitis caused by persistent replication of HBV.

Abstract

AIM: To study the effect of mucilage obtained from cladodes of *Opuntia ficus-indica* (Cactaceae) on the healing of ethanol-induced gastritis in rats.

METHODS: Chronic gastric mucosa injury was treated with mucilage (5 mg/kg per day) after it was induced by ethanol. Lipid composition, activity of 5'-nucleotidase (a membrane-associated ectoenzyme) and cytosolic activities of lactate and alcohol dehydrogenases in the plasma membrane of gastric mucosa were determined. Histological studies of gastric samples from the experimental groups were included.

RESULTS: Ethanol elicited the histological profile of gastritis characterized by loss of the surface epithelium and infiltration of polymorphonuclear leukocytes. Phosphatidylcholine (PC) decreased and cholesterol content increased in plasma membranes of the gastric mucosa. In addition, cytosolic activity increased while the activity of alcohol dehydrogenases decreased. The administration of mucilage promptly corrected these enzymatic changes. In fact, mucilage readily accelerated restoration of the ethanol-induced histological alterations and the disturbances in plasma membranes of gastric mucosa, showing a univocal anti-inflammatory effect. The activity of 5'-nucleotidase correlated with the changes in lipid composition and the fluidity of gastric mucosal plasma membranes.

CONCLUSION: The beneficial action of mucilage seems correlated with stabilization of plasma membranes of damaged gastric mucosa. Molecular interactions between

INTRODUCTION

The *Opuntia ficus-indica* (*O. ficus-indica*) is a plant belonging to the Cactaceae family, located preferentially in arid zones^[1]. The main substance produced by this plant is mucilage composed mostly of water and polysaccharides, which may participate in adaptation mechanisms preventing dehydration or freezing^[2]. The mucilage obtained from cladodes of *O. ficus-indica* is soluble in water and produces colloidal solutions of high viscosity^[3].

The polysaccharide in mucilage with a high molecular weight^[4,5], is produced by specialized cells in the Cactaceae^[6]. Chemically, mucilage is composed of α -D-galactopyranosiluronic acid and β -L-rhamnopyranose, forming the main chain and β -D-galactopyranose, β -D-xylopyranose and α -L-arabinofuranose in the side chains^[7,8].

In Mexico, mucilage obtained from *O. ficus-indica* can cure topical inflammation and skin ulcerations^[9]. In addition, recent data suggest that mucilage derived from this plant can treat acute gastric damage. The anti-ulcer activity of mucilage from *O. ficus-indica* has been reported^[10]. The beneficial effect of cladodes from *O. ficus-indica* when simultaneously administered with ethanol seems related to an enhancement of gastric mucus production^[11]. Likewise, polygalacturonic acid^[4,7] and arabinogalactan protein in mucilage, probably act in combination with some protective factors including

macromolecules or small ligands of the gastric mucosa^[12]. Although these possibilities remain unproved, mucilage from *O. ficus-indica* could exert a cytoprotection as an anti-inflammatory agent, which can prevent rat gastric mucosal damage when administered concomitantly with the noxious agent^[13].

To solve the problem, we have developed a model of ethanol administration to rats, which could elicit a histological profile of gastric injury characterized by loss of surface epithelium and infiltration of polymorphonuclear leukocytes. This model produces evident alterations in plasma membranes of the gastric mucosa^[14]. After ethanol withdrawal^[15], these alterations may lead to increased membrane lipid peroxidation accompanying spontaneous restitution of the gastric mucosa epithelium.

Taking advantage of these histological alterations, as well as those in membrane lipid composition present in our model of chronic ethanol-induced rat gastric mucosal damage^[14], the present study assessed whether administration of mucilage extracted from *O. ficus indica* had a therapeutic effect on this experimental model of gastritis in rats.

MATERIALS AND METHODS

Preparation of mucilage

The cladodes were isolated from a cultivation of *O. ficus-indica* located in Milpa Alta village (near to Mexico City) and the identity of the plant was confirmed by the bibliographic data^[1]. Two kg of fresh cladodes free of spines was cut into cubes of 2 cm × 2 cm × 1 cm and placed in one liter of distilled water for 24 h. The supernatant was frozen and lyophilized, from which 41g of mucilage as a yellow-powder was obtained. A 0.25% solution of mucilage in water was prepared.

Animal treatment

A model of gastritis induced by chronic ethanol administration to rats has been described in detail elsewhere^[14]. Briefly, two groups of 20 and 15 male Wistar rats weighing 240–260 g, after an overnight fasting, received 1 mL of 50% ethanol through a gastric tube for one day and water containing 5% of ethanol *ad libitum* to achieve a daily intake of 9–10 g of ethanol per kg of body weight for five days. Then the animals developed gastritis. This was considered as time zero (once histological evidence of gastritis was achieved), at this time the ethanol ingestion was discontinued. The group of 20 animals was considered as the gastritis control group, which was divided into four subgroups of 5 animals. The first subgroup was studied at time zero whereas the second, third and fourth subgroups were studied after 24, 48, and 72 h, respectively. The group of 15 rats served as the gastritis group treated with mucilage (5 mg/kg of body per day, starting at time zero) and divided into three subgroups, 5 animals in each subgroup, and studied after 24, 48, and 72 h, respectively. The complementary control group of 15 healthy animals (divided into three subgroups, 5 animals in each subgroup), received only saline solution and was studied after 24, 48, and 72 h, respectively. The animals were killed by decapitation after administration of an overdose of

sodium pentobarbital. All the procedures were performed according to the Federal Regulations for *Care and Use of Experimental Animals* (Ministry of Agriculture and Animal Breeding; SAGARPA).

Histological assessment and subcellular fractionation of gastric mucosa

The stomach was removed from each rat, dissected along the greater curvature and rinsed in cold saline solution. Strips of gastric wall were embedded in paraffin, stained and analyzed as reported elsewhere^[14]. The remnant gastric tissue from the forestomach to the pylorus through the entire glandular mucosa, was homogenized in a buffer containing 0.25 mol/L of sucrose and 10 mmol/L of TRIS-HCl (pH 7.5). Plasma membrane was obtained from the whole homogenate by the method of Loten and Redshaw-Loten^[16], while the cytosolic fraction was obtained by differential centrifugation^[14]. Identity and purity of the subcellular fractions were routinely assessed by determining the activities of marker enzymes, namely 5'-nucleotidase and lactate dehydrogenase (LDH)^[14]. 5' nucleotidase was also used to assess the *in vivo* plasma membrane fluidity^[14].

Analytical procedures

In extracts of total lipids from isolated plasma membranes, phospholipid content was determined as previously described^[17]. Total cholesterol was determined with the colorimetric method described by Abell *et al.*^[18]. The cytosolic fractions were used as an enzyme source to determine the specific activities of LDH (EC 1.1.1.27) and alcohol dehydrogenase (ADH; EC 1.1.1.1) using the spectrophotometric methods of Vassault^[19] and Caballeria *et al.*^[20] respectively. In all the assays, protein content was determined according to Lowry *et al.*^[21].

Statistical analysis

Statistical difference among groups was calculated by the two-way ANOVA test, and expressed as mean ± SE. In case of significance, student's-*t* test was applied.

RESULTS

Histological assessment of gastric samples from animals with gastritis and treated with mucilage

When compared to control rats (Figure 1A), at the onset of gastritis (T0), disrupted superficial epithelial cells, loss of specialized cells (glandular), slight submucosal edema, marked margination and infiltration of polymorphonuclear (PMN) leukocytes were found in gastric mucosa, proving clearly an inflammatory process (Figures 1B and 1C). The histological abnormalities generated by ethanol remained unchanged 24 h after spontaneous recovery (Figure 1C), but restoration of the gastric mucosa started 48 h after ethanol withdrawal. Therefore, three days after spontaneous recovery, a histological pattern corresponding to a moderate gastritis was observed in these animals (Figure 1D, Table 1). On the contrary, animals with gastritis and treated with mucilage showed an earlier recovery as reflected in a great amelioration of the inflammatory

Figure 1 Representative micrographs of gastric mucosa of rats with gastritis and treated with mucilage. **A:** control animals; **B:** animals subjected to gastritis (T0); **C:** animals 24 h after ethanol withdrawal. process (Figure 1E, Table 1).

