Abstract

Alcohol consumption causes cellular injury. Recent developments indicate that ethanol induces epigenetic alterations, particularly acetylation, methylation of histones, and hypo- and hypermethylation of DNA. This has opened up a new area of interest in ethanol research and is providing novel insight into actions of ethanol at the nucleosomal level in relation to gene expression and patho-physiological consequences. The epigenetic effects are mainly attributable to ethanol metabolic stress (Emess), generated by the oxidative and non-oxidative metabolism of ethanol, and dysregulation of methionine metabolism. Epigenetic changes are important in ethanol-induced hepatic steatosis, fibrosis, carcinoma and gastrointestinal injury. This editorial highlights these new advances and its future potential.

INTRODUCTION

Ethanol actions are diverse and fascinatingly complex. Chronic ethanol causes injury to almost all organ systems including liver and gastrointestinal (GI)^[1] and has serious medical and public health implications^[2]. Alcohol increases the risk for hepatocellular carcinoma (HCC) and colon

cancer. Although these effects of ethanol are now widely known, our knowledge on the mechanisms of actions of ethanol at the subcellular and molecular levels is poor. Therapeutic tools to control or reverse the ethanol-induced cellular damages, such as alcoholic liver injury, are also lacking. In addition to its direct actions, ethanol-induced effects are also mediated by oxidative [e.g. acetaldehyde, reactive oxygen species (ROS)] and non-oxidative [e.g. phosphatidylethanol (PEth), fatty acid ethyl ester (FAEE)] metabolites/products and impairment in the methylation process. It is the combination of these metabolic stress pathways, termed as “ethanol metabolic stress” (Emess), which contributes to the epigenetic effects of ethanol (Figure 1).

The question of how a single cell can differentiate into many different cell types in a multicellular organism has long led to the hypothesis that additional information that regulates genomic functions must exist beyond the level of the genetic code. This concept led to the introduction of the term ‘epigenetics’ in the 1940’s, a term that has now evolved to mean heritable changes in gene expression that do not involve changes in DNA sequence^[3-5]. Interestingly, these epigenetic changes are heritable and normally stably maintained. They are also reversible. The molecular basis of epigenetics has largely focused on mechanisms such as DNA methylation and histone modification. In fact, emerging evidence indicates that both mechanisms act in concert to provide stable and heritable silencing.

ETHANOL EFFECTS ON DNA METHYLATION IN RELATION TO HEPATOCELLULAR AND GASTROINTESTINAL INJURY

DNA methylation specifically occurs at the C5 position of cytosine residues that are associated with CpG dinucleotides. Eighty percent of all CpG dinucleotides in the mammalian genome are methylated. The remaining unmethylated CpG residues are mostly located in the promoter regions of constitutively active genes and are referred to as CpG islands. Methylation of DNA is known to modulate transcriptional repression, genomic imprinting and modulation of chromatin structure^[4,5].

Global hypomethylation involves mainly repetitive sequences but hypomethylation of coding regions may also occur^[6]. Hypermethylation of normally unmethylated genes can result in silencing of tumor suppressor genes. Stepwise distinct methylation events are likely to be the features of the sequence from hepatitis to HCC and may

contribute to the process of hepatic carcinogenesis^[7,8]. Regional hypermethylation and global hypomethylation are also well recognized in gastrointestinal cancer^[9-12].

Only a few studies have addressed regional methylation of DNA in relation to alcohol and cancer. Alcohol either alone or in combination with tobacco has been shown to be an important risk factor for oral cancer^[13,14]. Promoter hypermethylation of p16INK4a, p14ARF, RB1, p21Waf1, p27Kip1, PTEN, p73, O⁶-methyl guanine DNA methyl transferase (O⁶-MGMT), and GST-P genes has been examined in relation to smoking and alcohol use. Overall, gene methylation can be detectable in 46.9% of samples and is closely correlated with tobacco use and/or alcohol consumption^[15]. The relative risk of alcohol consumption for the development of esophageal cancer is also very high^[16] and alcohol potentiates chemical carcinogenesis of the esophagus induced by nitrosomethylbenzylamine^[17]. Alcohol consumption has also been shown to be a risk factor for head and neck cancers that usually originates from the aerodigestive tract. Interestingly, p15 promoter hypermethylation has been observed in the healthy individuals who are smokers and/or alcohol consumers^[18], suggesting that hypermethylation plays a significant role in progression of cancer. Although alcohol consumption is not a significant risk factor for gastric carcinoma compared to oral or esophageal cancer, both smoking and alcohol consumption are associated with a higher risk of gastric cancer with hypermethylation of the hMLH1 gene promoter. Hypermethylation of the hMLH1 gene promoter is inversely correlated with mutation of the p53 gene^[19]. In a recent study, promoter hypermethylation of APC, p14 (ARF), p16 (INK4A), hMLH1, O⁶-MGMT, and RASSF1A was observed in colorectal cancer (CRC). For each of the tested genes, the prevalence of promoter hypermethylation is higher in CRCs derived from patients with low folate/high alcohol intake when compared with CRCs from patients with high folate/low alcohol intake^[20].

Although methylation changes have been described as stable for aging and carcinoma, recent studies have shown that epigenetic alterations are also dynamic as observed in inflammatory responses and tissue injury^[21]. Altered DNA methylation occurs after alcohol consumption during initial periods of alcohol abuse. Global hypomethylation of DNA in liver after long term ethanol exposure has been reported^[22] but hypermethylation of DNA from peripheral blood cells after ethanol consumption has also been reported in human subjects with alcohol dependence^[23]. Regional hypomethylation of the c-myc gene occurs in liver after long term consumption of alcohol^[22]. Another study showed that chronic alcohol consumption produces global genomic DNA hypomethylation in the colonic mucosa^[24].

Four known or putative mammalian DNA methyl transferases have been identified thus far: DNMT1, DNMT2, DNMT3a and DNMT3b. In contrast to types 1 and 3, the function of type 2 DNMT remains less clear. Mammalian DNMT2 does not methylate CGs. Non-CG cytosine methylation is also reported^[25]. Increased expression of DNA methyl transferases occurs in hepatocellular carcinoma^[26] and gastrointestinal cancer but this increased expression is associated with both

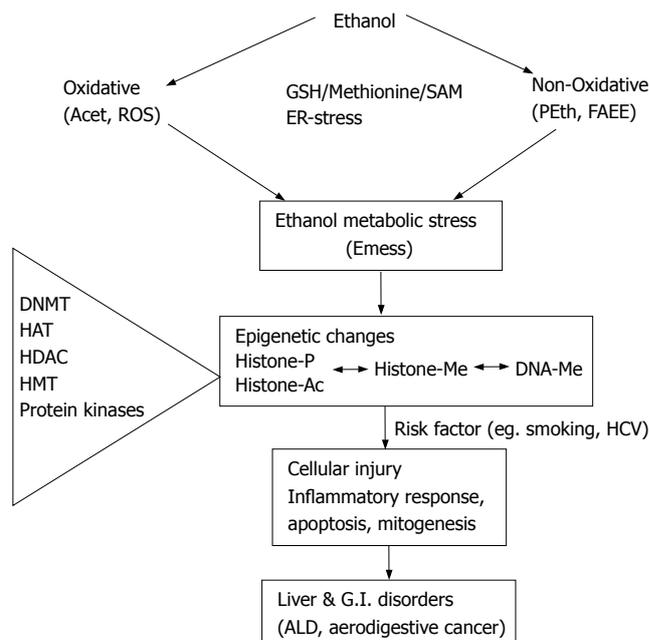

Figure 1 A diagram depicting relationship among ethanol metabolic stress, epigenetics and tissue injury. hypomethylation and hypermethylation of DNA^[27-29]. Decreased DNA methylation with a concomitant decrease in DNA methyl transferase activity after ethanol exposure of pregnant rats has been reported in fetal tissues^[30]. Decreased activity of methyl transferase has been reported in peripheral blood cells from alcoholics but with a concomitant increase in DNA methylation^[31]. This raises the possibility of regional methylations in a gene specific manner.

ETHANOL AND EPIGENETIC MODIFICATIONS IN HISTONE

Chromatin is the entire DNA-protein complex packaged into chromosomes. It exists as a highly ordered structure and is composed of repeated nucleosome subunits. Each nucleosome contains a core of histone around which DNA is wrapped. Eukaryotes have five major classes of histones: H1, H2A, H2B, H3, and H4. Histones were once thought as static, non-participating structural elements; and now considered integral and dynamic components in the machinery responsible for regulating gene transcription^[32]. The core histones (e.g. H3) have a similar structure with a basic N-terminal domain, a globular domain and a C-terminal tail. Modifications of histones can occur by mechanisms involving acetylation, phosphorylation, methylation, ubiquitination, sumoylation and ADP-ribosylation, *etc.* Some of these post-translational modifications affect packaging of genes, increase accessibility of transcription factors to DNA templates and initiate transcriptional processes^[32,33]. Such modifications can serve as 'co-activators' (e.g. acetylation,

methylation) or 'co-repressors' (e.g., deacetylation) or 'gene silencers' (e.g. methylation). In histone H3 from most species, the main acetylation sites include lysines 9, 14, 18 and 23. A steady state balance between two key enzymes, histone acetyl transferase (HAT) and histone deacetylase (HDAC), is crucial in this process. Various HATs^[34] and HDACs^[35] have been identified (about 15 types of HATs and 10 types of HDACs). H3 acetylation at lysine 9 or at lysine 14 plays a role in chromatin assembly^[32], gene expression^[36,37] and apoptosis^[38]. Histones, particularly H3 and H4, are methylated at a number of lysines (Lys) and arginine residues. The major sites of lysine-methylation identified are: Lys4, Lys9, Lys27, Lys36, and Lys79 on H3 and Lys20 on H4. In addition, lysine residues can be methylated in the form of mono-, di- or trimethylation and this differential methylation provides further functional diversity to each site of Lys methylation^[4,39]. Emerging evidence suggests that DNA and histone methylation likely have a cyclical and mutually reinforcing relationship, and both are required for stable and long-term epigenetic silencing^[4,39,40]. Lysine 9 is also interesting in that this site can be either methylated (gene silencing) or acetylated (gene activation). Histone H3 can also be phosphorylated at ser-10 and ser-28 by cellular protein kinases^[4,32,39]. The precise pattern of histone modification has been suggested to mediate biologically diverse effects and proposed as the 'histone code' hypothesis^[32]. The relationship among Emess, histone modification, DNA methylation and changes in the expression level of genes is an emerging topic of investigation.

HISTONE ACETYLATION BY ETHANOL IN LIVER

Initial studies with primary cultures of rat hepatocytes have established important characteristics of ethanol-induced histone acetylations. Ethanol causes a dose- and time-^[41] dependent selective acetylation of histone H3 at Lys9 (H3AcK9). Other H3 lysine residues i.e. Lys14, Lys18 and Lys23 are not acetylated under these conditions. Trichostatin A, a reversible HDAC inhibitor, shows an increase in H3 acetylation. These increases in acetylation are not due to the increased expression of H3 protein as their levels do not change. It is also not due to the simple physical effect of ethanol since it requires more than 4 h of ethanol exposure to elicit H3 acetylation. The acetylation is reversible when ethanol is withdrawn after 24 h of treatment.

Ethanol causes activation of p42/44 MAPK, p38 MAPK and JNK in hepatocytes, while inhibition of p42/44 MAPK and JNK results in inhibition of ethanol-induced acetylation^[42,43]. These results indicate that MAPK signaling plays a role in ethanol-induced epigenetic effects.

Ethanol acutely affects histone acetylation *in vivo*. Intra-gastric administration of ethanol increases 2-3 fold compared to the level of acetylated H3-Lys9 in the liver after 12 h, but has no effect on Lys14, Lys18 and Lys23. Further analysis indicates that the increased acetylation is tissue specific as it is noted in liver, lung and spleen but not in tissues from the brain, heart, kidney, muscle, vessels,

stomach and intestine. Thus ethanol-induced histone H3 acetylation appears to be organ specific^[44]. In rat liver stellate cells, ethanol increases H3 Lys 9 acetylation^[45] but its significance remains to be determined.

EFFECTS OF ETHANOL ON HISTONE METHYLATION

Ethanol also affects histone H3 methylations in an interesting manner. The influence of ethanol on histone H3 Lys9 and Lys4 methylations in primary cultures of rat hepatocytes is determined using site specific antibodies. Western blot analysis using methylated forms of Lys4 and Lys9 histone H3 antibodies can show dramatically opposing changes in the methylated forms. The Lys9 methylation decreases but Lys4 methylation increases in hepatocytes. These results indicate that, like H3 acetylation, histone methylation is also sensitive to ethanol. A longer incubation with ethanol for 72 h does not change this methylation, indicating that ethanol-induced methylation produces a longer effect than that observed for acetylation which declines after 24 h (Bhadra, U and Shukla SD, Unpublished). Thus modifications in H3 methylation are likely to be coupled to hyperacetylation and orchestrate the fine tuning of the chromatin status in hepatocytes exposed to ethanol.

ETHANOL-INDUCED HISTONE/CHROMATIN MODIFICATIONS AND TRANSCRIPTION

In hepatocytes exposed to ethanol, chromatin immunoprecipitation (CHIP) assays demonstrate the association of the acetylated H3-Lys9 with the alcohol dehydrogenase I (ADH 1) DNA domain in the nuclear chromatin^[43]. These data argue that ethanol-elicited epigenetic changes cause an increased association between acetylated H3 and specific genes, a process which favors transcription^[43]. It should be noted that circular dichroism spectrophotometry has shown altered chromatin confirmation in alcoholic rat liver, and this relaxed state of chromatin can promote transcription^[46]. Thus ethanol modulates histone/chromatin to influence transcriptional activation. Further relevance of such epigenetic changes to the expression of genes involved in ethanol-induced tissue injury therefore merits investigation.

RAS AND p53 AS MOLECULAR SWITCHES IN ETHANOL-INDUCED EPIGENETIC EFFECTS

Although structural alterations in genes contributing to HCC are evident in transformed hepatocytes, initiation of hepatocarcinogenesis takes place during the early stages of liver insult and is associated with epigenetic alterations^[7]. The progression of cell injury to carcinoma occurs due to triggering of 'some' molecular switches caused by a 'second hit', e.g. hepatitis C virus infection or other agents. Treatment of hepatocytes with ethanol causes apoptosis whereas alcohol enhances hepatic DNA synthesis in embryonic or transformed hepatocytes,

through potentiation of G-protein mediated ras/MAPK signaling. This underscores the importance of normal versus embryonic or transformed hepatocytes contributing to the opposing effects of ethanol^[47].

In this context, upregulation of ras signaling^[48,49] concomitant with down regulation of p53-dependent apoptotic pathway^[50-52] is seen in most cancers. Hypermethylation of apoptosis-related genes in ras transformed cells^[53] and hypermethylation of genes implicated in apoptosis in HCC associated with alcohol consumption, viral infection and aflatoxin contamination have been reported^[54]. Additionally, ras itself is subjected to epigenetic alteration by DNA methylation.

Hypomethylation of ras has been demonstrated in gastritis and gastric carcinoma^[49]. Ethanol induces ras activation in gastric epithelial cells^[55] and chronic alcoholic liver injury is associated with upregulation of ras activity^[56]. C-myc, which regulates both apoptosis and proliferation, is overexpressed in HCC and cooperates with ras in the development of carcinoma^[57]. Ethanol also causes an increased expression of c-myc, which is associated with hypomethylation of the c-myc gene^[22].

p53 is also a modulator of histone acetylation and methylation^[58,59]. Hyperacetylation of H3K9 with concomitant loss of dimethyl-H3K9 and increased methylation of H3K4 is seen with delayed suppression of hepatic alpha fetoprotein (AFP, a marker of embryonic phenotype) in p53-null mice^[60]. There is loss of p53 function by its hypermethylation in hepatocellular carcinoma^[61] and p53 mutation is common in gastrointestinal carcinoma^[62]. Apoptosis in chronic alcoholic liver injury is associated with p53 accumulation^[63]. In support of this, p53 null mice fed with ethanol exhibit suppression of apoptosis and increased proliferation of hepatocytes^[64]. The preceding observations strongly indicate that ras and p53 as switch targets play a role in ethanol-induced epigenetic mechanisms.

EMESS

Actions of ethanol are unique in that, ethanol or its metabolites have their own effects and can also sensitize (or desensitize) responses to other agonists. This "double edge" effect combined with the metabolic features of ethanol renders its actions multifaceted. Ethanol is oxidatively metabolized by alcohol dehydrogenase (ADH) or Cyt p450 to acetaldehyde which is next metabolized by aldehyde dehydrogenase (ALDH) to acetate^[65]. Phosphatidylethanol (PEth)^[66] and fatty acid ethyl esters (FAEE)^[67] are generated non-oxidatively from ethanol. Ethanol also causes generation of the reactive oxygen species (ROS) and modulates superoxide dismutases (SOD). Oxidative stress also leads to endoplasmic reticulum (ER) stress resulting in amplification of the injury^[68]. It is a combination of these metabolic stresses, including oxidative and non-oxidative, that causes injury to cells (Figure 1) and we term this as Emess.

A function of Emess is dysregulation of methionine metabolism leading to decreased generation of S-adenosylmethionine (SAM)^[22,69], a crucial methyl group donating step for DNA and histone methylations^[70]. Ethanol feeding affects several enzymes involved in

methionine metabolism including a decreased methionine synthetase activity and changes in hepatic SAM, S-adenosyl-L-homocysteine (SAH), SAM/SAH ratio^[70,71]. Dysregulation of methionine metabolism is further induced by folate deficiency associated with alcohol abuse^[72]. Disturbance in folate metabolism is also related to methylene tetrahydrofolate gene polymorphism^[69]. Another part of Emess is glutathione depletion^[72]. Glutathione depletion causes both global and regional hypomethylation of DNA^[73,74]. SAM administration decreases alcoholic liver injury when given for preventive intervention^[22,71]. Although SAM administration improves hepatic function, long term administration of SAM may have deleterious effects because of the accumulation of homocysteine. Betaine supplementation not only maintains SAM levels but also prevents homocysteine accumulation and elevates glutathione levels resulting in amelioration of ethanol-induced hepatic injury^[71]. Thus Emess-induced effects on glutathione and methionine levels have profound implications in epigenetic changes.

ACETALDEHYDE, DNA METHYLATION AND HISTONE ACETYLATION

One of the mechanisms underlying DNA hypomethylation is the direct inhibitory effects of acetaldehyde on enzymes implicated in DNA and histone methylations. Indeed acetaldehyde has been shown to inhibit both DNA methyltransferase^[30] and methionine synthase^[72,75].

Ethanol metabolism is involved in histone acetylation since inhibitors of alcohol dehydrogenase (4-methyl pyrazole) and aldehyde dehydrogenase (cyanamide) decrease ethanol-induced H3-Lys9 acetylation. This partial effect of inhibitors may imply that part of the ethanol effect on H3 acetylation, may also be independent of its metabolism. Since cyanamide increases the levels of acetaldehyde; and decreases acetylation of histones, acetaldehyde adduct formation is unlikely to account for the observed increases in H3-Lys9 acetylation. Interestingly, treatment of hepatocytes with ethanol metabolite acetate also elicits similar acetylation. Exposure of hepatocytes to acetaldehyde (0.01-1.0 mmol/L) for 24 h also increases H3AcK9. Antioxidant N-acetyl-L-cysteine (NAC, 10 mmol/L) decreases ethanol-induced H3 acetylation by about 50% in rat hepatocytes, suggesting that ROS may play a role in the acetylation^[41,43]. Ethanol thus causes characteristic changes in histone acetylation with sensitivity to ethanol metabolic/oxidative stress.

FUTURE ISSUES IN RESEARCH ON ETHANOL AND EPIGENETICS

Acute and chronic effects of ethanol on DNA methylation and regional hypermethylation or hypomethylation have yet to be established. Likewise, the effects of ethanol on promoter methylation of repetitive sequences as well as key genes that are implicated in survival and regeneration of liver remain to be explored. A comprehensive investigation into the molecular steps involved in ethanol-induced epigenetic changes and inter-relationships (cross-talks)

among epigenetic modifications, i.e. DNA methylations, histone methylations, is warranted. It will be interesting to examine the specificity of the effect of ethanol on individual DNA methyl transferases and histone methyl transferases. The effect of ethanol on histone acetyl transferases^[43] or on protein kinases involved in histone phosphorylation^[76] has to be ascertained. In parallel, the role of demethylases or deacetylases also needs to be assessed. In therapeutic strategies, drugs which modify the enzymes involved in these pathways can be predicted to alter ethanol-induced tissue damage and should constitute an important goal for future investigations. Additional measures, other than SAM or betaine, to suppress Emes and replenish hepatic glutathione by other agents (e.g. vitamin E, folic acid) should be considered. It must be mentioned here that ethanol-induced epigenetic changes are not limited to liver and GI. Evidence from other systems, e.g. fetal alcohol syndrome^[30], neuronal NMDA receptor^[77], synuclein^[78], brain^[79] and HERP gene^[80] further emphasizes the importance and potential role of epigenetic changes in alcohol-induced disorders in diverse systems.

Finally, it can be postulated that, as far as ethanol actions are concerned, the 'epigenetic' effects of ethanol may be more crucial than its effects on classical 'genetic alterations' like DNA deletions or mutations. This remains to be proven. Obviously, epigenetics is set to occupy the center stage of alcoholism research in the next decade.

Abstract

A disease is suitable for screening if it is common, if the target population can be identified and reached and if both a good screening test and an effective therapy are available. Of the most common liver diseases only viral hepatitis and genetic hemochromatosis partially satisfy these conditions. Hepatitis C is common, the screening test is good and the therapy eliminates the virus in half of the cases, but problems arise in the definition of the target population. In fact generalized population screening is not endorsed by international guidelines, although some recommend screening immigrants from high prevalence countries. Opportunistic screening (case finding) of individuals with classic risk factors, such as transfusion before 1992 and drug addiction, is the most frequently used strategy, but there is disagreement whether prison inmates, individuals with a history of promiscuous or traumatic sex and health care workers should be screened. In a real practice setting the performance of opportunistic screening by general practitioners is low but can be ameliorated by training programs. Screening targeted to segments of the population or mass campaigns are expensive and therefore interventions should be aimed to improve opportunistic screening and the detection skills of general practitioners. Regarding genetic hemochromatosis there is insufficient evidence for population screening, but individual physicians can decide to screen racial groups with a high prevalence of the disease, such as people in early middle age and of northern European origin. In the other cases opportunistic screening of high risk individuals should be performed, with a high level of suspicion in case of unexplained liver disease, diabetes, juvenile arthropathy, sexual dysfunction and skin pigmentation.

SCREENING STRATEGIES

Screening is defined as the application of a diagnostic test to an asymptomatic population in order to detect a disease at a stage when intervention may improve its outcome and natural history^[1]. For many years screening has attracted physicians and policy makers as a way of reducing the mortality of chronic illness with a cost effective model of medical care. It was perceived that generalized screening for the most common diseases, could reach the poorest population at higher health risk and in greatest need of medical care. With the advent of evidence based medicine, skepticism about the benefits of screening arose however in the medical community, particularly regarding the adverse consequences of false-positive and false-negative results of the tests utilized in the screening programs^[2]. It was evident that false positive results could produce anxiety, unnecessary examinations and incorrect labeling of part of the population, while false negative results could impair the cost efficacy of the screening. Criteria were therefore established to appraise the effectiveness and appropriateness of these programs^[3] and for their acceptability proof was required of evidence for the reduction of disease specific mortality from randomized controlled trials.

Together with the demand for more evidence based policies came also a better understanding of the different screening strategies. Screening can be performed in different ways and with different target populations.

(1) Population screening is the application of a test to the entire population, generally with age or sex, restrictions, e.g. mammography applied to women of more than 50 years of age.

(2) Targeted screening is the approach of screening only patients at higher risk for a specific disease, e.g. searching for atrial fibrillation in patients with a history of myocardial infarction, angina, diabetes mellitus, hypertension *etc*^[3,4]. Targeted screening utilizes existent disease registers in general practice and local health districts or prescribing information from computerized records.

(3) Opportunistic screening, also termed opportunistic case finding or simply case finding, looks for additional illnesses in a population already complaining of medical problems. In this strategy health professionals, most commonly general practitioners, apply a screening test

Table 1 Characteristics of the most common liver diseases and feasibility of screening

	Hepatitis C	Hepatitis B	Fatty liver	Hemochromatosis
Disease common and causing morbidity/mortality	Yes	Yes	Common, but increased mortality only if advanced NASH	Common, but only 1% of screened population with complications ^[13]
Target population identifiable	High risk groups	High risk groups	Obese, diabetics	Northern European ancestry
Screening test	HCV Antibody test	HBsAg test	Ultrasound	Transferrin saturation or genetic testing (unsettled)
Performance of test	Good	Good	Low PPV and NPV for fibrosis	Under investigation
Effective therapy	50% cure ^[14]	4%-24% HBsAg loss, 70% no progression ^[15,16]	Only lifestyle modification	Yes, but may be unnecessary

to individuals with specific risk factors for the disease and attending their offices with other medical problems. Opportunistic screening is the simplest and less expensive form of screening because there is no need of additional staff and of complicated reach out or recall procedures. The screening test is requested during the patient's consultation and the next appointment is scheduled immediately at the time of the first visit. This strategy however may miss a significant proportion of people who do not present for consultation, but who would otherwise benefit from treatment. Another drawback is that it can be conducted only in those countries with a well established primary care network.

(4) Surveillance is the application of targeted screening over time to a particular category at risk and already harboring a disease. Well known examples of this strategy are the use of periodic ultrasonography and upper gastrointestinal endoscopy in cirrhotic patients in order to detect early stage hepatocellular carcinoma or varices at higher bleeding risk. Another type of surveillance that has been proposed in the field of hepatology is the use of periodic liver chemistry for the detection of drug induced liver toxicity. The terms screening, case finding and surveillance are not uniformly used in the literature and are often inappropriately used interchangeably^[5]. In fact surveillance, strictly speaking is different from screening, being applied not to healthy and asymptomatic people, but to individuals who have already been recognized to suffer from a specific disease.

FEASIBILITY OF SCREENING IN LIVER DISEASE

The implementation of a screening program is requested to meet some basic criteria^[6]: (1) the disease must be common and produce significant morbidity and mortality. (2) The target population must be easily identifiable. (3) The screening test must have good sensitivity and specificity. (4) There must be well defined recall procedures (5) The test should be accepted by the population to be screened. (6) There must be an effective therapy for the disease.

Liver disease seems to meet at best only the first and third of the 6 established criterions. The three main causes of liver disease are viral hepatitis, alcoholic and non-alcoholic fatty liver, which are all quite common. Hepatitis C virus affects 200 million people in the world with an

expected increased mortality for end stage liver disease and hepatocarcinoma in the next 10-20 years^[7,8]. The global disease burden of Hepatitis B is also substantial: it is estimated that there are in the world 350 million chronic hepatitis B carriers^[9] and that 500 000 to 1.2 million people will die annually from the complications of HBV infection^[10]. The other most common causes of liver disease are fatty liver and alcoholic liver disease, which are widespread in the western world and a rising problem also in the developing world^[11]. However the natural history of fatty liver is less well defined compared to viral hepatitis and is characterized by concomitant cardiovascular risk factors such as the metabolic syndrome, diabetes and obesity. It is therefore difficult to predict its liver related mortality in the next 20 years. Alcoholic liver disease is, on the contrary, a multifaceted problem which is beyond the goals of population screening, even if physicians are using a wide array of diagnostic tools to detect alcohol problems on an individual basis. In addition to viral hepatitis, genetic hemochromatosis has also been proposed for population screening, being a common and treatable disease, but it is doubtful which is the optimal test to be used and if only people with northern European ancestry should be subjected to screening^[12]. The specific liver diseases potentially amenable to population screening are listed in Table 1.

In conclusion among the most common liver diseases only fatty liver lacks the characteristics that would render it feasible for a screening program. Both viral hepatitis and hemochromatosis can be considered for some form of screening and will be discussed in detail.

HEPATITIS C

Hepatitis C has many characteristics that render it potentially suitable for screening. In fact, it causes significant morbidity, high risk groups are identifiable as a target population and the screening test is good. The testing strategy utilizes the antibody test which has excellent specificity and sensitivity, if we exclude some false negative cases in acute infections and in the immunocompromised state^[17]. In these situations the diagnosis can be made with HCV-RNA by using amplification techniques. For the majority of patients the usual approach is to test them initially for the antibody and then to use HCV RNA to detect viremia and decide whom to treat^[17]. Current treatment of Hepatitis C is not entirely

Table 2 Indications for screening with anti-HCV antibody

Risk factors for which testing is indicated by all the guidelines	Risk factors for which testing is indicated by some of the guidelines	Additional risk factors for which testing is not formally recommended
Intravenous drug use (past and present)	Populations with high HCV prevalence ^[12,30]	Injections with reusable glass syringes ^[32]
Blood transfusion or transplantation before 1992 (or by known HCV positive donor)	Incarceration ^[12,33]	Heavy marijuana use ^[34]
Administration of clotting factors before 1997	Hepatitis B virus infection ^[12,33]	Promiscuous sex ^[34]
Clinical or biochemical evidence for chronic liver disease	Sharing intranasal cocaine equipment ^[12,33]	Poverty ^[34,35]
Percutaneous exposures to HCV	History of sexually transmitted disease ^[12,33] with genital erosions ^[28]	History of invasive procedures ^[36]
Haemophilia	Traumatic sex or vaginal sex during menstruation ^[14,33]	History of surgery ^[36]
Children born to HCV + ve mothers	Health Care Workers performing procedures at risk of transmission to the patient ^[37]	Beauty treatments ^[38]
HIV positivity		
Stable sexual partners of HCV + patients		

satisfactory because it can eradicate the virus in only half of the cases^[18,19], but in the future new treatments will be available with far greater efficacy^[14]. The low yield of treatment has prompted the US Preventive Services Task Force to dismiss Hepatitis C as a potential candidate for screening^[20]. Sufficient evidence from the literature has not found that screening and treatment of hepatitis C could prevent chronic liver disease and decrease mortality. This opinion has been challenged by other experts^[21] who pointed out that the lack of studies showing a favorable impact of antiviral therapy on mortality is due to the long history of the disease. According to these experts eradication of the virus with normalization of liver enzymes could be considered a surrogate marker for increased life expectancy, as indicated by studies with a long follow up of sustained responders to antiviral therapy^[22-24].

For this reason several international societies have now endorsed screening strategies for hepatitis C^[25-30]. Their official guidelines recommend selective screening targeted for high risk groups, but none of them endorse generalized population screening, mainly for the relatively low prevalence of hepatitis C outside the categories at risk. Other arguments against population screening are that nearly half of the detected patients will have normal ALT and a slow progressing disease^[31], that many patients will harbor conditions contraindicating antiviral treatment and last but not least, that many persons with mild disease will have deterioration in their quality of life after knowing the result of the test^[28]. These drawbacks limit the effectiveness of a mass screening program and render it not cost effective. The optimal method to detect HCV infection, according to all international guidelines is therefore to screen individuals with identifiable risk factors (Table 2).

There is general agreement among all the guidelines that there are major risk factors for hepatitis C and that all individuals with one or more of these factors should be screened with the antibody test. These factors are listed in the first column of Table 2 and basically include intravenous drug use and blood transfusions before 1992, the year when HCV testing of blood units was introduced. Other categories at increased risk that should be tested are

the hemophiliacs, HIV positive patients and children born to HIV positive mothers. Although many studies have shown that HCV transmission is rare^[39-41] or virtually non-existent^[42] in stable monogamous couples, all the guidelines recommend testing of the spouse or partner, mainly for reassurance.

Though there is consensus on the most important risk factors some disagreement exists for other conditions at risk, which are mentioned only by some of the guidelines and not by others. For example the Canadian College of Family Physicians emphasizes the problem of sexual exposure and recommends testing in case of promiscuous, traumatic or vaginal sex during menstruations^[33]. The Italian guidelines suggest testing individuals with high risk sexual behavior only if they have a history of genital erosions^[28]. Promiscuous sex is not considered an indication for testing by the other guidelines, being discussed in detail only by the US Preventive Services Task Force who examining 4 large population studies^[43-46] could not rule out a concealed association between promiscuous sex and unacknowledged drug use^[20]. For this reason systematic testing of individuals with multiple sex partners or homosexuals was not recommended. Another debated issue is whether health care workers performing exposure prone procedures should be screened for hepatitis C. For exposure prone procedures it is indicated that the performance of invasive procedures are putting the patient at risk to contract a blood borne virus. From 1994 to 2002 fifteen British patients have been infected by health care workers (HCWs) carrying the hepatitis C virus. Following these incidents the British Department of Health recommended screening all HCW performing or intending to perform exposure prone procedures first with an anti HCV antibody test and if they test positive, with an HCV RNA assay. Anti-HCV positive HCWs carrying the virus are restricted from performing such procedures until they receive treatment and get rid of the virus^[37]. This opinion is not shared by the other guidelines that do not recommend HCW screening, regardless of their type of duty.

Another source of disagreement is population screening. In spite of an apparent unanimity among the

guidelines against generalized population screening, two of them^[12,30] suggest to screen individuals coming from high prevalence countries, which is an indirect form of population screening. The two guidelines do not set a threshold to define a high prevalence country, but many experts think of Egypt and Pakistan, which have an anti HCV prevalence of more than 10% in the general population^[47-49]. Another particular form of screening a segment of the population is the testing of prison inmates, recommended by the Canadian Guidelines^[14,33].

Many other risk factors have been found to be associated with an increased risk of HCV infection in epidemiological studies, but none has proven useful in clinical practice. For example in the Mediterranean area many infections have been transmitted in the past through the use of reusable glass syringes. However, due to their widespread use, a positive history for this risk factor has a very low positive predictive value and is practically useless in the clinical setting^[32]. The same applies for the history of surgery and invasive procedures after a French study demonstrating that screening for these additional risk factors is not cost effective in general practice^[50].

In conclusion, there is only partial consensus among the international guidelines on the appropriate risk factors to be used in the clinical setting, but there are other problems to be considered. First, none of the guidelines indicate how the screening strategy should be actuated-e.g. if the screening should be targeted or opportunistic. In other words it is not clear if an active search for individuals belonging to categories at risk should be implemented or if the less demanding opportunistic screening will suffice. It is true that hemophiliacs, hemodialysis patients, HIV positive individuals and drug addicts on detoxification programs are usually registered on files and record charts that could be accessed for screening. In this case, individuals at risk easily recalled, but what about people transfused earlier than 1992? Many of them are women who received few blood units after delivery, a bad habit of the past, but are not aware of being at risk. Should we actively search for them in the blood bank files of our hospitals or simply wait until they come to their general practitioner and rely solely on his history skills? In addition the patient's privacy could be at issue when browsing into these records. There are also doubts that an organized, widespread targeted screening would be cost effective, as shown in a study conducted in a pilot French area highlighting the difficulty and cost of mobilizing a considerable number of health professionals in the screening campaign^[47]. In the only cost effectiveness study published in the literature, Josset^[36] calculated a cost of 2247-3318 € per identified case for the reference strategy, consisting of the opportunistic screening of individuals at risk. This cost skyrocketed to 10994 € for targeted organized screening with mobilization of health professionals^[47], which is surely a waste of money considering that only half of the detected cases can be cured.

If we admit that the most rational approach is opportunistic screening and not population or targeted screening, we are faced with the problem of assessing the performance of general practitioners in detecting the patients at risk. Many studies have addressed this issue,

chiefly using questionnaires, mail surveys and phone interviews, but the overall results are confusing. Some of them found a good knowledge of risk factors by family physicians^[51-54], but others have not^[55-60] irrespective of the geographical areas. The actual behavior of family physicians in real practice was investigated in one study, by scrutinizing the medical records of 229 hepatitis C patients from 26 primary care clinics in Michigan^[61]. It was found that testing was initiated based on physician-identified risk factors only in 20% of the patients, while the majority of them were tested because of liver enzyme elevations, history of hepatitis B or by direct patient request. It is noteworthy also that a minority of the patients already knew their HCV status and that only 10% of them were asked about risk factors during their first visit at the clinic. This means that, in a real practice setting, family physicians are less aware of the risk factors of hepatitis C, than when questioned in formal interviews. In another real practice study comparing different screening strategies, HCV infection was found in only 5% of the tested patients^[62] showing that, irrespective of the adopted strategy, the yield of this screening is rather low. These real practice studies depict a bleaker scenario than what was apparent from questionnaire and interview studies. Hopefully the performance of family physicians can be improved by training interventions and by the participation of these physicians to hepatitis C networks, as shown by the French experience^[63]. Both the screening efficacy and the appropriateness of referrals can be ameliorated by long term training and by the adoption of specific guidelines for family practice. These guidelines consist of easy to use flow charts for the identification and referral of the patients and can be utilized by general practitioners in their offices^[64]. The same goals can be achieved in far to reach rural areas by the use of CD based software, mailed to physicians practicing in the same areas. This comprehensive software contains the various aspects of the care of hepatitis C, including diagnosis, counseling, treatment and follow up^[65].

In summary, we can conclude that opportunistic screening of categories at risk is the best form of screening recommended in the literature, but that no consensus exists on some of the risk factors. Population screening is recommended only for some particular ethnic groups and only by some of the guidelines. In a real practice setting the performance of this type of screening by general practitioners is low but could be ameliorated by training interventions. The cost of other forms of screening is too high to merit consideration and therefore interventions should be aimed to improve the detection skills of general practitioners.

HEPATITIS B

The case of hepatitis B is completely different from hepatitis C. In fact, the treatment can eradicate the virus in only a small minority of the patients^[15,16,66], but an effective vaccine is available to prevent transmission of the infection. Screening therefore has been implemented in the categories at risk to optimize the vaccination strategies and not to detect infected individuals to be cured, as

in the case of hepatitis C^[67-69]. In some high prevalence populations such as Asian and Pacific island immigrants in the United States, some screening for treatment programs have been conducted. In the New York City program^[70] 1836 people were tested for HBV infection: 24% of them were found HBsAg positive and 90% returned for further evaluation and possible treatment. A total of 505 (27.5%) were negative for hepatitis B markers and were vaccinated with a discrete coverage rate (70% after the third dose). The results of the New York City program show that screening a high prevalence segment of the population is feasible and can identify in a cost effective way both susceptible people to be vaccinated and infected individuals to be treated. Control of hepatitis B is however achieved worldwide by means of vaccination and in fact the World Health Organization recommends the addition of HBV vaccine to all national immunization programs^[71]. The vaccination strategy depends on the prevalence of HBsAg carriers in the general population: in countries with intermediate and high prevalence (more than 2% and 8% of the general population), universal neonatal or infant vaccination is recommended. Even in countries at low risk (1%-2% prevalence) universal infant or adolescent vaccination is cost effective if the vaccine can be delivered efficiently^[67]. Only in countries at very low risk (around 0.05%) such as the United Kingdom, Scandinavia and the Netherlands a selective risk group vaccination could be more cost effective than universal vaccination^[67,72]. Regarding the categories at risk that should be screened and vaccinated, there is full consensus in the literature on their definition^[69,73]. These categories are listed in Table 3. Individuals with these risk factors should be screened with a case finding strategy in the context of vaccination delivery programs^[72] and those found to be HBsAg carriers evaluated by the specialist for possible treatment.

HEMOCHROMATOSIS

Hereditary Hemochromatosis is a genetic disorder of iron metabolism in which iron is excessively absorbed by the intestinal tract and accumulates in the liver, heart, joints, pancreas and other endocrine glands. There are 4 different forms of hereditary hemochromatosis: (1) HFE gene mutations which result in upregulation of iron absorption by intestinal cells (2) Juvenile hereditary hemochromatosis with mutations in the hemojuvelin gene HJV (type 2A) or in the HAMP gene (type 2B), (3) TFR-2 related hemochromatosis in which mutations in the transferrin receptor may lead to an increased uptake of iron by hepatocytes and (4) Ferroportin related iron overload in which mutations of the ferroportin gene cause the absence of ferroportin activity and the inappropriate iron sequestration within the reticuloendothelial cells^[74].

The most common form of hereditary hemochromatosis is related to the substitution of tyrosine for cysteine at position 282 of the HFE protein (C282Y): homozygosity for the C282Y mutation predisposes to iron accumulation and is found in 50%-95% of classic hemochromatosis, depending on the geographic areas. The highest frequency of this mutation is observed in people of northern European descent (0.3%-0.5% of the general population) while lower

Table 3 Categories at risk for hepatitis B that should be screened and vaccinated

Immigrants from high prevalence areas (> 8% population) Asia, Pacific Islands, Alaska, Greenland, Africa, Middle East, former USSR, Eastern Europe (except Hungary), Malta, Amazonian areas of Peru, Brazil, Bolivia and Venezuela
Refugees, adopted children, residents for more than 6 mo in the same areas
Blood transfusion before 1973
Drug addicts
Individuals with clinical or biochemical evidence for chronic liver disease
Percutaneous exposures to HBV
Haemophilia
Pregnant women
Haemodialysis
Household, sexual and needle sharing contacts of HBsAg patients
Sexual partners of HBsAg patients
Health Care Workers

frequencies (less than 0.1%) are found in Asians, Blacks and Hispanics^[75]. The second most common mutation of the HFE gene, linked to hemochromatosis, is the H63D mutation. One to 2 percent of people with compound heterozygosity for C282Y and H63D will eventually express the disease, while homozygosity for H63D does not seem to be associated with significant iron accumulation^[74]. A third mutation of the HFE gene, S65C has been described, but it is debated whether this mutation is associated with hemochromatosis in the compound heterozygous form with C282Y^[76]. Mutations in other genes different from HFE have been reported in Italian families with iron overload comparable to the classic HFE form^[77-79].

Hemochromatosis is a common disease and also amenable to treatment because venesection is safe and can change the natural history of the disease^[80,81]. It would therefore be advantageous to submit individuals to a screening test for hemochromatosis in order to detect the disease at an early stage, before the occurrence of damage to vital organs. Genetic testing of large samples of the general population in the USA (HEIRS Study: Hemochromatosis and Iron Overload Screening in a racially diverse population) and Norway^[75,82] showed that hemochromatosis is a common disease in non-Hispanic whites (0.44%) and Norwegian males (0.66%) while individuals of other racial origin show a much lower prevalence. For example only 0.027 of Hispanics and 0.014 of American Blacks were homozygous for the C282Y mutation. Asians have the lowest prevalence (0.00039%) of HFE mutations, but surprisingly have more iron overload than the other racial groups. Iron overload was defined as a serum ferritin greater than 300 mg/L in man and 200 mg/L in women plus serum transferrin saturation greater than 50% in men and 45% in women. These data clearly show that genetic testing is not sensitive enough to detect all cases of iron overload and neither is highly specific, since as reported in the HEIRS study 88% of men and only 57% of women homozygous for the C282Y mutation had elevated serum ferritin. In addition, it is by no means certain if these patients will develop significant life threatening complications over time. In fact in a large population based study

the prevalence of these complications in C282Y homozygosity was found as low as 1%^[13]. Other studies searching for a genotype-phenotype correlation in C282Y homozygosity have yielded varying results: increased ferritin levels were found in 19%-75% of these subjects with a median of 65%^[83,84]. Regarding liver damage approximately 50% of the C282Y homozygous with abnormal iron indexes in the Norwegian study underwent liver biopsy, and only a small minority was found to have cirrhosis^[82] indicating that finding a high ferritin and transferrin saturation does not necessarily indicate the presence of severe liver disease. The other genotypes linked with the development of familiar hemochromatosis, such as the C282Y/H63D compound heterozygous, have a lower risk of iron accumulation^[85] and are not worth screening. Similarly the non-HFE related hemochromatosis, such as ferroportin disease and mutations in the HJV and TFR1-genes are much less frequent than the homozygous C282Y form and their diagnostic tests have not yet been validated for population screening^[86]. In conclusion genotypic screening is not the ideal screening tool for hereditary hemochromatosis because it is uncertain whether the detected individuals will progress into overt disease.

Many guidelines have addressed the issue of population screening in genetic hemochromatosis^[87,88], the most recent of which was published in 2005 on behalf of the American College of Physicians^[89]. In none of these guidelines is widespread population screening recommended, but the American College of Physicians leave the specialist and general practitioner free to perform a once in a life phenotypic screening of asymptomatic non-Hispanic white men with ferritin and transferrin saturation (phenotypic test). The central issue is the sensitivity and specificity of these tests to detect true hemochromatosis and which is the best cut off to be used. Schmitt and colleagues^[90] require that the gold standard be an independent demonstration of iron overload through iron deposition by liver biopsy or the amount of iron removed by phlebotomy. Among the main studies of the literature^[80,82,85], however, a small minority of the identified patients was further investigated with liver biopsy or the amount of depleted iron precisely calculated. Hemochromatosis was diagnosed in all of these cases and therefore phenotype testing seems to give a higher yield compared to HFE genotyping in detecting both iron overload and liver disease^[89]. The key point is that genotypic testing identifies many patients that will not progress into overt disease, while phenotypic testing circumvents this problem, because the combined use of serum ferritin and transferrin saturation is directly related to iron overload. Serum ferritin is unreliable as a sole marker, but is beneficial in classifying patients with regard to the presence or absence of cirrhosis^[88]. Serum ferritin has a high sensitivity but poor specificity for iron overload^[87] and therefore needs to be supplemented by the use of transferrin saturation. The best thresholds for these tests have been defined in the HEIRS studies and have already been discussed^[75]. Transferrin saturation has the advantage that it is independent of body mass index^[91] but care should be taken to draw the blood sample in the morning to avoid interference by the post absorptive state

and circadian rhythm^[88]. Another advantage of phenotypic compared to genotypic testing could be the negative psychosocial consequences derived by stigmatization of the patients by a positive genotypic test, albeit two studies addressing this problem did not provide evidence of negative psychosocial consequences to the patients^[92,93]. What can be said in summary regarding screening of this disease?

(a) Both the American Association for the Study of the Liver and the American College of Physicians deem that there is insufficient evidence for population screening, but recommend targeted screening of individuals at high risk. The target population should be: (1) patients with unexplained liver disease or known liver disease with elevated serum iron markers, (2) type 2 diabetics, (3) first degree relatives of hemochromatosis patients, (4) patients with early onset atypical arthropathy, cardiac disease or male sexual dysfunction, (5) unexplained changes in skin pigmentation. There is no data available to risk-stratify the patients according to these conditions and to recommend more intensive screening for a particular group. (b) Individual physicians can decide to screen persons belonging to racial groups with high prevalence of genetic hemochromatosis, such as people of northern European origin. This disease could be a candidate for opportunistic screening as part of routine health maintenance when Caucasian patients in early middle age are seen by general practitioners in their offices. This strategy however has not yet been validated by a cost efficacy study. (c) Screening should be performed once in life with serum ferritin and transferrin saturation using the thresholds defined by the HEIRS study.

OTHER GENETIC LIVER DISEASES

Alpha-1-antitrypsin deficiency and Wilson's disease are the other most important metabolic diseases that could potentially be considered for population screening. Alpha-1-antitrypsin deficiency is a common autosomal recessive condition which may cause liver cirrhosis in children and young adults. The classic homozygous form of alpha-1-antitrypsin deficiency affects 1:1800 newborns and predisposes to the early development of pulmonary emphysema, cirrhosis and hepatocellular carcinoma^[94]. Population studies conducted in Sweden have shown a wide variation in the expression of liver disease among the homozygous carriers of the z allele, which is associated with alpha-1-antitrypsin deficiency^[95,96]. In one of these studies only 10% out of 127 homozygotes followed for over 20 years were found to develop significant liver disease. In another more recent study conducted in Austria 16410 asymptomatic individuals were tested for the alpha-1-antitrypsin phenotype. Eighty six percent of them were found to be carriers of the normal Pi-MM phenotype, 7% were heterozygous for the Pi-Z phenotype, 5% heterozygous for the less common Pi-S phenotype and 0.7% were found homozygous for the Pi-ZZ phenotype. There was no difference both in liver related mortality and cumulative survival in the four groups of individuals, even after a very long period of follow up, that is after a median of 53 years^[97]. All these data show that other

genetic and environmental factors may modify the expression of this abnormal genotype and render alpha-1-antitrypsin deficiency unfeasible for population screening in newborns, children and young adults. It should also be stressed that alpha-1-antitrypsin replacement therapy is not effective in preventing liver disease and therefore the identification of affected individuals could only be used for the prevention of pulmonary emphysema^[98].

Wilson disease, caused by copper accumulation within the liver parenchyma, is another important genetic disease that could benefit from effective chelation therapy^[99]. In the early nineties a putative gene causing Wilson disease was discovered (ATP 7B) and it was named the WND gene. This offered promise for its use as a genetic marker of the disease and also for population screening^[100,101]. However, the mutations of the ATP 7B gene are quite complex and a recent study failed to show significant correlations between symptoms, ceruloplasmin levels, hepatic copper content and any specific pattern of mutations^[102]. The prevalence of Wilson's disease in the general population is also relatively low, being on average 30 affected individuals per million people^[103] and therefore screening for this disease on a widespread scale is not justified.

Abstract

AIM: To shed light on the possible role of mismatch repair gene Mlh3 in familial esophageal cancer (FEC).

METHODS: A total of 66 members from 10 families suggestive of a genetic predisposition to hereditary esophageal cancer were screened for germline mutations in Mlh3 with denaturing high performance liquid chromatography (DHPLC), a newly developed method of comparative sequencing based on heteroduplex detection. For all samples exhibiting abnormal DHPLC profiles, sequence changes were evaluated by cycle sequencing. For any mutation in family members, we conducted a segregation study to compare its prevalence in sporadic esophageal cancer patients and normal controls.

RESULTS: Exons of Mlh3 in all samples were successfully examined. Overall, 4 missense mutations and 3 polymorphisms were identified in 4 families. Mlh3 missense mutations in families 9 and 10 might be pathogenic, but had a reduced penetrance. While in families 1 and 7, there was no sufficient evidence supporting the monogenic explanations of esophageal cancers in families. The mutations were found in 33% of high-risk families and 50% of low-risk families.

CONCLUSION: Mlh3 is a high risk gene with a reduced penetrance in some families. However, it acts as a low risk gene for esophageal cancer in most families. Muta-

INTRODUCTION

Esophageal carcinoma (EC) is one of the most common malignant tumors in China^[1,2]. Although various therapeutic strategies have been improved in recent years, the 5-year survival remains poor, therefore, early diagnosis and treatment of EC are still urgently needed^[3,4].

Current studies showed that multiple factors and steps contribute to its tumorigenesis, however the definite mechanisms remain to be determined yet^[5,6]. While in cancer families, genetic predisposition may play a more important role in carcinogenesis than other factors^[7]. Genetic susceptibility can be identified by detecting germline mutation of certain genes from peripheral blood.

Denaturing high performance liquid chromatography (DHPLC) is a newly developed technique suitable for the detection of heteroduplex mutations. DHPLC has the advantages of being highly automated, sensitive, and could be used for screening of gene mutations on a large scale^[8].

Great attention has been paid to mismatch repair (MMR) genes due to their association with hereditary non-polyposis colorectal cancer (HNPCC)^[9]. Mlh3 gene was first identified in 2000, which is a putative MMR gene normally expressed in multiple epithelia. It is located on 14q24.3 with a coding length of 4.3 kb, and is composed of 12 exons, of which exon 1 is 3.3 kb, accounting for 75%^[10]. Some investigations showed that it might play a certain role in the tumorigenesis of colorectal cancer^[11-14]. However, some studies indicate that there is no strong

association between currently known Mlh3 variants and colorectal cancer predisposition risk^[15,16]. A recent study on familial gastric cancer showed that Mlh3 can act as a low risk gene^[17].

Therefore, in an attempt to further evaluate its possible role in the cancer family, we performed mutation screening of Mlh3 in familial esophageal cancer (FEC) with DHPLC.

MATERIALS AND METHODS

Subjects

A total of 10 families with a hereditary background of esophageal carcinoma were collected (Table 1). The criteria were set as: at least 2 generations with esophageal cancers, at least two affected members, first-degree relatives, and carcinogenesis at earlier ages (< 50 years old). In addition to 66 members from these 10 esophageal families, 96 cases of sporadic esophageal cancer and 96 normal controls were recruited from the Department of Thoracic Surgery, First Hospital, China Medical University. Blood samples were collected from the members of each family after giving their informed consent.

DNA Extraction

DNA was extracted using the standard phenol/chloroform extraction protocols.

PCR

Seventeen primers were used for a total of twelve exons in Mlh3. Exon 1 was divided into seven overlapping fragments, and exons 8 and 9 were amplified together because of their small size and the small intron between them. The length of PCR fragments, primer sequences and corresponding annealing temperature for each fragment are shown in Table 2. All products were examined for specificity and quantity by 2% agarose gel electrophoresis.

DHPLC

PCR products were denatured at 95°C, and gradually cooled down to room temperature to enable efficient formation of heteroduplexes. DHPLC was carried out in a transgenomic wave DNA fragment analysis system, an automated DHPLC instrumentation equipped with a DNASep column. Abnormal elution profiles were identified by visual inspection of the chromatogram on the basis of the appearance of one or more additional earlier eluting peaks. Temperatures used in DHPLC analysis have been described elsewhere^[14].

Direct sequencing

Genomic DNA was re-amplified with DHPLC primers. After purification, DNA sequence changes were evaluated by direct sequencing in both directions. After treatment with ethanol, cycle sequencing products were analyzed on an ABI PRISM[®] 377 DNA sequencer.

Segregation study

For any specific variant of Mlh3 gene, we also detected its percentage in 96 cases of sporadic esophageal cancer and 96 normal controls in addition to the segregation study in

families. If there was no such mutation in sporadic cancer or in normal controls, then this mutation might be pathogenic in this family. On the other hand, it might be a polymorphism not associated with the disease.

Table 3 Possible mutations of MLH3 in familial esophageal cancer

Exon	Nucleotide change ¹	Amino change	Family	Family type	Cosegregation	Frequency in FEC <i>n</i> (%)	Frequency in sporadic EC <i>n</i> (%)	Frequency in normal control <i>n</i> (%)

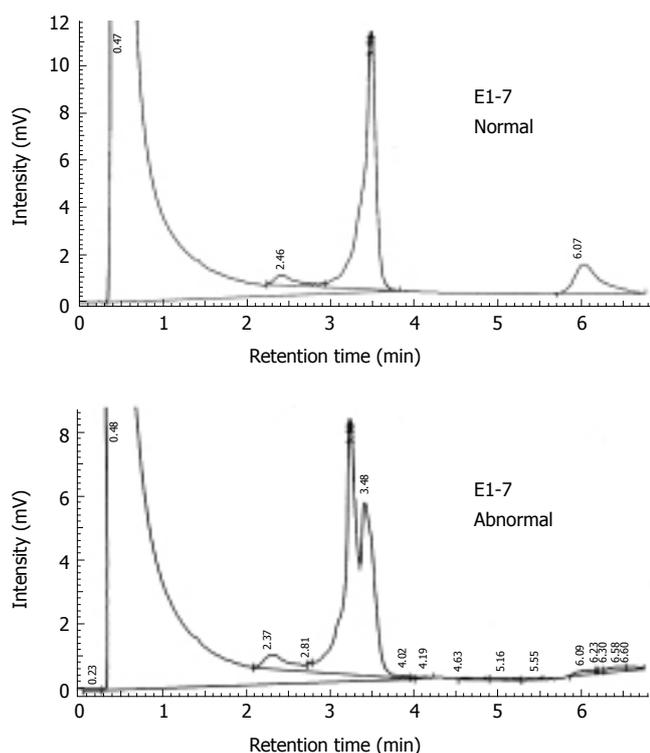

Figure 2 Normal and abnormal DHPLC chromatogram. The normal control appears as a clear elution peak, while one or more additional earlier eluting peaks result from heteroduplex for mutated DNA.

RESULTS

All the exons were successfully amplified (Figure 1), analyzed with DHPLC (Figure 2) and sequenced (Figure 3). Four missense mutations and 3 polymorphisms were identified in 4 families (Tables 3 and 4). One variant C2531T (Pro8441Leu) had almost the same prevalence in familial cancer, sporadic cancer and controls. One silent variant C2838A (Ser947Ser) and an intronic variant (between

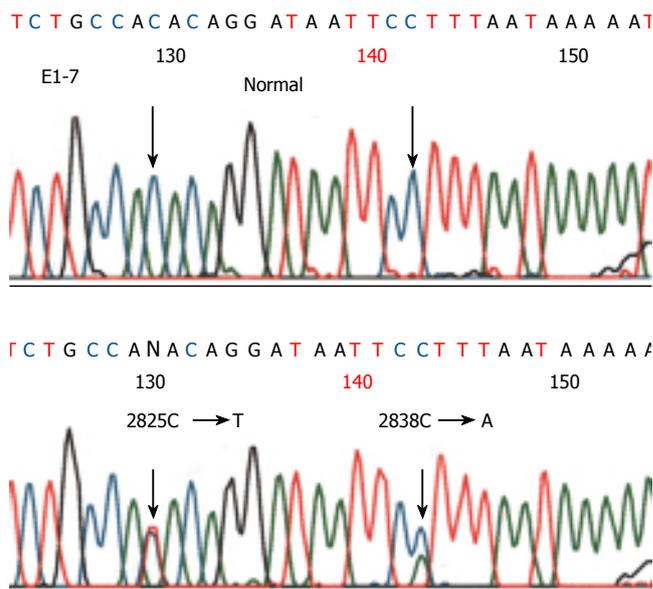

Figure 3 Sequencing results revealing two heterozygous variants in fragment 7 of exon 1, C2825T and C2838A. On the basis of amino acid variation, C2825T (Thr942Ile) is considered a missense mutation, while C2838A (Ser947Ser) a polymorphism.

Table 4 Polymorphism of MLH3

Exon	Nucleotide change ¹	Amino change	Family
1	C2531T	Pro8441Leu	Many
1	C2838A	Ser947Ser	Many
9/10	IVS9 + 66A→G	Unknown	Many

exons 9 and 10) A→G, were considered polymorphisms (Table 4). All variants were not in the conserved homologous regions of the MutL protein at the NH₂ and COOH terminals, and none of the variants was evolutionarily conserved in yeast or *E. coli*^[18,19].

The families with identified mutations were of two types, high risk families consisting of more than three affected first degree relatives (MCR), and low risk families consisting of two affected first degree relatives (TCR) (Table 1). There were 6 high risk families and 4 low risk families. Two missense mutations (T3826C and C2825T) were found in two low risk families (families 1 and 10), the

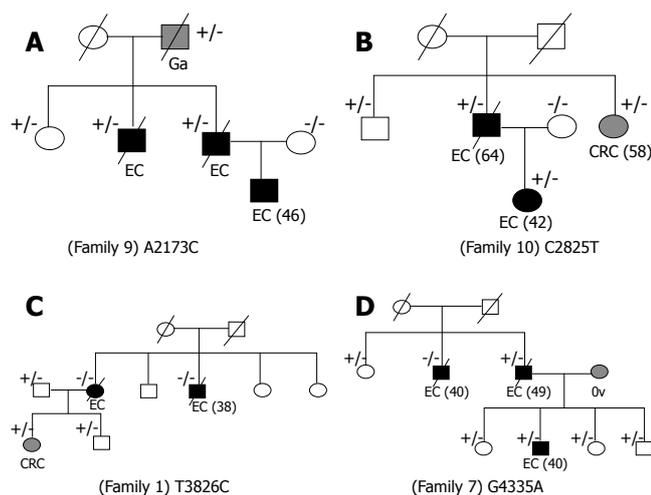

Figure 4 Pedigree of families with hMLH3 variants. Symbols and abbreviations used are denoted as black symbols for esophageal cancer, gray symbols for other cancers; EC: Esophageal cancer; CRC: Colorectal cancer; Ga: Gastric cancer; Ov: Ovarian cancer; Numbers next to the diagnosis denote age at onset; genotypes are on the top right of family member symbols; +: Variant carrier; -: Nonvariant carrier.

other two variants (G4335A and A2173C) were observed in high risk families (families 7 and 9). Mutations were found in 33% (2/6) of the high risk families and 50% (2/4) of the low risk families.

To elucidate the pathogenic nature of these 4 variants, we also detected their prevalence in sporadic cases and normal controls (Table 3). The data demonstrated that the frequency in families was far higher than that in sporadic cases and normal controls, suggesting that they might contribute to the disease in these families.

Missense mutation A2173C was found in 3 patients with esophageal cancer, one gastric cancer patient and one 76-year old unaffected relative in family 9 (Figure 4A), suggesting that the mutation could be inherited from the grandfather. Furthermore, no such variant was detected in controls and sporadic cases, suggesting that the mutation could be associated with the occurrence of esophageal cancer, but might have a reduced penetrance.

Missense mutation C2825T was found in family 10 (Figure 4B). The mutation was shared by the father and daughter with esophageal cancer, unaffected brother (66 years old) and sister with colon cancer, which was consistent with the mutation associated with the disease but having a reduced penetrance. Moreover, the mutation was found in 4.5% of family members and 1.0% of sporadic cases, but not in controls.

Variant T3826C (Trp1276Arg) in exon 7 was found in family 1 (Figure 4C). However, the mutation did not segregate well with the disease. Two affected members with esophageal cancer had no such mutation. While one female with colon cancer and two males with no colon cancer had this mutation. T3826C was not detected in controls and sporadic cases.

Variant G4335A was found in a male patient with esophageal cancer and his affected son in family 7, but not in his brother with esophageal cancer, whereas his unaffected sisters and three healthy children shared this mutation (Figure 4D). G4335A was not detected in sporadic

cases and normal controls.

Among the esophageal cancer families, Mlh3 mutation A2173C in family 9 and C2825T in family 10 could be causative, but had a reduced penetrance. These mutations were segregated with the disease, and neither of them was found in sporadic cases and normal controls. In variant T3826C in family 1 and G4335A in family 7, there was a lack of evidence of the monogenic high risk predisposition to esophageal cancer associated with these identified variants, because there was no clear association between mutation and the disease. However, these variants were more prevalent in families but not in sporadic cases and the controls, indicating a possible pathogenic nature in these families. Surprisingly, mutations were found in 50% (2/4) of low risk families and in 33% of high risk families (2/6).

DISCUSSION

The mismatch repair system is composed of a highly diverse group of proteins that interact with numerous DNA structures during DNA repair and replication^[20].

The MutL homologue, Mlh3 gene was first identified as a new member of the DNA MMR gene in yeast, and has been mapped to the region of the mouse complex trait locus, colon cancer susceptibility I^[10]. It is highly conserved in evolution. The protein encoded by its carboxyl-terminal may interact with the currently known mismatch repair gene MLH1, and is very similar to Mlh3p in yeast, indicating that it may play a role in the DNA mismatch repair system^[10]. It is essential not only for DNA repair and microsatellite stability, but also for meiosis. In *S. cerevisiae*, Mlh1-Mlh3 complex acts competitively in a distinct way to promote crossing over during meiosis along with the Msh4-Msh5 and Mus81-Mms4 complexes^[21]. The significant heterogeneity in localization of the MutL homologues, Mlh1 and Mlh3, directly results in defective crossing over during meiotic recombination in prophase I, and consequently 30% of human oocytes are predisposed to aneuploidy^[22].

Furthermore, Wu *et al*^[23] used knockout *mlh3* (-/-) mice to address the role of Mlh3 in class switch DNA recombination (CSR) and somatic hypermutation (SHM), and found that Mlh3 deficiency alters both CSR and SHM, suggesting that the MMR Mlh3 protein plays a role in both CSR and SHM.

A recent study reported that Mlh3 contributes to tumor suppression in mice. Mlh3 deficiency causes microsatellite instability, impaired DNA-damage response, and increased gastrointestinal tumor susceptibility^[24]. There is evidence that mismatch repair gene mutations is significantly associated with an increased risk of developing colorectal cancer^[25] and that the mismatch repair gene Mlh3 plays an important role in DNA repair.

There is evidence that mismatch repair gene Mlh3 plays an increasingly important role in DNA repair after replication, microsatellite stability, meiosis and tumor suppression.

In this study, among the 66 members in 10 esophageal cancer families, 4 missense mutations and 3 possible polymorphisms were identified. Even though all the

identified mutations were not in the conserved region and none of them changed a codon conserved in yeast and *E. coli*, their possible role in tumorigenesis cannot be ruled out. In fact, many reported missense mutations are not within the conserved region of hMLH1, another important mismatch repair gene^[26].

Current investigations have been mainly focused on its susceptibility to colorectal cancer (CRC)^[11-16]. By using DHPLC to screen Mlh3 mutations in 70 families with likely genetic predisposition to colon cancer, Liu *et al.*^[14] found that the frequency of its germ-line variants, including one frameshift mutation, 10 missense mutations and 5 polymorphisms was high (23%). By analyzing 30 CRC cases for germline mutations by sequencing, Hienonen *et al.*^[15] have found 5 missense variants, 4 of which were also found in cancer-free controls. The only remaining variant does not appear to be an attractive candidate for a disease-associated mutation because the amino acid change is located outside the conserved residues. Furthermore, they have not found the reported frameshift mutation in the 30 CRC cases or in 700 cancer-free controls. While it is a difficult task to exclude the role of Mlh3 in HNPCC, their study could not confirm the role of Mlh3 in CRC predisposition. Similarly, De Jong *et al.*^[16] have found two variants (S845G and P844L) in Dutch patients with suspected HNPCC, but further investigation has failed to demonstrate an association between the two variants and colorectal cancer risk. Zhao *et al.*^[17] performed an investigation on Mlh3 in 16 suggestive hereditary gastric cancer families with DHPLC and identified 5 missense mutations. However, no strong association has been verified between these 5 variants and gastric cancer risk, indicating that Mlh3 probably acts as a low risk gene in familial gastric cancer.

To establish whether the mutations segregate with disease in a family, we tried to collect DNA samples from members of each family. Two variants (A2173C and C2825T) showed a segregation pattern consistent with a monogenetic risk factor in families 9 and 10. Additionally, neither of them was detected among sporadic esophageal cancer cases and normal controls. However, because the sizes of these families were small, and the affected individuals were all first-degree relatives, Mlh3 could not be defined as a high penetrant predisposing FEC gene. The other variants (T3826C and G4335A) had no clear segregation pattern consistent with the disease, even the frequencies in families were higher than those in sporadic cases and controls.

Although the mutations of Mlh3 identified in our study did not provide sufficient evidence supporting a monogenetic explanation for the familial aggregation of EC, we would still like to propose that some or all of these mutations might work as low risk genes, perhaps in an accumulated manner, resulting in increased risk for EC. We believe that the majority of EC are caused by some low risk genes, which act on their own or interact in an additive manner. Therefore, the monogenetic susceptibility is still suggested for the disease in high risk families (family 7 and 9), while multiple genetic inheritance of susceptibility could be the reason in low risk families (family 1 and 10). Chen *et al.*^[24] found mismatch repair Mlh3 and Pms2

double-deficient mice have tumor susceptibility, shorter life span, microsatellite instability, and DNA-damage response phenotypes. Al-Tassan^[27] found that in MYH, another DNA repair gene, several missense mutations act in a recessive manner and cause colorectal cancers in three sibs, with compound heterozygous missense mutations in this gene. Some mutations were also found as heterozygous missense mutations in healthy members of the same family and normal controls. Although, the predisposition seems to be inherited in a recessive manner, it is possible that heterozygous mutations in this gene also act in an additive manner as a low risk gene. And in our previous study on colorectal cancer families, we found a hMLH3 mutation segregated with disease together with a missense mutation in hMSH2^[14]. The missense mutations of both Mlh3 and Msh2 contributes to the failure of mismatch repair-mediated tumor suppression, resulting in the family aggregation of colorectal cancer.

Additionally, DHPLC analysis is very sensitive, robust and reproducible. Nevertheless, the relatively high expensive apparatus and related reagents have limited its wide use.

Based on previous reports and our results, the Mlh3 gene might occasionally appear as a high risk gene predisposing to EC, while in most cases it works as a low risk mismatch repair gene, contributing to the increased risk of developing EC. Despite our findings, much is yet to be learned about the molecular basis of correlations between genetic changes and clinical features of the disease. DHPLC is a sensitive and robust technique for screening gene mutations.

Abstract

AIM: To investigate whether the recombinant adenovirus induces the TNF- α -mediated apoptosis *in vivo*.

METHODS: Human hepatocarcinoma cell line (HepG₂) cells were transfected into BALB/c nude mice, and the tumor growth curve was drawn. We analyzed apoptosis in HepG₂ cells by TUNEL, HE staining and electron microscopy.

RESULTS: AdI κ B α M was expressed stably and efficiently in HepG₂ and could not be degraded by induction of TNF- α . Tumor growth in mice could be reduced remarkably if treated by AdI κ B α M plus TNF- α . There was apoptosis of > 70% of cells treated with AdI κ B α M plus TNF- α and about 50% of cells treated with AdI κ B α M. In contrast, there was few cell apoptosis in HepG₂ cells treated with phosphate buffered saline and AdI κ B α . HepG₂ cells in mice also exhibited a high level of apoptosis after *in vivo* injection with AdI κ B α M. The tumor growth curve indicated the tumor transfected with AdI κ B α M could be restrained.

CONCLUSION: AdI κ B α M gene therapy greatly enhances apoptosis due to inhibition of an NF- κ B-mediated antiapoptosis signaling pathway.

INTRODUCTION

Resistance of tumor cells toward induction of apoptosis is one of the main reasons for failure of anticancer treatment^[1]. NF- κ B is a ubiquitous transcription factor that is activated by a variety of cytokines and mitogens^[2] and is thought to be a key regulator of genes involved in inflammation, response to infection, and stress. Classic NF- κ B is a heterodimer of p50 (NF- κ B-1) and p65 (Rel-A), but proteins that constitute the NF- κ B family form a variety of homodimers and heterodimers^[3]. NF- κ B is retained in an inactive form in the cytoplasm through association with one of the I κ B inhibitory proteins, including I κ B α , I κ B β and I κ B ϵ ^[4]. After cellular stimulation, the phosphorylation, ubiquitination, and subsequent proteolysis of I κ B α in proteasomes enables NF- κ B to translocate into the nucleus^[5-8], where it regulates the transcription of NF- κ B-response genes by interacting with κ B binding sites^[9,10]. Recently, abundant evidence has implicated cellular NF- κ B transcription factors in the control of apoptosis in many systems. It has been suggested to be associated with increased survival in many tumor cells. A number of studies implicated NF- κ B in apoptosis resistant tumor cells^[11-16]. A superrepressor form of I κ B α contains a serine-to-alanine mutation at amino acids 32 and 36, which inhibits signal-induced phosphorylation and subsequent proteasome-mediated degradation of I κ B α . This I κ B superrepressor has been used to demonstrate that inhibition of NF- κ B induces apoptosis through a variety of cancer therapeutic agents and TNF- α ^[17,18]. Based on this, we have successfully cloned the I κ B α gene and constructed the superrepressor I κ B α M in Chinese. We have generated recombinant adenovirus AdI κ B α M, which will provide a solid basis for the study of I κ B α -mediated antitumor gene therapy. In the present study, we investigated whether the recombinant adenovirus induces the TNF- α -mediated apoptosis in the human hepatocarcinoma cell line (HepG₂) and *in vivo*.

MATERIALS AND METHODS

Cell culture

HepG₂ cells, HeLa cells and 293 cells were maintained in RPMI 1640 medium with 10% fetal bovine serum, penicil-

lin (100 mg/L), and streptomycin (100 mg/L).

Construction of recombinant adenovirus AdI κ B α M

The full-length cDNA of I κ B α superrepressor(I κ B α M), whose serines 32, 36 were mutated into the alanine, was kindly provided by Dr Bing-Rong Liu (from our laboratory). The I κ B α M was inserted into the adenoviral shuttle plasmid Track-CMV(a gift from Mr TC He, Molecular Oncology Laboratory, the University of Chicago Medical Center). It contains green fluorescent protein(GFP). We thus constructed the recombinant adenoviral plasmid pAdI κ B α M. However, pAdI κ B α did not have replacement of serines 32, 36 with alanines. Recombinant adenoviral plasmids were digested with *Pac* I. Then, the digested recombinant adenoviral plasmid was transfected into 293 cells with FuGENE™ 6 transfection reagent(Roche). Viral transfection products (AdI κ B α M, AdI κ B α) were monitored by GFP expression. The recombinant adenovirus was selected and purified using standard procedures^[19]. To obtain a large quantity of recombinant adenovirus (AdI κ B α M, AdI κ B α), the 293 cells were infected and grown for 48 h at 37°C. The infected cells were harvested and centrifuged using a tabletop centrifuge at 1000 r/min for 5 min. The infected cells were resuspended in PBS. The cells were lysed by 4 freeze-thaw cycles to release the virus. The virus was purified through 1 CsCl gradient. The purified recombinant adenovirus was then titrated by the plaque assay^[19], aliquoted, and stored at -70°C until use.

HepG₂ cell analysis in BALB/c nude mice

All mice whose age was 4 wk, weighing between 15-18 g were provided by SLACCAS, China. Number of females was equal to males. Approximately 2×10^5 HepG₂ cells in 200 μ L of PBS media were injected subcutaneously into the back of 40 BALB/c nude mice. All mice were maintained and handled under specific pathogen-free conditions at the Animal Center in Chongqing University of Medical Sciences. The tumors of 8 mice in each group were directly injected with 2×10^9 plaque-forming units(PFU) of AdI κ B α M. Eight mice were injected with 2×10^9 pfu of AdI κ B α . The third group of mice was injected with 2×10^8 pfu of AdI κ B α M and the fourth group with 2×10^7 pfu of AdI κ B α M. Groups of control mice were injected with phosphate buffered saline (PBS). All mice were injected 5 times in total, every other day, 100 μ L each time. After the injection was finished, on the fourth day all mice were killed. The tumor growth curve was drawn. The volume of tumor was calculated according to the formula: Tumor volume = Length \times Width² \times 0.4.

Hematoxylin and eosin staining

HE staining analysis was carried out for evaluation of cell necrosis and apoptosis. The percentage of cells undergoing apoptosis was determined as the number of HE-positive cells in at least 10 randomly selected vision fields of sections obtained from tumors in each group of mice.

TUNEL analysis of HepG₂ cell apoptosis in BALB/c nude mice

HepG₂ cell apoptosis in BALB/c mice was determined

using *in situ* apoptosis staining with the TUNEL staining kit according to the manufacturer's instructions (Roche). Tissues from the mouse tumor were fixed in 4% buffered paraformaldehyde for 4 h and decalcified in 59 mmol/L EDTA, pH 7.8, for 3 wk. The tissue was then dehydrated with different concentrations of ethanol and xylene, and embedded in paraffin. Tissue specimens were cut into 8- μ m sections and mounted onto glass slides. Slides were incubated with fresh proteinase K (20 mg/L)-streptavidin-labeled horseradish peroxidase (HRP) at room temperature for 10 min. The slides were covered with a cover glass and incubated at 37°C for 1 h in a humidified chamber. Nonspecific staining was blocked by incubating the slides with blocking buffer at room temperature for 30 min. The slides were incubated with a klenow labeling buffer in the presence of biotin-labeled dNTP for 1.5 h at 37°C. After washing 6 times with PBS, the slides were incubated with streptavidin-conjugated antibody at a 1:50 dilution in Tris buffer, pH 7.4 with PBS and developed by incubation with diaminobenzidine solution for 5 min. Cells undergoing apoptosis were identified by dark brown staining of the nuclei. For quantitative analysis of the percentage of apoptotic cells, a total of 10 random vision fields were evaluated.

Electron microscopy

Electron microscope analysis was carried out for evaluation of cell necrosis and apoptosis.

Statistical analysis

Student's *t*-test was used for testing the statistical significance of the differences between the groups. A *P* value of less than 0.05 was considered statistically significant.

RESULTS

Construction and analysis of recombinant adenovirus AdI κ B α M

The recombinant adenovirus plasmids were generated by cloning the I κ B α M/I κ B α construct into adenoviral shuttle plasmid Track-CMV. The recombinant adenovirus plasmids were digested with *Pac* I. The digested products were identified by 0.8% agarose gel electrophoresis (Figure 1A). pAdI κ B α M was digested into 2 fragments: one was about 3 kb, the other probably 30 kb; pAdI κ B α was digested into fragments of about 4.5 kb and 30 kb. The digested recombinant adenovirus plasmid was transfected into 293 cells. Two days after transfection, the fluorescence was observed (Figure 1B, C). The results showed that we have successfully cloned the I κ B α M/I κ B α gene into the plasmid Track-CMV, and the recombinant adenovirus AdI κ B α M/AdI κ B α was established. The virus was grown to a titer of 2×10^{12} pfu/L by purification over a CsCl gradient. AdI κ B α M could be expressed in HepG₂ cells after infection for 48 h (Figure 1D).

Induction of apoptosis of HepG₂ in BALB/c nude mice by AdI κ B α M *in vivo*

HepG₂ cells (2×10^5) were injected into the back of 40 BALB/c nude mice subcutaneously. After 2 wk, a tumor

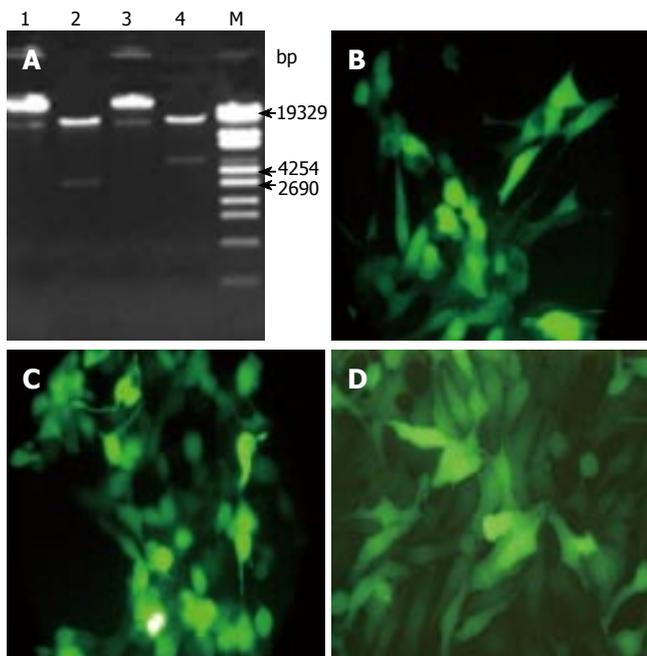

Figure 1 M: DNA Marker; Lanes 1, 3: Recombinant adenoviral plasmids pAd-IκBαM/pAd-IκBα un-cleaved with *Pac I*; Lanes 2, 4: Recombinant adenoviral plasmids pAd-IκBαM/pAd-IκBα cleaved with *Pac I*. **A:** Identification of recombinant adenoviral plasmids by restriction analysis; **B, C:** The pAd-IκBαM/pAd-IκBα was transfected into 293 cells and GFP expression was observed by fluorescence microscopy after transfection for 36 h; **B:** pAd-IκBαM; **C:** pAd-IκBα ($\times 200$). **D:** The recombinant adenovirus AdIκBαM infected into HepG2 and GFP expression was visualized by fluorescence microscopy after transfection for 48 h, ($\times 200$).

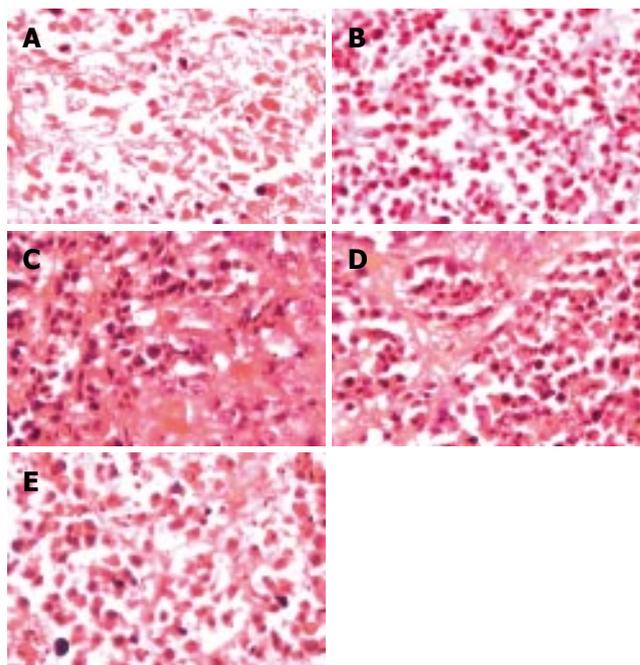

Figure 3 Morphological changes of HepG2 cells from mice treated with different methods were analyzed by HE staining. **A:** PBS control; **B:** AdIκBαM (2×10^{10}); **C:** AdIκBαM (2×10^{11}); **D:** AdIκBαM (2×10^{12}); **E:** AdIκBα (2×10^{12}).

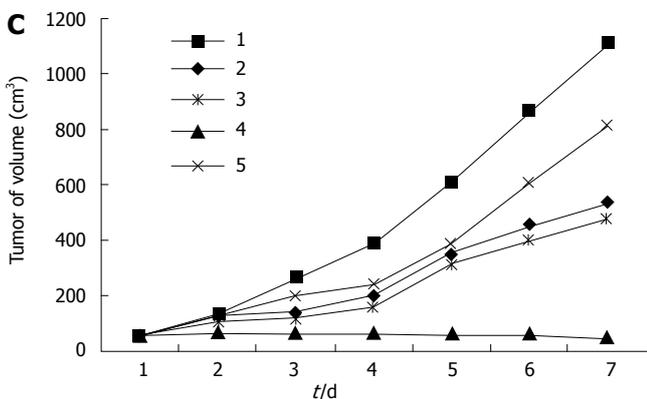

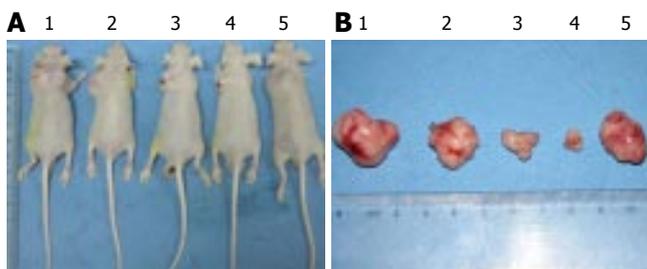

Figure 2 **A:** Mice were killed on the fourth day after different injections (1: Control PBS, 2: AdIκBαM 2×10^{10} , 3: AdIκBαM 2×10^{11} , 4: AdIκBαM 2×10^{12} , 5: AdIκBα 2×10^{12}); **B:** Tumors from mice were processed for histologic analysis. The sequence of mice is according to that in **A**; **C:** The tumor growth curve. The sequence of mice is according to that in **A, B**.

about 5 mm was observed in all mice. All mice were

killed on the fourth day after a different treatment in the different groups (Figure 2A). The tumors from all mice were processed for histologic analysis (Figure 2B). Tumor volumes were calculated (Figure 2C). No effect was observed in mice injected with control PBS. In contrast, BALB/c nude mice treated with AdIκBαM (2×10^{12} pfu/L) exhibited the most obvious inhibition of tumor growth, the tumor growth being stopped. Injection with AdIκBα (2×10^{12} pfu/L) had a slight effect on tumor growth at first, which then diminished.