Effects of mucilage on plasma membrane lipid composition and cytosolic activities of soluble enzymes in rats with chronic gastric mucosal injury

Along with the histological findings, the lipid composition of isolated mucosa plasma membranes in the experimental groups changed significantly. Table 2 depicts the phospholipid species found in plasma membranes obtained from mucosa of rats with gastritis and treated with mucilage. Chronic ethanol treatment (T0) had a dual effect on phospholipid distribution. Both phosphatidylinositol (PI) and phosphatidylcholine (PC) decreased significantly accompanying a progressive enhancement of phosphatidylethanolamine (PE) in plasma membrane. The less abundant phospholipid in plasma membranes of gastric mucosa was phosphatidic acid (PA). Likewise, the level of phosphatidylserine (PS) had no

significant change due to the presence of gastritis (Table 2). The ethanol treatment-induced alteration of PI and PC in plasma membrane persisted for up to 72 h after ethanol withdrawal. However, PE levels were normalized 48 h after spontaneous recovery. A single dose of mucilage (24 h) did not have any significant effect on ethanol-induced alterations in the lipid composition of gastric mucosal membranes, but subsequent administrations promptly normalized the content of phospholipids and their relative distribution in gastric membranes of animals undergoing gastritis (Table 2). Then, mucilage administration elicited a restoration of PC levels, close to the control levels (Table 2). Although mucilage exerted its effects on distribution of plasma membrane phospholipids during the treatment, neither the degree of mucosal damage nor the treatment with mucilage significantly modified the amount of total

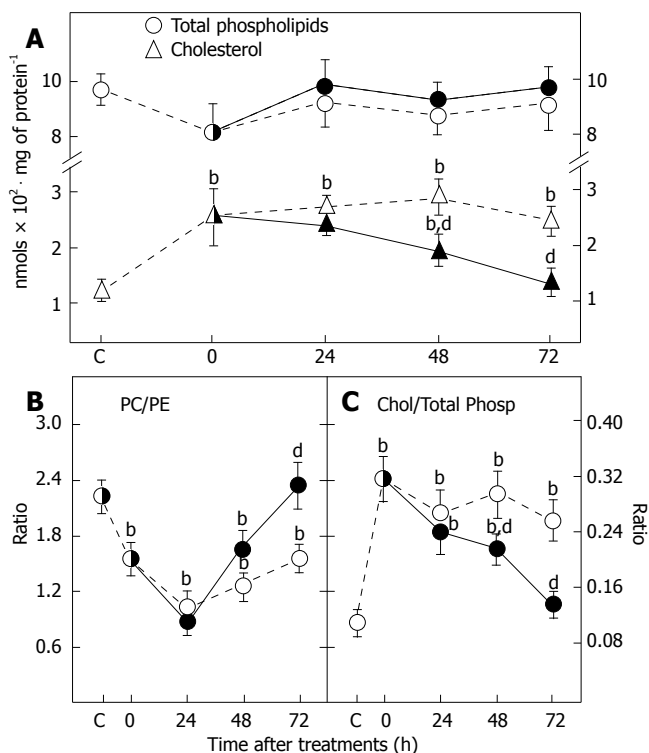

Figure 2 Total phospholipids and cholesterol in plasma membranes of mucilage-treated rats with gastritis (A) and the phosphatidylcholine (PC)/phosphatidylethanolamine (PE) methylation ratio (B) and cholesterol (chol)/total phospholipids (total phosp) ratio (C). In all cases mean \pm SE, $n = 5$. Animals subjected to gastritis are represented by empty symbols while those treated with mucilage are represented by solid symbols. ^b $P < 0.01$ vs healthy animal control. ^d $P < 0.01$ vs animals with gastritis not treated with mucilage.

membrane phospholipids (Figure 2A). However, plasma membrane cholesterol increased as a response to mucosal injury (Figure 2A). Thus, the group of rats subjected to gastritis showed an early increase of cholesterol content, which remained significantly higher than that in the control group during the experiment. In this context, administration of mucilage successfully restored the normal amount of cholesterol in mucosa plasma membranes (Figure 2A), and consequently, the cholesterol/phospholipids ratio was also modified (Figure 2C). This ratio was greatly enhanced in mucosal plasma membranes obtained from rats undergoing gastritis, and remained higher at all the tested time points. On the contrary, treatment with three doses of mucilage (72 h after ethanol withdrawal) normalized the cholesterol/phospholipids ratio (Figure 2C). The methylation index represented by the PC/PE ratio also decreased in animals with gastritis. This effect induced by ethanol, persisted even after 72 h of ethanol administration (Figure 2B). Interestingly, mucilage also corrected this parameter of the lipid composition of mucosal plasma membranes. This was more evident at the end of its administration to animals undergoing gastritis (Figure 2B). Therefore, alterations in the lipid composition of plasma membranes of injured gastric mucosae, were promptly normalized by the administration of mucilage.

Due to the effect of mucosal damage induced by ethanol, some cytosolic enzyme activities were significantly affected (Figure 3). As previously reported^[14], animals with gastritis showed a significant drop in ADH activity (54%).

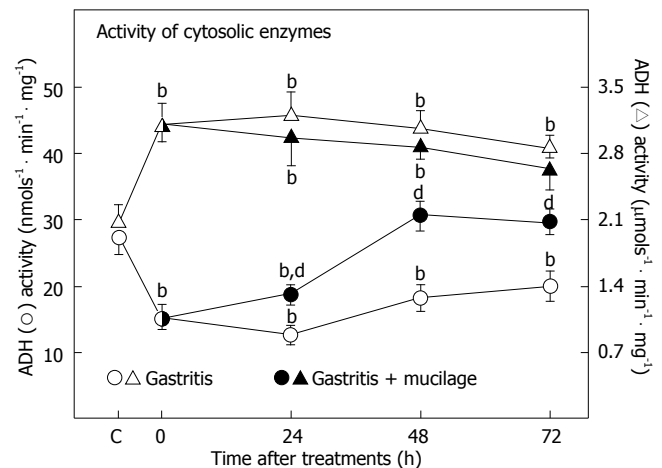

Figure 3 Effects of gastritis and mucilage from *O. ficus-indica* on cytoplasmic specific ADH and LDH activities. The results are expressed as mean \pm SE of five individual observations per experimental group for the alcohol (ADH) and lactate (LDH) dehydrogenases in the cytosolic fraction. Statistical significance is shown in Figure 2.

Regardless of the ethanol withdrawal, the activity of ADH remained abnormal during the tested recovery period (up to 72 h). However, mucilage promoted an early recovery of the ADH activity when administered to rats undergoing gastritis (Figure 3). The opposite to the LDH activity was observed. This cytosolic enzyme with a very high specific activity increased after chronic ethanol administration (133% over controls) and its activity remained significantly higher even 72 h after ethanol withdrawal. In this case, administration of mucilage also normalized LDH activity, but only after 3 doses (Figure 3), suggesting that administration of mucilage from *O. ficus-indica* to animals with ethanol-induced gastritis, could not only correct the alterations found in plasma membranes, but also practically normalize the activities of some soluble enzymes present in the cytosolic fraction obtained from the gastric mucosa.

Effects of gastritis and mucilage on membrane 5'-nucleotidase activity

The effects of gastritis and mucilage on the activity of 5'-nucleotidase were also evident. This ectoenzyme could respond to changes in the lipidic microenvironment, thus its activity could indirectly indicate the fluidity status of gastric mucosa plasma membranes. This enzyme presented a decreased activity at the onset of gastritis (T0) and was still lower 24 h after ethanol withdrawal (Figure 4, left panel). Thereafter, the activity of 5'-nucleotidase was suddenly enhanced and normalized after 72 h of spontaneous recovery. When rats undergoing gastritis were administered with mucilage, an early recovery of the plasma membrane activity of 5'-nucleotidase (24 h) was noted, which was followed by a sustained increase in the 5'-nucleotidase activity during the whole treatment period (Figure 4, left panel). The influence of the lipidic composition of plasma membranes on 5'-nucleotidase activity was evident when this enzymatic activity was plotted against indicative parameters of plasma membrane fluidity (Figures 2B and 2C). As shown in Figure 4B (right panel), the activity of 5'-nucleotidase correlated directly

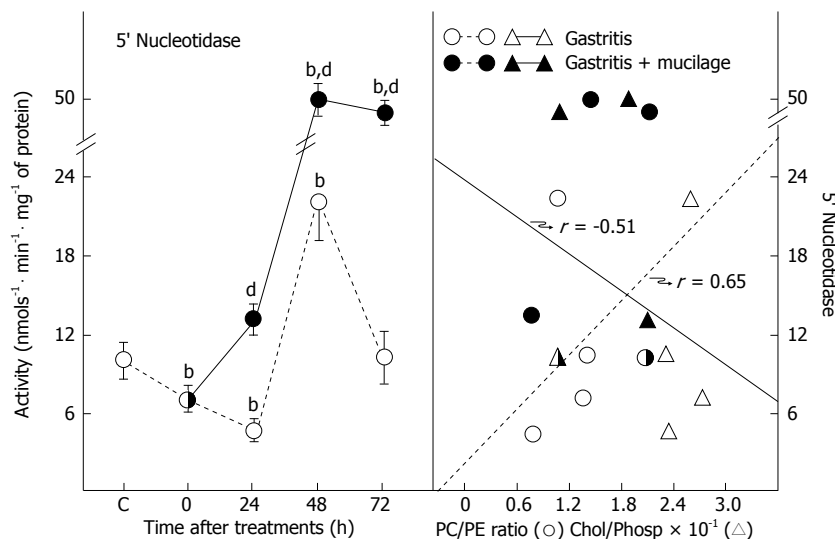

Figure 4 Activity of 5'-nucleotidase and its relation with the cholesterol/ phospholipid ratio in plasma membranes of mucilage-treated rats with gastritis. Left panel represents the mean \pm SE of five individual observations per experimental group for 5'-nucleotidase activity. The correlation between activity of this enzyme and the PC/PE ratio or the cholesterol (chol)/ phospholipid (phos) ratio is shown in the right panel of Figure 2. Statistical significance is indicated in the left panel of Figure 2.

with the PC/PE ratio ($r = 0.65$, $P < 0.005$), while increased cholesterol/phospholipids ratio negatively affected the activity of plasma membrane 5'-nucleotidase ($r = -0.51$, $P < 0.01$; Figure 4B, right panel).

DISCUSSION

Administration of concentrated ethanol solutions could induce damage to the gastric mucosa, including a disruption of up to 80% of the surface epithelial cells throughout the glandular stomach of rats^[22,23]. Indeed, ethanol administration could result in a reduction in resistance, transmucosal potential difference, H^+ secretion, and increased appearance of Na^+ in the lumen at neutral pH^[24,25], indicating that ethanol can induce profound changes in membrane permeability.

The present model resembles an active gastritis, similar to that found in humans. In fact, this model has been already validated by histological and biochemical findings^[14,15]. Furthermore, the main histological findings, such as inflammation and reduction of surface epithelial cells, as well as alterations in mucosal glands (Figure 1) and parietal cells^[26] are described in another model of chronic gastritis in rats^[27]. Our experimental model of ethanol-induced gastritis in rats is characterized by decreased PI and PC, and increased PE in plasma membranes of the gastric mucosa. PC is abundant in the gastric mucosa of rats, and the PC/PE ratio represents the lipid methylation activity^[28]. Additionally, the cholesterol/phospholipid ratio significantly decreased, strongly suggesting that ethanol-induced gastritis diminishes the membrane permeability^[14]. In fact, the cholesterol/phospholipid ratio influences the fluidity of a variety of membranes, and increases during the occurrence of altered membrane permeability^[29,30]. All these modifications in the membrane lipid composition of gastric mucosa obtained from animals with gastritis are due to the changes in the rate of lipid peroxidation^[15].

Lipid peroxidation and its effects on the composition and function of plasma membranes seem to play their part in chronic ethanol-induced gastric mucosa injury, promoting diminished binding of ligands to membrane histaminergic H₂-receptors, which is inversely correlated

with the rate of restoration of the surface epithelium in gastric mucosa^[13]. In this regard, the effects of administration of mucilage obtained from *O. ficus-indica* on gastric mucosal lesions need to be further studied.

In the present model, mucilage administration was capable of correcting the alterations found in plasma membrane, especially its lipid composition, suggesting that mucilage can accelerate the repair of gastric mucosal lesions in rats undergoing gastritis (Figures 1-3). Histological examination revealed that the main action of mucilage in injured gastric mucosa was an anti-inflammatory effect, which seemed to be involved in the further restitution of the mucosal integrity. Along with this, mucilage contains polygalacturonic acid^[4] and arabinogalactan, which could interact with macromolecules or small ligands of the gastric mucosa, enhancing gastric mucus production^[11].

In addition to the partial blocking effect on the PMN infiltrate, the specific activity of cytosolic enzymes ADH and LDH also normalised after the treatment with mucilage. These enzymes seem related to the condition of the gastric mucosa in some extent, since altered LDH and ADH activities seem to be associated with processes of gastric carcinogenesis and intestinal metaplasia^[31,32].

The change of phase from gel to liquid of membrane phospholipids can result from an abnormal increase of permeability and loss of cellular functionality. In this sense, polysaccharides may stabilize and protect the biological membranes, allowing the transitional phase remaining within the range of biological activity, and avoiding the damage induced by dehydration or freezing^[2]. Polysaccharide interaction between κ -carrageenan^[33] or thehalose^[34] or fructanes^[35] and the polar heads of phospholipids, plays a role in stabilizing membranes. Saccharides interact with proteins such as mucin, and/or the polar heads of membrane phospholipids. Therefore, they could originate a protective effect once they replace hydrogen bonds of water molecules, generating and increasing local viscosity^[36]. This can avoid dehydration such as that produced by alcohol. The changes observed in cell membrane after chronic ethanol treatment, such those in the lipid composition, could decrease or even induce a

complete loss of the selective membrane barrier function which could eventually lead to cell death.

Alterations of gastric mucosal cell membranes seem correlated with the activity of 5'-nucleotidase, which permits monitoring the *in vivo* changes in the membrane lipid composition after mucilage treatment. The effects of gastritis and mucilage on the 5'-nucleotidase activity deserve some comments. Changes in the lipid composition and the cholesterol/phospholipid molar ratio differentially affect the activities of 5'-nucleotidase, Mg^{2+} -ATPase, and γ -glutamyltransferase^[37]. Since 5'-nucleotidase is attached to the membrane bilayer through a glycosylphosphatidylinositol anchor, PC and PE can induce the highest degree of activation of 5'-nucleotidase^[38]. Ethanol alone (up to 400 mM) does not affect the 5'-nucleotidase activity, but its derivative phosphatidylethanol, enhances 5'-nucleotidase activity^[39]. The present data indicate that changes found in the activity of this enzyme reflect changes in the lipidic microenvironment of gastric plasma membranes.

On the other hand, the activity of ecto-5'-nucleotidase constitutes a key enzyme responsible for adenosine production in rat hearts^[40]. In the rat stomach, adenosine has been demonstrated to inhibit gastric acid secretion probably by indirectly inhibiting gastrin release, which seems to be regulated through participation of A(1)-adenosine receptors^[41]. Adenosine also increases somatostatin release by acting on A(2A) receptors^[42] and may have a putative gastroprotective effect against several types of inductors of gastric mucosal injury such as deficient circulatory conditions^[43] and indomethacin-induced gastric lesions^[44], as well as against stress- and ethanol-evoked gastric lesion formation^[45]. Whether endogenous increase of gastric mucosal levels of adenosine, mediated by mucilage-induced activation of 5'-nucleotidase, participates in the beneficial action of mucilage, remains to be clarified.