HE staining and TUNEL analysis

There was a difference in the incidence of cell destruction by HE staining, which was exhibited by almost all mice (Figure 3). BALB/c mice injected with AdIκBα demonstrated a slight effect. In contrast, BALB/c mice treated with AdIκBαM (2×10^{12} pfu/L) exhibited extensive pyknotic nuclei and cell destruction. There were masses of cell necrosis in BALB/c mice injected with PBS, because ischemia in tumor resulted in cell necrosis. The number of apoptotic cells in the AdIκBαM (2×10^{13}) group was 16.8 ± 3.1 ($P < 0.01$); in the AdIκBαM (2×10^{11}) group 13.1 ± 2.3 ($P < 0.01$); in the AdIκBαM (2×10^{10}) group 10.1 ± 2.1 ($P < 0.01$); in the AdIκBα group 5.3 ± 1.8 ($P > 0.05$); in the PBS control group 3.8 ± 1.8 ($P > 0.05$). Moreover, to determine if AdIκBαM induced apoptosis *in vivo*, the tumor was sectioned and analyzed by *in situ* TUNEL staining (Figure 4). There was significant apoptosis of HepG2 cells infected with AdIκBαM (2×10^{12} pfu/L) but not of HepG2 treated with control PBS and some apoptosis in HepG2 cells injected with AdIκBα. Furthermore, there was a direct correlation between AdIκBαM dosage and cell apoptosis. The number of apoptotic cells in the AdIκBαM (2×10^{13}) group was 14.7

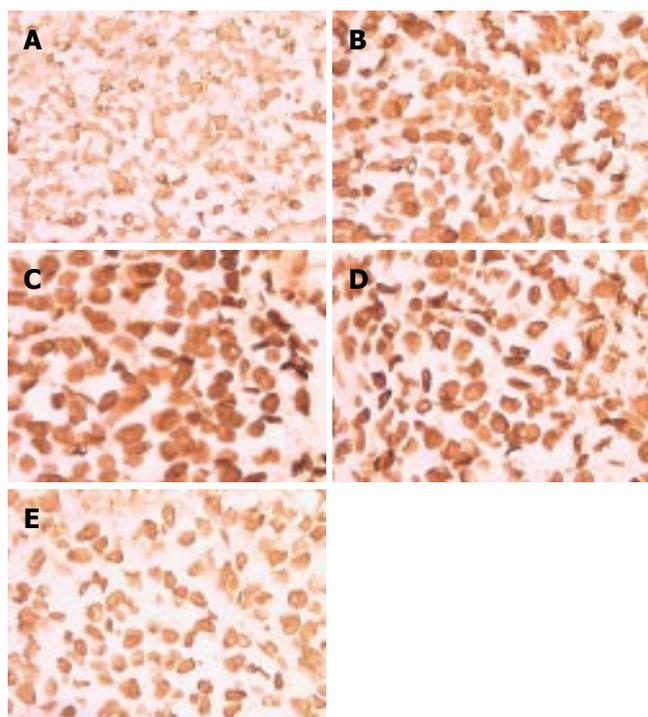

Figure 4 TUNEL was used to evaluate apoptosis of HepG₂ cells in BALB/c mice. **A:** PBS control; **B:** AdIκBαM (2×10^{10} pfu/L); **C:** AdIκBαM (2×10^{11} pfu/L); **D:** AdIκBαM (2×10^{12} pfu/L); **E:** AdIκBα (2×10^{12} pfu/L).

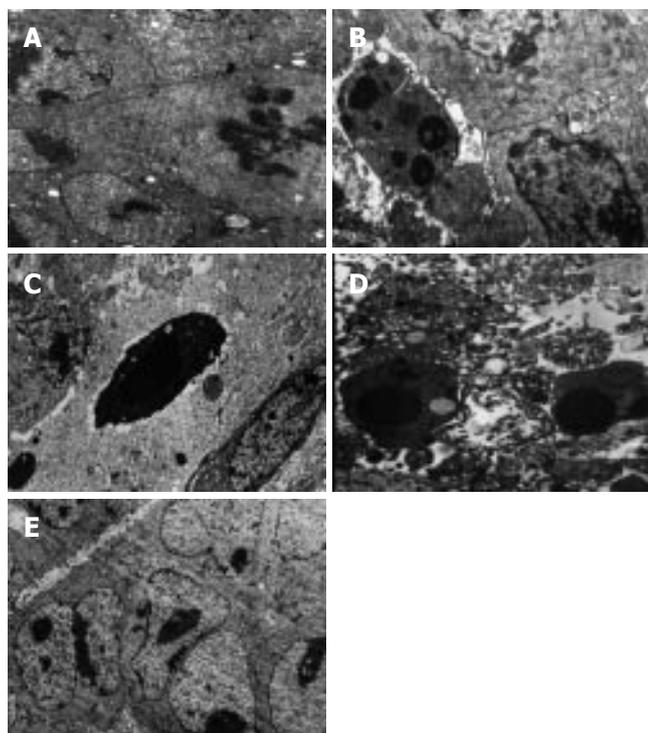

Figure 5 Electron microscopic analysis was used to evaluate apoptosis in HepG₂ cells in mice. **A:** PBS control ($\times 4000$); **B:** AdIκBαM 2×10^{10} pfu/L ($\times 6000$); **C:** AdIκBαM 2×10^{11} pfu/L ($6000 \times$); **D:** AdIκBαM 2×10^{12} pfu/L ($\times 6000$); **E:** AdIκBα 2×10^{12} pfu/L ($\times 4000$).

± 2.4 ($P < 0.01$); in the AdIκBαM (2×10^{11}) group 12.4 ± 2.2 ($P < 0.01$); in the AdIκBαM (2×10^{10}) group 8.3 ± 2.0 ($P < 0.01$); in the AdIκBα group 3.4 ± 1.6 ($P > 0.05$); in the PBS control group 4.2 ± 1.7 ($P > 0.05$).

Results of electron microscopy

Those cells with dark concentrated nuclei under EM were considered as apoptotic cells. In the AdIκBαM (2×10^{12}) group, there were 1-2 apoptotic cells in a random vision field ($\times 4000$ - 6000 , Figure 5A). Necrotic tissue or cells were observed around the apoptotic cells, but no proliferative phase was found. In the AdIκBαM (2×10^{11}) group, there were 0-2 apoptotic cells in a random vision field ($\times 4000$ - 6000 , Figure 5B). In the AdIκBαM (2×10^{10}) group, apoptotic cells could seldom be found (Figure 5C), whereas in the PBS control and AdIκBα group, there were few apoptotic cells, and many tumor cells were in the proliferative phase; however, necrotic tumor cells could also be found (Figures 5D, E). Necrotic tumor cells could be found in the AdIκBαM (2×10^{12}) group, probably because AdIκBαM could induce the tumor cells to apoptosis, and then to necrosis. Necrotic tumor cells could be found in the PBS control group probably because the tumor developed too fast and the blood supply was inadequate. Because the results of electron microscopy are the most reliable evidence of apoptosis, we could speculate that recombinant adenovirus could induce apoptosis of human hepatocarcinoma and inhibit the tumor cell proliferation.

DISCUSSION

TNF- α is an important cytokine in the promotion of growth and invasion of cells. It interacts with TNFR I and TNFR II. Signaling through both TNFR I and TNFR II can induce apoptosis^[20-22]. Interactions with TNFR I produce a proapoptotic signal by recruitment of TNFR I-associated death domain (TRADD) protein to the death-inducing signaling complex (DISC) of the TNFR I timer^[23,24]. TRADD recruits the Fas-associated death domain (FADD), which in turn, recruits caspase 8 and signals apoptosis^[25]. Simultaneously, an anti-apoptosis pathway involves recruitment of cellular LAP (cLAP), receptor interactive peptide (RIP), and TNFR-associated factor 2 (TNFR2), which leads to activation of NF- κ B-inducing kinase (NIK)^[26]. This results in phosphorylation of IκBα and IκBβ and translocation of NF- κ B to the nucleus. This second signal predominates in hepatocarcinoma, and NF- κ B translocation to the nucleus plays a role in transcription of several genes, including TNF- α , interleukin-1β, and IL-6, as well as collagenase, stromelysin, and adhesion molecules^[27,28]. At the same time, NF- κ B translocation inhibits apoptosis in many cell types, including tumor cell lines. HepG₂ cell line, like other cell lines, does not undergo apoptosis in response to TNF- α . Therefore, we propose that TNF- α acts as a growth factor in the HepG₂ cell line, as well as induces production of cytokines and invasive enzymes. Taken together, it implies that NF- κ B may play a role in preventing maximal apoptotic killing in treatment regimens such as TNF, radiation therapy, and certain chemotherapeutic agents. Resistance to anticancer therapies appears to be mediated by resistance to apoptosis. Therefore, modulation of NF- κ B activity could potentially lead to improved cell killing in the HepG₂ cell line and *in vivo*. Based on this understanding, we have successfully constructed the superrepressor of NF- κ B (AdIκBαM), in which 32, 36

serines were replaced with alanines and could not be phosphorylated by NIK.

The studies by Duffey *et al.*^[29] demonstrated that human head and neck squamous carcinoma cell transfected with I κ B α M was significantly restrained. The results of our study with AdI κ B α M showed that the HepG₂ cell line could be sufficiently infected with this recombinant adenovirus. Furthermore, I κ B α M could be expressed stably in HepG₂ cells. This was especially prominent with induction by TNF- α . Overexpression of mutated I κ B α by an AdI κ B α M construct resulted in inhibition of nuclear translocation of NF- κ B after TNF- α stimulation of HepG₂ cells. Under these conditions, the HepG₂ cell underwent extensive apoptosis in response to TNF- α *in vitro*. There was distinct apoptosis in HepG₂ cells treated alone with AdI κ B α M and little apoptosis treated with AdI κ B α and no apoptosis treated with PBS. This indicated that AdI κ B α M could facilitate or induce apoptosis in HepG₂ cells *in vitro*. There are histocyte cells and T cells in BALB/c nude mice, and the BALB/c mice may contain TNF- α *in vivo*. In light of the results of the experiment *in vitro*, we did not use TNF- α *in vivo*. BALB/c mice treated with AdI κ B α M (2×10^{12} pfu/L) exhibited the most extensive inhibition of tumor growth. In contrast, no effect was observed in mice injected with PBS and a slight effect in mice treated with AdI κ B α . Mice treated with AdI κ B α M (2×10^{12} pfu/L) underwent extensive apoptosis *in vivo*. However, there was little apoptosis in mice treated with AdI κ B α (2×10^{12} pfu/L). In this study, we focused particularly on the suppression of tumor growth and the induction of cell apoptosis by the recombinant adenovirus. Although various degrees of necrosis could be observed by HE staining, more work should be done on whether the recombinant adenovirus could lead to tumor death through inducing the damage of tumor blood vessels. Meanwhile, we should pay more attention to the toxicity of recombinant adenovirus, the first-pass effect of liver, the antigenicity and the targeting of recombinant adenovirus.

In conclusion, the AdI κ B α M is expressed in HepG₂ cell effectively and stably. It could inhibit the activity of NF κ B, and cause increased apoptosis as well as suppression of liver tumor.

Abstract

AIM: To assess the efficacy of triple therapy (peginterferon or high dose standard interferon, plus ribavirin and amantadine) in nonresponders to prior combination therapy.

METHODS: A total of 196 patients were enrolled in a multicenter, open, randomized study. Patients were given 180 µg/wk of peginterferon-alpha-2a (40 kDa) plus ribavirin (800-1000 mg/d) and amantadine (200 mg/d) for 48 wk (group A) or interferon-alpha-2a (6 MU/d for 4 wk, 3 MU/d for 20 wk, and 3 MU tiw for 24 wk) plus ribavirin (800-1000 mg/d) and amantadine (200 mg/d) for 48 wk (group B).

RESULTS: Overall sustained virologic response (SVR) was 26.6% (32.1% and 19.5% in group A and B, $P = 0.057$). Baseline ALT >120 UI/L (OR 2.4; 95% CI:1.11 to 5.20; $P = 0.026$) and HCV RNA negativity after 12 wk (OR 8.7; 95% CI: 3.87 to 19.74; $P < 0.0001$) were independently associated with SVR. Therapy discontinuation occurred less frequently in patients treated with peginterferon than standard interferon ($P = 0.036$).

CONCLUSION: More than 25% of nonresponders to combination therapy can eradicate HCV infection when retreated with triple therapy, especially if they have a high baseline ALT and are treated with pegylated interferon.

INTRODUCTION

While advances in the treatment of HCV chronic hepatitis have markedly improved outcomes for treatment-naïve patients, a large number of patients still fail to eradicate HCV infection^[1-4], and improving the re-treatment success rates of these nonresponsive patients remains a key challenge in hepatitis care^[5-7]. It has been reported that 12%-20% of patients who did not respond to standard interferon (IFN) monotherapy can achieve a sustained response when retreated with high doses of interferon plus ribavirin (RBV)^[8-12]. However, the most effective treatment strategies for patients who fail to respond to combination therapy have yet to be established, and results for re-treatment with pegylated interferon and ribavirin in these patients are generally more variable and less positive^[13-17]. The results can also be difficult to interpret since most of the available data derive from studies that included both relapsers and nonresponders to different therapeutic schedules. However, considering the high number of patients who do not respond to combination therapy, the need for new antiviral re-treatment regimens becomes evident.

It has recently been suggested that the addition of amantadine (AMA) to interferon and ribavirin (triple therapy) may improve the therapeutic efficacy of combination therapy, possibly by potentiating the antiviral activity through interleukin production^[18]. Amantadine has an intrinsic antiviral activity against influenza A virus by blocking its cellular internalization and possibly interferes with the replication of other viruses including HCV^[19-21]. Results on the use of triple therapy in patients with HCV chronic hepatitis are conflicting. A recent meta-analysis^[22] reported that triple therapy was of no advantage compared to standard combination therapy in treatment-naïve

patients or in relapsed patients^[23,24], whereas it markedly improved the sustained virologic response in nonresponders to interferon monotherapy^[25-27]. The efficacy of triple therapy in nonresponders to combination therapy has primarily been investigated in only a small series of patients, making it difficult to draw defined conclusions from these data on the use of triple therapy in such patients^[28-32]. A recent study in a larger patient population of nonresponders ($n = 200$) found a higher sustained virological response in patients receiving triple therapy (24%) *vs* combined therapy (16%), although the difference was not statistically significant^[33].

The aims of this multicenter, randomized study carried out in a well-selected series of patients nonresponsive to combination therapy were (1) to define the rate of sustained virological response in patients previously nonresponsive to combination therapy, when retreated with triple therapy (consisting of recombinant interferon or peginterferon (PegIFN) plus ribavirin and amantadine); (2) to assess whether PegIFN is superior to a high daily dose of IFN when used in a triple therapy regimen; and (3) to compare the tolerability, side effects and adherence to therapy in patients treated with the two different schedules.

MATERIALS AND METHODS

From February 2001 to June 2002, 196 patients aged between 18 and 65 years were included in this multicenter cooperative study. All patients had to be nonresponders to interferon plus ribavirin given for at least 24 wk. Patients who had previously been treated with interferon alone or who had received combination therapy for a shorter period were excluded from the study. Patients were recruited by 21 Liver Centers operating in 21 General Hospitals sited in Lombardy (North of Italy) and belonging to the Gruppo Epatologico Lombardo (GEL). A noncompetitive recruitment was employed and each center had to enroll at least 5 patients. The failure to respond to previous combination therapy was defined as absence of normalization of transaminases and/or detectable serum HCV RNA level after 24 wk of therapy. A washout period of at least 6 mo from the end of therapy to inclusion in this study was required. For inclusion, patients had to fulfill the following criteria: (1) persistent transaminase elevation throughout the previous 6 mo; (2) a liver biopsy taken within the past 18 mo showing histological findings compatible with chronic hepatitis or cirrhosis; (3) serum HCV RNA positive by quantitative polymerase chain reaction (PCR) test (second-generation Amplicor HCV, Roche Diagnostic System, Basel, Switzerland). Patients were excluded from the study if one of the following criteria were present: (1) decompensated cirrhosis; (2) co-infection with human immunodeficiency virus; (3) positivity for HBsAg; (4) autoimmune hepatitis; (5) alcohol abuse (daily alcohol intake > 60 g in males and > 40 g in females); (6) haemoglobin concentration less than 120 g/L in women and 130 g/L in men; (7) white cell count less than 3×10^9 /L, platelet count below 100×10^9 /L; (8) moderate/severe depression or other psychiatric diseases; (9) seizure disorders; (10) cardiovascular, respiratory or renal clinically manifested diseases; (11)

hemoglobinopathies; (12) poorly controlled diabetes mellitus; (13) immunologically mediated disease; (14) ultrasonographic evidence of focal liver lesions.

Study design

This was a multicenter, open-label, randomized, parallel-group study. Randomization was centralized and patients were stratified by HCV genotype (genotype 1 *vs* other genotypes).

Patients were randomized to receive peginterferon- α -2a (Pegasys; Roche, Basel, Switzerland) at the dose of 180 mcg once a wk for 48 wk (Treatment A) or interferon alfa-2a (Roferon; Roche) at the dose of 6 MU/d for 4 wk followed by 3 MU/d for the next 20 wk and 3 MU tiw until the end of the study (wk 48) (Treatment B). Both groups received ribavirin (Copegus, Roche, Basel, Switzerland) at the dose of 800 mg (for patients weighing less than 75 kg) or 1000 mg (for patients weighing 75 kg or more) and amantadine (Mantadan; Boehringer Ingelheim, Florence, Italy) at a total daily dose of 200 mg. The treatment period lasted 48 wk, with a 24-wk follow-up period. Sustained virological response was defined as persistent negative HCV RNA at 6 mo after completion of therapy. Patients were considered nonresponders and therapy was stopped if HCV-RNA was still positive at 24 wk of therapy.

Basal laboratory assessment consisted of liver function tests, hematologic tests, renal function tests, autoantibodies (ANA, AMA, ASMA, antiLKM), alphafetoprotein, serum iron, transferrin and ferritin, HBsAg, anti-HBc. Quantitative HCV RNA was measured by standardized PCR assay with a lower limit of detection of less than 1×10^6 copies/L (second-generation Amplicor HCV Monitor, Roche), qualitative HCV RNA was measured by a standardized PCR assay with a lower limit of detection of 0.1×10^3 copies/L (second-generation Amplicor HCV, Roche Diagnostic System). Determination of infecting HCV genotype was performed in serum samples prior to therapy using Innolipa, Genetics Technique (Innogenetics, Belgium/Bayer Diagnostics, USA).

Patients were clinically evaluated at regular intervals: 15, 30, 45 and 60 d after the first dose of treatment and every month thereafter until the end of the study. Biochemical tests were performed at 15 and 30 d and at monthly intervals until the end of treatment and every 3 mo during follow-up. During treatment, HCV-RNA was assayed after 12, 24, 36, and 48 wk of therapy and after 12 and 24 wk from the end of the treatment. At 12 and 72 wk, the serum HCV RNA level was assayed by qualitative analysis.

Histology

Liver biopsies were formalin fixed, embedded in paraffin and stained by hematoxylin-eosin, reticulin and Masson's trichrome method. Histologic diagnosis was made by one independent pathologist and classified according to the internationally accepted criteria as chronic hepatitis (mild, moderate or severe) or cirrhosis. Inflammatory activity (grading) and fibrosis (staging) were semi-quantified using the Ishak scoring system^[34]. Local institutional committees of participating hospitals approved the study protocol and all amendments. All patients provided written informed

consent. All the study procedures were in accordance with the principles of the Helsinki Declaration.

Primary and secondary endpoints

Clearance of HCV RNA at the end of the 6-mo follow up period was the primary end-point. Safety, adherence to therapy and therapy interruption were considered as secondary end-points.

Safety assessment

Safety was assessed by physical examinations, laboratory tests and spontaneous reports of clinical adverse events. According to the study protocol, Peginterferon- α -2a dose modification to 135, 90 or 45 mg/wk and ribavirin dose reductions were allowed in patients with clinically significant adverse events or laboratory abnormalities, including hematological toxicity as manifested by the hemoglobin level of less than 100 g/L, white cell count of less than 2.5×10^9 /L, granulocyte count of less than 1×10^9 /L, and platelet count of less than 70×10^9 /L. Therapy was discontinued in patients with neutrophils below 0.7×10^9 /L, Hb below 85 g/L, and platelets below 50×10^9 /L. Adherence to treatment was considered when drug consumption (either pegylated/standard IFN or ribavirin or both) was higher than 70% of the scheduled dose for a time period longer than 70% of the scheduled time.

Statistical analysis

It was calculated that at least 100 patients per group were needed to detect a difference of 20% in the proportion of SVR between treatment A and treatment B with an alpha error of 0.05 and study power (beta error) of 0.8. Summary statistics (no. of cases, mean, median, standard deviation, minimum and maximum) were calculated for continuous variables, and the number and percentage of patients in each category were provided for categorical data. The treatment comparison of interest was the recombinant interferon- α -2a plus ribavirin plus amantadine against peginterferon- α -2a plus ribavirin plus amantadine. Differences between the treatments were assessed by the Cochran-Mantel-Haenszel test stratified according to HCV genotype (HCV genotype 1 *vs* other genotypes). The relationship between patients' baseline characteristics and SVR was examined by logistic regression analyses. Univariate logistic regressions were used to confirm the importance of previously identified prognostic factors. To assess the independence of these factors, a backward elimination procedure was then undertaken using the factors that were significant in the univariate analyses. A log-linear model was used to investigate the interactions between HCV-RNA eradication after 12 wk of therapy and the variables predictive of sustained virologic response. All *P* values reported are two-sided.

All patients who received at least one dose of study medication were included in all efficacy analyses, and if they had undergone at least one safety assessment after baseline, they were included in the safety analysis. Patients with missing data in the primary or secondary efficacy endpoints were considered as nonresponders.

RESULTS

Two hundred thirty two consecutive nonresponder patients to combination therapy were considered eligible for this study. Thirty six patients were not randomized because of refusal of therapy (23 cases) or inability to attend a regular follow up (13 cases). One hundred six patients were randomized to receive peginterferon- α -2a plus ribavirin and amantadine and 90 to receive interferon α -2a plus ribavirin and amantadine. Eight patients randomized to treatment B refused to take the study drugs and were not further evaluated (Figure 1). The characteristics of patients at baseline are shown in Table 1. None of the variables considered was statistically significantly different between the two groups.

A SVR of 26.6% was obtained in the overall series of patients. However, when the two treatments were compared, a better but not significant SVR was achieved in patients receiving PegIFN than in those receiving high doses (daily doses for 6 mo) of standard interferon (32.1% *vs* 19.5%, *P* = 0.057). The better response in patients treated with PegIFN was present at all on-treatment time intervals (Figure 2). The rate of sustained response in the 30 patients with cirrhosis was 30% with no difference between patients treated with PegIFN or standard IFN.

Univariate analysis performed on non-missing data, considering the overall series of patients, showed that genotype non 1, higher grade score and baseline ALT were significantly associated with sustained virologic response (Table 2). Patients younger than 40 years had a significantly better response when treated with PegIFN than standard IFN (48% *vs* 11%, *P* = 0.017). Also patients with fibrosis less than 3 and those with viremia higher than 2 million

copies had a significantly better response when treated with PegIFN than standard IFN (respectively 38% *vs* 18%, *P* = 0.018 and 46% *vs* 7%, *P* = 0.029) (Table 3).

The chance of achieving a sustained response was significantly higher in patients who were HCV RNA negative as compared to those who were HCV RNA positive at 12 wk of therapy (39/78, 50% *vs* 11/110 10%, *P* < 0.0001).

To examine the influence of potentially important prognostic factors on SVR, factors known to affect response (HCV genotype, age, BMI, stage and grade, ALT value, previous IFN total dose taken, biochemical and virologic response after 12 wk of treatment) were first examined individually by univariate logistic regression analysis for each factor for all treatment groups combined. ALT (< 120 UI/L *vs* > 120 UI/L), the biochemical and the virologic response at wk 12 were associated with SVR (*P* < 0.10). These predictive factors were entered in the final backward regression analysis. Two factors independently and significantly increased the odds of achieving a sustained virologic response: a baseline ALT value greater than 120 UI/L (odds-ratio 2.40; 95% CI: 1.11 to 5.20; *P* = 0.026), and the virologic response after 12 weeks of therapy (odds-ratio 8.75; 95% CI: 3.87 to 19.74; *P* < 0.0001). Logistic regression analysis was used to characterize further the relation between SVR, patients' characteristics at baseline, biochemical and virologic response after 12 wk of treatment, and the study treatments. In the final backward regression analysis were entered the treatment given, the ALT value at baseline, the biochemical and the virologic response after 12 wk of treatment. The model confirmed that the baseline ALT value greater than 120 UI/L and the virologic response after 12 wk of treatment were prognostic factors that significantly increased the odds of achieving a sustained virologic response. Odds-ratios and their 95% confidence intervals and the associated p-values were equal to those obtained in the logistic regression model reported above.

Twenty-seven patients discontinued the study treatments: 10 in group A and 17 in group B (9.4% *vs*

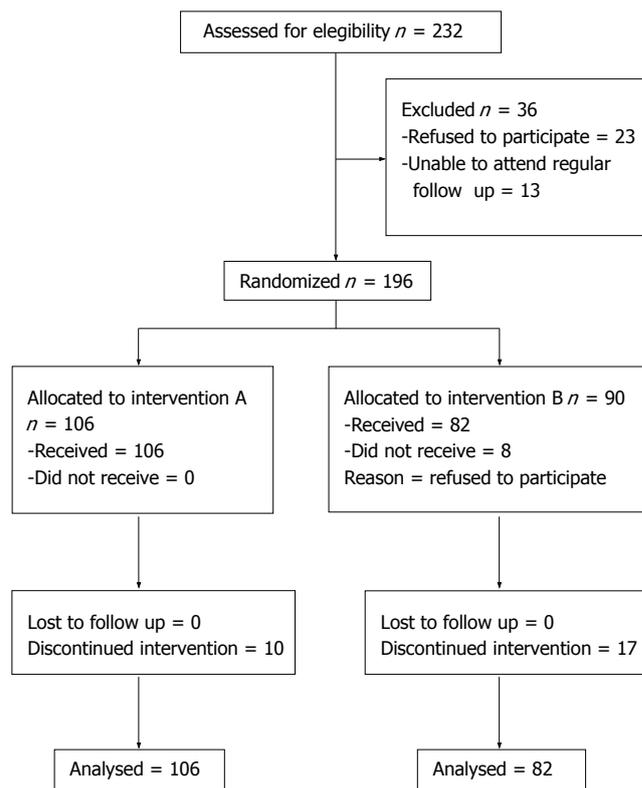

Figure 1 Progress of patients through the trial showing details of patients' recruitment, enrollment, randomization and therapy withdrawal until completion of the study.

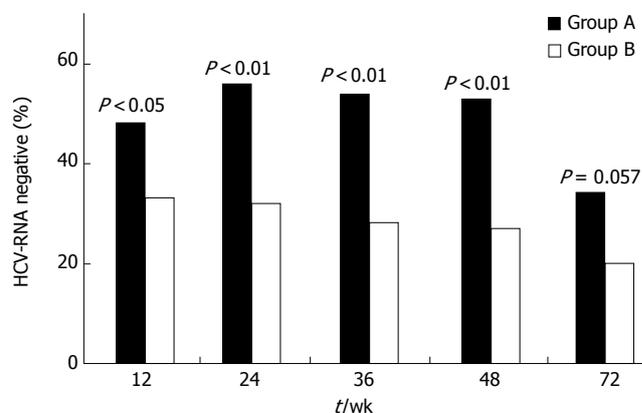

Figure 2 Comparison of virologic responses over time in patients treated with peginterferon plus ribavirin and amantadine (Group A), and with standard interferon plus ribavirin and amantadine (Group B). Percentages of patients negative for HCV-RNA during and after therapy with peginterferon plus ribavirin and amantadine (black bar) or standard interferon plus ribavirin and amantadine (white bar) are shown. Significance between the two treatments is shown at each time interval.

20.7%, *P* = 0.036). The reasons for discontinuation are reported in Table 4. Dosage reduction, reported in 30 patients (17 treated with PegIFN and 13 with standard IFN), was related to hematological alterations in 12 of the patients who received pegylated interferon and in 7 of those treated with standard interferon. Dermatological manifestations (mainly reported in patients treated with pegylated interferon) and cephalgia were the causes of dosage reduction in the remaining patients. Adherence

lower than 70% in the first 24 wk of therapy was observed in 8/106 (7.5%) patients in treatment A and in 8/82 (10%) in treatment B. No significant difference in the rate of response was observed between patients who did or did not reduce therapy.

DISCUSSION

This is the first randomized study to compare the efficacy of two triple therapy regimens-recombinant interferon α -2a either standard or pegylated, in combination with ribavirin and amantadine-in a well-selected series of patients nonresponsive to previous treatment with interferon and ribavirin. Our data demonstrate that after 12 mo of treatment, a sustained virologic response is obtained in a surprisingly high number of these difficult-to-treat patients. Better results in terms of sustained response (32% vs 19% of SVR) were observed in patients treated by pegylated interferon than in those treated by a high daily dose of standard interferon. Baseline elevated ALT level and undetectable serum HCV RNA at wk 12 of therapy were the independent predictors of sustained response, irrespective of the interferon used (pegylated interferon or high dose standard interferon). As a whole, triple therapy was well tolerated and safe, with a higher frequency of therapy discontinuation in patients treated by standard interferon than in those treated by pegylated interferon.

The overall rate of SVR observed in the present study of nonresponders to combination therapy (standard interferon plus ribavirin), most of whom had been already submitted to several treatments, is higher than that generally observed in previously reported studies. The results are even more impressive when considering patients treated by pegylated interferon. In particular, patients with high viral load seemed to respond better when treated with pegylated interferon, even if the small number of cases in which basal viral load was available does not allow definite conclusions to be drawn. Only a few studies have been carried out to assess the efficacy of retreatment in patients

nonresponsive to combination therapy and most of them included small series of patients and did not disaggregate relapsers from true nonresponders^[24,25,27]. Schiffmann *et al.*^[14] reported an overall SVR rate of 18% after retreatment for 48 wk with PegIFN plus RBV, and even lower rates were observed in patients with unfavourable predictors such as genotype 1 and/or high viral load. Teuber *et al.*^[28] reported a 22% SVR in previous nonresponders either to interferon or combination therapy when retreated with triple therapy including amantadine, however, the SVR rate dropped down to 12% in those patients who had previously been given two or more courses of antiviral treatment. Typically, SVR rates in nonresponders to combination therapy retreated with triple therapy have averaged approximately 12%^[29-32], although in a recent placebo-controlled study the SVR with amantadine triple therapy was 24%^[33], while in a small group of genotype 1, nonresponsive patients without cirrhosis, a SVR of 42% was reported^[35].

We cannot exclude that a selection bias may partially explain the high rate of response found in our study. Although the main clinical and virologic characteristics (age, prevalence of genotype 1) of our patients are those usually observed in nonresponders to combination therapy, in our series the prevalence of cirrhosis was only 16% and the majority of patients had a fibrosis stage lower than 3 according to the Ishak score, differing from Schiffman's^[14] study which included only patients with bridging fibrosis or cirrhosis. However, we observed a high SVR (30%) in patients with cirrhosis (stage 5 and 6) by the Ishak score and no significant difference in sustained response between patients with or without cirrhosis. We are therefore more prone to think that the higher antiviral efficacy found in our study is more likely linked to the addition of amantadine to combination therapy. In keeping with our results Maynard *et al.*^[33] demonstrated that 24% of nonresponders treated by triple therapy achieved an SVR of 16% of those treated by double therapy. The mechanism by which amantadine enhances the antiviral effect of interferon and ribavirin is unclear and remains largely speculative. It is well known that amantadine may act as an antiviral drug and its synergistic action in combination with IFN and RBV may function through the modulation of the host immune-response^[36]. Although the mechanism

underlying the potential synergism between these drugs is not clear, our results suggest that triple therapy, in particular when PegIFN is used, has to be considered as a valid option in nonresponders to combination therapy since it allows a sustained viral clearance in about one third of otherwise nonresponsive patients.

In keeping with the results obtained in treatment-naïve patients and in relapsers^[1-4], PegIFN achieved a better response than standard interferon even though the latter was administered at a high daily dosage. Although the difference in SVR observed between the two treatment groups did not reach a statistical difference ($P = 0.057$), our results strongly suggest that in nonresponders, pegylated interferon should represent the first choice interferon in retreatment strategies. Our suggestion is further strengthened by the evidence of a lower incidence of therapy discontinuation in patients treated with PegIFN than in those treated with high dose standard interferon.

Baseline ALT value and undetectable serum HCV RNA at wk 12 of therapy were the variables independently associated with sustained response. Unexpectedly, HCV genotype did not emerge as an independent predictor of response by univariate analysis. In fact, in the present series, although genotype 1 patients responded less well than those with other genotypes, the difference did not maintain the significance at multivariate analysis. One possible explanation of this discrepancy is that the previous treatments may have selected patients in whom several and possibly new mechanisms of therapeutic resistance have emerged over time. In the present series the SVR in patients with genotype 1 was 22% (26% and 17% in those treated with PegIFN or standard IFN, respectively), a rate that is markedly higher than reported in other studies^[14,37]. Interestingly, in treatment-naïve patients infected with genotype 1 the addition of amantadine to interferon therapy also led to an increased rate of SVR^[38]. Although the problem remains of whether or not the retreatment of genotype 1 nonresponders is justified in terms of cost-efficacy^[39], at the moment triple therapy including amantadine should be regarded as the most useful regimen to be proposed for these patients.

In the present study the addition of amantadine did not negatively affect the safety profile of combination therapy. In fact, triple therapy was found to be safe and well tolerated in the large majority of patients and the frequency and type of side effects did not differ from that observed in other series of nonresponders treated with standard or pegylated interferon plus ribavirin^[1,2,40,41]. The higher rate of treatment withdrawal in patients treated with high dose standard recombinant interferon than in those receiving pegylated interferon parallels the results observed in treatment-naïve patients receiving pegylated interferon when compared to high dose induction therapy^[42]. Interestingly, in our study, only two patients experienced depression severe enough to require treatment discontinuation. It is possible that the addition of amantadine, which is known to possess antidepressant properties^[43,44], may have decreased the overall incidence of depression, which is often the cause of premature therapy withdrawal. This is another relevant aspect that, in association with the low cost of amantadine, supports the

use of triple therapy in nonresponsive patients.

Although our study was not specifically designed to assess the predictive value of virologic response, some information can be drawn. Undetectable serum HCV RNA at wk 12 of therapy was the strongest independent predictor of SVR, in fact 50% of the patients who were HCV-RNA negative after 12 wk of treatment and 10% of those who were still positive, became sustained responders. In particular, the predictive negative value (90%) observed in our series at week 12 is slightly lower than that usually observed in treatment-naïve patients receiving combination therapy^[45], suggesting that it may be more useful to wait until wk 24 before deciding whether to withdraw therapy. These findings further confirm that in this group of difficult-to-treat patients the variables and prognostic factors usually associated with response cannot be employed.

In conclusion, the present multicenter randomized study demonstrated that triple therapy, in particular employing pegylated- α -2a interferon plus ribavirin and amantadine, is an effective therapeutic option for patients nonresponsive to previous treatment with interferon plus ribavirin and can rescue at least one-fourth of these patients to sustained viral clearance. Although many questions remain regarding the role of amantadine in the treatment of HCV chronic hepatitis, these results, taken together with data from recent studies, provide encouragement for retreatment of nonresponders to combination therapy with triple therapy. Although our results need to be confirmed further in placebo-controlled studies, they seem to be particularly interesting when taking into account that addition of amantadine is low cost and safe and could offer hope to patients for whom no alternative therapies are available.

Abstract

AIM: To develop a PCR assay using mutant-specific primers to detect mutation of tyrosine-methionine-aspartate-aspartate (YMDD) motif of HBV to tyrosine-valine-aspartate-aspartate (YVDD) or tyrosine-isoleucine-aspartate-aspartate (YIDD).

METHODS: Cloned wild-type and mutant HBV sequences were used as templates to test the sensitivity and specificity of the assay. A variety of primer construction, primer concentration, dNTP concentration, and annealing temperature of primers were systematically examined. Pair primers specific to rtL180M and rtM204V were selected for YVDD detection. Primer specific to rtM204I with an additional 3'-penultimate base mismatched to both the mutant and wild-type sequence was selected for YIDD detection. We applied this assay to study YMDD mutants in 28 chronic hepatitis B patients before and after lamivudine treatment.

RESULTS: We could detect as little as 0.001%-0.00001% of mutant viruses coexisting in 10^8 - 10^9 copies of wild-type HBV using this assay. YMDD mutants were detected in 8 of 12 HBeAg-positive patients and 8 of 16 HBeAg-negative patients before lamivudine treatment. After treatment, two more patients in HBeAg-positive patients and seven more patients in HBeAg-negative patients developed YMDD mutations.

CONCLUSION: We developed a highly sensitive and specific assay for detecting YMDD mutants. This assay can be applied to monitor chronic hepatitis B patients before and during lamivudine treatment.

Key words: Hepatitis B virus; Lamivudine; Tyrosine-

INTRODUCTION

Hepatitis B virus (HBV) is one of the most common infectious diseases in the world. More than 300 million people worldwide are estimated to have chronic HBV infection. Ten percent of these patients will die as a direct consequence of persistent viral infection^[1]. Nucleoside analogue therapy allows safe, long-term suppression of HBV and is a major milestone in the treatment of chronic hepatitis B. Lamivudine, the first of these agents approved worldwide, effectively suppresses viral replication, reduces disease activity, improves liver histology, and delays clinical progression^[2-4]. However, the development of lamivudine resistant mutations occurs in 14%-32% of patients after 1 year of therapy^[5,6]. The longer the treatment is continued, the more frequently resistance is seen (65% at 5 years)^[7]. Lamivudine-resistant HBV is associated with mutations of the YMDD motif in the polymerase gene. The key mutations are the substitutions of methionine at the rtM204 (domain C) to either isoleucine (rtM204I, YIDD variant) or valine (rtM204V, YVDD variant)^[8,9]. The rtM204V variant is almost always accompanied by an additional rtL180M mutation in the domain B^[10,11].

Several assays, including DNA sequencing^[12], restriction fragment length polymorphism (RFLP)^[13,14], peptide nucleic acid (PNA) mediated PCR clamping^[15], line probe assay^[16,17], and oligonucleotide microarray^[18,19], have been developed to detect YMDD mutations. The best sensitivity achieved so far was 10^4 copies of variant in the mixture of 10^9 copies of the wild-type virus and 10^1 in 10^5 of wild-type^[15].

In this study, we developed a simple but highly sensitive and specific assay using mutant-specific primers to detect lamivudine-resistant mutations. We applied this method to detect YMDD mutants in chronic hepatitis B patients before and after lamivudine treatment.

MATERIALS AND METHODS

Clinical samples and method for extraction of HBV DNA

Serum samples were collected from 28 chronic hepatitis B patients who had histologically confirmed cirrhosis and had received lamivudine treatment for 12 to 48 mo. Informed consent was obtained from all patients according to the ethical guidelines of the 1975 Declaration of Helsinki. HBV DNA was extracted from serum using a DNA extraction kit (Qiagen, Hilden, Germany).

Subcloning of the HBV gene

Sera with wide-type HBV DNA, YVDD or YIDD mutants were amplified by PCR with a primer set (sense primer: 5'-GATGTGTCTGCGGCGTTTTA-3', antisense primer: 5'-CAGCAAAGCCCCAAAAGACCCAC-3'). The obtained PCR products (625bp, containing site codons rt180 and rt204) were then cloned into pOSI-T vector (GeneMark, Taichung, Taiwan) using the standard method.

Detection of YMDD mutation using PCR with mutant-specific primers

We used cloned YVDD, YIDD and wild-type HBV genomes as templates to determine the optimal conditions of mutant-specific PCR. A variety of primer construction (Table 1), primer concentration, dNTP concentration and annealing temperature of primers were systematically examined (data not shown). The primers finally selected were listed with boldface in Table 1. The single-step PCR for YVDD detection was carried out with the primers YVDD669 and YVDD758R in a 25 μ L reaction volume containing 10 mmol/L Tris HCl, pH 8.3, 50 mmol/L KCl, 2.0 mmol/L MgCl₂, 0.03 mmol/L of each dNTP, 2.5 pmol of each primer, 1.5 units of Taq polymerase (Viogene, Taipei, Taiwan). The PCR condition included initial denaturation for 3 min at 94°C, 48 cycles of amplification with denaturation at 94°C for 30 s, primer annealing at 57°C for 30 s, extension of primer at 72°C for 25 s, and final extension at 72°C for 1 min. The nest-PCR was performed with HBV376 and HBV1021R as outer primers. The first PCR was conducted in a 20 μ L reaction volume with 0.0375 mmol/L dNTP and 1 pmol of each outer primer. The PCR condition was initial denaturation for 3 min at 94°C, 30 cycles of amplification with denaturation at 94°C for 30 s, primer annealing at 53°C for 30 s, extension of primer at 72°C for 50 s, and final extension at 72°C for 2 min. One microliter of the first reaction was used for the second PCR. The second PCR condition was the same as the single-step PCR except the annealing temperature was 55°C. The single-step PCR for YIDD detection was carried out with primers HBV379 and YIDDR2T in the same reaction condition as for YVDD detection except the annealing temperature was 59°C. The first PCR of the nest-PCR for YIDD detection was performed in the same condition as for YVDD detection. One microliter of the first reaction was used for the second PCR. The second PCR was carried out in a 25 μ L reaction volume with 0.03 mmol/L of each dNTP, 2.5 pmol of each primer (HBV485 and YIDDR2T) and 0.1U of Perfect Match PCR enhancer (Stratagene, La Jolla, California, USA), 1.5 units of Taq polymerase. The reaction condition was initial one cycle of

94°C for 5 min, 62°C for 5 min and 72°C for 30 s, 48 cycles of amplification with denaturation at 94°C for 30 s, primer annealing at 62°C for 30 s, extension of primer at 72°C for 30 s, and final extension at 72°C for 1 min. The PCR products were subjected to electrophoresis in a 3% agarose gel.

HBV DNA quantification and Sequencing

HBV DNA quantification was performed using the Lightcycler real-time PCR assay^[20]. PCR amplification of the HBV genome was carried out using the same primers as subcloning of HBV DNA described above. PCR-amplified HBV DNA was purified and sequenced using specific sequencing primers and a commercial sequencing Kit (ABI Prism Dye Terminator Cycle Sequencing, Perkin Elmer, Warrington, UK). The sequencing reactions were analyzed on an automatic DNA sequencer.

RESULTS

We assessed the sensitivity and specificity of this method using mutant type and wild-type HBV plasmid. For single-step PCR, the detection limit was 10⁴ copies for YVDD variant or 8 × 10⁴ copies for YIDD variant (data not shown). For nest-PCR, the detection limit was up to 10¹ copies for both variants (Figure 1A, B). Wild-type HBV, even up to 10¹⁰ copies, was not detected using these mutant-specific primers for both single-step PCR (data not shown) and nest-PCR (Figure 1A, B). We then tested the mixture of wild-type and mutant HBV using nest-PCR. Various copies of wild-type plasmid (10⁷-10¹⁰ copies) were mixed with YVDD variant at the indicated concentrations (10¹-10⁴ copies). In the presence of 10⁸ wild-type sequences, a total of 10¹ copies of both variants could be detected (Figure 1A, B). A total of 10⁴ copies of YVDD variants or 10³ copies of YIDD variants were detected in the mixture of 10⁹ copies of the wild-type sequences (Figure 1A, B). Thus, the detection limit was

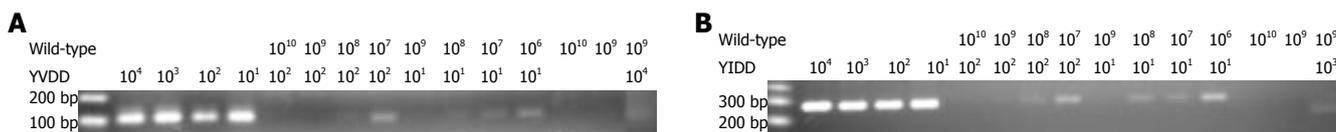

Figure 1 Sensitivity and specificity of the YMDD mutant detection by mutant-specific PCR. **A:** Various copies of wild-type sequence, YVDD mutant sequence, and mix of both sequences at the indicated concentrations. The left most lane contains molecular weight marker in base pair unit. The detection limit was 10¹ copies of YVDD mutant in 10⁸ copies of wild-type HBV or 10⁴ copies of YVDD mutant in 10⁹ copies of wild-type HBV; **B:** Various copies of wild-type sequence, YIDD mutant sequence, and mix of both sequences at the indicated concentrations. The left most lane contains molecular weight marker in base pair unit. The detection limit was 10¹ copies of YIDD mutant in 10⁸ copies of wild-type HBV or 10³ copies of YIDD mutant in 10⁹ copies of wild-type HBV.

We then applied this method to 28 chronic hepatitis B patients who had been treated with lamivudine for 12 to 48 mo (Table 2). Before treatment, there were 12 patients with positive HBeAg and 16 patients with negative HBeAg and positive anti-HBe. Among 12 HBeAg-positive patients, four were free of YMDD mutant, seven with YIDD mutant, and one with YVDD mutant. One developed HBeAg sero-conversion after treatment. Among 4 patients with initial negative YMDD mutant, two developed mixed mutation, and two remained free from YMDD mutation. Among 7 patients with initial YIDD mutant, three developed mixed mutations, and four remained with

YIDD mutation. The patient with initial YVDD mutant developed mixed mutation. Among 16 HBeAg-negative patients, before treatment, twelve were free of YMDD mutation, two with YIDD mutation, and two with mixed mutation. Among 12 patients with initial negative YMDD mutant, five developed YVDD mutation, one developed YIDD mutation, one developed mixed mutation, and five remained free of YMDD mutation after treatment. The other four patients, two with YIDD mutant, two with mixed mutation, remained with the same mutation. Conventional sequencing of post-treatment sera showed 11 cases of wild-type HBV, 8 cases of YVDD mutation, and 9 cases of YIDD mutation. Among 11 cases of wild-

type HBV, eight were wild-type, two were YVDD, one was YIDD, and one was mixed mutation by nest-PCR. Among 8 cases of YVDD mutation, four were YVDD and four were mixed mutation by nest-PCR. Among 9 cases of YIDD mutation, six were YIDD and three were mixed mutation by nest-PCR (Table 2). Overall, mutant-specific PCR agreed with sequencing on YMDD mutation detection, but was more sensitive in detecting additional mutations.

DISCUSSION

Taq DNA polymerases extend mismatches much less efficiently than correct matches. Depending on the nature of the mismatch composition, the elongation efficiency of the mismatched duplex can vary from 0.0001% to 0.1% of the elongation efficiency of the perfectly matched duplex^[21]. Reduced dNTP and primer concentration can increase the specificity of mutant-specific PCR^[22]. We have lowered 2-4 fold the dNTP and primer concentration of conventional PCR and compensated for the reduced efficiency by increasing amplification cycles. With this modified PCR condition, we found that in the presence of 10^6 to 10^7 copies of wild-type HBV DNA, a single 3'-end mismatch primer still showed a false positive result (data not shown). For the YVDD mutation, rtL180M mutation is almost always accompanied by an additional the rtM204V mutation^[10,11]. We therefore selected pair primers with 3'-end specific to rtL180M and rtM204V to detect YVDD mutation. For YIDD mutation detection, we designed primers containing a mutant-specific 3'-terminal base and a 3'-penultimate base mismatched to both the mutant and wild-type sequence. We checked 3 forward (YIDD2G, YIDD2A, and YIDD2C) and 3 reverse (YIDDR2T, YIDDR2A, and YIDDR2C) primer constructions. The YIDDR2T primer had the greatest specificity and sensitivity in detecting YIDD mutation. Besides, we add Perfect Match PCR enhancer to increase the specificity of the assay^[23]. The present assay had a detection limit of 0.0001%-0.00001%, which was better than that of PNA mediated PCR clamping (0.001%-0.0001%)^[15] and that of RFLP assay (1%-10%)^[13]. However, the latter two methods have the advantage of detecting both wild-type and mutant HBV simultaneously in one reaction. The choice of assay should depend on the context of the application.

Hepatitis flare can occur during lamivudine treatment because of the emergence of YMDD mutants. The serum titer of the mutant viruses during hepatitis flare is well above 10^5 copies/mL^[24]. The single-step PCR in this study only detected YMDD mutation at copy number greater than 10^4 , and can be applied in this clinical context. In fact, we have applied single-step PCR to check two cases of hepatitis flare during lamivudine treatment. It correlated well with HBV DNA quantification and sequencing (data not shown).

Because HBV employs reverse transcription to copy its genome, mutant viral genomes are found frequently. Under conditions of high levels of viral replication, it is likely that HBV mutations conferring resistance to lamivudine may pre-exist. Indeed, pre-existing YMDD mutants have been demonstrated in some lamivudine-naive asymptomatic

HBV carriers^[25] or chronic hepatitis B patients^[15]. The patients with pre-existing YMDD mutants were all positive for anti-HBe antibody^[15,25]. In this study, twelve patients were shown to have pre-existing YMDD mutants, and eight of them were HBeAg-positive. Seven cases with pre-existing mutation had a serum HBV DNA level greater than 10^8 copies/mL. However there were also cases with a high level of HBV DNA but without a pre-existing mutation. We suspect that with more sensitive detecting methods, more cases of pre-existing mutation will be demonstrated. The patients with a pre-existing mutation had persistent mutation or developed mixed mutation during treatment, but only five of them had a poor virological response. Whether patients with a pre-existing lamivudine-resistant mutation should be treated with other nucleoside analogues requires further prospective studies.

In conclusion, we have developed a sensitive and specific method using mutant-specific primers to detect the YMDD mutation. This PCR assay might be an effective procedure for monitoring chronic hepatitis B patients treated with lamivudine or screening them before starting this anti-viral therapy.

facts during the earlier time points of *H pylori* infection. This effect is possibly mediated by the ability of MHC class II to modulate the activation of the pro-apoptotic receptor Fas by blocking the recruitment of the accessory molecule FADD, and this delay in apoptosis induction could allow for prolonged cytokine secretion by *H pylori*-infected gastric epithelial cells.

Abstract

AIM: To investigate the role of MHC class II in the modulation of gastric epithelial cell apoptosis induced by *H pylori* infection.

METHODS: After stimulating a human gastric epithelial cell line with bacteria or agonist antibodies specific for MHC class II and CD95, the quantitation of apoptotic and anti-apoptotic events, including caspase activation, BCL-2 activation, and FADD recruitment, was performed with a fluorometric assay, a cytometric bead array, and confocal microscopy, respectively.

RESULTS: Pretreatment of N87 cells with the anti-MHC class II IgM antibody RFD1 resulted in a reduction in global caspase activation at 24 h of *H pylori* infection. When caspase 3 activation was specifically measured, crosslinking of MHC class II resulted in a marked reduced caspase activation, while simple ligation of MHC class II did not. Crosslinking of MHC class II also resulted in an increased activation of the anti-apoptosis molecule BCL-2 compared to simple ligation. Confocal microscope analysis demonstrated that the pretreatment of gastric epithelial cells with a crosslinking anti-MHC class II IgM blocked the recruitment of FADD to the cell surface.

CONCLUSION: The results presented here demonstrate that the ability of MHC class II to modulate gastric epithelial apoptosis is at least partially dependent on its crosslinking. Furthermore, while previous research has demonstrated that MHC class II signaling can be pro-apoptotic during extended ligation, we have shown that the crosslinking of this molecule has anti-apoptotic ef-

INTRODUCTION

H pylori infects over half of the people in the world. Seropositivity may reach 80%-100% in underdeveloped nations. This gram negative bacterium is a major contributor to chronic gastritis and peptic ulcer formation, and is strongly associated with gastric carcinoma and lymphoma^[1,2]. Gastric carcinoma remains the second most deadly form of cancer^[3]. While much is known about the clinical manifestations of *H pylori* infection, the methods by which this pathogen manipulates gastric epithelial cells in the host to its advantage are unknown.

Previous reports by our group have demonstrated that MHC class II expressed on the surface of gastric epithelial cells serve as a receptor for *H pylori*^[4,5]. A potential consequence of bacterial interaction with MHC class II proteins is the subsequent crosslinking of these molecules which may impact cellular responses key to the initiation and propagation of *H pylori* pathogenesis that results in tissue damage of the gastro-duodenal mucosa.

One such clinically significant cellular response to *H pylori* infection is apoptosis. The induction of apoptosis in MHC class II⁺ host cells able to direct the immune response would represent a mechanism by which the bacteria could impair local antigen presentation to T cells. Furthermore, induction of apoptosis would cause "leakiness" of the epithelium, leading to inflammation that could upregulate the

expression of *H pylori* receptors on surrounding cells. For example, IFN γ , an inflammatory cytokine produced by CD4⁺ T cells within the infected gastric mucosa, upregulates class II MHC expression in gastric epithelial cells. However, uncontrolled epithelial apoptosis would quickly lead to the destruction of the *H pylori* niche within the gastric mucosa. Thus, mechanisms by which this bacteria could moderate the host apoptotic response must also be considered.

Previous reports show that CD95 (Fas) plays an important role in *H pylori*-mediated apoptosis of the gastric epithelium^{6,7}. Once Fas is activated on the cell surface, the FADD (Fas associated death domain) protein is recruited to the cytoplasmic domains of the trimerized Fas on the plasma membrane. FADD is then responsible for the activation of caspase 8. However, the interaction between *H pylori* receptors and pro-apoptotic death receptors such as Fas has not been well investigated. This, combined with our previous data demonstrating the role of MHC class II in *H pylori* binding to gastric epithelial cells (GEC), suggests that the complex dynamics regulating apoptosis during infection might be due to either complementary or antagonistic interactions between multiple signaling receptors on the cell surface. Furthermore, the possibility that MHC class II crosslinking modulates pro-death accessory molecules within the cytoplasm must also be investigated. We hypothesize that MHC class II has differential, and possibly opposing, effects on epithelial cell apoptosis during *H pylori* infection depending on several factors, including crosslinking *vs* simple ligation, the duration of MHC class II interaction with the bacteria, and MHC class II interaction with other cell surface signaling molecules. More specifically, we suspect that complex surface crosslinking of MHC class II will have a distinctly different effect on the recruitment and activation downstream accessory and effector molecules, such as FADD and caspases, when compared to non-crosslinking ligation.

MATERIALS AND METHODS

Cell culture

The human gastric epithelial cell line N87 was obtained from ATCC and cultured in RPMI containing 10% fetal calf serum and supplemented with glutamine.

Bacterial culture

H pylori cag⁺ clinical isolate LC-11⁸ was grown on a blood agar base (Becton Dickinson) at 37°C under microaerobic conditions and harvested into Brucella broth containing 10% fetal bovine serum. Bacteria in broth were rocked gently overnight at 37°C under microaerobic conditions prior to centrifugation. *H pylori* was resuspended in PBS and concentration was determined by absorbance at 530 nm using a spectrophotometer (1 A = 2 × 10⁸ cfu/mL) (DU-65 Becton Dickinson Instruments, Fullerton, CA).

Antibodies

Monoclonal anti-human MHC class II IgM (clone RFD1) was obtained from Serotec, Raleigh, NC. Monoclonal

IgM antibody against CD-95 (clone IPO-4) used to induce apoptosis was obtained from Kamiya Biomedical Co., Seattle, WA. The hybridomas secreting anti-human MHC class II IVA-12 and L243 (mIgG) were obtained from ATCC and were used to produce ascites fluid in mice and the antibodies were purified with a protein G column. Anti-human CD95-PE was obtained from Becton Dickinson/Pharmingen, San Jose, CA. Alexa-conjugated secondary antibodies were from Molecular Probes Inc., Eugene, OR.

Global caspase activation assay

The global (non-specific) activation of caspases in our cell line was quantified using the Homogeneous Caspase Activation kit from Roche Applied Science, Indianapolis, IN. Cells were grown in serum containing media in 96-well plates at a seeding density of 10⁴ cells/well for 18 h prior to treatment. After treatment, the media was aspirated and a substrate-containing lysis solution was applied to the cells. After 2 h incubation at 37°C, the cleaved substrate product resulting from the action of activated caspases was quantitated using a fluorimeter (γ = 521 nm).

Caspase 3 and BCL-2 activation

Caspase 3 activation and BCL-2 expression were quantitated using the Human Apoptosis Cytometric Bead Array kit from Becton Dickinson, Franklin Lakes, NJ. The experiments were conducted according to the kit instructions. Briefly, bead populations with distinct fluorescent intensities were coated with antibodies specific for activated caspase 3 and BCL-2. The capture beads, sample lysates, and PE-conjugated detection reagent were incubated together to form sandwich complexes. After washing, the beads were run through a flow cytometer to generate MFI data, which was then analyzed with Becton Dickinson CBA Analysis Software. Sample data was normalized with specific protein standards to provide quantification of the proteins of interest.

Confocal microscopy

Cells were grown on Collagen I-coated tissue culture inserts (BD Biosciences) to 50%-75% confluency. After cell permeabilization and intracellular staining, the inserts were mounted on glass slides with coverslips. Images were obtained on a Zeiss LSM510 META advanced laser scanning confocal microscope (LSCM). Approximately 50 separate images were obtained at 0.5-0.6 micron increments for X-Z axis reconstruction.

Statistical analysis

Data is presented as the mean \pm SE and analyzed using Student's T test. Significance is defined as $P < 0.05$.

RESULTS

Global caspase activation assay

To determine the effect of MHC class II crosslinking at the cell surface on the activation of caspases, we cultured the gastric epithelial cell line N87 in the presence of 100 U/mL IFN γ for 48 h to induce the upregulation of

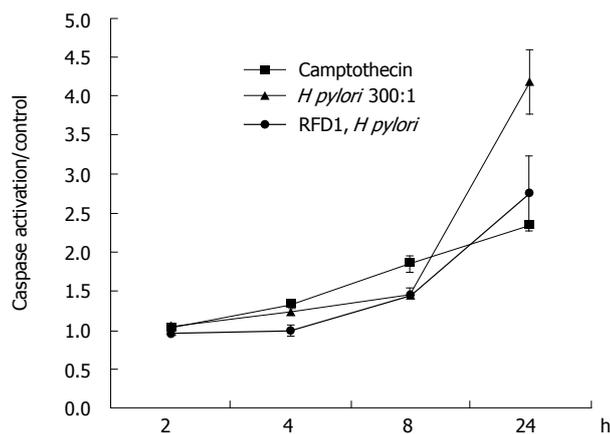

Figure 1 Total caspase activation was detected using a colorimetric assay. Values are expressed as the means of the treatments/control (untreated) samples.

surface MHC class II. Cells were then rested in serum containing medium alone for 2 d prior to bacterial and antibody treatment. Cells pretreated with antibody were exposed to RFD1 (10 mg/L) for 30 min prior to the addition of *H. pylori*. Camptothecin (10 μ mol/L) was used as a positive control for caspase activation and an isotype antibody, which had no effect on the cells. After 24 h of infection, crosslinking MHC class II prior to the addition of *H. pylori* significantly ($P < 0.05$) reduced global caspase activation compared to *H. pylori* infected samples with no pretreatment (Figure 1).

Apoptosis cytometric bead array

Caspase 3 is an effector caspase whose activation is central in the apoptosis pathway triggered by Fas trimerization. To specifically examine the activation of caspase 3 as a result of MHC class II ligation versus crosslinking, we used a cytometric bead array that incorporates antibodies to the activated form of caspase 3. Two experimental groups and one untreated, control group were used. (All groups were pre-treated with IFN γ to upregulate surface MHC class II). The first experimental group consisted of cells treated with a monoclonal IgG antibody cocktail specific to MHC class II. The purpose of this group is to mimic simple bacterial ligation to MHC class II. The second experimental group contained cells treated with biotinylated anti-MHC class II antibodies plus streptavidin. The purpose of this treatment group is to mimic complex MHC class II crosslinking by *H. pylori*. The untreated group was not exposed to *H. pylori* or antibodies. At 4 and 8 h treatment of N87 cells, crosslinking MHC class II with biotinylated anti-MHC class II IgG antibodies L243 and IVA12 resulted in a reduced activation of caspase 3 activation compared to ligating MHC class II with unbiotinylated cocktail. After 4 h of treatment, ligation of MHC class II resulted in a 103% increase in caspase 3 activation compared to just a 33% increase after crosslinking. At 8 h of treatment, crosslinking MHC class II resulted in a negligible increase in caspase 3 activation compared with control, while ligation with the antibody cocktail increased caspase 3 activation by 33% over control (untreated) samples (Figure 2).

The expression of the anti-apoptotic BCL-2 molecule

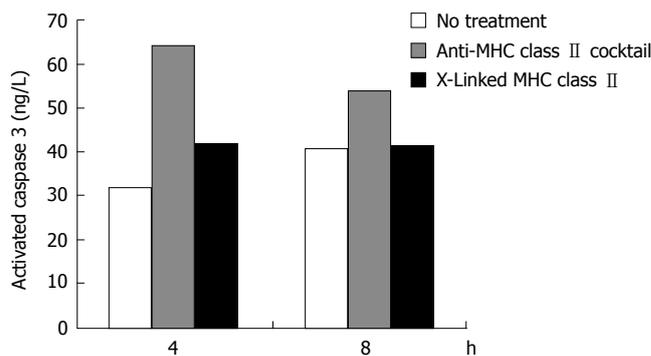

Figure 2 The effects of ligating versus crosslinking N87 cell surface MHC class II molecules on caspase 3 activation. Using the apoptosis cytometric bead array kit, beads exposed to the samples were run through a flow cytometer to obtain MFI data. These results were normalized to activated caspase 3 standards to give values expressed as ng/L of activated caspase 3.

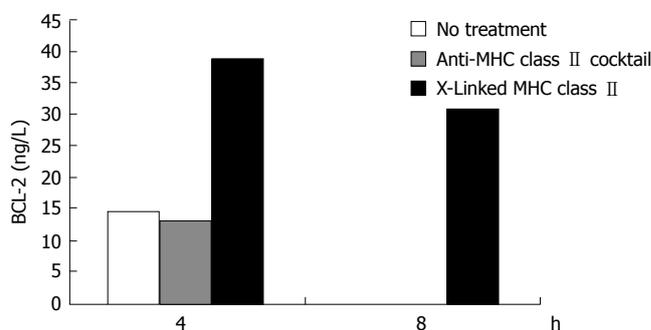

Figure 3 The effects of ligating versus crosslinking N87 cell surface MHC class II molecules on BCL-2 expression. Using the apoptosis cytometric bead array kit, beads exposed to the samples were run through a flow cytometer to obtain MFI data. These results were normalized to BCL-2 standards to give values expressed as ng/L of BCL-2.

was measured simultaneously with caspase 3 activation. Just as crosslinking of MHC class II resulted in reduced activation of the pro-apoptotic caspase 3 compared to MHC class II ligation, MHC class II crosslinking but not ligation produced an increase in the expression of BCL-2. MHC class II crosslinked samples showed a 169% increase over control in BCL-2 expression at 4 h treatment. After 8 h treatment, the MHC class II crosslinked samples contained over 30 ng/L of BCL-2 while the untreated and MHC class II ligated samples had no detectible BCL-2 (Figure 3).

Confocal microscopy analysis of FADD recruitment

Fas aggregation induces the recruitment of the adapter protein Fas-associated death domain (FADD) to the cytoplasmic tail of Fas. To determine whether MHC class II crosslinking affects FADD recruitment, we did confocal microscopy in gastric epithelial cells treated with anti-Fas with and without pretreatment with anti-MHC class II. N87 cells were treated with 100 U/mL IFN γ for 48 h to increase the surface expression of MHC class II and Fas. Cells were then seeded onto filter inserts with media alone for 24 h before treatment. Prior to permeabilization, fixation, and staining, samples were (a) left untreated (control), (b) treated for 1 h with the anti-Fas IgM clone IPO-4 or (c) pretreated with the anti-MHC class II IgM clone RFD1

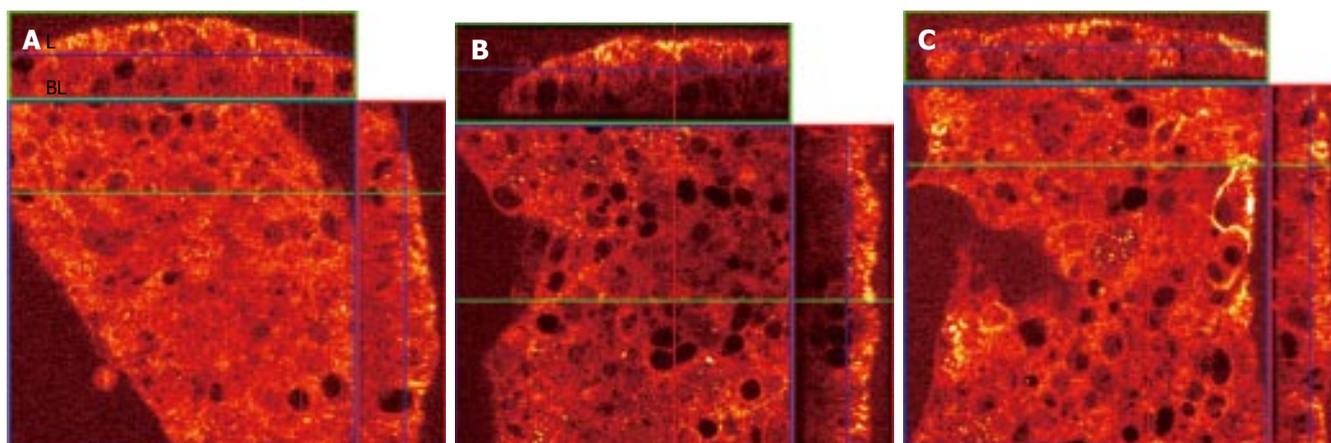

Figure 4 A: Viewing the X-Z panels, the FADD (stained red, with higher densities staining yellow) in untreated (control) cells can be seen distributed equally throughout the cytoplasm. "L" represents the apical (luminal) surface and "BL" represents the basolateral surface of the N87 monolayer; B: Labeled FADD in cells treated with the Fas trimerizing antibody is recruited to the apical surface, leaving much of the cytoplasm with reduced FADD staining; C: When the anti-MHC class II IgM RFD1 is applied to the cell monolayer 30 min prior to treatment with the Fas agonist IPO4 IgM, the recruitment of FADD to the cell surface is markedly reduced.

for 30 min prior to adding IPO-4. After washing, the cells were then permeabilized and fixed to allow staining of intracellular FADD. The filter inserts were then mounted onto slides and immediately visualized with a confocal microscope. The large square panel represents an X-Y axis "top-down" perspective on the adherent N87 cells. The top and side rectangular panels in each figure represent X-Z axis reconstructions, which provide an elevation view of the apical and basolateral sides of the cell section (Figure 4).

DISCUSSION

Apoptosis accounts for most of the cell loss in the gastrointestinal tract^[9]. Because cellular turnover in the gut epithelium is so high, disturbances in the homeostasis of cell proliferation and cell death can potentially lead to disease states. If apoptosis were induced at a higher rate than new cell generation, tissue atrophy and ulceration might occur. Conversely, downregulation or blocking of apoptotic pathways might result in neoplasia. Furthermore, it is possible that hyperplasia is a response to pro-apoptotic stimuli or that increased apoptosis results from an induced hyperproliferative stimulus^[10].

These potential scenarios, and the molecular dynamics responsible for them, become particularly important when considering the divergent clinical manifestations of *H pylori* infection. Two clinical observations support the concept of mutually exclusive disease states resulting from a disturbance in the delicate balance between apoptosis and proliferation of the mucosal epithelium. The first stems from multiple studies concluding that patients exhibiting duodenal ulcers have a lower risk of developing gastric cancer^[11,12]. The second suggests an inverse association between *H pylori* infection and esophageal adenocarcinoma^[13,14]. Although these correlations continue to be scrutinized, clearly, any factor affecting the apoptotic levels within, or causing the formation of, ulcerative or neoplastic epithelial tissue is critical in influencing the ultimate disease state. Therefore, the divergent and somewhat mutually exclusive nature of *H pylori* disease

pathology provides a strong incentive to elucidate the epithelial receptors for *H pylori* during infection, and to investigate results of receptor ligation and crosslinking on host cell apoptosis.

The apoptosis-inducing effect of *H pylori* on gastric epithelial cells has been thoroughly demonstrated^[4-7,10,15-18]. Furthermore, our group's findings that MHC class II not only binds *H pylori*, but also can initiate signals affecting apoptotic pathways, suggests an important role for this molecule in influencing *H pylori* pathogenesis. The literature offers conflicting reports on the apoptotic versus anti-apoptotic effects of MHC class II binding. More specifically, there are opposing reports on the effect of MHC class II ligation on the Fas death pathway in mouse and human B cells^[19,20].

Previous studies from our group have revealed that signals induced by the long term (72 h) crosslinking of MHC class II are pro-apoptotic^[4,5]. However, the results we have reported here indicate that crosslinking of MHC class II can induce anti-apoptotic effects at time points less than 24 h. Furthermore, we have demonstrated the ability of MHC class II crosslinking to inhibit a key component of the Fas death pathway. These findings become more logical in hindsight when one considers a key characteristic of the MHC class II heterodimer: its cytoplasmic tail is very short, consisting of 12-15 amino acids. Just as a T cell receptor requires crosslinking and association with other surface molecules to recruit accessory proteins and effect downstream events, we suspect that the short tail of MHC class II leads to the necessity for crosslinking and interaction with other surface molecules to alter apoptotic pathways. Recent studies by our group have led to the discovery that *H pylori* also binds to the MHC class II-associated invariant chain (Ii)^[21]. Because the cytoplasmic tail of Ii is significantly longer, and potentially more potent as a functional recruiter of transduction molecules, we envision a scenario in which simple ligation of *H pylori* to either MHC class II or Ii might induce a pro-apoptotic effect via the cytoplasmic tail of Ii. This pro-apoptotic scenario would functionally oppose the result of a more extensive bacterial interaction with the epithelium, leading

to crosslinked MHC class II with the resulting increase in BCL-2 and suppression of FADD recruitment, leading to a reduction of apoptosis. The method by which the crosslinking of MHC class II inhibits CD95-mediated apoptosis is, at this point, speculation. However, we hypothesize that one explanation, focusing on a presumed intimate association between MHC class II and Fas on the epithelial surface, is that crosslinked (but not ligated) MHC class II sterically inhibits the trimerization, and thus activation, of surface Fas molecules.

Our findings that MHC class II crosslinking inhibits *H pylori*-induced caspase activation, that ligation versus crosslinking of MHC class II has differential effects on apoptotic-associated molecules, and that MHC class II crosslinking inhibits FADD recruitment are intriguing because of their potential role in the divergent pathophysiologic host response to this human pathogen. By acting as a bacterial receptor, as well as modulating the important apoptotic processes during infection, MHC class II becomes a critically important molecule in the context of *H pylori* pathogenesis.

Nonetheless, it is important to continue to study all GEC surface molecules that have the potential to influence the signal events initiated by *H pylori* binding. There is significant evidence that other surface molecules in addition to MHC class II are capable of binding *H pylori*; there have been numerous studies demonstrating the role of Lewis b (Le^b) blood group antigen in *H pylori* adherence to the epithelium^[22,23]. More recently, it has been suggested that the dimeric form of the trefoil protein TFF1 avidly binds *H pylori*^[24]. The implications of each of these findings in the physical interaction between bacterium and host is important not only because of the need to understand the molecules responsible for bacterial adhesion, but also because of the possibility that a particular bacterial receptor influences the downstream signal transduction events initiated when *H pylori* binds to a secondary receptor, or activates a death receptor.

Deciphering the complexity of *H pylori* pathogenesis in order to reduce its contribution to human gastric disease will require continued investigation into the interactions between bacterial receptors and their effects on the host epithelial cell homeostasis.

Abstract

AIM: To meta-analyse the European abstracts presented between 1997-2004 at the European *H pylori* Study Group, United European Gastroenterology Week meetings and World Congresses of Gastroenterology.

METHODS: The abstracts of randomized/controlled prospective studies were classified into groups based on first-line eradication schedules. The quality of the abstracts was checked by a validated score system. The pooled eradication rates (PER) and combined odds ratios (OR) were calculated and compared with the published meta-analyses.

RESULTS: The PER of proton pump inhibitor-based (PPI) one week triple therapies was 81.4% (confidence interval, 95% CI: 78.5-84.5). Ranitidine bismuth citrate-based (RBC) triple regimens have an efficiency rate of 78.5% (95% CI: 70.5%-84.3%) ($P = 0.28$ vs PPI). The OR for PPI effect vs RBC regimens was 1.1 (95% CI: 0.92-1.30). H₂ receptor antagonist-based triple therapies achieved 64.1% (95% CI: 52.6-75.6) ($P = 0.02 < 0.05$ vs PPI), the OR vs PPI regimens was 1.55 (95% CI: 0.72-3.78). PPI-based double combinations were less efficient than triple regimens (PER: 55.0%, OR: 4.90, 95% CI: 2.36-9.70). Quadruple regimens were successful in 82.6% (95% CI: 76.0-89.7), the OR vs triple therapies was 0.80 (0.62-1.03). Clarithromycin + amoxicillin or nitroimidazole combinations were efficient in 80.5% (95% CI: 77.2-84.2) and 83.8% (95% CI: 81.7-85.9), respectively. Amoxicillin + nitroimidazole therapies eradicated the infection in 73.5% (66.6-78.5) ($P = 0.01 < 0.05$ vs clarithromycin-based regimens).

CONCLUSION: PPI/RBC-based triple therapies achieved comparable results with the meta-analyses. H₂-receptor antagonists and PPI-based double combinations were less efficient. Triple and quadruple regimens were

equally effective. Clarithromycin + either amoxicillin or nitroimidazole containing regimens were more effective than amoxicillin + nitroimidazole combinations. High quality congress abstracts constitutes a valuable pool of data which is suitable for meta-analytical workup.

INTRODUCTION

Numerous treatment regimens have been tested for their efficacy in curing *H pylori* infection worldwide^[1-3]. Meta-analysis has become a frequently used method for resolving such uncertainties and obtaining sound data in evidence-based medicine. The purpose of a meta-analysis is to statistically combine the results of similar trials and such studies are aimed at improving the estimation of treatment effects and minimizing the potential biases of such estimations. Following the increased rate of randomized controlled trials (RCT) published, the importance of meta-analyses has risen and its methodology has become more and more sophisticated. This is particularly true for *H pylori* eradication where we see an exponential rise of studies published worldwide. As a part of the evidence-based medicine, most of the meta-analyses only addressed the RCTs. However, it was rapidly realized, that RCTs do not come close to covering the complete range of studies and therefore, the inclusion of studies representing lower levels of evidence or congress abstracts was also accepted in some of the studies^[2,3]. Score systems for assessing the quality of meta-analyses, RCTs^[4,5] and abstracts^[6] have also been worked out. Participation at scientific meetings represents a popular opportunity to disseminate results which, because of linguistic barriers would hardly be published in peer-reviewed journals.

The aim of our study was the meta-analysis of the European abstracts dealing with the first-line treatment of the

H. pylori infection, presented at the European *H. pylori* Study Group (EHPSG), United European Gastroenterology Week (UEGW) and World Congress of Gastroenterology (WCOG) meetings held between 1997-2004. We thus investigated an unexplored area which was only in part covered by meta-analyses published so far.

MATERIALS AND METHODS

Data collection

Abstracts presented at the EHPSG, UEGW and WCOG meetings between 1997-2004 were reviewed independently by the authors. These meetings were chosen because acceptance of the papers is decided after a peer-review process similar to submitting to journals. The randomized and prospective controlled open studies dealing with the first-line eradication of *H. pylori*, provided by European authors were included. Accepted abstracts had to include at least 2 treatment arms, to specify the diagnosis of patients, the exact drug doses, the duration of treatment and method of eradication control (histology, culture, rapid urease test or ¹³C-urea test). Exclusion criteria: studies coming from other continents or multi-center studies with participating centers outside Europe were not considered. Duplicate abstracts were identified and considered only once. Meta-analyses, audits and papers presenting prescribing practices were not included. Trials not specifying the type of PPI/antibiotic used, duration of treatment or incomplete data were excluded. Only eradication trials in peptic ulcer, chronic gastritis and functional dyspepsia were included, conditions in which treatment of the infection are recommended by the 1st and 2nd Maastricht consensus conference^[7,8]. Trials performed in the extragastric manifestations of the infection, MALT lymphoma and pediatric population were not part of the study. Studies using PPIs, antibiotics given intravenously or probiotics were also omitted. A flow-chart of the study is presented in Figure 1. The quality of the abstracts was verified by a validated score system including 19 items, in order to compare to the most relevant methodological details^[6]. Abstracts having a quality score under 0.50 were not accepted.

The treatment arms of the abstracts were classified and groups of similar regimens were constructed as follows: (1) PPI-based one week triple combinations; (2) Ranitidine bismuth citrate (RBC)-based one week triple combinations; (3) H₂-receptor antagonist-based triple regimens; (4) Double combinations (PPI/RBC + 1 antimicrobial); (5) Quadruple therapies (PPI + bismuth compound + 2 antimicrobials); (6) Antimicrobial-based analysis: - PPI + clarithromycin + amoxicillin or a nitroimidazole, - PPI + amoxicillin + nitroimidazole, - RBC + clarithromycin + amoxicillin or a nitroimidazole.

The results obtained were compared with the available meta-analyses based on the data of RTCs in order to assess whether the results of abstracts overlap with the latest data of the evidence-based medicine.

Statistical analysis

The eradication regimens were pooled into groups shown above. The data were entered in an Excel database which

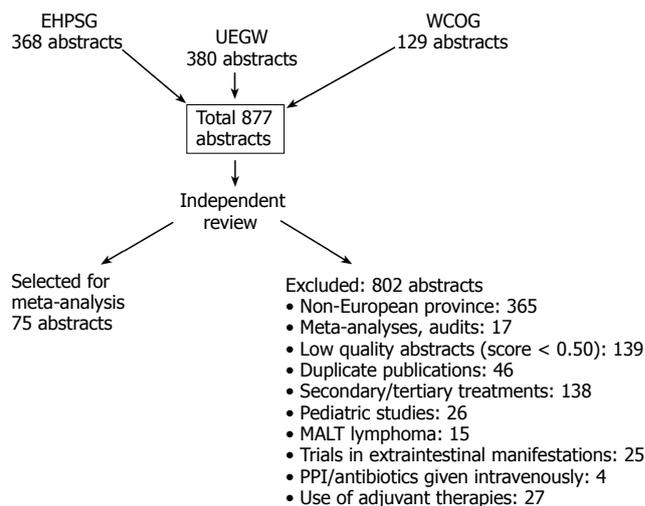

Figure 1 Flow-chart of the meta-analysis.

was checked by hand for errors. While the 'per protocol' (PP) data were given only in a part of the abstracts, the results on 'intention-to-treat' (ITT) basis were taken into consideration. The groups were checked for homogeneity by the chi-square test^[9]. The 'pooled eradication rate' (PER) of the groups including all treatment arms of similar regimens (i.e. groups 1-6) was calculated using equal effect analysis, assuming that different populations have the same outcome (N-weighted calculation). Differences between the groups were assessed by the chi-square test and the level of $P = 0.05$ was considered significant. The 95% confidence intervals (CI) were calculated. Within the groups 1-6, from the comparative trials the individual Peto odds ratios (OR) were estimated and the combined ORs were assessed assuming a random effect model^[9]. The change over time of the eradication rates of PPI-based therapies was performed by calculating the PERs for each year of the period studied (1997-2004). The statistical formulae were used as described in the literature^[9,10]. The statistical work was performed using the 'Statistica 9.0' software (Tulsa, Oklahoma, USA).

RESULTS

General information

In the post-Maastricht period, between 1997-2004, 877 papers dealing with the therapy of *H. pylori* infection were presented during the selected meetings, from which 75 met the inclusion criteria. The accepted abstracts included 188 study arms and 15 634 patients. Eight hundred and one abstracts were excluded for the reasons shown in the flow-chart. The accepted abstracts had a mean quality score of 0.66 (95% CI: 0.52-0.77). Data on the homogeneity of the groups are given in the text and Tables 1-5.

Results of primary treatment

PPI-based one week triple regimens: Most of the authors adhered to the provisions of the Maastricht 1 consensus and administered PPI-based triple regimens as first-line therapy^[12-15,17-19,21-30,32-65,78-85]. The PERs of the PPI-

¹P: 1997 *vs* other years; $P = 0.04 < 0.05$ 2002 *vs* 1999; no other significant difference in between-year comparisons; Test of homogeneity: 1997, $\chi^2 = 9.98$, $P = 0.19$; 1998, $\chi^2 = 0.71$, $P = 0.39$; 1999, $\chi^2 = 3.0$, $P = 0.08$; 2000, $\chi^2 = 5.17$, $P = 0.15$; 2001, $\chi^2 = 0.15$, $P = 0.72$; 2002, $\chi^2 = 0.2$, $P = 0.7$; 2003, $\chi^2 = 0.14$, $P = 0.8$; 2004, $\chi^2 = 0.14$, $P = 0.8$.

based regimens and homogeneity values are given in Table 1. The overall efficacy of the PPI-based one-week triple therapies was 81.4% (95% CI: 78.5-84.5). Therapeutic experience was gained with all 5 commercially available PPI. There was no statistically significant difference of the PERs between the groups. All PPIs obtained eradication rates around 80% on ITT basis. In comparative studies, using omeprazole as the index drug, the combined ORs showed equivalence to the other PPIs (Table 2). An example is given in Figure 2 representing the results of comparative trials using omeprazole and lansoprazole-based triple regimens. The rates of *H pylori* eradication by the PPI-

based triple therapies from 1997 to 2004 are presented in Table 3. No change over time of the eradication rates was recorded.

RBC-based triple regimens: They were administered to 2051 patients in 24 studies/27 treatment arms and obtained a PER of 78.5% (95% CI: 70.5-84.3)^[11-31]. (Test for homogeneity: $\chi^2 = 2.79$, $P = 0.16$). The OR for the effect of PPI's *vs* RBC in triple combinations was 1.10 (0.92-1.30). Including all treatment arms, there was no significant difference of the PERs between PPI- and RBC-based triple regimens ($P = 0.28$).