In any case, the association between mucilage polysaccharides and membranes may contribute to the repair of damaged membranes^[2]. This may occur following the insertion of polysaccharides into membranes, originating a lateral spacing among the phospholipid polar heads, reducing the van der Waals interactions within the hydrocarbon chains, increasing viscosity and reducing mobility around the disturbed membrane. All these changes accompany capturing and associating water molecules^[2].

In conclusion, mucilage may exert its anti-inflammatory effect by promoting the healing process of gastritis in at least three ways: formation of a viscous protective cover against the damage induced by ethanol or other noxious substances; restoration of stomach epithelial surface and stabilization of plasma membranes; participation in enzyme recovery, restoration of both the cholesterol/phospholipid ratio and membrane fluidity.

Abstract

AIM: To assess the correlation between the fibrotic area (FA) as calculated by a digital image analysis (DIA), and to compare the diagnostic accuracy of FibroScan to the other existing Liver fibrosis (LF) markers using the receiver operating curve analysis.

METHODS: We recruited 30 patients who underwent a liver resection for three different etiologies including normal liver, hepatitis B, and hepatitis C. Liver stiffness was measured by using a FibroScan. The FA was then calculated by DIA to evaluate LF in order to avoid any sampling bias.

RESULTS: The FA negatively correlated with Prothrombin time (PT), platelet count, lecithin-cholesterol acyltransferase (LCAT), and pre-albumin (ALB). On the other hand, the findings of FibroScan correlated with similar markers. The FA positively correlated with FibroScan, serum hyaluronate level, and type IV collagen level, and aspartate transaminase to platelet ratio index (APRI). The area under the receiver operating curve for FibroScan was higher than that for the other markers, even though the statistical significance was minimal.

CONCLUSION: Our findings suggest that FibroScan can initially be used to assess LF as an alternative to a liver biopsy (LB) and serum diagnosis, because it is a safe method with comparable diagnostic accuracy regarding

INTRODUCTION

Liver fibrosis (LF) is characterized by the accumulation of an extracellular matrix, which distorts the hepatic architecture^[1,2]. The major etiologies of LF are viral-associated hepatitis, alcohol abuse, non-alcoholic steatohepatitis and autoimmune disease. The progression of LF increases the stiffness of liver and the resistance of liver blood flow^[1,3]. An insufficiency of liver blood flow results in liver failure and eventual liver cirrhosis. Once cirrhosis develops, liver transplantation is the only therapy to avoid a fatal condition^[4]. Therefore, an accurate assessment LF is very important in order to predict the prognosis and start the appropriate prophylactic therapy to prevent disease progression.

Liver biopsy (LB) is still the gold-standard method for assessing LF^[1,2,5]. However, it is difficult to perform LB for all patients who need to be assessed repeatedly due to its invasiveness and prohibitive cost. In addition, biopsy samples are usually too small to diagnose the disease accurately and diagnostic opinions often differ among pathologists^[6,7]. As a result, a pathological examination does not always provide an accurate diagnosis. Furthermore, histological quantification of LF is also difficult because of the diagnostic variability^[2,8]. Some studies have shown that the diagnostic accuracy of a digital image analysis (DIA) for LF is more reliable than histological scoring systems^[8-10] such as METAVIR and Ishak score. Therefore, we assessed LF using DIA, which could accurately calculate the fibrotic area (FA), in order to avoid diagnostic variability

and errors.

The liver plays a very important role in maintaining such serum proteins as albumin, cholesterol and coagulation factors. The production of such proteins decreases in liver cirrhosis^[11-13]. Although these protein levels decrease in the late stage of liver cirrhosis, it is still not fully understood which markers represent liver damage in the early stage or which liver functional marker is correlated with LF.

Recently, transient elastography (FibroScan®: Echosens, Paris, France) has become available for the assessment of LF as a rapid noninvasive method, which can measure liver stiffness from outside of the body^[14-17]. FibroScan has been compared to such classical markers as hematological test [the aspartate transaminase to platelet ratio index (APRI)] and fibrotest, accurately representing the state of liver fibrosis evaluated by METAVIR scoring system. The diagnostic accuracy of FibroScan has thus been found to be comparable with that using traditional markers.

In the present study, we selected patients who underwent a hepatectomy for this study. In this setting, a large amount of tissue could be used for analysis in order to reduce the risk of sampling bias. In addition, three different backgrounds of liver disease could be evaluated in order to make an accurate diagnostic value of FibroScan for LF without any sampling bias. We first measured the FA precisely using DIA to avoid any diagnostic variability. We next evaluated the correlation between FA and multiple biochemical markers to identify which markers could represent a deterioration of liver function associated with FA. In addition, we also evaluated the correlation between FibroScan and multiple biochemical markers to see whether FibroScan could accurately represent liver function. Furthermore, we also evaluated the correlation between FA and existing LF markers including FibroScan, hyaluronate, type IV collagen, and APRI. The final aim of this study was to assess the correlation of our findings to FA and to compare the clinical diagnostic accuracy of FibroScan and other markers.

MATERIALS AND METHODS

Patients

We examined 30 patients who underwent a liver resection from January 2003 to May 2005. We recruited 10 patients each with three different etiologies including a normal liver, hepatitis B, and hepatitis C. The pathological diagnosis for the liver was made in all 10 samples of normal liver, liver fibrosis, and liver cirrhosis. The indications for a hepatectomy in the normal liver were metastatic liver tumor while the indications for those with viral hepatitis were hepatocellular carcinomas. Informed consent was obtained from each patient included in this study and the study design conformed to the ethical guidelines of the Declaration of Helsinki as reflected in a priori approval by the institution's human research committee.

Liver stiffness measurement

The principle of elastography using a FibroScan® (EchoSens) has been described previously^[14]. All measurements were performed in the right lobe of the liver through the

intercostal spaces in patients lying in the dorsal decubitus position with their right arm in maximal abduction. The tip of the probe transducer was covered with coupling gel and placed on the skin between the ribs at level of the right liver lobe. The operator, assisted by ultrasound time-motion and A-mode images provided by the system, located a portion of the liver that was at least 6 cm thick and free of any large vascular structures. Once the area of measurement was located, then the operator pressed the probe button to begin image acquisition. The measurement depth ranged from 25 mm to 45 mm and 10 validated measurements were performed in each patient. The success rate was calculated as the number of validated measurements divided by the total number of measurements.

The results were expressed in kPa. The median value was considered representative of the elastic liver modulus. The whole examination lasted less than 5 min. Only procedures with 10-validated measurements and a success rate of at least 60% were considered reliable.

Digital image analysis of liver fibrotic area

Liver fibrosis was evaluated using a computer program (NIH Image V1.62, National Institutes of Health, Bethesda, MD). Tissue sections were examined with Azan-Mallory staining. The fibrotic area was stained blue and depicted as the only blue signal using Adobe Photoshop CS (Adobe Systems Incorporated, San Jose, CA). Each patient was examined with 15 different fields in 3 different specimens. One field contained at least 10 portal tracts. The area of blue signals was calculated.

Statistical analysis

A statistical analysis of the relationship between pathological fibrosis and other clinical data was performed with Spearman's rank correlation coefficient using the StatView 4.5 software package (Abacus Concepts Inc., Berkeley, CA). The area under the receiver operating characteristic curve (AUC) analysis was performed using the MedCalc software package (Ver 8.0.1.0, Mariakerke, Belgium). All results are expressed as mean \pm SD. $P < 0.05$ was considered statistically significant.

RESULTS

We selected patients who underwent a hepatectomy with three different etiologies (Table 1). A large enough specimen for histological assessment could only be obtained from a surgical specimen since biopsy specimens are often insufficient to make an accurate diagnosis. We assessed the exact fibrotic area (FA) of LF using a digital image analysis (DIA), which is a simple and reliable method. We depicted only the blue signals from the full color image, and calculated FA. Representative photographs of the Azan-Mallory stain and the blue signals after depiction are shown in Figure 1. This method could thus be used for evaluating the pathological FA without diagnostic bias.