H₂-receptor antagonist-based triple regimens: They

$r = 5, \chi^2 = 1.43, P = 0.92$

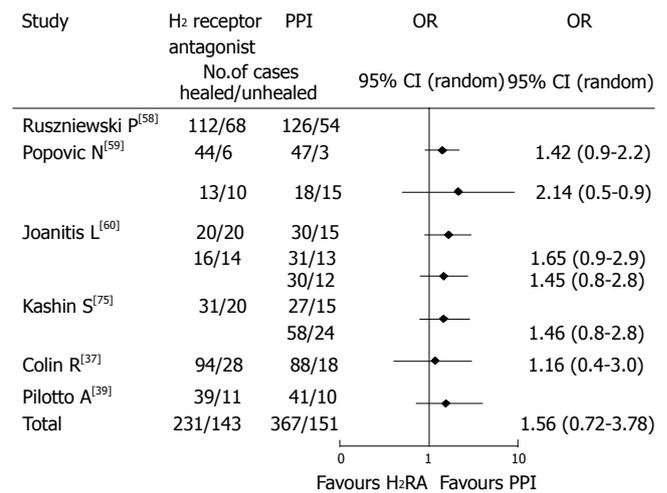

Figure 2 Omeprazole vs lansoprazole-based triple therapies: results of the comparative trials (Peto graph of the individual and combined ORs).

were given to 374 cases for 7-10-14 d in 4 studies/8 treatment arms,^[58-60,75] and obtained 64.1% (52.6-75.6) eradication, which was significantly lower as compared to PPI-based regimens (74.4%, 95% CI: 59.5-84.8) $P = 0.028 < 0.05$. (Test for homogeneity: $\chi^2: 0.21 P = 0.56$). The OR for the effect of PPI vs H₂-RA based regimens was 1.55 (0.72-3.78) (Figure 3). However, these groups were heterogeneous (Figure 3).

Double combinations: PPI + 1 antimicrobial schedules given for 7-14 d were administered to 1051 cases in 10 studies/14 treatment arms and achieved PER of 55.0% (38.6-71.4)^[67-77]. (Test for homogeneity: $\chi^2: 2.47, P = 0.12$.) In comparative trials, triple combinations were efficient in 82.48% (75.4-89.3) ($P = 0.000 < 0.05$), the combined OR favoring triple combinations (4.90, 95% CI: 2.36-9.70) (Figure 4). The groups were heterogeneous (see Figure 4). RBC-based dual therapies lasting 7-14 d were given to 268 cases in 4 studies/4 treatment arms^[12,18,77,78] and obtained 77.6% (69.6-85.5) PER, which was not significantly lower than the rates of triple RBC combinations (80.8%, 72.9-88.5) ($P = 0.43$). (Test for homogeneity: $\chi^2: 0.16 P = 0.60$.) In direct comparative trials, the OR for the effect of RBC double vs triple combinations was 0.83 (0.51-1.33).

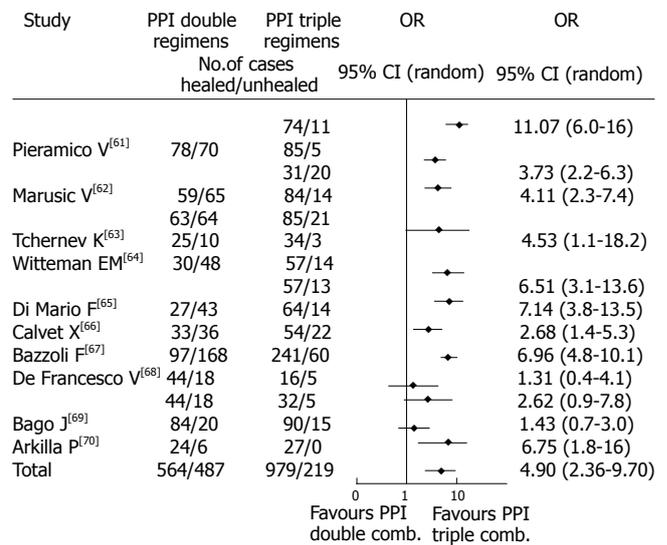

Quadruple therapies: They were administered as first-line regimens to 611 cases in 10 treatment arms, and the PER was 82.6% (76.0-89.2)^[76,79-82]. (Test for homogeneity: $\chi^2: 0.13, P = 0.61$.) In comparative trials, triple therapy's PER was 81.2% (76.4-86.0) ($P = 0.07$). The combined OR for the effect of triple vs quadruple therapies was 0.80 (0.62-1.03) (80-82).

Antibiotic combinations: The eradication rates obtained with PPI + clarithromycin or either amoxicillin or nitroimidazole regimens compared with PPI + nitroimidazole + amoxicillin are presented in Table 4 (all treatment arms). Clarithromycin + amoxicillin or a nitroimidazole containing regimens were significantly more efficient than amoxicillin + nitroimidazole combinations ($P = 0.01 < 0.05$ and $P = 0.001 < 0.05$, respectively) (Table 4) and the OR favored the former therapies over the latter (Table 5). There

$r = 5, \chi^2 = 16.73, P = 0.005 < 0.05$

Figure 3 H₂-receptor antagonists and PPI-based triple regimens: results of the comparative trials (Peto graph of the individual and combined ORs).

$r = 11, \chi^2 = 126.8, P = 0.0000 < 0.05$

Figure 4 PPI-based double and triple regimens: results of the comparative trials (Peto graph of the individual and combined ORs).

was no significant difference in the efficiency rate of RBC + clarithromycin + amoxicillin and RBC + clarithromycin + nitroimidazole regimens ($P = 0.90$), the combined OR values indicating these combinations were equivalent (OR:1.03, 95% CI: 0.65-1.38).

DISCUSSION

In the present study, we assessed the eradication rates of different anti-*H. pylori*-regimens given in European countries in the post-Maastricht period. Several meta-analyses evaluated the efficacy of the eradication regimens^[1-3,87-91,93,95,96]. To our knowledge, this is the first meta-analysis based solely on abstracts coming from the European countries, thus exploring a previously unexplored database. Our purpose was to assess whether or not these

results are comparable with the results of the latest meta-analyses. According to our data most of the European authors followed the recommendations of the Maastricht 1-2 consensus meetings^[7,8]. Thus, the PPI-based triple therapies were the most frequently used regimens. The PER of all treatment branches using these combinations was comparable with the earlier meta-analyses. In the first such review evaluating the pre-Maastricht era studies (1992-1996), a PER of 78.3% (64.6%-88.4%) was obtained^[86]. In the largest meta-analyses published thus far, 666 publications summarizing 53 228 patients were reviewed and the PER of different PPI-based combinations was between 80%-85%, which is also compatible with our data^[2]. In another study^[87], in 22 RCTs performed before 1999, the PER of PPI + clarithromycin/amoxicillin or metronidazole regimens was 81% (95% CI: 79-83). No differences of the PERs of the available PPIs were observed in the eradication of *H pylori* and in direct comparative trials, the OR analysis showed that neither of the PPIs was favored. This is compatible with the recent data showing that in comparative trials, the efficacy of omeprazole and pantoprazole^[88,89], rabeprazole^[90] lansoprazole^[88] and esomeprazole^[91] was similar. There are data suggesting a decrease in

the eradication rate of PPI-based triple regimens in recent years^[92]; however, as shown in Table 3, such changes over time could not be confirmed in our analysis. The PER of RBC-based triple regimens is similar with that of PPIs and in comparative trials, the OR values indicated these therapies were equivalent, which is in accordance with a meta-analysis^[93], and is in agreement with the Maastricht consensus recommendations.

According to our data, H₂-receptor antagonist-based therapies were inferior to either PPI or RBC-containing regimens and the ORs favored the later schedules. The heterogeneity of the groups, however, needs caution in the interpretation of these results. In a meta-analysis, the overall efficacy of H₂ receptor antagonists and PPIs as adjuvants for *H pylori* therapy was similar (78% vs 81% on ITT basis); including clarithromycin in the regimens, a non-significant trend favoring H₂ receptor antagonists was observed (OR1.14, 95% CI: 0.76-1.71)^[95]. In another study, the overall efficacy of PPI was superior to H₂ receptor antagonists (74% vs 69%, OR: 1.31, 95% CI: 1.09-1.58); however, prescribing high doses of H₂ blockers could improve the results^[96]. This discrepancy warrants further study while in case of equivalence, the use of H₂-receptor

blockers would have pharmaco-economic advantages.

PPI-based double combinations^[61-71] were clearly inferior to triple regimens, which is in accordance with the evidence-based data^[2] and they are probably not more recommended in the first-line treatment of the infection. Interestingly, RBC-based double combinations have similar efficacy with the triple regimens^[11,16,71,72]. However, no meta-analysis addressed this issue. Here again, heterogeneity of the groups might influence the results. Quadruple therapies have been demonstrated to be very effective and safe either as first or second-line therapies. Concerns have been raised regarding the optimal duration of treatment, efficiency and side effects, because prolonging the therapy is not cost-effective, the gain in effectiveness is modest and the tolerability could be impaired. Overall, quadruple regimens were not better than triple therapies^[70,73-76] and this is in agreement with a recent meta-analysis, where these therapies seem to be roughly equivalent (81% vs 78%, OR: 0.81, 95% CI: 0.55-1.20)^[97]. The Maastricht 2 Consensus recommended their use as a second-line treatment but, and according to a recent meta-analysis, they could equally be used as first-line, based on their efficacy^[5].

The choice of antimicrobials is of crucial importance while resistance to antibiotics is a major determinant of the eradication outcome^[3,97]. In our study, clarithromycin + amoxicillin or a nitroimidazole combination have a superior yield as compared to amoxicillin + a nitroimidazole combination, which is in accordance with a meta-analysis^[87].

We conclude, that selection of high-quality abstracts of major gastroenterologic meetings constitutes a valuable pool of data for meta-analysis. The results obtained by us are mainly in accordance with the existing data. Some discrepancies must be resolved by further studies. Primary treatment for *H pylori* infection is usually successful in over 80% of the patients; however, there is no ideal first-line regimen^[98,99]. Nevertheless, it was not our intention to analyze all aspects of the eradication therapy, which would be far beyond the scope and extent of this work. Other details, i.e. data on the influence of initial diagnosis (i.e. gastric or duodenal ulcer, functional dyspepsia), treatment duration, antimicrobial resistance, newer antibiotic combinations, rescue treatments, geographical distribution of the eradication results merit further analysis and updated research.

ACKNOWLEDGMENTS

The correction of the English manuscript by Mr. Douglas Arnott (EDMF Translation Bureau, Budapest, Hungary) is highly acknowledged.

Abstract

AIM: To investigate the effects of taurolithocholate (TLC) on the canalicular motility in isolated rat hepatocyte couplets (IRHC).

METHODS: TLC was added to IRHC at concentrations of 10 and 50 $\mu\text{mol/L}$, respectively. In each group, five time-lapse movies containing 3 representative bile canaliculi were taken under phase-contrast microscopy for 12 h. The number of bile canalicular contractions and the intervals between consecutive canalicular contractions were calculated. Furthermore, the effects of TLC on IRHC were examined by transmission electron microscopy.

RESULTS: The bile canalicular contractions were spontaneous and forceful in the controls. Active vesicular movement was observed in the pericanalicular region. Immediately after the addition of TLC, the bile canaliculi were deformed, and canalicular bile was incorporated into the vacuoles. The canaliculi were gradually dilated, and canalicular contractions were markedly inhibited by TLC. The vesicular movements became extremely slow in the pericanalicular region. The number of canalicular contractions significantly decreased in the TLC-treated groups, as compared with that in the controls. The time intervals were prolonged, as the TLC dosage increased, indicating that bile secretion into the canaliculi was impaired with TLC. Transmission electron microscopy revealed the lamellar transformation of the canalicular membranes in IRHC treated with TLC.

CONCLUSION: TLC impairs both the bile canalicular contractions and the canalicular bile secretion, possibly by acting directly on the canalicular membranes in TLC-induced cholestasis.

INTRODUCTION

The concept that pericanalicular actin filaments may subserve a contractile function to facilitate bile flow was first proposed in 1974^[1]. Contractile proteins are found to be present throughout the cytoplasm in hepatocytes and are particularly numerous in the pericanalicular region by electron microscopy^[2,3], immunohistochemistry^[4,5], and biochemical analysis^[6]. Strong evidence for bile canalicular motility came from *in vitro* studies using isolated rat hepatocyte couplets (IRHC)^[7,8], which indicated dynamic contractions of the bile canaliculi. The canalicular motility is impaired by actin inhibitors such as cytochalasin B and phalloidin^[9,10]. Taurocholate, a choleric bile acid, also increases the contraction rate, thus providing further support for a role of canalicular contractions in the bile secretory mechanism^[11]. More importantly, canalicular contractions have been demonstrated in living rats^[12], and this finding substantiates a number of *in vitro* data regarding the mechanisms of bile canalicular contractions.

Lithocholic acid, a hydrophobic secondary bile acid, is well known to cause intrahepatic cholestasis^[13]. There have been extensive studies on the mechanisms of lithocholate-induced cholestasis in animals. Lithocholate diminishes both the bile acid-dependent and independent bile flow^[14]. Regarding the mechanisms of the bile acid-independent bile flow, it has been explained by the inhibition of Na^+ , K^+ -ATPase^[15,16], the inhibition of gap junction permeability^[17], and the impairment of hepatic transporters such as the bile acid export pump (Bsep)^[18-20]. In humans, elevated levels of lithocholic acid are found in patients with chronic cholestatic liver disease^[21,22]. From an ultrastructural point

of view, the lamellar transformation of the canalicular membranes reported by Miyai *et al.* has been considered the hallmark of lithocholic acid-induced cholestasis^[23,24]. To elucidate the precise mechanism of cholestasis, we investigated the direct effects of tauroolithocholate (TLC) on the canalicular motilities in IRHC using time-lapse cinematography and transmission electron microscopy.

MATERIALS AND METHODS

Liver cell culture

Wistar strain female rats, weighing 170–230 g, were used. These rats were fed with a laboratory pellet rat diet and tap water *ad libitum*. All animals were given humane care in compliance with institutional guidelines. Primary isolated hepatocytes were prepared using the same method reported previously^[8,9]. Briefly, liver perfusion and dissociation were based on the method of Seglen^[25] as modified by Laishes and Williams^[26]. After an initial washout perfusion was performed through the portal vein using Ca²⁺ and Mg²⁺ free Hanks balanced salt solution containing 0.5 mmol/L EGTA, the rat livers were then perfused with L-15 medium containing 0.05% type I collagenase (Sigma Chemical Company). One million isolated hepatocytes were inoculated into a 60 mm Corning culture dish (Corning Glass Works, Corning, NY), and then maintained with L-15 medium which contained 10% fetal bovine serum, 10 mmol/L HEPES, penicillin (100 U/L) and streptomycin (100 U/L). The viability of isolated hepatocytes by trypan blue exclusion test was approximately 95%. These cells were preincubated at 38°C for 4 h to facilitate cell attachment to the bottom of the dish and to allow time for recovery from the cell isolation procedure. The incompletely separated groups of cells, especially couplets and triplets, were selected for this experiment.

Time-lapse cinematography

A Nikon inverted microscope (Diaphot-TMD) with phase-contrast optics and a 16 mm movie camera (H16, RX-5 Bolex) operated by a Nikon cine auto-timer with a drive system (CFMA) were used. This equipment was housed in a temperature-controlled room maintained at 38°C. Time-lapse movies were taken at a speed of 1 frame/15 s for 12 h after the addition of TLC. Five time-lapse movies containing 3 representative bile canaliculi from 5 rats were taken for each of the experimental and control groups.

Experimental design and methods of analysis

In the experimental groups, sodium tauroolithocholate (grade A, purity > 99%, Calbiochem, San Diego, CA) was added to the culture media at concentrations of 10 and 50 µmol/L, respectively. The TLC solution was prepared from the stock solution containing 20 mmol/L TLC dissolved in propylene glycol. In the controls, the same solution without TLC was added to the culture media. Three representative bile canaliculi in each movie were used for analysis. A total of 2880 frames, i.e., 12 h of real time were examined in each canaliculus using an analytic movie projector (Photo-Optical Data Analyzed 2240A,

MK-V, L-W International, Woodland Hills, CA). Bile canalicular contraction was defined as a visible decrease in canalicular diameter. The minimum size of the canalicular lumen was taken as the end point of the contraction. Analysis of the movies was performed using the frame numbers of the movie films at the point of beginning and end of the contractions. The time intervals between adjacent contractions were calculated as the difference in the frame counts between consecutive contractions. These frame counts were then converted into real time.

Statistical analysis

The frame numbers obtained from all the movies were stored and analyzed by a personal computer. The number of bile canalicular contractions was determined for 3 canaliculi from each movie of 5 rats and evaluated by analysis of variance test for each dose of TLC used. The intervals between consecutive canalicular contractions were calculated and compiled to make a histogram. The histograms of 10 and 50 µmol/L TLC and controls were assessed statistically, presuming that these data have a Poisson distribution as reported previously^[8,11].

Electron microscopy

Representative samples of IRHC after the addition of 10 and 50 µmol/L TLC and the controls were examined by transmission electron microscopy. The cells cultured on plastic cover slips were fixed in universal fixative^[27] at 1, 3 and 6 h after the addition of either TLC or propylene glycol. For postfixation, 1% osmium tetroxide in 0.1 mol/L cacodylate buffer (pH 7.4) for 30 min was used. The cells were dehydrated in a graded series of alcohol and embedded in Epon 812. Ultrathin sections were cut using LKB ultramicrotome and stained with Sato's lead solution^[28]. The specimens were examined using a Philips EM 400T electron microscope (Philips Electronic Instruments Inc., Mahwah, N.J.).

RESULTS

Remarkable motilities of isolated hepatocyte couplets and triplets were observed in the time-lapse movies. In the controls, bile canaliculi revealed spontaneous and forceful contractions (Figure 1). The canalicular contractions were most striking for cell motility, while Brownian-like movement and cell ruffling were also seen. Active movements of small particles, which may represent cytoplasmic vesicles and vacuoles, were noted in the pericanalicular regions of the cytoplasm. TLC-treated hepatocytes manifested a marked reaction to this bile acid as compared with the controls. Immediately after the addition of TLC, the bile canaliculi were deformed, and canalicular bile was incorporated into the vacuoles in hepatocyte cytoplasm. The canaliculi were gradually dilated, and canalicular contractions were markedly inhibited by TLC (Figure 2). This phenomenon was most prominent with a high dose (50 µmol/L) of TLC. Some bile canaliculi showed only a few contractions approximately 6 h after the addition of TLC. The pericanalicular movements of the small particles observed by phase-contrast microscopy

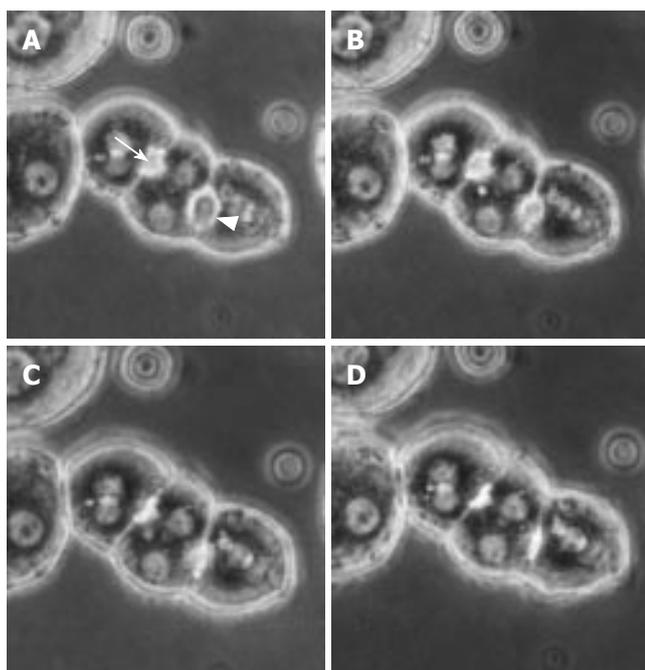

Figure 1 Representative phase contrast micrographs of an isolated hepatocyte triplet in the controls. Figures A, B, C and D show a sequence of the bile canalicular contractions. A bile canaliculus indicated by an arrowhead started to contract (A) and completed contraction (D). Another canaliculus indicated by an arrow started its contraction (B) and completed contraction (C). These canalicular contractions were forceful and repetitive.

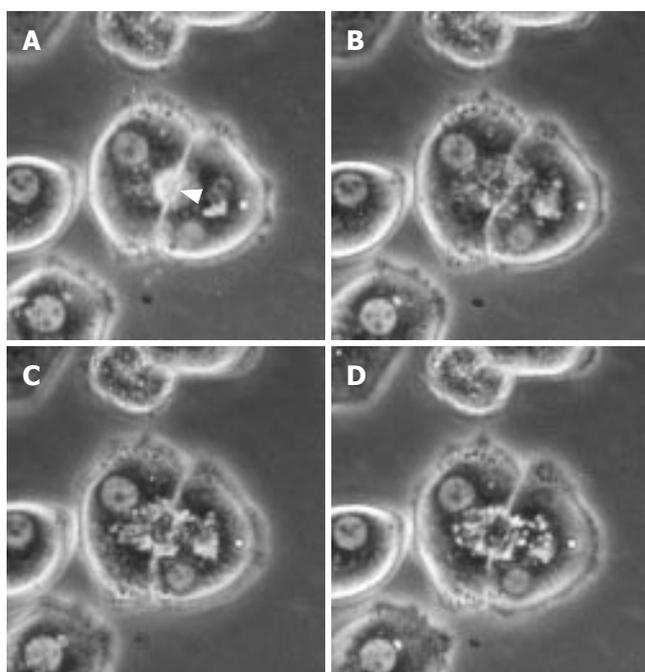

Figure 2 Representative phase contrast micrographs of an isolated hepatocyte couplet in the taurolicholate (TLC)-treated groups (50 $\mu\text{mol/L}$). Prior to addition (A) and after the addition of TLC (B, C, D). A canaliculus (arrowhead) between two hepatocytes (A) was deformed, and canalicular bile was incorporated into the vacuoles in the hepatocyte cytoplasm immediately after the addition of TLC (B). Thereafter, the bile canaliculi were gradually dilated, and the canalicular contractions were markedly impaired (C, D). In the TLC-treated groups, the movements of small particles became extremely slow, and cytoplasmic vesicles and vacuoles were noted in the pericanalicular region.

became extremely slow with the progression of time. A number of cytoplasmic vesicles and vacuoles were found

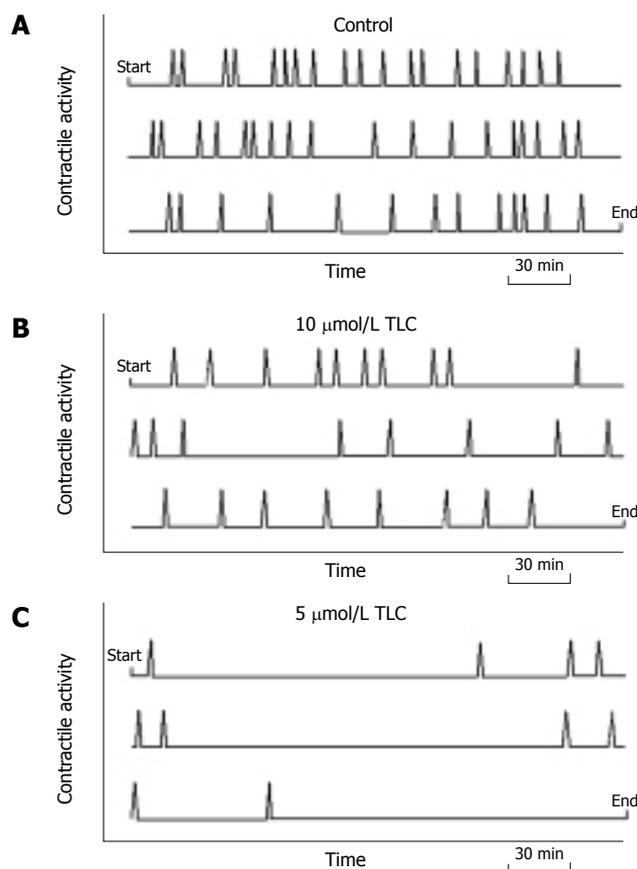

Figure 3 Graphic display of the representative contraction activity of bile canaliculi. Diagrams represent the 12 h period of observation, beginning at the upper left corner and ending at the lower right corner. The canalicular contractions (spikes) occurred at regular intervals in the control groups (A). The contraction activity visibly diminished as the TLC dosage increased (B, C).

in the pericanalicular region. The graphic displays of representative canalicular contractions in the controls and the TLC-treated groups are shown in Figure 3. Whereas canalicular contractions occurred at regular intervals in the control groups, the contraction activity was visibly diminished, as the TLC dosage increased.

To examine the detailed functions of the canalicular contractions, we analyzed the number of contractions and the contraction interval for 12 h. The total contraction number of 3 bile canaliculi in the TLC-treated groups significantly decreased to 82.4 ± 6.1 (mean \pm SE) at 10 $\mu\text{mol/L}$ and 30.2 ± 3.1 at 50 $\mu\text{mol/L}$, as compared with that in the control groups (139.4 ± 4.5) (Figure 4). The histogram of the canalicular contraction interval revealed the Poisson distribution. In the TLC-treated groups, there was a tendency for the peak height to decrease and shift to the right. In other words, the time intervals between adjacent contractions were prolonged, as the TLC dosage increased. The calculated theoretical peak values, which reflect the maximum likelihood of the next contraction, were 4.7 min in the control groups, 5.7 min at 10 $\mu\text{mol/L}$ and 7.0 min at 50 $\mu\text{mol/L}$ TLC (Figure 5).

Transmission electron microscopy revealed that IRHC prior to the addition of TLC showed either normal or slightly dilated bile canaliculi. The canaliculi between two hepatocytes were filled with microvilli and sealed by tight junctions. A rich network of microfilaments, i.e.,

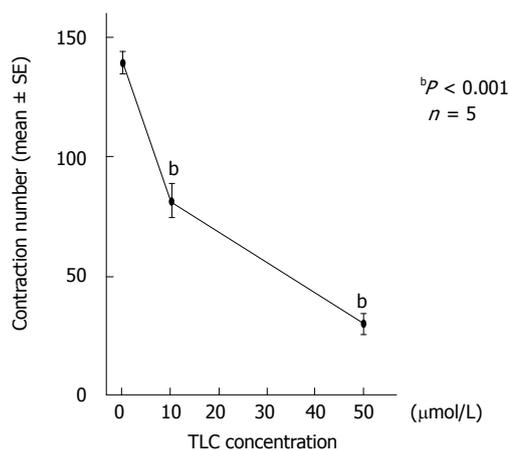

Figure 4 Effects of taurolicholate (TLC) on the contraction number of bile canaliculi. The total contraction number of 3 bile canaliculi for 12 h was 139.4 ± 4.5 (mean \pm SE) in the controls, and it significantly decreased to 82.4 ± 6.1 at 10 $\mu\text{mol/L}$ TLC and 30.2 ± 3.1 at 50 $\mu\text{mol/L}$. The contraction number markedly decreased as the TLC dosage increased.

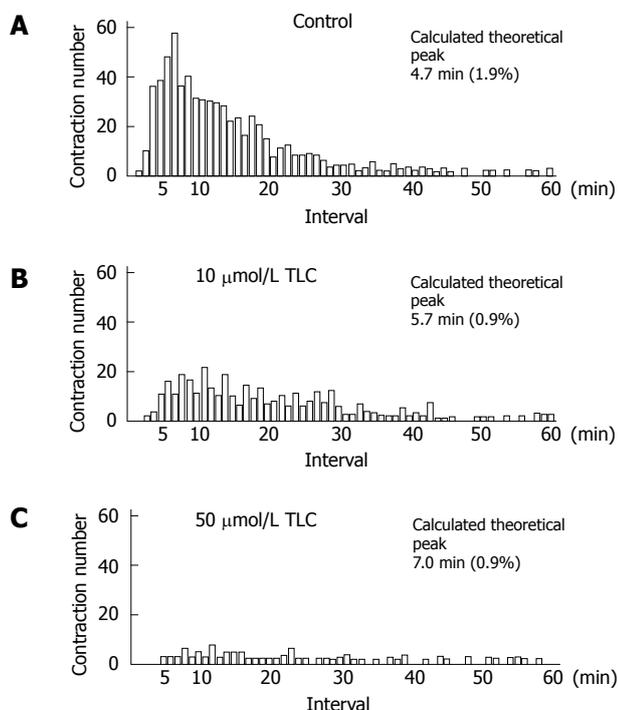

Figure 5 Effects of taurolicholate (TLC) on the contraction interval of bile canaliculi. The histogram of the canalicular contraction interval revealed Poisson distribution. In the TLC-treated groups, there was a tendency for the peak height to decrease and shift to the right. The calculated theoretical peak values for each dose were 4.7 min in the control groups (A), 5.7 min at 10 $\mu\text{mol/L}$ TLC (B) and 7.0 min at 50 $\mu\text{mol/L}$ (C). Normalized errors are indicated in parentheses.

actin filaments were recognized around the canaliculi. It was noted that TLC caused characteristic lamellar transformation of the bile canalicular membranes (Figure 6). This lamellar structure became more prominent and widely spread with the progression of time after the addition of TLC. The bile canaliculi were deformed and tended to become dilated with the loss of microvilli. Electron dense membranous structures of the biliary materials were found to be incorporated into the

Note the characteristic lamellar transformation of the bile canalicular membranes. A bile canaliculus (BC) was deformed and dilated with a loss of microvilli. Electron dense membranous structures of biliary materials (arrowheads) were found in the vacuoles in the pericanalicular region.

vacuoles in the hepatocyte cytoplasm, especially in the pericanalicular region.

DISCUSSION

The present study using time-lapse movies permits the continuous recording of the dynamic cell motilities in IRHC. The bile canaliculi between adjacent isolated hepatocytes manifested a marked reaction to TLC. The canaliculi were immediately deformed after the addition of TLC, and thereafter they became dilated with the marked impairment of the canalicular contractions. The contraction number of the canaliculi significantly decreased to 82.4 ± 6.1 at 10 $\mu\text{mol/L}$ and 30.2 ± 3.1 at 50 $\mu\text{mol/L}$, as the TLC dosage increased. Since Phillips and his co-workers demonstrated dynamic contractions of the bile canaliculi^[7,8], a number of studies using IRHC have been performed to elucidate the mechanisms of the bile canalicular contraction. The results indicate the active contraction process of the bile canaliculi mediated by the pericanalicular contractile proteins. It is notable that the contractions are Ca^{2+} , calmodulins and ATP-dependent^[4,9,10,29]. Hence, the mechanism of canalicular contraction has features in common with the actin-myosin based cytoplasmic motility behavior found in other non-muscle cells. The canalicular contractions are spontaneous but highly ordered. In triplets, when one bile canaliculus contracts, a neighboring canaliculus is likely to contract after an interval of 1.25 min, thus indicating a coordination in the contractile activity of the BC^[30]. In the present study, the BC in the control couplets and triplets showed spontaneous and forceful contractions. The total contraction number of 3 bile canaliculi was 139.4 ± 4.5 in the control groups, which is almost equal to the findings of previous reports^[9-11].

The permeability of cell membranes is greatly influenced by cholesterol, including specific changes in the membrane cholesterol affected by both the functional properties of the lipid bilayer and the function of mem-

brane-bound proteins^[31-33]. In physiological conditions, cholesterol has been viewed as a modulator of membrane fluidity and permeability^[34,35]. The alterations in membrane permeability or fluidity in the liver have been considered to be one of the mechanisms of intrahepatic cholestasis^[36]. In this regard, lithocholate-induced cholestasis is of special interest, since the canalicular membrane itself is the site of cholesterol deposition^[16,23]. A biochemical analysis of canalicular enriched isolated plasma membrane preparations revealed an eight-fold increase in cholesterol in TLC-induced intrahepatic cholestasis^[24]. It is therefore anticipated that pathological alterations in cholesterol of the canalicular membranes may affect the membrane structure and function, especially bile canalicular contractions.

In this study, a canaliculus between adjacent isolated hepatocytes manifested a marked reaction to TLC. Immediately after the addition of TLC, the bile canaliculi were deformed and gradually dilated, leading to a remarkable reduction in the canalicular contraction number. The prompt responses of the bile canaliculi to TLC suggest that TLC may directly act on the canalicular membranes, resulting in the alteration and dysfunction of the canaliculi. TLC is mainly taken up by the hepatocytes through the Na⁺ taurocholate cotransporting polypeptide (Ntcp)^[37], and the canalicular secretion of TLC is mainly mediated by Bsep^[38]. It is therefore speculated that TLC taken up by IRHC may directly act on the canalicular membranes, resulting in the formation of the lamellar structure as recognized by electron microscopy. In normal IRHC, a rich network of microfilaments is found in the pericanalicular region, and the circumferential band of microfilaments surrounding the bile canaliculi is considered to fulfill a contractile function^[4]. Since the ultrastructural alterations of the pericanalicular microfilaments were not evident after the TLC treatment in this study, it is considered that the impairment of the canalicular contraction in IRHC may thus be due to the abnormalities of the canalicular membranes themselves, without affecting the cytoskeletal organization around the bile canaliculi.

It is likely that the canalicular motility events are related to bile secretion. We analyzed the contraction interval of the bile canaliculi to elucidate the effect of TLC on the canalicular secretory function by the same method as previously reported^[11]. The histogram of the canalicular contraction interval indicates that there was a tendency for the peak height to decrease and shift to the right, as the TLC dosage increased. The calculated theoretical peak values, which reflect the maximum likelihood of the next contraction, were 4.7 min in the control groups, 5.7 min at 10 $\mu\text{mol/L}$ and 7.0 min at 50 $\mu\text{mol/L}$ TLC, indicating that the time intervals between adjacent contractions are prolonged by TLC. The bile canaliculi are the smallest biliary passages across which bile secretion occurs. Taurocholic acid causes a linear increase in bile secretion in IRHC, suggesting that canalicular contractions may be a function of canalicular bile secretion^[11]. The present study demonstrates that TLC impairs not only the bile canalicular contractions, but also canalicular bile secretion. The reduction in the contractions after a lag period probably indicates that secretion is impaired, and hence the need for contractions is reduced. Since colchicines, an

inhibitor of microtubules, also inhibits both the canalicular contractions and bile secretion in IRHC^[39], these results therefore support the view that canalicular motility is closely associated with canalicular bile secretion.

Recent research on bile secretion has focused on the characterization of hepatobiliary transporters such as Ntcp and Bsep, indicating that TLC impairs the expression of Bsep^[18-20]. Bsep is a major bile acid transporter in the liver, and mutations in Bsep result in progressive intrahepatic cholestasis. Crocenzi et al. reported that TLC impairs bile salt secretion at the canalicular level and induces the internalization of Bsep into a cytosolic vesicular compartment without affecting the cytoskeletal organization in IRHC treated with TLC^[20]. Bsep expression has also been reported to be regulated by ligands of the nuclear receptor farnesoid X receptor (FXR), and TLC decreases the expression of Bsep through FRX^[19]. Taking all of these findings into consideration, the reduction of the canalicular secretion recognized in the present study may thus be associated with the decreased expression of Bsep in addition to the alterations in membrane permeability. The relationship of Bsep expression to the canalicular membrane permeability is still unknown, so the answer to this question must await further studies. In conclusion, TLC directly alters the bile canalicular membranes, thereby impairing both the canalicular motility and canalicular bile secretion.

Abstract

AIM: To compare, in a pig liver transplantation model, the protective effect of UW with that of IGL-1, a high-sodium preservation solution containing polyethylene glycol (PEG) as an oncotic supply.

METHODS: All livers were harvested and grafted orthotopically according to standard techniques. The livers were washed out and preserved for 7 h in IGL-1 ($n = 6$) or in UW solution ($n = 7$) at 4°C. In a sham group ($n = 4$), the livers underwent a 60-min warm ischemia at 37°C. The hepatocellular injury was assessed in organ preservation solution washed out from the graft at the end of ischemic storage (before revascularization), and in serum 2 h after reperfusion and daily for up to 6 d.

RESULTS: Livers preserved in IGL-1 solution released markedly less AST than that preserved in the UW solution before and after revascularization ($P < 0.05$). Besides, the activity of creatine kinase-BB, a marker of sinusoidal lining cells injury, was higher in the UW group than in the IGL-1 group ($P < 0.05$). Histological results showed less necrotic regions in livers preserved in IGL-1 solution; however, no difference was observed for inflammation.

CONCLUSION: IGL-1 liquid effectively protects parenchymal and non-parenchymal cells against preservation-reperfusion injuries.

INTRODUCTION

Reperfusion injury after cold preservation is associated with the occurrence of primary non-function and delayed graft function, which predisposes allografts to acute and chronic rejection^[1]. Despite these obstacles, organ transplantation has become a clinical routine for several years. Nevertheless, the need of extended ischemia times and the recruitment of marginal donors indicates that this therapy must be optimized. Consequently, it has become necessary to look for better ways to improve cold storage solutions.

The golden standard liquid for the cold preservation of abdominal organs is the University of Wisconsin (UW) solution. Although largely used and incontestably efficient, its performance is continually questioned^[2,3]. It has been reported that performances of this solution are limited by its adjunction of hydroxyethyl starch (HES) that has a hyper-aggregating effect on rat and human red blood cells^[4,5], and by its high potassium concentration that could damage cells^[6,7].

Our previous works on isolated perfused rat livers and kidneys indicates that polyethylene glycol (PEG-35) could be efficiently substituted for HES in an extracellular-like UW solution^[8,9]. The clinical use of this Na-PEG-UW solution, also known as IGL-1, suggests a superiority of IGL-1 compared to standard UW for human kidneys preservation^[10]. However, to our knowledge, no studies have been reported for liver transplantation. Therefore, we aimed to evaluate the preservative effect of IGL-1 solution using an orthotopic liver transplantation (OLT) model in pigs, and to compare its effectiveness with that of the UW solution.

MATERIALS AND METHODS

Animals

Female large white pigs, weighing 25-30 kg, were used as organ donors and recipients. All animals were given humane care and handled in compliance with French regulations. Animals were fasted for 24 h prior to the intervention but had free access to water. All animals received pre-anesthesia with tiletamine (10 mg/kg), zolazepam (7.5 mg/kg) and atropine sulfate (10 µg/kg). After intubation, inhalation anesthesia was maintained by halothane (0.5%-1%), nitrous protoxide and oxygen.

Orthotopic liver transplantation

We used a standard technique for the donor operation. Portal vein (PV), infrahepatic vena cava (IHVC) and suprahepatic vena cava (SHVC) were dissected. The hepatic artery was kept in continuity with the celiac trunk, and the abdominal aorta up to the diaphragmatic pillars. Livers were harvested and washed out *ex situ* with 2 L of chilled preservation solution through PV. The harvested grafts were then cold stored at 4°C for 7 h.

In each recipient animal, a catheter was placed into the aorta to monitor blood pressure during the operation. It has been observed that complete vascular clamping during the anhepatic phase generates severe hypotension, acidosis and hyperkalemia, which may cause the death of the animal^[11]. We, therefore, placed a porto-jugular passive bypass (PJB). Just before and during the anhepatic phase, 500 mL of Hesteril solution (60 g/L of HES in 9 g/L of NaCl) was infused into the recipient to maintain a stable hemodynamic condition. The graft was positioned in the hepatic fossa, SHVC and IHVC and PV of the donor were then anastomosed, respectively, to those of the recipient with running sutures of 4/0 Prolene (for SHVC and IHVC) and 5/0 Prolene (for PV). During portal anastomosis, the graft was flushed out by Hesteril at room temperature (200 mL, IHVC was used as a vent), to purge the preservation solution and waste metabolites accumulated throughout the cold storage period. The donor aorta was implanted end-to-side to the recipient infra-renal aorta with running 7/0 Prolene, and finally the biliary continuity was re-established by using the intra-ductal stent. Reperfusion was thus started after finishing the portal anastomosis and completed after the arterial anastomosis. After OLT, no immunosuppression was given to the animals.

Experimental groups

Animals were divided into three experimental groups. Livers of the UW group ($n = 7$) were cold stored in the original Belzer liquid without dexamethasone, insulin and antibiotics. Livers of the IGL-1 group ($n = 6$) were preserved in the same solution but with inverted concentrations of Na⁺ and K⁺ and containing PEG-35 that was substituted for HES (Table 1). A sham group ($n = 4$) was designed for the purpose of evaluating the effect of warm ischemia throughout OLT. Indeed as for recipients, after complete vascular clamping, a PJB was installed for 60 min. Livers were then rinsed with Hesteril solution and finally PV and IHVC were anastomosed.

Table 1 Composition of UW and IGL-1 preservation solutions

	UW	IGL-1
HES (mmol/L)	0.25	-
PEG-35 (mmol/L)	-	0.03
Lactobionic acid (mmol/L)	100	100
Raffinose (mmol/L)	30	30
MgSO ₄ (mmol/L)	5	5
KH ₂ PO ₄ (mmol/L)	25	25
Glutathione (mmol/L)	3	3
Adenosine (mmol/L)	5	5
Allopurinol (mmol/L)	1	1
Na ⁺ (mmol/L)	30	125
K ⁺ (mmol/L)	125	30
Osmolality (mOsm/Kg)	320	320
pH	7.2-7.4	7.2-7.4

Biochemical determinations

The follow-up was of 6 duration. In order to assess the extent of parenchymal cell damage, the release of AST and ALT in serum was monitored 2 h after reperfusion and then daily for 6 d. Kinetic measurements of enzymes were determined at $A_{340\text{ nm}}$ on a Hitachi 747 analyzer. In addition, activities of total creatine kinase (CK) and CK-BB isoenzyme^[12] were monitored in the organ preservation solution washed out from the graft at the end of ischemic storage and 2 h after reperfusion. Total CK activity was determined with a commercial kinetic UV reagent (BioMérieux, Charbonnières-les-Bains, France). CK isoenzymes were separated electrophoretically on agarose gels with a Paragon kit (Beckman instruments, France). After electrophoresis, CK isoenzymes were detected under UV light, and gels were scanned with a fluorimetric densitometer (SEBIA, France).

Histological study

Liver biopsies were performed after cold storage and on the 6th d. In sham animals, the biopsies were performed only on the 6th d. Histology was achieved on 4-µm thick paraffin-embedded sections by using conventional hematoxylin-eosin staining. The analysis focused on hepatocellular necrosis, sinusoidal dilatation and inflammatory cellular infiltration. The severity of the histological lesions were scored from 0 (normal liver) to +++ (maximal damage).

Statistical analysis

Results were expressed as mean \pm SE. Data between groups were compared using the ANOVA test, followed by the student Newman-Keul test. $P < 0.05$ was considered statistically significant.

RESULTS

All the animals survived for up to 6 d. At time of sacrifice, sites of anastomosis were carefully observed, and all were patent. The groups were comparable with regard to warm and cold ischemia.

The activities of CK-BB and AST were assessed in the first sample retrieved during initial graft rinsing. The CK-

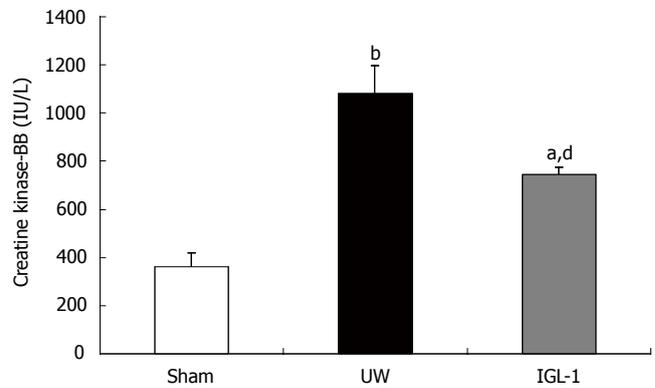

Figure 2 Serum creatine kinase-BB isoenzyme activity 2 h after reperfusion. Data are expressed as mean ± SE. ^a*P* < 0.05 vs sham; ^b*P* < 0.01 vs sham; ^c*P* < 0.01 vs UW.

BB isoenzyme was shown to be a marker of sinusoidal lining cells injury^[12]. There was no significant difference between sham and IGL-1 groups (Figure 1A). In contrast, livers preserved in UW solution released significantly more CK-BB (*P* < 0.05) and AST (Figure 1B, *P* < 0.01) compared to the sham group. Furthermore, the IGL-1-preserved livers released obviously less AST than those preserved in UW liquid (215 ± 78 vs 507 ± 115 IU/L, *P* < 0.05).

Creatine kinase-BB isoenzyme was also monitored 2 h after reperfusion (Figure 2). The data support the view that the levels of this marker after reperfusion are related to the degree of preservation injury. Indeed, livers preserved in UW released significantly more CK-BB (1081 ± 117 IU/L) than livers of sham (361 ± 59 IU/L, *P* < 0.01) and those cold stored in IGL-1 (746 ± 29 IU/L, *P* < 0.01).

After transplantation, the highest activities of AST (Figure 3A) were reached at d 1-2 in both UW and IGL-1 groups (*P* < 0.01 vs sham). They were significantly higher in the UW vs IGL-1 group (1275 ± 215 vs 847 ± 103 IU/L at d 1 and 1046 ± 214 vs 658 ± 122 IU/L at d 2, *P* < 0.05). When livers were preserved in IGL-1 liquid, the activity of ALT (Figure 3B) did not vary at the different times of reperfusion. In contrast, ALT released by livers preserved

in the UW peaked at d 2, although there were no statistical differences between the experimental groups.

The histological study (Figure 4 and Table 2) showed no cellular alterations in the sham group. Livers preserved in IGL-1 liquid were normal with mild necrosis. In contrast, the UW group revealed multiple and extensive areas of hepatocyte necrosis.

DISCUSSION

The prevention of preservation injury is still a subject of interest, the main target of which is the reduction of primary graft non-function or sub-optimal graft function. In this study, the preservative effects of UW and IGL-1 (a PEG-high Na-UW solution) were investigated by using a pig OLT model. The results showed that liver cells integrity was best preserved with IGL-1 liquid.

Our previous studies demonstrated that the simple inversion of Na⁺ and K⁺ in the UW (high Na-UW) solution decreased reperfusion injuries and improved rat liver and kidney functions^[6,13,14]. With the isolated perfused rat liver model, we showed that PEG substitution

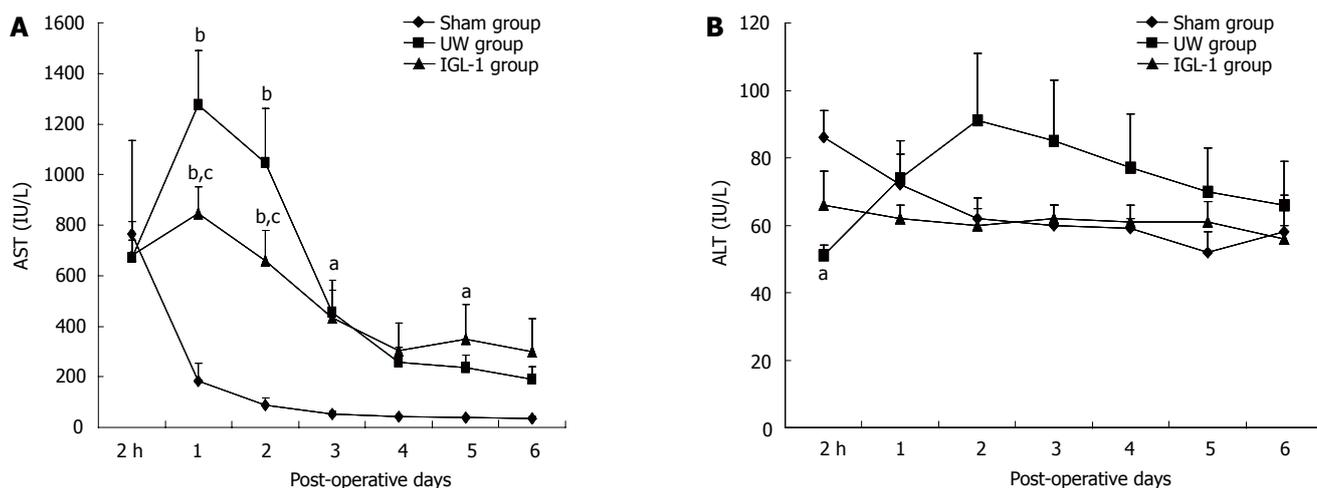

Figure 3 Serum aspartate aminotransferase (A) and alanine aminotransferase (B) activities after liver transplantation. Data are expressed as mean \pm SE. ^a $P < 0.05$ vs sham; ^b $P < 0.01$ vs sham; ^c $P < 0.05$ vs UW.

for HES in high Na-UW solution (IGL-1) was able to reduce parenchymal and non-parenchymal cell damage^[8]. In the autotransplanted pig model, kidneys preserved in IGL-1 solution showed a better function and a significant reduction of MHC class II expression, cellular apoptosis and interstitial fibrosis compared to the kidneys preserved in UW liquid^[9]. In a preliminary clinical study, we found an important improvement in creatinine clearance and a reduction in cellular apoptosis when IGL-1 was used^[10].

It is well known that porcine livers are very sensitive to cold ischemia. In the pig liver transplantation model and after 12 h of cold ischemia, it was reported that all animals died within 24 h of reperfusion, regardless of the cold storage solution used^[15]. That is why we preserved livers for 7 h in order to optimize the animal viability.

There is strong evidence that the period of rewarming ischemia after cold preservation and before reperfusion increases hepatocellular injury and affects graft outcome. Devlin *et al.*^[16] examined liver enzyme (AST, LDH, purine nucleoside phosphorylase and CK-BB) activities present in the organ preservation solution washed out from the graft at the end of ischemic storage prior to reperfusion. They found a correlation between AST activity level and early post-operative graft viability^[16], thereby suggesting that AST is a discriminative marker for post-transplant graft function. In addition, preservation-reperfusion injury is characterized biochemically by high serum AST levels in the early post-operative period^[1,17]. In our hands, a statistical difference in AST levels was found between the use of IGL-1 and UW preservation solutions in effluent preservation fluid during graft rinsing. The same results were also observed at 1-2 post-operative days. Although the results of ALT were not significantly different between the three experimental groups, we could notice the absence of any peak after the use of IGL-1. Our biochemical results suggest that IGL-1 preserves parenchymal architecture after cold storage. This is confirmed by the histological study where few necrotic regions were observed in livers cold stored in IGL-1.

Numerous previous studies demonstrated the

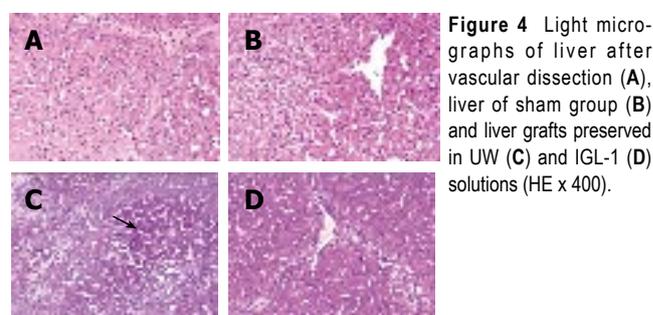

Figure 4 Light micrographs of liver after vascular dissection (A), liver of sham group (B) and liver grafts preserved in UW (C) and IGL-1 (D) solutions (HE x 400).

susceptibility and functional consequences of sinusoidal cells to hypothermic and reperfusion injury. Maintenance of endothelial cells integrity and viability is, therefore, of primary importance during organ transplantation. During the last few years, preservation injury and especially the endothelial cells injury occurring during liver preservation have been described to be due to apoptosis^[18-20]. This process is an early event after reperfusion, since it was observed that 3 h after rewarming, almost all cultured liver endothelial cells lost viability^[21]. One of the common parameters used in the assessment of sinusoidal cell viability is the release of CK-BB isoenzyme in the blood^[12]. Our results revealed that UW does not offer any protection against endothelial cell injury. In comparison to livers preserved in UW solution, livers preserved in IGL-1 released markedly less CK-BB after 2 h of reperfusion. Thus, IGL-1 seems to better protect non-parenchymal cells than UW.

During the last few years, several preservation solutions have been developed and studies comparing these solutions to UW have been carried out. Histidine-tryptophan-ketoglutarate (HTK) preservation solution, designed as a cardioplegia liquid, is now used routinely by many centers of abdominal organs preservation. Recent data suggested HTK to be an effective preservation solution of livers^[22]. Interestingly, HTK offered a powerful ability to preserve endothelial structure and function during warm ischemia^[23].

During storage, the preservation solution is in direct contact with the vascular endothelial bed. Injured endothelial cells are potent producers of cytokines and adhesion molecules that directly facilitate graft invasion by humoral and cellular components of inflammation^[24]. These mediators increase damage caused by ischemia or reperfusion and promote acute rejection and chronic rejection. It is reported that HES in UW enhances red blood cell aggregation^[4], leading to microvessel occlusive events and inflammation. In contrast, it is described that PEG in UW reduces the inflammatory injury due to cold ischemia-reperfusion in an autotransplanted pig kidney model^[25]. Our histological results showed no significant difference for inflammation between the two preserved groups.

In conclusion, data reported here indicate that IGL-1 efficiently preserves parenchymal and non-parenchymal cells associated with orthotopic liver transplantation. Despite the fact that the UW solution is the most commonly used cold storage liquid, HES and K⁺ limit its performances. IGL-1 (a PEG high-Na UW solution) could represent a valid alternative in organ preservation.

Abstract

AIM: To study the selective killing of human umbilical vein endothelial cells (HUVECs) by a double suicide gene under the regulation of a kinase domain insert containing receptor (KDR) promoter and mediated by an adenoviral gene vector.

METHODS: Human KDR promoter was cloned by polymerase chain reaction (PCR), and two recombinant adenoviral plasmids pAdKDR-CdglyTK, pAdCMV-CDglyTK were constructed according to a two-step transformation protocol. These two newly constructed plasmids were then transfected into 293 packaging cells to grow adenovirus, which were further multiplied and purified. HUVECs and LoVo cells were infected with either of the two resultant recombinant adenoviruses (AdKDR-CDglyTK and AdCMV-CDglyTK) respectively, and the infection rates were estimated by detection of green fluorescent protein (GFP) expression. Infected cells were cultured in culture media containing different concentrations of 5-fluorocytosine (5-FC) and ganciclovir (GCV), and the killing effects were measured.

RESULTS: The two recombinant adenoviral plasmids pAdKDR-CdglyTK, pAdCMV-CDglyTK were successfully

constructed and transfected into 293 cells. The resultant recombinant adenoviruses infected cells caused similar infection rates; and the infected cells exhibited different sensitivity to the prodrugs: HUVECs infected with AdCMV-CDglyTK and LoVo cells infected with AdCMV-CDglyTK were highly sensitive to the prodrugs, and HUVECs infected with AdKDR-CDglyTK were similarly sensitive but significantly more sensitive than the LoVo cells infected with AdKDR-CDglyTK ($P < 0.001$).

CONCLUSION: Selective killing of HUVECs may be achieved by gene transfer of double suicide gene under the regulation of the KDR promoter. This finding may provide an optional way to target gene therapy of malignant tumors by abrogation of tumor blood vessels.

INTRODUCTION

Gene therapy is a novel technology leading to improved treatments of some types of cancer^[1-3]. On the other hand, anti-angiogenic therapy has also been proven to be a rational approach in the treatment of solid tumors also^[4-9]. Selective delivery of the suicide gene into tumor endothelial cells and target expression of it to abrogate tumor vasculature may be a good way for tumor therapy.

A suicide gene is a gene encoding an enzyme that converts nontoxic prodrugs into toxic forms. The herpes simplex virus-thymidine kinase (TK) gene is one of the most widely studied suicide genes^[10], and the *E. coli* cytosine deaminase (CD) gene is another widely studied one^[11-13]. However, results of numerous investigations aimed at eradicating tumors employing either CD or TK demonstrate their limitations. Whether the limitations

stem from unfavorable pharmacokinetics, loss of transgene expression or biochemical resistance is not clear. Nevertheless, fusion gene of CD and TK shows exciting superiority in many studies^[14-17].

The adenovirus vector system has many advantages^[18-20]. First, adenovirus vectors can be prepared at much higher titers than retroviral vectors and have a high efficiency of gene transfer regardless of the proliferative states of the tissues whereas retroviral vectors insert their genes only into dividing cells. Second, adenovirus genomes usually do not integrate into the host cell chromosome, and the level of therapeutic gene expression is very high. Human umbilical vein endothelial cells (HUVECs) are primary cells that can be used to investigate the mechanisms underlying the role of endothelial cells^[21]. The kinase domain insert containing the receptor (KDR) gene is strictly expressed only in vascular endothelium cells. The activity of the KDR promoter in endothelial cells is similar to that of the potent SV40 promoter/enhancer and that this high level activity is specific to endothelial cells^[22].

We constructed two recombinant adenoviruses to transfer the double suicide gene under the KDR promoter or the CMV promoter into HUVECs respectively, and LoVo cells (a cell system of colon carcinoma) were used as the control. Prodrug sensitive experiments were performed to evaluate the killing effect of the fusion double suicide gene under the regulation of the KDR promoter, mediated by the adenovirus vector on HUVEC cells.

MATERIALS AND METHODS

Materials

Shutter plasmid pAdtrack, pAdtrack-CMV, adenoviral backbone plasmid pAdEasy-1 and *E. coli* BJ5183 were provided by Dr. Belt Vogelstein at Johns Hopkins Oncology Center, Howard Hughes Institute of Medicine. pMD18-T vector was purchased from TaKaRa Biotechnology (Dalian) Co. Ltd. 293 cells, and HUVECs were obtained from American Type Culture Collection (ATCC). All sorts of exonuclease, T4 DNA ligase, and Taq DNA polymerase were purchased from New England Biolabs Co. DMEM, fetal bovine serum (FBS), transfection reagents, and LipofectAMINE2000 were products of Gibco Co. Primers of KDR promoter gene, CD gene, TK gene were synthesized and sequenced by Sangon Biotechnology (Shanghai) Co., Ltd.

KDR promoter sequence and CDglyTK sequence

KDR promoter genes (including the minimum core of the gene sequence -226~+268) were generated by PCR using human blood genome as the template (the upstream primer sequence: 5'-GGAAGATCTAGTTGCTCAGC-GCCCGTTAC-3', the downstream primer sequence: 5'-CCCAAGCTTGGCGAAATGCCAGAACTCG-3'). The resulting fragment containing Bgl at the 5' end, and HindIII restriction sites at the 3' end respectively were linked to pMD18-T vector to generate pMD-18KDR. Another two PCR protocols were performed to generate CD and TK gene sequences (the upstream primer sequence of CD: 5'-AAGCTTAGGCTAGCAATGTC-GAATAACGCT-3', the downstream primer sequence: 5'

-GGATCCTCCACGTTTGTAAATCGATGGCTTC-3'; the upstream primer sequence of TK: 5'-GGATCCG-GCGGGGGCGGTGGAGGAGGGGGTATGGCTTC-GTAC-3', the downstream primer sequence of TK: 5'-TCTAGATTAGTTAGCCTCCCCCATCTC-3'. The chromosome DNA of *E. coli* JM109 was used as template for CD gene amplification, and plasmid pREP8-TK for TK gene). According to the protocols, the initiation codon of the resulting CD gene was converted to ATG, termination codon of TAG to GGA which is to code for glycine, and its 5' end was to have BglII, and 3' end to have Hind III restriction sites respectively. The two amplified fragments were subcloned into pcDNA3 vectors to generate pcDNA3-CDglyTK.

Transfer plasmids construction

KDRs were removed from pMD-18KDR by BglII, Hind III and subcloned into pcDNA3-CDglyTK to generate pcDNA3-KDR-CDglyTK, which was digested with BglII and PvuII to get KDR-CDglyTK fragment. The resulting KDR-CDglyTK fragments were subcloned into pAdtrack to generate pAdtrackKDR-CDglyTK. CDglyTK fragment from pcDNA3-CDglyTK (HindIII, XbaI) was subcloned into pAdtrackCMV to construct pAdtrackCMV-CDglyTK.

Construction and identification of recombinant adenovirus vector plasmid

pAdEasy-1 plasmid was transformed into *E. coli* BJ5183, followed by growing of transformants on LB agar plates containing ampicillin and streptomycin. The transformed bacterium was named "AdEasy-1 bacteria".

pAdtrackKDR-CDglyTK was linearized and transformed into AdEasy-1 bacteria. Transformants were selected on LB agar plates containing 25 µg/mL kanamycin. Plasmid DNA was prepared from individual colonies, and agarose gel electrophoresis was performed. The correct recombinant pAdKDR-CDglyTK could be clearly identified by size, as only the 11.2-kb pAdtrackKDR-CDglyTK plasmid and the 37-kb pAdKDR-CDglyTK were selectable by kanamycin resistance.

The same protocol was performed to transfer pAdtrackCMV-CDglyTK into AdEasy-1 bacteria to recombine with pAdCMV-CDglyTK.

Propagation, purification, titer determination and identification of the recombinant adenovirus

Both pAdKDR-CDglyTK and pAdtrackCMV-CDglyTK were transferred into 293 cells mediated by LipofectAMINE2000 vector. Their further propagation was visualized under fluorescence microscope by GFP expression of transgene, and ultracentrifugation in CsCl gradient was performed to purify the viruses, and the titration of AdKDR-CDglyTK and AdtrackCMV-CDglyTK was measured by plaque formation assay.

The resultant recombinant viruses were boiled to be used as templates. PCR protocols were performed either to ensure the presence of CDglyTK gene in the viruses, in which upstream primer sequence of CD and downstream primer sequence of TK were used, or to ensure the

presence of the KDR promoter gene in AdKDR-CDglyTK. Primers of KDR promoter were used.

Cell culture and virus infection rate

HUVECs and LoVo cells, obtained from ATCC, were maintained in calorstart of 37°C, with 5% CO₂ and in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum (FBS). Cells (2×10^5 /well, 6-well plate) were infected with AdKDR-CDglyTK or AdCMV-CDglyTK at different multiplicity of infection (MOI). Percentages of cells expressing GFP were counted under fluorescence microscope within 3 d.

Prodrug sensitivity assays

HUVECs or LoVo cells (1×10^4 cells/well, 96-well plate, inoculated one day before) were infected with AdKDR-CDglyTK or AdCMV-CDglyTK at MOI of 100, 16 h later. The medium was removed and replaced with fresh medium with different concentrations of 5-FC and/or GCV. Cells were cultured in the presence of prodrugs for 72 h. Cell viability was determined by 3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide (MTT) assay according to the manufacturer's protocol.

Statistical analysis

Statistical analyses were made by ANOVA and LSD test. The values were calculated as means \pm SD. $P < 0.05$ was considered statistically significant.

RESULTS

Amplification or construction of gene fragments

The products of PCR amplification or constructed KDR promoter gene, CD and TK genes and CDglyTK gene were sequenced and verified by Sangon Biotechnology (Shanghai) Co., Ltd.

Recombinant viral plasmids

Newly constructed pAdtrackKDR-CDglyTK and pAdtrackCMV-CDglyTK were identified by restriction analysis and transferred into AdEasier-1 bacteria. Recombinant bacteria were selected by kanamycin. Figure 1 is the map of plasmids from 10 clones of transferred bacteria selected by kanamycin. Nine of them were correctly recombined, with a correction rate of 90% (9/10).

Recombinant viruses

Three days after transferring pAdKDR-CDglyTK and pAdCMV-CDglyTK into 293 cells, we found that most transferred 293 cells expressed GFP (Figure 2). The titer of the purified virus after being sufficiently propagated was 3.5×10^{12} pfu/L. No difference between AdKDR-CDglyTK and AdCMV-CDglyTK was observed.

The products of the PCR using the recombinant viruses as templates were proven to be correct by size comparison (Figure 3), with KDR promoter of 580-bp and CdglyTK of 2.5-kb.

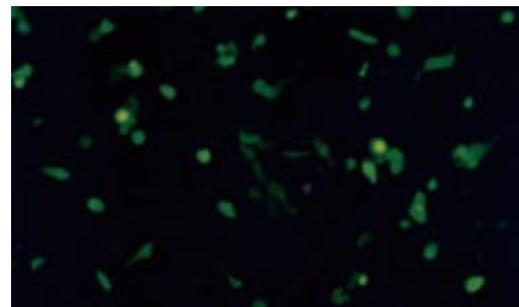

Figure 2 Recombinant viruses propagating in 293 cells. GFP expression was visualized by fluorescence microscopy 3 d after transfer of recombinant plasmids into 293 cells.

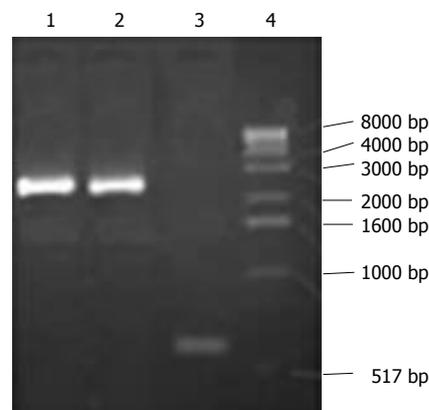

Figure 3 PCR amplification of CDglyTK and KDR promoter gene from the recombinant adenoviruses DNA. 1: PCR products of AdCMV-CDglyTK DNA using the upperstream and downstream primers of CDglyTK gene; 2: PCR products of AdKDR-CDglyTK DNA using the upstream and downstream primers of CDglyTK gene; 3: PCR products of AdKDR-CDglyTK DNA using the upstream and downstream primers of KDR promoter gene; 4: 1 kb DNA ladder (products of Dingguo Biotechnology Development Center Co., Ltd.)

or AdCMV-CDglyTK at different MOI were observed 3 d post-infection (Figure 4). It was indicated that cell infection rate increased with the increase of MOI of the virus: when MOI = 1, only a few cells expressed GFP; when MOI = 100, most cells expressed GFP; when MOI = 200, almost all cells expressed GFP. There was no difference between the two recombinant viruses in infecting HUVECs and LoVo cells.

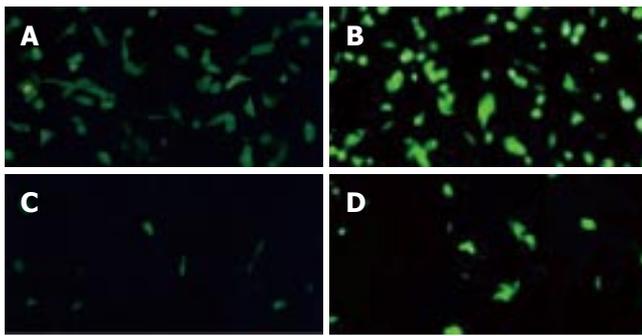

Figure 4 The recombinant viruses infected cells and transgene expression. **A, C:** GFP expression of HUVECs 5 d after infected with AdKDR-CDglyTK at MOI = 100 and MOI = 1; **B, D:** GFP expression of LoVo cells 5 d after infected with AdKDR-CDglyTK at MOI = 100 and MOI = 1.

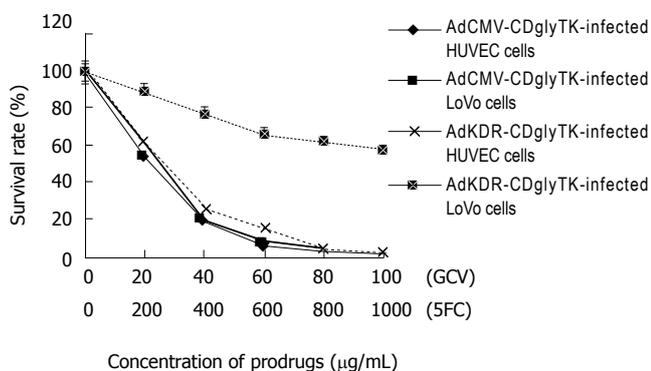

Figure 5 Killing effect of prodrugs to transgenic cells.

Killing effect of prodrugs

HUVECs and LoVo cells infected with AdKDR-CDglyTK or AdCMV-CDglyTK at MOI of 100 were maintained in culture medium of different concentration of GCV and 5-FC for 3 d, and the survival rates were measured (Figure 5). Both AdCMV-CDglyTK-infected HUVECs and AdCMV-CDglyTK-infected LoVo cells were highly sensitive to the prodrugs. More than 80% of both transgene cells were killed when they were treated with 40 µg/mL GCV + 400 µg/mL 5-FC; almost all of both types of cells were killed when treated with 100 µg/mL GCV + 1000 µg/mL 5-FC. The sensitivities of these two transgenic cells were of no much difference ($P = 0.518$). AdKDR-CDglyTK-infected HUVECs were highly sensitive to the prodrugs, similarly ($P > 0.2$); however, AdKDR-CDglyTK-infected LoVo cells were far less sensitive to the prodrugs ($P < 0.001$). There was still 57.2% survival of cells 3 d after treatment with 100 µg/mL GCV + 1000 µg/mL 5-FC.

DISCUSSION

A blood supply is required for a tumor to progress in excess of 1-2 mm³[23,24]. Recent data suggest that tumor cells can co-opt surrounding vasculature from an even smaller size in certain tumor types[25]. The expanding growth of a primary tumor is associated with neo-angiogenesis and vessel maturation of the tumor.

Abrogation of tumor blood vessel should lead to the eradication or suppression of solid tumor. Moreover, Folkman proposed that the prevention of tumor vascularization essentially stops neoplastic invasion, which may lead to the ablation of metastatic disease[26]. The rapid growth of a tumor results in hypoxia[27] which induces the production of pro-angiogenic factors such as vascular endothelial growth factor (VEGF)[28]. VEGF is a potent and specific mitogen for endothelial cells. It plays a major role in angiogenesis and vasculogenesis. KDR and Flt-1 are the two receptor tyrosine kinases that regulate the actions of VEGF and are expressed in endothelial cells. KDR is critically involved in the regulation of angiogenesis, both in the developing and adult animals[29]. The vascular endothelial cell is renewed at a low speed in normal conditions, and its KDR expression level is very low, while tumor vascular endothelial cells proliferate quickly and with a KDR expression level 500 times higher than that of vascular endothelial cells of normal tissues[30]. Therefore, it is possible to realize targeted expression of therapeutic genes in tumor vascular endothelial cells by transcriptional regulation of the KDR promoter, thus markedly reducing the toxicity and side effects of gene therapy targeting vascular endothelial cells of tumors.

In our experiments, we constructed two replication-incompetent recombinant adenoviral vectors with the AdEasy system in a "two-step transformation protocol" to transfer the KDR-promoter-controlled/CMV-promoter-controlled double suicide gene into HUVEC/LoVo cells. The results indicated that "two-step transformation protocol" is a convenient and efficient way to generate adenoviral vectors. The resultant adenoviruses infected HUVECs with a great efficiency and the transgenes were efficiently expressed, which was delineated by the reporter gene GFP as it was expressed in almost all HUVECs when they were infected with the virus at MOI of 200. The subsequent prodrug sensitivity experiments demonstrated that this high level expression was strong enough for cell killing *in vitro*. The prodrug sensitivity experiment also demonstrated that CMV-promoter-controlled double suicide gene/prodrugs system unselectively killed both HUVECs and LoVo cells; however, the KDR-promoter-controlled double suicide gene/prodrugs system displayed a targeted killing effect on HUVECs: treated with 40 µg/mL GCV + 400 µg/mL 5-FC, 74.8% KDR-CDglyTK-transferred HUVECs were killed while 77.6% KDR-CDglyTK-transferred LoVo cells were alive; treated with 100 µg/mL GCV + 1000 µg/mL 5-FC, 98.5% KDR-CDglyTK-transferred HUVECs were killed while the killing rate of KDR-CDglyTK-transferred LoVo cells was 42.8%. All these come to an exciting conclusion that: the KDR-promoter-controlled double suicide gene/prodrugs system bears a selectively killing effect on HUVEC. This finding may provide an optional way for targeting gene therapy of malignant disease by abrogation of tumor blood vessels.

Abstract

AIM: To simultaneously evaluate the presence of defects in gallbladder and gastric emptying, as well as in intestinal transit in gallstone patients (GS) and the effect of chronic ursodeoxycholic acid (UDCA) administration on these parameters and on serum bile acids and clinical outcome in GS and controls (CTR).

METHODS: After a standard liquid test meal, gallbladder and gastric emptying (by ultrasound), oroileal transit time (OITT) (by an immunoenzymatic technique) and serum bile acids (by HPLC) were evaluated before and after 3 mo of UDCA (12 mg/kg bw/d) or placebo administration in 10 symptomatic GS and 10 matched healthy CTR.

RESULTS: OITT was longer in GS than in CTR ($P < 0.0001$); UDCA significantly reduced OITT in GS ($P < 0.0001$), but not in CTR. GS had longer gastric half-emptying time ($t_{1/2}$) than CTR ($P < 0.0044$) at baseline; after UDCA, $t_{1/2}$ significantly decreased ($P < 0.006$) in GS but not in CTR. Placebo administration had no effect on gastric emptying and intestinal transit in both GS and CTR.

CONCLUSION: The gallstone patient has simultaneous multiple impairments of gallbladder and gastric emptying, as well as of intestinal transit. UDCA administration restores these defects in GS, without any effect in CTR. These results confirm the pathogenetic role of gastrointestinal motility in gallstone disease and suggest an additional mechanism of action for UDCA in reducing bile cholesterol supersaturation.

INTRODUCTION

Cholesterol gallstone disease is frequent, in fact its prevalence ranges from 10% to 20% in Western countries^[1]. Although most gallstone patients (GS) are asymptomatic^[1,2], a progressively increased rate of cholecystectomies has been reported^[3], thus confirming that gallstone disease is one of the major gastrointestinal problems throughout the Western world. Cholesterol gallstone pathogenesis is complex and multifactorial, involving both genetic defects and environmental factors^[4,5], all of which contribute to cholesterol-supersaturated bile, rapid nucleation time of cholesterol microcrystals (as a result of excess promoters and/or a deficiency of crystallization inhibitors), and impaired gallbladder motility. However in GS not only is gallbladder motility defective^[6], but it has been recently documented^[7-9] that also intestinal transit time and gastric emptying are delayed. However, no study has simultaneously evaluated gallbladder and gastric emptying and intestinal transit in GS.

Ursodeoxycholic acid (UDCA) is a drug known to be able to reduce bile cholesterol supersaturation and to dissolve cholesterol gallstones^[10], without significant side effects^[11]. Reduction in bile cholesterol supersaturation is reached, according to some^[12,13] but not to others^[14,15], mainly through a reduction in intestinal cholesterol absorption and by formation of a liquid crystalline phase^[16]. Furthermore, UDCA has been proposed in gallstone prevention in subset populations, i.e. obese patients during weight loss^[17] and more recently, it has been shown that chronic, long-term UDCA administration reduces biliary pain in GS^[18]. Conflicting results exist regarding the effect of UDCA on gallbladder motility, since fasting and residual gallbladder volumes were found to be increased while gallbladder emptying has been

found to be either decreased or unmodified^[6,19]. Moreover, no definitive data is available on the effect of chronic UDCA administration on gastrointestinal (GI) motility in man.

In a preliminary study aimed at simultaneously evaluating gallbladder and gastric emptying and intestinal transit before and after UDCA treatment in GS and healthy subjects, we found^[20] that GS presented impaired gallbladder and gastric emptying and delayed intestinal transit and that UDCA administration improved these defects in GS without inducing any significant effect in healthy subjects.

Since these observed effects of UDCA administration could have been biased by the lack of a placebo arm in the study protocol, we performed a new placebo-controlled study aimed at evaluating the effect of chronic administration of UDCA on gastric and gallbladder emptying and intestinal transit in GS and controls.

MATERIALS AND METHODS

Study design

This single blinded, placebo controlled study was designed to evaluate the effects of UDCA, or placebo, on meal stimulated gallbladder and gastric emptying, small intestinal transit and serum bile acid pattern in GS and healthy controls (CTR). All individuals were assigned to UDCA for the first treatment period of the study lasting 3 mo, then after an interim 15 d washout period, placebo was administered for additional 3 mo. Patients and controls were unaware of the study design, while ultrasonographers were unaware of the results of biochemical analyses (serum bile acid determination, intestinal transit time), and biochemical investigators were unaware of the results of ultrasonographic investigations.

The study design was in accordance with the ethical guidelines of the Declaration of Helsinki and approved by the Local Ethical Committee. Written informed consent was obtained from all subjects.

Study population

The studied population was comprised of 10 consecutive GS (4 males, 6 females, mean age 49.5 ± 2.2 years, range

30-63; mean body mass index (BMI) 23.0 ± 0.8 kg/m²) and 10 matched CTR (4 males, 6 females, mean age 50.5 ± 1.4 years, range 28-61; mean BMI 22.8 ± 0.4 kg/m²). CTR were recruited from local staff members of our department. Characteristics of patients and controls are shown in Table 1, while in Table 2 the biochemical parameters are reported. All enrolled GS had cholesterol gallstones, as evaluated by oral cholecystography. They had a history of biliary pain, defined according to the previously identified criteria^[2], as a pain at the epigastrium or right hypochondrium, unrelated to meal ingestion, which does not disappear with bowel movements. No GS had past or present signs of complicated gallstone disease (i.e. acute cholecystitis, biliary obstruction or biliary pancreatitis). Furthermore, no GS had other GI and/or liver diseases or was taking drugs potentially affecting gastrointestinal function. All GS were suitable to bile acid dissolution therapy according to the indications of a recent Working Team Report^[21], i.e. radiolucent gallstones less than 1.5 cm in diameter, in functional gallbladder. All GS patients and controls had daily bowel evacuation and fertile female subjects were studied within the follicular phase to prevent any influence of hormones on GI motility behaviour.

Study protocol

Gallbladder and gastric emptying, oro-ileal transit time (OITT) and serum bile acids were assessed in all subjects at enrollment, after 3 mo administration of UDCA (*Deursil*® *Sanofi-Synthelabo, Paris-Cedex, France*) (12 mg/kg bw/d), after the wash-out period and at the end of placebo administration. Furthermore, the presence of biliary pain and/or dyspeptic symptoms (i.e. heartburn, vomiting, nausea, belching, bloating feeling after meals, intolerance to fatty or fried foods, epigastric discomfort, uncomfortable feeling at the right hypochondrium), were evaluated before and during treatment.

Gallbladder emptying

Gallbladder emptying was evaluated by a previously described ultrasonographic technique using the ellipsoid method^[6]. Both GS and control subjects were studied after an overnight fast. Gallbladder volume variations were measured in response to a standard liquid test meal (200 mL containing 375 kcal, 17 g fats, 10.4 g proteins, 10 g carbohydrates); measurements were performed before and

every 10 min after meal ingestion until 80% gallbladder refilling was reached. Results were expressed as fasting gallbladder volume (FV, in mL), given as the mean of four measurements obtained before meal intake; residual gallbladder volumes (RV, mL), given by the minimal gallbladder volume after postprandial gallbladder emptying, and percent gallbladder emptying (%E), given by: $(FV - RV / FV) \times 100$. All measurements were performed by two sonographers (AC, LS) and inter- and intra-observer variations less than 8% were documented.

Oro-ileal-transit time

OITT was evaluated as previously described^[8], using the tauroursodeoxycholic acid (TUDCA) load test and evaluating serum TUDCA appearance time. TUDCA was used since this bile acid is selectively and rapidly absorbed in the terminal ileum^[22]. After 12 h of fasting, each individual was given the standard liquid test meal to which 1.5 g of TUDCA was added. Blood samples were collected by peripheral venous catheter every 30 min for 7 h and then stored at -20°C until analyzed. OITT was evaluated measuring serum concentrations of TUDCA by means of an enzymatic immunoassay using a specific antibody against this bile acid^[23]. The assay fulfils all the requirements of precision and accuracy; the intra- and inter- assay precision, evaluated on six replicates of human serum samples spiked with three levels of TUDCA (0.001, 0.01, 0.1 μmol/L), presents a CV % below 8%. The accuracy of the method has been evaluated by comparison with the results obtained using a high-pressure-liquid chromatography -ES- mass spectrometry (HPLC-ES-MS) reference method^[24].

OITT was defined, as previously described^[8], as the time-interval between test meal administration and peak serum concentration of TUDCA.

Serum bile acid levels

Fasting serum bile acids were measured by HPLC-MS^[24]. In brief, serum samples (0.1 mL) were diluted with 3.5 mL of 0.1 mmol/L NaOH, incubated at 64°C for 30 min and submitted to a clean-up procedure by means of a conventional C18 reverse-phase extraction. The apparatus consisted of an analytical HPLC system (Alliance 2695 Waters, Milford, MA, USA) connected with a triple quadrupole mass spectrometer (Quattro LC, Micromass, Wythenshawe, UK), with electrospray interface. Individual bile acids were separated on a C18 analytical column (Ultrasphere XL, 3 μm, 70 mm × 4.6 mm I.D., Beckman Instruments, Berkeley CA, USA) and analysed by electrospray mass spectrometry in the negative-ion acquisition mode following the procedure previously described^[24].

Gastric emptying

Gastric emptying was evaluated simultaneously with gallbladder motility, monitoring changes in the gastric antral area by an ultrasonographic technique^[9,25]. Gastric antral area variations were evaluated before and after administration of the same standard liquid test meal used to assess gallbladder motility. Results were expressed as

half-emptying time ($t_{1/2}$): the time, in minutes, to observe a 50% decrease in maximal antral area measured by linear regression analysis.

Statistical analyses

All results were analysed using the Statistical Package for Social Science (SPSS version 11.5). Unless otherwise stated, all results were expressed as mean ± SE. Student's *t* test for paired and unpaired data was used to evaluate significant intra- or inter-group differences. A repeated measure ANOVA model was individually fitted for each of the following variables: gallbladder basal and residual volume, gallbladder emptying, intestinal transit time, gastric emptying, serum levels of cholic (CA), deoxycholic (DCA), lithocholic (LCA), ursodeoxycholic (UDCA) and chenodeoxycholic (CDCA) acids. Treatment (basal, UDCA and placebo) was considered as the within-subject factor and controls versus GS was considered as the between-subject factor.

Univariate and multivariate linear regression analyses were performed to evaluate the relationship between serum bile acid levels and gastric $t_{1/2}$, OITT, fasting gallbladder volume and gallbladder emptying. Each statistical test was conducted at the significance level of 0.05 (two-sided).

RESULTS

Clinical outcome

All enrolled individuals completed UDCA or placebo treatment and no adverse treatment-related events, and in particular stool frequency change, were recorded. At enrolment, all GS were symptomatic and dyspeptic symptoms were present in 4 out of 10 GS (40%). No significant difference was present between controls and GS in terms of frequency and severity of dyspeptic symptoms. Biliary pain disappeared during UDCA treatment in all GS, while during placebo administration 20% of patients had symptom recurrence. No significant change (reduction or increase) in the number or size of the gallstones was observed during the study period.

Serum bile acids

Serum bile acid profiles were different in GS and CTR (Figure 1) groups. Baseline serum DCA was significantly higher in GS than controls (DCA%: 25.7 ± 0.5 vs 16.7 ± 0.4 , $P < 0.05$); LCA was higher in GS than controls (LCA% = 2.6 ± 0.5 vs 1.1 ± 0.2), but not significantly, while CA and CDCA were significantly lower in GS than in CTR (CA%: 33.2 ± 1.1 vs 37.2 ± 0.6 ; $P < 0.02$; CDCA %: 37.8 ± 0.7 vs 43.7 ± 0.6 ; $P < 0.05$).

After UDCA administration, CA, DCA and CDCA significantly decreased both in GS and CTR ($P < 0.05$); UDCA significantly increased ($P < 0.05$), reaching up to 60% of total serum bile acids in both groups (Figure 1). After placebo administration, in both GS and CTR, serum bile acid proportion did not significantly change compared to baseline values.