The characteristics of the patients are shown in Table 1. The liver stiffness was measured by FibroScan in all patients. We also measured serum hyaluronate, type IV collagen, and HGF levels in addition to performing routine

chemical laboratory tests. Furthermore, we measured pre-albumin (ALB), retinol-binding protein (RBP), lecithin-cholesterol acyltransferase (LCAT), Apo AI, and indocyanine green (ICG) R₁₅ levels to investigate the relationship between LF and liver function. The patients enrolled for this study showed a mixed etiology and various types of liver damage. However, the mean value of all biochemical data showed a nearly normal range, indicating that the sample bias might be minimal. Among the examined biochemical data, PT-INR, platelet count, RBP, pre-ALB, and LCAT levels correlated with FA (Table 2). On the other hand, ALB, platelet count, pre-ALB, LCAT levels and ICGR₁₅ all correlated with the FibroScan findings (Table 3). A linear regression analysis revealed two types of correla-

Figure 1 Hematoxylin-eosin staining of the surgical specimens (A, C, and E). The images scanned and depicted only blue signals using a computer program. The blue signals were calculated as the area of fibrosis (B, D, and F). The results of such fibrosis were 3.2% for B, 12.2% for D, and 27.7% for F. The bar shows 100 μm.

tions between FA and the findings of a biochemical analysis. One showed a negative correlation, which was seen for ALB, pre-ALB, LCAT, and platelet count (Figures 2 A-D). The other showed a positive correlation to the FibroScan findings, which was seen for ZTT and ICGR₁₅ (Figures 2 E and F). The pre-ALB levels showed the highest correlation with both FA and FibroScan among the examined biochemistry findings.

We compared the correlation between FA and existing LF markers including FibroScan, hyaluronate, type IV

Figure 2 A linear regression analysis of FibroScan and clinical laboratory tests including liver functional markers. A negative correlation was seen for ALB (A), pre-ALB (B), lecithine-cholesterol acyltransferase (LCAT) (C), and platelet count (D). On the other hand, a positive correlation was seen for ZTT (E) and ICGR15 (F). ○: NBNC and normal liver; △: HBV and chronic hepatitis; □: HCV and liver cirrhosis.

Figure 3 A linear regression analysis of the fibrotic area and liver fibrotic markers including FibroScan. A positive correlation was seen for all the markers such as FibroScan (A), hyaluronate (B), type IV collagen (C), and aspartate transaminase levels in comparison to the platelet ratio index (APRI) (D). ○: NBNC and normal liver; △: HBV and chronic hepatitis; □: HCV and liver cirrhosis.

collagen, and APRI (Figure 3). All markers correlated with FA. The correlation with the FibroScan findings was much higher than that with any other markers, even though the serum hyaluronate level was formerly believed to be the best available marker for evaluating LF^[8,18,19].

We investigated the area under the receiver operating curve (AUC) in order to compare the diagnostic accuracy of FibroScan and other markers (Table 4). The diagnostic specificity of FibroScan increased when the FA increased. The AUC of FibroScan was the highest among the markers at any level of FA, even though the statistical difference was minimal.

Table 4 Comparison of diagnostic accuracy of FibroScan and other markers

DISCUSSION

We found that the biochemical data correlated with FA based on DIA. Among the examined markers, pre-ALB showed a higher negative correlation to FA and FibroScan than the other markers. The diagnostic accuracy of FibroScan was higher than that of the other existing markers although the statistical significance was minimal. FibroScan can therefore be used to evaluate LF and liver function without any unnecessary invasiveness.

Biochemical assessment of LF

There are many ways to assess LF by serum biomarkers and pathological evaluations^[1,8,18-22]. Most such studies have been designed to evaluate fibrosis in chronic hepatitis C patients. Simple biomarkers such as those for aspartate aminotransferase (AST)/alanine aminotransferase (ALT) ratio (AAR) and AST-to platelet ratio index (APRI), and commercial tests such as Fibrotest® (Biopredictive, Paris, France) have been validated to distinguish between patients with severe LF and a normal liver. However, it is unclear whether they represent FA accurately regarding liver disease with various etiologies. APRI correlated with FA in our study. However, the relative factor was much less than observed for the other markers. It is easy to examine APRI in clinical examinations. However, it may not accurately represent FA until the liver disease has already reached a severely advanced stage. Therefore, the clinical benefit of the existing markers or their combinations may be limited by the etiology or stage of the disease. On the other hand, hyaluronate and type IV collagen were significantly correlated with FA in our results. Hyaluronate and type IV collagen are deposited in perisinusoidal lesions and can be used as specific markers to detect liver fibrosis^[8,18-20]. In addition, the serum levels both in liver cirrhosis and in fibrosis have been found to correlate with severity of the disease^[21,22]. In fact, they demonstrated a good correlation with FA in our results although AUC of them decreased in fewer FAs. Our findings suggest that hyaluronate and type IV collagen can thus be used to assess severe LF or cirrhosis. However, it would be difficult to assess LF at its early stage.

Liver stiffness as a novel marker for assessment of LF

Recently, FibroScan has been tested for assessment of LF in comparison to the classical markers^[14-17]. The diagnostic accuracy of FibroScan increases when it is used for severe fibrosis, whereas it decreases when it is used for a nearly normal liver. In our study, the diagnostic accuracy of FibroScan for livers with more than 20% FA was higher than that for livers with 10% FA. Our optimal cut-off level for FibroScan was 13.6 kPa, which could thus distinguish livers with more than 20% FA. This result is consistent with those in recent reports^[15,16] investigating viral hepatitis C patients with severe fibrosis or cirrhosis. Although AUC of the tested markers for more than 20% FA was higher than that for more than 10% FA, AUC of FibroScan for more than 10% FA maintained a fairly high level. Therefore, our results suggest that FibroScan is useful and reliable for assessment of earlier fibrotic stage compared to other existing markers and can be used for assessment of LA. However, these findings should be tested in prospective studies using a large number of cases because our results are based on a preliminary study. Especially, reduction of AUC for fewer FAs implies limitation of the diagnostic value of FibroScan in early LF stage.

Why AUC of FibroScan for fewer FAs decreases may be due to the system itself. Elasticity of the liver can be calculated by the different velocities between ultrasound (5MHz) and low-frequency (50 Hz) elastic waves^[17]. Wave velocity in liver was affected by fibrosis and watery distributions in liver^[23]. In general, watery distributions in the organ could be altered in the general systemic condition of the body such as inflammation which induces organ edema^[24]. In addition, watery contents in earlier LF stage may alter due to active hepatitis. On the other hand, watery distributions in late LF stage may be more stable than that in its earlier stage. Liver atrophies in severe LF and cirrhosis may reduce the space to store watery contents. One dimensional transient method could not eliminate the bias of watery distributions in liver, which may affect velocity and elasticity. However, we found that FibroScan could be used for primary assessment of LF among the existing non-invasive markers.

DIA for accurate assessment of LF

Quantification of LF is very important for detecting severity of the disease. There are several scoring systems, such as histology activity index of Knodell *et al.*, and its modification by Ishak *et al.*, and METAVIR system^[5]. However, such diagnostic variability cannot be ignored in pathological examinations due to the bias of pathologists and small samples^[7,8]. Therefore, digital image analysis should be performed for quantification of LF^[8]. On the other hand, the clinical benefits of digital image analysis remain controversial^[25]. The problem of this approach is the methodology used to depict fibrous signals. Once original pathological images are converted into gray scale, it becomes very difficult to distinguish between stained and non-stained areas for specific types of staining. In fact, a histogram of the depicted images can show overlapping curves between them^[25]. Therefore, specific fibrotic signals should be depicted in a full color image in order to eliminate any other colored signals, which could thus be

other cellular components. In this setting, the area of LF could be assessed precisely reflecting the actual state of FA. Whether this strategy can be used for small pathological specimens from LB remains unclear. We used large samples after surgical removal of the tissue to eliminate any sampling errors due to a small size. Therefore, the usefulness of DIA for LB specimens should be evaluated in other settings in future.