Oro-ileal-transit time

At baseline, GS showed longer OITT compared to

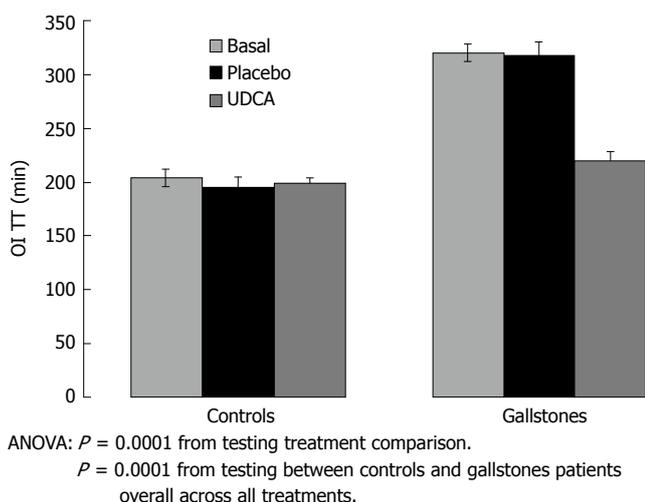

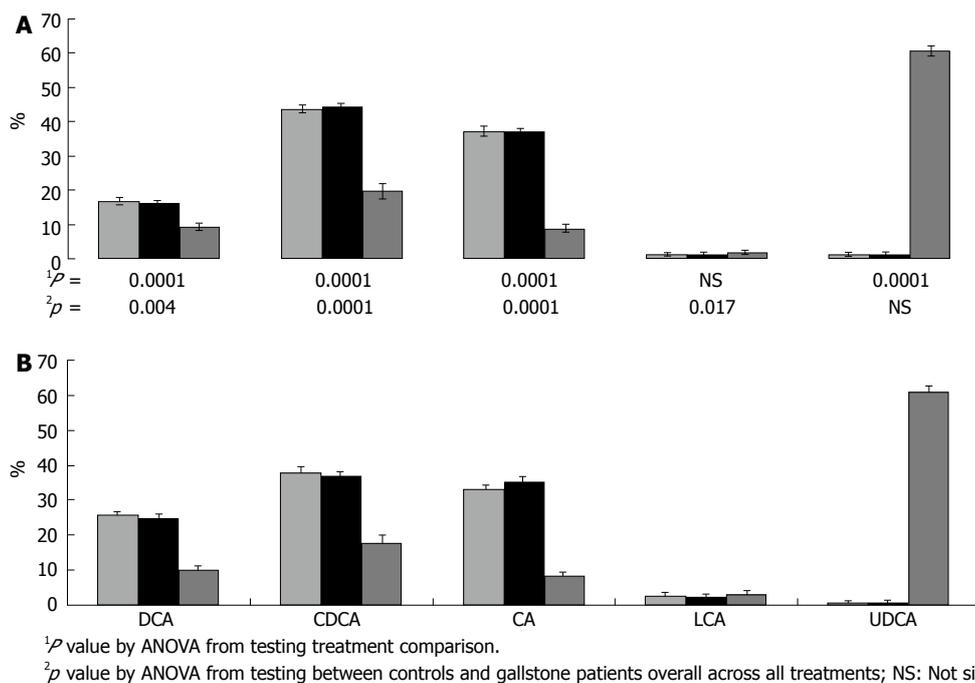

Figure 2 Oro-ileal transit time (OITT) in gallstone patients and healthy controls before (□) and after placebo (■) and ursodeoxycholic acid (UDCA) (▨) administration.

controls (GS: 320.0 ± 6.9 min *vs* CTR: 204.0 ± 7.2 min.; $P < 0.05$) (Figure 2). UDCA treatment significantly reduced OITT in GS patients ($P < 0.05$) but not in controls. At the end of treatment, OITT was no longer significantly different in GS and controls (219.5 ± 8.9 min and 198.0 ± 8.8 min, respectively). Placebo administration did not significantly modify OITT in both GS and controls.

Gallbladder emptying

At baseline, with respect to controls, GS showed significantly larger fasting gallbladder volume (GS: 23.5 ± 0.9 mL *vs* CTR: 18.8 ± 0.9 mL, $P < 0.05$) and residual gallbladder volume (GS: 8.5 ± 0.3 mL *vs* CTR: 4.7 ± 0.8 mL, $P < 0.05$) than controls; percent gallbladder emptying was significantly smaller in GS than in controls (63.8 ± 2.4 and 76.0 ± 2.3 , respectively, $P < 0.05$) (Table 3).

Table 3 Fasting and residual gallbladder volumes, and percent gallbladder emptying before and after ursodeoxycholic acid (UDCA) and placebo administration in gallstone patients ($n = 10$) and healthy controls ($n = 10$)

	Basal	UDCA	Placebo	P^2
Fasting Volume (mL):				
Controls	18.8 (0.9)	22.9 (0.6)	19.1 (0.9)	0.001
Gallstones	23.5 (0.9)	26.2 (0.5)	24.1 (0.9)	
P^1	0.0001			
Residual Volume (mL):				
Controls	4.7 (0.8)	6.4 (0.7)	4.9 (0.7)	0.003
Gallstones	8.5 (0.3)	11.0 (1.0)	8.5 (0.2)	
P^1	0.0001			
Gallbladder emptying (%)				
Controls	76 (2.3)	71.9 (3.2)	74.5 (2.2)	0.066
Gallstones	63.8 (2.4)	59.5 (3.3)	61.6 (2.2)	
P^1	0.001			

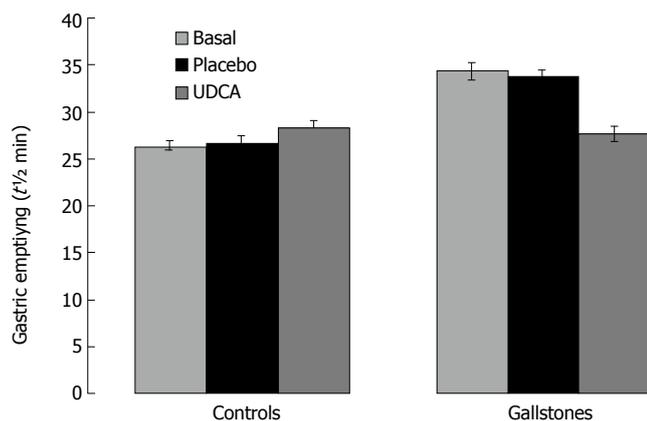

Repeated measures Analysis of Variance. ¹From testing between controls and gallstone patients overall across all treatment; ²For testing the treatment effect (basal, UDCA, placebo).

No significant effect was observed after placebo treatment in both GS and controls; after UDCA treatment, fasting and residual gallbladder volumes significantly increased both in GS and controls, while the percent of gallbladder emptying did not significantly change in both groups, as shown in Table 3. No difference was observed in fasting and gallbladder emptying between basal UDCA and basal placebo treatment.

Gastric emptying

At baseline half emptying time ($t_{1/2}$) was significantly longer in GS than in controls (34.3 ± 1.8 min and 26.4 ± 1.7 min, respectively, $P < 0.05$) (Figure 3).

Following UDCA, $t_{1/2}$ was significantly reduced only in GS, while no significant change was observed in controls; as a consequence, half-emptying time was similar in the

ANOVA: $P = 0.03$ from testing treatment comparison.

$P = 0.015$ from testing between controls and gallstones patients overall across all treatments.

Figure 3 Gastric half emptying-time ($t_{1/2}$, min) in gallstone patients and healthy controls before (□) and after placebo (■) and ursodeoxycholic acid (UDCA) (▨) administration.

two groups (GS: 27.6 ± 1.6 min, controls: 28.3 ± 1.6 min). Gastric $t_{1/2}$ did not change significantly after placebo in either GS or controls (Figure 3).

Relationship between serum bile acid, gallbladder and gastric emptying, and intestinal transit

At baseline, a direct linear correlation between serum DCA and OITT ($P = 0.0001$) and serum DCA and gastric $t_{1/2}$ ($P = 0.024$) was observed, while an inverse relationship was present for CA and OITT ($P = 0.001$) as well as for CDCA *vs* OITT ($P = 0.0001$) (Table 4). Furthermore, serum DCA percent concentrations directly related with fasting gallbladder volume ($P = 0.0007$) and inversely with percent gallbladder emptying ($P = 0.004$). At multivariate analysis, only DCA significantly related to OITT ($b = 12.1$, 95% CI = 6.2-17.9, $P = 0.0001$). The relationships found to be present at univariate analysis remained after placebo administration, but they disappeared at the end of UDCA treatment.

DISCUSSION

Data emerging from the present study, simultaneously evaluating the motor behaviour of the various GI segments in cholesterol gallstone patients and in healthy subjects, documented in GS the presence of multiple defects involving the gallbladder, the stomach and the small intestine. However, the most important aspect of this paper is that only chronic UDCA administration, and not placebo, significantly influenced gallbladder and gastric emptying, and intestinal transit. Furthermore, this effect is achieved only in GS, being UDCA ineffective in controls. In fact, only in GS did oro-ileal transit time and gastric emptying become faster, normal values being achieved at the end of the UDCA treatment period. All of these effects occurred with a significant improvement in clinical manifestations of the gallstone disease; in fact, most patients no longer experienced episodes of biliary pain during treatment with UDCA.

Table 4 Relationship between serum bile acids and intestinal transit time (OITT), gastric half emptying time ($t_{1/2}$ min) and gallbladder emptying (%) in gallstone patients ($n = 10$) and healthy controls ($n = 10$) (univariate analysis)

	OITT (min)		Gastric emptying ($t_{1/2}$, min)		Gallbladder emptying (%)	
	<i>r</i>	<i>P</i>	<i>r</i>	<i>P</i>	<i>r</i>	<i>P</i>
CA	-0.696	0.001	-0.118	0.62	0.44	0.05
DCA	0.887	0.0001	0.503	0.024	-0.617	0.004
CDCA	-0.728	0.0001	-0.547	0.012	0.594	0.006

CA: Cholic acid; DCA: Deoxycholic acid; CDCA: Chenodeoxycholic acid.

It is accepted that among the different events contributing to gallstone formation, motility defects could play an important role^[5]; however only gallbladder dysfunction has been extensively studied and confirmed evaluating both gallbladder volume variations by US and gallbladder contractility^[26]. In the present study, GS showed, when compared to controls, greater fasting and residual gallbladder volumes, and a decrease in percent gallbladder emptying, confirming previous observations from our experience^[6] and that of other groups^[19,27].

In GS a prolonged time of the migrating motor complex and an altered motilin release pattern have been demonstrated during the interprandial period, leading to an increased fasting gallbladder volume^[28]. The pathogenetic mechanism responsible for gallbladder hypocontractility has been related to an excessive accumulation of cholesterol molecules within the sarcolemma membrane of smooth muscle cells leading to stiffening of the cell membrane and to impairment in the agonist-receptor signal transduction and defective relaxation^[29,30]. Moreover, a role of mucosal inflammation and of inflammatory mediators induced by cholesterol accumulation has also been suggested to be present in the pathway of events leading to defective gallbladder contractility^[31].

In the present study GS patients showed longer OITT than controls, confirming previous observations from our^[8] and other laboratories^[7,27]. The pathogenetic mechanisms underlying this intestinal abnormality are not well understood, even if some hypotheses have been advanced.

The sluggish intestinal transit, together with gallbladder stasis, could contribute to the increase of DCA formation, allowing longer exposure of CA to intestinal bacteria^[32]. In fact we observed higher serum DCA concentrations in GS than in controls. However, this observation is in agreement with some authors^[7,8,27], but in contrast with others^[33,34]. Furthermore, we found in GS a direct linear correlation between serum DCA levels and OITT, and an inverse correlation between serum CA and OITT. As far as concerns the DCA mechanism of action on intestinal motility, it has been demonstrated in experimental animals that DCA directly delays OITT inducing a defective contractility of intestinal smooth muscle cells in response to cholecystokinin (CCK)^[35] or inhibits the pace-maker currents of interstitial cells of Cajal by activating ATP-sensitive K^+ channels through the production of PGE_2 ^[36]. However a cause-effect relationship is not proven.

In the present study, a direct correlation was demonstrated in GS between fasting gallbladder volume and serum DCA levels and an inverse correlation between percent gallbladder emptying and DCA serum levels. It is important to note that DCA also has an effect on gallbladder motility, since it has been demonstrated that it is able to induce both relaxation and defective contraction of gallbladder smooth muscle, probably involving intramural neurons^[37].

As far as gastric motility is concerned, we found a delay in half emptying-time in GS compared to controls. Although this result was obtained using a liquid meal, and not a solid or semi-solid meal, which is considered as the gold standard, it was obtained in the same subject before and after treatments. However, the liquid meal has just been previously used in evaluating gastric emptying by others^[9]. Even for this defect the pathogenetic mechanism is not clear, although a detrimental effect of DCA on smooth muscle cells could be proposed^[38] and it has been speculated that this impaired motility could be related with hormonal alterations, in particular of neurotensin, as suggested for gallbladder^[39] and gastric motility^[40].

Apart from the speculation based on a pathogenetic role for DCA, other hypotheses could be formulated to explain the mechanisms underlying the diffuse motility defects present in GS. Bile cholesterol supersaturation (e.g. the main and indispensable pathogenetic factor in GS formation)^[10], in itself, could play a role. In experimental studies, a cholesterol-rich diet was associated with impaired small intestinal smooth muscle contractility and prolonged small intestinal transit time^[41]. Cholesterol accumulation in the intestinal smooth muscle cells could modify membrane fluidity, which, in turn, affects the activity of membrane regulatory proteins, such as receptors and ion channels^[42,43]. These proteins control electrical excitability and influence the periodicity of events, such as migrating motor complex^[28]. Alternatively it has been recently speculated in an experimental study^[44] that a key event underlying cholesterol gallstone pathogenesis could be a CCK-r deficiency, that could provoke intestinal and gallbladder motility dysfunction, thus allowing an excessive cholesterol absorption by both organs and inducing a vicious cycle.

The most important result emerging from the present study concerns the effect of UDCA on gastric and gallbladder emptying and intestinal transit. UDCA significantly improved gastric emptying and OITT, but only in GS since no significant change occurred in controls, while placebo administration had no effect in both GS and controls.

This result could be partially biased by the study design, which was a single blinded, placebo controlled one. However, since both patients and controls were unaware of the study design, we believe to have correctly detected the different effects of UDCA and placebo.

This result confirms those of our previous, uncontrolled study^[20], stresses the effects of UDCA on gallbladder and gastric emptying and intestinal transit. These effects could be due to a protective action of UDCA^[35,43] towards the damaging action of DCA (the relative proportion of which we found to be significantly diminished) and/or to an abil-

ity to reduce cholesterol bile supersaturation by influencing cholesterol bile secretion^[10] and/or intestinal cholesterol absorption^[13]. The reduction of cholesterol bile saturation could improve intestinal contractility by a mechanism similar to that observed at the level of gallbladder smooth muscle cells^[46].

As far as gallbladder motility in GS is concerned, while there is a general agreement regarding the effect of UDCA in increasing fasting and residual gallbladder volumes, that on gallbladder emptying is controversial. In fact either a decreased or unmodified emptying was observed in *in vivo* studies^[6,19].

As far as the different effects of UDCA on gastric emptying and intestinal transit time and on gallbladder emptying is concerned, we can only suggest some hypotheses. The damaging effect of lithogenic bile on gallbladder could be more pronounced with respect to other organs and, consequently, more time is probably needed to obtain a positive effect.

All these documented effects of UDCA on gastrointestinal motility suggest for this bile acid an additional mechanism of action^[10] in inducing bile cholesterol under saturation. In particular, the reduction in intestinal transit time could influence intestinal cholesterol absorption, as suggested by the experimental study performed by Wang *et al.*^[44].

A further effect of UDCA administration was the reduction in biliary pain rate. In fact, all our GS patients were symptomatic at enrollment, but none of them reported further episodes of biliary pain during UDCA treatment. On the contrary, during placebo treatment, a 20% recurrence of biliary pain rate was observed. Although these results were obtained in a small population and after a relatively short period, it seems important from a clinical point of view. Furthermore, a positive effect of UDCA on symptom frequency has been reported by us in a randomized study comparing UDCA and CDCA as gallstone dissolving agents^[47] and more recently by others on a larger population and for a longer period of time^[18]. Different hypotheses have been advanced to explain the effect of UDCA on biliary pain frequency: dissolution of microlithiasis or crystals^[18], increased bile wash-out within the gallbladder^[48] and reduction of bile viscosity and sedimentable fractions^[49].

In conclusion, this study documents that gallstone patients do not have a single defect (defective gallbladder emptying), but simultaneous, multiple defects (delayed gastric emptying and intestinal transit). Chronic UDCA administration influences these parameters only in gallstone patients, but not in controls; thus restoring impaired OITT and gastric emptying, and suggesting an additional mechanism of action for UDCA in reducing bile cholesterol saturation. Furthermore UDCA improves clinical outcomes in gallstone patients. Further experimental and clinical studies are needed to better elucidate the mechanisms of action of UDCA on gastrointestinal motility. Furthermore, it will be important to evaluate the presence of gastrointestinal motility defects also in patients at high risk of gallstone development (obese subjects, patients with insulin-resistance syndrome,

pregnant women, etc), to confirm their pathogenetic role in GS formation and to identify a possible relationship with genetic and/or environmental factors.

Abstract

AIM: To evaluate peripheral blood lymphocyte subsets in patients with acute pancreatitis (AP).

METHODS: Twenty patients with mild AP (M-AP) and 15 with severe AP (S-AP) were included in our study. Peripheral blood lymphocytes were examined at d 1-3, 5, 10 and 30 by means of flow cytometry.

RESULTS: A significant depletion of circulating lymphocytes was found in AP. In the early AP, the magnitude of depletion was similar for T- and B- lymphocytes. In the late course of S-AP, B-lymphocytes were much more depleted than T-lymphocytes. At d 10, strong shift in the CD7+/CD19+ ratio implicating predominance of T-over B-lymphocytes in S-AP was found. Among T-lymphocytes, the significant depletion of the CD4+ population was observed in M-AP and S-AP, while CD8+ cells were in the normal range. Lymphocytes were found to strongly express activation markers: CD69, CD25, CD28, CD38 and CD122. Serum interleukin-2 (IL-2), IL-4, IL-5, IL-10, interferon- γ (IFN- γ) and tumor necrosis factor- α (TNF- α) levels were significantly increased in both forms of AP. The magnitude of elevation of cytokines known to be produced by Th2 was much higher than cytokines produced by Th1 cells.

CONCLUSION: AP in humans is characterized by significant reduction of peripheral blood T- and B-lymphocytes.

INTRODUCTION

Excessive leukocyte activation with cytokinemia represents one of the most important mechanisms of increased mortality in early acute pancreatitis (AP). It has been hypothesized that fatal pancreatitis is a consequence of excessive leukocytic phagocyte stimulation provoked by severe trauma or persistent injury due to an agent noxious to the pancreas^[1]. Lymphocytes and inflammatory mediators released by these cells are one of the most potent regulators of leukocytic phagocytes. It has been suggested that T- and B- lymphocytes activation is a key factor in the modulation of the inflammatory reaction in different diseases, including AP^[2]. The role of different inflammatory mediators in AP has already been extensively studied, while the role of lymphocyte activation and its relation to disease severity in humans are still poorly understood^[3-6]. Few studies have demonstrated the reduction of total peripheral lymphocytes as well as CD4+, CD8+, CD3+DR- and CD3-DR+ lymphocyte subsets in early severe AP^[7-10]. In the most recent study, T cell activation has been reported in mild acute pancreatitis^[11]. Another study showed that treatment with high-dose vitamin C partially restored depleted peripheral blood CD4+ cells and increased the ratio of CD4+/CD8+ cells^[12]. Under the normal or pathologic conditions, CD4+ T helper (Th) lymphocytes polarize into two major subsets: Th1 and Th2. Both environmental and genetic factors act in concert to determine the Th1 and Th2 polarization. The collective data available so far are not sufficient to determine the role of specific Th cells subsets in acute pancreatitis in humans.

In this study, we, therefore, aimed to provide broad and complex evaluation of peripheral blood lymphocyte subsets in patients with AP.

MATERIALS AND METHODS

Clinical evaluation

Thirty five patients (16 women and 19 men; age 32-77 years, median 56 years) with AP were prospectively included into our study. In all patients, the time between the abdominal pain onset and admission to the hospital was not longer than 48 h. The control group comprised of 15 healthy volunteers (7 women and 8 men; age 19-77 years, median 41 years) without the history of recent inflammatory disease. The diagnosis was made on the basis of a history consistent with AP and serum amylase activity > 3 times the upper limit of normal range (20-90 U/L). For all the patients, additional biochemical and imaging (ultrasound and computed tomography) tests have been done to confirm the diagnosis as well as to determine the etiology and severity of AP according to Ranson's^[13] and Balthazar's^[14] criteria supplemented by serum C-reactive protein (CRP) concentration measurements. At d 2-3, CRP concentrations higher than 150 mg/L were considered as indicative of S-AP. Using these criteria, our patients were divided into mild AP ($n = 20$) and severe AP ($n = 15$) (Table 1). Among the patients with S-AP, the following systemic complications were found: pulmonary in 8 patients, circulatory in 3, renal in 3, coagulation disorders in 1 and septic complications in 1 patient. Local complications, such as acute fluid collections in 10 patients, infected necrosis in 1 and pancreatic abscess in 1 patient, were found. By etiology, 18 patients presented biliary pancreatitis, 16 alcoholic pancreatitis and 1 idiopathic pancreatitis. In the course of hospitalization, 2 patients with severe AP died. Medical University of Bialystok Ethical Committee approval had been granted for performing this study.

Treatment

In patients with S-AP, in addition to standard treatment, prophylactic therapy with antibiotic (meropenem 500 mg tid for 10-21 d) and enteral nutrition have been implemented since the d 2-3 of the disease.

Laboratory methods

EDTA-anticoagulated blood samples were taken at admission (d 1), on d 2, 3, 5, 10 and 30. Blood samples were drawn from the antecubital vein. The absolute number of leukocytes (granulocytes, lymphocytes, monocytes) was estimated with a hematological analyzer Advia 120 (Bayer). Surface lymphocyte antigens (CD) were assayed by the direct fluorescence method for whole blood, using a flow cytometer (EPICS XL, Coulter) and double staining (FITC/PE) monoclonal antibodies (Becton Dickinson). Briefly, 100 μ L samples of whole blood were incubated with 5 μ L of respective monoclonal antibody solution. After 30 min of incubation in the dark at 4°C, erythrocytes were lysed, while leukocytes were fixed, stabilized (ImmunoPrep, Coulter) and analysed by EPICX XL. The use of "gate-check" [CD45-FITC/CD14-PE (BD)] allowed the division of the leukocytes population into granulocytes, lymphocytes and monocytes. Matched labelled anti-idiotypic antibodies were used as negative controls (IgG1-FITC/IgG1-PE).

Table 1 Clinical characterization of studied patients with mild AP and severe AP

	Mild AP $n = 20$	Severe AP $n = 15$	<i>P</i> M-AP vs S-AP (Mann-Whitney <i>U</i> test)
Etiology			
Biliary	9 (45.0%)	9 (60.0%)	
Alcohol	10 (50.0%)	6 (40.0%)	
Idiopathic	1 (5.0%)	0 (0%)	
Median ranson score (range)	1 (0-2)	4 (2-8)	$P < 0.01$
Balthazar score			
A	6 (30.0%)	0	
B	14 (70.0%)	0	
C	0	2 (13.3%)	
D	0	5 (33.3%)	
E	0	8 (53.3%)	
CRP (mg/L) median (range)			
D 1	22.9 (5.0-139.0)	216.0 (5.0-466.1)	$P < 0.01$
D 2	50.5 (5.2-135.4)	186.2 (43.1-342.0)	$P < 0.01$

Populations and subpopulations of lymphocytes

Populations and subpopulations of lymphocytes were evaluated using the following differentiation antigens: CD19-/CD7+ (T-lymphocytes), CD3+/CD4+ (Th-lymphocytes), CD3+/CD8+ (cytotoxic T-lymphocytes) and CD19+/CD7- (B-lymphocytes).

Activation markers of T-lymphocytes

The following CD antigens were examined: CD3/CD69, CD7/CD122 and CD8/CD38, CD8/CD28.

Activation markers of B-lymphocytes

CD19/CD122 expression was determined in B-lymphocytes.

Determination of apoptosis

Cell preparation: Mononuclear cells were isolated by density gradient concentration on Histopaque 1077 (Sigma). Highly purified mononuclear cells (about 98%, by Advia 120) were obtained. The cells were subsequently suspended in tubes with phosphate-buffered saline.

Determination of spontaneous apoptosis: Apoptosis was determined using Annexin V-Fluos and propidium iodide double staining. Apoptosis is accompanied by a loss of membrane phospholipid asymmetry, resulting in the exposure of phosphatidylserine at the surface of the cell. Quantitative measurement of phosphatidylserine exposure was possible using the binding of fluorescein isothiocyanate-labelled annexin V to phosphatidylserine. For the annexin V assay, cells were incubated for 1 h at 37°C in 2 mL of buffer containing FITC-labelled annexin V and propidium iodide (PI) and line specific markers (CD3, CD19, CD33, CD14, PE). Flow cytometric analysis was performed by Coulter EPICS XL.

Determination of stimulated apoptosis

Determination of stimulated apoptosis was carried out as previously described^[15]. Isolated lymphocytes were incubated in six-well plates (Falcon, Becton Dickinson)

with RPMI 1640 medium (GIBCO) without fetal bovine serum at 37°C in a humidified atmosphere containing 50 mL/L CO₂. After 24 h of incubation, cells were stained with a dye mixture (10 μmol/L acridine orange and 10 μmol/L ethidium bromide; Sigma) prepared in phosphate-buffered saline (PBS). Two-hundred cells per sample were examined by fluorescence microscopy, and the cells were characterized according to the following criteria: (1) native cells-fine reticular pattern of green stain chromatin; (2) necrotic cells-bright orange stain chromatin; and (3) apoptotic cells-green stain chromatin which was highly condensed and uniformly stained by acridine orange.

Determination of cytokines produced by Th1/Th2 subsets

The BD Human Th1/Th2 Cytokine CBA kit was used to measure IL-2, IL-4, IL-5, IL-10, TNF-α and IFN-γ levels in serum samples. The samples diluted with the appropriate volume of Assay Diluent were transferred into the assay tubes containing capture beads (covered with respective cytokine antibody) and PE detection reagent. The standard curve for each cytokine was defined for concentrations from 20-5000 ng/L. The assay was performed using a FACSCalibur (BD) flow cytometer.

Statistical analysis

Statistical analysis was performed using the non-parametric Mann-Whitney's *U* test. *P* values less than 0.05 were considered statistically significant. Results were expressed as mean ± SD.

RESULTS

At d 1, significant decrease of total lymphocyte number to 63% and 39% of the healthy control was found in patients with M-AP and S-AP, respectively (Figure 1A). In the course of the disease, lymphocyte number gradually increased, reaching 79% and 97% of the control in M-AP and S-AP at d 10, respectively. At d 30, lymphocyte number fell again to 65% and 42% of the control, respectively, in M-AP and S-AP. Analysis of CD7 and CD19 molecule expression showed that T-lymphocyte (CD7+) population was especially reduced in the early course of S-AP (Figure 1B). Thereafter, it was constantly increasing, returned to normal at d 10 and decreased again to 46% of the control at d 30. In M-AP, depletion of T-lymphocyte population was less evident (Figure 1B). Some reduction of B-lymphocyte (CD19+) number was found in the early S-AP, while marked depletion to 36% and 34% of the control was noticed at d 10 and 30, respectively (Figure 1C). In M-AP, the decrease of B-lymphocyte number was not so persistent.

Two major subsets of T-lymphocytes are represented by CD4+ and CD8+ cells, also known as T4-helper cells and T8-cells or cytotoxic T-lymphocytes (CTLs), respectively. At d 1, the number of circulating CD4+ cells significantly dropped in both M-AP and S-AP to 68% and 45% of the control, respectively (Figure 1D). In M-AP, at d 5 and 10, it returned to the range of normal level, while in S-AP it remained significantly depleted until d 30. The number of circulating CD8+ cells remained in the range

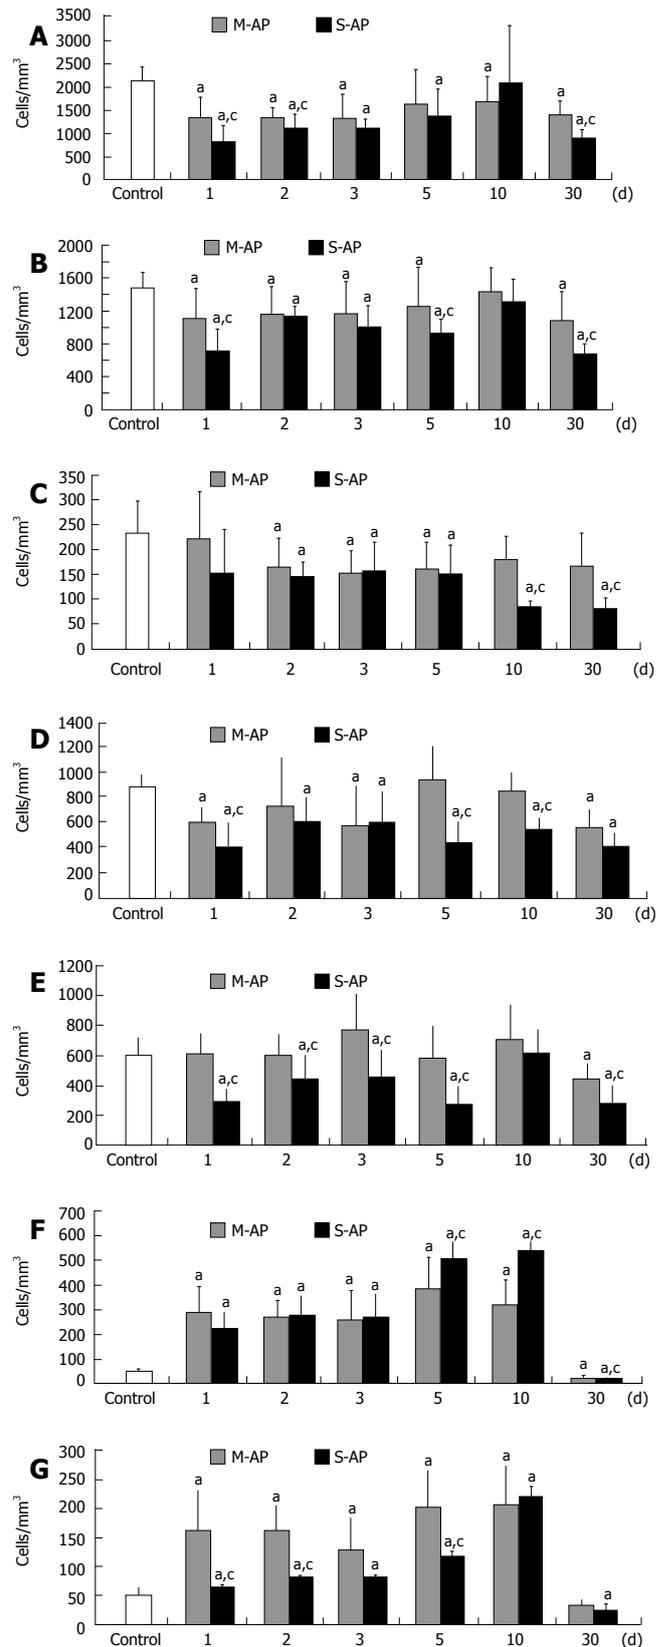

Figure 1 Peripheral blood lymphocytes in patients with AP. **A:** Total count; **B:** CD7+; **C:** CD19+; **D:** CD4+; **E:** CD8+; **F:** CD69+; **G:** CD25+. Results are expressed as mean ± SD. ^a*P* < 0.05 vs control; ^{a,c}*P* < 0.05 vs mild AP at the same day of observation.

of the normal level in the early M-AP, including the d 10 (Figure 1E). At d 30, it decreased to 73% of the control.

^a*P* < 0.05 vs control; ^c*P* < 0.05 vs mild AP at the same day of observation.

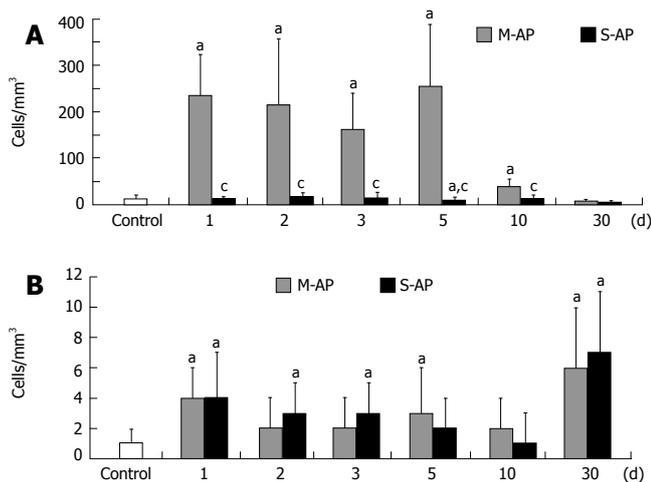

Figure 2 Peripheral blood T-lymphocytes (CD7+) (A) and B-lymphocytes (CD19+) (B) expressing CD122 in patients with AP. Results are expressed as mean ± SD. ^a*P* < 0.05 vs control; ^c*P* < 0.05 vs mild AP at the same day of observation.

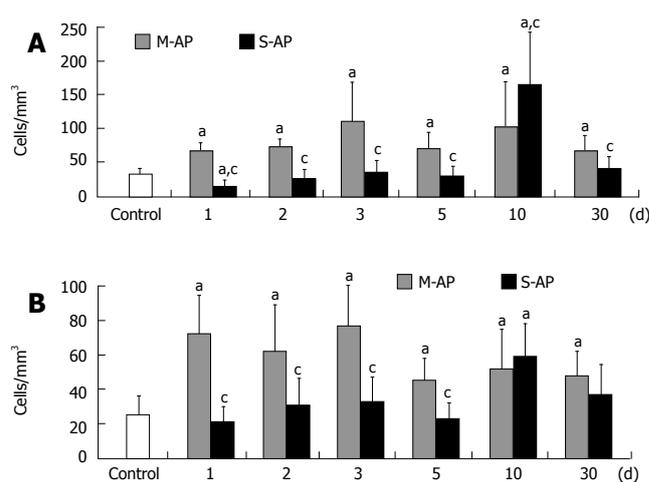

Figure 3 Peripheral blood CD8+ cells expressing CD38 (A) and CD28 (B) in patients with AP. Results are expressed as mean ± SD. ^a*P* < 0.05 vs control; ^c*P* < 0.05 vs mild AP at the same day of observation.

At d 1 of S-AP, CD8+ cells were markedly depleted to 47% of the control and remained below normal level until d 5. CD8+ returned to normal level at d 10, and depleted again to 47% of the control at d 30.

In patients with both M-AP and S-AP, some fluctuations of lymphocyte T/B (CD7+/CD19+) ratio were observed (Table 2). At d 10, the ratio was markedly increased because the T-lymphocyte number was close to normal and the significantly diminished B-lymphocyte level. In M-AP and S-AP, the lowest CD4+/CD8+ cells ratio was found at d 3 and 10, respectively (Table 2).

Peripheral blood lymphocytes in both M-AP and S-AP patients showed a dramatic increase of intracellular signaling manifested by CD69 expression. At d 1, it was elevated 6.0-fold and 4.6-fold in M-AP and S-AP, respectively (Figure 1F). At d 10, CD69 expression in peripheral blood lymphocytes reached a maximum (11.2-fold over the control level) in S-AP and then dramatically declined to 52% and 40% of the healthy control in M-AP and S-AP, respectively.

CD25/IL-2R α expression, known as the lymphocyte proliferation marker, was elevated especially in M-AP (Figure 1G). At d 1 and 10, it increased to 3.3-fold and 4.2-fold over the control, respectively. In S-AP, a marked elevation of CD25/IL-2R α expressing lymphocytes (4.5-fold over the control) was found at the d 10. At d 30, the number of the lymphocyte subpopulation significantly decreased to 63% in M-AP and to 47% in S-AP. The

number of peripheral blood T-lymphocytes expressing CD122 sharply increased in patients with M-AP (Figure 2A). At d 1, it increased almost 20-fold compared to the control, and remained highly elevated until d 5. At the d 10, the number of lymphocytes significantly diminished and at d 30, reached 50% of the control level. In the course of S-AP, the number of T-lymphocytes expressing CD122 did not significantly change. However, at d 30, it dropped to 33% of the normal level.

The number of peripheral blood B-lymphocytes with the same marker of activation was significantly elevated in both M-AP and S-AP patients (Figure 2B). Interestingly, concerning CD122 expression, the highest level of B-lymphocyte activation, 6- and 7-fold were found in M-AP and S-AP at the d 30, respectively. Figure 3 shows the pattern of activation of T-lymphocyte CD8+ subset. In M-AP, the number of cells expressing CD38 increased to 20.6% of the control level at d 1, reached the maximum level of 33.9% at d 3 and remained elevated at 20.3% at d 30 (Figure 3A). In S-AP, the opposite trend was noted with significant diminishing of CD8+CD38+ lymphocytes to 45% of the control at d 1. It returned to normal level at d 3, while a strong temporary elevation to 49.7% of the control at d 10 was noted.

Concerning CD28 expression, CD8+ T-lymphocyte activation was the strongest observed in M-AP patients (Figure 3B). At d 1, it reached 28.8% of the control, remained at the similar level until d 3 and then slightly decreased to 19.2% of the control at d 30. In S-AP, it oscillated around normal

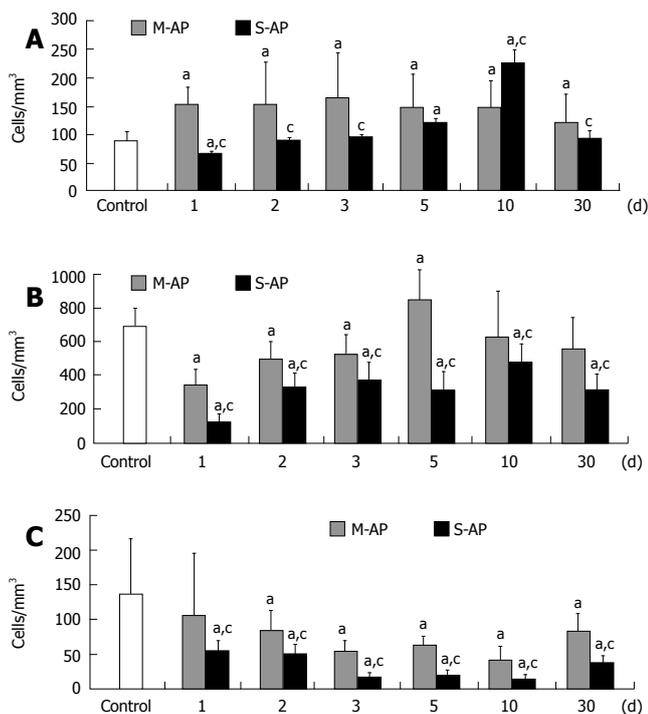

Figure 4 Markers of lymphocyte apoptosis in patients with AP. Peripheral blood lymphocytes expressing CD95 (A), CD3+ lymphocytes expressing Annexin V (B) and CD19+ lymphocytes expressing Annexin V (C). Results are expressed as mean ± SD. ^a*P* < 0.05 vs control; ^c*P* < 0.05 vs mild AP at the same day of observation.

level until d 5, increased to 23.6% of the control at d 10, and remained slightly elevated at d 30.

Expression of CD95/Fas-R/Apo-1 receptor protein, which plays an important role in apoptosis initiation, was enhanced in early M-AP and reached a maximum (18.8% of the control) at d 3 (Figure 4A). It remained slightly elevated throughout the course of the disease. In S-AP, the number of lymphocytes expressing CD95/Fas-R/Apo-1 slightly decreased to 7.6% of the control at the d 1 and then constantly raised up to 26.8% at d 10. Thereafter, it returned to the control level at the d 30.

At d 1, the number of peripheral blood T-lymphocytes that stained for annexin V (AnnV+CD3+) significantly decreased in M-AP and S-AP to 49% and 17% of the normal level, respectively (Figure 4B). Thereafter, it gradually increased, and in M-AP slightly exceeded normal level (12.2% of control) at d 5. In S-AP, the number of AnnV+CD3+ lymphocytes remained diminished during the course of whole observation. The number of peripheral blood B-lymphocytes that stained for annexin V (AnnV+CD19+) started to decrease at d 1 in both forms of AP, and at d 10, reached the minimum value, i.e. 30% and 10% of the normal level in M-AP and S-AP, respectively (Figure 4C). Table 3 shows the viability of lymphocytes isolated from peripheral blood of patients with pancreatitis. In both forms of pancreatitis, in non-stimulated cells, the rates of apoptosis and necrosis were at similar levels as in the control. Stimulated cells from the healthy control died predominantly by necrosis. However, in stimulated cells of patients with pancreatitis, lymphocytes died predominantly by apoptosis, without

showing any significant difference between M-AP and S-AP.

We measured serum concentrations of cytokines produced by Th1 and Th2 lymphocytes in the first 10 days of the disease (Tables 4, 5). IL-2, IFN-γ and TNF-α represent the pattern characteristic for Th1, while IL-4, IL-5 and IL-10 are produced by Th2. IL-2 and IFN-γ levels were much higher in S-AP than in M-AP, while TNF-α was slightly elevated in both forms of pancreatitis (Table 4). At d 1, we observed a huge increase by 27-fold and 33-fold in the IL-4 level in M-AP and S-AP, respectively (Table 5). It remained highly elevated in the whole early course of pancreatitis. IL-5 was significantly increased in both forms of pancreatitis during the first 5 d of observation. However, it returned to normal level at d 10. A remarkable increase of IL-10 was noted in both forms of pancreatitis. The peak, 36-fold and 44-fold elevation, was observed in M-AP and S-AP at d 2, respectively (Table 5).

DISCUSSION

Alteration of the immune system is one of the major mechanisms responsible for early and late mortality in severe AP. Excessive inflammatory reaction, known as systemic inflammatory response syndrome (SIRS), is considered as the leading cause of death in early AP^[4,6]. The role of lymphocytes in this phenomenon has been partly studied and the knowledge of the mechanisms in humans is still incomplete^[7-11,16]. Our study provides, probably for the first time, a broad and complex analysis of peripheral blood lymphocyte subsets with reference to different time points and different severity forms of acute pancreatitis. In agreement with the previous studies^[7-11,16], we also found a significant depletion of circulating lymphocytes which was much more profound in the severe form of pancreatitis. In the early period of 1-5 d of the disease, the magnitude of peripheral depletion was similar for T- (CD7+) and B- (CD19+) lymphocytes. However, in the second week and at d 30 of S-AP, B-lymphocytes were found to be particularly depleted. Concerning the relations between these subsets of lymphocytes, the middle of the second week (d 10) was critical because of the strong predominance of T- over B-lymphocytes in S-AP. Depletion of the CD19+ lymphocyte subset in early acute pancreatitis has also been recently reported^[16]. Among T-lymphocytes, at d 1 and 3 of M-AP as well as at d 10 of S-AP, we observed significant depletion of the CD4+ population, while CD8+ cells were in the normal range. It created a temporary imbalance in the cell ratio with the apparent prevalence of CD8+ over the CD4+ cells. CD8+ cells are known as cytotoxic T-lymphocytes (CTL) and some of them differentiate into T8-suppressor cells. Significant depletion of peripheral blood CD4+ and CD8+ subpopulations of T-lymphocytes in the course of acute pancreatitis has previously been reported^[7-9,12,16]. However, observations made by the others were restricted mostly to one or up to three different time periods of pancreatitis.

The spectrum of cytokines known to modulate lymphocyte differentiation and function (IL-2, IFN- γ , TNF- α , IL-4, IL-5 and IL-10), evaluated in the early course of pancreatitis, showed all of them significantly increased in both forms of AP, however, the highest values were observed in S-AP. Previous studies showed the elevated IL-2, TNF- α and IL-10 levels in human AP^[11,12,17,18]. To our knowledge, no data are available in literature on serum levels of IFN- γ , IL-4 and IL-5 in human AP. In our study, the magnitude of elevation of cytokines known to be produced by Th2 cells, namely IL-4, IL-5 and IL-10, was much higher than cytokines produced by Th1 cells, represented by IL-2 and IFN- γ . This finding suggests that in the course of AP, Th1 subpopulation of CD4+ cells is suppressed more strongly than Th2. Early IL-4 expression during an immune response is critical for determining the development of Th2 cells^[19]. Cytokines produced by Th2 cells enable activated B-lymphocytes to proliferate, stimulate activated B-lymphocytes to synthesize and secrete antibodies, promote the differentiation of B-lymphocytes into antibody-secreting plasma cells, and enable antibody-producing cells to switch the class of antibodies being

produced^[20]. In our study, B-lymphocyte activation was the strongest at d 30, while T-lymphocyte activation remained normal or even below the control level. This pattern of lymphocyte activation might be the consequence of shift from Th1 to Th2 in patients with AP. Th1 and Th2 cells represent polarized forms of the CD4+ Th cell-mediated immune response. Th1 cells produce IL-2, IFN- γ and TNF- α which cooperate with B-cells for the production of antibodies, activate phagocytic cells and CD8+ T-cells, thus promoting cell-mediated immunity and cytotoxic T-cell responses^[21]. In contrast, cytokines released by Th2 cells (IL-4, IL-5, IL-9 and IL-13) induce B-cells to produce high amounts of IgG4 and IgE in humans, promote the differentiation and growth of mast cells and eosinophils, and inhibit several phagocytic functions^[21]. Of note, while IL-4 inhibits the development of Th1 cells, IFN- γ inhibits the development of Th2 cells^[21]. Treg cells are a highly heterogeneous family, which includes type 3 Th (Th3) cells, T regulatory 1 (Tr1) cells, and CD4+ CD25+ T cells. Interestingly, Tr1 cells are mainly able to produce IL-10. Therefore, the huge elevation of serum IL-10 level found in our study may suggest that Tr1 cells are especially active in the course of AP.

In our study, significant activation of lymphocytes was observed, which was shown by strong expression of CD69, CD25, CD28, CD38 and CD122 on T-lymphocytes as well as CD122 on B-lymphocytes. The surface receptors CD69 and the IL-2 receptor (CD25) are early markers of activation. Increased expression of CD69 as well as CD25 on CD3+, CD4+ and CD8+ cells has recently been reported in mild AP^[11]. It has also been reported that the number of B-lymphocytes (CD19+) expressing CD69+ was significantly lower in patients with severe pancreatitis than in patients with mild pancreatitis^[16]. Consequently, the conclusion has been made that patients with severe pancreatitis show impaired early activation of peripheral CD19+ cells. Interestingly, in our study, evaluation of CD19+ cells expressing CD122, which is another marker of lymphocyte activation, showed significant activation of the B-lymphocyte subset bearing this marker. These observations may suggest that the CD19+ cell subset is heterogeneous and the subsets of these cells react in a different manner in the course of pancreatitis.

Marked activation of different subsets of lymphocytes may explain why we have observed strong elevation of different cytokines in peripheral blood despite a significant decrease in the number of circulating lymphocytes. The question remains, however, what was the reason for significant depletion of peripheral blood lymphocytes in pancreatitis. One of the possible reasons is strong migration of activated lymphocytes to the site of inflammation, including the pancreas and other tissues like lungs or kidneys, as a part of SIRS^[22]. Another possible explanation is an excessive elimination of lymphocytes by apoptosis. Expression of CD95, known as Apo-1, Fas or death receptor on lymphocytes was increased in early M-AP and in S-AP at d 10. Surprisingly, the expression of annexin V, which is a marker of ongoing apoptosis, was decreased in early and late S-AP on both T- and B-lymphocytes. In the late period of M-AP, annexin V expression on T-lymphocytes was in the normal range,

while it was decreased on B-lymphocytes. This finding is in agreement with our observation of increased activation of B-lymphocytes in the late course of pancreatitis. It is known that stimulation by factors inducing cell proliferation may inhibit apoptosis^[23]. This phenomenon is the basis of the method evaluating cell susceptibility to apoptosis^[15]. Using this *in vitro* method, we found that lymphocytes from patients with pancreatitis were primed to apoptosis. Similar results of *in vitro* incubation of lymphocytes from patients with S-AP have previously been reported^[10]. Taken together, peripheral blood lymphocyte depletion in acute pancreatitis may result from both excessive apoptosis and migration to the site of inflammation.

Tissue damage caused not only by severe AP but also by traumatic incidents, like severe burns, accident trauma, major surgical interventions or sepsis, induces commensurate with the severity of damage (damage load), genetic factors (gene polymorphism), the general condition of the host and the type of antigens (antigenic load), both local and systemic release of pro-inflammatory cytokines and phospholipids^[24-26]. Polymorphonuclear leukocytes, monocytes, tissue macrophages, lymphocytes, natural killer cells, and parenchymal cells are involved in a complex network of the host defense response. An overwhelming pro-inflammatory response (hyperinflammation) leads to the clinical manifestations of SIRS and finally to host defense failure expressed by multiple organ dysfunction syndrome (MODS) or multiple organ failure (MOF). The up-regulation of pro-inflammatory factors, such as TNF, IL-1 and IL-6, observed during the SIRS phase can be followed by a second response that involves down-regulation of IFN- γ and increase in anti-inflammatory cytokines, such as IL-10 and transforming growth factor- β . This counter-regulatory phenomenon is called the compensatory anti-inflammatory response syndrome (CARS)^[24]. Aside from cytokine profiles, critical injury and sepsis are also correlated with dysfunction of many immune cells. After severe injury, CD4+ T-cell differentiation into Th phenotypes is altered and there is an early expression of Th1 cytokines (IL-12, IFN- γ), followed 24 to 72 h later by a predominance of the Th2 cytokine (IL-4) and depression in the production of IL-2 and IFN- γ ^[24]. It has been found that severe AP, burns, accident trauma, major surgical interventions or sepsis are associated with a significant decrease in total systemic lymphocyte counts, including both CD4+ and CD8+ cells. The development of immunosuppression in subjects suffering from traumatic events is often associated with elevation of IL-10 and the shift of the Th1/Th2 balance towards a Th2 response^[24,26]. The majority of data about lymphopenia in trauma-related cellular immune defects refer to T-cells with scant information about B-cells. Lung and/or kidney failure may take place in the course of specific diseases affecting these organs or may be a part of MOF or MODS resulting from tissue damaging events, including S-AP. It has been found that peripheral blood B-cells, but not CD4+ and CD8+, were significantly lower in uremic patients. This phenomenon may be partially attributed to an increased susceptibility to apoptosis associated with a decreased expression of

Bcl-2^[27]. On the contrary, T lymphopenia with normal counts of peripheral blood B-cells has recently been reported in end-stage renal disease^[28,29]. *Ex vivo* evaluation of T-cells showed an increased number of annexin V and CD95 (Fas)-positive T-cells, suggesting that apoptosis may be responsible for excessive elimination of this lymphocyte subpopulation^[28]. A progressive decrease in renal function associated with activation and selective loss of naïve CD4+ and CD8+ T-cells as well as CD4+ central memory cells has recently been reported. These changes may contribute to the clinical phenomena of the uremia-associated immune defect in patients with chronic renal disease^[29]. Acute respiratory distress syndrome (ARDS), a sudden, life-threatening lung failure, can complicate the course of severe AP and other diseases with critical tissue damage. Severe lymphopenia has recently been reported in patients with severe acute respiratory syndrome (SARS) who developed ARDS^[30]. ARDS occurring in renal transplantation patients with pneumonia is accompanied by a significant decrease in blood CD4+ and CD8+ T cells. In these patients, the recovery of the disease met the recovery course of their immune system^[31]. In conclusion, the available data indicate that lymphopenia caused by the decrease of different lymphocyte subpopulations is characterized not only for severe AP but also for other diseases with severe tissue damage. However, with the exception of our study, the available data provide mostly the information about a single or just a few representatives of lymphocyte subpopulations in a specific disease. Further studies involving broad spectra of immune processes regulation are necessary in order to better understand the complex phenomenon of immunity disorders in diseases with critical tissue damage.

In summary and conclusion, in patients with acute pancreatitis, we found a significant depletion of circulating lymphocytes which was much more profound in the severe form of the disease. In the early period of pancreatitis, the magnitude of peripheral depletion was similar for T- and B- lymphocytes. However, in the late course of S-AP, B-lymphocytes were particularly depleted. The second week of the disease seems to be critical for the cellular immunity function, because of the strong shift in the CD7+/CD19+ ratio implicating predominance of T- over the B-lymphocytes in S-AP. Among T-lymphocytes, the significant depletion of CD4+ population was observed in M-AP and S-AP, while CD8+ cells were in the normal range. It created a temporary imbalance in the cell ratio with the apparent prevalence of CD8+ over the CD4+ cells. Serum IL-2, IFN- γ , TNF- α , IL-4, IL-5 and IL-10 levels were significantly increased in both forms of AP, with the highest values found in S-AP. The magnitude of elevation of cytokines known to be produced by Th2 cells was much higher than cytokines produced by Th1 cells. This finding suggests that in the course of AP, Th1 subpopulation of CD4+ cells is suppressed more strongly than Th2. The pattern of lymphocyte activation we found in AP patients may be the consequence of shift from Th1 to Th2. Strong elevation of serum level of different cytokines, despite a significant decrease in the number of circulating lymphocytes, may be explained by the significant activation of T- as well as B-lymphocytes. Peripheral blood

lymphocyte depletion in acute pancreatitis may result from both excessive apoptosis and migration to the site of inflammation. The data obtained in this study systematize our current knowledge on different lymphocyte subsets in acute pancreatitis and show avenues for future research on cellular immunity in this disease.

Abstract

AIM: To verify and expand the known spectrum of serine protease inhibitor Kazal type 1 (*SPINK1*) gene mutations in chronic pancreatitis.

METHODS: DNA extracted from 172 chronic pancreatitis patients was assayed for *SPINK1* gene mutations by PCR and DNA sequencing. A control cohort of 90 unrelated healthy individuals was analysed by the same methods for presence of common populational polymorphisms, and frequency of five-loci haplotypes was calculated. Linkages of gene aberrations in single *SPINK1* gene copies were analysed by long-distance PCR followed by allele-specific PCR and DNA sequencing.

RESULTS: The most frequent *SPINK1* gene mutation N34S was found at a frequency of 6%. Furthermore, we detected the heterozygous intervening sequence (IVS) 3 + 2 T > C mutated gene in 2 German patients and 1 Macedonian chronic pancreatitis patient. In all three *SPINK1* gene copies an additional rare base substitution was found: 5'untranslated region (UTR)-215 G > A. Polymorphism analysis revealed that all three affected genes carried the same five-loci haplotype. DNA sequencing of another chronic pancreatitis-related gene *PRSS1* (cationic trypsinogen) did not reveal any mutations in these 3 patients.

CONCLUSION: We found in 3 (2%) of 172 chronic pancreatitis patients an IVS3 + 2 T > C *SPINK1* gene mutation and a base substitution 5'UTR-215 G > A in

INTRODUCTION

In approximately one-third of all patients with chronic pancreatitis, no etiological factor can be found, and these patients are classified as having idiopathic disease. Recent genetic discoveries have added much to our understanding of chronic pancreatitis^[1]. The identification of a clear 'gain-of-function' mutation, R122H, in a cationic trypsinogen gene (*PRSS1*) that causes hereditary pancreatitis has been of high significance^[2]. Loss of trypsin inhibitor function may cause pancreatitis. Several studies have demonstrated mutations in the serine protease inhibitor Kazal type 1 (*SPINK1*) gene (MIM#167790), also known as pancreatic secretory trypsin inhibitor gene (*PSTI*). This gene is approximately 7.5 kb long, consists of 4 exons and is located on chromosome 5^[3]. It encodes a polypeptide of 79 amino acids that is processed into a mature active protein consisting of 56 amino acids. Due to its molar ratio of 1:5 to trypsin, it inhibits about 20% of its activity. *SPINK1* gene variations are clearly associated with chronic pancreatitis^[4,5]. They are probably a disease modifying factor, possibly by lowering the threshold for development of chronic pancreatitis caused by other genetic or environmental factors^[4,6,7].

The most frequent mutation of human *SPINK1* gene is a heterozygous or homozygous missense mutation of codon 34 in exon 3 (c.101 A > G), and its incidence is about 80% in familial and idiopathic chronic pancreatitis^[4,5].

This mutation leads to an A to G transition resulting in substitution of asparagine by serine (N34S). The high prevalence of this mutation in chronic pancreatitis led to the hypothesis that the N34S mutation could reduce the antiproteolytic activity of *SPINK1* subjects^[7,8].

To date, many variants of the *SPINK1* gene have been reported, however other mutations than N34S are rare (for an up-to-date list of pancreatitis-associated *SPINK1* mutations visit the website^[9]). Concerning other *SPINK1* gene sequence abnormalities, only two of them can probably be recognised as true mutations. Mutation c.2 T > C (M1T) destroys the translation initiation codon^[5]. The base substitution intervening sequence (IVS)3 + 2 T > C (also named c.194 + 2 T > C) destroys the splicing of exons 3 and 4, and was described in approximately 10 cases^[9]. A splicing mutation IVS2 + 1 G > A (c.87 + 1 G > A) and the frameshift mutations c.27delC and 98insA, both detected in single families, may be fatal for protein synthesis because of preliminary termination of the translation^[10]. The base substitution 5' untranslated region (UTR)-215 G > A in the untranslated 5'-region of *SPINK1* has been reported in two Japanese chronic pancreatitis families up to now, but in no healthy individuals^[11].

The aim of this study was to verify and extend the known spectrum of *SPINK1* gene mutations. We found 3 chronic pancreatitis patients carrying an IVS3 + 2 T > C *SPINK1* gene mutation together with a base substitution 5'UTR-215 G > A in the same gene copy. Our finding implicates that the 5'UTR-215 G > A substitution most probably represents a rare polymorphism and not a mutation as previously concluded^[11]. The same haplotypes in these genes suggest a common origin of the IVS3 + 2 T > C mutation in all 3 patients.

MATERIALS AND METHODS

Patients and controls

This study was approved by the ethics committee of the Chamber of Physicians in Hamburg, Germany. Written informed consent was obtained from all patients for use of tissue and blood samples. One hundred and seventy-two patients with chronic pancreatitis who underwent surgery in the Clinic for General, Visceral and Thoracic Surgery, University Medical Center Hamburg-Eppendorf, Germany between 1992 and 2002 were included. Pancreatic disease was confirmed by histopathological evaluation of all cases. Blood samples of 90 unrelated and healthy individuals (donors) were used as a source of control DNA and for the study of populational polymorphism.

DNA extraction and PCR

Genomic DNA from peripheral blood leukocytes and tissue specimens was extracted and purified according to the established protocols using the QIAamp blood-tissue kit (Qiagen, Hilden, Germany). All four exons of the *SPINK1* gene were amplified by polymerase chain reaction (PCR) using Taq DNA-polymerase (Perkin-Elmer, Foster City, USA) and oligonucleotide primers as previously described^[5]. PCR products were analysed by electrophoresis on a 2% agarose gel and purified by the QIAquick spin PCR-purification kit (Qiagen). Direct

DNA sequencing of the PCR products was carried out using the BigDye terminators sequencing kit (Perkin-Elmer, Foster City, USA) and nested primers on an automatic sequencer ABI 377 (Perkin-Elmer). The presence of the 5'UTR-215 G > A substitution was also tested by performing *Bgl*I restriction endonuclease digestion and gel electrophoresis analysis. *SPINK1* genes from chronic pancreatitis patients carrying the substitutions IVS3 + 2 T > C and 5'UTR-215 G > A were amplified by PCR to generate two fragments (5'-UTR-exon 3 and exon 3-3'-UTR). The long-distance PCR was performed in a 100 μ L reaction mix supplemented with the TaqPlus long polymerase mixture, a high-salt buffer (Stratagene, La Jolla, USA) and the following primers: *SPINK1* pr-F 5'-TTTGAGTTCATCTTACAGGTGAG and *SPINK1* 3-R 5'-GTTTGCTTTTCTCGGGGTGAG, *SPINK1* 3-F 5'-CCAAATCACAGTTATTCCCCAGAG and *SPINK1* 4-R 5'-CCAAAGTCCCCTGACCCTGG. PCR products were analysed electrophoretically on an 0.8%-1% agarose gel and purified as described above. Allele-specific PCRs were performed in a 100 μ L reaction with 1 μ L of long-distance PCR products as templates and Taq DNA-polymerase. The following primers were used: Spl3-T-R 5'-AAGAAACTCAAGTTTGTACTCA or Spl3-C-R 5'-AAGAAACTCAAGTTTGTACTCG and *SPINK1* pr-F, Pr-215G-F 5'-CATGTTTCAGGCCACCTGG or Pr-215A-F 5'-CATGTTTCAGGCCACCTGA and *SPINK1* 3-R for amplification of the 5' region of the *SPINK1* gene; Spl3-T-F 5'-GTGTTATGTTTGTGAAAATCGGT or Spl3-C-F 5'-GTGTTATGTTTGTGAAAATCGGC and *SPINK1* 4-R for amplification of the 3' region of the *SPINK1* gene. The amplification was performed by 10-15 PCR cycles using 0.5 units of Taq DNA-polymerase. The products of the allele-specific PCRs were analysed by gel electrophoresis on an 0.8%-1% agarose gel and purified as described above. For detection of the IVS3 + 2 T > C and 5'UTR-215 G > A substitutions and polymorphisms the amplified DNA was sequenced.

Haplotype analysis

The frequency of polymorphic variations in the normal population was estimated from the results obtained from DNA sequencing of the appropriate amplified DNA fragments which were extracted from leukocytes of the peripheral blood from 90 healthy unrelated individuals (180 alleles). The IVS2-352 A/G polymorphism was additionally assessed by *Msp*I restriction endonuclease digestion. The distribution of haplotypes in normal subjects for single-nucleotide polymorphic loci (SNP's) was calculated by the expectation-maximisation-algorithms (EM-algorithms) described by Weir^[12] for two-, three- and four-loci haplotypes, and according to a method proposed^[13] for two- to five-loci haplotypes. The comparison of the calculated results and probabilities of both methods led to concordant data.

RESULTS

DNA sequencing revealed mutations in *SPINK1* gene

To determine the frequency of *SPINK1* gene aberrations, DNA was isolated from consecutive surgical specimens

Table 1 Haplotype frequencies at five positions of the *SPINK1* gene from 90 individuals (180 chromosomes) as estimated by EM-algorithm

Haplotype	IVS2-352 A/G	IVS3-1643 G/C	IVS3-1568 C/A	IVS3-476 T/G	IVS3-321 C/T	n _{hapl} ¹	Haplotype frequency ²

¹ Estimated number of haplotypes. ² The remaining 17 possible haplotypes could not be found in any individual.

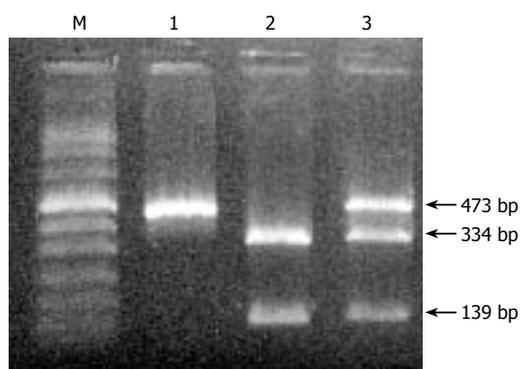

Figure 1 Detection of 5'UTR-215 G/A heterozygote in *SPINK1* gene by *Bgl*I restriction endonuclease cleavage. 1: untreated prF-1R PCR fragment; 2: normal (-215 G/G) prF-1R PCR fragment treated with *Bgl*I endonuclease; 3: heterozygote (-215 G/A) prF-1R PCR fragment treated with *Bgl*I endonuclease [M: marker (Boehringer-Mannheim marker VIII); bp: base pairs].

and blood samples of 172 patients suffering from chronic pancreatitis and analysed for *SPINK1* gene mutations. The most frequent mutation found in the *SPINK1* gene of chronic pancreatitis patients examined in our study was the N34S (A > G in position c.101), but with a rather low frequency of about 6% (10 of 172 patients).

In 3 (2%) of 152 patients a heterozygous IVS3 + 2 T > C splicing mutation was detected. DNA sequencing revealed the presence of another heterozygous base substitution in the same gene copy in the promoter region of exon 1. The detection of the 5'UTR-215 G > A substitution was also confirmed by *Bgl*I restriction endonuclease cleavage and subsequent gel electrophoresis analysis (Figure 1).

Both mutations IVS3 + 2 T > C and 5'UTR-215 G > A were present in the same gene copy

Genomic DNA from IVS3 + 2 T > C and 5'UTR-215 G > A carrying patients was amplified into two long DNA fragments (each about 4 kb) by long-distance PCR using *SPINK1* gene-specific primers. To examine the linkage

of IVS3 + 2 T > C/5'UTR-215 G > A mutations and *SPINK1* gene polymorphisms (Table 1), allele-specific PCR with a limited number of cycles was performed. Whereas the discrimination of alleles in the PCR reaction was incomplete, DNA sequencing could demonstrate the enrichment of the A peak at the position 5'UTR-215 of the product which was synthesized with the specific primer Spl3-C-R, and, accordingly, the enrichment of the G peak of the product which was synthesized with the specific primer Spl3-T-R (Figure 2). Concordant results were found for all three patients. Based on these findings, we concluded that both single-nucleotide substitutions IVS3 + 2 T > C and 5'UTR-215 G > A were located in the same *SPINK1* gene copy of the diploid genome.

Family history of IVS3 + 2C/5'UTR-215A gene carriers was disclosed

The investigation of the relatives revealed that one patient inherited both gene aberrations of the same *SPINK1* gene copy from his mother. Interestingly however, the patient did not suffer from chronic pancreatitis but from celiac disease. These results might be a hint for a role of *SPINK1* gene mutations in celiac disease. Unfortunately, the family history of the other 2 patients was not available.

Haplotype analysis suggested a common origin of IVS3 + 2C/5'UTR-215A mutations

The haplotypes, composed of five common SNP markers, were evaluated in a population of 90 healthy individuals (blood donors) and calculated by using an EM-algorithm^[12,13]. The observed frequencies of 15 out of 32 possible haplotypes are presented in Table 1. The remaining 17 haplotypes could not be found in any individual. Long-distance PCR followed by allele-specific PCR and subsequent DNA sequencing of the IVS3 + 2C/5'UTR-215A-mutant genes showed that all three genes carried the most frequent haplotype 1. In contrast, the haplotype of the other IVS3 + 2C/5'UTR-215A-free *SPINK1* gene copy of the heterozygous gene set of all three patients

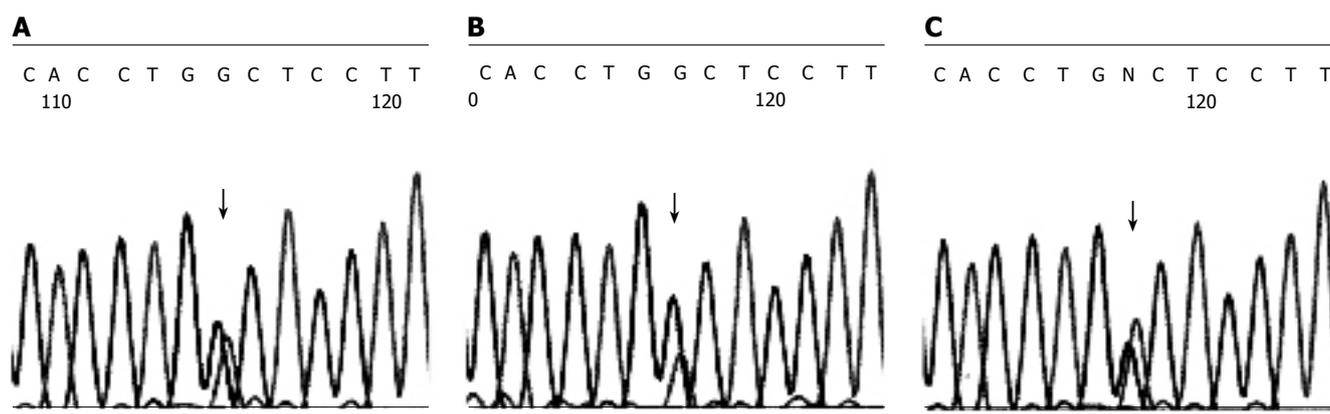

Figure 2 Linkage between 5'UTR-215 G > A and IVS 3 + 2 T > C mutations in SPINK1 gene. **A:** sequencing of -215 G/A heterozygote; **B:** sequencing of IVS 3 + 2 T (normal allele) enriched by allele-specific PCR; **C:** sequencing of IVS 3 + 2 C (mutant allele) enriched by allele-specific PCR.

appeared to be random. One of them represented the same most frequent haplotype 1, one belonged to haplotype 2 and the third to the relatively rare haplotype 6. In spite of the low number of mutant samples, these findings suggested a common origin of the IVS3 + 2C/5' UTR-215A mutation in these patients. The conclusion of a common origin is supported by the assumption that 5' UTR-215A is a rare polymorphism and not a mutation as previously proposed^[11].

No mutations of PRSS1 gene could be detected in IVS3 + 2C/5'UTR-215A carriers

DNA sequencing did not reveal any mutation in the other chronic pancreatitis-related gene *PRSS1* in these three patients.

DISCUSSION

The most frequent variation of the human *SPINK1* gene is the heterozygous or homozygous c.101 A > G (N34S) transition representing about 80% of all *SPINK1* aberrations found in familial and idiopathic chronic pancreatitis^[4,5]. In our study we detected the N34S with a frequency of 6% in chronic pancreatitis patients. In accordance with previous reports, this substitution is also the most frequent mutation of the *SPINK1* gene. Other mutations of this gene are rare, but may be of high interest concerning the role of *SPINK1* in development of hereditary chronic pancreatitis. More than 10 proposed *SPINK1* gene mutations have been described until now^[9]. However, to avoid incorrect interpretation, functional analysis has to be done to investigate the influence of the suggested mutations on the activity of the *SPINK1* gene. Particularly, examination of the artificially produced N34S mutant protein demonstrated no change in its trypsin-binding ability differing from the wild-type protein^[14]. On the other hand, an inactivating effect could be postulated *a priori* for other *SPINK1* gene mutations, like IVS3 + 2 T > C, that destroys the splicing site of exons 3 and 4 and consequently leads to inactivation of the gene. We found three of these IVS3 + 2 T > C *SPINK1* mutations in two German and a Macedonian patient with chronic pancreatitis. Another base substitution, 5'UTR-215 G > A,

was also detected in all three mutant gene copies and for the first time in Caucasians. Up to now this substitution has only been detected as a homozygous base substitution in two chronic pancreatitis patients from Japan. Supported by the fact that this abnormality has never been found in healthy controls it has been considered to be an inactivating *SPINK1* gene mutation^[11]. Furthermore, 1 of the 2 Japanese patients had a family history of chronic pancreatitis. In our study, we only detected the 5'UTR-215 G > A substitution in direct linkage with the known *SPINK1* gene inactivating mutation IVS3 + 2 T > C. The probability of the occurrence of 2 true mutations in the same gene copy seems to be rather seldom. Therefore, our conclusion is that the associated base substitution 5' UTR-215 G > A in the same *SPINK1* gene copy is a rare polymorphism rather than a mutation. This assumption is supported by the fact that this base substitution is located outside the known coding and controlling sequences of the *SPINK1* gene^[11].

All 3 *SPINK1* gene copies carrying these 5'UTR-215A/IVS3 + 2C aberrations had an identical haplotype of common polymorphism, namely haplotype 1. Although only 3 cases were discovered in our study, this finding hints for a single origin of the IVS3 + 2C mutation in these 3 patients. This can also substantiate that the 5'UTR-215 G > A base substitution is rather rare.

Family data were available for one patient with 5'UTR-215A/IVS3 + 2C mutant *SPINK1* gene. This mutated gene was inherited from his mother who did not suffer from chronic pancreatitis, but from celiac disease. In some families the celiac disease was mapped close to the *SPINK1* locus on chromosome 5 (5q31)^[15,16]. Our results might be the first data suggesting a role of *SPINK1* gene mutations in celiac disease.

The data from Kume *et al.*^[17] are compatible with our findings described in the present study. They showed that the 5'UTR-215 G > A and IVS3 + 2 T > C substitutions were in complete linkage in 9 of 116 pancreatitis patients. The published frequency of 8% in this report is higher than our incidence of 2% and suggests that the linkage of both substitutions may rather play a role in Japanese patients^[17]. It would be interesting to compare the haplotypes of these mutant genes in both populations,

Mongoloids and Caucasians, to evaluate the origin of these mutations.

Taken together, we found 3 chronic pancreatitis patients carrying an IVS3 + 2 T > C *SPINK1* gene mutation and the rare base substitution 5'UTR-215 G > A in the same gene copy. Most probably, the 5'UTR-215 G > A substitution represents a rare polymorphism and not a mutation as previously concluded^[1]. Future studies with a larger patient sample and functional analysis of the *SPINK1* gene mutations are required to closer evaluate our findings and increase our understanding of their clinical manifestations.

Abstract

AIM: To investigate features of the posterior gastric artery (PGA) with respect to incidence, location and size by using autopsy subjects.

METHODS: Autopsies were performed on 72 cadavers of adults with no history of abdominal operations. The localization of the PGA, the distance between the root of the splenic artery and the origin of the PGA, and the external diameter of the PGA were examined.

RESULTS: The PGA was recognized in all patients. In 70 (97.2%) cadavers, the PGA branched from the splenic artery, and one female in this group had two PGAs. In 1 (1.4%) patient, the PGA originated from the root of the celiac trunk and in another (1.4%) patient, the PGA branched from the superior polar artery. Overall, the PGA extended for a length of 5.8-12.2 (mean, 8.4) cm from the root of the splenic artery, and the external diameter of the PGA was 1.2-3.2 (mean, 2) mm.

CONCLUSION: The anatomical features of the PGA can be readily observed and characterized by autopsy. This study has provided valuable information on the features of the PGA useful in the planning of surgical treatment.

INTRODUCTION

Blood is supplied to the stomach *via* four main arteries including the right/left gastric artery, the right/left gastroepiploic artery, the short gastric artery, and the posterior gastric artery (PGA)^[1,2]. While surgeons pay a great deal of attention during upper gastric operations to the PGA, due to the technical attending point and potential for cancer metastasis to lymph nodes, their knowledge of PGA features and characteristics stems from experience only^[1,3-10]. Traditional or anatomical charts lack information on the anatomical features of the PGA^[11-14]. Therefore, the aim of the present study was to investigate features of the PGA with respect to incidence, location and size using autopsy subjects.

MATERIALS AND METHODS

Subjects

Autopsies were performed on 72 cadavers of adults with no history of abdominal operations. Of the 72 cadavers evaluated in this study, 33 were men and 39 were women, ranging in age from 45 to 98 (mean, 77.6) years. Cadavers were preserved by injection of 40 g/L formaldehyde solution.

Methods

Once the abdominal cavity was opened, the celiac trunk was identified following tissue dissection of the hepatoduodenal ligament in the direction of the pancreatic head along the common hepatic artery. The splenic artery was then carefully dissected from its origin to the hilum of the spleen and its branches, including the superior and inferior polar arteries, which were identified. Special attention was paid to the vessels of the posterior wall of the stomach. For each of these arteries, the origin, caliber, length, branching, and distribution were observed and measured directly. We determined the length of the splenic artery from the root to the hilum of the spleen

to its branching point into the superior and inferior polar arteries. Identification of the PGA was performed by experienced upper digestive tract surgeons from the Kochi Medical School.

Statistical analysis

The findings were compared by the unpaired *t*-test. $P < 0.05$ was considered significant.

RESULTS

The PGA was recognized in all cadavers. In 70 (97.2%) of 72 cadavers, the PGA branched from the splenic artery, except for 2 cadavers (2.8%). One female cadaver had two PGAs that branched from the splenic artery. The PGA originated from the root of the celiac trunk in one (1.4%) cadaver, and originated from the superior polar artery in another (1.4%). The length of the splenic artery was 11.8-18.8 (mean, 15.3) cm. Thus, there were no significant differences in the length of the splenic artery according to gender or age (Table 1).

The features of branching of the PGA from the splenic artery are summarized in Table 1. The length between the root of the splenic artery and the point of branching of the PGA ranged between 5.8-12.2 (mean, 8.4) mm, the shortest being about half the length of the longest. The length of the PGA from its origin at the splenic artery in males and females was 5.8-12.2 (mean, 9.0) cm and 6.2-10.8 (mean, 8.3) mm, respectively. The external diameter of the PGA in males and females was 1.5-3.2 (mean, 2.1) mm and 1.2-3.0 (mean, 2.0) mm, respectively. Overall, the external diameter of the PGA ranged between 1.2-3.2 (mean, 2.0) mm. There was no significant difference in the length or external diameter of the PGA with respect to gender or age.

DISCUSSION

The blood supply of the stomach is well described^[1,2]. In the upper part of the stomach, the most important nutritional blood vessel is the left gastric artery, followed by the PGA, short gastric artery, and left gastroepiploic artery. Although the PGA is one of the most important vessels supplying the upper third of the stomach the anatomical features of the PGA are not well established. Based on diagnostic imaging the incidence of the PGA is reported to range from 36% to 86%^[1,3-10]. These results are inconsistent with our previous findings using digital subtraction angiography (DSA) and multi-detector row computed tomography (MD-CT) which indicate that almost all men have a PGA^[10,15]. In the present study, the incidence of the PGA was further investigated together with features of the PGA, including location and size, using autopsy investigations by experienced upper digestive tract surgeons.

We found that all men had a PGA and the average distance between the root of splenic artery and the origin of the PGA, was 8.4 cm, which is not significantly shorter than our previous findings of 9.1 cm using MD-CT ($P = 0.1057$). The present results support our previous finding that the PGA usually (in 97.2% of humans) branches

Table 1 Features of posterior gastric artery as seen in autopsy subjects

Characteristics	<i>n</i>	Length of SA (cm)	Distance from root of SA (cm)	External diameter of PGA (mm)	<i>P</i>
Overall	70	15.3 (11.8-18.8)	8.4 (5.8-12.2)	2.0 (1.2-3.2)	0.0963
Gender					0.2274
Male	32	15.6 (12.7-18.8)	8.6 (5.8-12.2)	2.1 (1.5-3.2)	0.2462
Female	38	15.1 (11.8-18.2)	8.3 (6.2-10.8)	2.0 (1.2-3.0)	
Age (yr)					0.6897
< 80	31	15.3 (12.7-18.8)	8.5 (6.2-12.2)	2.0 (1.2-3.0)	0.4985
≥ 80	39	15.4 (11.8-17.9)	8.3 (5.8-10.1)	2.1 (1.3-3.2)	0.7876

SA: Splenic artery; PGA: Posterior gastric artery. All *P* values were non-significant between males and females, between < 80 yr and ≥ 80 yr for length of SA (cm), distance from root of SA (cm), and external diameter of PGA (mm). Data are expressed as mean (range).

from the splenic artery. According to previous reports, there are several different branching patterns of the PGA with PGA branching not only from the splenic artery but also from the celiac trunk or superior polar artery. In our previous study, using DSA and MD-CT, it was not possible to examine the relationship between the PGA and the superior polar artery. In the present study anatomical variation of the PGA was revealed by autopsy examination. In one person (1.4%) the PGA originated directly from the root of the celiac trunk and in another person (1.4%) the PGA originated from the superior polar artery.

The average external diameter of the PGA was 2.0 mm with a range of 1.2-3.2 mm, which is significantly larger than our previous finding of 1.0-1.4 mm for the internal diameter using DSA or MD-CT ($P < 0.01$). Due to its significant size, the PGA was recognized by surgeons during operation of the upper digestive tract. It is important for surgeons to be aware of the anatomical variations of the PGA, including those identified in the present study in which the PGA originated from the root of the celiac trunk or from the superior polar artery.

The incidence of adenocarcinoma of gastric cardia and/or the upper third of the stomach has recently increased in Japan as in the West^[16,17]. Of note, lymph node metastasis in gastric cancer is *via* the major lymphatic vessels in the upper third of the stomach along the left gastric artery, the PGA and the short gastric artery. Since lymph node metastasis is one of the main factors determining the prognosis of patients with gastric carcinoma, it is considered important that lymph nodes along the left gastric artery and the PGA be carefully observed and dissected when gastrectomy with regional lymphadenectomy is performed for patients with gastric carcinoma^[18-21]. In gastric carcinoma it is important to identify the PGA, not only to perform an accurate lymphadenectomy, but especially to avoid vascular complications. The high incidence of the PGA (as here reported) and its hidden origin create a significant risk of dangerous bleeding if damaged. Awareness of this anatomical structure during stomach surgery would help minimize vascular complications. Although we did not clarify the contribution of lymph nodes associated with the PGA in this case, it is likely that lymph node metastases

are associated with the PGA. Findings from the present study provide valuable information towards understanding anatomical variation of the PGA. To fully investigate the features of the PGA requires further collection and evaluation of data.

In conclusion, the present study shows that anatomical features of the PGA can be observed and evaluated efficiently by autopsy investigations and has provided valuable information on the features of the PGA useful in the planning of surgical treatment.

Abstract

AIM: To review clinical and pathologic features of Gastrointestinal stromal tumors (GISTs) occurring synchronously with other primary gastrointestinal neoplasms.

METHODS: Twenty-eight patients with primary GIST were treated at our institution between 1989 and 2005. Clinical and pathologic records were reviewed.

RESULTS: The gastrointestinal stromal tumor occurred simultaneously with other primary GI malignancies in 14% of all patients with GIST. The synchronous stromal tumors were located in the stomach and were incidentally found during the operation. The coexistent neoplasms were colon adenocarcinoma, gastric cancer (2 cases) and gastric lymphoma.

CONCLUSION: The synchronous occurrence of GISTs and other gastrointestinal malignancies is more common than it has been considered. The development of gastrointestinal stromal tumors and other neoplasms may involve the same carcinogenic agents.

Key words: Gastrointestinal stromal tumors; Synchronous neoplasms

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are an uncommon mesenchymal neoplasm affecting the GI tract. The synchronous occurrence of mesenchymal tumors and other primary gastrointestinal malignancies has been rarely reported in the literature^[1,2]. Most of these publications describe single case reports. We present a series of four patients, from a single institution, with GIST and a second primary neoplasm occurring synchronously. The aim of this study was to evaluate clinical and pathologic features of GISTs concomitant with other gastrointestinal malignancies.

MATERIALS AND METHODS

Patients

Between 1989 and 2005, 28 patients with primary gastrointestinal stromal tumor were treated operatively at the department of General and Gastroenterological Surgery and Nutrition, Warsaw University of Medicine. Most of the patients were women (62%). Median age of the patients at the time of presentation was 63.5 years. The primary tumor was located in the stomach (57%), small intestine (32%), large intestine (7%) and mesentery (4%). GIST was incidental in 29% of the patients. Hospital charts, operative and pathological reports were reviewed for each patient.

Methods

The histological diagnosis of all GISTs was confirmed at the department of pathology of the Warsaw University of Medicine. Specimens were fixed in 10% formaldehyde and processed routinely for paraffin embedding. 5- μ m-thick sections were stained with HE. Mitoses were counted in 50 high-power fields. Malignant potential of the GISTs was stratified according to the risk categories proposed by Fletcher *et al*^[3].

Immunohistochemistry was performed using commercially available antibodies against CD117 (polyclonal, Dako, Glostrup, Denmark) and against CD34 (monoclonal, Dako, Glostrup, Denmark).

RESULTS

GIST occurred synchronously with an other gastrointestinal malignancy in four patients (14%) out of all the patients with primary gastrointestinal stromal tumor treated

Table 1 Characteristics of the patient population

No.	Age	Sex	Synchronous malignancy	Clinical presentation
1	63	F	Colon cancer	Intestinal obstruction
2	77	F	Gastric lymphoma	Abdominal pain
3	64	F	Gastric cancer	Pyloric stenosis
4	66	M	Gastric cancer	Abdominal pain, weight loss

Table 2 Pathologic features of the synchronous GISTs and other primary gastrointestinal neoplasms

No.	GIST		Synchronous gastrointestinal malignancy		
	Location	Size (cm)	Type	Location	Size (cm)
1	Anterior gastric wall (corpus)	2	Adenocarcinoma (pT4, N2, M0)	Cecum	10
2	Anterior gastric wall (fundus)	1	Lymphoma (diffuse large B cell)	Lesser curvature at the gastric angle	2
3	Anterior gastric wall (corpus)	2	Adenocarcinoma -Lauren diffuse type (pT4, N0, M0)	Antrum	5
4	Anterior gastric wall (corpus)	1	Adenocarcinoma -Lauren intestinal type (pT1, N0, M0)	Posterior wall at the gastric angle	1

Table 3 Histopathologic features of the synchronous GISTs

No.	CD117 reactivity	CD34 reactivity	Tumor size(cm)	Mitotic index	Risk category for malignant behavior ^[3]
1	+	+	2	2/50 hpf ¹	Low
2	+	+	1	0/50 hpf	Very low
3	+	+	2	2/50 hpf	Low
4	+	+	1	0/50 hpf	Very low

in our department. Twenty-five percent of the gastric stromal tumors and 50% of the incidental GISTs were synchronous with the second gastrointestinal malignancy. The concomitant neoplasms were also primaries. All these GISTs were located in the stomach. In 75% of the cases, GIST was synchronous with other gastric malignancies, and one patient had a coexistent gastric stromal tumor and colorectal cancer. The patients presented clinically with abdominal pain, weight loss or partial intestinal obstruction. All the patients required operation due to the symptoms as a result of the tumor and GIST synchrony. The stromal tumor was always an incidental finding during the operation. The clinical characteristics of the patient population are shown in Table 1.

The synchronous gastric tumors were located in the different parts of the stomach. The average size of GIST was 1.5 cm. Morphologically, the 1-cm GISTs were a whitish, smooth and firm intramural nodule that was slightly elevated above the stomach wall. Larger GISTs were irregular, soft and a lobulated mass attached to the stomach (Figure 1). In one of the patients, the GIST was initially considered intraoperatively as a metastatic lymph node (Case 3). However, the intraoperative frozen section revealed GIST tissue. The pathologic features of the synchronous tumors are summarized in Table 2.

Figure 1 Intraoperative view of the gastric stromal tumor that was synchronous with colon adenocarcinoma (Case 1).

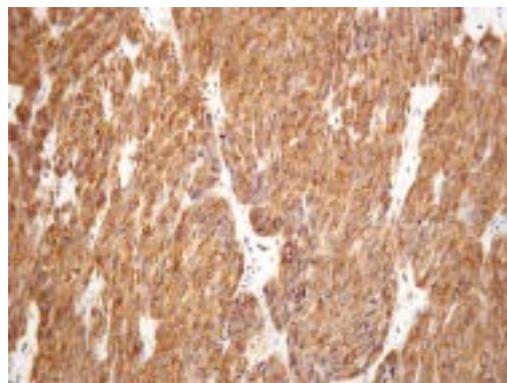

Figure 2 Strongly positive CD117 immunostaining in the synchronous gastric stromal tumor (Case 2).

Total ($n = 1$) or subtotal gastrectomies ($n = 2$) were performed in the patients with gastric malignancy. In these cases, the concomitant GIST was located within the resection margins. The patient with both colon cancer and gastric stromal tumor had a right hemicolectomy and additionally local resection of the stromal tumor.

The synchronous gastrointestinal stromal tumors were uniformly CD117 and CD34 positive (Figure 2) and could be classified as low and very low risk tumors for malignant potential. The histopathologic features of the synchronous GISTs are shown in Table 3.

DISCUSSION

Gastrointestinal stromal tumors are uncommon mesenchymal neoplasms occurring within the abdominal cavity. Most GISTs are located in the stomach and small intestine^[4]. GISTs usually develop in a sporadic fashion. However, familial occurrence has also been reported^[5]. In patients with Carney's triad, GISTs may develop together with pulmonary chondroma and extra-adrenal paraganglioma^[6]. Although 10% of the patients enrolled in the Polish GIST Clinical Registry had a second neoplasm^[7], these were usually metachronous and occurred earlier than the GIST. Slightly above 30 cases of the synchronous occurrence of mesenchymal tumors (including GIST) and other gastrointestinal malignancy have been reported in the literature^[1]. Most of these

publications describe gastric stromal tumors synchronous with another gastric malignancy. We also observed such gastric tumor association in our group. In one of our patients, GIST occurred simultaneously with colon cancer. To our knowledge, only a few reports of such tumor co-occurrence have been published in the literature^[8].

GISTs have been reported to occur synchronously with adenocarcinoma, lymphoma and carcinoid^[1,9]. Similar to other authors, GIST was most frequently synchronous with adenocarcinoma also in our series (75%). High percentage of synchronous GISTs and other gastrointestinal tumors in our series is both surprising and difficult to explain. 14% of all the GISTs and 25% of the gastric stromal tumors developed synchronously with a second gastrointestinal malignancy. This rate of neoplasm co-occurrence is greater than twice that observed in the largest group of synchronous GISTs published by Maiorana *et al*^[1]. In their series, 11.5% of gastric GISTs (6 cases) were associated with other gastrointestinal malignancies.

Although the synchronous occurrence of GIST and other abdominal malignancy seems to be just a coincidence, the development of these tumors may involve common carcinogenic agents. For example Sugimura *et al*^[10] revealed that enteral nitrosoguanidine produces adenocarcinoma in rats. In contrast, simultaneous exposure to both nitrosoguanidine and acetylsalicylic acid causes synchronous development of both gastric cancer and leiomyosarcoma^[11]. In conclusion the synchronous occurrence of GISTs and other gastrointestinal malignancies is more common than it has been considered. The concomitant GIST is usually discovered incidentally during the operation performed because of the other malignancy. The development of GIST and other neoplasms may involve the same carcinogenic agents.

INTRODUCTION

Phenolic acids are plant components ubiquitously present in many fruits, vegetables and grains. They constitute a major portion of the human daily intake of non-nutrients^[1]. There is increasing evidence of positive health benefits of the high dietary intake of such compounds. These dietary phenolic acids have demonstrated antioxidant^[2], anti-inflammatory^[3], cardioprotectant^[4] and anticancer properties^[5].

Ferulic acid, a hydroxycinnamic acid, is found in rice, wheat, barley, roasted coffee, tomatoes, asparagus, olives, berries, vegetables, citrus fruits and leaves, and many other plants. Ferulic acid exhibits strong antioxidant and anti-inflammatory activities^[6]. Moreover, it has been claimed to protect against chemotherapy-induced side effects by enhancing the natural immune defense^[7].

There are previous reports that indicate beneficial effects of phenolic acids on the gastrointestinal tract^[8] and caffeic acid may enhance intestinal motility. Green tea polyphenolics improved bowel movement regularly^[9] and softened stool consistency^[10]. Also black tea polyphenols have been shown to enhance gastrointestinal motility both *in vitro* and *in vivo*^[11].

Cancer chemotherapy causes severe nausea, vomiting and abdominal discomfort which limits its administration^[12]. Most anticancer agents slow down gastric emptying^[13-15]. Cisplatin is extensively used for management of oncological disorders, particularly of the ovary, testis, bladder, head and neck^[16]. Although effective, cisplatin is associated with many adverse drug reactions, such as renal damage, gastrointestinal dysfunction, auditory toxicity and peripheral nerve toxicity^[17]. Cisplatin produced dose-related inhibition in gastric emptying reflects an accumulation of food in the stomach^[18]. Cisplatin-induced side effects in the gastrointestinal tract may be altered by metoclopramide^[19], 5HT₃ receptor antagonists^[14,15] and antioxidants^[20].

The aim of the present study was to investigate the effect of ferulic acid on gastrointestinal tract both *in vitro* and *in vivo*. The effect of ferulic acid, in selected doses, on cisplatin-induced delay in gastric emptying in rats was also investigated. Specific 5HT₃ receptor antagonists are effective against drug-induced emesis^[21] and ondansetron has been shown to reverse the delay in gastric emptying in rats^[14], therefore ondansetron was used for comparison.

Abstract

AIM: To study the effects of ferulic acid on gastrointestinal motility both *in vitro* and *in vivo*.

METHODS: Ferulic acid induced concentration-dependent stimulation of the basal tone of isolated guinea pig ileum (2-20 μmol/L) and isolated rat fundus (0.05-0.4 mmol/L).

RESULTS: Ferulic acid significantly accelerated the gastrointestinal transit and gastric emptying in rats in a dose-dependent manner (50-200 mg/kg, po). Cisplatin (2.5-20 mg/kg, ip) induced a dose-dependent delay in gastric emptying in rats. Pretreatment with ferulic acid dose-dependently, significantly reversed the cisplatin-induced delay in gastric emptying.

CONCLUSION: The endogenous prostaglandins (PGs) are involved in mediating the stimulant effects of ferulic acid. This effect of dietary ferulic acid may help improve other accompanying gastrointestinal symptoms such as abdominal discomfort and also may protect against emesis induced by cytotoxic drugs.

Badary OA, Awad AS, Sherief MA, Hamada FMA. *In vitro* and *in vivo* effects of ferulic acid on gastrointestinal motility: Inhibition of cisplatin-induced delay in gastric emptying in rats. *World J Gastroenterol* 2006; 12(33): 5363-5367

MATERIALS AND METHODS

Chemicals

All chemicals, unless specified otherwise, were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA).

Animals

Experiments were performed using Egyptian Giza strain guinea pigs (300-500 g) of either sex and adult male Wistar albino rats (175-210 g), both bred in the animal facility of Faculty of Pharmacy, Al-Azhar University. The animals were housed under conditions of $24 \pm 2^\circ\text{C}$, 50 ± 10 relative humidity and 12 h light and dark cycles. The animals were fed with a laboratory diet manufactured by Al-Nasr Co., Cairo, Egypt, and were fasted overnight before drug administration.

In vitro experiments

Isolated rat fundus: The experiment was made according to Vane^[22]. Adult male Wistar albino rats were fasted overnight with free access to water, and then they were sacrificed. The abdomen of each animal was opened, and the entire stomach was dissected free from the abdomen and placed into a dish containing aerated Krebs solution at 37°C . The grey fundal part was separated from the pink pyloric part of each stomach. Each part was cut longitudinally to form a sheet strip of gastric fundus approximately 4 cm long and 3 mm wide (the cuts were parallel to the longitudinal muscle fibers by making alternate transverse cuts on opposite sides of the muscle). A thread was attached to each end of the preparation, and then it was suspended in a 20 mL organ bath filled with Krebs solution at 37°C and aerated with a mixture of oxygen (95%) and carbon dioxide (5%). One thread was attached to a fixed pin in the bath and the other to isotonic transducer (Washington 400 MD2C Bioscience, Sheerness, Kent, UK). The gastric fundus preparation was allowed to equilibrate for 30 min under tension of 1 g before starting the experiment. Ferulic acid at different concentrations was allowed to contact with the preparation for 6 min. Serotonin ($14 \mu\text{mol/L}$) was used at the beginning of each experiment to test the sensitivity of the tissue used. To determine the site of action of ferulic acid, a submaximal concentration (0.05 mmol/L) was tested before and after complete blockade of H_1 receptors (mepyramine $10 \mu\text{mol/L}$), muscarinic receptors (atropine sulfate $10 \mu\text{mol/L}$), 5HT_3 receptors (partially blocked by ondansetron 1 mmol/L) and PGE_2 effect (blocked by indomethacin 0.08 mmol/L).

Isolated guinea pig ileum: Experiments were done according to Perry^[23]. Guinea pigs were killed by exsanguination. The guinea pig ileum preparation was set up in a 20 mL organ bath containing Tyrode solution at 37°C gassed with 95% O_2 and 5% CO_2 . The normal tone and changes in force of contraction after different concentrations of ferulic acid ($2\text{-}20 \mu\text{mol/L}$) were measured (at a speed of recording 0.25 mm/sec) using isotonic transducer (Washington 400 MD2C Bioscience, Sheerness, Kent, UK). Histamine ($2\text{-}25 \mu\text{mol/L}$) was used to test the sensitivity of the tissue. To determine the site of action of ferulic acid, mepyramine ($0.8 \mu\text{mol/L}$), atropine sulfate ($1 \mu\text{mol/L}$), ondansetron ($5 \mu\text{mol/L}$)

and indomethacin (0.14 mmol/L) were used to mediate blockade of H_1 receptors, muscarinic receptors, 5HT_3 receptors and the PGE_2 effect, respectively.

In vivo experiments

Intestinal transit rate in rats: Gastrointestinal transit was measured in the charcoal propulsion test^[24]. The test compound (50, 100 or 200 mg/kg) and saline (control) were administered orally. Rats were distributed into groups (8 each): group 1 received 1 mL saline (control); groups 2-4 were treated with ferulic acid in 3 doses (50, 100 or 200 mg/kg, oral); group 5 was given indomethacin (0.75 mg/kg , ip)^[11]; and Group 6 received indomethacin (0.75 mg/kg , ip) 50 min after oral administration of ferulic acid (100 mg/kg). One hour after ferulic acid administration, each rat was orally administered 1 mL charcoal meal (5% activated charcoal suspended in 10% aqueous tragacanth). Rats were killed 30 min later by cervical dislocation. The extent of charcoal propulsion in the small intestine was measured (distance traveled by the charcoal head from the pylorus as well as total length of the small intestine). Intestinal transit rate% = distance traveled by charcoal head/length of the small intestine $\times 100$.

Gastrointestinal emptying in rats: The rate of gastric emptying of the non-nutrient semisolid meal was determined according to the method described previously^[25]. Male Wistar rats were fasted overnight with water *ad libitum*. Briefly, a test meal (0.05% phenol red in a 1.5% aqueous methylcellulose solution) was given (1.5 mL/rat) by gastric tube. Thirty minutes after the meal was given, the animals were sacrificed. The cardia and the pylori were clamped, the stomach was removed out, homogenized with its contents in 100 mL of 0.1 mol/L NaOH. Proteins (in 5 mL homogenate) were precipitated with 0.5 mL of trichloroacetic acid (20% w/v) and centrifuged. The supernatant was mixed with 4 mL of 0.5 mol/L NaOH and absorbance of the sample was read at a wavelength of 560 nm. Phenol red was recovered from the stomach of rats killed immediately after administration of the methylcellulose meal served as the standard stomach. The percentage of gastric emptying was calculated from the following formula: Gastric emptying (%) = $1 - (\text{amount of phenol red recovered from the test stomach} / (\text{average amount of phenol red recovered from the stomach}) \times 100$.

Activity is expressed as the percent change of gastric emptying in treated rats versus controls.

Tested compounds

Effect of ferulic acid: Ferulic acid at three different doses (50, 100 or 200 mg/kg) was orally administered 30 min before the test meal.

Effect of cisplatin: To assess the dose dependency of cisplatin-induced delay in gastric emptying and to standardize the dose that would be more suitable to study the effect of ferulic acid pretreatment, cisplatin was administered at different doses of 2.5, 5, 10 and 20 mg/kg, ip, 30 min before the test meal administration.

Effect of ferulic acid on cisplatin-induced delay in gastric emptying: Effect of ferulic acid (100 mg/kg) was investigated on the delay of gastric emptying induced by cisplatin 10 mg/kg , ip. Ferulic acid was given 20 min before cisplatin. The effect of ferulic acid was compared with

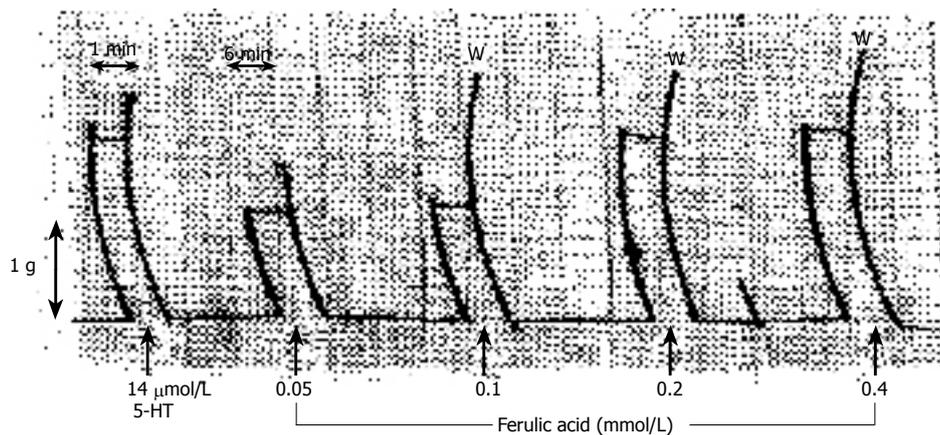

Figure 1 Effect of ferulic acid on isolated rat fundus. Fundic strip was suspended in oxygenated Krebs solution at 37°C. The 1 min and 6 min scales represent the speed of recording and the 1-g scale represents the calibration tension and W is a wash.

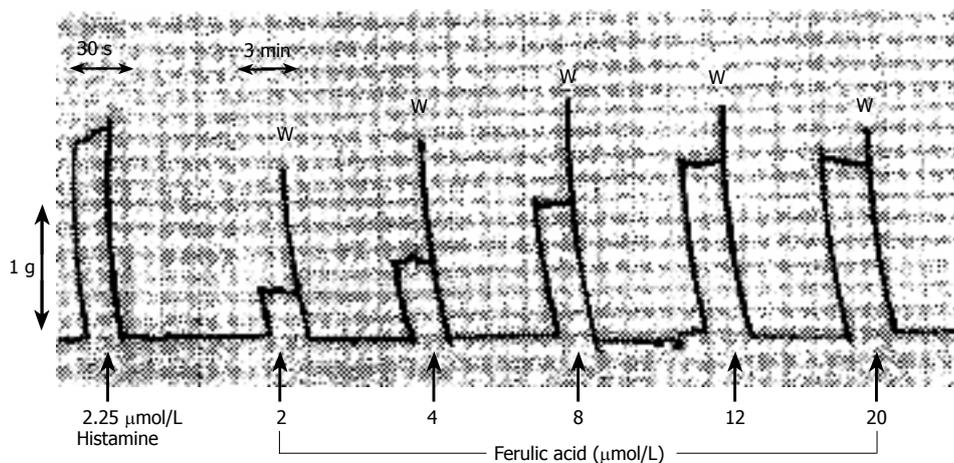

Figure 2 Effect of ferulic acid on isolated guinea pig ileum. Ileum was suspended in oxygenated Tyrode solution at 37°C. The 30 s and 3 min scales represent the speed of recording and the 1-g scale represents the calibration tension and W is a wash.

the 5HT₃ receptor antagonist ondansetron administered at a dose of 3 mg/kg, po, 30 min before cisplatin administration.

Statistical analysis

The results are expressed as the mean \pm SE. One way analysis of variance (ANOVA) followed by Bonferroni test for multiple comparisons was used for statistical comparison. *P* values less than 0.05 were considered statistically significant.

RESULTS

Isolated rat fundus

Ferulic acid (0.05-0.4 mmol/L) produced concentration-dependent contractions of isolated rat fundus (Figure 1). These contractions were not affected by blockade of muscarinic receptors by atropine sulfate (10 μ mol/L) or by the histaminergic receptor with mepyramine (10 mmol/L). On the other hand, ondansetron (1 mmol/L) did not affect the contraction. Complete blockade of PGE₂ by indomethacin partially decreased the contractile response due to ferulic acid.

Guinea pig ileum

Ferulic acid (2-20 μ mol/L) induced a significant (*P* < 0.05) increase in the height of contraction of isolated guinea pig ileum with a maximum concentration of 20 μ mol/L (Figure 2). A submaximal concentration (4 μ mol/L) of ferulic acid was used to investigate the site of its stimulant

effect. Complete blockade of either H₁ or muscarinic receptors by mepyramine or atropine did not affect the response of ileum to ferulic acid. Also, partial blockade of 5HT₃ receptors by ondansetron failed to prevent the stimulant effect. The stimulant effect of ferulic acid was partially inhibited by indomethacin (0.14 mmol/L). This stimulant effect may be mediated at least partly *via* stimulation of PGE₂ receptors.

Intestinal transit rate in rats

Ferulic acid significantly induced a dose-dependent increase in the distance traveled by charcoal meal in the gut of rats at 50, 100 or 200 mg/kg. The facilitatory effect of ferulic acid (100 mg/kg) was significantly reduced after pretreatment with indomethacin. Indomethacin alone significantly reduced the intestinal transit rate as compared with the control group (a decrease of 12.1%). Ferulic acid (100 mg/kg) significantly increased the intestinal transit rate of the indomethacin-treated group (by 27.5% compared with the indomethacin group and 12.1% compared with the control group) (Table 1).

Gastric emptying rate

Effect of cisplatin: Intraperitoneal administration of cisplatin dose-dependently inhibited the gastric emptying rate of the phenol red methylcellulose meal in rats. After administration of cisplatin 2.5, 5, 10, and 20 mg/kg, the gastric emptying was 41% \pm 3.1%, 25% \pm 2.2%, 15% \pm 1.2% and 6% \pm 0.4%, respectively as compared with the control 61% \pm 3.0%.

Table 1 Effect of ferulic acid on gastrointestinal transit rate of a semisolid charcoal meal in rats

Treatment	Dose	Transit rate (% ± SE)	% change of control
Saline (control)	1 mL, oral	58 ± 1.5	0.0
Ferulic acid	50 mg/kg, oral	73 ± 3.1	25.9
	100 mg/kg, oral	85 ± 2.1	46.6
	200 mg/kg, oral	91 ± 3.2	56.9
Indomethacin	0.75 mg/kg, ip	51 ± 2.0	-12.1
Indomethacin + ferulic acid	0.75 mg/kg, ip + 100 mg/kg, po	65 ± 3.3	12.1

Compounds were orally administered 60 min before the test meal (10 mL/kg body weight of 5% charcoal in 5% gum tragacanth). $P < 0.05$ vs control group or indomethacin group, using ANOVA followed by Bonferroni test for multiple comparisons.

Effect of ferulic acid: Ferulic acid induced a dose-dependent (50-200 mg/kg, po) significant increase on the gastric emptying rate. The percentage increases at 50, 100 and 200 mg/kg were 22.4%, 48.3% and 70.7%, respectively.

Effect of 5HT₃ receptor antagonist ondansetron: Ondansetron 3 mg/kg, po when administered 30 min before cisplatin significantly increased the gastric emptying rate to 49% ± 2.5% compared with cisplatin (10 mg/kg, ip) group 15 ± 1.2 (Figure 3).

Effect of ferulic acid on cisplatin-induced delay in gastric emptying: Pretreatment with oral ferulic acid at doses of 100 and 200 mg/kg, increased gastric emptying to 30% ± 1.7% and 51% ± 3.1%, respectively as compared to cisplatin (10 mg/kg) alone. The reversal of delayed gastric emptying was statistically significant at both doses ($P < 0.05$) (Figure 3).

DISCUSSION

The present data revealed the prokinetic effect of ferulic acid *in vitro* and *in vivo*. Ferulic acid showed a significant dose-dependent stimulation of the basal tone of isolated rat fundus and isolated guinea pig ileum. The findings have provided evidence for the involvement of endogenous PGs in mediating the stimulant effect of ferulic acid. Both the gastric and intestinal mucosa synthesize large amounts of PGs^[26]. PGE₂ was shown to contract longitudinal smooth muscles^[27] and relax the circular smooth muscle of the intestine^[28], while indomethacin could relax the longitudinal intestinal smooth muscles^[29] and contract the circular muscles due to inhibition mostly of PGE₂ and PGI₂^[30]. The antagonistic effect of ferulic acid on gastrointestinal transit time by indomethacin indicates a role of PGs in the mechanism of action of ferulic acid on gastrointestinal motility.

The effect of ferulic acid on peristalsis and gastric emptying further supports the gastrokinetic effect of ferulic acid. The observation that indomethacin could reduce the facilitatory effect of ferulic acid further indicates the partial PG involvement in the mechanism of action of ferulic acid on gastrointestinal motility.

Phenolic acids were reported to inhibit lipoxygenase activity^[31], leukotrienes^[32] and thromboxan^[33] biosynthesis,

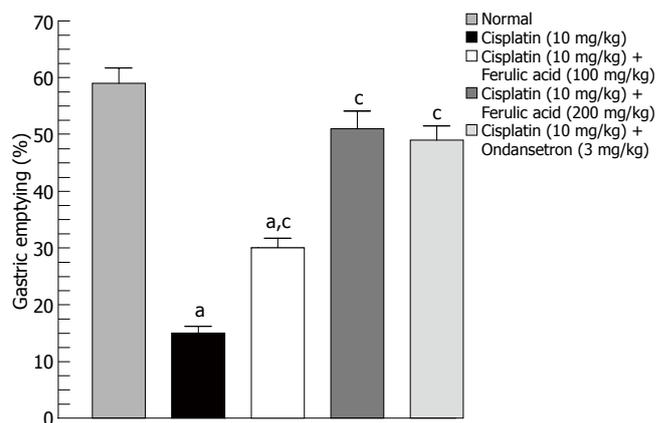

Figure 3 Effect of ferulic acid and ondansetron on cisplatin-induced delay in gastric emptying in rats (mean ± SE, $n = 8$, $^{a,c}P < 0.05$, vs control or cisplatin group, respectively).

so ferulic acid may shunt the arachidonic acid metabolism to the cyclooxygenase pathway especially towards PGs biosynthesis direction.

There is a possibility, although not investigated in the current study, that the gastrokinetic activity of ferulic acid may be partially mediated *via* interference with nitric oxide (NO) production, and NO plays a key role in regulation of gastrointestinal motility by its smooth muscle relaxing and vasodilating activity^[34]. Based on this assumption, Soliman and Mazzi^[35] and Son *et al*^[36] reported that caffeic acid significantly inhibited NO production probably *via* inhibition of NO synthase gene expression.

Further studies on the mechanism of action of ferulic acid on gastrointestinal motility may be helpful in determining the therapeutic values of ferulic acid in gastrointestinal motor disorders.

Cisplatin plays an important role in the treatment of malignant diseases^[14]. It causes severe nausea and vomiting, accompanying gastrointestinal symptoms such as abdominal discomfort in the patients^[37]. Cisplatin when given intravenously in dogs causes abnormal myoelectric activity in the antrum and small intestines^[38], abdominal distension and delayed gastric emptying in rats^[14,20].

In the present study in rats, ip administration of cisplatin dose-dependently inhibited the gastric emptying rate after a non-nutrient meal. These results are consistent with the finding that cisplatin causes a delay in gastric emptying in rats^[14,15,20]. This effect may be due to the release of 5HT from the mucosal enterochromaffin cells in the gastrointestinal tract. The 5HT releases the peripheral 5HT₃ receptors on the vagal afferent fibers and causes relaxation of the stomach possibly leading to delay in gastric emptying^[37]. Also, cisplatin-induced free radical generation in the intestine^[39] may lead to subsequent release of 5HT^[40] which may act on peripheral 5HT₃ to the relax the stomach and lead to the delay in gastric emptying.

The inhibitory action of cisplatin on gastric emptying was significantly reversed by pretreatment with ferulic acid. The effect of ferulic acid was dose-dependent. The beneficial effect of ferulic acid could be attributed at least partly to its stimulant effect on gastrointestinal tract and its antioxidant effect. Ferulic acid, as one of the phenolic acids, has demonstrated strong antioxidant properties

as its structure dependent hydrogen-donating abilities and its propensity for nitrate make these compounds powerful scavengers of reactive oxygen species and reactive nitrogen species^[2]. Ferulic acid has been shown to protect gastrointestinal organs against carcinogenesis^[41] and antioxidants may prevent cisplatin-induced delay in gastric emptying in rats. In conclusion, ferulic acid inhibits the cisplatin-induced delay in gastric emptying in rats. This agent may be useful in reducing cisplatin-induced emesis and improve gastrointestinal symptoms such as abdominal discomfort induced by cytotoxic agents.

Abstract

AIM: To investigate the reactivity of a panel of 8 mouse anti-hepatitis B surface antigen (HBsAg) monoclonal antibodies (mAbs) using a collection of 9 recombinant HBsAg mutants with a variety of amino acid substitutions mostly located within the "a" region.

METHODS: The entire HBs genes previously cloned into a mammalian expression vector were transiently transfected into COS7 cells. Two standard unmutated sequences of the ayw and adw subtypes served as controls. Secreted mutant proteins were collected and measured by three commercial diagnostic immunoassays to assess transfection efficiency. Reactivity of anti-HBs mAbs with mutated HBsAg was determined by sandwich enzyme-linked immunosorbent assay (ELISA).

RESULTS: Reactivity of anti-HBs mAbs with mutated HBsAg revealed different patterns. While three mutants reacted strongly with all mAbs, two mutants reacted weakly with only two mAbs and the remaining proteins displayed variable degrees of reactivity towards different mAbs. Accordingly, four groups of mAbs with different but overlapping reactivity patterns could be envisaged. One group consisting of two mAbs (37C5-S7 and 35C6-S11) was found to recognize stable linear epitopes conserved in all mutants. Mutations outside the "a" determinant at positions 120 (P→S), 123(T→N) and 161

INTRODUCTION

In spite of the progress made in vaccine development, hepatitis B virus (HBV) infection remains a major health care problem worldwide. Upon exposure to HBV, 5%-10% of healthy adults fail to mount a protective antibody response and become chronically infected^[1]. A similar proportion of healthy individuals do not respond to HB vaccination^[2,3]. Lack of response has largely been attributed to parameters associated to the host immune system, including defective antigen presentation^[4,5], diminished Th1/Th2 response^[6,7], restricted HBsAg-specific T- and/or B-cell repertoires^[8,9] and HLA-linked B-cell deletion or suppression^[10,11]. Viral factors, however, particularly evolving mutant variants may also play an important role. The unique replication cycle of HBV^[12] provides much opportunity for mutations to appear^[13]. In addition, immune response is considered as a synergistic pressure for emergence of these mutants^[13,14]. Amino acid substitutions resulting from such mutations may affect the structure of hepatitis B surface antigens (HBsAg) that consist of three overlapping molecules, namely large (L), middle (M) and small (S) proteins^[13].

The small protein, traditionally known as HBsAg, contains the immunodominant "a" determinant shared by all serotypes and genotypes of HBV, together with

serotypic epitopes determining the four major subtypes of HBV, that is *dm*, *ym*, *dr* and *yr*^[15]. The “a” determinant (amino acids 124-147) is located within a large antigenic area referred to as the major hydrophilic region (MHR). Tertiary structure of this area is crucial for its recognition by the immune system. Hence, mutations within this area may allow emergence of escape mutants with reduced binding affinity to HBsAg-specific antibodies. Such mutants may also skip identification by antibody-based diagnostic assays^[16,17].

Monoclonal antibodies (mAbs) against HBsAg are widely used in diagnostic immunoassays^[18,19]. However, these assays may not detect all cases of infection with variant viruses carrying mutations in some critical positions of the MHR^[16,18,20,21]. Emergence of mutant HBV variants due to the escape from immunological pressure, either following immunoprophylaxis with polyclonal or monoclonal anti-HBs antibody and/or vaccination with HBsAg, may hinder detection of HBsAg by the current monoclonal antibody-based immunoassays. Such mutations, predominantly accumulated within the “a” determinant, could also result in breakthrough infection in a number of vaccinated subjects^[22,23]. These mutants will have selective advantage for propagation and vertical or horizontal transmission to vaccinated individuals^[16,24].

Recent reports of accelerated accumulation of “a” determinant mutants in vaccinated children following an universal vaccination program^[25,26], together with a high prevalence of “a” determinant mutations in natural HBsAg mutants collected from unvaccinated carriers^[27], have brought serious concerns to the current vaccination policy. This has prompted the Viral Hepatitis Prevention Board of WHO to consider development of strategies to prepare for eventual increase of mutant viruses and to recommend establishment of an independent global network for appropriate monitoring of such mutants^[28,29].

In the present study, we have characterized eight murine HBsAg-specific mAbs as potential tools for detection of HBsAg mutants. The results presented in this paper and similar papers reported previously^[20,30,31] will help to identify the most influential mutations relevant to vaccine escape and immunodetection failure.

MATERIALS AND METHODS

Monoclonal antibodies

Eight murine mAbs were raised against a recombinant wild-type hepatitis B surface antigen (rHBsAg) of the adw subtype (Heberbiovac, Heberbiotec, Cuba) as described elsewhere^[19]. Characteristics of these mAbs are summarized in Table 1.

Production, purification and biotinylation of polyclonal anti-HBs antibody

White New Zealand rabbits were administered four injections with 10 µg of standard rHBsAg (adw) at two-week intervals. The first dose was given in complete Freund's adjuvant (Sigma, USA), whereas other doses were administered in incomplete Freund's adjuvant (Sigma, USA). Following serum titration of anti-HBs antibody

Table 1 Characteristics of monoclonal anti-HBs antibodies

Clone	Isotype	K _{aff} (M ⁻¹)	Recognized epitope
34D7-S3	IgG1	5.24 × 10 ⁸	Conformational
33D7-S4	IgG1	3.27 × 10 ⁸	Conformational
38F3-S6	IgG1	3.75 × 10 ⁸	Conformational

from immunized rabbits, hyperimmune sera were collected and purified using a column of rHBsAg coupled to CNBr-activated sepharose-4B (Amersham Biosciences, Sweden). Purified antibody was biotinylated using biotinyl N-hydroxysuccinimide (BNHS) ester (Sigma) as previously described by Bayer *et al.*^[32], with some modifications. Briefly, IgG (1 mg/mL) was dialyzed overnight in sodium bicarbonate (pH 8.5). BNHS ester freshly dissolved in dimethyl sulfoxide (Merck, Germany) at 1 mg/mL was added to predialyzed IgG at a 1:10 (v/v) ratio and incubated at 25°C for 4 h. The mixture was then dialyzed overnight against 0.1 mol/L Tris-HCl (pH 7.4) dispensed into small aliquots and stored at -20°C to avoid frequent freezing and thawing.

Preparation of expression plasmid clones encoding HBsAg mutants

Plasmid DNA (pRK5) of nine HBsAg variants and two unmutated standard adw and ayw isolates (Table 2) were constructed as described previously^[20]. Plasmid DNA was propagated by transformation of *E coli* strain DH5α (CinnaGen, Iran) by electroporation^[33]. In brief, appropriate amount (depending on the clone) of plasmid DNA was mixed with electrocompetent cells, incubated on ice and subsequently pipetted into a cold electroporation

cuvette (Bio-Rad, USA). Pulse of electricity was delivered and super optimal catobolite (SOC) medium was added immediately to electroporated cells. Following 2 h incubation at 37°C, different volumes of electroporated cells were plated onto LB agar (Sigma) containing 75 µg/mL ampicillin (Sigma). Electrocompetent cells without DNA were used as a negative control. Transformed colonies were selected, tested and cultured in LB broth containing 75 µg/mL ampicillin. Plasmid DNA was subsequently purified using GIAGEN plasmid extraction kit (QIAGEN, USA).

Transfection of expression plasmids

COS7 cells (NCBI C143) provided by National Cell Bank of Iran (Pasteur Institute of Iran, Tehran) were cultured in RPMI-1640 (Gibco, USA) containing 100 mL/L heat-inactivated fetal bovine serum (Biochrom, Germany), penicillin (100 IU/mL) and streptomycin (100 µg/mL). Cells were transiently transfected using Lipofectamin 2000 (Invitrogen, USA). The amount of viral DNA was adjusted in all experiments to 0.8 µg/well in a 24-well plate (Nunc, Denmark). A subconfluent monolayer of COS7 cells was washed with growth medium without antibiotics and 500 µL of Opti-MEM I Reduced Serum Medium (Invitrogen) was added. Plasmid DNA was diluted in 50 µL of Opti-MEM I. Then 2 µL Lipofectamin 2000 pre-diluted in 50 µL of Opti-MEM I was added to diluted DNA and kept at room temperature for 20 min. The complex was added to the cells and the cells were incubated at 37°C in a humidified atmosphere containing 50 mL/L CO₂. Following a 2 h incubation, 500 µL of complete medium was added and culture supernatant was harvested 48-96 h later. pRK5 plasmid with or without the insert carrying a standard sequence of HBV DNA [adw (Gly D) and ayw (Gly Y) subtypes] was used as negative and positive controls, respectively.

Commercial HBsAg detection kits

Supernatants of transfected cells were tested for the presence of HBsAg using three different sandwich enzyme-linked immunosorbent assay (ELISA) kits according to the manufacturer's guidelines. The Bioelisa HBsAg colour kit (Biokit, Spain) employs polyclonal Ab as the capture (coating) layer, whereas the Hepanostika HBsAg Uni-Form II (BioMerieux, The Netherlands) and the ETI-MAK-4 (Diasorin, Italy) kits employ mAb as the coating Ab. All three kits contain peroxidase-conjugated polyclonal anti-HBs antibody as detector.

Determination of reactivity of anti-HBs mAbs with HBsAg mutants by sandwich ELISA

A panel of eight mAbs was used in this study. Monoclonal anti-HBs Abs were dissolved in phosphate-buffered saline (0.15 mol/L PBS, pH 7.2) at a final concentration of 10 µg/mL. The wells of 96-well flat-bottom microtiter plates (Maxisorp, Nunc, Denmark) were coated with anti-HBs Ab (100 µL/well) and incubated for 90 min at 37°C. The wells were then washed three times with PBS and plates were blocked with PBS containing 30 g/L skim milk (Merck, Germany) for 90 min at 37°C. After washing with

Results are expressed as absorbance (A) measured at 450 nm, index (ratio of absorbance of mutant sample to absorbance obtained for 1.25 ng/mL of standard adw HBsAg) and concentration (Conc.) presented as ng/mL. Concentration was measured only by the Hepanostika kit using the standard adw HBsAg to construct the standard curve.

PBS containing 0.5 mL/L Tween 20 (PBS/T, Sigma), 100 µL of supernatant of the transfected cells was added to the plates. Following incubation at 37°C for 90 min, the plates were washed and filled with appropriate dilution of biotinylated-rabbit anti-HBs Ab. After incubation for 90 min and washing, appropriate dilution of peroxidase-conjugated streptavidin (Sigma) was added and the reaction was then revealed with tetramethylbenzidine (TMB, Sigma) substrate. Finally, the reaction was stopped with 200 mL/L H₂SO₄ and the absorbance (A₄₅₀) was measured by a multiscan ELISA reader (Organon Teknika, Boxtel, The Netherlands) at 450 nm.

RESULTS

Detection of expressed HBsAg mutants by commercial ELISA kits

Transfection efficiency of all expressed HBsAg clones, including nine mutants and two unmutated standard sequences, was measured using 3 commercial diagnostic kits. To obtain a comparable index in each assay, absorbance (A₄₅₀) of each sample was represented as the ratio to absorbance obtained for 1.25 ng/mL of a purified recombinant unmutated HBsAg of the adw subtype (immunogen) (Table 3). All expressed HBsAg proteins were detectable by all three assays, albeit at different levels. While the index value for 91-4696 was similar to the standard sequences (Gly D and Gly Y), BA3.2 mutant showed the lowest index using all three assays, significantly lower than the standard sequences. Overall, the Hepanostika diagnostic kit gave higher absorbance and relative indexes implying better sensitivity compared to the other two kits. This kit was subsequently used to quantify the concentration of secreted HBsAg in culture supernatants of transfected cells by extrapolation from known input of the standard adw HBsAg (Table 3).

Reactivity patterns of anti-HBs mAbs to the expressed HBsAg mutants

Immunoscreening was carried out on supernatants from cells transfected with all constructs using the mAbs as the coating layer. Supernatants of untransfected cells or cells transfected with pRK5 plasmid vector alone were used as background (blank) and negative control, respectively. The results are presented in Figure 1 and summarized in Table 4. While the standard sequences (Gly Y and Gly D) and 3 mutant proteins (91-4696, SA6 and SA7) were detectable by all eight mAbs, only two of the mAbs (37C5-S7 and 35C6-S11) reacted with BA3.2 having two mutations at positions 123 and 124. The remaining mutants displayed different reactivity patterns. Cross-inhibition studies were performed to find out whether binding of an antibody could inhibit binding of other mAbs to their epitopes, enabling identification of overlapping epitopes recognized by different mAbs. The results illustrate different inhibitory patterns, partly compatible with those obtained from the direct binding assays (Table 5).

DISCUSSION

In the present study, eight mAbs raised to a recombinant unmutated HBsAg of the adw subtype were tested for their bindings to a panel of nine mutants HBsAg. We have recently demonstrated that these mAbs recognize different conformational or linear epitopes common to adw, ayw and adr subtypes, supposedly the “a” determinant^[19].

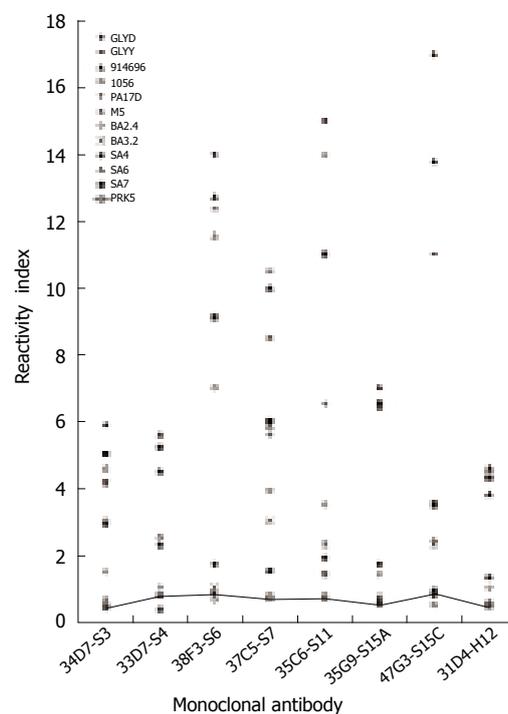

Figure 1 Reactivity of mouse monoclonal anti-HBs antibodies with recombinant HBs antigen mutants. Reactivity is expressed as relative index defined as the ratio of absorbance (A) of a given mutant to the absorbance obtained for 1.25 ng/mL of the standard adw HBs antigen. The horizontal line represents the results obtained for pRK5 plasmid without insert used as the negative control.

This determinant is conserved in all subtypes of HBV and confers a protective antibody response to HBV infection by all subtypes^[34,35]. Vaccination of healthy individuals with recombinant HBsAg has also been shown to induce an antibody response restricted to the “a” determinant^[36]. Although the structure of the “a” determinant has not been thoroughly characterized and seems to encompass a large number of amino acid residues common to all subtypes of HBV, an important region of this determinant lies between residues 124 and 147. This region is a part of a highly hydrophilic area located between residues 100 and 160. Presence of 5 cysteine residues at positions 124, 137, 138, 139 and 147 creates at least 2 loops protruding from the surface of

HBsAg as highly immunogenic epitopes. The majority of mAbs produced against HBsAg have been shown to recognize conformational epitopes within one of these loops^[16,17,30,31]. The tertiary structure created by these disulphide bonds is critical for antigenicity of HBsAg and replacement of cysteine residues at positions 124 and 147 with serine destroys its antigenicity^[37], demonstrating the conformational nature of the epitopes. Five of our mAbs reacted with conformational epitopes (Table 1), which were destroyed upon treatment of the molecule with a reducing agent, such as 2-ME.

Both type and position of substituted amino acids within the "a" determinant seem to be equally important. This is clearly reflected in the reactivity patterns of our mAbs. Thus three of the mutants including SA7, SA6 and 91-4696 were strongly reactive with all our mAbs. The reactivity indexes obtained for some of these mutants, particularly 91-4696, were similar to/or higher than those obtained for the two standard sequences (Figure 1). They also displayed strong reactivity with the three commercial diagnostic kits employed in this study. Similar reactivity patterns have already been reported for these three mutants, using a variety of commercial diagnostic kits and HBsAg-specific mAbs^[20,30]. Altogether six replacement mutations, including S113T/T143S (91-4696), Q129R/G130N/A166V (SA6) and M133T (SA7), were identified in these three mutants, none of which seemed to be crucial for HBs antigenicity. Of the two substitutions occurring at positions 113 and 143 in the 91-4696 mutant, the latter is more relevant to antigenicity of the "a" determinant. However, replacement of threonine with serine at this position has also been observed in sequences from a number of unmutated isolates of HBV deposited in the GenBank. This may explain the preserved binding activity of this mutant with all our mAbs. Surprisingly, replacement of serine with leucine at the same position in another mutant (1056) resulted in either substantial reduction or complete loss of reactivity towards most of the mAbs. Three of the mAbs (35G9-S15A, 31D4-H12 and 47G3-S15C) were completely negative and two mAbs (37C5-S7, 35C6-S11) were weakly positive (Figure 1 and Table 4). This mutant, however, contains another mutation at position 120 leading to replacement of proline with serine. This mutation could have a significant effect on reactivity of some mAbs^[30,38] and has also been reported as a vaccine escape mutant with reduced binding affinity to anti-HBs Ab^[13]. To distinguish whether the P120S or S143L mutation is responsible for diminished reactivity of the 1056 mutant, we looked at binding patterns of M5 mutant. This mutant contains an S143L mutation together with 7 more mutations, mostly located within the first and second loops of "a" determinant, but not the P120S substitution. Reactivity of 3 of the 1056 non-reactive or low-reactive mAbs (37C5-S7, 35C6-S11 and 47G3-S15C) was restored, suggesting direct or indirect influence of this residue on their binding activity. Since the M5 mutant contains 8 substitutions, a definite conclusion cannot be drawn from this comparison. Ideally, a mutant with a single mutation at P120 is required to study the influence of this residue.

Altogether, from the reactivity patterns observed in

this study, our mAbs could be broadly classified into four distinct, but overlapping groups (Table 4). The first group includes 34D7-S3, 33D7-S4 and 38F3-S6 mAbs. Reactivity of these mAbs with the 1056 mutant distinguished this group of mAbs from other groups. None of these mAbs reacted with PA17D, M5 and BA3.2 mutants, carrying multiple mutations extending from residue 100 to 145. Lack of reactivity with BA3.2 (T123N/C124R) that has a cysteine to arginine substitution at position 124 could largely be attributed to low immunoreactivity or a low secretion rate of this mutant from transfected cells (Tables 3, 4). This mutation resulted in disruption of the disulphide bond of the first loop of "a" determinant with drastic conformational changes leading to retention of the molecule in transfected cells. Complete lack of secretion of this mutant by transfected COS7 cells has already been reported by two groups^[20,30] who demonstrated the presence of low levels of BA3.2 molecule in cell lysate, but not in the culture supernatant of transfected cells. In the present study, however, BA3.2 was readily detected in culture supernatant of the transfected cells by three diagnostic kits, as well as two of mAbs (37C5-S7 and 35C6-S11). Loss of reactivity of the first group of mAbs (34D7-S3, 33D7-S4 and 38F3-S6) with BA3.2 seems to be primarily affected by conformational changes due to disruption of the disulphide bond. Indeed, these mAbs recognize highly conformational overlapping epitopes, as judged from the Western blot (data not shown) and cross-inhibition results (Table 5).

The BA3.2 reactive mAbs (37C5-S7 and 35C6-S11) constitute the second group of mAbs. Reactivity of 37C5-S7 and, to a lesser extent, 35C6-S11 with BA3.2 could be due to the linear nature of the epitopes recognized by both mAbs. However, the reduced binding activity of these antibodies with BA3.2 seems to be affected by the T123N mutation. Furthermore, recognition of three other mutants, namely PA17D, M5 and BA2.4 having multiple mutations, by these two mAbs makes a distinction between this group of mAbs with other groups. A variety of mutations exist within the first and second loops of "a" determinant of these mutants, including residues 133, 134, 144 and particularly 145, which are critical for binding many of the mAbs^[31]. These mutations, however, do not significantly influence reactivity of 37C5-S7 and 35C6-S11 mAbs. Instead, a few mutations located outside these loops at positions 120 (1056), 123 (BA 3.2), 133 and 161 (SA 4) induced a significant reduction of reactivity of 37C5-S7 and 35C6-S11 mAbs with the corresponding mutants. The reduced reactivity observed for both mAbs with 1056 (P120S, S143 L) and SA 4 (M133 T/Y 161F) mutants does not seem to be related to replacements of 143 and 133 residues, because the same mutations are found in 91-4696 and SA7 mutants which strongly bind to both mAbs (Table 4). Therefore, the P120S, T123 N and M161T mutants are suspected to contribute to formation of the linear epitopes recognized by 37C5-S7 and 35C6-S11 mAbs. Amino acid 161 has been proposed to be located at the surface of HBsAg^[39] which could potentially influence antigenicity of the molecule. Such escape and natural mutants with altered antigenicity have already been reported^[40,41]. Deletion mutagenesis and phage display technology may help to

map these epitopes more precisely.

The third group of mAbs includes only one member, that is 47G3-S15C which cannot bind to either of four mutant proteins (1056, PA17D, BA3.2 and SA4), but reacts with M5 and BA2.4 mutants. The most influential mutations are thought to be P120S, T123N and Y161F similar to the pattern predicted for the second group of mAbs. However, unlike 37C5-S7 and 35C6-S11 mAbs, 47G3-S15C does not bind to the PA17D mutant. This molecule has been reported to carry a mutation at position 144 (D→E), as well as many other undisclosed residues^[30], making it difficult to assign the contributing residues. Involvement of D144E mutation seems to be unlikely, since this mAb reacts with the M5 mutant having multiple mutations at both sides of this amino acid, including P142S, S143L and G145R. This mAb may recognize a conformational epitope within the “a” determinant which is affected by mutations outside this region. Interestingly, mutations at residues close to the “a” determinant, particularly at positions 120 (P→Q or P→S) and 123 (T→N), were found to have a significant impact on the conformation and antigenicity of the “a” region epitopes leading to loss of reactivity of some “a” determinant-specific mAbs^[30,38].

The fourth group of mAbs is comprised of 35G9-S15A and 31D4-H12 antibodies. Both mAbs did not react with four mutants (1056, PA17D, M5 and BA3.2) and reacted weakly with two other mutants (BA2.4 and SA4). Although the epitopes recognized by 35G9-S15A and 31D4-H12 are structurally different (conformational and linear, respectively), they overlap to some extent (Table 5), suggesting their close spatial location on HBsAg. Considering the number of mutated residues in non-reactive and low-reactive mutants, assignment of the contributing amino acids and localization of the corresponding epitopes could not be predicted with certainty. Employment of mutants with overlapping mutations at one or two amino acids covering the entire major hydrophilic region and particularly the “a” determinant will help to map the epitopes and to determine the crucial amino acids involved in interaction with our anti-HBs mAbs.

In summary, our results could have important clinical implications for immunoscreening and diagnosis of HBV infection and design of new generation of recombinant HB vaccines. Although recent epidemiological survey failed to demonstrate close association between breakthrough infection and mutant HBV variants in vaccinated children in Taiwan^[26], incorporation of such mutants within the current standard recombinant HBs vaccines may later be considered as the new generation vaccines to prevent transmission of HBV mutants.

Abstract

AIM: To detect *H pylori* infection and to evaluate the anti CagA seropositivity in adult Turkish dyspeptic patients.

METHODS: We evaluated anti-*H pylori* IgA, IgG and anti-CagA antibodies using commercial enzyme-linked immunoassay (ELISA) and Western blot in dyspeptic Turkish patients. *H pylori* status was determined by histology and rapid urease testing.

RESULTS: Fifty-six patients were entered. Forty-eight (85.7%) out of the 56 patients were positive for *H pylori*. *H pylori* IgG seropositivity was 82.1%, IgA seropositivity 48.2%. CagA ELISA showed that IgG was positive in 50% and IgA in 30.4% of those with *H pylori* infections. Western blot showed that IgG seropositivity was 80.4% and IgA seropositivity 33.9%. Western blot detected IgG antibodies with reactivity to CagA in 50%, VacA in 62.5%, UreB in 87.5%, UreA in 80.4%, and OMP in 57.1%. None of the tests had a sensitivity and specificity above 80%.

CONCLUSION: None of these commercial tests seems clinically useful for *H pylori* detection in adult dyspeptic patients, while Western blot can give seropositivity and determine anti-CagA, VacA virulence factor status of Turkish dyspeptic patients in the Izmir region.

INTRODUCTION

H pylori colonizes in the mucosa of the human stomach where it establishes a long-term infection associated with acute or chronic gastric inflammation, which may progress to peptic ulcer disease, atrophic gastritis with intestinal metaplasia, or gastric cancer. A variety of clinical outcomes of *H pylori* infection are associated both with host factors and with bacterial virulence factors^[1]. Several *H pylori* virulence genes have been identified, of these, oipA, vacA, cagA and babA appear to play a major role in pathogenicity. The cytotoxin-associated gene (CagA) is a marker for the cag pathogenicity island (PAI), a 40-kb genomic region^[1,2]. Most strains of *H pylori* from patients with peptic ulcer disease carry the CagA gene (CagA positive strains)^[1] and the presence of the CagA gene increases the risk of developing peptic ulceration, atrophic gastritis, and adenocarcinoma in the stomach. Consequently the discrimination of CagA positive and CagA negative *H pylori* strains might prove useful in predicting the chance for complications as well as for clinical and epidemiological studies of *H pylori* infection^[1,2].

H pylori cag PAI status is typically assessed by the immune response to the immuno-dominant CagA or by detection of the CagA gene. Available serological tools to characterize the infecting *H pylori* strains have been questioned because of their inadequate sensitivity and specificity^[3].

Current guidelines for the management of *H pylori* infection recommend eradication treatment without performing endoscopy in patients (< 45 years of age) with no alarm symptoms, thus making the availability of simple and reliable noninvasive tests important^[4]. Currently

available noninvasive tests for the diagnosis of *H pylori* infection include UBT, stool antigen test, and detection of anti-*H pylori* antibodies (e.g., serology).

This study compared five different diagnostic tests: rapid urease test, histology, anti-*H pylori* CagA Enzyme-linked immunoassay (ELISA) of IgA and IgG, anti-*H pylori* ELISA of IgA and IgG, Western blot of IgA and IgG including CagA and other antigens in untreated adult dyspeptic Turkish patients.

MATERIALS AND METHODS

Patients

The study population consisted of adult Turkish dyspeptic patients admitted to the Dokuz Eylül University Hospital, Gastroenterology Clinic. The patients were eligible if they had no *H pylori* eradication treatment in the previous 6 mo or did not receive antibiotics, H₂-receptor antagonists, sucralfate or omeprazole one month prior to examination, and had no previous history of gastric or duodenal malignancies. The patients with a history of coagulopathy or other disorders that were contraindications for endoscopy and/or biopsy sampling were excluded.

Endoscopy and biopsy sampling

Two antrum and two corpus biopsy specimens were taken from each patient undergoing upper endoscopy: one from the antrum and one from the corpus were used for the rapid urease test and the others were immediately fixed and transported in 10% phosphate-buffered formalin solution for histopathologic examination.

Histopathologic examination of biopsy specimens

Paraffin-embedded gastric biopsy specimens were routinely processed. Hematoxylin and eosin, alcian blue and Giemsa stains were used for morphologic examination of *Helicobacter*-like organisms (HLO). The updated Sydney system was used for determining gastritis activity and grading bacterial density of *H pylori*. Gastritis activity was graded on a four-point scale as none (grade 0), mild (grade 1), moderate (grade 2), and severe (grade 3)^[5]. *H pylori* infection was defined as positivity of histopathology and rapid urease test. Histology was performed by a specialized pathologist. A patient was defined as *H pylori* negative when both histological examination and urease test were negative and as *H pylori* positive when both histological examination and urease test were positive.

Serological tests and sera

Sera were collected on the same day as the biopsies from patients undergoing endoscopy. Serum samples were aliquoted and stored at -20°C until used.

Enzyme-linked immunoassay

Anti-*H pylori* IgA and IgG Western blot, IgA and IgG ELISA, anti-CagA IgA and IgG ELISA (EUROIMMUN Medizinische Labordiagnostika, Lübeck, Germany) were used to detect the presence of *H pylori*-specific serum antibodies according to the manufacturer's instructions. The recommended cut-off values were used.

Immunoblot assay

Western blot (EUROIMMUN Medizinische Labordiagnostika, Lübeck, Germany) was used to detect the presence of *H pylori*-specific serum antibodies according to the manufacturer's instructions. Western blot test consisted of *H pylori* antigen extracts with the following molecular weights of the corresponding bands to these proteins which were 120 kDa (CagA); 95 kDa (VacA); 67 kDa (flagellar sheat protein, nonspecific); 66 kDa (UreB); 57 kDa (heat-shock protein homolog); 33 kDa, 30 kDa, 29 kDa (UreA); 26 kDa, 19 kDa and 17 kDa. Anti-*H pylori* IgG antibodies were positive determined by Western blot when the 120 kDa (CagA) band, as well as at least two distinctive antigen bands from species-specific and highly specific antigens with the molecular weights of 95 kDa (VacA), 33 kDa, 30 kDa, 29 kDa (UreA), 26 kDa, 19 kDa and 17 kDa were present. Faint bands or no band was regarded as negative.

Statistical analysis

The McNemar's χ^2 test was used. The sensitivity, specificity, positive predictive values (PPV), negative predictive values (NPV), the likelihood ratios (+, -) and diagnostic accuracies of the anti-*H pylori* CagA IgA and IgG ELISA, IgA and IgG ELISA were computed against the gold standards (SPSS, version 11.0 for Windows). The receiver operating characteristic (ROC) curve analysis was also done.

Ethics

The research protocol was approved by the Institutional Review Board and the Ethical Committee of the Dokuz Eylül University, Faculty of Medicine, Izmir, Turkey. All patients gave their written consent to participate in the study.

RESULTS

A total of 56 adult Turkish dyspeptic patients (19 males, 37 females; mean age, 46.41 ± 13.12 years; age range, 21 to 78 years) were enrolled. *H pylori* infection was diagnosed in 48 (85.7%) patients by rapid urease test and histopathology. ELISA showed that *H pylori* seropositivity was 48.2% for IgA and 82.1% for IgG antibodies. CagA ELISA showed that IgA seropositivity was 30.4% and IgG seropositivity was 50% which was the same as the Western blot results. Western blot showed that IgA was positive in 33.9% and IgG in 80.4%. No significant statistical difference was found between CagA IgA and IgG antibodies by CagA ELISA but anti-*H pylori* IgG ELISA was significantly different with gold standards ($P < 0.05$) (Table 1, Table 2, Table 3).

Anti-*H pylori* Western blot of IgG antibodies also showed reactivity with p120 (CagA), p95 (VacA), p66 (UreB), p29 (UreA) and p19 (OMP) antigens: 28, 35, 49, 45 and 32 were positive, respectively (Table 4). A significant correlation with gastritis activity was also observed according to updated Sydney system ($P < 0.0001$). ROC analyses of all serological tests used in the study were also done and did not show any difference.

Table 1 Detection of *H pylori* status by Western blot, ELISA and CagA ELISA of IgA

Patients	Western blot <i>n</i> (%)			<i>H pylori</i> IgA ELISA <i>n</i> (%)		CagA ELISA <i>n</i> (%)		Total

DISCUSSION

H pylori infection can be diagnosed by a variety of invasive and non-invasive tests. Serology can be performed on non-invasively collected clinical samples. Serological detection of infection with a CagA containing strain of *H pylori* by anti-CagA ELISA and Western blot of CagA is the only noninvasive diagnostic test at present available for assessing strain virulence potential and possible disease risk. The reliability of CagA serology as a predictive test for determining the CagA genotype of the infecting strain is important because various serological assays are now available^[2].

Infection with *H pylori* evokes both local and systemic antibody responses^[6]. CagA is the important pathologic marker with a high immunogenic response^[6,7]. In Europe, CagA-positive *H pylori* has been reported to account for 60% to 70% of *H pylori* strains^[2,8], while reports from East Asian countries have shown that more than 90% of *H pylori* strains are CagA positive irrespective of the disease presentation^[8].

Noninvasive tests are becoming more and more important in the clinical management of dyspeptic patients, followed by the treatment of *H pylori* in primary care according to “the Maastricht 2-2000 European Consensus report^[4]. A “test and treat” approach is recommended in adult patients under the age of 45-55 years with no alarm symptoms. But choosing the ‘right’ noninvasive test is not easy. Serological tests have limitations in detecting the exposure to *H pylori*. A meta-analysis of 21 studies with commercially available ELISA serology kits has reported an overall sensitivity and specificity of 85% and 79%, respectively. Thus, the accuracy of these tests is no longer adequate to justify their use on clinical or economic grounds. However, new serological kits are available to detect antibodies to CagA or VacA by ELISA and Western blot, and can achieve rather good sensitivity and specificity^[9,10]. Because serological tests for *H pylori* vary

in different populations, largely due to the *H pylori* strain heterogeneity and variations in antigenic preparations, their accuracy must be confirmed in the target populations^[11,12]. Unfortunately, none of these new tests has a sensitivity and specificity above 80% and therefore they should be used with care for *H pylori* detection in Turkish dyspeptic patients in our region.

Serin *et al*^[13] compared the frequencies of serum positive CagA in patients from two separate regions of Turkey and found that the rate of CagA serum prevalence is high (97.2%) in patients with non-ulcer dyspepsia but similar in *H pylori*-positive patients. They also observed similar frequencies of CagA (+) *H pylori* strains in dyspeptic patients irrespective of ulcer status, suggesting that factors other than CagA can contribute to severe gastrointestinal pathology in patients with *H pylori*. We found that 50% of patients with *H pylori* infection had CagA positive serology which is below the percentage expected, suggesting that the test is not accurate.

A set of serological tests may give more accurate determinations of *H pylori* infection than one test detecting specific antibody or bacterial antigen. In this study it seemed that there was a good correlation with Western blot and ELISA test results compared to the gold standard methods. *H pylori* seropositivity was 82.1% by ELISA IgG antibodies and 80.4% by Western blot IgG antibodies. We suggest that ELISA, CagA ELISA and Western blot techniques should be used together where both the incidence of *H pylori* and the treatment failure rates are very high. We should emphasize more on anti-CagA status determination because anti-CagA positive patients are substantially associated with atrophic gastritis, persistent active inflammation and atrophic gastritis.

In conclusion, anti-*H pylori* IgA testing seems clinically useless and IgG testing is not clinically possible because the tests are based on antigens from European strains. Since Izmir is a cosmopolitan area under the influence of both Asian and Western countries, the common strains may differ significantly from those in Europe.

ACKNOWLEDGMENTS

The authors would like to thank EUROIMMUN Medizinische Labordiagnostika, Lübeck, Germany for providing some of the anti-*H pylori* test kits.

Abstract

AIM: To evaluate the effects of dexamethasone on liver damage in rats with bile duct ligation.

METHODS: A total of 40 male Sprague-Dawley rats, weighing 165-205 g, were used in this study. Group 1 (sham-control, $n = 10$) rats underwent laparotomy alone and the bile duct was just dissected from the surrounding tissue. Group 2 rats (untreated, $n = 10$) were subjected to bile duct ligation (BDL) and no drug was applied. Group 3 rats (low-dose dexamethasone, $n = 10$) received a daily dose of dexamethasone by orogastric tube for 14 d after BDL. Group 4 rats (high-dose dexamethasone, $n = 10$) received a daily dose of dexamethasone by orogastric tube for 14 d after BDL. At the end of the two-week period, biochemical and histological evaluations were processed.

RESULTS: The mean serum bilirubin and liver enzyme levels significantly decreased, and superoxide dismutase (SOD), catalase (CAT) and glutathione peroxidase (GSH-Px) values were significantly increased in low-dose dexamethasone and high-dose dexamethasone groups when compared to the untreated group. The histopathological score was significantly less in the low-dose and high-dose dexamethasone groups compared to the untreated rats. In the low-dose dexamethasone group, moderate liver damage was seen, while mild liver damage was observed in the high-dose dexamethasone group.

CONCLUSION: Corticosteroids reduced liver damage produced by bile duct obstruction. However, the histopathological score was not significantly lower in the high-dose corticosteroid group as compared to the low-dose group. Thus, low-dose corticosteroid provides a

INTRODUCTION

Obstruction of bile flow through the extrahepatic biliary system results in development of oxidant injury, hepatic fibrosis, biliary cirrhosis, and portal hypertension^[1,2]. Patients with obstructive jaundice are at significant risk for severe complications, particularly sepsis^[3,4]. Although preoperative percutaneous biliary drainage has been attempted to reduce perioperative complications, it failed to demonstrate a significant benefit despite successful reduction in serum bilirubin levels^[5]. Preventing or minimizing the deleterious effects of bile acids might represent a potential therapeutic target for patients with obstructive jaundice. However, effective pharmacological therapy in chronic liver diseases is not yet available.

Since the inflammatory process is important in the development of liver injury following biliary obstruction, the purpose of this study was, therefore, to evaluate the effects of dose-related dexamethasone (dexa) on liver damage caused by bile duct ligation in rats.

MATERIALS AND METHODS

Forty male Sprague-Dawley rats (Dicle University Research Center), weighing 165-205 g, were used in the study. All of the experimental protocols were performed according to the guidelines for the Ethical Treatment of Experimentation Animals. The animals were divided into 4 groups, each group containing 10 animals. Each rat was anesthetized with ketamine (50 mg/kg) and xylazine (4 mg/kg). The rats were subjected to either bile duct ligation (BDL) or sham operation using aseptic

techniques, as previously described by Criado *et al*^[6]. Group 1 rats (sham-control) underwent laparotomy alone and the bile duct was dissected from surrounding tissue. Group 2 rats (untreated) were subjected to bile duct ligation alone and received 1 mL of saline by orogastric tube. Group 3 rats (low-dose dexamethasone) received a daily dose of dexamethasone (0.125 mg/kg per day) by orogastric tube for 14 d after BDL. Group 4 rats (high-dose dexamethasone) received a daily dose of dexamethasone (0.400 mg/kg per day) by orogastric tube for 14 d after BDL. The rats were housed in standard cages in a room at 12 h:12 h light-dark condition, temperature (20°C) and humidity (60%), and maintained on a standard rat pellet diet. At the end of the two-week period, all animals were anesthetized with 100 mg/kg inactin ip, placed on a thermoregulated table, and a short segment of polyethylene (PE)-240 catheter was inserted into the trachea to assist the spontaneous respiration. After opening the abdomen through a midline incision, the abdominal aorta was punctured and 5 mL of blood was taken into heparinized tubes. Plasma was separated by centrifugation for biochemical studies, and the activities of alanine aminotransferase (ALT) (IU/L), aspartate aminotransferase (AST) (IU/L), alkaline phosphatase (ALP) (IU/L), γ -glutamyltranspeptidase (GGT) (IU/L) and the concentrations of total bilirubin (TB) (mg/dL) in plasma were determined by standard auto-analyzer methods on an Abbot Aeroset (USA). Just before the rats were sacrificed, the livers were extracted for histopathological evaluation. During this period of surgical preparation, the rats in all groups received 1% of their body weight of Ringer's lactate solution.

Histopathological examination

The extracted liver was divided into two pieces in each rat. One of the pieces was immediately placed into 100 g/L formaldehyde solution overnight, embedded in paraffin, and cut into 5-mm thick sections; stained either with hematoxylin-eosin (HE) or Masson's trichrome for light microscopic analysis. Histopathological scoring of groups for degree of fibrosis (ductular proliferation, focal ductular cholestasis, portal tract expansion, mixed inflammation, necrosis, and fibrosis) was scored as: 0 = absent; 1 = slight; 2 = moderate; and 3 = severe^[7]. Histopathological evaluation was performed twice in four sections per slide from all animals in each group. In addition, the number of infiltrating neutrophils per portal tract was assessed by counting neutrophils manually at a 400 \times magnification (Olympus Eyepiece Micrometer[®]) in 10 portal tracts per slide ($n = 10$ in each group).

The other piece was washed in ice-cold saline and homogenized in 0.1 mol/L Tris-HCl buffer (pH 7.4). The homogenate was then centrifuged and the supernatant obtained was used for the assay of various enzymes. Superoxide dismutase (SOD) was assayed as previously described by Misra and Fridovich^[8]. Based on the inhibition of epinephrine auto-oxidation by the enzyme, catalase (CAT) activity was measured by following decomposition of H₂O₂ according to the method described by Beers and Sizer^[9]. Glutathione peroxidase (GSH-Px) was assayed using H₂O₂ as the substrate as previously described^[10].

Table 1 Comparative biochemical measurements at the two week of the study (mean \pm SD)

Groups	Biochemical parameters				
	ALP (IU/L)	GGT (IU/L)	TB (mg/dL)	AST (IU/L)	ALT (IU/L)
Sham-control	177 \pm 20	1.9 \pm 0.3	0.3 \pm 0.2	117 \pm 3.3	55 \pm 10
Untreated	386 \pm 44 ^a	49 \pm 10 ^a	11 \pm 1.3 ^a	1378 \pm 256 ^a	258 \pm 62 ^a
Low-dose dexamethasone	297 \pm 78 ^c	20 \pm 2.3 ^c	8 \pm 0.8 ^c	1037 \pm 215 ^c	198 \pm 39 ^c
High-dose dexamethasone	300 \pm 60 ^e	19 \pm 2 ^e	8 \pm 1.1 ^e	963 \pm 139 ^e	150 \pm 43 ^e

ALP: Alkaline phosphatase; GGT: γ -glutamyltranspeptidase; TB: Total bilirubin; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase. ^a $P < 0.05$ vs sham-control; ^c $P < 0.05$ vs untreated; ^e $P < 0.05$ vs untreated.

Table 2 Comparative SOD, CAT and GSH-Px measurements at the two week of the study (mean \pm SD)

Groups	SOD (IU/L)	CAT (IU/L)	GSH-Px (mg/dL)
Sham-control	16 \pm 2.5	5.1 \pm 0.9	430 \pm 31
Untreated	6.9 \pm 0.9 ^a	0.8 \pm 0.1 ^a	142 \pm 13 ^a
Low-dose dexamethasone	10.6 \pm 1.2 ^c	2.7 \pm 0.6 ^c	254 \pm 15 ^c
High-dose dexamethasone	10.7 \pm 0.9 ^e	2.6 \pm 0.6 ^e	255 \pm 19 ^e

SOD: Superoxide dismutase; CAT: Catalase; GSH-Px: Glutathione peroxidase. ^a $P < 0.05$ vs sham-control; ^c $P < 0.05$ vs untreated; ^e $P < 0.05$ vs untreated.

Statistical analysis

Data were entered and analyzed on an IBM compatible personal computer using SPSS version 9.0. All values were expressed as mean \pm SD. The significance of the data obtained was evaluated by using analysis of variance (ANOVA). Differences between means were analyzed by using the post-ANOVA (Tukey's b) test. $P < 0.05$ was considered statistically significant.

RESULTS

The mean weights of the animals from the four groups before and after BDL were, respectively, as follows: 192 \pm 15 g vs 196 \pm 9 g, 204 \pm 12 g vs 166 \pm 3 g, 203 \pm 12 g vs 167 \pm 9 g, and 190 \pm 9 g vs 119 \pm 11 g. These data showed that the mean weights of the three study groups decreased significantly compared to the control group after BDL ($P < 0.0001$ for all). In addition, the mean weight of group 4 rats decreased significantly compared to groups 2 and 3 ($P < 0.0001$ for all).

The values of biochemical measurements for the different groups are shown in Table 1. Serum levels of ALP, GGT, TB, AST and ALT were significantly increased in the untreated, low-dose dexamethasone and high-dose dexamethasone groups in comparison with the sham-control group (all $P < 0.05$). ALP, GGT, total bilirubin, AST and ALT values were decreased in the low-dose dexamethasone group and high-dose dexamethasone group when compared to the untreated group (all $P < 0.05$). However, no significant difference was found between the low-dose dexamethasone and high-dose dexamethasone groups.

The values of SOD, CAT and GSH-Px measurements for the different groups are shown in Table 2. Mean values were significantly decreased in the untreated, low-dose

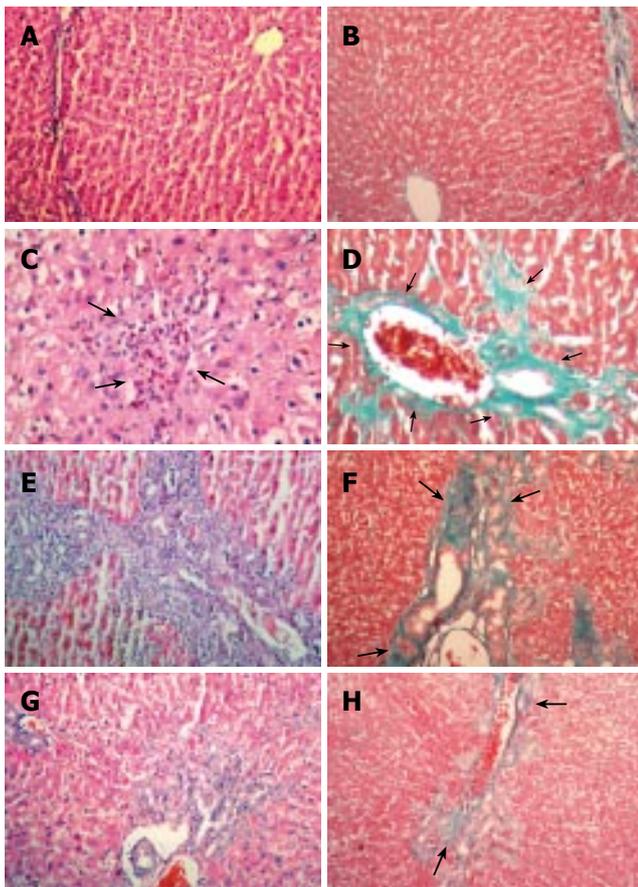

Figure 1 Morphological changes in the livers of different group rats (HE $\times 200$; Masson's trichrome $\times 200$). No morphological damage was observed in any of the rats in the sham-control group (A and B). In the untreated group, proliferation of portal and periportal biliary ductules with disorganization of the hepatocytes plates, dilated portal spaces and areas of polymorphonuclear leukocyte infiltrate, hepatocytes necrosis and fibrosis were observed (C and D). Moderate hepatocytes necrosis and fibrosis were present in the low-dose dexamethasone group (E and F). The high-dose dexamethasone group showed a remarkably less necrosis and fibrosis (G and H). A, C, E and G are stained with HE; B, D, F and H are stained with Masson's trichrome.

dexamethasone and high-dose dexamethasone groups in comparison with the sham-control group (all $P < 0.05$). However, these values were significantly increased in low-dose and high-dose dexamethasone groups when compared to the untreated group (all $P < 0.05$).

The mean count of polymorphonuclear leukocytes (PNL) in the control group was less than one in portal spaces of hepatic parenchyma, whereas it was 15 ± 3 , 4.6 ± 0.9 and 3.4 ± 0.8 in the untreated, low-dose dexamethasone and high-dose dexamethasone groups, respectively. The number of PNL was significantly decreased in low-dose and high-dose dexamethasone groups when compared to the untreated group ($P < 0.0001$). However, no significant difference was found between the high-dose dexamethasone and sham-control group.

No morphological damage was observed in any of the rats in the sham-control group (Figure 1A, 1B). In the untreated group, severe damage (dilated central veins, proliferation of portal and periportal biliary ductules with disorganization of the hepatocyte plates, dilated portal spaces and hepatocyte necrosis) was observed (Figure 1C, 1D). In the low-dose and high-dose dexamethasone groups, moderate damage (dilated central veins and minimal disorganization of the hepatocyte plates, and hepatocyte necrosis) was

observed (Figure 1F). Mild damage (less necrosis and less fibrosis) was observed in the high-dose dexamethasone group (Figure 1G, 1H).

The histopathological scores found in the sham-control, untreated, low-dose dexamethasone and high-dose dexamethasone groups were 0.1 ± 0.3 , 2.6 ± 0.5 , 1.9 ± 0.7 and 1.8 ± 0.6 , respectively. The histopathological score tended to be more in the untreated, low-dose dexamethasone and high-dose dexamethasone groups as compared with the sham-control groups (all $P < 0.0001$). However, the histopathological score was significantly less in the low-dose and high-dose dexamethasone groups compared to the untreated rats ($P < 0.05$, $P < 0.02$, respectively). Moreover, no significant difference was observed in the histopathological score between the low-dose dexamethasone and high-dose dexamethasone groups.

DISCUSSION

Bile duct ligation (BDL) in rats induces portal fibrosis, which begins with an early proliferation of biliary duct epithelial cells and portal periductular fibroblasts^[11]. In the early phases, there is neither substantial hepatocyte necrosis, nor fibrotic reaction in the centrilobular region^[12]. Later, fibrosis distributes more widely and alters intrahepatic vascular resistances and blood flow, leading to the establishment of portal hypertension^[13]. In this experimental study, the rats subjected to BDL for two weeks showed changes in plasma levels of bilirubin, AST, GGT and ALP, thereby indicating the presence of cholestasis and diffuse hepatic injury. These observations are in agreement with those of several authors^[14,15]. After BDL, we observed a significant decrease in the mean weights of rats, including group 4. It has been demonstrated in previous studies that the administration of dexamethasone was ineffective in increasing the liver weight in advanced liver fibrosis in rats or in improving body weight or body weight gain^[16]. In fact, the body weight (or body weight gain) was further decreased by dexamethasone treatment in rats with liver fibrosis^[17], which is in agreement with our study.

BDL affects the balance between antioxidant and prooxidant activities and increases the prooxidant activity. It increases production of free radicals^[18] and decreases free radical scavengers (GSH-Px, SOD and CAT). High level of free radicals induces lypoperoxidation^[19] and alteration of fluidity and functionality of cell membranes^[20]. It has been suggested that the increase of intrahepatocyte concentration of biliary acids induces mitochondrial toxicity in chronic cholestasis^[24]. Furthermore, increased lipid peroxidation in the BDL model has been described^[21]. A significant correlation between TB levels and lipid peroxidation has also been described in hepatic toxicity or biliary tract diseases^[22]. In addition, nitric oxide (NO) has been shown to be related to the development of hepatic fibrosis. The hepatocytes are mainly responsible for the production of NO radicals^[23]. Dexamethasone can either inhibit the release of inflammatory mediators and consequently the formation of NO radicals or block the up-regulation of inducible NO synthetase^[24]. Also, previous studies have indicated a dual role for dexamethasone; besides blocking

the release of pro-inflammatory cytokines, it also reduces the release of anti-fibrotic mediators by Kupffer cells and sinusoidal endothelial cells in the liver^[25,26]. In our study, dexamethasone protected the levels of such antioxidant enzymes as SOD, CAT and GSH-Px in both doses.

The main liver injury following biliary obstruction is periductal inflammation, bile duct proliferation and portal fibrosis. Prominent among the inflammatory cells that invade obstructed livers are neutrophils; it has been evidenced by several experimental studies that neutrophils infiltrate the liver within 3 h of BDL^[27], and remain there for days to weeks as fibrosis progresses^[27-29]. In addition, dexamethasone was found to prevent infiltration of inflammatory cells, PMNs and monocytes *in vivo*^[16,30]. A connection between neutrophils and liver fibrosis was first suggested by Parola *et al*^[27]. They quantitated hepatic neutrophils in an experimental model of bile duct obstruction and found that the number of infiltrating cells correlated directly with the degree of liver fibrosis. In the present study, we found that the number of PNL decreased in the low-dose and high-dose dexamethasone groups, which is in accordance with previous studies.

Glucocorticoids are used as anti-inflammatory and immunomodulatory agents in a wide variety of diseases^[31]. Their physiological effects may be accomplished largely by modulating the expression of many cytokine genes, such as IL-1^[32], IL-2^[33], TNF- α ^[34], interferon- β ^[35], interferon- γ ^[33], and monocyte chemotactic and activating factor^[36]. Dexamethasone is also a phospholipase A2 inhibitor and has been shown to inhibit endothelin-1-stimulated arachidonic acid production^[37]. Dexamethasone also blocks conversion of arachidonic acid by cyclooxygenase into prostaglandins and suppresses the production of various inflammatory mediators^[38]. Although dexamethasone enhances hepatocyte viability and improves the expression of liver-specific genes in liver diseases, there is controversy over the beneficial effects of dexamethasone for liver fibrosis treatment. Dexamethasone has been used as an anti-inflammatory drug in the treatment of chronic active hepatitis for the prevention of liver fibrosis^[39]. Glucocorticoids suppress collagen synthesis and gene expression by fibroblasts. Nevertheless, glucocorticoids do not have an inhibitory effect on extracellular matrix synthesis by hepatic stellate cells^[16]. In our study, dexamethasone, particularly in high dose, decreased proliferation and infiltration of inflammatory cells in portal and periportal biliary ducts. The results of previous studies provide evidence that dexamethasone fails to therapeutically improve liver function during fibrosis. Thus, the beneficial effect of dexamethasone in ascites formation may be attributed to its anti-inflammatory effect and to a decrease in the production of vasoactive substances from inflammatory cells, but not to improve liver functions and decrease fiber accumulation^[16,40]. In our study, however, ALP, GGT, total bilirubin, AST and ALT values were decreased in the low-dose dexamethasone and high-dose dexamethasone groups compared to the untreated group. Although dexamethasone is widely used in the management of inflammatory diseases, it may cause such serious side-effects as immunosuppression and growth retardation, especially when used at high doses. In the present study,

parallel to the literature, dexamethasone caused growth retardation when used at high doses.

In conclusion, using corticosteroids reduced liver damage produced by bile duct obstruction. The finding that no significantly lower histopathological score in the high-dose dexamethasone group compared to the low-dose group suggests that high-dose dexamethasone does not provide any additional protective effect on liver damage. Moreover, high-dose dexamethasone causes obvious growth retardation. Thus, low-dose corticosteroid provides a significant reduction in liver damage without increased side effects, while high dose is associated not with lower fibrosis but with increased side effects.

in this population (mean age 9.97 ± 3.1 years). The factors associated with *H pylori* positivity were number of siblings ($P < 0.001$), presence of pet cats ($P = 0.03$) and birds ($P = 0.04$) in the household, and antecedents of gastritis among family members ($P = 0.01$). After multivariate analysis, number of siblings [Odds ratio (OR) = 1.39; 95% CI, 1.20-1.61] and contact with pet cats (OR = 1.76; 95% CI, 1.00-3.09) remained as variables associated with *H pylori* infection.