Biochemical markers for the liver function show a negative correlation to LF

Liver function deteriorates during progression of LF and cirrhosis. However, whether serum proteins decrease with severity of the disease has not been fully understood and whether they are markers for LF remain unclear. Child-Turcotte-Pugh (CTP) score is a classical liver functional indicator, which comprises serum albumin level, bilirubin, prothrombin time, and other clinical signs^[26]. However, CTP score in early stage of the disease does not show alteration^[26,27] along with the disease progression, suggesting that factors in CTP score are stable in early LF stage. On the other hand, we found that LCAT and pre-ALB significantly correlated with LF. Previous reports indicate that LCAT^[28,29] and pre-ALB^[30] correlate with severity of the disease and galactose elimination test, respectively. Our results showed that LCAT and pre-ALB were significantly correlated with FA assessed by DIA for LF, suggesting that LCAT and pre-ALB are markers for detecting LF. Although our study was a preliminary one using only a small number of patients, the results nevertheless support the findings of previous reports.

In conclusion, we assessed FA using DIA to eliminate the diagnostic variability often observed in pathological specimens. We examined the diagnostic accuracy of FibroScan, which was compared to that of simple biomarkers used in routine laboratory tests and extracellular matrix markers. FibroScan therefore showed a better correlation with FA than the existing LF markers, suggesting that FibroScan can be used as an alternative to LB in assessment of LF, as it is safe and has a sufficient diagnostic accuracy.

Abstract

AIM: To clarify the mechanism underlying the anti-diabetic activities of *cortex cinnamomi* extract (CCE).

METHODS: To induce *in vivo* diabetes, mice were injected with streptozotocin (STZ) *via* a tail vein (100 mg STZ/kg body weight). To determine the effects of CCE, mice were administered CCE twice daily for 7 d by oral gavage starting 1 wk before the STZ injection. Blood glucose and plasma insulin concentration were measured as an index of diabetes. Also, to induce cytotoxicity of RINm5F cells, we treated with cytokines (IL-1 β (2.0 ng/mL) and IFN- γ (100 U/mL)). Cell viability and nitric oxide production were measured colorimetrically. Inducible nitric oxide synthase (iNOS) mRNA and protein expression were determined by RT-PCR and Western blotting, respectively. The activation of NF- κ B was assayed by using gel mobility shift assays of nuclear extracts.

RESULTS: Treatment of mice with STZ resulted in hyperglycemia and hypoinsulinemia, which was further evidenced by immunohistochemical staining of islets. However, the diabetogenic effects of STZ were completely prevented when mice were pretreated with CCE. The inhibitory effect of CCE on STZ-induced hyperglycemia was mediated through the suppression of iNOS expression. In rat insulinoma RINm5F cells,

CCE completely protected against interleukin-1 β and interferon- γ -mediated cytotoxicity. Moreover, RINm5F cells incubated with CCE showed significant reductions in interleukin-1 β and interferon- γ -induced nitric oxide production and in iNOS mRNA and protein expression, and these findings correlated well with *in vivo* observations.

CONCLUSION: The molecular mechanism by which CCE inhibits iNOS gene expression appears to involve the inhibition of NF- κ B activation. These results reveal the possible therapeutic value of CCE for the prevention of diabetes mellitus progression.

INTRODUCTION

Insulin-dependent diabetes mellitus (IDDM) is an autoimmune disease that results from the selective destruction of pancreatic β -cells^[1]. At earlier stages of the disease, histological findings show features of insulitis characterized by the infiltration of immune cells, such as T lymphocytes, macrophages, and natural killer cells into pancreatic islets. These cells produce and release various cytokines which act as humoral mediators of the immunologic process. Thus, cytokines such as interleukin-1 β (IL-1 β), tumor necrosis factor- α , and interferon- γ (IFN- γ) have been implicated as key effector molecules in β -cell function and viability^[2,3].

Alloxan and streptozotocin (STZ) are two commonly used diabetogenic agents. These structurally diverse compounds have a long history of use in diabetes research and are known to be specifically toxic to pancreatic β -cells. Alloxan is thought to produce oxygen free radicals, whereas STZ releases nitric oxide (NO) and oxygen free radicals

during its metabolism^[4-8].

The biochemical mechanisms that mediate the detrimental effects of cytokines and streptozotocin remain elusive. Recent studies suggest that oxygen free radicals or NO mediates the deleterious effects of cytokine or streptozotocin on β -cell dysfunction and destruction^[9,10]. NO is produced by the oxidation of L-arginine to L-citrulline by nitric oxide synthase (NOS)^[11], and excess NO generated in cells may inhibit mitochondrial metabolism, protein modification, and DNA cleavage, any one of which could lead to insulin secretion impairment and β -cell death^[9,12,13].

The induction of iNOS is regulated by transcription factors that bind to specific sites in the promoter of the iNOS gene. It is known that the activation of the transcription factor NF- κ B, which can be induced by various stimuli, e.g., IL-1 β , INF- γ , bacterial lipopolysaccharide and streptozotocin, is essentially required for iNOS expression^[14,15]. NF- κ B is initially located in the cytoplasm as an inactive form complexed with I κ B, an NF- κ B inhibitory factor. Various inducers cause this dissociation of this complex presumably *via* the phosphorylation of I κ B, and allow NF- κ B to be released from the complex. NF- κ B then translocates to the nucleus, where it interacts with its DNA recognition sites to mediate gene transcription^[16]. In light of the possible role of NO in the pathogenesis of autoimmune diabetes, we^[17,18] and others^[19-21] have previously shown that NF- κ B-dependent NO production plays a key role in the dysfunction and destruction of β -cells.

Cortex cinnamomi (CC) is the name given to the bark of *Cinnamomum cassia* Presl, which belongs to the *Lauraceae* family, and is commonly used in traditional Chinese medicine for treating dyspepsia, gastritis, blood circulation disturbances, and inflammatory disease. Moreover, it has been reported that CC extract (CCE) has anti-inflammatory activity and an anti-thrombotic effect^[22,23]. In the present study, we observed the preventive effects of CCE on cytokine- and STZ-induced pancreatic β -cell damage both *in vitro* and *in vivo*. CCE was found to prevent NF- κ B activation, iNOS mRNA and protein expression, and subsequent NO production, and thus protected RINm5F cells and pancreas from cytokine and STZ induced damage.

MATERIALS AND METHODS

Animals

Specific pathogen-free female ICR mice were purchased from the Korean Research Institute of Chemical Technology (Daejeon, Korea) and housed at our animal facility for one week before use. All mice used were 5-6 wk old, and were kept under specific pathogen-free conditions with free access to a standard commercial diet.

To induce diabetes, mice were injected with STZ *via* a tail vein (100 mg STZ/kg body weight). STZ was dissolved in 0.1 mol/L sodium citrate buffer (pH 4.0) and injected within 5 min. To determine the effects of CCE, mice were divided into the following groups; 1) the non-treated control group, 2) the STZ group, 3) the CCE (100 mg/kg) + STZ group, 4) the CCE (250 mg/kg) + STZ group, and the 5) CCE (500 mg/kg) + STZ group ($n = 7$, each group). Mice were administered CCE twice daily for 7 d by oral gavage starting 1 wk before the STZ injection. The day of

injection was defined as d 1. Control group animals were administered citrate buffer alone, i.e., they were not treated with STZ or CCE. All experimental procedures were approved by the Institutional Animal Care and Use Committee at Wonkwang University, Oriental Medical School. On the day of sacrifice, mice were decapitated without anesthesia and trunk blood was collected into prechilled tubes containing 1 mg/mL of EDTA for insulin and glucose determinations.

Cell culture

RINm5F is an insulinoma cell line that was derived from a rat islet cell tumor^[24]. Cells were purchased from the American Type Culture Collection and grown at 37°C in a humidified 50 mL/L CO₂ atmosphere in RPMI 1640 medium (Gibco BRL) supplemented with 10% fetal bovine serum and 2 mmol/L glutamine, 10000 units/mL of penicillin, 10 mg/mL of streptomycin, and 2.5 μ g/mL of amphotericin B.