CONCLUSION: The prevalence of *H pylori* infection in children with upper gastrointestinal symptoms in Argentina was similar to that reported in developed countries. Children from families with a higher crowding index and presence of pet cats have a higher risk of being colonized with *H pylori*.

Abstract

AIM: To determine prevalence of *H pylori* infection in symptomatic children in Buenos Aires, Argentina, and to investigate factors associated with *H pylori* positivity.

METHODS: A total of 395 children with upper gastrointestinal symptoms referred to the Gastroenterology Unit of the Children Hospital "Sor Maria Ludovica" were evaluated for the presence of *H pylori* by the ^{13}C -Urea Breath Test (^{13}C -UBT). A questionnaire was applied to the recruited population.

RESULTS: Prevalence of *H pylori* infection was 40.0%

INTRODUCTION

H pylori bacterium is now recognized as a major etiologic factor in the development of chronic superficial gastritis and peptic ulcer disease in adults and children^[1]. Because its association with gastric cancer *H pylori* was classified in 1994 as a group 1 carcinogen by the International Agency for Research on Cancer^[2]. *H pylori* acquisition occurs predominantly during early childhood, and its incidence and prevalence is higher in developing than in developed countries^[3-5]. Several risk factors have been associated with acquisition and transmission of *H pylori* infection, those factors are mainly correlated with poor sanitary conditions and low socioeconomic status^[5-7].

Controversial results have been found in establishing the role of *H pylori* as the etiology for the presence of specific symptoms in children such as recurrent abdominal pain (RAP)^[8,9]. Specific symptoms suggestive of acute *H pylori* infection are vague, inconsistent, and similar to several other more common childhood disorders, manifesting as recurrent abdominal pain, dyspepsia or epigastric pain^[10].

The aims of our study were to determine prevalence of *H pylori* infection in symptomatic children in Buenos Aires, Argentina, and to investigate risk factors associated with *H pylori* positivity.

MATERIALS AND METHODS

Subjects

The study was performed in 395 children with age ranging from 2 to 17 years (mean age 9.97 ± 3.1 years), who were referred to the Gastroenterology Unit of the Children Hospital "Superiora Sor Maria Ludovica" for upper gastrointestinal symptoms evaluation (gastroesophageal reflux, esophagitis symptoms, ulcerous syndrome, abdominal pain, and upper digestive haemorrhage). The Hospital is a tertiary level health care referral institution with the highest clinical complexity for attending children in the Province of Buenos Aires. The Gastroenterology Unit receives a monthly average of 600 patients who are referred from other services within the same hospital and from primary health care units located in the Province of Buenos Aires. Parents or grandparents identified as the responsible adults of the children, were instructed to carefully read the protocol information and to sign a written consent form according to the Helsinki declaration. Children with a signed consent were included in the study. Participation consisted in the diagnosis of *H pylori* infection by means of the ¹³C-Urea Breath Test (¹³C-UBT) and the completion of a questionnaire for epidemiological purposes.

¹³C-urea breath test (¹³C-UBT)

Children were instructed to fast for at least 6 h before the diagnostic test was performed. ¹³C-UBT consisted of the following: two samples of exhaled air were taken previous to the ingestion of the labeled solution to determine basal ¹³C/¹²C ratios. Then, 150 mL of reconstituted powdered non-fatty milk containing 50 mg of ¹³C-urea (Cambridge Isotope Laboratories Inc., Massachusetts, USA) were taken by each patient. Breath samples were collected at 30 and 45 min after the ingestion of the labeled solution in hermetically sealed containers (Labco limited, United Kingdom). Each sample of exhaled air was measured in a mass spectrometer coupled to a gas chromatographer (FinniganMAT GmbH, ThermoQuest Corp., Bremen, Germany). A change of > 3.5% in the delta over baseline (DOB) values was considered positive. The ¹³C-UBT is a highly accurate diagnostic test, with values of sensitivity and specificity over 95%^[11].

Epidemiological questionnaire

Parents or grandparents of the participant children were

instructed to complete a questionnaire for epidemiological purposes. The questionnaire was focused on variables that might affect the risk for *H pylori* positivity. The evaluated variables were demographic data, family crowding (number of siblings, rooms in the house), socioeconomic status and sanitary standards [type of house (masonry, wooden, rustic), type of flooring (wooden, cement, soil), type of toilet (sewer, septic tank, pit latrine), source of water (well-shaft treated, well-shaft not treated, treated system)], presence of pets in the house, food intake [raw food (uncooked meat, chicken or fish) *vs* cooked food], drinking of beverages shared from the same container (with a special focus on the consumption of "mate", a traditional argentine green herbs infusion), habit of chewing the nails, and history of digestive diseases among family members (gastritis, gastric and duodenal ulcers, or gastric cancer).

Statistical analysis

The Fisher Exact test was used to analyze dependency between *H pylori* positivity and other categorical variables. The Chi squared test was applied to variables with more than two categories. To analyze if variances of quantitative variables were homogeneous for both *H pylori* positive and negative groups, the Levene test was applied. Student's *t* test was used when it was proven that variances were homogeneous, if not, the non-parametric Mann-Whitney test was applied. A binary logistic regression equation was used to estimate the impact of different characteristics as predictive variables for *H pylori* status, by the Forward Stepwise (Likelihood Ratio) method. The results of logistic regression included odds ratios (OR) as well as 95% confidence intervals (CI) for each of the variables. Significance levels were set at alpha less than 0.05. The SPSS 10.0 statistical program (SPSS, Chicago, IL) was used to perform all the statistical analyses presented in this article.

RESULTS

All the 395 participating children were tested for *H pylori* infection by means of the ¹³C-UBT. A total of 158 patients were found to be *H pylori* positive. Prevalence of *H pylori* infection in this symptomatic population was 40.0% (95% CI, 35.2-44.8). Among the 395 enrolled children, 332 (84.1%) completed the epidemiological questionnaire. *H pylori* prevalence was similar between the studied population and those excluded from the analysis because of the lack of the questionnaire. Prevalence of *H pylori* infection among different age groups was as follows: 2-5 years (*n* = 29), 34.5%; 6-7 years (*n* = 47), 48.9%; 8-9 years (*n* = 59), 37.3%; 10-11 years (*n* = 75), 45.3%; 12-13 years (*n* = 73), 37.0%; 14-17 years (*n* = 44), 47.7%. Table 1 summarizes the demographics of the population included in the study. No significant differences were found among age (*P* > 0.70), gender (*P* > 0.60), ethnic group (*P* > 0.15), educational level (*P* > 0.50) and place of residence (inner city *vs* suburban areas) (*P* > 0.40), between *H pylori* positive and negative patients.

The most relevant factors evaluated to influence the prevalence of *H pylori* infection are shown in Table 2. As

Table 1 Demographical data of the children included in the study

	<i>H pylori</i> (+) n (%)	<i>H pylori</i> (-) n (%)	<i>P</i>
<i>n</i>	140	192	
Age (yr) (mean ± SD)	9.89 ± 3.16	10.02 ± 2.96	0.708

an indicator of domestic crowding, “number of siblings” was significantly associated with *H pylori* positivity ($P < 0.001$). None of the variables depicting socioeconomic status and sanitary standards were correlated to the infection. On the other hand, we found a significant correlation between having contact with cats and birds, and being positive for the infection ($P = 0.02$ and $P = 0.04$ respectively). Neither the ingestion of raw or cooked food nor drinking of “mate” or other shared drinks were significantly linked to *H pylori*. The habit of chewing nails was also not correlated to the infection. We found a significant correlation between history of gastritis in family members and a positive *H pylori* result in the studied child (index case) ($P = 0.01$).

To estimate the impact of different characteristics as predictive variables for *H pylori* status, the binary logistic regression equation was used by the Forward Stepwise (Likelihood Ratio) method. Under this analysis, predictive variables for *H pylori* positivity were “contact with pet cats” (OR = 1.76; 95% CI, 1.00-3.09) and “number of siblings” (OR = 1.39; 95% CI, 1.20-1.61).

DISCUSSION

Prevalence of *H pylori* infection has been reported to be higher both in children and adults from developing countries than from developed ones^[10,12,13]. In Argentina, *H pylori* prevalence has been evaluated in the asymptomatic population in two different studies that included both adults and children^[14,15]. Mean age of the children in those previous studies was 7.9 ± 4.6 years^[14] and 7.8 ± 5.5 years^[15]. The prevalence of *H pylori* in asymptomatic children was 15.7% in both studies. In the present study we evaluated slightly older children with gastrointestinal symptoms (mean age 9.97 ± 3.1 years), and we found a

40.0% prevalence of *H pylori* infection. The differences in prevalence rates found in asymptomatic and symptomatic children from our country, are consistent with one multicenter study representing various parts of the United States of America, in which the seropositivity rate was significantly higher in symptomatic (22.3%) than in asymptomatic children (14.1%)^[6]. In a study from the Czech Republic^[16], it was also reported a higher prevalence of *H pylori* infection in symptomatic children (33%) when compared with asymptomatic controls (7.5%). These findings suggest that the presence of gastrointestinal complaints may be associated with *H pylori*. Moreover, the lack of association between age and *H pylori* prevalence observed in this study could also be explained by the inclusion of symptomatic children only. Nevertheless, a causal relationship between *H pylori* infection and recurrent abdominal pain in children is still not proven^[8]. Although Argentina is considered a developing country, results obtained in the present study (40% *H pylori* prevalence in symptomatic children) versus 15% in asymptomatic children reported previously^[14,15] are interestingly similar to the ones obtained in developed countries such as the US.

According to the National Institute of Statistics and

Census of Argentina, INDEC, there is a 44.4 % poverty rate among the population living in Great Buenos Aires metropolitan area. A possible explanation that our studied population of children had good socioeconomic status and high sanitary standards is that more than 95% of the studied children were from inner city and they might mainly represent middle class. This phenomenon may be explained by the following reasons: (1) recurrent abdominal pain is not usually a reason for seeking medical attention among people with low socioeconomic status. (2) patients with a lower socioeconomic status who are referred to the Gastroenterology unit, who are rarely assisted due to monetary limitations, and (3) people belonging to the middle class who used to pay for private medical care attention, have turned to public health care centers due to the fact that economic conditions have become impaired in Argentina during the last years.

The factors associated with *H pylori* positivity were the number of siblings, presence of cats and birds in the house, and antecedents of gastritis among family members (Table 2). After binary logistic regression analysis, only the number of siblings and contact with pet cats remained factors for increasing risk of *H pylori* infection.

The observation that the presence of cats in the house may increase the probability of being positive for *H pylori* infection in children with gastrointestinal symptoms require further investigation, especially because controversial results have been reported for the role of cats and other domestic pets in association with *H pylori*^{16,15-18}. Cats are commonly infected with gastric *Helicobacter*-like organisms (GHLOs) as “*H. heilmanni*”, that might be transmitted to humans¹⁹⁻²¹. Therefore, a positive Urea Breath Test result in a patient could represent a gastric presence of urease positive *Helicobacter* species other than *H pylori*. However, as prevalence of “*H. heilmanni*”-like organisms in humans is relatively low, this topic requires further clarification.

Low socioeconomic status and poor sanitary standards were described as risk factors for the acquisition and transmission of *H pylori*⁴⁵⁻⁷. Given that most of the studied population had good socioeconomic conditions, we could not demonstrate an association between *H pylori* status, socioeconomic conditions and sanitary standards. It is important to point out that the correlation coefficients depends strongly on sample sizes and balance between them²². Another factor associated with *H pylori* infection in the studied population was the history of gastritis among family members. In contrast, other authors have not found a correlation between family history of gastric disease and *H pylori* infection in the children^{16,17}. Major limitations in the association of clinical history with *H pylori* status are, first, the definition used to establish gastric diseases and second, the technique employed to diagnose *H pylori* infection.

In conclusion, we found that prevalence of *H pylori* infection in children with upper gastrointestinal symptoms referred to a Gastroenterology service in the Province of Buenos Aires, Argentina was 40%, similar to the prevalence reported in developed countries. In addition, number of siblings in the household and presence of pet cats are predicting variables for *H pylori* colonization. Our study

provides important information regarding the prevalence of *H pylori* infection in symptomatic children in Buenos Aires, Argentina, and factors associated with increasing risk for *H pylori* positivity in a developing country.

Abstract

AIM: To observe the curative effect of Weiansan (WAS) on gastric precancerous lesions (GPL) and *H pylori* elimination.

METHODS: Seventy-six patients with GPL were randomly divided into two groups: WAS group ($n = 42$) and Weifuchun (WFC) group ($n = 34$). The patients in the WAS group were administered 5 g WAS 3 times a day, and the patients in the WFC group took WFC (4 tablets) 3 times a day. To monitor inflammation of gastric mucosa, degree of glandular atrophy (GA), intestinal metaplasia (IM) and dysplasia, and *H pylori* infection, all patients underwent gastroscopy and biopsy with pathological examination before and after treatment. Fifty male Sprague-Dawley (SD) rats were used in animal experiments. Of these, 10 served as the control group ($n = 10$), 40 were given ranitidine combined with *N*-methyl-*N*¹-nitro-*N*-nitrosoguanidine (MNNG) for 12 wk and divided into 4 groups randomly: model group ($n = 10$), high-dose WAS group ($n = 10$), low-dose WAS group ($n = 10$) and WFC group ($n = 10$). Twelve weeks later, all rats were killed and a 2 cm × 1 cm tissue was taken from the lesser curvature of the gastric antrum. *H pylori* infection was determined by the fast urease method.

RESULTS: The curative effect in WAS groups was similar to that in WFC groups. There was no statistical difference in degree of GA, IM and dysplasia between WAS and WFC groups. The rate of *H pylori* infection in the model group (positive/negative: 9/1) was significantly higher than that in the control group (positive/negative: 1/9) ($P < 0.01$). *H pylori* elimination in the high-dose WAS group (positive/negative: 4/6) and low-dose WAS group (positive/negative: 6/4) was similar to that in the WFC group (positive/negative: 4/6) ($P > 0.05$).

INTRODUCTION

Gastric precancerous lesion (GPL) is one of the diseases of the digestive system, easily occurring in gastric mucosa with changes such as gastric epithelial dysplasia (GED) and intestinal metaplasia (IM) resulting in chronic atrophic gastritis (CAG)^[1]. Traditional Chinese medicine (TCM) can prevent and cure GPL, and has become one of the hotspots in research^[2]. In order to find its accurate and effective therapy, GPL was treated with Weiansan (WAS) and its effect on eliminating *H pylori* was evaluated.

MATERIALS AND METHODS

Patients

Seventy-eight patients were diagnosed as insufficiency of the spleen- and stomach-qi or stagnation of qi and stasis of blood. CAG was confirmed by gastroscopy. The patients were randomly divided into two groups: WAS group ($n = 42$) and Weifuchun (WFC) group ($n = 34$).

The WAS group included 32 males and 10 females aged 24-69 years with a mean age of 40 ± 2.1 years. Of the 42 patients in this group, 20 had mild CAG and 22 had moderate to severe CAG.

The WFC group included 24 males and 10 females aged 25-68 years with a mean age of 41 ± 2.3 years. Of the 34 patients in this group, 14 had mild CAG and 20 had moderate to severe CAG. There was no significant difference between the two groups.

Experimental animals

Fifty 15-d old male Sprague-Dawley rats weighing

Table 1 Changes of GA in WAS and WFC groups after treatment

Group	Cases (n)	Atrophy improvement			No change	Severe
		0	+	++<-

WFC	34	2	16	8	8	0

0: Have changes but not achieve a state (less than a +); +: Effective; ++<-: Obviously effective.

100-150 g were bought from Experimental Animal Centre, Chinese Academy of Medical Sciences. The feed was purchased from Keao Xieli Feed Limited Company.

The evaluation standard of clinical curative effects was drawn up according to the 2nd version of "Clinical Research Guiding Principle of New Medicine of TCM" and other corresponding reports^[3].

Disappearance of clinical symptoms and active inflammation, improvement of chronic inflammation, reduction of GA, IM and gastric epithelial dysplasia (GED) were judged as curative. Disappearance of main clinical symptoms, improvement of acute and chronic inflammation, two-degree reduction of GA, IM and GED were judged as obviously effective. Improvement of clinical symptoms, one-degree reduction of GA, IM and GED were judged as effective. No improvement of clinical symptoms and pathological change was judged as ineffective.

Clinical research method

To observe the mucous membrane inflammation, degree of GA, IM and GED, all the patients underwent gastroscopy and pathological examination before and after 24 wk of treatment. The rate of *H pylori* infection was also determined. The patients in WAS group received 5 g WAS 3 times a day, while the patients in WFC group were given 4 tablets of WFC 3 times a day for 12 wk as a course of treatment. The two groups received two courses of the treatment.

Experimental method

One week after increasing compatibility, the rats drank MNNG (50 µg/L) and were fed standard powder feed containing 0.03% ranitidine for 12 wk as previously described^[4]. Ten rats in the control group were fed normally. After administration of MNNG for 12 wk, the other 40 rats were divided into 4 groups, 10 rats in each group. The rats in the model group were given physiological saline *via* gavages (1 mL/100 g) once a day; the rats in the high-dose WAS group were physiological saline *via* gavages (5 g*20/65 g body weight); the rats in the low-dose WAS group and WFC group were fed by gavages individually (1 mL/100 g) once a day. After administration of WAS and WFC for 12 wk, all the rats in the 5 groups were killed and their stomachs removed. The gastric cavity was cut open along the greater curvature, cleaned and fixed in buffered formalin solution. A 2 cm × 1 cm tissue was removed from the lesser curvature of the gastric antrum. *H pylori* situation was determined by the

Table 2 Changes of GED and IM in WAS and WFC groups after treatment

Group	Cases (n)	GED and IM improvement			No change	Severe
		0	+	++<-		
WAS	20	2	8	2	4	2
WFC	16	0	4	6	4	2

0: Have changes but not achieve a state (less than a +); +: Effective; ++<-: Obviously effective.

fast urease method. The *H pylori*-eliminating effect in the 5 groups was compared.

Statistical analysis

The pairs-*t* test was applied to the data before and after the treatment, the ratio was examined with chi-square test, and the rank material was examined with Ridit. All analyses were performed with SPSS 10.0. $P < 0.05$ was considered statistically significant.

RESULTS

Effect of WAS and WFC on glandular atrophy

The degree of GA, IM and GED was classified into mild, moderate and severe grades according to gastroscopy findings. The patients received gastroscopy and pathological examination respectively before and after 24 wk of treatment. Improvement of clinical symptoms was analyzed. According to the evaluation standard, clinical curative effects were judged as curative, obviously effective, effective and ineffective, respectively.

The results suggested that the above-mentioned indexes had no significant difference between the WAS and WFC groups before and after treatment ($P > 0.05$). After treatment, such indexes were improved both in the WAS group and in the WFC group ($P < 0.05$), suggesting that both WAS and WFC could improve GA, IM and dysplasia. The total effective rate for alleviating the GA degree was 71.43% in the WAS group and 76.47% in the WFC group, respectively (total effective rate for alleviating the GA degree = the alleviated GA degree/total cases × 100%)

The total effective rate for alleviating the GED and IM degree was 60.00% in the WAS group and 62.50% in the WFC group, respectively (total effective rate of alleviating the GED and IM degree = the alleviated GED and IM degree/total cases × 100%). The histological changes in GED and IM were not obvious in both groups after treatment. It might be due to a too short period of treatment, concentration of medicine, and combined herbal medicine treatment.

Elimination of *H pylori* in patients after treatment with WAS and WFC

Before treatment, *H pylori*-infected patients were examined in both groups. After treatment, the eradication rate of *H pylori* in the WAS group was higher than that in the WFC group ($P < 0.05$), indicating that the *H pylori*-eliminating effect in WAS group was better than that in the WFC group (Table 1, Table 2, Table 3, Table 4).

Table 3 Curative effect in WAS and WFC groups

Group	Cases (n)	cure	Obviously effective	Effective	Ineffective	Effective rate (%)
WAS	42	4	20	12	6	85.71
WFC	34	4	12	12	6	82.35

Table 4 *H pylori* elimination in WAS and WFC groups

Group	Cases (n)	Positive	Negative	Negative rate (%)
WAS	42	6	36	85.74 ^a
WFC	34	13	21	61.71

^a*P* < 0.05 vs WFC group.

H pylori situation in animal experiment and eliminating effects of WAS and WFC

Compared with the control group (positive/negative: 1/9), the *H pylori* situation in the model group (positive/negative: 9/1) was noticeably better (*P* < 0.01). The *H pylori*-eliminating effect in the high-dose WAS group (positive/negative: 4/6) and low-dose WAS group (positive/negative: 6/4) was similar to that in the WFC group (positive/negative: 4/6) (*P* > 0.05). The eradication rate of *H pylori* in the three groups was obviously higher than that in the model group (*P* < 0.05, Tables 5 and 6).

DISCUSSION

GPL belongs to the “stomach distension” and “epigastralgia” category in traditional Chinese medicine. It results from spleen and stomach injury, blood stasis due to impeding circulation of qi and blood caused by improper diet, the 6 abnormal climatic factors and the 7 abnormal emotions. The keys are spleen deficiency, qi stagnation and blood stasis. The main local symptoms are distension and fullness of the stomach, belches and poor appetite, constipation or diarrhoea. The general symptoms are lassitude and weakness, dizziness and emaciation, sallow complexion, pale and dark tongue. The basic factor and pathogenesis are deficiency in origin and excess in superficiality, and complicated syndromes of deficiency and excess. Therefore it should be treated both causally and symptomatically. The corresponding principle of WAS is to strengthen the spleen, replenish and regulate qi, invigorate blood. Our clinical study demonstrated that the total effective rate for GPL was about 85.70%, indicating that WAS plays a certain role in blocking GPL. WAS is composed of astragalus root, pilose asiabell root, bighead atractylodes rhizome, cinnamon bark, red sage root, scorpion, rhizome corydalis, fructus anrantii, processed grain and wheat, *etc.*

In the decoction, astragalus root, pilose asiabell root, bighead atractylodes rhizome, and cinnamon bark increase the gastric mucosa barrier, enhance the immunity, strengthen the phagocytic function of the reticuloendothelial system, elevate the lymphocyte transformation rate and promote anti-body formation.

Table 5 *H pylori* situation in GPL of model and control groups after 12 wk of treatment

Group	Cases (n)	Positive	Negative	Infective rate (%)
Model group	10	9	1	90 ^a
Control group	5	0	5	0

^a*P* < 0.01 vs control group.

Table 6 *H pylori* eliminating situation after 12 wk of treatment

Group	Cases (n)	Positive	Negative	Eliminating rate (%)
High-dose WAS group	10	4	6	60
Low-dose WAS group	10	6	4	40
WFC group	10	4	6	60
Model group	10	9	1	10

Red sage root, scorpion, and rhizome corydalis containing a broad spectrum of anti-neoplastic components, may invigorate the blood to remove blood stasis, relieve spasm and pain, inhibit tumour occurrence, improve the gastric mucosa blood circulation, accelerate topical inflammation absorption, help atrophic glands to restore and remove the deleterious substance in epithelial cells. Fructus anrantii, processed grain and wheat can relieve depression of liver-qi, activate qi and promote digestion^[5]. These herbal medicines cooperate in harmony and exert a major effect on GPL.

A total of 7496 cases related to CAG have been reported, and the insufficiency type of the spleen and stomach ranks first^[6], indicating that insufficiency of the spleen correlates positively with the severity of gastric diseases. The *H pylori* infection rate and the degree of infection in patients with qi-stagnation and middle-warmer deficiency are remarkably different from those in patients with other types of CAG, suggesting that the *H pylori* infection rate is closely related to insufficiency of the spleen which has become the most important factor for stomach cancer development. Therefore insufficiency of the spleen and qi stagnation should be closely monitored because of their high carcinogenic tendency. Our study has confirmed that strengthening the spleen can improve GPL, reduce gastric mucosa inflammation, help atrophic glands to regenerate and restore, reverse and restore gastric mucosa dysplasia and IM, promote differentiation and maturation of atypical cells to normal cells. Drugs strengthening the spleen increase the gastric mucosa barrier effect and protect carcinogens from attacking by enhancing immunity, strengthening the phagocytic function of the reticuloendothelial system and promoting the lymphocyte transformation rate. All these indicate that the method of strengthening the spleen can prevent GPL, and this method has become one of the therapies for preventing and treating gastric mucosa precancerous lesions^[7,8].

In addition, studies also indicate^[9-11] that microcirculation dysfunction is generally followed by CAG. The

common clinical symptoms include fixed stomach pain and purple dark or dark red or pale dark or ecchymosed tongue. In our study, gastroscopy demonstrated that the degree of GA, IM and GED in blood stasis type of GPL was more severe than that in other types, suggesting that the mechanism underlying blood stasis exists in GPL. Gastric mucosa dysplasia and IM highly correlate with microcirculation. Blood-invigorating herbal medicines can remove blood stasis and protect gastric mucosa by improving GPL, gastric mucosa microcirculation, establishing collateral circulation, improving local ischemia and hypoxia, increasing gastric mucosa blood flow, reducing inflammation and helping atrophic glands to regenerate. Therefore invigorating the blood to remove blood stasis has also become the key to preventing and treating gastric mucosa precancerous lesions.

In conclusion, according to the pathogenesis of insufficiency of the spleen and blood stasis, the therapy for GPL can be established. Treatment of PGL with WAS is to strengthen the spleen, replenish and invigorate qi and blood. Furthermore, WAS can improve the clinical symptoms of GPL by suppressing GA, IM and dysplasia and eliminating *H pylori*.

Abstract

We report the case of a 65-year old male patient who initially presented with recurrent episodes of upper abdominal pain, lack of appetite and weight loss. Abdominal ultrasound indicated enlarged intrahepatic bile ducts, abdominal CT scan and ERC were performed and bile duct carcinoma (Klatskin Type III b) was diagnosed. The tumor was located in the segments 2,3,4 and 1 with possible invasion of the left intrahepatic portal vein. Both the segments 2 and 3 of the liver were atrophic and displayed a cholestatic bile duct system. Preoperatively an intraductal stent was placed in the left bile duct using ERC to drain the left hepatic lobe. A specimen of the ascites present preoperatively displayed no malignant cells. After evaluation of the preoperatively obtained data left hepatic resection was planned. Following laparotomy we found local peritoneal carcinosis in the ligamentum hepatoduodenale with lymphatic nodules that tested positive for cholangiocellular carcinoma in online pathological examination. In the course of further exploration of the abdomen a solid tumor was detected in the sigmoid colon. Regarding the advanced stage of the neoplasm it was decided to cancel hemihepatectomy and perform sigmoid resection only in order to guarantee uncomplicated intestinal passage. The sigmoid colon was removed by a typical resection technique with end-to-end anastomosis. Histological examination of the resected sigmoid revealed transmural manifestation of a malignant neoplastic process with both a tubular and a solid growth pattern in conformity with metastasis of a Klatskin tumor. The mucosal layer showed no neoplastic alteration. Peritoneal carcinosis is a common phenomenon in the dissemination pattern of advanced-stage Klatskin tumors, yet to our knowledge this is the first case of intramural colonic growth following peritoneal metastasis.

INTRODUCTION

Bile duct tumors are rare neoplasms with an incidence of 0.5-1/100 000^[1]. Predisposing factors include mainly PSC with a thirty-fold increased risk as well as choledochal cysts and parasitic infections (*Clonorchis sinensis*, *Opisthorchis viverrini* et *felinus*)^[1,2]. These tumors usually present with clinical symptoms such as upper right abdominal pain, weight loss or jaundice at a rather advanced stage when the process has already grown to a rather significant extent. The tumor type and localisation are categorized according to the Bismuth criteria^[3]. After quite a sceptical approach towards surgical therapy for Klatskin tumors until the early 1990s, during the last years surgical results have demonstrated that even patients with a locally advanced stage of proximal bile duct carcinoma without distant metastasis profit from surgical resection^[3,4,5]. Today 5-year survival rates from 10% to 40% are reported with even higher survival rates in specialized centers^[6,7,8].

CASE REPORT

We report the case of a 65-year old male patient who had experienced episodes of upper abdominal pain for several months. When presentation at our institution he did not develop jaundice, bilirubin was 0.6 mg/dL after stent-placement in the left hepatic duct prior to admittance to our institution.

Due to lack of appetite he had lost five kilograms over the last four months. Laboratory values at admission time were as follows: total bilirubin 0.6 mg/dL, conj. 0.4 mg/dL, AST 75 U/L, ALT 39 U/L, gGT 63 U/L, AP 82 U/L, lipase 210 U/L, amylase 278 U/L, leukozytes 9.29/nL, thrombozytes 206/nL, Hb 11.5 g/dL, TPZ 83%, INR 1.15 CEA 2.6 µg/L, AFP 29 µL/L, CA 19-9 803 U/mL.

Clinical examination revealed a man of reduced physical fitness considering his age and upper right abdominal pain at palpation. After abdominal ultrasound indicating enlarged intrahepatic bile ducts a CT scan was

Figure 1 CT scan shows Klatskin tumor type III b with intrahepatic bile duct enlargement, cholestasis and atrophy of the left hepatic lobe.

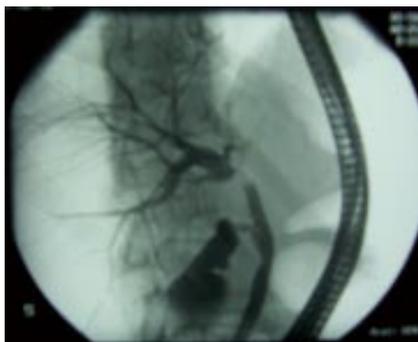

Figure 2 ERC displays good filling of the right intrahepatic bile duct system whereas the left system could not be displayed due to tumorous stenosis in the distal part of the ductus hepaticus sinister reaching into the ductus hepaticus communis.

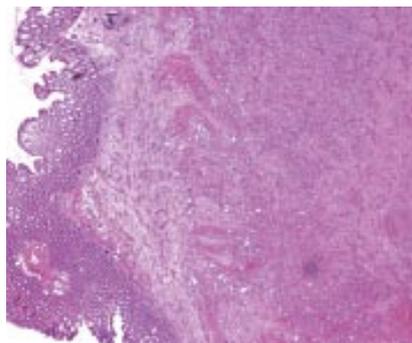

Figure 3 Histological examination of the resected colonic neoplasm reveal intramural metastasis of adenocarcinoma infiltrating the muscular and submucosal layers.

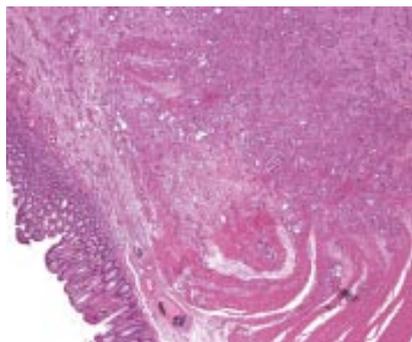

Figure 4 Histological examination of the resected colonic neoplasm reveals intramural metastasis of adenocarcinoma infiltrating the muscular and submucosal layers.

performed demonstrating a mass of hypervascularized tissue in the central liver hilum within the segments 2, 3, 4 and 1. Enlarged lymphatic nodes in the hepato-duodenal ligament could also be detected. The left intrahepatic bile duct system proximal of the tumor was markedly enlarged with signs of massive cholestasis.

CT scan showed Klatskin tumor Typ III b growth with intrahepatic bile duct enlargement, cholestasis and atrophy of the left hepatic lobe (Figure 1).

An endoscopic retrograde cholangiography (ERC) was then conducted to examine the detailed bile duct anatomy. This displayed good filling of the right intrahepatic bile duct system whereas the left system could not be displayed due to tumorous stenosis in the distal part of the ductus hepaticus sinister reaching into the ductus hepaticus communis (Figure 2). After careful preoperative evaluation the patient was subjected to surgical resection. At the start of the surgical procedure multiple positive lymphatic nodules were detected in the hepatoduodenal ligament. While further exploring the peritoneal cavity for potential additional manifestations of the tumor a solid mass could be found in the sigmoid colon. As this was a preoperatively unknown process which appeared highly suspicious to be of neoplastic origin, it was decided to resect this segment of the colon. Sigmoid resection was performed using the standard no-touch technique. The resected sigmoid colon was then subjected to histological examination: Histomorphology and immune-histochemistry revealed an intramural colonic metastasis of a badly differentiated adenocarcinoma of the bile duct displaying solid as well as tubular segments of growth with a large number of mitotic cells. No neoplastic alteration of the colon mucosa could be detected.

A separately growing sigmoid neoplasm of colonic

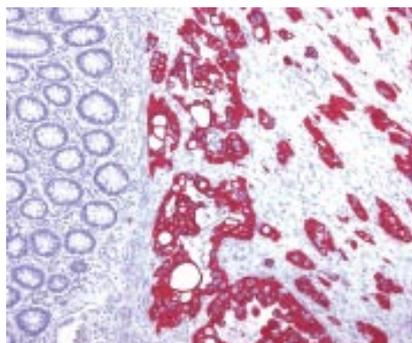

Figure 5 Immunohistological staining shows adenocarcinoma of the non-intestinal klatskinoid type.

origin could be ruled out (Figures 3, 4). Histological examination of the resected colonic neoplasm revealed intramural metastasis of adenocarcinoma infiltrating the muscular and submucosal layers (Figure 5). Immunohistological staining showed adenocarcinoma of the non-intestinal klatskinoid type.

DISCUSSION

As far as our clinical experience and the extensive literature research are concerned, this is the first case ever reported of colonic metastasis of Klatskin type bile duct carcinoma.

Lymphatic metastasis of Klatskin tumors into lymph nodes along the hepatoduodenal ligament is a common and well-known phenomenon as is intrahepatic dissemination to areas distant from the original tumor location^[1,3,6]. In more advanced stages of the disease we have also found peritoneal carcinosis and lung metastasis. Intestinal dissemination of a Klatskin tumor has not been reported up to date.

As careful pathological inspection-revealed colonic

metastasis is not merely due to peritoneal carcinosis spreading to the serosa of the sigmoid colon but originates within the intestinal wall.

In the advanced stage of bile duct carcinoma, peritoneal carcinosis leads to spreading of neoplastic cells within the abdominal cavity and consecutive tumor growth in multiple and various locations. Furthermore dissemination of cancer cells during surgery for bile duct carcinoma can lead to tumor cell spreading followed by metastasis in surgical scars^[9,10]. Whereas these phenomena lead to malignant cell growth originating from the serosal layer where metastatic cells are initially implanted, our case describes the continuing growth of disseminated bile duct carcinoma cells into and within the intestinal wall of the sigmoid colon.

While this case remains unique up to date, it may suggest to include colonoscopy in the preoperative staging procedures in selected cases.

Abstract

A 37-year old woman presented with a 9-year history of hepatitis of unknown origin and aminotransferases within a 3-fold upper limit of normal. Autoimmune hepatitis (AIH) was diagnosed on the basis of elevated aminotransferases, soluble liver antigen/liver pancreas (SLA/LP) autoantibodies and characteristic histology. Immunosuppressive therapy led to rapid normalization of aminotransferases. Two years later, the patient developed left sided hemisensory deficits under maintenance therapy of prednisolone and azathioprine (AZT). Later she developed right foot drop and paraesthesia in the ulnar innervation territory on both sides. Magnetic resonance imaging (MRI) and cerebral panangiography suggested cerebral vasculitis. Neurological investigation and electromyography disclosed multiplex neuritis (MN) probably due to vasculitis. Consistent with this diagnosis, autoantibodies to extractable nuclear antigens were detectable in serum. Immunosuppression was changed to oral 150 mg cyclophosphamide (CPM) per day. Prednisolone was increased to 40 mg/d and then gradually tapered to 5 mg. Oral CPM was administered up to a total dose of 40 g and then substituted by 6 times of an interval infusion therapy of CPM (600 mg/m²). Almost complete motoric remission was achieved after 3 mo of CPM. Sensibility remained reduced in the right peroneal innervation territory. Follow-up of cranial MRI provided stable findings without any new or progressive lesions. This is the first report of multiplex neuritis in a patient with autoimmune hepatitis.

INTRODUCTION

Autoimmune hepatitis (AIH) is a chronic autoimmune disease of the liver of unexplained aetiology associated with autoantibodies^[1]. Overlapping syndromes with other autoimmune liver diseases, such as primary biliary cirrhosis or primary sclerosing cholangitis are increasingly reported. AIH can also be associated with extra-hepatic autoimmune diseases such as Graves' disease, Hashimoto thyroiditis, mixed connective tissue disease^[2], membranous glomerulonephritis^[3], Sjogren's syndrome^[4] and more often with systemic lupus erythematosus (SLE)^[5]. While SLE is often associated with neuropathic symptoms, only four cases of neuropathy in AIH are published to date.

Multiplex neuritis (MN) results from multifocal injury of the peripheral nerves. Causative processes include vasculitis (frequently related to diabetes or polyarteritis nodosa), sarcoidosis, lymphoma and peripheral nerve tumours^[6].

We observed a patient with AIH who developed MN due to vasculitis during combined immunosuppressive treatment with corticosteroids and azathioprine two years after AIH diagnosis. Treatment with cyclophosphamide led to remission of both conditions.

CASE REPORT

A 37-year old woman presented in June 2000 with a 9-year history of hepatitis of unknown origin and aminotransferases ranging from 70 U/L to 100 U/L (2-3 × ULN). Two years before presentation, antibodies to TPO were found, but the patient since then was still euthyretic. Except for that, she had no previous medical history and was asymptomatic. Physical examination showed no pathological findings. She had no history of alcohol abuse and did not commonly use any medications. She had no neurological symptoms. At presentation, aspartate aminotransferase (AST; 37 U/L, normal value < 32 U/L) and alanine aminotransferase (ALT; 54 U/L,

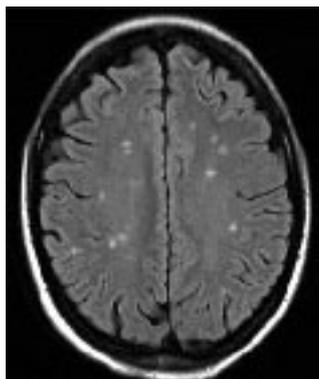

Figure 1 MRI (T2w/FLAIR) of the centrum semiovale showing multiple foci of subcortical signal enhancements which are characteristic but not specific for vasculitis.

normal value < 31 U/L) were slightly elevated. In contrast, gamma-glutamyltransferase (gamma-GT; 19 U/L, normal value ranging 5-36 U/L), alkaline phosphatase (AP; 123 U/L, normal value ranging 70-180 U/L), total bilirubin (0.24 mg/dL, normal value < 1.2 mg/dL), total serum protein (79 g/L, normal value ranging 60-80 g/L), albumin (65.5%), gamma-globulin (16.4%) and serum IgG (13.4 g/L) were normal. Complete peripheral blood count, blood urea nitrogen and creatinine levels were normal. Testing for hepatitis B surface antigen (HBsAg) and antibodies to hepatitis B core antigen (HBcAb) was negative, testing for antibody to hepatitis C virus (HCV) by ELISA and HCV-RNA by polymerase chain reaction was also negative. Serum levels of copper and ceruloplasmin were normal. Autoantibodies to soluble liver antigen/liver pancreas (SLA/LP) were found at a titre of > 200 U/mL by ELISA. The presence of SLA/LP autoantibodies was confirmed by immunoblot. At that time no other autoantibody was found. Liver biopsy showed mild periportal hepatitis, some areas showed dissection of the liver parenchyma by inflammatory cells with hepatocyte ballooning and rosetting.

Based on these findings, the diagnosis of SLA/LP positive AIH was made. Treatment with prednisolone at a daily dose of 20 mg was initiated and due to a quick and complete normalization of aminotransferases, prednisolone could be gradually tapered to a maintenance dose of 5 mg per day. Six months later, treatment was tapered out, but the disease slowly relapsed with a mild elevation of liver enzymes and progressive fatigue. Therefore, immunosuppressive treatment was readjusted to a daily dose of 40 mg prednisolone, which was then reduced weekly down to a maintenance dose of 10 mg per day. Serum aminotransferase levels rapidly normalized and clinical symptoms disappeared. Azathioprine was added at a dose of 75 mg per day and increased to 100 mg per day after two weeks.

In the following months, complete remission of AIH was maintained by medication with 7.5 mg/d prednisolone and 100 mg/d azathioprine. At this stage, the patient developed acute neurological disturbances, initially with a left sided hemisensory deficit. A few weeks

later, the patient developed paraesthesia in both ulnar innervation territories and subsequently a right sided peroneal paresis and mild weakness of hip flexion. She never had any lumbar pain. An infection with *Borrelia burgdorferi* and *Treponema pallidum* was ruled out by the absence of antibodies. MRI of the brain showed multiple paraventricular lesions, which were assumed to be of vasculitic character (Figure 1). Angiography of the brain showed irregularities of intracerebral arteries (Figure 2) consistent with vasculitis. Cerebrospinal fluid examination and electrophysiological examination (evoked potentials) were normal. Electromyography showed acute denervation in the anterior tibialis muscle and to a lesser degree in the medial proportion of the thigh muscle. To exclude radicular lesions, MRI of the spinal cord was performed, which showed distant degenerative changes, but no pathology on the right-sided L4 and L5 nerve roots. Accordingly, neurological examination revealed no loss of deep tendon reflexes or radicular pain. History, clinical and neurophysiological examination, cerebral angiography and MRI together with the emergence of autoantibodies to Ro/SSA supported the clinical diagnosis of MN, due to vasculitis of the nervous system.

For the treatment of vasculitis, azathioprine was replaced by cyclophosphamide (CPM) at an initial dose of 150 mg/d given orally. CPM is also effective in the treatment of AIH^[7]. Prednisolone was increased to 40 mg/d and then gradually tapered to 5 mg/d. According to the guidelines for the treatment of isolated vasculitis of the nervous system, oral CPM was administered at a total dose of 40 g. Thereafter, CPM was given 6 times by infusion therapy (600 mg/m²) at an 8-wk interval. Total recovery of the motoric deficits and almost complete recovery of the sensory deficits were achieved after 3 mo. Sensibility was only diminished in the peroneal nerve segment of the right leg. Cranial follow-up MRI, performed 6 mo after the initiation of CPM provided stable findings. The patient was in the fifth year of follow-up after AIH diagnosis and was receiving maintenance therapy consisting of 5 mg prednisolone and 100 mg azathioprine, AIH was still in remission and the patient remained free of further neurologic symptoms at the time she reported.

DISCUSSION

Multiplex neuritis (MN) occurs as a complication of vasculitis but can also develop in toxic or metabolic processes. Small vessel vasculitis typically affects the 50-400 micron vessels of the vasa nervorum, leading to randomly distributed ischemia along the nerve^[8]. This, in turn, may lead to a distinctive clinical picture of scattered neurological symptoms, which can be attributed to multiple complete or incomplete peripheral nerve or nerve root lesions. It is reported that more than half of vasculitis patients present with MN^[9]. The most frequent single nerve lesion is the peroneal nerve paresis^[10].

To date multiplex neuritis in hepatic diseases has been reported as a rare complication in patients with chronic hepatitis B^[11-13], in one patient with acute hepatitis A infection^[14] and in patients with hepatitis C and associated cryoglobulins^[15]. This latter manifestation is likely due to the cryoglobulinemic vasculitis seen in hepatitis C. The pathogenesis of this neuropathy in viral hepatitis without cryoglobulins has not yet been fully elucidated. It has been suggested that nerve lesions result from viral factors directly or from deposits of immune complexes in the vasa nervorum, which then may cause vasculitis and ischemia of the nervous fibers, as it has been shown for cryoglobulinemic neuropathies^[11,12,16].

Neuropathies in AIH patients are an extremely uncommon finding. Four patients have been described in the literature suffering from AIH and peripheral neuropathy^[17,18] and one patient suffering from AIH and cranial neuropathy, but this patient also had positive HCV serology and polymyositis^[19]. The patient described here suffered from clearly defined SLA/LP-positive AIH without any evidence for viral infection. Her asymmetric sensory and motor symptoms of both central and peripheral nervous system origin, with a clear stepwise onset developing over months, suggested vasculitis of the nervous system, which was compatible with the multifocal peripheral nerve involvement and ischemic brain lesions on MRI. Cerebral angiography provided objective evidence for nervous system vasculitis, and neurophysiological studies confirmed multiple peripheral nerve involvement.

To our knowledge, this is the first reported patient with AIH associated with vasculitic MN. Our report indicates that MN can develop in non-viral hepatitis. Both AIH and vasculitic MN are autoimmune systemic disorders of unknown origin, which occurred sequentially in our patient, suggesting that MN seems to develop independently of AIH. In our patient, the disease activity of AIH was not associated with that of MN, and MN developed despite immunosuppressive therapy with 7.5 mg prednisolone and 100 mg azathioprine per day, suggesting that MN may need higher levels of immunosuppression for remission than AIH.

In conclusion, medication with cyclophosphamide in combination with intensified prednisolone therapy can rapidly improve neurological symptoms and offer an

option for the prevention of further nerve injury.

Abstract

Left-sided periappendiceal abscesses occur in association with two types of congenital anomaly: intestinal malrotation and situs inversus. It is difficult to obtain an accurate preoperative diagnosis of these abscesses due to the abnormal position of the appendix. We present an unusual case of a left-sided periappendiceal abscess in an adult with intestinal malrotation, the diagnosis of which was a challenge.

INTRODUCTION

Intestinal malrotation is a congenital anomaly referring to either nonrotation or incomplete rotation of the primitive intestinal loop around the axis of the superior mesenteric artery during fetal development. While most cases of intestinal malrotation present with bilious vomiting in the first month of life^[1], rare cases present in adulthood^[2]. It is important that physicians be aware of the possibility of

this disease when treating adult patients with abdominal pain because diagnosis of intestinal malrotation can be difficult. The present report details an unusual case of a left-sided periappendiceal abscess with intestinal malrotation in an adult who presented with a painful mass in the left lower quadrant.

CASE REPORT

A 43-year-old man with no previous abdominal complaints presented to the emergency room of our hospital with a 2-wk history of a painful mass in the left lower quadrant. Previously, his physician had administered intravenous antibiotics for suspected diverticulitis, but increasing abdominal pain led to his hospital presentation. Physical examination revealed a body temperature of 37.4°C and an 8 cm-sized painful mass in the left lower quadrant. Laboratory tests showed a normal white cell count ($4.6 \times 10^9/L$) and an elevated C-reactive protein concentration (104 mg/L). Computed tomography (CT) abdominal scanning revealed a solid fluid-containing tumor in the left lower quadrant (Figure 1), suggesting an inflammatory mass with abscess formation. We drained the abscess using percutaneous drainage (PCD) and administered intravenous antibiotics while trying to determine the exact cause of the abscess. One week later, the patient had a soft abdomen with no specific complaint.

To identify the cause of the abscess, we performed a contrast enema with gastrograffin. This procedure revealed that a fistulous tract of the colon did not exist, and the entire colon was seen in the left half of the abdomen with the cecum in the left lower quadrant (Figure 2). Contrast filling of the terminal ileum was apparent. An irregular contour of the cecum was also observed, with no contrast filling of the appendix. Figure 2 also shows a pig-tail catheter located in the area corresponding to an abscess pocket. With this information, the abdominal CT was again reviewed. Further review indicated a periappendiceal abscess with intestinal malrotation due to the anatomic location of the right-sided small bowel, left-sided large bowel, the abnormal position of the superior mesenteric vessels, and an inflammatory mass in the ileocecal area.

Surgery was performed through a lower midline incision after obtaining informed consent. Surgical findings confirmed the severe inflammatory changes of the appendix and ileocecal region located in the left lower quadrant (Figure 3). An ileocecectomy was performed. Pathology testing indicated gangrenous appendicitis with severe peri-

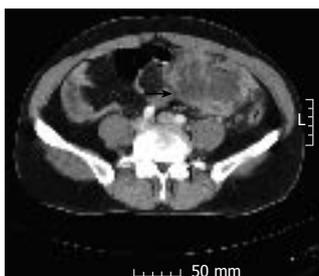

Figure 1 CT abdominal scan showing the presence of a solid fluid-containing tumor in the left lower quadrant (arrow).

Figure 2 Radiograph using water-soluble contrast media showing the entire colon present in the left half of the abdomen, with the cecum in the left lower quadrant. Contrast filling of the terminal ileum is shown (arrow). Irregular contour of the cecum (arrowhead) is shown with no contrast filling of the appendix. A pig-tail catheter is located at the area corresponding to the abscess pocket.

Figure 3 Intraoperative photograph showing severe appendix inflammation (arrow) and the ileocecal region located in the left lower quadrant.

cecal inflammation. The patient recovered uneventfully after surgery.

DISCUSSION

Intestinal malrotation is a congenital anomaly referring to either non-rotation or incomplete rotation of the primitive intestinal loop around the axis of the superior mesenteric artery during fetal development. As most complications associated with intestinal malrotation occur in the first month of life^[1], this disease may not be foremost in the mind of physicians with exclusively adult patients. However, all such physicians should be familiar with intestinal malrotation owing to its associated diagnostic difficulty and the devastating consequences of failure of recognition^[2]. In general, adults with intestinal malrotation present

in one of three ways^[3]. Some patients present with acute obstructive symptoms and signs of impending abdominal catastrophe. Others present with chronic abdominal complaints that include both pain and intermittent obstruction. Lastly, some present with atypical symptoms common to abdominal diseases unrelated to intestinal malrotation, such as in the present report.

The increasing use of abdominal CT as the first imaging modality in patients with various abdominal complaints means that the importance of identifying malrotation by CT cannot be overemphasized. Malrotation can be diagnosed on CT by the anatomic location of a right-sided small bowel, a left-sided colon, an abnormal relationship of the superior mesenteric vessels, and aplasia of the uncinate process of the pancreas^[4]. In the present case, such CT findings indicating malrotation were not immediately recognized due to the low frequency of this disease in the adult population. Malrotation was recognized only after a contrast enema showed that the entire colon was in the left half of the abdomen, with the cecum in the left lower quadrant. Furthermore, left-sided periappendiceal abscess was not suspected initially because there were no clinical characteristics suggesting appendicitis such as preceding vague central pain and there were only a few cases reported in the literature^[5].

We debated as to whether correction of the malrotation was indicated in this case. Dietz *et al*^[2] advocated that correction of the malrotation is probably not indicated unless there is evidence of intestinal obstruction. In contrast, Cathcart *et al*^[6] argued that surgical correction is warranted due to the risk of midgut volvulus.

In conclusion, all physicians with exclusively adult patients should be familiar with intestinal malrotation in order to make a timely and correct diagnosis that will lead to prompt and appropriate treatment.

Abstract

Stump appendicitis is an acute inflammation of the residual appendix and one of the rare complications after appendectomy. Paying attention to the possibility of stump appendicitis in patients with right lower abdominal pain after appendectomy can prevent the delay of diagnosis and treatment. In patients with stump appendicitis, CT scan not only assists in making an accurate preoperative diagnosis but also excludes other etiologies. We report a 47-year old man with preoperatively diagnosed stump appendicitis by CT, who underwent an open appendectomy 20 years ago.

INTRODUCTION

Stump appendicitis is an acute inflammation of the residual appendix and a rare complication after appendectomy^[1]. Although the signs and symptoms do not differ from those of acute appendicitis, the diagnosis is often not considered because of prior appendectomy^[2]. A small number of stump appendicitis cases have been reported^[3]. We report a 47-year old man with preoperatively diagnosed stump appendicitis by CT, who underwent an open appendectomy 20 years ago.

CASE REPORT

A 47-year-old male patient presented to the emergency department with a chief complaint of abdominal pain for 6 d. The pain was initially localized around the umbilicus, and subsequently localized at the right lower quadrant. The patient complained of anorexia and nausea after the pain started. He had four or five episodes of watery diarrhea daily for 3 d though he had no vomiting. His surgical history included an appendectomy 20 years ago and surgery for peptic ulcer disease 15 years ago. His axillary temperature was 37.1°C, rectal temperature 38.4°C, blood pressure 125/70 mmHg, pulse rate 76 beats/min, and respiratory rate 16 breaths/min. Physical examination of the abdomen revealed healed midline and right lower abdominal (McBurney incision) surgical scars. A mass without clear borders was found showing tenderness, muscular guarding and rebound in the right lower quadrant during abdominal palpation. Routine laboratory tests included normal electrolyte and blood cell panels except for a white blood cell count of 11700/ μ L. Urinalysis was unremarkable. Abdominal ultrasonography (USG) showed a heterogene hypoechoic mass at the right lower quadrant. There was no abdominal free fluid. No specific diagnosis could be made. CT scan of the abdomen and pelvis showed a tubular structure extending from the cecum, with an enhanced wall consistent with an inflamed appendical stump (Figure 1A). Thickened cecum wall, inflammatory change of mesenteric fat and enlarged lymph nodes could also be seen (Figure 1B). Preoperative diagnosis of stump appendicitis was made on the basis of the CT findings.

Abdomen was opened with McBurney incision. Plastron formation in omentum and intestine at the right quadrant and inflammation at the cecum wall were seen. This site was dissected and the purulent material was drained. Stump appendicitis perforated from the appendix radix of 2 cm with necrosis was detected. Appendectomy was performed. The material with necrosis was removed and washed. A drain was placed and the abdomen was closed. Operative findings were confirmed by pathology. The patient was discharged from the hospital three days after operation.

DISCUSSION

Stump appendicitis is one of the rare delayed complications of appendectomy^[4]. Twenty-nine cases have been reported in the worldwide medical literature since the first case reported by Rose in 1945^[5,6]. We have detected 7 new

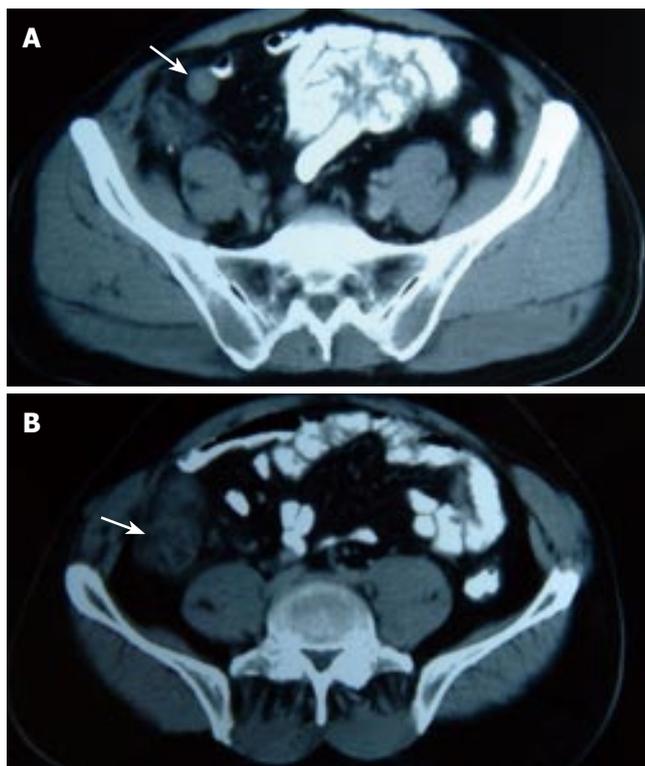

Figure 1 Contrast-enhanced CT scan of abdomen shows enlarged appendiceal stump with enhanced wall and local inflammatory changes (A) and distended cecum with thickening wall and stranding of adjacent mesenteric fat (B).

cases with our present case, thus 36 cases are available in the worldwide medical literature^[2,3,6-10].

The true incidence and prevalence of stump appendicitis are not known, but it is thought to be an underreported entity in the literature^[6]. The age of patients with stump appendicitis ranges from 11 to 72 years. The time intervals from initial appendectomy to stump appendicitis range from 2 mo to 51 years^[1,3]. A long appendiceal stump is reported to be a risk factor for stump appendicitis. The length of the stump ranges from 0.5 to 6.5 cm^[1,3,11,12]. Mangi and Berger^[12] reported that leaving an appendiceal stump less than 3 mm in depth with accurate visualisation of the appendiceal base, can minimise the incidence of stump appendicitis.

Whether simple ligation of the appendix or stump inversion into the cecum can reduce the risk of stump appendicitis remains controversial^[12]. Rao *et al*^[13] showed that all the cases reported in the literature undergo simple ligation of the appendix without invagination of the stump, suggesting that simple ligation with failure to amputate the appendix close to its origin from the cecum is a prerequisite for developing stump appendicitis. Mangi and Berger^[12] reviewed 2185 cases of appendectomy and found that there is no correlation between simple ligation and stump appendicitis. To leave the stump long may cause the inversion difficult. Therefore the length of stump may warn the surgeon.

Laparoscopic appendectomy is now a widely accepted surgical technique in treating appendicitis. The growing use of laparoscopic appendectomy may increase the frequency of stump appendicitis^[3,9,11,14] due to the potential

limitations of the technique such as smaller field of vision, lack of three-dimensional perspective, absence of tactile feedback, thus leaving a longer stump^[14]. In the reported 36 cases of stump appendicitis, only 10 had stump appendicitis after laparoscopic appendectomy^[15]. To date, no relationship between laparoscopic appendectomy and stump appendicitis has been demonstrated^[12].

A wide spectrum of diseases in the differential diagnosis of right lower quadrant pain of the abdomen and a past appendectomy history delay the diagnosis and treatment of stump appendicitis. It is usually diagnosed perioperatively when stump perforation and/or abscess occurs. In our case, the delay was due to the patient's late entry to the hospital.

Preoperative screening techniques may help to diagnose the disease^[2-4,13,16]. Only 1 case diagnosed by preoperative USG is available in the literature^[16]. In our case, although a pathologic lesion was detected at the right lower quadrant by USG, no specific finding of stump appendicitis was detected. Preoperative CT is a more efficient technique. To our knowledge, 4 cases have been diagnosed by CT having stump appendicitis apart from our case to date^[2-4,13]. In these studies, beside the appearance of inflamed appendix stump adjacent to the cecum, a cecal arrowhead sign indicating inflammation at the base of the appendix and appendicolith can be seen. CT findings may not be specific for stump appendicitis. Nonspecific inflammatory findings such as pericecal inflammatory changes, cecal wall thickening, abscess formation and fluid in the right paracolic gutter can be found in cases of stump appendicitis^[2-4,13].

In patients presenting with acute right lower quadrant findings mimicking appendicitis, the history of prior appendectomy does not absolutely rule out the possibility of appendicitis. But this situation usually causes an important delay of their diagnosis and treatment. In patients with stump appendicitis, CT scan not only assists in making an accurate preoperative diagnosis but also excludes other etiologies. Awareness of the possibility of stump appendicitis combined with a high index of suspicion can help to make an early diagnosis.

Abstract

A patient presented with hematemesis due to gastric variceal bleeding with an intratumoral arterioportal shunt. Contrast-enhanced CT revealed gastric varices and hepatocellular carcinoma with tumor thrombi in the right portal vein. Angiography and angio-CT revealed a marked intratumoral arterioportal shunt accompanied with reflux into the main portal vein and gastric varices. Balloon-occluded retrograde venography from the gastro-renal shunt showed no visualization of gastric varices due to rapid blood flow through the intratumoral arterioportal shunt. The hepatic artery was temporarily occluded with a balloon catheter to reduce the blood flow through the arterioportal shunt, and then concurrent balloon-occluded retrograde transvenous obliteration (BRTO) was achieved. Vital signs stabilized immediately thereafter, and contrast-enhanced CT revealed thrombosed gastric varices. Worsening of hepatic function was not recognized. BRTO combined with temporary occlusion of the hepatic artery is a feasible interventional procedure for ruptured high flow gastric varices with an intratumoral arterioportal shunt.

INTRODUCTION

Hematemesis of ruptured high flow gastric varices from intratumoral arterioportal shunt is a critical condition. The transjugular intrahepatic portosystemic shunt (TIPS)^[1-2] and percutaneous transhepatic obliteration (PTO) are contraindications for portal hypertension accompanied with a marked intratumoral arterioportal shunt. Balloon-occluded retrograde obliteration (BRTO)^[3-8] also has never been reported as a treatment of high flow gastric varices with an intratumoral arterioportal shunt because stagnation of the sclerosing agent cannot be obtained. Endoscopic intravariceal sclerotherapy is applicable for the ruptured gastric varices. However, it might induce rebleeding at the puncture site as a complication.

We report a case in which BRTO combined with temporary balloon occlusion of a hepatic artery for bleeding gastric varices accompanied by the intratumoral arterioportal shunt was effective in thrombosing the varices resulting in a lifesaving outcome.

CASE REPORT

A 69-year old man with hepatocellular carcinoma (HCC) was referred to our hospital to undergo transcatheter arterial anticancer drug infusion and radiation therapy for tumor thrombi in the right portal vein visualized on contrast-enhanced CT. Angiography was performed to delineate the extent of the tumor thrombi and to infuse anticancer drugs from the proper hepatic artery. Celiac arteriography using a 4F catheter (RC2; Medikit, Tokyo, Japan) showed a hypervascular tumor stain in the right lobe and a marked intratumoral arterioportal shunt accompanied with reflux into the main portal vein and gastric varices (Figure 1). Then, the 4F catheter was advanced to the proper hepatic artery and computed

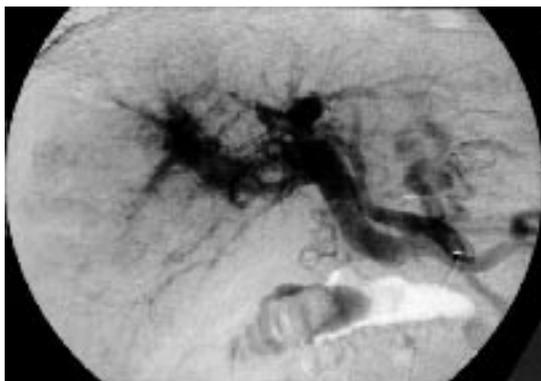

Figure 1 Celiac arteriography showing a marked arterioportal shunt with tumorous thread and streak sign and massive reverse flow to the main trunk of the portal vein.

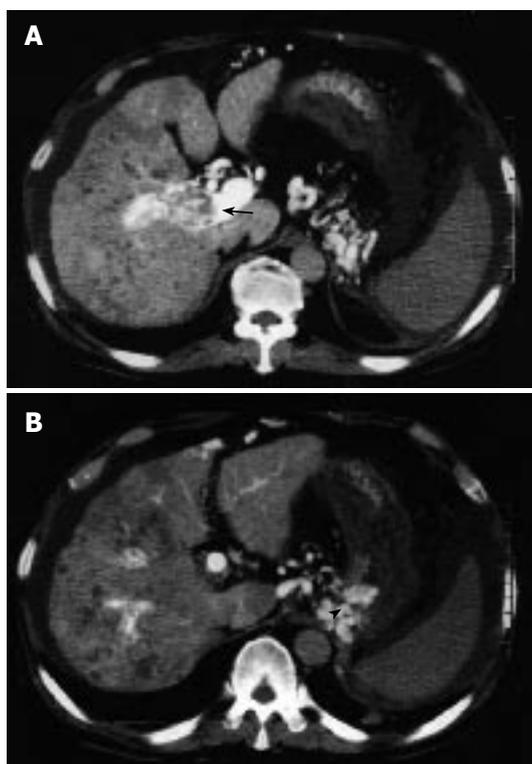

Figure 2 CT during proper hepatic arteriography showing tumor thrombi (arrow) in the right portal vein (A) and gastric varices (arrowhead) (B).

tomography during hepatic arteriography (CTHA) at 5 mm slices with injection of contrast agent (Iopamidol, 140 mgI; Daiichi, Tokyo) at a speed of 2 mL for a total volume of 60 mL. The CTHA showed HCC with the tumor thrombi in the right branch of the portal vein (Figure 2A) and a marked intratumoral arterioportal shunt with reflux into the main portal vein and gastric varices (Figure 2B). Anticancer drugs (10 mg mitomycin C and 40 mg farmorubicin) were infused from the proper hepatic artery. Ten days later, massive hematemesis occurred in the patient. Blood tests showed severe anemia and liver dysfunction (RBC/Hb/Hct 168/5.4/16.1, sGOT/sGPT/T.B 549/103/1.3). There was hesitation to perform an endoscopic intravariceal sclerotherapy because of apprehension of rebleeding by the direct puncture of the

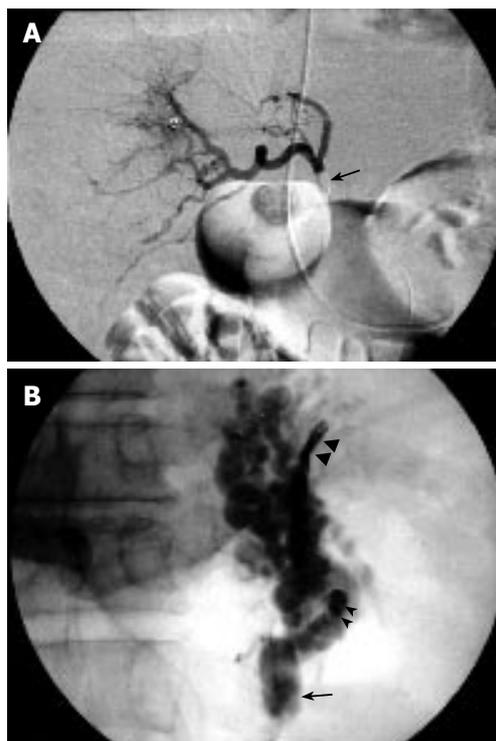

Figure 3 BRTO combined with temporary balloon occlusion of the hepatic artery. **A:** Proper hepatic arteriography through the balloon catheter during balloon occlusion (arrow); **B:** Balloon-occluded retrograde venography (arrow) after embolization of the left inferior phrenic vein and the retroperitoneal vein with micro-spring coils (arrowheads) showing the stagnant gastrorenal shunt and gastric varices. A 5% ethanolamine oleate mixture (30 mL) was then injected during dual balloon occlusion.

high flow varices. Then, endovascular intervention was selected. First, a 14 mm diameter balloon catheter (Selecon 7F Straight MP catheter; Clinical Supply, Gifu, Japan) through a 7F sheath (J Sheath; Medikid, Tokyo, Japan) was inserted from the right jugular vein and advanced into the outflow pathway of a gastrorenal (GR) shunt. The GR shunt was occluded by the inflated balloon and a retrograde injection of contrast agent was performed. However, the contrast agent was dispersed to the left inferior phrenic vein (IPV) and other flow tracts rapidly, and gastric varices were not visualized. Then, the left IPV and other flow tracts were embolized with micro-spring coils (Trufill; Cordis, Miami, FL and Tornado coil. Cook) through a 3 F microcatheter (Microphurette, Cook). After embolization of their tracts, however, the gastric varices remained unopacified by balloon-occluded retrograde venography. High blood flow through the arterioportal shunt was the main cause. In the absence of stagnation of the contrast agent, complete thrombolization of the gastric varices was impossible by BRTO and the complications due to massive systemic leakage of ethanolamine oleate (EO) as a sclerosing agent were also feared. In order to stagnate the blood flow of GR shunt, temporary balloon occlusion of the proper hepatic artery was performed using a 9 mm balloon catheter (Selecon, 5F Straight, Clinical Supply) (Figure 3A). Under temporary balloon occlusion of the proper hepatic artery, the outflow pathway of the GR shunt was reclosed by inflating the 14 mm diameter balloon. It led to the visualization

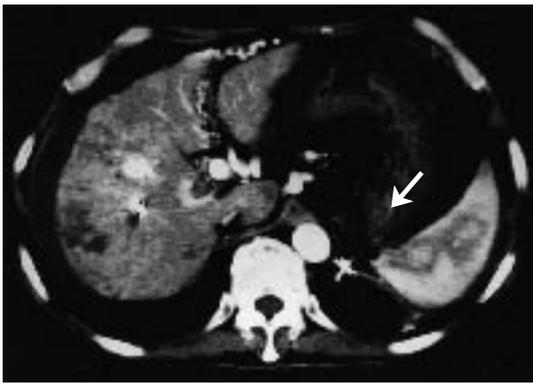

Figure 4 Contrast-enhanced CT showing thrombosed gastric varices (white arrow) on the following day.

of the stagnant gastric varices with balloon-occluded retrograde venography. Five percent EO solution, which is a mixture of 10% EO (Oldamin; Grelan Pharmaceutical, Tokyo, Japan) and the same dose of a nonionic contrast medium (Iopamiron 370 mgI/dL; Schering Osaka, Japan), were slowly injected into the GR shunt during the dual balloon occlusion after venous drip infusion of human haptoglobin (Mitsubishi Pharma, Osaka, Japan) at a total volume of 4000 units. The gastric varices were filled with 30 mL of 5% EO solution (Figure 3B). The balloon catheter in the proper hepatic artery was deflated and removed after one hour. Patency of the proper hepatic artery was confirmed by contrast agent injection from the catheter before removal. The balloon occlusion of the GR shunt was maintained for 24 h. Contrast-enhanced CT performed on the following day showed thrombosed gastric varices (Figure 4). Following BRTO, blood pressure and other vital signs stabilized, and progression of anemia was halted. Worsening of hepatic function was not recognized (sGOT/sGPT/T.B 108/73/1.3). After that, the patient could undergo radiation therapy for the portal tumor thrombi.

DISCUSSION

Kanagawa *et al*^[3] first introduced BRTO as an effective therapy for gastric varices in 1990. BRTO is performed by injecting a sclerosing agent from the balloon catheter through the outflow pathway of the gastrorenal shunt during balloon occlusion^[3,4]. The success rate of gastric varix sclerosis reaches 85%-100%^[3-8]. Five percent ethanolamine oleate iopamidol (EOI) is usually used as the sclerosing agent with retrograde injection. Massive systemic leakage of ethanolamine oleate causes various complications such as acute respiratory distress syndrome^[9,10], acute renal disorder^[11] and disseminated intravascular coagulation^[12]. Though human haptoglobin^[11,13] has been used to prevent such complications, leakage into the systemic circulation must be minimized. In cases of multiple outflow tracts such as inferior phrenic vein, pericardiophrenic vein, and other outflows, embolization of these outflow tracts with micro-spring coils is performed to reduce the injection volume of EO and prevent systemic leakage^[8].

In our case, BRTO alone was anticipated to lead to inadequate occlusion of the outflow tract and massive systemic leakage of EOI because of high blood flow from the intratumoral arteriportal shunt. According to the classification of the degree of progression of gastric varices^[6], the high flow gastric varices in which the GR shunt cannot be occluded with the balloon catheter alone, belong to the highest grade 5. In patients with the most progressive gastric varices, partial splenic embolization and PTO of the coronary vein as a main inflow route are required to reduce the blood flow into varices before BRTO^[6]. However, no description about the procedure to treat gastric varices accompanied with a marked intratumoral arteriportal shunt is available. Transcatheter embolization is an effective treatment for variceal bleeding due to portal hypertension caused by arteriportal fistulae^[14-16]. In cases of portal tumor thrombi, however, transcatheter embolization of the hepatic artery with gelatin sponge particles, metallic coils and other permanent embolic materials to reduce the arterial flow into varices can cause a large liver infarction and hepatic failure^[17]. Temporary occlusion of the proper hepatic artery using a balloon catheter to reduce blood flow through the arteriportal shunt prevents liver infarction, minimizes systemic leakage of EO and permits complete thrombosis of the gastric varices by concurrent BRTO. Temporary balloon-occluded proper hepatic arterial infusion of anticancer drugs can be performed for HCC with portal tumor thrombi and is a safe procedure because short-term ischemia has little effect on hepatic function^[18]. In this case, there was no deterioration of liver function after BRTO during temporary balloon occlusion of the hepatic artery. There is no previous report describing the feasibility of BRTO during temporary balloon occlusion of the hepatic artery for hemorrhagic gastric varices with a marked intratumoral arteriportal shunt.

In conclusion, BRTO combined with temporary occlusion of a proper hepatic artery is a safe and useful method for the treatment of ruptured high flow gastric varices with a marked intratumoral arteriportal shunt.

Abstract

We present a female patient with continuous melena, diagnosed with rectal variceal bleeding. She had a history of esophageal varices, which were treated with endoscopic therapy. Five years after the treatment of esophageal varices, continuous melena occurred. Since colonoscopy showed that the melena was caused by giant rectal varices, we thought that they were not suitable to receive endoscopic treatment. We chose the modified percutaneous transhepatic obliteration with sclerosant, which is one of the interventional radiology techniques but a new clinical procedure for rectal varices. After the patient received this therapy, her condition of rectal varices was markedly improved.

INTRODUCTION

Ectopic varices outside the esophagogastric lesion are rare in patients with portal hypertension^[1]. Among ectopic varices, rectal varices are comparatively common, but their rupture is often fatal although it is rarely reported^[2]. Though there are several case reports of rectal varices treated with endoscopic variceal ligation (EVL)^[3], endoscopic injection sclerotherapy (EIS)^[4,5], transjugular intrahepatic portosystemic shunt (TIPS)^[6,7] and surgery^[8,9], no single effective method has yet been established. Kimura *et al*^[10] have reported that a patient is successfully treated with a new interventional radiological procedure, double balloon-occluded embolotherapy (DBOE). We used the modified percutaneous transhepatic obliteration with sclerosant (MPTO) rather than DBOE in the treatment of giant rectal varices in our case.

CASE REPORT

A 77-year old woman with liver cirrhosis had bleeding from esophageal varices, which was treated with EIS in 1992. She presented with profuse melena in March 1998 and was admitted to a nearby hospital due to shock. She received 2000 mL of packed red blood cells and was transferred to our hospital for further treatment. On admission, physical examination revealed moderate anemic conjunctiva without scleral icterus. Tense ascites was present without abdominal tenderness. The functional reserve of the liver was assessed as Child-Pugh grade B. Esophago-gastroduodenoscopy did not find recurrence of gastroesophageal varices. Flexible sigmoidoscopy revealed huge tortuous rectal varices extending from outside the anus to the recto-sigmoid junction (Figure 1). Endoscopic Doppler ultrasonography (FG-32UA, Pentax Co., Ltd., EUB-555 US scanner, Hitachi Co., Ltd., Tokyo Japan) revealed that the largest diameter of varices was 8.8 mm and the blood flow velocity was 5 cm/s. Percutaneous transhepatic inferior mesenteric venography and pelvic angiography revealed that the blood of the rectal varices was supplied by the inferior mesenteric vein and flowed into the bilateral internal iliac vein *via* the internal pudendal vein (Figure 2). Percutaneous transhepatic portography revealed narrowing of the portal vein trunk

Figure 1 Flexible sigmoidoscopy reveals huge tortuous rectal varices extending from outside the anus to the recto-sigmoid junction (A: rectum, B: outside the anus).

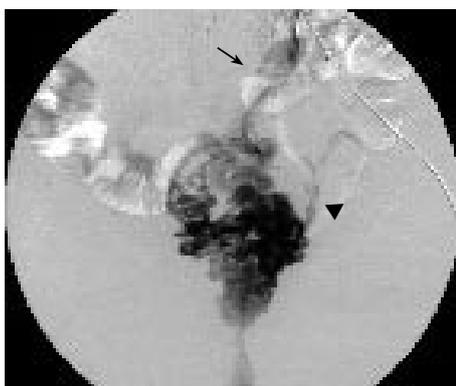

Figure 2 Percutaneous transhepatic portography demonstrates that the rectal varices are supplied by the inferior mesenteric vein (arrow) and flowed into the bilateral internal iliac vein (arrowhead).

and thrombosis of the superior mesenteric vein. For such extremely large rectal varices, treatment with EIS or EVL did not seem feasible. Instead, it was decided to treat her rectal varices with MPTO.

An occlusion balloon catheter (maximum external diameter of the balloon was 20 mm) and metallic coil were placed into the inferior mesenteric vein through the percutaneous transhepatic portogram route. When the rectal varices were fully visualized and contrast medium did not flow into the internal iliac vein, 5 mL of absolute ethanol was injected through the occluded inferior mesenteric vein followed by 7 mL of 5% ethanolamine oleate iopamidol (EOI) (Figure 3). The balloon was kept inflated for about 24 h. Twenty-four hours after the embolotherapy, PTP detected no blood flow in the rectal varices. There were no major complications during hospitalization. Four weeks after the embolotherapy, the sizes of the varices became markedly smaller (Figure 4). No rectal variceal bleeding occurred after treatment.

DISCUSSION

Rectal varices result from dilated submucosal veins which extend from the dentate line into the rectum and represent the portosystemic collaterals between the superior rectal vein flowing into the inferior mesenteric vein, and the

Figure 3 The sclerosant stagnates in the varices as a result of occlusion of the blood flow of the inferior mesenteric vein.

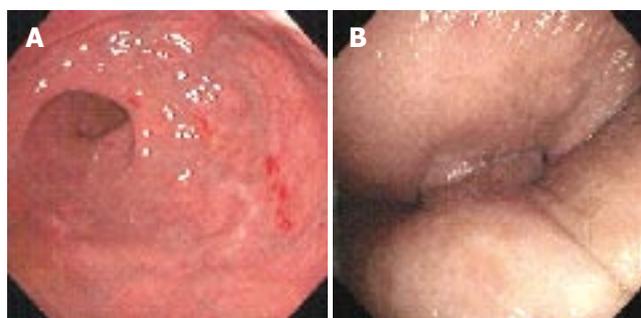

Figure 4 Sigmoidoscopy reveals disappearance of huge tortuous rectal varices extending from outside the anus to the recto-sigmoid junction (A: rectum; B: outside the anus).

middle and inferior rectal veins draining into the internal iliac vein^[11,12]. They are thought to be distinct from hemorrhoids, which do not occur in the rectum and have no direct communication with the portal circulation^[12-14].

The first case of rectal varices was reported in 1954^[15]. Izsak and Finlay^[16] have reported 29 cases and Gudjonsson *et al*^[17] have reviewed 69 cases of colonic varices since then. The incidence of colonic varices is low and has been reported to be 0.07%^[18].

The most common underlying condition associated with rectal varices is portal hypertension, which is present in approximately three-fourths of all cases^[17]. Other causes include localized portal hypertension resulting from blood flow disturbances through the mesenteric veins as a result of postoperative adhesion^[19], splenic vein obstruction associated with pancreatitis^[20], and carcinoid-induced mesenteric vein obstruction^[21]. In addition, familial vascular anomalies^[22], congenital vascular anomalies^[23], and congestive heart failure^[17] have been suggested as the possible causes of rectal varices. In our case, the patient received esophageal sclerotherapy six years ago. Keane *et al*^[24] have reported a case of massive bleeding from rectal varices following repeated injection sclerotherapy for esophageal varices. An incidental risk of rectal varices after eradication of esophageal varices seems to be increased where portal hypertension is present.

Previously reported therapies for rectal varices include EIS^[4,5], EVL^[3], TIPS^[6,7], surgery^[8], and more conservative

therapies such as drip infusion of vasopressin^[25]. There is no standardized treatment for rectal varices, but rectal varices are accessible through standard endoscopy. Several studies have reported their successful treatment with sclerosant injection or band ligation. Endoscopic therapy with sclerosant is not so satisfactory, especially for large rectal varices, because sclerosant may be diluted in large varices beyond a concentration sufficient to obliterate the varices and there may be a risk of developing severe complications, such as pulmonary embolism, due to the flow of high doses of sclerosant into the systemic circulation. EVL can be used to treat active bleeding from rectal varices as an emergency treatment modality. Norton *et al*^[26] reported that if the entire varix cannot be banded there is a risk of causing a wide defect in the varix after sloughing of the band, rendering the banding technique unsafe for large rectal varices.

Since surgery imposes a substantial burden and risk on patients, it may be advisable to reserve it for patients with Child-Pugh class A and extrahepatic portal vein thrombosis as the cause of portal hypertension. The efficacy of mobilization therapy or portosystemic shunt therapy using radiological techniques in the treatment of bleeding ectopic varices is rarely reported^[27]. There are some reports on successful treatment of severe rectal varices with TIPS^[6,7]. However, other reports showed that patients may die of rapidly progressive hepatic failure after TIPS procedure^[28]. We have only used it in the treatment of patients on a waiting list for liver transplantation. Only one report on embolization therapy for rectal varices is available in 1900 and 2005. Kimura *et al*^[10] reported that double balloon-occluded embolotherapy (DBOE) can lead to obliteration rectal varices. However, they have not stated whether contrast medium is stagnated in the varices as a result of occlusion of blood flow in the inferior mesenteric vein. In our case, since percutaneous transhepatic inferior mesenteric venography revealed that the blood of rectal varices was supplied by the inferior mesenteric vein only, we chose MPPTO to treat the rectal varices, as it is an easier and less invasive procedure than DBOE. The total amount of sclerosant needed for MPPTO or DBOE was 12 mL. If contrast medium stagnates in the rectal varices due to occlusion of the inferior mesenteric vein, as in our case, MPPTO may be appropriate.

MPPTO can also result in complications, such as renal failure causing hemoglobinuria because of hemolysis, and those associated with percutaneous transhepatic catheterization. Ohta *et al*^[29] reported that intraperitoneal bleeding after retraction of the catheter is found in 10.6% patients with rectal varices. These complications can also be seen after DBOE. MPPTO can close the in-flow and out-flow of rectal varices by occluding the blood flow of the inferior mesenteric vein.

In conclusion, MPPTO with sclerosant may prove to be an extremely useful method in the treatment of rectal varices. Further studies are needed to evaluate the efficacy and safety of this method.

Abstract

Downhill varices are located in the upper part of the esophagus and are usually related to superior vena cava obstruction. Bleeding from these varices is extremely rare. We describe a 77-year-old patient with hematemesis due to downhill varices as a result of recurrent goiter. A right lobe thyroidectomy was carried out with disappearance of the varices.

INTRODUCTION

Bleeding from distal esophageal varices is a frequent complication of portal hypertension. The portal blood drains into the superior vena cava by gastric and esophageal collaterals, also called uphill varices, referring to the upward direction of blood flow to the superior vena cava. In contrast to uphill varices, downhill varices have a retrograde blood flow and are located in the proximal esophagus. Downhill varices are rare and usually caused by superior vena cava obstruction due to bronchogenic carcinoma and mediastinal tumors, *etc*^[1,2]. They serve as collaterals either to bypass superior vena cava obstruction via the azygos vein or to drain the superior system to the

portal vein when both the superior vena cava and the azygos vein are occluded. In contrast to the high risk of hemorrhage from uphill varices in portal hypertension, bleeding from downhill varices is extremely rare. Although an increased variceal wall tension is the ultimate factor causing bleeding in both types of varices, several factors may underlie this difference in bleeding tendency. First, in patients with uphill varices, coagulation capacity may be reduced due to concomitant liver disease with an inherently increased bleeding tendency. Second, exposure to esophagogastric reflux damages distal rather than proximal varices. Third, because distal uphill varices predominantly distend at subepithelial levels compared to the submucosal location of downhill varices in the midthoracic and proximal esophageal wall, variceal rupture is much more likely to occur near the esophagogastric junction^[2]. We report a rare case of bleeding downhill varices in the absence of superior vena cava obstruction. Detailed diagnostic work-up showed that the downhill varices were caused by goiter. The varices disappeared after subtotal thyroidectomy.

CASE REPORT

A 77-year-old female was admitted to the hospital because of hematemesis. The patient had a one-year history of dysphagia and weight loss. The patient had recurrent goiter after a subtotal thyroidectomy in 1979 for multinodular goiter. Her medical history also revealed chronic obstructive pulmonary disease (COPD) and smoking. The medication consisted of inhalation of salbutamol and ipratropium bromide. Physical examination revealed a pale non-icteric woman with normal vital signs and a normal voice without stridor. There was a large, firm, nodular mass on the right side of the neck with a horizontal thyroidectomy scar. There were no dilated veins and no bruits audible over the mass. Physical signs of liver disease, Graves' disease and superior vena cava syndrome were absent.

Laboratory findings including thyroid function tests were normal except for 7 mmol/L hemoglobin (normal: 7.5-10.0 mmol/L) and 0.31% hematocrit (normal: 0.37%-0.47%), respectively. At emergency gastroscopy, the descending part of the duodenum and duodenal bulb were unremarkable. The stomach showed no abnormality except for a few adherent streaks of blood and a small amount of dark blood without clots. Careful gastric mucosal examination after use of a water jet was again unremarkable. The distal esophagus appeared normal

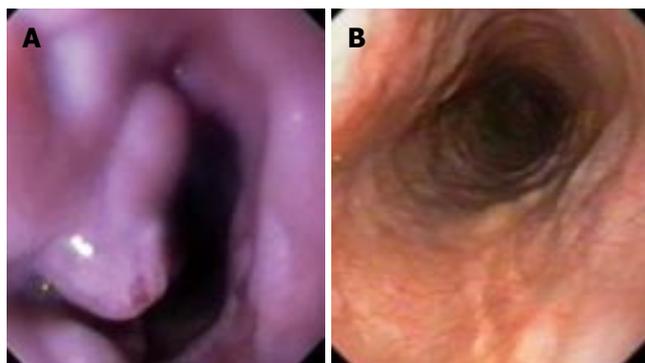

Figure 1 Endoscopic view demonstrating downhill varices (A) and almost complete disappearance of the downhill varices (B) before and 12 mo after thyroidectomy of the right lobe.

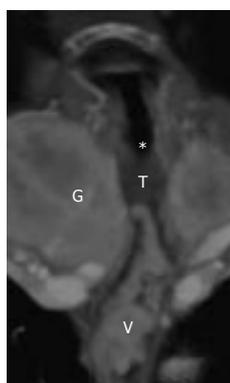

Figure 2 3D reconstruction of CT angiography with view at the dorsal wall of the trachea (T) demonstrating a venous plexus of downhill varices (V) on the wall between the esophagus and trachea connected with a thyroid vein at the goiter (G) of the right thyroid lobe; *, out of plane, cut off level thick slice.

without signs of reflux esophagitis or Mallory-Weiss lesion. However, proximal grade II-III downhill esophageal varices were visualized 6 centimeters below the upper esophageal sphincter. Importantly, one of the varices showed a small fibrin plug indicating recent bleeding. Since bleeding stopped spontaneously, no treatment was given except for blood transfusion and a diet of semi-solid food. A second gastroscopy after 48 h showed again grade II-III varices without signs of (re)bleeding (Figure 1A). CT of the thorax showed a substernal goiter and a slight compression of the trachea without any other abnormalities. CT angiography demonstrated a dilated venous plexus around the esophagus connected with a thyroid vein (Figure 2, Figure 3A). The venous plexus extended over 7.4 centimeters from the seventh cervical vertebra to the third thoracic vertebra and drained into the azygos vein. There was compression of the right internal jugular vein near the junction of the brachiocephalic vein and a dilatation of the more cranial part. Ultrasound and Doppler examination demonstrated a craniocaudal blood flow. Flebography excluded superior vena cava obstruction. Arteriography of the aortic arch excluded the presence of arteriovenous malformations. Since goiter seemed to cause the downhill varices, a thyroidectomy of the right lobe was carried out sparing the right recurrent laryngeal nerve and both parathyroids. Intraoperatively, a dilated right internal jugular vein was seen. The thyroid specimen weighed 85 g and was histopathologically diagnosed as multi-nodular goiter. The patient had a satisfactory

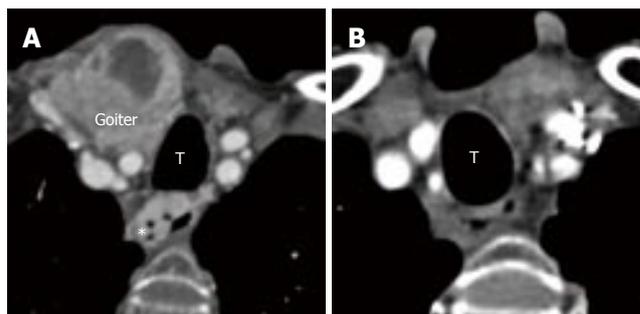

Figure 3 CT angiography demonstrating downhill varices one day after hemorrhage (A) and disappearance of the downhill varices 12 mo after thyroidectomy of the right lobe (B). * indicates varices around the esophagus; T, trachea.

recovery and was euthyroid after surgery with dysphagia complaints improved during follow-up. Twelve months after surgery, endoscopy and CT angiography showed almost complete disappearance of the varices (Figures 1B, 3B). Twenty months postoperation the patient was still non-symptomatic.

DISCUSSION

Downhill varices are usually associated with superior vena cava obstruction due to bronchogenic carcinoma, different types of mediastinal tumor and fibrosis, venulitis, surgical caval ligation and thyroid masses^[1,2]. Occasionally, as in our patient, downhill varices may develop without superior vena cava obstruction^[3,4]. Relatively few case reports have been published on bleeding downhill varices in relation to thyroid pathology (Table 1). In a study of 1051 patients with cervical and retrosternal goiter, 3% of patients developed non-bleeding downhill varices^[13]. Lagemann^[14] performed barium swallows in 50 patients with recurrent thyroid enlargement and demonstrated that more than 50% of the patients have non-bleeding downhill varices. Blood from the thyroid plexus flows through the inferior thyroid veins (also called thyroid ima veins) into the brachiocephalic vein. In case of obstruction of the inferior thyroid veins, blood flows *via* the deep esophageal veins leading to esophageal varices. The esophageal varices can drain into collaterals to the brachiocephalic, azygos, hemiazygos and accessory hemiazygos veins, all of which finally drain into the superior vena cava. In the present case, goiter caused compression of the internal jugular vein. Blood flow over the thyroid plexus draining into the inferior thyroid veins might bypass compression of the internal jugular vein. However, in this patient downhill varices developed and bypassed this compression, suggesting that the function of inferior thyroid veins is insufficient. Both previous thyroidectomy and recurrent goiter are possible explanations, since inferior thyroid veins can be occluded either by primary or recurrent thyroid tumors or by surgical ligation during thyroidectomy and fibrogenesis or mediastinitis secondary to surgery. In the present case, the downhill varices drained into the azygos vein as illustrated in Figure 4. Hemorrhage of downhill varices is an emergency. However, the experience with treatment is limited because of its rare bleeding propensity.

Table 1 Case reports on bleeding downhill varices associated with thyroid pathology

SVCO: Superior vena cava obstruction.

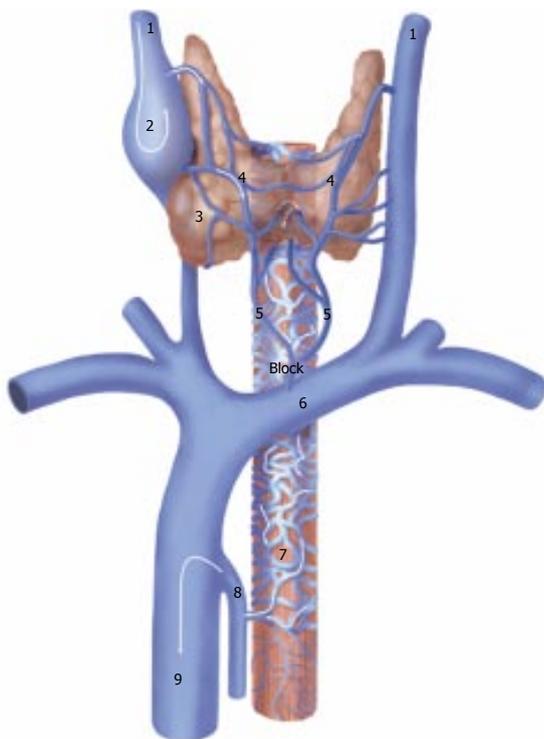

Figure 4 Venous blood flow of the downhill varices in relation to goiter. 1: internal jugular vein; 2: dilated right internal jugular vein; 3: goiter with compression of the right internal jugular vein; 4: thyroid plexus draining into the esophageal varices; 5: inferior thyroid vein; 6: brachiocephalic vein; 7: varices around the esophagus; 8: azygos vein; 9: superior vena cava; Block: Occlusion of the inferior thyroid vein, possibly as a result of previous surgery or recurrent goiter.

In contrast to uphill varices, endoscopic sclerotherapy is not generally performed to treat downhill varices up to 5 cm below the upper esophageal sphincter, because retrograde flow of sclerosant through the azygos vein

could result in spinal cord and vertebral body infarction^[15]. Fatal pulmonary embolism of cyanoacrylate used for endoscopic embolization of downhill varices has also been reported^[11]. Therefore, downhill varices should be recognized and distinguished from uphill varices. The use of a Sengstaken-Blakemore tube can be lifesaving^[8]. Endoscopic band ligation has been shown to be effective in preventing recurrent bleeding of downhill varices^[2]. Finally, definitive treatment is performed to eliminate the cause of venous obstruction. As in this patient, surgery can successfully relieve obstruction. For goiter-related downhill varices iodine therapy can also be effective^[8].

In conclusion, downhill varices although rare, can cause upper gastrointestinal bleeding and should be suspected in any patient with evidence of thyroid enlargement or having a history of thyroid surgery, even though signs of superior vena cava obstruction are absent. Management of the underlying cause, as in this case by thyroidectomy, can efficiently lead to recovery and disappearance of the esophageal varices.

Abstract

Hepatic venous outflow obstruction after piggyback liver transplantation is a very rare complication. An unusual mechanism aggravating it is reported. A 33-year-old man with end-stage hepatitis B liver cirrhosis underwent a piggyback orthotopic liver transplantation using a full-size cadaveric graft. Two months after transplantation, he developed gross ascites refractory to maximal diuretic therapy. Doppler ultrasound showed patent portal and hepatic veins. Serial computed tomography scans revealed a hypoperfused right posterior segment of the liver which subsequently underwent atrophy. Hepatic venography demonstrated a high-grade stenosis with an element of torsion of venous drainage at the anastomosis. The stenosis was successfully treated with repeated percutaneous balloon angioplasty. The patient remained asymptomatic six months afterwards with complete resolution of ascites and peripheral edema. We postulate that liver allograft segmental hypoperfusion and atrophy may aggravate or result in a hepatic venous outflow problem by the mechanism of torsion effect. Percutaneous balloon angioplasty is a safe and effective treatment modality for anastomotic stenosis.

INTRODUCTION

Hepatic venous outflow obstruction after piggyback

orthotopic liver transplantation is a rare complication^[1,2]. However, failure of early recognition and treatment of this complication can result in graft failure and even death of patients. We report here a case of hepatic venous outflow obstruction after piggyback orthotopic liver transplantation aggravated by an unusual mechanism and its successful treatment with percutaneous balloon angioplasty.

CASE REPORT

A 33-year-old man underwent cadaveric orthotopic liver transplantation for end-stage hepatitis B liver cirrhosis. A full-size graft was used and the caval anastomosis was performed with piggyback technique. Two weeks after transplantation, he was noted to have persistent leukocytosis ($27-37 \times 10^9/L$) though he was afebrile. A computed tomography (CT) scan of the abdomen was arranged to rule out intraabdominal collection or abscess formation. It revealed an extensive wedge-shaped region of low attenuation and decreased perfusion involving the right posterior segment of the liver graft, suggestive of an evolving infarct (Figure 1). He was treated conservatively with antibiotics and his white blood cell count gradually returned to a normal level.

Six weeks later, the patient developed rapidly progressive abdominal distension and edema in the lower limbs. Ultrasound of the abdomen showed gross ascites, but the portal and hepatic veins were patent. The ascites failed to respond to maximal diuretic therapy and paracentesis. He subsequently underwent a venography which demonstrated a high-grade stenosis with an element of torsion of venous drainage at the anastomosis (pressure gradient 33 mmHg) (Figures 2 and 3). A repeated CT scan showed that the right posterior segment (previously hypoperfused segment) underwent atrophy (Figure 4). The venous outflow obstruction was treated with repeated percutaneous balloon angioplasty with a 10 mm and a 14 mm balloons (Figure 5A, 5B). Pressure gradient across the venous anastomosis was successfully reduced from 33 mmHg to 2 mmHg. The patient remained asymptomatic six months afterwards with complete resolution of ascites and peripheral edema.

DISCUSSION

Standard orthotopic liver transplantation, as described by Starzl *et al*^[3] in 1963, involves an anhepatic phase during which the retrohepatic vena cava is resected. The main drawback of this classical technique is the decrease in venous return to the heart during this anhepatic

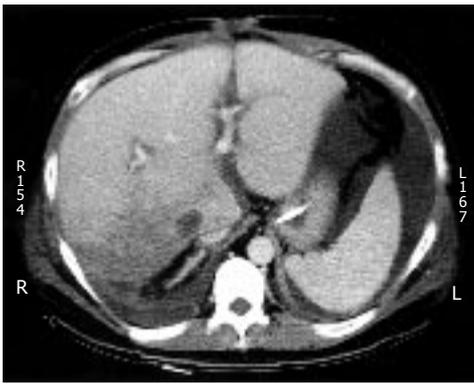

Figure 1 Computed tomography scan showing hypoperfusion at the right posterior segment of the liver graft.

Figure 3 Selective hepatic venogram showing high-grade stenosis at the caval anastomosis.

phase, which causes haemodynamic instability and renal impairment. The introduction of the extracorporeal venovenous shunt has circumvented these physiological complications from occurring. In late 1960s, an alternative technique with vena cava preservation was described by Sir Roy Calne *et al*^[4]. This technique was modified by Tzakis *et al*^[5] in 1989 and has become the well known piggyback technique since then. It has the advantages of preservation of the vena caval blood flow and maintenance of venous

return to the heart in the anhepatic phase. Haemodynamic alterations are avoided without the need of venovenous bypass. Many transplant centres are now favouring the piggyback technique as the technique of choice in both paediatric and adult liver transplantation.

Hepatic venous outflow obstruction from anastomotic stricture is a very rare complication after piggyback orthotopic liver transplantation, particularly in adult recipients who receive full-size liver grafts. In a retrospective study of 1112 piggyback liver transplantations performed in seven transplant units in Spain, the reported incidence of hepatic venous outflow obstruction is about 1%^[1]. In another review of 264 piggyback transplantations performed at Stanford University Medical Center, only two patients were found to have developed venous outflow obstruction, representing an incidence of 0.8%^[2]. The causes of hepatic venous outflow obstruction after piggyback liver transplantation are generally believed to be due to either anastomotic discrepancy or kinking of the venous anastomosis^[6,7]. Paediatric recipients receiving reduced-size liver grafts are more prone to develop this complication because of size discrepancy between the donor suprahepatic vena cava and the recipient vein cuff. The presence of a wide empty subphrenic space and the lack of peritoneal attachments are other possible factors that permit a small liver graft to rotate around the venous anastomosis axis and hence lead to anastomotic kinking

and obstruction. In adult liver transplantation, graft torsion is less likely to happen if a full-size graft is used because this effect is virtually eliminated by the presence of both liver lobes.

In our patient, a full-size liver graft was used, and theoretically the risk of graft torsion and venous anastomotic kinking should be very low. However, this rare complication of hepatic venous outflow obstruction still arose. On serial CT scans of the abdomen after transplantation, the right posterior segment of the liver graft was shown to be ischaemic and hypoperfused initially. The subsequent atrophy of the same segment resulted in rotation which in turn led to the kinking of the venous anastomosis. This unusual mechanism of hepatic venous outflow obstruction after piggyback liver transplantation, to the best of our knowledge, has never been described in the literature before.

Patients with hepatic venous outflow obstruction usually present with massive ascites and bilateral lower limb edema between 2 and 16 mo post-transplantation, which is refractory to oral protein supplements and maximal diuretic therapy^[1,2]. Some of the patients can develop acute Budd-Chiari syndrome early within the first week of post-transplantation^[1]. Failure of recognition of this complication can result in graft failure and death of patients. Diagnosis must be confirmed by hepatic venography and a pressure gradient study. Emergency revision of anastomosis or even retransplantation is occasionally required to remedy the condition. Nowadays with the advancement of minimally invasive endovascular intervention, selected cases of hepatic venous outflow obstruction can be successfully treated with percutaneous balloon angioplasty and stenting^[2,8,9]. The procedure is done under local anaesthesia with minimal morbidity and mortality. Symptoms of ascites and peripheral edema are relieved rapidly and dramatically after the treatment. Repeated balloon angioplasty is sometimes needed to treat recurrent stenosis. The combination of balloon angioplasty and stenting can improve the long-term durability of the treatment.

In conclusion, liver allograft segmental hypoperfusion and atrophy may aggravate or result in hepatic venous outflow obstruction by the mechanism of torsion effect. Hepatic venous outflow obstruction should be considered in all patients who present with intractable ascites after liver transplantation. Venography is mandatory for diagnosis. Percutaneous balloon angioplasty is a safe and effective treatment modality for anastomotic stenosis.

Abstract

Primary squamous cell carcinoma (SCC) of the liver is rare. Totally nine such cases have been reported in the literature. Primary SCC of the liver has been reported to be associated with hepatic teratoma, hepatic cyst, or hepatolithiasis. Complete remission of poorly differentiated SCC of the liver could be achieved by systemic chemotherapy followed by surgery or remarkably respond to hepatic arterial injection of low dose chemotherapeutic drugs. Here we report the first case of primary SCC of the liver presenting as a solid tumor and receiving successful hepatic resection with 9-mo disease free survival.

INTRODUCTION

Primary squamous cell carcinoma (SCC) of the liver is rare and reported sporadically. It has been reported to be associated with hepatic teratoma, hepatic cysts, or hepatolithiasis^[1-3]. Boscolo showed that a case of complete remission of poorly differentiated SCC of the liver could be achieved by systemic chemotherapy followed by surgery^[4]. Kaji demonstrated that a case of primary SCC of the liver could remarkably respond to hepatic arterial injection of low dose chemotherapeutic drugs^[5].

To our knowledge, a total of nine cases of primary SCC of the liver have been reported and here we report a case presenting as a solid tumor and receiving successful hepatic resection with disease free survival for 9 mo^[1-9].

CASE REPORT

A 40-year-old man presented with right upper quadrant (RUQ) pain for several weeks before admission in September 2005. He did not drink alcohol, smoke, or have hepatitis or a history of surgery. On admission, he had a fever and temperature elevated to 38°C. There was no vomiting, jaundice, dysuria, chills, or abdominal distention. Physical examination revealed tenderness over the RUQ area without a palpable abdominal mass. The following laboratory data were recorded: hemoglobin 13.5 g/dL; white blood cell count 14 600/mm³; platelet: 421 000/μL; prothrombin time (test/normal control): 13.4/11.2 s; international normalized ratio (INR): 1.19; albumin: 3.8 g/dL; direct bilirubin: 0.3 mg/dL; total bilirubin: 0.6 mg/dL; aspartate aminotransferase (AST): 28 IU/L; alanine aminotransferase (ALT): 5 IU/L; alkaline phosphatase (ALP): 163 U/L; blood urea nitrogen: 16 mg/dL; creatinine: 1.2 mg/dL; sodium: 131 meq/L; potassium: 4.1 meq/L; calcium: 10.5 mg/dL; C-reactive protein: 172.78 mg/L. The serum level of carcinoembryonic antigen (CEA) (< 5 ng/mL), alpha-fetoprotein (AFP) (< 15 ng/mL), and carbohydrate antigen 19-9 (CA 19-9) (< 37 U/mL) were 3.06 ng/mL, < 3 ng/mL, and 4.78, respectively. The plasma retention rate of indocyanine green (ICG) at 15 min was 0.21%. Subsequent abdominal ultrasonography (US) showed a mixed echoic mass about 7.8 cm occupying S5 of the right lobe of the liver (Figure 1A). The abdominal computed tomography (CT) showed a 9.5 cm × 7.0 cm irregular mass with inhomogeneous density and mild delayed enhancement in the central zone of the tumor near the gallbladder, at S5 of right lobe of the liver (Figure 1B). Angiography showed a large tumor with neovascularity and stretching the feeding arteries, located at S5 of right lobe of the liver. Diagnosis of a liver mass with hypervascularity at S5 of the right lobe of the liver was considered (Figure 1C).

In October 2005, we performed extended right lobectomy and cholecystectomy to remove the liver mass. Intra-operative finding showed non-cirrhotic liver with a 10 cm × 8 cm hard and white tumor mass with central necrosis located at S4, 5 and 6 (mainly S5) with no tumor rupture and no hemoperitoneum. The resection margin

Figure 1 A: Abdominal ultrasonography (US) shows a mixed echogenic mass about 7.8 cm occupying S5 of right lobe of the liver; B: Abdominal computed tomography (CT) shows a 7 cm x 9.5 cm irregular mass with nonhomogeneous density and mild delayed enhancement in the central zone of the tumor near the gallbladder, at S5 of right lobe of the liver; C: Angiography shows a large tumor with neovascularity and stretching the feeding arteries, located at S5 of right lob of the liver.

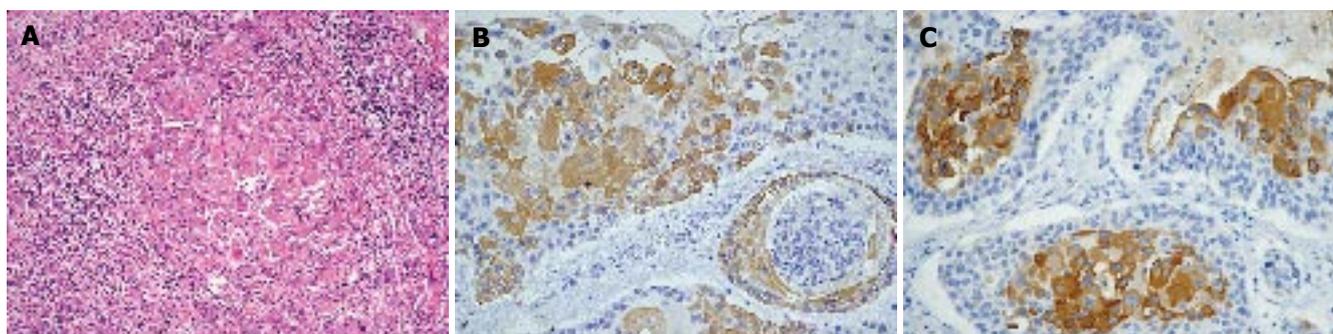

Figure 2 A: Microscopic findings of the resected liver tumor. The tumor is composed of squamous cells with keratinization (HE x 200); B: Squamous cells express strong positive CK14 staining immunohistochemically (IHC x 200); C: Squamous cells express strong positive CK10 staining immunohistochemically (IHC x 200).

was 2.0 cm in width.

Histopathological examination showed moderately differentiated SCC of the liver composed of squamous cells with keratinization (Figure 2A). An immunohistochemical study revealed positive for cytokeratin (CK) 10, CK14, CK19 and CEA. The occasional positivity for CK18 but negativity for thyroid transcription factor-I (TTF-1) indicated that it could be a primary SCC of the liver (Figure 2B, 2C). Subsequent panendoscopy showed negative findings for the esophagus. Chest CT revealed no mass over the lung field and ENT survey showed a negative finding in the oral cavity and nasopharynx. Postoperative course was uneventful and no tumor recurrence and distant metastasis developed during a 9-mo follow-up period.

DISCUSSION

Primary SCC of the liver is very rare. Although the carcinogenesis has been proposed of tumor transformation from chronic inflammation of the biliary epithelium or metaplastic and subsequent neoplastic transformation of pre-existing cysts of the liver^[1-3,8], as shown in this case, the true mechanism is still unknown.

Here, we reported the first case of SCC of the liver, presenting with a solitary solid tumor without parasitic infection and curatively treated by hepatic resection successfully. In this case, the pathology report

showed moderately differentiated SCC composed of squamous cells with keratinization. The positive staining of an acidic CK 14 indicated basal cells of keratinized squamous epithelium origin of the cancer cell. The strong, diffuse expression of biliary CK 19 confirmed the biliary ductular ontogeny of the neoplastic cells. Thus tumor transformation from chronic inflammation of the biliary epithelium might explain its origin. Because TTF-I, an indicator of small cell carcinoma of the lung or thyroid is negative, metastatic lung or thyroid cancer to the liver could be ruled out. Clinically, panendoscopy, chest CT, and ENT examination revealed negative findings in the case. Taken together, the tumor could be a primary SCC of the liver^[10,11].

The prognosis of primary SCC of the liver is dismal with overall survival less than one year^[7-9], because the tumor is usually diagnosed late. Complete remission of poorly differentiated SCC after systemic chemotherapy (cisplatin and 5-fluorouracil) and surgery has been reported^[4]. Hepatic arterial injection of low dose anti-cancer drugs (cis-diaminedichloroplatinum) (CDDP) and 250 mg of 5-fluorouracil (5-FU) could achieve remarkably good response^[5]. As shown in the case, the postoperative course was smooth with disease free survival for 9 mo. Aggressive and meticulous follow up is needed. If tumor recurrence is detected, re-hepatectomy, systemic chemotherapy (cisplatin and 5-fluorouracil), or hepatic arterial infusion of low dose chemotherapy could

be considered^[4,5].

In summary, we describe the first case of a primary SCC of the liver presenting as a solitary solid tumor, and non-parasitic infection, successfully treated by surgical resection. Postoperative course was uneventful with 9-mo disease free survival. Aggressive and meticulous follow-up is warranted.

Abstract

Internal herniation is one of the rare reasons of intestine clog, which is hard to diagnose and usually needs an urgent surgical treatment. We report 3 patients with internal herniation in the mesenteric cavity of the terminal ileum. Besides intestinal congestion, they also had peritoneal irritation. Laparotomy revealed that herniation caused disorder in nutrition of the intestine and necrosis. The patients underwent subtotal small intestine resection and were discharged 10, 12 and 14 d after operation.

<http://www.wjgnet.com/1007-9327/12/5422.asp>

INTRODUCTION

Internal herniation in intestine or in mesenteric cavities is a rare cause of intestinal congestions, accounting for less than 1% of intestinal congestions^[1]. Among the internal herniations, transmesenteric hernias constitute 12% of all intestinal hernias, 53% of intestinal hernias are seen in ileocecal area. In such hernias, there is no hernia bladder. Since the mesenteric cavities are narrow, strangulation is commonly seen and usually requires a surgical treatment^[1,2].

CASE REPORT

The first case was a 63-year-old male patient with the

complaint of common abdominal pain, intestinal gas and constipation, nausea and vomiting for 3 d. Physical examination revealed abdominal distension, defence, rebound tenderness and hypoactive bowel sounds. Other examinations were normal with no sign of previous abdominal surgery.

Laboratory examinations showed 11 000/mm³ leucocytes, 450 mg/dL glucose, 64 mg/dL BUN, 0.9 mg/dL creatine, other routine laboratory examinations were normal. Plain X-ray of the abdomen revealed a common air-fluid level on small intestine (Figure 1).

The second case was a 23-year-old male patient with the complaints of common abdominal pain, nausea, vomiting, intestinal gas and constipation. He had no history of any abdominal surgery. Physical examination showed abdominal sensitivity, defence and rebound tenderness, but no bowel sounds. Other examinations were normal. Laboratory examinations revealed 17 000/mm³ leucocytes, other laboratory examinations were normal. Plain X-ray of the abdomen showed a common air-fluid level in small intestine.

The third case was a 69-year-old male patient with the complaint of common abdominal pain, intestinal gas and constipation for a day. Physical examination showed abdominal distension and rebound tenderness, and a 10 cm × 10 cm mass in the lower right quadrant with hypoactive bowel sounds. Other examinations were normal. Laboratory examinations revealed 15 700/mm³ leucocytes, 82 mg/dL BUN, 0.7 mg/dL creatine. Plain X-ray of the abdomen, especially in the lower right quadrant displayed an intensified multiple air-fluid level in small intestine. All the three patients underwent surgical treatment with a pre-diagnosis of acute abdomen. Abdominal examination showed that most of the small intestines were passing through the cavity in the terminal ileum with a total disorder of nutrition and necrosis (Figures 2 and 3). All patients who underwent subtotal small intestine resection had diarrhea after surgery. They were treated with changed diet and medicine, and discharged 10, 12 and 14 d after operation.

DISCUSSION

The most common reason for intestinal congestion is the adhesions due to previous surgical operations (64%-79%)^[1]. The other reasons are incarcerated hernias in the abdominal wall, invagination, inflammatory bowel disease, trauma, bile stones, congenital atresia or stenosis, meckel diverticulum and internal herniations^[3,4].

Figure 1 Plain X-ray of the abdomen.

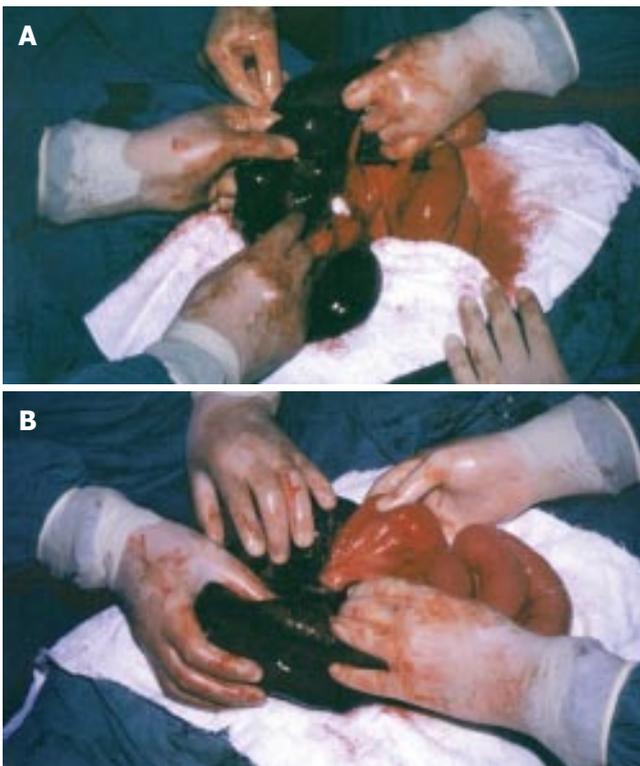

Figure 2 Disorder of nutrition(A) and necrosis (B) in terminal ileum.

Internal herniation, one of the rare causes, occurs as a result of herniation of the abdominal organs in openings or cavities of the peritoneum^[5]. Herniations are mostly due to anatomic structures such as paraduodenal fossa, and epiploic foramen, defects in mesentery and falciform ligaments^[3].

Also, intestinal rotation anomalies and peritoneal adhesions are causes of intestinal obstruction^[6]. The most common internal herniations according to their anatomic localizations are classified as follows: paraduodenal hernia, foraminal and pericecal, intersigmoidal, transmesenteric, transomental and retroanastomotic hernia^[5-8]. Mesenteric defect in the terminal ileum was found in our three patients who had no previous abdominal surgery or organ anomaly.

Internal herniations may cause chronic digestion disorders, postprandial pain and repetitive intestinal congestion.

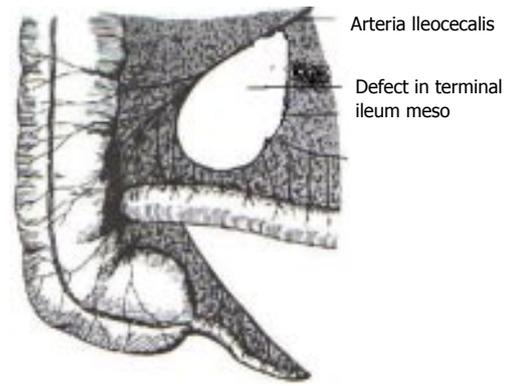

Figure 3 Defect in mesenteric cavity of terminal ileum (modified from figure published on Ankara Cerrahi Dergisi 2001; 3: 214).

Pain can be stopped by changing position. Vomiting is a common symptom and a quarter of the patients may have constipation. When the patients are given medical treatment due to these complaints, they sometimes can develop peptic ulcer or bile and biliary tract disease^[5]. Physical examination may show abdominal distension^[1]. The findings of laboratory and radiology support the diagnosis of intestinal congestion^[9]. Although no repetitive intestinal congestion was found in our patients, all of them had the main symptoms of intestinal congestion, such as abdominal pain, distension, intestinal gas, constipation, nausea and vomiting. In the preoperative period, the diagnosis is intestinal congestion, but it is almost impossible to diagnose internal herniation. Acute abdomen may develop into acute intestinal angina or malignancy in old patients, in which case laparotomy should be considered. Laparotomy can be performed in young patient with ileus and acute abdomen.

In conclusion, abdominal front wall herniation or malignancy should be considered first in adult patients with intestinal obstruction and previous surgical operations. Intestinal congestion may be caused by internal herniation in patients without such symptoms.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents/Clinical Medicine and Science Citation Index-Expanded, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, Nature Clinical Practice Gastroenterology and Hepatology, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology

Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
<http://www.wjgnet.com>
Telephone: +86-10-85381901
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is

Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

Key words

Please list 6-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P*<0.05, ^b*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, ^c*P*<0.05 and ^d*P*<0.01 are used. Third series of *P* values can be expressed as ^e*P*<0.05 and ^f*P*<0.01. Other notes in tables or under illustrations should be expressed as ¹*F*, ²*F*, ³*F*; or some other symbols with

a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (<http://www.wjgnet.com/cgi-bin/index.pl>), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 µg/L; CO₂ volume fraction, 50 mL/L CO₂ not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please download CAF from <http://www.wjgnet.com/wjg/help/9.doc>.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to *WJG* all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The *WJG* requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1) direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3) supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The *WJG* does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to *WJG* if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Final check list for authors

The format is at: <http://www.wjgnet.com/wjg/help/13.doc>

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: <http://www.wjgnet.com/wjg/help/10.doc>

Abstract

The hepatic sinusoids are lined by a unique population of hepatic sinusoidal endothelial cells (HSEC), which is one of the first hepatic cell populations to come into contact with blood components. However, HSEC are not simply barrier cells that restrict the access of blood-borne compounds to the parenchyma. They are functionally specialised endothelial cells that have complex roles, including not only receptor-mediated clearance of endotoxin, bacteria and other compounds, but also the regulation of inflammation, leukocyte recruitment and host immune responses to pathogens. Thus understanding the differentiation and function of HSEC is critical for the elucidation of liver biology and pathophysiology. This article reviews methods for isolating and studying human hepatic endothelial cell populations using *in vitro* models. We also discuss the expression and functions of phenotypic markers, such as the presence of fenestrations and expression of VAP-1, Stabilin-1, L-SIGN, which can be used to identify sinusoidal endothelium and to permit discrimination from vascular and lymphatic endothelial cells.

INTRODUCTION

The liver has a unique dual blood supply receiving blood from both the portal vein and the hepatic artery. Unlike other organs, which are supplied by arterial blood through arterioles, the liver receives venous blood at low pressures through the portal vein as well as arterial blood *via* the hepatic artery. The intrahepatic portal venous system consists of conducting and distributing systems that ensure blood is carried throughout the parenchyma and evenly delivered to individual hepatocytes *via* the sinusoidal network^[1]. A uniform and strict branching pattern appears at the level of the terminal vessels and is maintained throughout the distributing system. The first order branches of the distributing system arise from the terminal branches of the conducting system and give rise to second order vessels of approximately 70 μm diameter that correspond to the terminal portal vein branches seen in portal tracts. Third order vessels arise from these and correspond to the septal or interlobular branches. These exhibit a classical sinusoidal appearance, lack a connective tissue sheath and have no basement membrane. The distributing system then branches into the hexagonal lobule before draining into the hepatic vein. The hepatic artery supplies 25% of hepatic blood flow and provides blood to both the parenchyma and the portal tracts. Axial hepatic arterial branches run parallel to the conducting portal veins and terminate in inlet venules, terminal portal veins and the sinusoids, thereby supplying blood to the parenchyma. The axial arteries also give rise to peribiliary branches that supply the accompanying bile ducts and portal interstitium. These arteries form the peribiliary plexus consisting of efferent and afferent capillaries that wrap around the surface of bile ducts. Small channels from the peribiliary plexus drain into the sinusoids or portal vein branches. Thus, complex anastomoses exist between the axial arteries and peribiliary arteries^[2].

ISOLATION AND CULTURE OF HEPATIC SINUSOIDAL ENDOTHELIAL CELLS

Isolated cultures of hepatic sinusoidal endothelial cells present a valuable tool for the study of liver physiology and pathophysiology. Most published studies used cells isolated from rodent livers and have defined the role of fenestrations and specific receptors in uptake and

processing of circulating factors including pathogens (reviewed in^[3]). Most investigators use a combination of enzymatic digestion and density gradient centrifugation to isolate HSEC from liver tissue although there is considerable variation in the protocols used by different groups and for cells from different species. HSEC from rodents are commonly isolated by enzymatic digestion, either by perfusion of an intact organ with an enzymatic cocktail or by mechanical disruption followed by enzymatic digestion^[4-7]. The cell suspension generated by such methods is fractionated using differential centrifugation techniques, including counterflow elutriation or density gradient centrifugation. Endothelial cells are then grown on matrix coated flasks in selective growth media containing growth factors.

Similar methods can be used to isolate HSEC from human liver samples^[8-10] and between 10^3 - 10^6 cells have been isolated from whole livers unsuitable for transplantation^[9]. However, the limited access to intact human liver means that most groups use diseased tissue removed at transplantation or surgical resection or biopsy specimens that generate low numbers of cells per isolation. Nevertheless, successful isolation is aided by the large numbers of HSEC relative to other vascular endothelial cells present in the liver. Some researchers further reduce the potential of contaminating vascular endothelium by excising visible large vascular structures from the liver tissue prior to enzymatic digestion. Although several different isolation procedures have been described these are not all equally effective in our hands. Our experience, and that of other groups, suggests that counterflow elutriation alone is not useful for selection of human HSEC from a mixed non-parenchymal cell preparation as most of the cells have similar centrifugal densities^[6,11]. This led us to routinely include a step of immunomagnetic depletion to remove common contaminating cell populations, such as biliary epithelial cells, followed by positive selection of endothelial cells using antibody against CD31 (see later)^[10]. Similar methods using magnetic beads coated with *Evonymus europaeus* agglutinin have been used to isolate HSEC from the liver of other primates^[12] and there are now commercial antibody-based magnetic kits for isolation of rodent HSEC. Despite these refinements there is considerable variability in the yield and viability of cells obtained from diseased human liver tissue. Thus, although there are compelling reasons to study human HSEC *in vitro* low cell yields mean that it is difficult to use primary cells without passage.

PROBLEMS WITH EXISTING PHENOTYPIC MARKERS AND USE OF HSEC IN MONO-CULTURE

As scientific technology advances it is possible to carry out increasingly complex genetic, proteomic and functional analyses on cells grown in culture. However such techniques require highly purified populations of cells of defined phenotype. Some of the methods previously used to confirm HSEC purity and phenotype, such as AcLDL uptake^[8] and binding of *Ulex lectin*^[8], are

not specific. For example, other hepatic cell populations, including dendritic cells, take up AcLDL and *Ulex lectin* binds to fucosylated receptors on both Kupffer cells and HSEC^[13]. Similarly, endothelial cells share many cell surface receptors with leukocytes, including CD31, CD4^[14], CD11b, and CD11c^[11], which may contaminate endothelial cell preparations in culture. Care also needs to be taken when using antibody staining to define HSEC phenotype because HSEC express high levels of *FcγR*^[15] allowing them to bind antibodies non-specifically. In light of such problems, it has been suggested that the presence of open fenestrations arranged in sieve plates is the only true marker of hepatic sinusoidal endothelial cells^[16]. These pores are indeed classic features of liver sinusoidal endothelial cells *in vivo* but present problems when used to identify cells *in vitro* (see below).

All of these problems are compounded by the fact that HSEC are most commonly cultured as a monolayer of cells on matrix-coated tissue culture plates *in vitro*. This perturbs the normal morphology of the cells and they become flattened and rapidly lose fenestrations. Part of this effect may be the loss of paracrine signals from other cells of the sinusoid that maintain the phenotype and differentiation of HSEC *in vivo*. For example, crosstalk between hepatic sinusoidal endothelial cells and closely juxtaposed hepatocytes is essential for the maintenance of sinusoidal endothelial cell growth and differentiation. This is demonstrated by studies where implantation of foetal liver fragments into quail chorioallantoic membrane resulted in the acquisition of a sinusoidal phenotype by the chorioallantoic microvessels^[17] and also *in vitro* studies where co-culture of HSEC with other liver cells resulted in a more stable endothelial phenotype and function^[18]. Thus, markers used to determine phenotypes of HSEC must take into account alterations in phenotype as a consequence of culturing cells in isolation in the absence of local paracrine signals.

FENESTRATIONS

Endothelial cells throughout the adult organism are derived from common early embryological precursors and have broadly similar functions and histological appearance. However, there is important organ and tissue-specific heterogeneity that results in phenotypic and functional variations (reviewed in^[19]). For example, high endothelial venules in lymph nodes are lined by morphologically and phenotypically distinct endothelial cells that have the unique ability to promote the recruitment of naïve lymphocytes whereas lymphatic endothelium express several receptors that allow uptake of macromolecules found in lymph^[20]. Sinusoidal endothelial cells are found in the spleen and bone marrow, as well as in the liver, and in all these sites they have a minimal basement membrane and lack classical tight junctions. Hepatic sinusoidal endothelium differs from sinusoidal endothelium in these other beds by its discontinuous nature, being interspersed with kupffer cells and by the presence of open fenestrations arranged in sieve plates^[16].

The vascular architecture in the human liver develops by 17-25 wk of gestation, and the sinusoids acquire their

Table 1 The expression of classical markers of endothelial phenotype by human sinusoidal endothelial cells

Marker	Extra-hepatic endothelial expression	Sinusoidal endothelial cells <i>in vivo</i>	Sinusoidal endothelial cells <i>in vitro</i>	Problems with use in phenotyping?
CD31	Vascular and lymphatic endothelial cells	Yes, but at low levels	Yes	Widely expressed on all EC thus not specific for HSEC
vWF	Vascular endothelial cells	Controversial, Yes	Yes	Widely expressed on all EC thus not specific for HSEC
Ulex lectin binding	Endothelial cells	Yes	Yes	Widely expressed on all EC thus not specific for HSEC
Uptake of AcLDL	Endothelial cells	Yes	Yes	Also taken up by macrophages in liver and other EC
CD34	Vascular and lymphatic endothelial cells	No	Absent or low	May be upregulated during capillarisation or with passage <i>in vitro</i>
E-Selectin	Vascular endothelial cells	Low or absent under normal conditions	Low, can be upregulated by cytokines	Widely expressed on activated vascular EC, not specific for HSEC
Pal-E antigen	Vascular endothelial cells	No	No?	May be upregulated during capillarisation
CD105/endoglin	May be upregulated during capillarisation	Yes	Yes	Widely expressed on all EC, also by stellate cells and fibroblasts in liver

While many of the above markers are indeed expressed on hepatic sinusoidal endothelial cells and provide a means of confirming "sinusoidal endothelial identity", none is specific to sinusoidal endothelial cells.

distinctive fenestrated phenotype by wk 20 (reviewed in^[21]). The fenestrations act as a 'dynamic filter'^[3] allowing macromolecules in blood controlled access to parenchymal cells^[22]. Evidence from animal studies suggests that fenestrations constitute up to 40% of the cell and that the size, distribution and clustering of the pores in sieve plates varies with the zonal distribution of the endothelium^[23] and across the endothelial surface. Although normal hepatic sinusoidal cells in most mammals are characterised by the presence of fenestrations (reviewed in^[3]), caution must be exercised when translating these observations to human cells. Studies of fenestrations in human liver samples are rare, and suggest that the number and size of fenestrations differs from that observed in other mammals^[3]. Furthermore, the number of fenestrations per endothelial cell decreases in disease^[24,25], following viral infection^[22] or with ageing^[26]. During cirrhosis and chronic hepatitis, HSEC develop a more vascular morphology and produce a basement membrane in a process known as 'capillarisation' (reviewed in^[27]). This is associated with increased expression of CD31 and VCAM-1 and loss of fenestrations^[27]. These changes may impede the transfer of materials to and from the parenchyma and contribute towards regional hepatocyte hypoxia. Fenestrations are not unique to hepatic EC but are found in endothelium in endocrine glands, kidney, gastrointestinal tract, choroid plexus, lymphatic organs such as the spleen and are sometimes observed in tumour vasculature. Many studies have implicated VEGF as an essential factor for regulation of fenestrations in these organs (reviewed in^[28]).

Thus considerable variations in the number, size and localisation of fenestrations are seen among species and also in health and disease. The situation becomes more complex when cells are removed from the hepatic microenvironment and cultured *in vitro*. The fenestrations documented in freshly isolated rat HSEC begin to disappear within 48 h of cell culture^[29] and are almost gone within a week^[30]. We have made similar observations with human cells from normal livers and also find very few

fenestrated cells when HSEC are isolated from cirrhotic livers (Lalor and Adams unpublished observations). However, the number of fenestrations on rat HSEC can be maintained *in vitro* by the addition of VEGF and by culturing cells on extracellular matrix constituents, such as collagen, that are secreted by endothelial cells^[29,31]. Both human and rodent HSEC need growth factors and attachment to appropriate extracellular matrix molecules to survive and will rapidly undergo apoptosis in the absence of these. Thus in order to maintain cell survival, cultured HSEC must be grown in the presence of VEGF which induces and maintains expression of fenestrations as well as promoting HSEC proliferation. VEGF is also a growth factor for vascular endothelial cells which induces the production of matrix molecules essential for survival and proliferation^[32]. At higher concentrations, VEGF can induce the formation of fenestrations in vascular endothelial cells^[28,32,33] and, although these pores are not organised into sieve plates, they can be very difficult to distinguish from the fenestrations that characterise HSEC. This inducibility of fenestrations in vascular endothelial cells together with the impracticality of using electron microscopy for routine phenotyping means that the presence of fenestrations alone cannot be used to define HSEC in most experimental situations.

NORMAL 'ENDOTHELIAL' CELL PHENOTYPE AND FUNCTIONS

HSEC form a single cell barrier between the hepatocytes and the bloodstream and are strategically situated to interact with leukocytes and other blood constituents. The cells produce a minimal basement membrane^[34], which is mostly composed of type IV collagen in normal liver^[35], and have a high endocytotic capacity^[3]. They express some markers that are common to all endothelial cells and these provide a useful means to positively identify a cell of 'endothelial' lineage (Table 1).

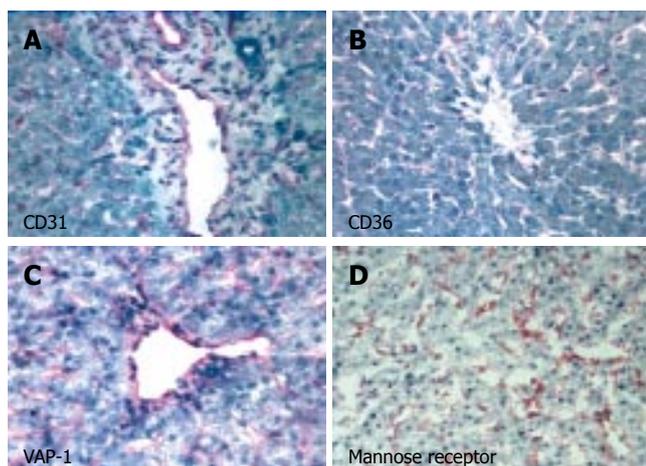

Figure 1 Human hepatic sinusoidal endothelial cells *in situ* express the classical endothelial phenotypic markers CD31 (A) and CD36 (B) as well as more recently identified markers such as VAP-1 (C) and Mannose receptor (D). Images represent immunohistochemical staining of human liver sections using specific primary antibodies in an indirect immunoperoxidase protocol with haematoxylin counterstain. Positive staining of sinusoidal endothelial cells is indicated by pink pigmentation. CD31, CD36 and VAP-1 are observed on both portal vessel endothelial cells and sinusoidal endothelium, whilst the mannose receptor is localised on sinusoidal endothelial cells and Kupffer cells.

CD31

CD31 or PECAM-1 is an abundantly expressed membrane glycoprotein member of the immunoglobulin superfamily (reviewed in^[36]). It is constitutively expressed on endothelial cells and some haematopoietic cells and has functions in cell adhesion and signalling. Expression of CD31 is used widely as a marker of 'continuous' or classical vascular endothelium, but expression of CD31 by hepatic sinusoidal endothelial cells remains controversial. In rodent studies, CD31 has been localised to normal sinusoidal endothelial cells using a variety of techniques^[4,37] and has been shown to be downregulated following CCl₄ or TNF α mediated liver injury^[37]. However, other studies suggest that the protein is absent under normal conditions^[34] and indeed a lack of CD31 has been used to characterise rodent HSEC^[7].

The situation is similarly complex in human HSEC. During human embryonic development CD31 is absent from HSEC until wk 25. In the adult, CD31 has been reported as present on HSEC by FACS and immunohistochemistry on sections from cirrhotic liver but is minimally present on normal liver^[8] or alternately present on normal liver and enhanced on cirrhotic liver^[38]. Our own data show that CD31 is expressed by both normal and diseased liver HSEC (Figures 1 and 2). In general, it seems that HSEC express lower levels of CD31 than vascular EC^[16] and our observations). However, one needs to interpret immunohistochemical analysis with caution because CD31 is present on kupffer cells in sinusoids. Studies on isolated HSEC using both PCR and antibody-based assessment of characteristic endothelial markers, such as CD31 and vWF (see below) in parallel, show varying results^[39]. Some studies suggest that subcellular localisation of CD31 can be used as a marker of HSEC phenotype to indicate whether cells have dedifferentiated in culture^[16].

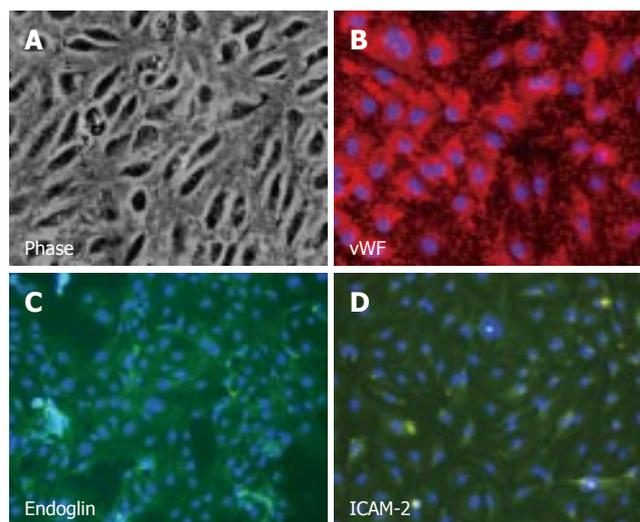

Figure 2 Isolated, cultured human hepatic sinusoidal endothelial cells exhibit classical morphology under phase contrast microscopy (A), and stain positively with antibody directed against endothelial phenotypic markers. Images represent immunofluorescent staining of cultured cells using specific primary antibodies in an indirect fluorescent protocol with DAPI nuclear counterstain (blue). Positive staining for vWF (B) is visualised using a Texas Red-labelled secondary antibody, whilst expression of endoglin (CD105, C) and ICAM-2 (D) are visualised with a FITC-conjugated secondary antibody (green).

Thus cells with cytoplasmic CD31 are 'normal' whereas dedifferentiated/capillarised EC demonstrate increased membranous expression.

Von Willebrand Factor (vWF)

vWF is a multimeric glycoprotein that binds and stabilises the coagulation factor FVIII as well as supports the adhesion of platelets to subendothelial structures during vascular damage. It is expressed by both platelets and endothelial cells and is often used as a marker to identify endothelium. In most vascular endothelial cells, von Willebrand Factor is stored in cytoplasmic vesicles called Weibel Palade bodies. Expression of vWF varies between different vascular beds *in vivo*^[40] and particularly low levels are observed in the liver, most of which is detected in vascular rather than sinusoidal endothelial cells. The low levels of vWF detected in HSEC are consistent with the reported lack of Weibel Palade bodies. However, definitive evidence supporting the presence or absence of these structures is also lacking. Studies in mice suggest that HSEC contain Weibel-Palade bodies^[41] and produce vWF at the mRNA and protein level^[4,11,41]. Other groups working with rat HSEC report that vWF is not expressed in normal rat cells^[42] and these findings are supported by porcine and rat studies showing absence of Weibel-Palade bodies in HSEC^[9,43]. In human cells, vWF expression has been reported in both normal^[18,44] and diseased samples^[45] and we and others^[8] have demonstrated expression on passaged, cultured HSEC *in vitro* (Figure 2).

E-Selectin

E-Selectin is a member of the selectin family of adhesion molecules that supports leukocyte binding. Expression of E-Selectin is restricted to cells of endothelial lineage^[46]

and is induced by inflammation *in vivo* and exposure of endothelial cells to proinflammatory cytokines and LPS *in vitro*. The ability to express E-selectin can thus be used to define endothelial cells in culture. However, expression of E-selectin is restricted to vascular endothelial cells in the normal liver^[47], although it may be upregulated on sinusoidal endothelium in disease and during metastatic processes^[48] and animal studies demonstrate a minimal role for E-selectin in leukocyte recruitment to liver tissue^[49]. However, we have reported expression of functional E-Selectin on cultured cytokine-stimulated human HSEC suggesting that HSEC can express E-Selectin under restricted circumstances *in vivo* and *in vitro*^[18]. Recent studies demonstrating that E-Selectin expression by HUVEC in response to TNF α is reduced by pretreatment with HGF suggest that paracrine factors from adjacent hepatocytes may suppress E-selectin in the sinusoids *in vivo*^[50].

Binding of lectins and Acetylated LDL uptake

The ability to bind Ulex lectin and take up acetylated LDL is often used to define HSEC. Ulex lectin, from the gorse family of plants, binds alpha-L fucose containing receptors and is commonly used as a histological marker for endothelial cells, although in some tissues it also binds epithelial structures^[51]. In the liver, different lectins bind differentially within the vasculature. Concanavalin A binds with equal affinity for all segments of the microvasculature whereas wheat germ agglutinins show preferential binding to the sinusoidal vasculature as a consequence of differences in distribution of glycosylated ligands throughout the acinus. In most studies Ulex lectins do not bind preferentially to sinusoidal endothelium as a consequence of the relative paucity of alpha-L fucose motifs. The ability of wheat germ lectins to bind sinusoidal endothelium has led to their use in selectively purifying sinusoidal EC and their preference for periportal HSEC has even led to the suggestion that they can be used to differentially purify periportal versus perivenous HSEC^[5]. Staining with Ulex lectin is increased in disease and is particularly pronounced during capillarisation of the sinusoids^[52]. Thus although binding of Ulex lectin is indicative of an endothelial phenotype, it is not restricted to 'sinusoidal' endothelial cells^[52] and is not a good marker of HSEC.

The liver is the major site for the scavenger receptor-mediated clearance of lipoproteins from the circulation. Acetylated LDL is mainly cleared by hepatic endothelial cells^[53] by binding to scavenger receptors including scavenger receptor class A (SR-AI/II). However, these receptors are expressed by both HSEC and macrophages^[54] and the ability to take up acetylated LDL is common to many extrahepatic endothelial cell populations, again reducing the specificity of acLDL uptake as a characteristic property of HSEC.

CD34

CD34 is a type 1 transmembrane sialomucin expressed by haematopoietic stem cells, capillary and lymphatic endothelial cells. CD34 is absent from most sinusoidal endothelial cells in normal liver but expression

increases^[8,27,55] during capillarisation in chronic inflammatory disease and in the sinusoidal-type vasculature within hepatocellular carcinomas^[56,57]. CD34 expression has also been shown to increase in other tissues including the rheumatoid joint and at sites of neolymphoid development during chronic inflammation. We have described CD34 positive lymphatic-like vessels in portal associated lymphatic tissue in chronic inflammatory liver diseases including PSC^[58] and hepatitis C (Heydtmann 2006 *J Immunol* in press). However, CD34 is not expressed on most HSEC in non-inflamed tissue *in vivo* and is absent from low passage human HSEC *in vitro*.

Pal-E Antigen

The antigen recognised by the Pal-E antibody is a widely used marker of vascular endothelial cells^[59-61]. The identity of the protein has been proposed as either a secreted form of vimentin produced by endothelial cells^[61] or a protein designated PV-1/FELS (plasmalemmal vesicle-1/fenestrated endothelial-linked structural protein)^[60]. PV-1 is particularly interesting in the context of HSEC. As its name implies, PV-1/FELS is expressed by fenestrated endothelial cells in the kidney and pancreas^[62] but it is absent from fenestrated hepatic sinusoidal endothelial cells^[60,62] and is restricted to vascular endothelium and neovessels in areas of capillarisation in chronic liver disease and hepatocellular carcinoma^[52,58].

Vascular Endothelial-Cadherin (VE-Cadherin)

Cadherins are a family of adhesion molecules that demonstrate cation-dependent homophilic and heterophilic binding. Endothelial cells express at least three cadherins: N-, P-, and VE-cadherin. VE-cadherin is localised to the inter-endothelial cell junction where it is an essential part of the adherens junctions that maintains endothelial permeability, monolayer integrity, morphogenesis and angiogenic responses. Most studies suggest that sinusoidal endothelium in normal liver lacks VE-cadherin or expresses it at low levels, although it can be detected in chronic inflammation^[38,63]. It seems likely that the relative lack of VE-cadherin on HSEC is a consequence of the absence of classical adherens junctions between HSEC and this is consistent with a lack of other junctional proteins, including vascular endothelial junctional adhesion molecule (VE-JAM/JAM-2), which is a member of the immunoglobulin superfamily structurally similar to JAM-1, which is absent from foetal and adult liver^[64].

CD105/endoglin

CD105 (endoglin) is a hypoxia-inducible protein that is widely expressed on endothelial cells and is upregulated during angiogenesis. It is a receptor for transforming growth factor (TGF) β 1 and β 3 and modulates TGF- β signalling by interacting with TGF- β receptors I and/or II (for review see^[65]). CD105 has been used as a marker of angiogenesis, particularly in tumour tissue^[66], and because it is a transmembrane molecule, it has been used in antibody-mediated positive selection strategies for endothelial cell isolation. However, expression of the

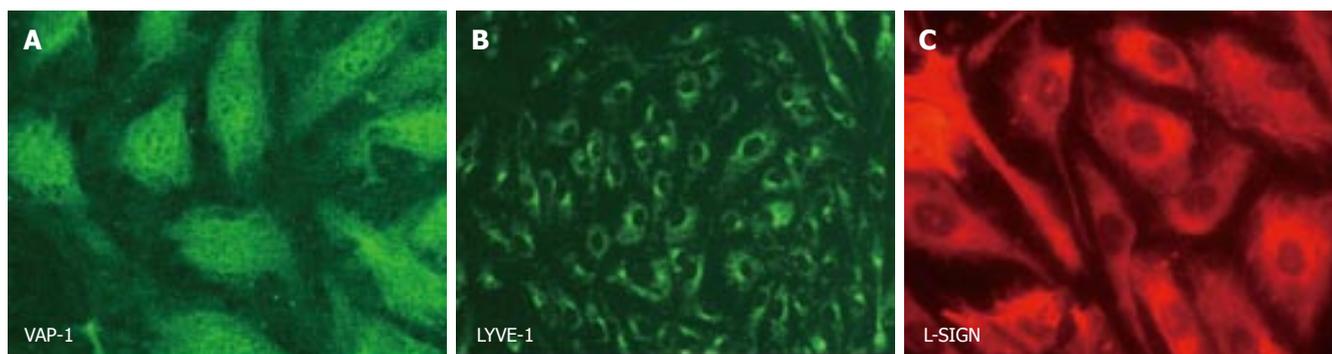

Figure 3 Cultured human hepatic sinusoidal endothelial cells stain positively with antibody directed against 'non-classical endothelial' phenotypic markers. Images represent immunofluorescent staining of cultured cells using specific primary antibodies in an indirect fluorescent protocol. Expression of VAP-1 (A) and LYVE-1 (B) are visualised with a FITC-conjugated secondary antibody (green), whilst positive staining for L-SIGN (C) is visualised using a Texas Red-labelled secondary antibody.

molecule is not restricted to endothelial cells^[65], and in the liver, expression has been reported in both stellate cells and myofibroblasts^[67]. We have demonstrated that CD105 is expressed on hepatic sinusoidal endothelial cells (Figure 2) but again emphasise that this is not a tissue- or cell lineage-specific marker and urge caution when using it as a phenotypic identifier.

NEWER MARKERS OF ENDOTHELIAL PHENOTYPE RELATE TO THE FUNCTIONS OF HSEC WITHIN THE LIVER MICRO-ENVIRONMENT

As well as exhibiting features characteristic of all endothelial cells, hepatic sinusoidal endothelial cells fulfil many specific features within the liver environment. These include providing a barrier to minimise access of blood-borne material into the parenchyma and specific protein/antigen uptake and presentation. The embryonic origins of these cells and their similarity with lymphatic endothelial cells (see later) mean that they express several markers that are not present on vascular endothelium and these can be used to distinguish them from other endothelial cells. Thus, it is possible to use protein markers related to these specific origins and functions to confirm the phenotype of HSEC *in vitro*.

Scavenger functions/lipid uptake functions of EC

The exposure of sinusoidal endothelial cells to blood originating from both the systemic circulation and the gut means that HSEC are strategically situated to remove and recycle blood-borne proteins and lipids. In combination with Kupffer cells, HSEC constitute the most powerful scavenger system in the body^[68]. The uptake of solutes is facilitated by the presence of fenestrae, the lack of a classical basement membrane and the expression of multiple scavenger receptors that allow them to bind and take up specific classes of molecules. These properties facilitate bidirectional transfer of materials to the parenchyma. Many of the scavenger receptor proteins can be used to determine the phenotype of HSEC.

The link family of proteins has recently been described

as scavenger receptors responsible for clearance of a variety of proteins, including advanced glycation end products, modified LDL and bacteria^[69]. Two members of this protein family, Stabilin-1 and -2, are constitutively expressed by hepatic sinusoidal endothelial cells^[69,70]. Stabilin-2 is the major lymph node and liver hyaluronan and glycosaminoglycan scavenger receptor whilst Stabilin-1 (also called Feel-1 or CLEVER-1^[71-73]) is a more promiscuous scavenger receptor. In common with many other scavenger-type receptors, these proteins are present on sinusoidal endothelial cells in spleen and lymph node as well as the liver. Most of the scavenger functions assigned to this molecule relate to endocytosis of hyaluronic acid, acetylated LDL and glycation end products, but there is also evidence to support roles for Stabilin-1 in leukocyte adhesion and tumour metastasis^[69,74]. Another member of the link protein family is LYVE-1, an endothelial hyaluronan receptor predominantly restricted to lymphatic endothelial cells (reviewed in^[75]). Putative functions for LYVE-1 include the uptake of hyaluronic acid and regulation of leukocyte adhesion or migration within the lymphatic circulation. Interestingly, hepatic sinusoidal endothelial cells also express LYVE-1 constitutively^[76] (Figure 3) with evidence of a zonal distribution, the highest levels being detected in acinar zone 2. This hyaluronan receptor is present on both normal and diseased human HSEC, although lower levels are observed in cirrhosis and the protein is absent in HCC^[76]. Expression is also seen on portal-associated lymphatics in chronic liver disease^[58,76].

The liver is the major site for synthesis and metabolism of cholesterol and scavenger receptors of class A (SR-A) on both KC and HSEC^[77] are responsible for the uptake of oxidised/acetylated LDL, which is subsequently passed on to hepatocytes. Another HDL/LDL receptor, CD36^[78], also known as GPIV, is expressed at high levels on platelets, monocyte/macrophages and vascular endothelial cells. In the liver, CD36 is strongly expressed on sinusoidal endothelial cells^[79] where it fulfills multiple functions including acting as a scavenger receptor for oxidised lipid^[80] and as an adhesion receptor for red blood cells infected with malarial parasite^[81]. There are two alternatively spliced members of the scavenger receptor B family (SR-BI and -B II). Scavenger receptor-B1 is expressed by HSEC and

is responsible for the uptake of HDL cholesterol esters to liver parenchymal cells and also acts as a coreceptor for HCV infection^[82].

The calcium-dependent C-type lectins, Dendritic Cell-specific ICAM-3 grabbing nonintegrin (DC-SIGN) or CD209 and the related molecule Liver/lymph node-specific intercellular adhesion molecule-3-grabbing nonintegrin (L-SIGN) or CD209L (Figure 3), are constitutively expressed on hepatic endothelial cells^[83]. DC-SIGN is expressed at high levels on myeloid dendritic cells in tissues where it interacts with ICAM-3 on T cells as part of the immunological synapse as well as being an attachment factor for HCV, ebola virus, CMV, HIV and other lentiviruses (reviewed in^[84,85]). We have recently reported that DC-SIGN is present on hepatic sinusoidal endothelial cells and that expression is increased in response to treatment with cytokines including IL-4^[86]. DC-SIGN on endothelial cells acts as an attachment factor for HCV but does not mediate HCV entry directly but rather enhances infection of hepatocytes in trans. DC-SIGN is absent from most other vascular beds, although it has been reported on a brain microvascular cell line^[87].

Liver/lymph node-specific ICAM-3-grabbing integrin (L-SIGN), otherwise known as DC-SIGN-related (DC SIGNR) (CD209L), shares 77% amino acid homology with DC-SIGN. Like DC-SIGN it can also bind ICAM-3, HIV and HCV. L-SIGN is strongly and constitutively expressed on sinusoidal endothelial cells in the liver and on endothelium in lymph nodes but not on DCs or on endothelium in other tissues. L-SIGN is thus an excellent marker of liver endothelium^[44,88]. A related molecule, Liver and Lymph node Sinusoidal Endothelial C-type lectin (LSEctin) is also expressed on sinusoidal endothelial cells and has recently been demonstrated to mediate attachment of filovirus and coronavirus particles^[89]. Thus sinusoidal endothelial cells^[90] can bind a wide variety of pathogens after which they pass hepatotropic viruses on to adherent hepatocytes in trans^[91] thereby concentrating viral pathogens within the liver.

Antigen presentation by HSEC

As well as being equipped with scavenger receptors that facilitate efficient uptake of viruses and potential antigens, HSEC also have the ability to phagocytose particles and to present antigen to lymphocytes (reviewed in^[92-94]). There is evidence that such interactions are important for generating immunological tolerance to gut-derived antigens although recent work suggests that local antigen presentation cannot explain liver tolerance and that, on the contrary, the liver may be an excellent priming site for naive CD8+ T cells^[95]. Antigen presentation is facilitated by the expression of MHC class I and II^[96,97] molecules together with co-stimulatory molecules such as CD40 and more contentiously CD80 and CD86^[98]. These receptors are upregulated on HSEC in fulminant liver failure^[99] and may contribute to disease pathogenesis by allowing ongoing presentation of stimulatory antigen. HSEC also express the mannose receptor (Figure 1), a 175 kDa transmembrane glycosylated protein involved in uptake of Ag by both DCs and HSEC^[97]. Competitive inhibition

of this receptor by mannan reduces antigen-specific T cell activation by murine HSEC^[97].

Similarities between lymphatic endothelial cells and sinusoidal endothelium

Both the liver and pancreas develop from buds of the embryonic endoderm^[100], however, the vasculature components of the liver have distinct origins. The portal vessels are derived from vitelline veins whereas the sinusoids develop from the capillary vessels of the septum transversum and acquire their distinctive fenestrated phenotype by wk 20 of gestation (reviewed in^[21]). From this point onward, sinusoidal endothelial cells remain functionally and phenotypically distinct from the other vascular endothelial cells in the liver and express several receptors that are otherwise confined to lymphatic endothelial cells that are derived from buds from the cardinal vein. Hence, both lymphatic and sinusoidal endothelial cells have minimal basement membranes, loosely organised cell junctions and constitutively express LYVE-1 and VAP-1 (SSAO/AOC3) but lack CD34 (reviewed in^[101]). VAP-1 is a type II transmembrane protein that can support leukocyte adhesion *via* interactions with sialic acid rich side chains. It is also an amine oxidase and enzyme activity is also involved in regulating leukocyte adhesion and transmigration^[101]. VAP-1 is expressed on all vascular compartments within the liver (Figures 1 and 2) where it supports the adhesion and transmigration of leukocytes^[10,102]. The only extrahepatic site where VAP-1 is constitutively expressed at high levels is endothelial cells in high endothelial venules within lymph nodes^[103] where again it is proposed to have a role directing the adhesion of lymphocyte populations^[104]. Similarly both lymphatic endothelium and HSEC express the Reeler gene product Reelin^[105]. Reelin is a secreted glycoprotein with roles in embryonic development and organisation. Expression is restricted during embryogenesis but in the adult organism high levels are detected on lymphatic endothelial cells and within the sinusoids localised either to stellate cells^[106] or HSEC^[105]. This has led to the hypothesis that reelin may be involved in the regulation of lymphoangiogenesis or regulation of lymphatic endothelial phenotype and thus may have similar roles within the liver sinusoids.

Thus there are many similarities between HSEC and lymphatic endothelial cells and some antigens originally defined on lymphatic endothelium can also be used to differentiate between HSEC and vascular endothelial cells in the liver. It is possible to exclude contamination with lymphatic EC in HSEC cultures on the basis that LYVE-1 positive HSEC do not express PROX -1, a transcription factor found exclusively in lymphatic EC^[107].

CONCLUSIONS

Cultures of endothelial cells are valuable tools to investigate mechanisms of liver physiology and pathophysiology *in vitro*. However, the study of endothelial cells *in vitro* is complicated by the marked heterogeneity of endothelial cells between and within different organs and the tendency for cells to lose tissue-specific markers

when cultured *in vitro*. Although all endothelial cells share some characteristic features (as described in the first part of this review), there is a need for specific markers or combinations of markers that define distinct populations of endothelial cells. To date, the study of HSEC *in vitro* has been hampered by the lack of specific markers that can conclusively identify these cells and discriminate them from vascular or lymphatic endothelial cells. To some extent this remains the case, since many classical endothelial markers are widely expressed (Table 1) and there is considerable reported variability in detection of phenotypic markers between animal and human systems (eg CD31 and vWF). To date there is no known single molecule that is only expressed on hepatic sinusoidal and no other type of endothelia. However, the increasing knowledge of endothelial receptors is providing us with a larger and better defined set of phenotypic markers. In addition to their use in phenotyping or sorting/selecting specific endothelial cells for culture, receptors that show tissue-specific expression provide clues to specific functions of the cells being studied. Examples of this are the large number of scavenger receptors expressed by HSEC. Cultured HSEC do exhibit some useful identifying features, however. Very low passage cells retain fenestrations *in vitro* for a short time but these rapidly disappear within a passage or two in culture^[8,16], as does expression of VAP-1^[10]. Apart from these changes, however, the cells remain relatively phenotypically stable for 7-8 passages^[8] and can be identified by expression of CD31, LYVE-1, DC-SIGNR(L-SIGN), Stabilin-1 and lack of CD34 and PROX-1^[107]. These markers confirm endothelial identity, while excluding vascular and lymphatic endothelial contamination and in conjunction with markers to exclude cells of leukocyte origin can be used to confirm the sinusoidal nature of the cells.

Abstract

Gastrinomas are defined as gastrin secreting tumors that are associated with Zollinger-Ellison syndrome (ZES). ZES is characterized by elevated fasting gastrin serum levels, positive secretin stimulation test and clinical symptoms such as recurrent peptic ulcer disease, gastroesophageal reflux disease and occasional diarrhea. Genetically, nonhereditary (sporadic) gastrinomas are distinguished from hereditary gastrinomas, which are associated with multiple endocrine neoplasia type 1 (MEN1) syndrome. In general, duodenal gastrinomas are small and solitary if they are sporadic and multiple as well as hereditary. The sporadic gastrinomas occur in the duodenum or in the pancreas while the hereditary gastrinomas almost all occur in the duodenum. Our series of 77 sporadic duodenal neuroendocrine tumors (NETs) includes 18 patients (23.4%) with gastrinomas and ZES. Of 535 sporadic NETs in the pancreas collected from the NET archives of the departments of pathology in Zürich, Switzerland, and Kiel, Germany, 24 patients (4.5%) suffered from sporadic pancreatic gastrinomas and ZES. These NETs have to be distinguished from

tumors with immunohistochemical positivity for gastrin but without evidence of ZES. An additional 19 patients suffered from MEN1 and ZES. These patients showed exclusively duodenal gastrinomas, but not pancreatic gastrinomas. The prognosis of sporadic and MEN1-associated duodenal gastrinomas is better than that of pancreatic gastrinomas, since they progress slowly to liver metastasis. In summary, sporadic and MEN1-associated gastrinomas in the duodenum and pancreas show different clinico-pathological and genetic features. The incidence of sporadic duodenal gastrin-producing tumors is increasing, possibly due to optimized diagnostic procedures. In contrast, pancreatic MEN1-associated gastrinomas seem to be extremely rare. A considerable subset of tumors with immunohistochemical expression of gastrin but without evidence of ZES should be designated as functionally inactive NETs expressing gastrin, but not as gastrinomas.

INTRODUCTION

Gastrinomas are defined as gastrin-producing tumors that are associated with Zollinger-Ellison syndrome (ZES) due to inappropriate gastrin secretion. ZES is characterized by elevated fasting gastrin serum levels, positive gastrin secretin stimulation test and clinical symptoms such as recurrent peptic ulcer disease, gastroesophageal reflux disease and occasional diarrhea^[1,2].

The first cases of ZES were described in 1955^[3].

One patient, a 36-year-old woman with severe recurrent ulcer disease and a family history strongly suggestive of multiple endocrine neoplasia type 1 (MEN1) background, was found to have several endocrine tumors, including microadenomas, in the pancreas. This case report already illustrates many of the issues that are still encountered in the diagnosis of gastrinoma. A closer look at the report by Zollinger and Ellison, on the basis of our current knowledge on gastrinomas, reveals that they were most likely dealing with a MEN1 patient. What is the reason for this assumption? Zollinger and Ellison described multiple endocrine tumors in the pancreas, which they thought were the cause of the ulcer syndrome, since their removal by a Whipple resection cured the patient. However, today we know that multiple gastrinomas virtually do not exist in the pancreas, but virtually always occur in the duodenum in the setting of MEN1. In this hereditary syndrome duodenal tumors producing gastrin are tiny and usually associated with multiple pancreatic tumors that do not produce gastrin, but may be large. In 1955, it was not possible to prove that the tumors produced gastrin. Firstly, gastrin still has to be isolated^[4,5], and secondly, immunohistochemistry for gastrin has not yet been invented. Therefore, it is a quite likely assumption that Drs. Zollinger and Ellison's patient suffered from a recurrent ulcer disease in the setting of MEN1 syndrome and had multiple small gastrinomas in the duodenum, which were removed together with non-gastrin producing endocrine tumors in the pancreas. While the tumors in the pancreas were easily noticed and described, the duodenal minigastrinomas probably escaped detection.

This review focuses on the clinical setting and morphological aspects of sporadic and MEN1-associated duodenal and pancreatic gastrinomas. In addition, the results of an analysis of epidemiology of sporadic and MEN1-associated duodenal and pancreatic gastrinomas in a large series of duodenal and pancreatic neuroendocrine tumors (NETs) from the Swiss and German NET archives are presented.

CLINICAL SETTING OF GASTRINOMAS

Between 60% and 75% of patients with ZES are found to have an isolated duodenal or pancreatic gastrinoma (sporadic ZES). In the remaining patients ZES is part of MEN1 syndrome and these patients usually exhibit multiple duodenal gastrinomas (hereditary gastrinoma)^[6-8]. The term pseudo-ZES (also called ZES type 1, as opposed to ZES type 2 caused by a gastrinoma) is coined for a syndrome with symptoms similar to ZES that appears to be caused by antral G-cell hyperfunction and hyperplasia^[9,10]. The fact that this syndrome has no longer been described in recent years raises questions of whether it exists at all. In rare cases the syndrome of recurrent and intractable peptic ulceration may be found in association with a pancreatic endocrine tumor that does not produce and secrete gastrin^[11]. The factor causing peptic ulceration in these patients has yet to be identified^[12].

Among the gastroenteropancreatic neuroendocrine tumors associated with hormonal syndrome, gastrinomas are second only in incidence to insulinomas and are

malignant in more than 60% of the cases. These tumors are classified as low grade malignant neoplasms, i.e. well differentiated neuroendocrine carcinomas. The peak incidence of gastrinomas lies between 40 and 50 years, children (5-15 years of age) are rarely affected^[1].

SPORADIC GASTRINOMA

Sporadic gastrinomas occur either in the pancreas or in the duodenum and are apparently solitary tumors. In the past, approximately 70%-80% of these gastrinomas were thought to occur in the pancreas, particularly in its head. Currently, gastrinomas are more frequently found in the duodenum.

In general, gastrinomas represent the only type of endocrinologically active duodenal NETs, while all other types of duodenal NET (i.e. functionally inactive NETs expressing somatostatin, serotonin or gastrin, gangliocytic paraganglioma and poorly differentiated neuroendocrine carcinomas) are found to be endocrinologically silent. The reason for the increasing incidence of sporadic duodenal gastrinomas and endocrinologically silent inactive gastrin-producing NETs may be that many of these small NETs were overlooked but their large periduodenal/peripancreatic lymph node metastases were noted and recorded as primary gastrinoma in the pancreas or as primary lymph node gastrinoma in the past (details are shown below).

Sporadic duodenal gastrinomas usually arise from the first part of the duodenum and are located in the submucosa. They are most often less than 1 cm in diameter^[13-16] (Figure 1A and 1B). Despite this small size metastases to regional lymph nodes are already found in 60% to 80% of the patients at the time of diagnosis^[13]. It seems that periduodenal and peripancreatic lymph node metastases may grow faster than their duodenal primary tumors and thus may form large tumors that are easily recognized, in contrast to the duodenal primary tumors. It has therefore been suggested that the so-called peripancreatic and periduodenal lymph node gastrinomas that were described in the past may in fact be metastases of duodenal microgastrinomas that are overlooked during diagnostic work-up and surgery, rather than true primary tumors^[17-19]. Apart from lymph node metastases, duodenal gastrinomas may metastasize to the liver, but only in a small percentage of cases (about 10%) and only many years after the manifestation of the disease^[13]. Thus the 10-year survival rate of 84% has been reported in patients with duodenal gastrinomas^[20,21]. Fast growing and metastasizing duodenal gastrinomas are rare.

Histologically, duodenal gastrinomas are often submucosal tumors that infiltrate the mucosa and may also infiltrate the muscular layer if they are larger than 1 cm in diameter. They most often show a trabecular or pseudoglandular pattern. Their proliferative activity is usually between 2% and 10% (Figure 2). Some of the tumors may show angioinvasion. Their prognostic classification is outlined in detail in Table 1. Immunocytochemically, gastrin can be detected in all tumors^[7,22]. Many duodenal gastrinomas are multihormonal and additionally contain single somatostatin or serotonin

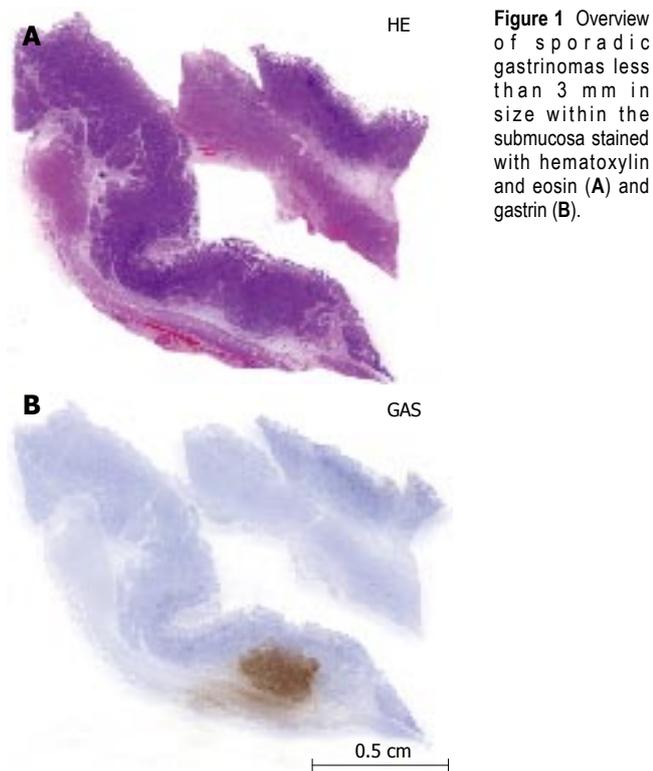

Figure 1 Overview of sporadic gastrinomas less than 3 mm in size within the submucosa stained with hematoxylin and eosin (A) and gastrin (B).

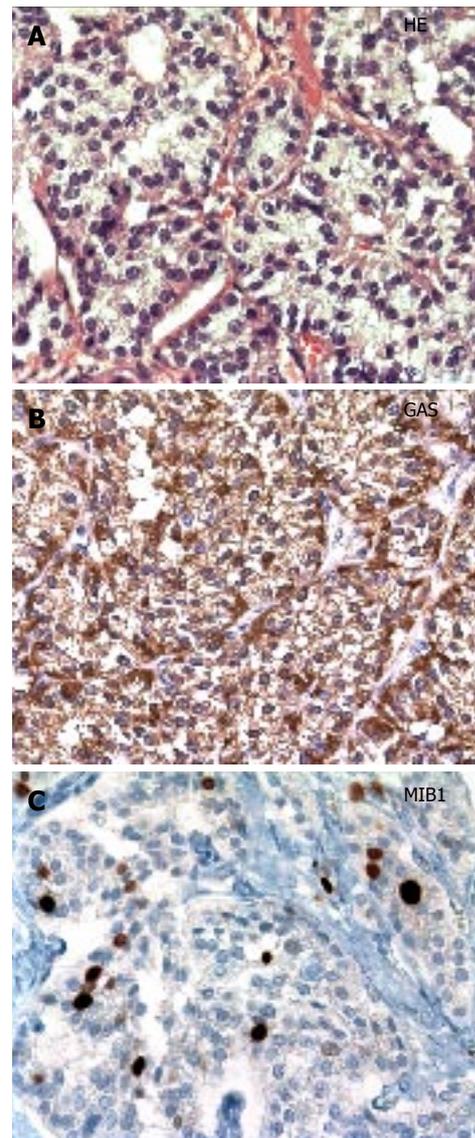

Figure 2 Morphology of sporadic duodenal gastrinoma stained with HE showing a trabecular and glandular growth pattern (A); strong immunoreactivity for gastrin (B), and expression of the nuclear proliferation antigen MIB1 in more than 2% of NET cells (C).

expressing cells in addition to gastrin cells.