Preparation of the Cortex cinnamomi extract

The herb was identified as *Cortex cinnamomi* (CC) by local experts. Voucher samples are preserved for reference in the Herbarium of the Department of Physiology, School of Oriental Medicine, Wonkwang University (ref. Omcphy, 2001-05). For extraction, 200 g of dried CC was added to 1800 mL of water and boiled for 2 h, filtered, and concentrated to 200 mL. The sterile extract (7.03 g) so obtained was stored at -20°C.

MTT cell viability assay

The viabilities of cultured cells were determined by using MTT assays, which involve the reduction of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) to formazan as described previously^[25]. In brief, after 24 h of incubation, cells (1×10^5 /well) in 96-well plates were washed twice with PBS, and MTT (100 μ g/0.1 mL of PBS) was added to each well. Cells were then incubated at 37°C for 1 h, and DMSO (100 μ L) was added to dissolve the formazan crystals. Absorbance was measured at 570 nm using a model Spectra MAX PLUS (Molecular Devices, Sunnyvale, CA).

Determination of blood glucose and insulin

Blood glucose was determined using a glucose oxidase kit (Asan Pharm. Co., Korea), and plasma insulin was assayed using a standard radioimmunoassay technique (Linco Research Immunoassay, St. Charles, MO).

Nitrite measurement

Biologically produced NO is rapidly oxidized to nitrite and nitrate in aqueous solutions^[26], and thus, nitrite concentrations in cell-free culture supernatant reflect NO production, and may be measured colorimetrically^[27]. Following incubation for 24 h, 100 μ L aliquots of culture supernatants were incubated with 100 μ L of a 1:1 mixture of 10 g/L sulfanilamide in 300 g/L acetic acid and 1 g/L N-(1-naphthyl) ethylenediamine dihydrochloride in 600 g/L acetic acid at room temperature. After 5 min, absorbances were measured at 540 nm using a spectrophotometer. Concentrations were determined using a linear standard curve

drawn using serial dilutions of sodium nitrite in working medium.

Western blot analysis of iNOS

Cells and pancreases were homogenized in 100 μ L of ice-cold lysis buffer (20 mmol/L HEPES, pH 7.2, 10 g/L Triton X-100, 100 g/L glycerol, 1 mmol/L phenylmethylsulfonyl fluoride, 10 μ g/mL leupeptin, 10 μ g/mL aprotinin). Homogenates containing 20 μ g of protein were separated by SDS-PAGE with 100 g/L resolving and 30 g/L acrylamide stacking gel, and transferred to nitrocellulose sheets (Millipore, Bedford, MA). These were then blocked with 20 g/L bovine serum albumin and incubated for 4 h with 1 μ g/mL anti-mouse macrophage iNOS antibody (Transduction Lab, Lexington, KY). iNOS protein expression levels were determined using a Chemi-doc image analyzer (Bio-Rad, Hercules, CA).

RNA isolation and reverse transcription-polymerase chain reaction (RT-PCR) for iNOS

Total RNA was isolated from cells and pancreases using TRIzol from Invitrogen (Carlsbad, CA), as instructed by the manufacturer. One microgram of total RNA was transcribed into cDNA in a 20 μ L final volume of reaction buffer (10 mmol/L Tris-HCl, pH 7.4, 50 mmol/L MgCl₂, 1 mmol/L each dNTP) and 2.4 μ mol/L oligo-d(T)16-primer, 1 unit RNase inhibitor, and 2.5 units MuLV reverse transcriptase by incubation for 10 min at 21°C and 15 min at 42°C. The reaction was stopped by incubation at 99°C for 5 min. For rat iNOS PCR, aliquots of the synthesized cDNA were added to a 45 μ L PCR mixture containing 10 mmol/L Tris-HCl, 50 mmol/L KCl, 1.5 mmol/L MgCl₂, 0.2 mmol/L of each dNTP, 2 units Taq DNA polymerase, and 0.4 μ mol/L of each PCR primer; iNOS upstream primer, 5'-CCACAATAGTACAATACTACTTGG-3', downstream primer, 5'-ACGAGGTGTTTCAGCGTGCTCCACG-3'. Amplification was initiated by 3 min of denaturation at 94°C, and amplification was performed using 26 cycles of 94°C for 1 min, 60°C for 1 min, and 72°C for 1 min and was followed by a single extension step of 5 min at 72°C. β -actin PCR was performed using a 2.5 μ L aliquot of synthesized cDNA using primers at a concentration of 0.15 μ mol/L; β -actin upstream primer, 5'-TGCCCATCTATGAGGGTTACG-3' downstream primer, TAGAAGCATTTGCGGTGCACG-3'. The obtained PCR products were analyzed on ethidium bromide-stained agarose (15 g/L) gels.

Preparation of nuclear extracts

Nuclear extracts were prepared as described previously^[18]. Cells and pancreases were immediately washed twice, scraped into 1.5 mmol/L of ice-cold PBS (pH 7.9), and pelleted at 12000 g for 30 s. Cell pellets were suspended in ice-cold hypotonic lysis buffer (10 mmol/L HEPES, 1.5 mmol/L MgCl₂, 0.2 mmol/L KCl, 0.2 mmol/L phenylmethylsulphonylfluoride, 0.5 mmol/L dithiothreitol), vortexed for 10 sec, and then centrifuged at 3000 r/min for 5 min. Cells pellets were resuspended with ice-cold hypotonic lysis buffer in the presence of 50 μ L of 100 g/L Nonidet P-40 and then incubated on ice for 25 min. Nuclear fractions were precipitated by centrifugation at 4000

rpm for 15 min, pellets were resuspended in 50-100 μ L of low salt extraction buffer (20 mmol/L HEPES, pH 7.9, 1.5 mmol/L MgCl₂, 250 g/L glycerol, 20 mmol/L KCl, 0.2 mmol/L EDTA, 0.2 mmol/L phenylmethylsulphonylfluoride, 0.5 mmol/L dithiothreitol) and added dropwise to equal volumes of high salt extraction buffer (20 mmol/L HEPES, pH 7.9, 1.5 mmol/L MgCl₂, 250 g/L glycerol, 80 mmol/L KCl, 0.2 mmol/L EDTA, 0.2 mmol/L phenylmethylsulphonylfluoride, 0.5 mmol/L dithiothreitol). Mixtures were then incubated with continuous shaking at 4°C for 45 min, centrifuged for 20 min at 12000 g, and nuclear extracts were aliquoted and stored at -80°C. Protein concentrations were determined using the method of Bradford^[28].

Electrophoretic mobility shift assay (EMSA)

The activation of NF- κ B was assayed by using gel mobility shift assays of nuclear extracts from control and treated cells^[18]. As a probe for gel retardation assays, an oligonucleotide containing the κ -chain binding site (κ B, 5'-CCGGT-TAACAGAGGGGGCTTTCGAG-3') was synthesized and labeled with [α -³²P]dCTP. Labeled oligonucleotides (10 000 cpm), 10 μ g of nuclear extracts, and binding buffer (10 mmol/L Tris-HCl, pH 7.6, 500 mmol/L KCl, 10 mmol/L EDTA, 500 g/L glycerol, 100 ng poly (dI-dC), 1mmol/L DTT) were incubated for 30 min at room temperature in final volume of 20 μ L. Reaction mixtures were analyzed by electrophoresis in 40 g/L polyacrylamide gels in 0.5 \times Tris-borate buffer. Gels were then dried and autoradiographed. Specific binding was controlled by competition with a 50-fold excess of cold κ B oligonucleotide.

Immunohistochemistry

Pancreases removed under anesthesia were immediately placed in fixative (40 g/L formaldehyde solution in 0.1 mol/L PBS) overnight, and washed with 0.1 mol/L PBS. To account for variations between pancreatic regions, tissues were cut into 4-mm blocks, which were then randomly inserted into a cassette and glycol methacrylate (GMA, Technovit 8100) embedded, sectioned (2 μ m), and stained with haematoxylin and eosin (H-E). For immunostaining studies, guinea pig anti-swine insulin antibody (working dilution 1:50; DakoCytomation, Belgium) was incubated with sections for 3 h at 37°C. FITC-conjugated goat anti-guinea pig IgG antibody (working dilution 1:25, Jackson ImmunoResearch Laboratories, Inc, West Grove, PA) was used for fluorescence imaging.

Statistical analysis

Statistical analysis was performed using the Student's *t*-test and ANOVA. *P* values of < 0.05 were considered statistically significant.

RESULTS

CCE has anti-diabetic effect on STZ-induced diabetes in mice

Mice that received 100 mg/kg of STZ became hyperglycemic at 72 h. Their blood glucose levels at 72 h were 16.43 \pm 2.16 mmol/L, a value within the acceptable diabetic

Table 1 Effect of CCE on STZ-induced diabetes in mice

	Control	STZ (100 mg/kg)			
		None	CCE (100 mg/kg)	CCE (250 mg/kg)	CCE (500 mg/kg)
Glucose (mmol/L)	5.88 ± 0.67	16.43 ± 2.16 ^b	8.27 ± 1.44 ^a	7.10 ± 2.55 ^a	6.71 ± 0.89 ^a
Insulin (ng/mL)	0.21 ± 0.04	0.06 ± 0.01 ^b	0.14 ± 0.03 ^a	0.17 ± 0.03 ^a	0.18 ± 0.01 ^a

Values are means ± SE, $n = 7$. ^b $P < 0.01$ vs Control. ^a $P < 0.05$ vs none.

range. In contrast, the mice pretreated with CCE and treated with STZ showed normal blood glucose values (Table 1). Moreover, this glucose lowering effect of CCE was dose-dependent. CCE treatment alone did not affect blood glucose values in mice (data not shown). Animals injected with STZ alone showed significant decreases in plasma insulin levels (0.06 ± 0.01 ng/mL) versus non-treated controls (0.21 ± 0.04 ng/mL). Pretreatment of mice with CCE attenuated the severity of STZ-induced hypoinsulinemia (Table 1). Thus, CCE was protective against STZ-induced diabetes.

CCE protects pancreatic islets from STZ

To elucidate the preventive effect of CCE on STZ-induced diabetes, pancreatic islets were histologically examined. Pancreatic tissues were obtained one week after STZ administration with or without CCE pretreatment and subjected to H-E staining and immunohistochemistry. In diabetic mice not treated with CCE, the most consistent findings in pancreatic sections stained with H-E were degenerative and necrotic changes, and islet shrinkage (Figure 1B). Immunohistochemical staining showed weak insulin-reactivity in a few β -cells (Figure 1F). However, diabetic mice pretreated with CCE showed near normal islets by both H-E staining and immunohistochemistry; i.e., round shaped and clearly defined islets with strong insulin positive staining (Figures 1C, 1D, 1G and 1H).

CCE inhibits STZ-induced NF- κ B activation in mice pancreases

To clarify the antidiabetogenic mechanism of CCE, we examined its effect on STZ-induced NF- κ B activation. The findings of this investigation are in accord with those of previous studies, which demonstrated that in mice, STZ treatment results in NF- κ B activation^[10]. Figure 2 shows a representative EMSA radiograph showing the ³²P-DNA/NF- κ B complex in nuclear extracts of pancreas 30 min after STZ injection. In contrast, this complex was not detected in nuclear extracts from CCE-pretreated mice. This result shows that CCE inhibits the translocation of NF- κ B to the nucleus in mice.

CCE inhibits STZ-induced iNOS protein and mRNA expression in mice pancreases

iNOS is a downstream target of NF- κ B activation. Thus, we examined whether CCE modulates the induction of iNOS protein after STZ injection (Figure 3A). STZ in-

Figure 1 Protection of islets from STZ-induced destruction by CCE. Pancreases were obtained from normal controls (A, E), from STZ-injected (B, F), and from CCE pretreated for 7 d with concentrations of 100 mg/kg per day (C, G) or 250 mg/kg (D, H) subsequently injected with STZ. Islets were labeled with insulin antibody and FITC-labeled anti-guinea pig IgG, and examined by fluorescence microscopy (E-H). The cellular morphologies of these same islets and of adjoining exocrine regions were counterstained with H-E (A-D). Bar = 50 μ m.

jected mice expressed high levels of iNOS protein. However, this STZ-induced upregulation of iNOS protein was totally suppressed by pretreating with CCE. We examined iNOS steady state mRNA levels after STZ injection by RT-PCR (Figure 3B). iNOS mRNA was found to be induced 24 h after STZ injection, whereas no iNOS mRNA was detected in pancreases of CCE-pretreated mice. The results suggest that iNOS, a down stream target of NF- κ B, is induced by STZ injection, and that CCE pretreatment inhibits this induction, possibly by inhibiting NF- κ B.

CCE prevents cytokine-mediated cell death by RINm5F cells

We next investigated the anti-diabetogenic effect of CCE at the cellular level. RINm5F cells, a rat pancreatic β -cell line, were cultured to near confluence, and treated with a high dose combination of cytokines (IL-1 β (2.0 ng/mL) and IFN- γ (100 U/mL)) with/without CCE for 24 h. Percentages of viable cells were detected using MTT assays. As shown in Figure 4, cytokine-treated cells had a viability

Figure 4 Prevention of cytokine-induced cell death by CCE. RINm5F cells (1×10^5) were incubated with cytokines in the presence or absence of CCE for 24 h. The concentrations of cytokines used were: IL- β , 2 ng/mL and IFN- γ , 100 U/mL. The percentages of viable cells after these treatments were determined by using MTT colorimetric assays and were calculated versus the A_{570} values of untreated control cells. Value are means \pm SE of four independent experiments. ^b $P < 0.01$ vs control; ^a $P < 0.05$ vs cytokines.

of $58.2\% \pm 4.5\%$, whereas cells pretreated with CCE (0.5 mg/mL) had a viability of $78.2\% \pm 6.8\%$. Moreover, a two-fold higher dose of CCE (1.0 mg/mL) increased cell viability to $88.3 \pm 4.2\%$. CCE alone did not affect the cell viability (data not shown).

NO production was evaluated using the same conditions. Control RINm5F cells generated 19.8 ± 2.0 μ mole/L of nitrite, whereas cytokine treated cells generated 51.8 ± 1.6 μ mole/L of nitrite in 24 h (Figure 5). On the other hand, RINm5F cells treated with cytokines plus CCE showed concentration dependent reductions in cytokine-mediated nitrite production. Near complete inhibition of nitrite production was observed at a CCE concentration of 1.0 mg/mL. Treatment with CCE alone did not produce nitrite (data not shown).

CCE inhibits cytokine-mediated iNOS expression by inhibiting NF- κ B

To investigate the regulatory effect of CCE on NO pro-

Figure 3 Expression of iNOS protein and mRNA induced by STZ in mice pancreases. Mice were injected with STZ (100 mg/kg) after being pretreated for 7 d with various concentrations of CCE. iNOS protein (A) and mRNA (B) were isolated and detected by Western blotting and RT-PCR, respectively. Representative results from three independent experiments are shown.

Figure 5 Effect of CCE on cytokine-induced NO production in RINm5F cells. RINm5F cells (5×10^5) were treated with cytokines with or without the indicated concentrations of CCE. The concentrations of cytokines used were same as those in Figure 4. Following 24 h of incubation, nitrite concentrations (indicative of NO synthesis) were measured in cell-free culture supernatants. Results of triplicate samples are expressed as means \pm SE of four independent experiments. ^b $P < 0.01$ vs control; ^a $P < 0.01$ vs cytokines.

duction, we examined the effects of CCE on cytokine-induced iNOS mRNA and protein expressions using RT-PCR and Western blotting, respectively. As shown in Figure 6, the above cytokine combination increased iNOS mRNA and protein levels. However, when CCE was added to the cytokine mixture, iNOS mRNA and protein levels reduced dose-dependently, though 0.125 mg/mL CCE was ineffective, 1.0 mg/mL of CCE completely blocked iNOS mRNA expression.