Sporadic gastrinomas in the pancreas usually have a diameter of 2 cm or more (Figure 3). It has been reported that they occur more frequently in the head of the pancreas^[13]. However, in our series they were found in all parts of the organ.

Metastasis of sporadic pancreatic gastrinomas to regional lymph nodes is found in approximately 60% of patients at the time of diagnosis^[23], and liver metastases occur more frequently (10%-20%) than duodenal gastrinoma liver metastasis^[17,18,23]. Thus the 10-year survival rate is worse in patients with pancreatic gastrinomas (57%) than in patients with duodenal gastrinomas (84%)^[20,21]. In rare cases, bone metastases may develop in the terminal phase of a metastasized gastrinoma.

Histologically, pancreatic gastrinomas are similar to duodenal gastrinomas, but may have a higher proliferation and angioinvasion rate. Table 1 shows their prognostic assessment. Immunocytochemically, gastrin can be detected in almost all tumors^[7,22]. Approximately 50% of gastrinomas are multihormonal and contain PP, glucagon and/or insulin in addition to gastrin.

Islet hyperplasia and nesidioblastosis have repeatedly been described in the non-neoplastic pancreas of patients with gastrinomas, but these findings cannot be confirmed by morphometry^[24]. Recently, however, morphometrically defined PP-cell hyperplasia has been described in the ventrally derived region of the pancreatic head^[25]. It has not been definitely established whether hypergastrinemia can influence these changes. In the stomach mucosa, however, sustained hypergastrinemia induces parietal cell hyperplasia with thickened mucosal folds and gastric acid hypersecretion. In addition, the number of enterochromaffin-like (ECL) cells is increased

in the fundal mucosa^[26-28]. ECL cell tumors in the fundus of the stomach, which are a well-known complication in patients suffering from pernicious anemia due to chronic type A gastritis, appear to be very uncommon in patients with sporadic ZES^[7]. They have, however, been reported in patients with ZES and MEN1. In these instances they probably represent another neoplastic manifestation of MEN1 syndrome (see below) rather than merely the result of a trophic effect of gastrin^[26,29].

MEN1-ASSOCIATED GASTRINOMAS

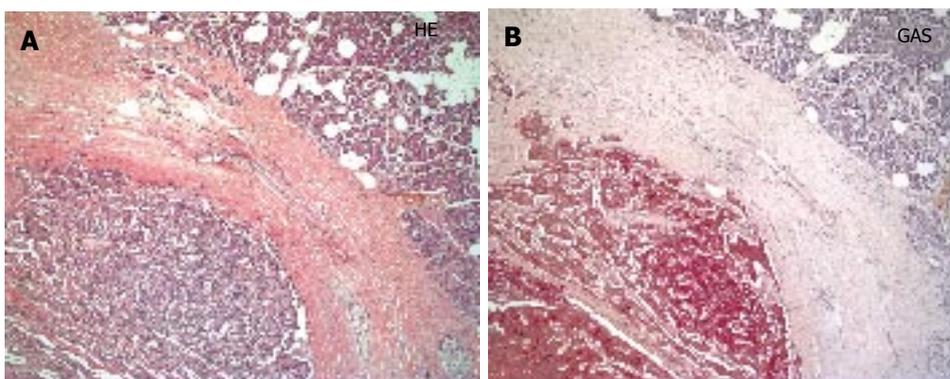

Approximately 25%-33% of patients with gastrinomas develop these tumors in the setting of MEN1. Almost all these gastrinomas reside in the duodenum^[30]. They are usually smaller than 1 cm in diameter and multicentric, arising from multifocal hyperplastic gastrin cell proliferations^[31] (Figures 4 and 5). Histologically,

Table 1 Classification of neuroendocrine tumors of the pancreas (WHO classification 2004)^[41]

1	Well-differentiated neuroendocrine tumor
	<ul style="list-style-type: none"> • Benign: confined to pancreas, < 2 cm in size, nonangioinvasive, ≤ 2 mitoses/HPF and ≤ 2% Ki-67-positive cells <ul style="list-style-type: none"> - Functioning: insulinoma - Nonfunctioning • Benign or low grade malignant (uncertain malignant potential): confined to pancreas, ≥ 2 cm in size, > 2 mitoses/HPF, > 2% Ki-67-positive cells, or angioinvasive <ul style="list-style-type: none"> - Functioning: gastrinoma, insulinoma, VIPoma, glucagonoma, somatostatinoma, or ectopic hormonal syndrome - Nonfunctioning

they show trabecular and pseudoglandular patterns and immunohistochemically they express gastrin and occasionally also somatostatin. Because of their small size they are (like sporadic duodenal gastrinomas) difficult to detect. Pancreatic gastrinomas associated with MEN1 are very rare^[6,32], although the pancreas of these patients usually contains multiple endocrine micro- and macrotumors^[33]. These tumors, however, virtually never produce significant amounts of gastrin^[6,32]. The metastatic and biological behavior of duodenal MEN1-associated

gastrinomas is similar to that of sporadic counterparts (Table 2).

EXTRADUODENAL AND EXTRAPANCREATIC GASTRINOMAS

Unusual sites of gastrinomas are the stomach^[34], jejunum^[35,36], biliary tract, liver^[37] and kidney^[38]. Ovarian or pancreatic mucinous cystic tumors that contain a sufficient number of active endocrine cells with gastrin production

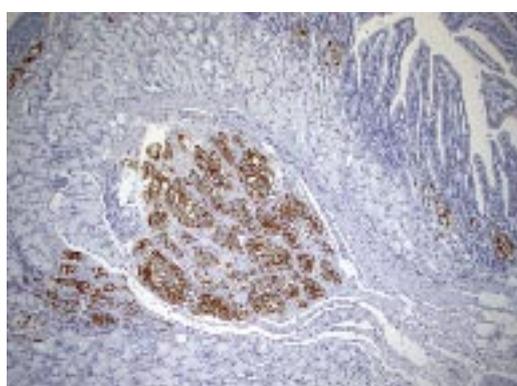

Figure 5 Tiny MEN1-associated duodenal gastrinoma within the submucosa revealing a diameter of less than 1 mm.

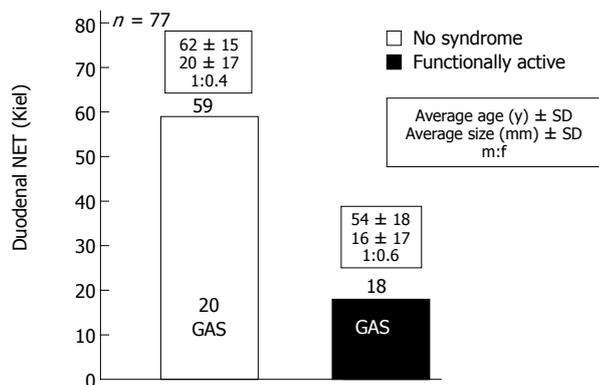

Figure 6 Duodenal NETs in the Kiel tumor archive. Fifty-nine (76.6%) out of the 77 NETs were endocrinologically not active, 20 of them expressed gastrin. These were not associated with ZES. All the functionally active NETs (18; 23.4%) were immunohistochemically positive for gastrin and showed a ZES.

may also cause ZES, but are uncommon^[39-41].

PERSONAL OBSERVATIONS

In our series of sporadic duodenal NETs collected from 1975 to 2006, duodenal gastrin producing tumors account for 49.4% (38) of 77 sporadic NETs (Figure 6). Surprisingly, only 47.4% (18) of the gastrin-immunoreactive sporadic NETs show an association

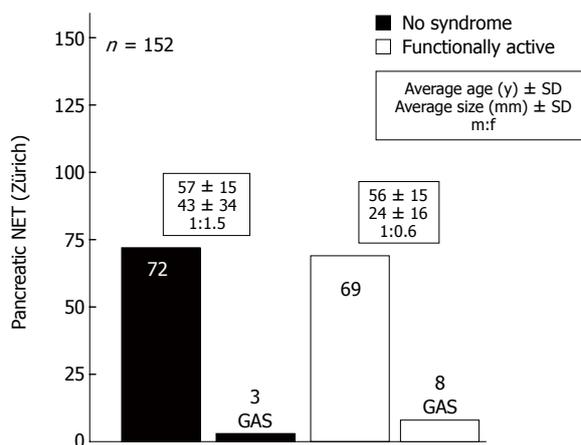

Figure 7 Pancreatic NETs in the Zürich tumor archives. Seventy-five (49.3%) out of the 152 pancreatic NETs were endocrinologically not active, of which 3 expressed gastrin. These 3 gastrin-expressing NETs were not associated with ZES. Eight of the 77 functionally active NETs were immunohistochemically positive for gastrin and associated with ZES.

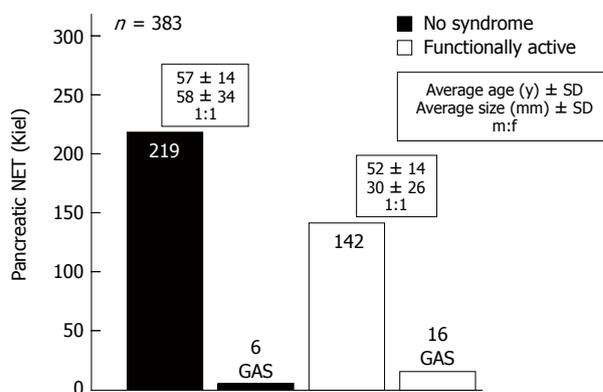

Figure 8 Pancreatic NETs in the Kiel tumor archives. Two hundred and twenty-five (58.7%) out of the 383 pancreatic NETs were endocrinologically not active. These gastrin-expressing NET were not associated with ZES. Sixteen of the 158 functionally active NETs were immunohistochemically positive for gastrin and showed a ZES.

with ZES (Figure 6). The reason for the lack of ZES in a considerable subset of patients with gastrin-expressing tumors remains to be analyzed in detail. Whether these gastrin producing tumors in the duodenum are similar in behavior to the duodenal gastrinomas remains unknown. However, it seems that they may have a different biology. Terminologically, these NETs with immunohistochemical expression of gastrin but without evidence of ZES should be designated as functionally inactive NETs expressing gastrin, but not as gastrinomas.

In two large series of sporadic pancreatic NETs from Kiel ($n = 383$) and Zürich ($n = 152$) pancreatic gastrinomas were found to be rare tumors, accounting for 4.2% (Kiel) and 5.3% (Zürich) of all collected sporadic tumors, respectively. Similar to duodenal tumors an additional 1.6% (Kiel) and 2.0% (Zürich) of sporadic gastrin-expressing tumors were not associated with ZES and were therefore designated as functionally inactive pancreatic NETs producing gastrin (Figures 7 and 8).

It was reported that 19 (59.4%) of 32 patients with MEN1 showed ZES. The source of ZES in these patients

is duodenal rather than pancreatic gastrinomas. Most of these exhibit multifocal duodenal gastrinomas and lymph node metastases^[31,33].

CONCLUSION

The preferred site of gastrinomas is the duodenum rather than the pancreas. Despite the small size of duodenal gastrinomas they may show the same rate of metastasis at the time of diagnosis as pancreatic gastrinomas, which are usually larger in size. However, the survival rate of patients with pancreatic gastrinomas is lower than that of patients with duodenal gastrinomas. MEN1-associated gastrinomas are virtually all localized in the duodenum. They are usually multiple. They probably arise from multifocal precursor lesions, i.e. diffuse gastrin cell proliferations that are lacking in sporadic duodenal gastrinomas. Biologically, the behavior of MEN1-associated gastrinomas is similar to that of sporadic duodenal gastrinomas. Gastrin expressing tumors both in the duodenum and in the pancreas without evidence of ZES should be designated as functionally inactive NETs producing gastrin, but not as gastrinomas. The reasons for the lack of hormonal symptoms in gastrin expressing NETs still need to be analyzed in detail.

Abstract

Several hundred species of bacteria inhabit the gut, and affect its cell biology, morphology and homeostasis. Many bacteria are however potential pathogens, especially if the integrity of the epithelial barrier is physically or functionally breached. Conversely, the interaction between host and commensal microbes can confer important health benefits. This has led to commercial and public interest in 'probiotics', live microbes principally taken as food supplements. Might probiotics also be used in disease therapy? Experimental evidence that probiotics modulate gut physiology, particularly barrier integrity and immunological function, underpins exciting new gastroenterological research. We discuss below the scientific basis for probiotic effects and present a critical perspective for their use in relation to gastrointestinal disease.

INTRODUCTION

The concept of probiotics probably dates back to 1908, when Nobel Prize winner Eli Metchnikoff suggested that the long life of Bulgarian peasants resulted from their consumption of fermented milk products^[1]. In 1965 Lilly and Stillwell first used the term 'probiotic' when describing 'substances secreted by one organism which stimulate the growth of another'^[2]. Parker^[3] described probiotics as

'organisms and substances which contribute to intestinal microbial balance' and Fuller proposed in 1989 that probiotics were 'a live microbial supplement which beneficially affects the host animal by improving its microbial balance'^[4]. Salminen *et al*^[5] defined them as 'foods containing live bacteria which are beneficial to health', whilst Marteau *et al*^[6] define them as 'microbial preparations or components of microbial cells that have a beneficial effect to health and well being'. Such definitions underpin the current popular commercial usage of various 'friendly bacteria' to secure non-specific benefits to health.

With improved understanding of the physiology and therapeutic role of probiotics, definitions have evolved bolder claims, which now enter medical territory. Charteris *et al*^[7] defined probiotics as 'micro-organisms, which when ingested, may have a positive effect in the prevention and treatment of a specific pathological condition'.

Two related terms are prebiotics and synbiotics: *prebiotics* are defined as "non digestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon that can improve host health"^[8]. When prebiotics and probiotics are administered together, this is referred to as a synbiotic.

NORMAL GUT MICROFLORA

The colon contains tenfold more bacteria than the total number of mammalian cells constituting the host. The relationship is symbiotic: for example, bacterial vitamin K synthesis contributes to haemostasis, whilst short chain fatty acids generated by colonic bacteria salvage additional energy from otherwise 'wasted' dietary fibre.

Colonisation of the gastrointestinal tract starts immediately after birth, initially with maternal vaginal and intestinal flora. Other sources are diet (breast or formula based feeds)^[9-12] and environment, as reflected by the different gut flora in infants born in developing and developed countries^[13-15]. Infants who are breast fed predominantly harbour *Bifidobacteria* whilst formula fed infants have a more complex bacterial profile comprising *Enterobacteria*, *Bacteroides*, *Clostridia*, *Lactobacilli*, *Bifidobacteria* and *Streptococci*^[11].

These 'pioneer' bacteria are important because they modulate epithelial cell gene expression, creating a favourable habitat for themselves by inhibiting the growth of bacteria introduced later^[16]. This renders initial colonisation causally determinant to the final composition of bacterial flora in adults^[17].

During development, the gut flora changes. The mouth

harbours mainly facultative and strict anaerobes including *Streptococci*, *Bacteroides* and yeasts. The oesophagus has no significant resident microbial colonisation but is constantly transited by swallowed organisms. The widely held idea that the upper gut is largely sterile is not valid. The stomach and duodenum harbour up to 10^4 colony forming units (CFU) per gm of *Candida albicans*, *Bacteroides*, *Lactobacillus* and *Streptococcus*. *H pylori* are specifically adapted for gastric residence. The jejunum again harbours *Bacteroides*, *Candida albicans*, *Lactobacillus* and *Streptococcus* but with a content of 10^5 - 10^7 CFU/g. Scepticism that probiotics will not survive the passage through the acidic stomach is therefore unfounded. From the ileum onwards bacterial colonisation increases from 10^7 - 10^8 CFU/g in the ileum to 10^{10} - 10^{11} CFU/g in the colon, with a predominance of *Bacteroides*, *Bacillus*, *Clostridium*, *Enterococcus*, *Peptostreptococcus*, and *Streptococcus* species^[18].

GUT MICROFLORA AND GUT PHYSIOLOGY

Recent research has demonstrated that a dynamic and reciprocal interplay exists between the gut microflora and the host. In particular, there is growing evidence that bacteria play an important role in directing epithelial differentiation and reinforcement of the gut barrier, through complex host-bacterial cross talk which occurs at a molecular level in interacting cells. This new biology underpins the putative effects of probiotics, since host-bacterial interactions can be re-engineered by purposeful manipulation of luminal ecology.

The physical barrier: bacteria and tight junctions

The intestinal epithelium constitutes an anatomical and functional barrier, effectively a bipolar monocellular obstacle between luminal microbes and the cells of the lamina propria. Barrier function is normally maintained by a complex interplay of numerous proteins, assembled to form the tight junction complexes (TJs)^[19,20] in the juxta-apical region of the cell membrane (Figure 1). Commensal organisms contribute uncharacterised constitutive signals supporting epithelial integrity. Disruption of TJs may be elicited by pathogenic bacteria, stress and injury, *via* pro-inflammatory cytokines. Disruption of TJ integrity results in increased paracellular permeability, which is measurable in a variety of experimental models, and which may initiate, exacerbate or perpetuate intestinal inflammation in disease^[21]. Altered intestinal permeability has been demonstrated in Crohn's disease, celiac disease, intestinal infections and NSAID-induced enteropathy^[22]. In order to counteract the harmful effects of luminal pathogens and toxins, and to protect barrier homeostasis, intestinal epithelial cells exhibit several additional defensive features, which include production of defence peptides and mucins^[23]. In addition, a class of bacterial-sensing immunocytes, the dendritic cells, are able to project sensory dendrites into the lumen between adjacent enterocytes *via* TJ regions. Dendritic cells express receptors evolved to sense bacterial components, through which highly patterned host immune responses are evoked appropriately and constantly. Supporting experiments in rats have shown

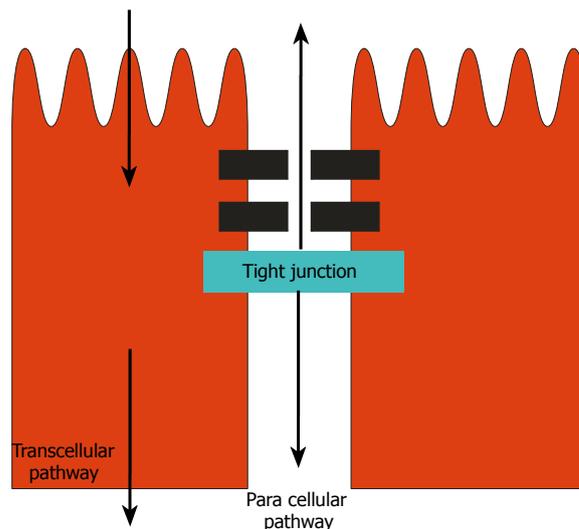

Figure 1 Tight junctions have a 'barrier' function in epithelia.

that colonisation of an excluded colonic loop with *E. coli* increased paracellular permeability, but this was partially reversed by colonisation with a putative probiotic, *Lactobacillus brevis*^[24]. In addition, the chronic colitis occurring in Interleukin-10 (IL-10) deficient mice^[25] is associated with increased colonic permeability, which is reversed in mice pre-treated for 4 wk. with a probiotic product, VSL#3 consisting of *Bifidobacterium*, *Streptococcus* and *Lactobacillus* species.

The potential cellular basis has also been addressed in human cell models^[26]. The influence of whole probiotic bacteria *E. coli* Nissle 1917 (EcN) or VSL#3, bacterial cell lysates or conditioned medium from bacterial cultures were assessed against a variety of barrier and defensive parameters in human intestinal epithelial cell lines. These included a measure of TJ function (transepithelial resistance, TER) and tight junction protein abundance, IL-8 secretion and mucin gene expression. In addition, protective effects on pathogen (*Salmonella dublin*) induced alterations were analyzed. The probiotic mixture and soluble protein released from it, increased basal TER, prevented pathogen-induced decrease in TER, and stabilized TJs. This suggested that the organisms, or their secretory products, functionally modulate the intestinal epithelium of the host. These include competition of organisms for contact with the epithelial surface, stabilization of the cytoskeletal and barrier function, and the induction of mucin gene expression. Gram-negative and gram-positive organisms differed in the cellular mechanisms activated: perhaps a combination of organisms might be more effective than the application of a single strain^[26]. The stumbling block inevitably lies in translating observations in these reductionist models to a proven clinical effect.

Recent interest has centred on regulation of the barrier *via* epithelial sensing of microbial components. The Toll-like receptors (TLRs) are a class of pattern-recognition receptors that specifically discriminate between self and microbial non-self based on the recognition of molecular patterns^[27]. TLRs thereby play an important role in im-

immune responses and the induction of antimicrobial effector pathways, leading to elimination and exclusion of host-threatening pathogens. It has been shown that the intestinal epithelium expresses several TLRs, which include TLR2, TLR3, TLR4 and TLR5^[24-34]. It is possible that certain probiotic agents contain TLR-specific immunostimulatory features, leading to the amelioration of colitis by restoring intestinal epithelial barrier to protect the host^[35].

The functional barrier: probiotics and mucosal immunity

The gastrointestinal mucosa is the primary interface between the external environment and the immune system. In the complete absence of intestinal microflora antigen transport is increased, indicating that the normal gut microflora maintain gut defences^[25]. The microflora affect the development of gut associated lymphoid tissue at an early age by directing the regulation of systemic and local immune responsiveness, including promoting tolerance via hypo-responsiveness to antigens from micro-organisms and food^[36]. Probiotic organisms have been shown to modulate immunoglobulin production. Secretory IgA plays an important role in mucosal immunity, contributing functionally to the barrier against pathogenic bacteria and viruses^[37-40]. An enhanced IgA immune response has been shown in children with Crohn's disease treated with *Lactobacillus* GG^[41]. Interestingly, Madsen *et al.*^[42] demonstrated that IL10 deficient mice displayed significantly higher basal numbers of adherent bacteria compared with healthy control mice. When the colon was repopulated with *Lactobacillus reuteri* enemas the proportion of adherent and translocated bacteria, and the development of colitis, was significantly decreased. Further, Schultz^[43] demonstrated that feeding *Lactobacillus plantarum* attenuated established colitis in IL-10 knockout mice. In rats, the effects of *Lactobacilli* and fibre (oatbase) were studied in Methotrexate-induced enterocolitis. Rats received an intragastric infusion of an elemental diet, with or without supplementation of oatbase, *Lactobacillus reuteri* R2LC and *Lactobacillus plantarum* DSM9843^[44]. Methotrexate was injected intraperitoneally on d 3. By d 6 *Lactobacillus* decreased intestinal inflammation, re-established intestinal microecology and reduced bacterial translocation to extra-intestinal sites.

Data from human studies support a role for the gut microflora in the development of several gut associated inflammatory conditions, most likely triggered by immune response to their antigenic structures^[45]. Thus probiotics may exert clinical effects by altering the intestinal inflammatory response to the luminal microflora.

Trophic and nutritional effects of gut microflora

Probiotic organisms exert a potentially positive effect on gut function through a trophic action on gut mucosa. In experimental models, crypt cell turnover is reduced in the colon of rats bred in germ free environments (gnotobiotic animals). Germ free crypts also contain fewer cells than those of colonised rats^[46]. Butyrate is an important source of energy for colonocytes^[47], whilst acetate and propionate are found in portal blood and are eventually metabolised in the liver or peripheral tissues, in particular muscle^[47,48]. The most important role of SCFA is probably their trophic

effect on colonic epithelium. Short chain fatty acids stimulate epithelial cell proliferation and differentiation in large and small bowel *in vivo*^[49]. Butyrate however inhibits cell proliferation in epithelial cell lines of neoplastic origin^[50]. Further, butyrate is pro-apoptotic and promotes reversion of cells from neoplastic to non-neoplastic phenotypes^[51]. SCFA generation can clearly be altered by manipulating colonic micro-ecology, so probiotics and prebiotics may find a role in the prevention of colonic neoplasia and in the therapy of inflammatory bowel diseases.

Colonic micro-organisms play an important role in vitamin synthesis^[52,53] and in the absorption of calcium, magnesium and iron^[54-56]. Ion absorption in the caecum is improved by carbohydrate, and production of short chain fatty acids particularly acetate, propionate, and butyrate.

Interactions with mucus

A mucus gel covers the gut epithelium acting as a protective barrier against pathogens and reducing physical trauma. Change in the mucus content or structure compromise barrier function. Interactions occur between bacteria and mucus, including the probiotic bacteria that bind to intestinal mucus^[57]. This is potentially advantageous since it inhibits adhesion of enteropathogenic bacteria to mucus. For example *Enterococcus faecium* inhibits the adhesion of enterotoxigenic *E. coli* K88 to porcine small intestine mucus^[58].

PROBIOTICS IN CLINICAL GASTROENTEROLOGY

The experimental data discussed above demonstrate that several 'probiotic' organisms exert biological effects which might translate into clinical benefits. Current clinical evidence is limited and non-uniform. Key observations in relevant conditions are discussed below.

Probiotics in GI infections

Probiotics have an emerging role in the treatment of gastrointestinal infections. Probably the best described is in acute infantile diarrhoea. *Lactobacillus* strain GG in fermented milk or freeze-dried powder was shown to reduce the duration of diarrhoea in acute rotavirus infection compared to a placebo group given pasteurised yoghurt^[59]. Other studies have confirmed these results^[60,61]. Suggested mechanisms of action are stabilisation of indigenous microflora^[62], reduction in the increased gut permeability caused by rotavirus infection^[63] and reduction in the duration of virus shedding^[64]. This may be cause-specific. In a multicentre European trial of probiotics in acute childhood diarrhoea caused by rotavirus and other pathogens^[65], probiotics (*Lactobacillus* GG) shortened the duration of diarrhoea in rotavirus diarrhoea, but showed no such effect with other pathogens.

Probiotics may also have a role in the prevention of acute infantile diarrhoea. In a double blind, placebo controlled trial hospitalised infants were randomised to receive a standard infant formula alone or supplemented with *Bifidobacterium bifidum* and *Streptococcus thermophilus*. After a 17-mo follow up period, 7% of those receiving a probiotic

had experienced diarrhoea compared to 31% given the standard formula^[66]. Viral shedding was lower in the probiotic supplemented group. Prophylactic use of *Lactobacillus* GG in 204 undernourished children followed up for 15 mo also decreased the incidence of acute diarrhoea^[67]. This effect was confined to non-breast fed infants. In a more recently reported double blind randomised placebo controlled trial, 81 children between 1-3 years of age, hospitalised for reasons other than diarrhoea, and were given *Lactobacillus* GG or placebo for the duration of their admission. The incidence of nosocomial diarrhoea was lower in the probiotic group (7% as compared to placebo, 33%)^[68]. Furthermore, although the prevalence of rotavirus infection was similar in both groups, the risk of rotavirus gastroenteritis was lower in the probiotic group. Finally, the benefits of *Lactobacillus* GG in rotavirus associated diarrhoea mainly comprise a reduction in duration of diarrhoea by 1-2 d compared to a median of 3 d.

The positive results for *Lactobacillus* GG in acute viral diarrhoea cannot necessarily be extrapolated to other probiotic strains, nor to other causes of acute diarrhoea. The data imply species and disease specificity. For example, in a study comparing various probiotic strains, *Lactobacillus* GG was found to have a beneficial effect in rotavirus gastroenteritis but this was not shared by *L. rhamnosus*, *L. delbrueckii* or *Streptococcus thermophilus*^[60]. *Saccharomyces boulardii* has also displayed beneficial effects in acute diarrhoea in children and adults^[60,70]. Enterococcus SF68 in adults with acute diarrhoea has however shown inconsistent results^[71-73]. It is unclear whether the modest benefits suggested by these studies justify routine use of probiotics in diarrheal illnesses since most acute diarrhoeal diseases are self limited. The benefit may be greatest in situations where patients are at risk for complications such as in children with malnutrition in developing countries.

Antibiotic-associated diarrhoea

Diarrhoea can occur as an adverse effect of antibiotic therapy, in up to 39% of antibiotic treated hospitalised patients^[74]. Broad spectrum antibiotics are more commonly implicated, possibly because of more profound alteration in colonic flora^[75]. Several placebo-controlled studies have shown a decrease in the incidence of diarrhoea or change in stool consistency when patients were treated with probiotics in addition to antibiotics^[76-82]. The probiotic organisms studied were *Lactobacillus* spp., Enterococcus and *Saccharomyces boulardii*. Not all studies support this possibility. A recent study of 267 patients on antibiotics randomised to *Lactobacillus* GG or placebo failed to show any decrease in incidence of diarrhoea, with 29% in both groups developing symptoms^[83]. Three other smaller studies were also negative^[78,84,85]. Although most studies looking at probiotics in antibiotic-associated diarrhoea are placebo controlled and conducted on a reasonable number of subjects, different antibiotics were used in these studies contributing to their heterogeneity. Two recent meta-analyses (of nine and seven randomised placebo controlled double blind trials) have looked at the effect of probiotics in prevention of antibiotic-associated diarrhoea^[86,87]. The meta-analysis by D'Souza *et al*^[87] reviewed nine randomised, double blind, placebo controlled trials. Four trials used yeast (*Saccharomyces*

boulardii); four used *Lactobacilli* and another used a strain of enterococcus that produced lactic acid. Three trials used a combination of probiotic bacteria. Antibiotics were given with probiotics (or with placebo, in the control group) in all nine trials. The combined odds ratio in favour of active treatment over placebo in preventing diarrhoea associated with antibiotics was 0.37 (95% confidence interval, 0.26 to 0.53; $P < 0.001$). In the meta-analysis by Cremonini *et al*^[86], twenty two studies using *Lactobacillus* and *Saccharomyces* species, matched the inclusion criteria of which seven studies were homogenous. The combined relative risk was 0.399 (95% confidence interval, 0.27-0.57) suggesting a strong benefit of probiotic administration on antibiotic associated diarrhoea. The pooled results suggested that probiotic administration had an overall benefit. However, the published data is discordant in that it is unclear what the optimal dose and timing of supplementation should be.

Clostridium difficile associated diarrhoea (CDAD)

Clostridium difficile is a Gram positive bacterium that can cause colitis, mediated by two enterotoxins, enterotoxin A and B. The pathophysiology is not fully clear but risk factors include intercurrent or continued antibiotic therapy, elderly age, renal disease and female sex^[88,89]. Probiotics have been partially evaluated in the prevention of CDAD. Early uncontrolled trials using *Lactobacillus* GG^[90-92] and a preliminary report of a controlled trial using *Lactobacillus* GG suggested benefit in recurrent CDAD^[93]. Similarly uncontrolled or open label studies^[94,95] and subsequently two controlled trials^[96,97] have suggested efficacy of *Saccharomyces boulardii* in recurrent CDAD. In the study by McFarland *et al*^[94], 124 patients were studied, including 64 patients with an initial episode of CDAD and 60 who had at least one previous episode of CDAD. Subjects received oral *Saccharomyces boulardii* (1 g/d for 4 wk or placebo) and were followed up for an additional 4 wk after therapy. Multivariate analysis showed that patients treated with *S. boulardii* and standard antibiotics had a significantly lower risk of CDAD (relative risk 0.43; 95% confidence interval, 0.20-0.97) compared with placebo. In their subsequent study, Surawicz *et al*^[97] tested patients receiving a standard antibiotic for 10 d and then added *S. boulardii* (1 g/d for 28 d) or placebo. A significant decrease in recurrence of CDAD (16.7%) was observed in patients treated with high-dose Vancomycin (2 g/d) compared with those receiving Vancomycin and placebo (50%; $P < 0.05$). Most studies were small and were mostly not placebo controlled.

A recent systematic review looking at studies in which probiotic therapy was used for prevention and treatment of *C. difficile*- associated diarrhoea concluded that the evidence for routine clinical use of probiotics in this setting was insufficient^[98]. Again, although probiotics are generally considered safe, case reports have described *Saccharomyces cerevisiae* fungaemia and deaths in immunocompromised and critically ill patients who received a commercial preparation of *S. boulardii* (genomically identical to *S. cerevisiae*)^[99]. Their routine use can therefore not be recommended.

Probiotics in Inflammatory Bowel Diseases

Although the etiology of inflammatory bowel diseases is

not entirely clear, dysfunctions in both innate and acquired immunity are implicated. There has been an increased interest in pathogenic and endogenous intestinal flora, with supportive data derived from several animal models. As noted above spontaneous colitis may develop in mice deficient in the immunoregulatory cytokine IL-10 but IL-10 deficient germ free mice remain disease free^[100-102].

Clinical studies suggest a significant role for bacteria in the pathogenesis of human IBD. Crohn's disease activity has been shown to improve with antimicrobial therapy, faecal diversion^[103,104], bowel rest and intestinal lavage^[105]. Furthermore, antibiotics may reduce postoperative relapse^[106], postoperative pouchitis^[107] and fistula related complications^[108]. There has been particular interest recently in polymorphisms in the CARD15/NOD2 gene, an intracellular bacterial pattern recognition receptor, as a risk factor for the development of Crohn's disease^[109]. Probiotics may therefore exert benefits in IBD management by modulatory effects on intestinal flora. For example *Lactobacillus* GG, when administered to children with Crohn's disease, increased mucosal IgA levels^[41] improved intestinal permeability and reduced disease activity^[110]. Further, the relapse rate in 32 adults with inactive Crohn's disease was reduced to 6% when subjects in remission were treated with mesalazine and *S. boulardii* as compared to 38% with mesalazine alone^[111]. However, in a placebo controlled study of 37 Crohn's disease patients treated with *Lactobacillus* GG for 12 mo after curative resection, the probiotic did not prevent relapse: in fact more severe endoscopic findings were reported in the *Lactobacillus* group^[112].

Recent clinical studies have evaluated the effect of non-pathogenic *E. coli* strain Nissle 1917 versus mesalazine for maintenance of remission in ulcerative colitis. Kruis *et al*^[113] studied 120 and Rembacken *et al*^[114] 116 patients with inactive ulcerative colitis over a period of 12 wk and 1 year respectively given either *E. coli* strain Nissle 1917 (MutaflorR) or mesalazine. These unblinded studies found a similar relapse in both groups (73% in the mesalazine group and 67% in the *E. coli* group), suggesting that probiotic therapy may be an alternative maintenance therapy. Similar results were suggested in a third RCT study^[115]. 327 patients were treated with mesalazine or *E. coli* Nissle 1917 for twelve months. Relapse rates were similar (45.1% in the probiotic group versus 36.4% in the mesalazine group). In a controlled trial by Tursi *et al*^[116], low dose balsalazide with VSL#3 was shown to be more effective than balsalazide or mesalazine alone in patients with acute mild to moderate ulcerative colitis. The combination of a prebiotic and a probiotic (*Bifidobacterium longum*/Synergy 1) was associated with improvement in histological scores and measures of immune activation in a randomised controlled pilot study^[117].

A recent study investigated the expression and function of CARD15/NOD2 in intestinal epithelial cell lines. CARD15/NOD2 mRNA was expressed in both intestinal epithelial cell lines and primary intestinal epithelial cells. CARD15/NOD2 mRNA and protein were up-regulated by tumor necrosis factor alpha (TNF alpha) in SW480 cells. This study suggests that CARD15/NOD2 may serve as a key component of innate mucosal responses to luminal bacteria as an antibacterial factor^[109]. Failure in this acti-

vity may contribute to the development of Crohn's disease.

Probiotics in pouchitis

Pouchitis is an inflammation of an ileal reservoir surgically constructed in the management of IBD. It is associated with reduced counts of *Bifidobacteria* and *Lactobacilli* with increased numbers of *Clostridia* and anaerobes in faecal samples^[118]. Increases in bile acids and decreases in short chain fatty acids, with a net increase in pH, may also be seen^[118]. In a double blind randomized placebo controlled trial a probiotic mixture VSL#3 was studied over 9 mo in 40 patients with chronic relapsing pouchitis^[119]. Relapse was defined by a pouch disease activity index (PDAI)^[120] of 2 points or more and confirmed by endoscopy and histology, and was, strikingly, only identified in 15% of the VSL#3 group as against 100% in the placebo group. In a prophylactic study, 2 of 20 patients (10%) receiving 1 packet of VSL#3 1 year developed pouchitis, versus 40% of placebo treated patients^[121].

Somewhat different conclusions were reached in two recently published studies^[122,123]. In a group of 36 patients with recurrent or refractory pouchitis who had required antibiotics at least twice in the past year, patients were randomly assigned to VSL#3 or placebo after achieving remission, once daily for a year. More patients remained in remission in the probiotic group (85% *vs* 6%)^[122].

In an observational study involving 31 patients treated with VSL#3 after achieving remission with Ciprofloxacin, only a minority of patients remained on probiotic therapy and in sustained remission, having stopped them due to recurrence of disease or adverse effects^[123]. In summary then, the benefit of probiotics in Crohn's disease remains unproven. The benefit of probiotics in ulcerative colitis remains unproven. *E. coli* Nissle 1917 appears promising and may be of value in patients intolerant of or resistant to 5-ASA preparations. Limited data from small controlled studies would suggest that VSL#3 is a reasonable therapy in the primary and secondary prevention of pouchitis.

Probiotics in critical illness

Some advocates propose that probiotics have an important emerging role in managing critical illnesses originating in the gastrointestinal tract. In a recent study from Hungary patients with severe acute pancreatitis were randomised upon arrival to hospital to receive one week of treatment with a twice daily administration of a freeze dried preparation containing 10⁹ live *L. plantarum* 299 with a substrate of 10 g oat fibre, or a similar preparation containing *Lactobacillus* which had been inactivated^[124]. The study was stopped when the infection rate showed a significant difference in the two groups. This occurred when 45 patients had completed the study, 22 had received treatment with live and 23 with heat killed *L. plantarum* 299. Infected pancreatic necrosis occurred in 1 out of 22 subjects (4.5%) in the treatment group as against 7 of 23 (30%) in the heat killed group. The length of hospital stay was shorter in the live LAB group but it did not reach statistical significance due to small sample size^[124].

Studies on cirrhotic patients have shown a decrease in the incidence of encephalopathy. A Chinese study recently reported 55 patients with minimal hepatic encephalopathy

who were randomised to receive a synbiotic preparation, fermentable fibre alone or placebo. Synbiotic treatment was associated with a reduction in serum ammonia, endotoxaemia, reversal of encephalopathy and improvement in Child-Turcotte-Pugh score in 50% patients^[125]. Following liver transplantation, bacterial and fungal infections may occur in the first month despite extensive antibiotic treatment and selective digestive tract decontamination. A German study showed a reduction in post-transplant infective complications using probiotics^[126]. Another recent study looked at the effects of a synbiotic preparation on gut barrier function and in critically ill patients admitted to the Intensive Care Unit (ICU). Ninety patients admitted to ICU were randomised (45 in each group) to receive either synbiotic preparations (*Lactobacillus acidophilus* La5, *Bifidobacterium lactis* Bb12, *Streptococcus thermophilus* and *Lactobacillus bulgaricus* with oligofructose (as a prebiotic) or placebo. Patients in the synbiotic group had a lower incidence of potentially pathogenic bacteria (43% vs 75%, $P = 0.01$) and multiple organisms (39% vs 75%, $P = 0.01$) but there were no significant differences in both groups in terms of intestinal permeability, septic complications or mortality^[127]. It should be pointed out that the study lasted only one week.

Probiotics and colon cancer

Colon cancer is one of the leading causes of death in the Western world. Dietary intake of red meat is probably associated with a higher risk whereas the intake of fruit, vegetables, fish and calcium are arguably associated with a lower risk. It is interesting that colon cancer risk is also lower in countries such as Netherlands and Finland where a larger quantity of yoghurt is consumed^[128,129]. Could diet exert its effects *via* the microflora? If so, mechanisms involved might include altered metabolic activity of the intestinal microflora, binding and degradation of potential carcinogens, production of antitumorigenic or mutagenic compounds and enhancement in host immune response. In animals where colon cancer was induced by chemical carcinogens, administration of lactic acid bacteria resulted in a suppression of DNA damage, tumour formation and growth^[130-133].

One bio-epidemiological study showed a higher risk of colon cancer in the simple presence of *Bacteroides* species, but lower risk with *Lactobacillus acidophilus*, *Lactobacillus* S06 and *Eubacterium aerofaciens* identifiable in faecal flora^[134]. This raises the intriguing hypothesis that similarly shifting the resident bacterial populations may be accompanied by parallel reductions in neoplastic risk. However, biodiversity in the colon may merely represent an epiphenomenological consequence of the dietary and environmental risk factors listed above.

Probiotics and digestion

Probiotics may have a promising role in certain aspects of human digestion as illustrated by some interesting studies. Lactose digestion has been shown to improve in lactose malabsorbers who consume live yoghurt rather than milk^[135,136]. The beneficial effects of yoghurt in lactose malabsorbers may result from improved digestion of lactose in the colon from stimulation of colonic bacterial activity by lactic acid bacteria^[137].

Probiotics in irritable bowel syndrome

Irritable bowel syndrome (IBS) is a collection of functional gastrointestinal symptoms such as abdominal pain, defaecatory frequency and or constipation. This area is inevitably contentious, since it remains unclear how much intrinsic intestinal pathology exists in IBS. However, changes in gut sensitivity and defaecatory function are clearly present. Alterations in the composition of intestinal flora have been reported but not proven including a decrease in faecal *Lactobacilli*, *E. coli* and *Bifidobacteria*^[41,110,111] and an increase in other faecal anaerobes^[138-140]. Symptomatic improvement was noted in a very small crossover trial of 18 patients with IBS given *L. acidophilus*^[141] and in an uncontrolled study using *E. faecium* PR88^[142]. On the other hand, no improvement was seen in bloating, pain or urgency to defaecate after the consumption of *Lactobacillus* GG for 8 wk^[143,144]. In a study reported by Saggiaro *et al*^[145], 50 patients with IBS according to Rome II criteria were randomly assigned to a probiotic preparation (a combination of *Lactobacillus plantarum* LPO 1 and *Bifidobacterium breve* Bro or placebo for 4 wk). Pain and severity scores decreased significantly after 14 d of treatment. In a more recent study, 77 patients were randomly assigned to a malted drink containing *Lactobacillus salivarius* UCC4331 or *Bifidobacterium infantis* 35 624 or a malted drink alone^[146]. Significant improvement in symptoms was noted in the *B. infantis* group. A corresponding normalisation in the ratio of IL-10/IL 12 was also noted suggesting that the probiotic may help reduce a proinflammatory state associated with IBS.

However the heterogeneity of the various studies makes it difficult to draw conclusions on the effect of probiotics in IBS, and the field is bedevilled by the fact that all therapeutic interventions in IBS produce a 30%-50% placebo response.

Probiotics and *Helicobacter pylori*

H. pylori infection is associated with gastritis, gastro duodenal ulcers and gastric malignancies. The majority of *H. Pylori* hosts become hypochlorhydric with time. Clinical studies and experimental models have shown that the secreted products of *Lactobacillus acidophilus* can suppress *H. Pylori* growth *in vitro* and *in vivo*. *L. johnsonii*^[147] and LG21^[148] are effective in suppressing the growth of *H. pylori* and reducing gastric inflammation. Placebo controlled studies have demonstrated a reduction in side effects of standard triple therapy if probiotics were administered concurrently^[149-151]. Daily intake of inactivated *L. acidophilus* was shown to improve the efficacy of eradication treatment^[152]. Only one study^[153] showed that supplementation with fermented milk, containing live special probiotic *L. casei* DN-114001, confers an enhanced therapeutic benefit on *H. pylori* eradication in children with gastritis on triple therapy. The theory that probiotic therapy enhances the disappearance of *H. pylori* does not gain any strength from the available literature. Further clinical studies would be needed to evaluate the effects of long term ingestion of probiotics in preventing *Helicobacter*-associated diseases, but are unlikely to supplant *H. pylori* eradication which is rapidly and

highly effective.

In conclusion probiotics are live microbial food supplements or components of bacteria which may have beneficial effects on gastrointestinal health. Innate bacterial floras clearly play an important role in reinforcement of the physical gut barrier, affecting paracellular permeability, mucosal trophic action and microbiological interactions with mucosal lining of the gut. The key and unanswered question is whether the deliberate manipulation of the bacterial complement in the gut can confer clinical benefit. Probiotics do now appear to have a potential role in the prevention and treatment of various gastrointestinal illnesses, but it is likely that benefits achieved are specific to the bacterial species used and to the underlying disease context. Much further work is required from bench to bedside before we can realise the potential of these new interventions.

Abstract

Infection with *H pylori* leads to a persistent chronic inflammation of the gastric mucosa, thereby increasing the risk of distal gastric adenocarcinoma. Numerous studies have determined a clear correlation between *H pylori* infection and the risk of gastric cancer; however, general eradication is not recommended as cancer prophylaxis and time points for treatment remain controversial in different areas of the world. Prevalence rates in Western countries are decreasing, especially in younger people (< 10%); and a decline in distal gastric adenocarcinoma has been observed. Risk groups in Western countries still show considerably higher risk of developing cancer, especially in patients infected with *cagA*⁺ strains and in persons harboring genetic polymorphism of the *IL-1B* promoter (-511T/T) and the corresponding *IL-1* receptor antagonist (*IL-1RN**2). Thus, general eradication of all infected persons in Western countries not recommended and is limited to risk groups in order to achieve a risk reduction. In contrast, infection rates and cancer prevalence are still high in East Asian countries. A prevention strategy to treat infected persons may avoid the development of gastric cancer to a large extent and with enormous clinical importance. However, studies in China and Japan indicate that prevention of gastric cancer is effective only in those patients that do not display severe histological changes such as atrophy and intestinal metaplasia. Thus, prophylactic strategies to prevent gastric cancer in high risk populations such as China should therefore especially aim at individuals now at younger age when the histological alterations caused by the bacterial infection was still reversible. In countries with a low prevalence of gastric cancer, risk groups carrying *cagA*⁺ strains and *IL-1* genetic polymorphisms should be identified and treated.

INTRODUCTION

Since the discovery of *H pylori* in 1983, intensive research has led to the conclusion that infection with this bacterium is the major cause for the development of distal gastric cancer. Infection with the bacterium leads to a chronic inflammation of the gastric epithelium, associated with multifocal gastric atrophy, dysplasia, and malignant transformation in some of the infected patients^[1-6]. Controversy remains why only a minority of infected patients develops distal adenocarcinoma, and how geographic differences between Western and Asian countries may contribute to these differences. *H pylori* infection rates average at about 30% in Western populations; in this part of the world, approximately 0.1%-1% of the patients with *H pylori* induced gastritis will develop distal gastric cancer^[7,8]. Infection rates in Asian countries are higher and range at 60%-88%; distal gastric adenocarcinoma is even more frequent in these countries. Overall, gastric cancer was responsible for almost 650 000 deaths worldwide in the year 2000^[9]. Death from gastric cancer is second only to lung cancer in men and thus contributes to approximately 10% of all cancer deaths annually (see: www.who.org). Since the diagnosis of early gastric cancer is difficult and in most cases diagnosis is made at a more progressed stage, treatment becomes cost-intensive. Therefore, there is a considerable interest to understand the underlining mechanisms and to find strategies to eradicate *H pylori* infection which could prevent gastric carcinogenesis. Such statistical calculations have already been anticipated 10 years ago in high risk populations of Japanese immigrants in Hawaii; currently, however, no guidelines exist when and whom to treat^[10,11].

EPIDEMIOLOGICAL FEATURES IN EAST AND WEST

H pylori infection and gastric cancer in Western countries

In Germany in the year 2000, 21 000 patients suffered from gastric cancer with an equal distribution among males and females^[12]. In the US (<http://seer.cancer.gov>),

a similar occurrence has been reported with more than 45000 deaths per year. In countries such as the USA or Germany, the prevalence of *H pylori* is decreasing, so that meanwhile less than 10% of the children are infected with this bacterium, underlining that a prophylactic eradication or vaccination in childhood is of little interest in these countries^[8,13-15]. Nevertheless, infection rates are high in elderly populations above the age of 50, and this group is particularly suffering from gastric cancer. A reduction of cancer risk may be achieved when patients are cured from the infection. It may thus be important to identify those patients who are at increased risk.

Gastric cancer in Japan and East Asia

Gastric cancer is the second highest cause of cancer-related deaths in Japan, and the death rate due to gastric adenocarcinoma has actually marginally increased to approximately 50000 deaths per year in this country^[13,14,16]. In China, a similar prevalence of gastric cancer has been reported. *H pylori* infection rates in these countries are high and range from 60% in the younger population (10-40 years old) to 80%-90% in elderly patients above the age of 50. In Japan, mortality from distal gastric adenocarcinoma is among the highest scores of the world and could be attributed to the very high rates of *H pylori* infection in this country and the fact that the most common strain of *H pylori* found in Japan is extremely virulent. A prophylactic eradication in people at younger age could save millions of lives as well as enormous costs resulting from ulcer disease, gastrointestinal bleeding and gastric cancer treatment. Therefore, a successful eradication of this pathogen is of crucial socio-economical importance especially in countries such as Japan or China, particularly especially in persons who are at age < 50 years.

The "Asian paradox"

Although there is a considerable high rate of *H pylori* infection in Asian countries such as China, Japan, Thailand and Indonesia, there is a remarkable difference regarding the outcome of gastric cancer within these countries. This observation has also been termed as the "Asian paradox": Although there is a high infection rate in Thailand and Indonesia, there is only little risk of developing gastric cancer in these countries^[14,17]. As discussed below, bacterial virulence factors as well as the individual host immune response may be different among those countries and account for the differential development of the infection outcome. Questions remain whether to treat all infected patients, subgroups of patients, or wait until serious histological alterations have occurred in the various countries mentioned above. The outcome of infection, however, is difficult to predict. Recent studies have elucidated some of the mechanisms of chronic inflammation and thus enable a more precise prediction of the clinical course of infection in different countries.

Impact of strain types on development of distal gastric adenocarcinoma

In recent studies, a new analytical investigation to overcome a potential underestimation of the association of *H pylori* with gastric cancer was performed in a

Western population. Applying various more stringent exclusion criteria to minimize a potential bias from this source increased the odds ratio (95% confidence interval) of non-cardia gastric cancer from 3.7 to 18.3 for any *H pylori* infection, and from 5.7 to 28.4 for *cagA*⁺ *H pylori* infections in Germany^[18-20]. A similar approach has been performed in a study from Sweden, and the results were remarkably consistent with the German study. The observations made in these studies are further supported by a recent cohort study from Japan, in which 36 out of 1246 *H pylori* infected subjects, but none of 280 uninfected subjects developed gastric cancer during a mean follow-up of 7.8 years^[21]. These very stringent epidemiological studies strongly support that the *H pylori* gastric cancer association may have been strongly underestimated the risks in previous studies, and consequently, underline that infection especially with certain *cagA*⁺ *H pylori* can be considered as a true carcinogenic factor. Determination of *cagA* status may thus help the physician to identify people who are at increased risk for gastric cancer. Meanwhile, tests have become available as a serological test and a specific antibody staining for histological specimens^[16].

IMPORTANCE OF BACTERIAL STRAIN TYPES: MOLECULAR AND IMMUNOLOGICAL MECHANISMS

Bacterial virulence factors, especially genetic diversity in the *cagA* region, have been claimed to account for this diverging development. The *H pylori* *cag* pathogenicity island (*cagPAI*) is a 35 to 40 kb genetic element that encodes a type IV secretion system. One of the key factors of this system is the CagA protein; *cagA*⁺ strains inject the CagA protein directly into host cells where it undergoes tyrosine phosphorylation by a host-cell kinase, and the phosphoprotein alters the physiology of the affected cells. Huang *et al* conducted a meta-analysis of the relationship between CagA seropositivity and gastric cancer^[22]. Based on 7 studies with 1707 gastric cancer patients and 2124 matched controls the analysis showed that infection with *cagA*⁺ *H pylori* strains increases the risk for gastric cancer 2.87 fold over the risk associated with *H pylori* infection alone.

Hatatekayama *et al* recently reported that CagA proteins isolated in East Asia, where gastric cancer is prevalent, have a distinct sequence at the phosphorylation site compared with CagA proteins from Western *H pylori* strains^[23-25]. This CagA diversity may be one important variable in determining the biological activity of CagA and the clinical outcome of infection. Translocated CagA forms a physical complex with the SRC homology 2 domain (SH2)-containing tyrosine phosphatase (SHP-2) in a phosphorylation-dependent manner, and stimulates phosphatase activity. SHP-2 is known to play an important inductive role in mitogenic signal transduction. Deregulation of SHP-2 by CagA may induce abnormal proliferation of gastric epithelial cells. In addition, the CagA protein is polymorphic. Thus, CagA proteins isolated in northern parts of East Asia, where gastric cancer is prevalent, have a distinct sequence at the phosphorylation site and thus contribute to the differential outcome.

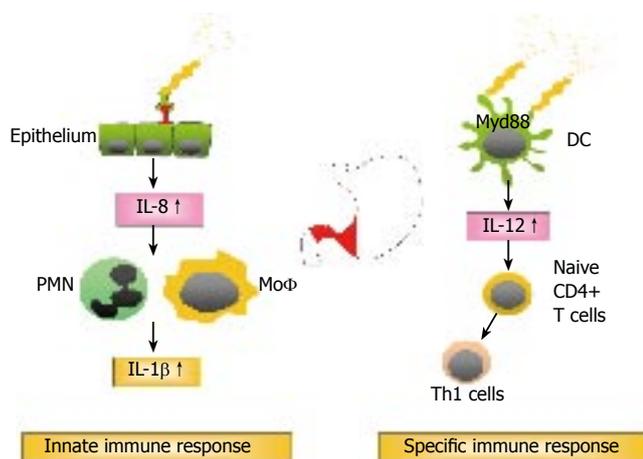

Figure 1 *H pylori*: Immune response and suppression.

Importance of bacterial adherence factors

cagA⁺ *H pylori* strains also are more likely to express the *babA* product, which mediates adherence to Lewis^b antigens on gastric epithelial cells^[26]. European studies have determined that bacteria expressing the adherence factor BabA are detected more frequently in patients with gastric cancer or severe histological changes in the mucosa. Comparing several independent studies in different countries, the relative risk for the development of distal gastric adenocarcinoma was increased up to 20-fold. These results support the hypothesis, that the risk of developing severe gastric pathologies is dramatically increased once the correct determination of the *cagA* status is performed^[27-31].

Current model for the initiation of heightened gastric inflammation

A new concept has now emerged why *cagA*⁺/*babA*⁺ *H pylori* strains induce higher levels of the proinflammatory cytokines IL-1β and IL-8. Adherence of *H pylori* to epithelial cells *via* BabA favors a more tight adhesion to the epithelial cell and thus promotes bacterial colonisation. Injection of CagA into epithelial cells is associated with IL-8 secretion, which in turn, acts as a local chemoattractant for polymorphic mononuclear cells (PMN)^[29]. These PMNs are considered to be of critical importance for the breakdown of the local epithelial barrier and may lead to a further infiltration of the bacteria into the submucosa. Thus, several studies outline the view that bacterial virulence and adherence factors contribute to the development of severe diseases in the stomach. Infection with certain *H pylori* strain types is therefore more dangerous than smoking a pack of cigarettes per day, leading to a 21-fold increased relative risk for the development of lung cancer.

Figure 1: Events during the initial infection process with *H pylori*

Infection with so called type 1 strains harboring *cagA/vacAs1* and *babA* is associated with a dramatically increased risk to develop distal gastric adenocarcinoma. Infection with specific strain types thus is the major determinant of the further sequence of events.

IMPORTANCE OF HOST GENETICS FOR THE *H PYLORI* INDUCED INFLAMMATION AND CANCER DEVELOPMENT

Genetic polymorphisms contribute to severe gastric inflammation

In addition to bacterial factors, but less important in terms of relative risk increment, are host factors that seem to influence the inflammatory response and the development of a more severe pathology. *H pylori* induced inflammation is implicated in the development of mucosal damage and is characterised by strong granulocytic and lymphocytic infiltration. The T helper cell response towards *H pylori* is generally considered to be of the Th1 phenotype, leading to a cell mediated immune response^[32-35] (Figure 1). There is increasing evidence that the *H pylori* induced Th1 response contributes to cancer development. Downregulation of the Th1 response in mice by concurrent enteric helminth infection or p53 mutation was shown to protect against the development of atrophy, intestinal metaplasia, and invasive gastric carcinoma^[35-37]. Important cytokines characterising Th1 mediated immune responses are interferon-γ (IFN-γ), tumour necrosis factor-α (TNF-α), and interleukin-1β (IL-1β), all being upregulated during chronic *H pylori* infection^[38-40]. IL-10, which is also highly expressed in the *H pylori* infected stomach, is one of the most important regulatory cytokines, inhibiting cell mediated immune responses^[38,41,42].

Genes encoding cytokines and related molecules harbour polymorphic regions, which are considered to alter gene transcription and thereby influence inflammatory processes in response to infectious diseases. Polymorphisms in the human *IL-10*, *IL-1B*, *TNF-α*, *IFN-γ*, and *IL-1* receptor antagonist (*IL-1RN*) genes have been reported to influence cytokine expression^[43-47]. In the promoter region of the *IL-1B* gene, *IL-1B-511T*, which is in complete linkage disequilibrium with *IL-1B-31C*, was previously associated with slightly, but not significantly, increased IL-1β secretion from stimulated PBMC. The *IL-1RN* gene has a penta-allelic 86 bp variable number of tandem repeat region (VNTR) in intron 2, of which allele 2 (*IL-1RN*2*) was previously associated with enhanced IL-1β secretion^[46] and the development of gastric cancer^[44]. Presence of certain genetic polymorphisms of the host, in contrast to the bacterial factors, increase the relative risk for distal gastric adenocarcinoma by 1.5-4 fold. In a German population^[48], the homozygous genotype *IL-1RN*2/2* of the *IL-1RN* gene was strongly associated with early-stage gastric cancer ($P < 0.0001$), whereas further associations with the *IL-1* gene cluster were not observed. A Korean group^[49] determined that patients with intestinal-type gastric cancer showed a higher frequency of *IL-1B-31T* homozygotes [odds ratio (OR) = 2.2; 95% confidence interval (CI) = 1.1-4.3] compared with controls. Risk was also significantly increased in these patients for *IL-1B-31T* homozygotes compared with patients with diffuse-type gastric cancer (OR = 3.4; 95% CI = 1.5-7.7). In a Chinese study, it was reported that the relative risks associated with the *IL-1B* variant genotypes were 1.64

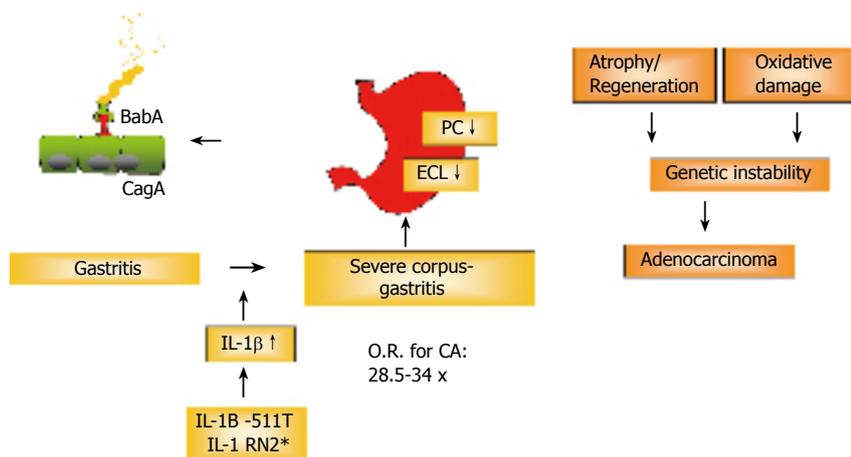

Figure 2 *H. pylori*: Chronic inflammation and carcinogenesis.

(95% CI, 1.01-2.66) for -31TT and 1.52 (95% CI, 0.91-2.54) for -511CC, respectively, compared with their wild-type homozygotes^[50]. The risks were significantly more evident in individuals with *H. pylori* infection (adjusted OR = 2.14; 95% CI, 1.13-4.06 for -31TT; adjusted OR = 2.00; 95% CI, 1.02-3.89 for -511CC), which was consistent with the biological effects of IL-1 β .

Chen *et al.*^[51] identified that the carriage of IL-1RN*2 polymorphism, male gender, old age and *H. pylori* infection independently increased the risk of gastric cancer, with odds ratios of 3.3 (95% CI, 1.4-7.7), 2.1 (95% CI, 1.2-3.8), 5.3 (95% CI, 3.1-9.0) and 2.2 (95% CI, 1.3-3.8), respectively. *H. pylori*-infected individuals who were carriers of IL-1RN*2 showed increased risks for both intestinal and diffuse types of gastric cancer, with odds ratios of 11.0 and 8.7, respectively. Thus, IL-1RN*2 was interpreted to be an independent factor governing the development of gastric cancer in Asian individuals.

In areas of high and low prevalence of gastric cancer in China^[52], the IL-1B -511T/T genotype frequency was significantly higher among patients with gastric cancer (25.0%) than control subjects (12.5%) in a region with low GC prevalence. While *H. pylori* infection alone had only a modest effect on the risk of gastric cancer development (OR = 5.0, 95% CI 1.5-16.3), combined with the IL-1B -511T/T genotype the risk was markedly elevated (OR = 17.1, 95% CI 3.8-76.4). The study underlines the synergy between *H. pylori* infection and the host immune response to induce gastric cancer.

A recent German study confirmed this synergistic effect also in regard to the induction of premalignant changes. In a large group of *H. pylori* infected patients^[29], carriers of the proinflammatory IL-1B -511T/-31C and IL-1RN*2 alleles had an increased risk for the development of atrophic gastritis (AG), intestinal metaplasia (IM), and severe inflammation, ORs of 1.7 (95% CI, 0.8-3.4) to 4.4 (95% CI, 1.5-12.9). The highest prevalence of severe gastric abnormalities was found in patients with both host and bacterial high-risk genotypes (*cagA*⁺/*vacAs1*⁺/IL-1B -511T/IL-1RN*2), with ORs of 24.8 (95% CI, 5.2-117.3) for severe lymphocytic infiltration, 9.5 (95% CI, 2.8-32.1) for severe granulocytic infiltration, 6.0 (95% CI, 2.4-15.5) for IM, and 2.4 (95% CI, 0.93-6.2) for AG. These dramatically elevated values underline the importance

of the infection for gastric cancer development. It may thus be concluded from the above studies, that combined bacterial/host genotyping thus may provide a clinical tool to identify patients at high risk of developing gastric cancer. This current concept of gastric carcinogenesis is illustrated in Figure 2.

Figure 2: Concept of gastric carcinogenesis

There is overwhelming evidence that *H. pylori* infection, especially with *cagA*⁺ strains, leads to a strong granulocytic and lymphocytic infiltration; a subgroup of infected patients will develop gastric cancer, especially in high-risk countries such as Japan, China and East-European countries. Reasons for this progression include genetic polymorphisms, e.g. IL-1B/IL-1RN polymorphisms associated with high levels of IL-1 β . IL-1 β is a strong antisecretory cytokine. These genetic polymorphisms lead to a heightened cytokine release, which in turn decreases acid secretion. Subsequently, the association of hypochlorhydric conditions with the persistent inflammation in the gastric corpus is considered to be a true risk factor (RR: 34.5-fold!) for the development of gastric cancer. Studies should therefore aim not only at preventing gastric cancer, but also at preventing the development of severe corpus gastritis, leading to potentially irreversible atrophy and hypochlorhydria.

PROPHYLAXIS OF GASTRIC CANCER

Prospective intervention studies

Data from a Chinese trial^[53] investigating *H. pylori* eradication in gastric cancer showed that the incidence of gastric adenocarcinoma development was similar in patients undergoing eradication therapy compared with placebo over a 7.5-year period. Interestingly, in a subgroup of *H. pylori*-positive patients without atrophy, intestinal metaplasia or dysplasia (pre-cancerous lesions), eradication therapy significantly decreased the development of gastric adenocarcinoma to a frequency of zero. The data are in accordance with a recent study in Japan^[4]: in this prospective study, no carcinomas were observed in the *H. pylori* negative group. This study supports the view that a prospective eradication study should be performed in young adults in which histological alterations have not

proceeded too far and may be reversible.

Zhou *et al*^[54] investigated histopathological changes in *H pylori* eradicated subjects in China over a period of more than 5 years. The authors report in a group of 552 *H pylori*-positive subjects that, the severity and activity of inflammation in both the antrum and body were markedly reduced after *H pylori* eradication. Within the five years after eradication of *H pylori*, intestinal metaplasia in the antrum regressed or showed no progression, while the proportion of intestinal metaplasia in the *H pylori*-positive group increased significantly. After *H pylori* eradication, the atrophy in both the antrum and body had no significant regression. After eight years of observation, the authors report a significantly higher incidence of gastric cancer in the *H pylori* infected group (5/1530) than in the *H pylori*-negative (1/1230) group in the Yantai area of China, underlining the need for eradication in early stages.

Serum pepsinogen levels as risk factors for developing gastric cancer

A recently published study^[55] reports that subjects seropositive for either *H pylori* or CagA who had low pepsinogen (PG) I levels had the highest OR (9.21 95% CI 4.95-17.13) for noncardia cancer, compared with subjects with neither factor. The results suggest that individuals with both *H pylori* or CagA seropositivity and a low PG I level or low PG I / II ratio are highly susceptible to development of noncardia gastric cancer. Such tests can easily be performed in clinical routine. Watabe *et al*^[56] have confirmed that *H pylori* infection and gastric atrophy are both risk factors for gastric cancer in a study group with a total of 9293 participants. The annual incidence of gastric cancer was 0.04%-0.60%. As expected, the highest relative risk for gastric cancer was found in *H pylori* infected subjects with gastric atrophy and high serum pepsinogen levels [OR = 8.2 (3.2-21.5)].

H pylori eradication and the risk of esophageal cancer

Concerns exist whether eradication of *H pylori* might lead to the development of esophageal cancer. To clarify the role of *H pylori* infection in these tumors with divergent incidence trends, Chow *et al*^[57] analyzed serum IgG antibodies to *H pylori* and to a recombinant fragment of CagA by antigen-specific ELISA among 129 patients newly diagnosed with esophageal/gastric cardia adenocarcinoma, 67 patients with noncardia gastric adenocarcinoma, and 224 population controls. Infection with *cagA*⁺ strains was not significantly related to risk for noncardia gastric cancers (OR = 1.4; CI = 0.7-2.8) but was significantly associated with a reduced risk for esophageal/cardia cancers (OR = 0.4; CI = 0.2-0.8). The study thus contradicts previous reports and may be biased by the selection of patients in a rather small group. While Wu *et al*^[58] found no significant association, Ye *et al*^[59] determined the opposite: *H pylori* infection may protect from esophageal cancer (OR = 0.3). Thus, at this point, several works indicate that CagA has a protective effect on the development of esophageal cancer, however, no general conclusions can be made.

However, this association does not justify a general refusal of *H pylori* eradication because of two reasons. First, esophageal adenocarcinoma is far less common

than gastric cancer. Second, the risk of developing adenocarcinoma of the esophagus is lowered by a factor 2-2.5 in the presence of *cagA*-positive *H pylori* infection whereas the risk for distal gastric cancer associated with *cagA*-positive strains is much higher (5-28x).

CONCLUSIONS

H pylori is a clear cut carcinogen. Infection with certain strain types in the presence of genetic polymorphisms leading to a heightened inflammatory response is associated with a dramatically increased relative risk to develop gastric cancer. Such developments can be foreseen by evaluating gastric biopsies, but also by determining serum pepsinogen levels as a marker of gastric atrophy. Endoscopy of the upper gastrointestinal tract (GI) should be performed before eradication to determine the status of gastric inflammation. Eradication of *H pylori* as prophylaxis of gastric adenocarcinoma is effective in early stages in which no severe histological changes have occurred. In countries with a high prevalence of infection and high cancer risks such as Japan or China, a general prophylactic eradication strategy seems to be beneficial especially in younger patients (< 50 years); nevertheless, the outcome of such long term prospective prophylactic studies needs to be evaluated. In Western countries with low prevalence rates and low cancer rates, a test-and-treat strategy is not cost-effective to prevent cancer; however, identification and treatment of risk groups seems rationale. Risk groups can be identified by evaluation of family history, presence of histological alterations in the gastric corpus, or by determining infection with *cagA*⁺ strains as well as determining the status of genetic polymorphisms in the IL-1RN*2 gene.

Conversely, neither VEGF-R1 expression nor MVD was related to p53 expression. However, *H. pylori* was not related to any angiogenic markers except for the plasma VEGF level ($P = 0.026$).

CONCLUSION: *H. pylori* antigen is related to higher plasma VEGF levels, but not to angiogenic characteristics. It can be hypothesized that the toxic effects of *H. pylori* on angiogenesis occurs in early preclinical disease phase or in long-lasting aggressive infections, but only when high *H. pylori* IgG levels are persistent.

Abstract

AIM: To investigate *H. pylori* expression in gastric cancer patients in relation to primary tumor angiogenic markers, such as microvessel density (MVD), thymidine phosphorylase (TP), vascular endothelial growth factor receptor-1 (VEGF-R1), p53 and circulating VEGF levels.

METHODS: Angiogenic markers were analyzed immunohistochemically in 56 primary gastric cancers. *H. pylori* cytotoxin (*vacA*) and the cytotoxin-associated gene (*cagA*) amplification were evaluated using PCR assay. Serum *H. pylori* IgG antibodies and serum/plasma circulating VEGF levels were detected in 39 and 38 patients by ELISA, respectively.

RESULTS: A total of 69% of patients were positive for circulating IgG antibodies against *H. pylori*. *cagA*-positive *H. pylori* strains were found in 41% of gastric patients. *vacA* was found in 50% of patients; s1 strains were more highly expressed among *vacA*-positive patients. The presence of the s1 strain was significantly associated with *cagA* ($P = 0.0001$). MVD was significantly correlated with both tumor VEGF expression ($r = 0.361$, $P = 0.009$) and serum VEGF levels ($r = -0.347$, $P = 0.041$).

INTRODUCTION

H. pylori infection is a well-known risk factor for the development of pre-neoplastic and neoplastic gastric mucosal alterations^[1,2]. An increase in proliferative activity of gastric epithelial cells without a corresponding increase in apoptosis has been implicated in *H. pylori* gastric carcinogenesis^[3,4]. In addition, specific virulence determinants of *H. pylori* strains can influence the outcome of the infection. Urease, vacuolating cytotoxin *vacA*, and the pathogenicity island (*cag* PAI) gene products are the main virulence factors of this organism involved in the development of gastric carcinoma. Thus, individuals infected with strains that express these virulence factors are prone to develop severe local inflammation which may induce the development of peptic ulcers and gastric cancers. Also, *H. pylori* activity may be associated with virulence; in fact, urease activity may be an important colonization factor and exert a direct toxic effect upon intercellular junctions, resulting in alteration of gastric mucosal permeability^[5]. The subsequent passage toward cancer is probably prompted by other factors, such as the onset of infection or other agents independent of *H. pylori*.

Several studies have suggested that angiogenesis might also contribute to gastric tumorigenesis^[6-8]. Angiogenesis is a complex multistep cascade modulated by positive soluble factors, such as the vascular endothelial growth factor (VEGF). The tumor neo-angiogenesis has been demonstrated in almost all solid tumors using various morphological techniques. The current method of angiogenesis quantification is the evaluation of CD34 antigen expression, a cell surface glycoprotein also present in the vascular endothelium permitting the study of intratumor endothelial cells^[9]. The cellular receptor for VEGF, VEGF-R1 or Flt-1, is highly expressed in gastric carcinoma cells, suggesting that this pathway could influence tumor growth and metastasis through paracrine and autocrine mechanisms^[10]. An additional tissue factor is thymidine phosphorylase (TP), an enzyme involved in pyrimidine nucleoside metabolism, which is identical to the platelet-derived endothelial cell growth factor and is endowed with angiogenic activities in various solid tumors^[11]. Furthermore, the *p53* oncosuppressor gene has been reported to be involved in inhibition of tumor vascularization by fostering unopposed angiopoietin-2 activity^[12].

Recent publications have suggested that *H pylori* infection may regulate the angiogenesis and invasion of gastric carcinoma. In fact, *H pylori* influences *in vitro* angiogenesis-related gene expression; in particular, it has been demonstrated to up-regulate VEGF expression in gastric epithelial cells, an effect which appears to be related to *vacA*-expression^[13,14]. Moreover, *H pylori* has been shown to up-regulate the expression of epidermal growth factor (EGF)-related growth factors and COX-2 in *in vitro* human gastric epithelial cells as well as in human gastric mucosa *in vivo*^[15,16]. Lastly, its relationship with *p53*, which has been described as an angiogenesis-related factor, has been documented^[17-20]. In spite of these evidences originating from *in vitro* studies, suggesting a relationship between pathophysiological roles for *H pylori* in the induction of tumor neo-angiogenesis, to our best of knowledge, no data are available in literature in patient series. Our hypothesis was that *H pylori*-related gastric cancer could involve different neo-angiogenic characteristics with respect to tumors without bacterial infection.

To verify the association between *H pylori* infection and different angiogenesis-related characteristics, 56 gastric cancer patients were studied for microvessel density (MVD), thymidine phosphorylase (TP), vascular endothelial growth factor-receptor (VEGF-R1) and *p53* expressions in addition to circulating serum and plasma VEGF levels. *H pylori* was investigated at the molecular and at circulating blood levels.

MATERIALS AND METHODS

Patients

Fifty-six patients (37 men and 19 women; median age 64 years, range 42-83 years) with T₁₋₄ N₀₋₁ M₀₋₁ gastric carcinoma were enrolled in this study. All patients had primary surgery for gastric cancer at National Cancer Institute of Bari. Primary tumor tissues were utilized for the immunohistochemical analysis of MVD, *p53*,

VEGF-R1 and TP expressions.

Formalin-fixed and paraffin-embedded specimen of the primary tumor was selected by the pathologist for each patient on the basis of the quality of morphological preservation and neoplastic cellularity. In accordance with standardized sampling protocols, the sample was comprehensive both at the deeper portions of tumor, as well as the edges of the lesions. Five-micrometer thick sections were cut for immunohistochemical assay and for determination of *H pylori* status by means of polymerase chain reaction (PCR). A section contiguous to those selected for immunohistochemistry and DNA extraction was always stained with haematoxylin and eosin and confirmed by the pathologist as rich in neoplastic cellularity. Enzyme-linked immuno-sorbent assay (ELISA) for IgG antibodies against *H pylori* was performed on blood samples from 39 patients. Circulating VEGF levels were detected by ELISA in serum and plasma of 38 patients. The patients characteristics are shown in Table 1.

DNA extraction and PCR analysis

DNA extraction from paraffin-embedded specimens was performed using the method described by Lin *et al*^[21]. Briefly, samples were incubated with a lysis buffer and proteinase K for 3 h at 55°C. Total DNA was extracted with phenol/chloroform, precipitated with acidic ethanol, and dissolved in sterile water.

Amplification of *cagA* and *vacA*

The extracted DNA was subjected to PCR for detection of *H pylori* genes, *cagA* and *vacA*. The *cagA* gene was amplified using the primers described elsewhere^[22,23]. The *vacA* gene

was amplified using primers described by Atherton *et al.*^[24] which evaluate the mid region (*m*) and the region encoding for the signal peptide (*s*) of the gene. Four different PCR products were obtained: *s1* or *s2* from the *s* region, and *m1* and *m2* from the *m* region. PCR products were analyzed by electrophoresis on 20 g/L agarose gel. Positive and negative controls were examined with each batch of PCR.

Detection of anti-*H pylori* IgG

An enzyme-linked immuno-sorbent assay was used to detect *H pylori*-specific IgG serum antibodies (Anti-*H pylori* EIA Quant- COBAS2- Roche Diagnostics). The anti-*H pylori* IgG EIA is a second-generation two-step EIA for the detection of IgG antibodies to *H pylori* in human serum, based on a set of fast protein liquid chromatography-purified cell surface antigens, including the native urease enzyme^[25]. According to the manufacturer, patients were considered positive for IgG against *H pylori* when IgG value was higher than 7 U/mL.

Immunohistochemistry

Serial sections of paraffin-embedded gastric tissue were deparaffinized and rehydrated. For antigen retrieval, the sections were microwaved at 500 W for 10 min in citrate buffer (pH 6) and endogenous peroxidase activity was blocked with 30 mL/L hydrogen peroxide solution. Adjacent slides were incubated with different monoclonal antibodies. The bound antibody was visualized using a biotinylated secondary antibody, avidin-biotin peroxidase complex, and 3-amino-9-ethylcarbazole (Ultra Vision Detection System anti-Polyvalent, HRP/DAB, Lab Vision Corporation). For negative control sections, primary antibody was replaced with phosphate-buffered saline and processed in the same manner. Gastric carcinomas known to express high levels of CD34, p53, TP and VEGF-R1 proteins were used as positive controls.

Anti-CD34 (QB-END/10, Novocastra Laboratories Ltd) was diluted at 1:50 for 1 h at room temperature as a pan-endothelial marker for MVD analysis. The modified Weidner's method was utilized for the evaluation of MVD according to CD34 endothelial cell immunostaining^[26]. For the microvessel counting, positive stainings for MVD, in five most highly vascularized areas ('hot spots') in each slide, were counted in 400 × fields with an image analysis system (Quantimet 500 Leica; 0.19 mm²/field) and MVD was expressed as the average of the microvessel count in these areas^[27]. Any EC or endothelial cluster positive for CD34 (brown yellow staining) was considered to be a single countable microvessel. Sclerotic areas, both hypocellular and necrotic, within the tumor were not considered for vessel evaluation.

Anti-p53 monoclonal antibodies (PAb 1801, Neo-Markers), grown against human p53 and recognizing wild-type and mutant forms of the p53 protein, were diluted at 1:150 for 1 h at room temperature. Tumor cells expressing p53 immunoreactivity were quantified by evaluating a total of 1000 neoplastic cells in random fields from representative areas. Exclusive nuclear staining was scored as positive. The immunoreactive cells were expressed as percentages^[28]. Anti-TP monoclonal antibodies (P-GF.44C Neo-Markers), recognizing full

length human TP protein, were diluted at 1:100 for 1 h at room temperature. TP positivity was determined at 400 × fields with the image analysis system and was evaluated on the basis of percentage of stained epithelial tumor cells. Tumor cells with moderate or strong staining intensity were counted. TP expression in macrophages was considered an internal positive control. The polyclonal antibody anti-VEGF-R1 (Flt-1 polyclonal rabbit antibody, Santa Cruz Biotechnology Inc.), recognizing the carboxyl terminus of the receptor for VEGF, VEGF-R1 or the Flt-1 protein of human origin, was used at a dilution of 1:100 for 1 h at room temperature. VEGF-R1 positivity was scored as cytoplasmic immunostaining using an image analysis system (Quantimet 500 Leica). Immunoreactivity was expressed as the percentage ratio between the area of immuno-positive tumor cells and the entire area of invasive neoplastic tissue.

The laboratory, where the immunohistochemical analyses were performed, participated to Quality Control programs managed by INQAT^[29].

Circulating VEGF detection

Blood samples were collected before surgery. Venous blood was dispensed into a serum separator tube (Becton Dickinson Vacutainer Systems) for serum obtainment, and into sodium citrate, theophylline, adenosine, dipyridamole (CTAD) tubes for plasma (Becton Dickinson Hemogard Vacutainer Systems).

Circulating VEGF levels were examined in plasma and serum using the Quantikine Human VEGF-enzyme-linked immuno-sorbent assay (ELISA, R&D System Inc.) which recognizes VEGF165. According to the manufacturer, the minimum detectable dose of VEGF is typically less than 9.0 ng/L. Values below 9.0 ng/L were equal to zero. VEGF levels in plasma and serum were analyzed, as we previously demonstrated that the two determinations provide alternative and additional information on circulating VEGF, also in relation to the role played by the activation and quantity of platelets in VEGF release^[30].

Statistical analysis

The associations between MVD, TP, VEGF-R1 and p53 expression, markers of *H pylori* status and histological diagnosis were evaluated using the Chi-square test. A correlation analysis among the aforementioned biomarkers, considered as continuous variables, was performed by Pearson's correlation coefficient (*r*). In the statistical analysis, *vacA* genotypes were classified into two subgroups: "cytotoxic strains" which included s1m1, s1m2 and s1m1/s1m2 strains and "others" which included negative and s2m2. Patients with s1m1/s1m2 strains were infected by multiple genotypes. Backwards stepwise logistic regression analysis was used to estimate the independent association of any biological markers with *H pylori* characteristics. Statistical analysis was carried out using the software SPSS for windows, release 9.0.

RESULTS

H pylori status

Cytotoxin-associated gene (*cagA*)-positive *H pylori* strains

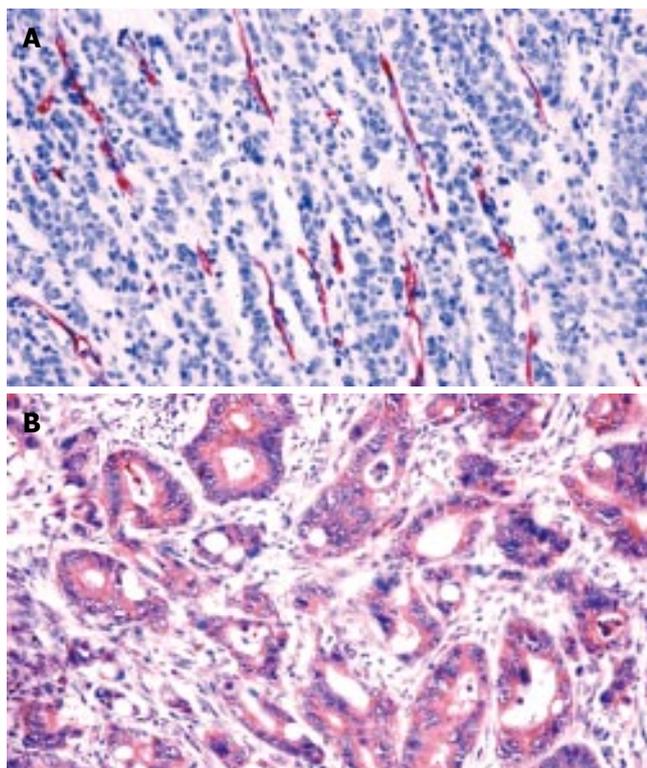

Figure 1 Immunohistochemical assay for detection of microvessel density (A) and VEGF-R1 protein expression (B) in gastric cancer. VEGF-R1 is stained in the cytoplasm of cancer cells.

were found in 41% of gastric patients. *vacA* was found in 50% of patients; s1 strains were more highly expressed among *vacA*-positive patients. Moreover, a single patient was found to be infected with different *H pylori* strains (multiple genomes). The results are summarized in Table 1. The presence of the s1 strain was significantly associated with *cagA* ($P = 0.0001$). Only one patient infected with the s2 strain showed *cagA*-positivity, while 26 (81%) patients were negative for both *cagA* and *vacA*. A total of 69% of patients were positive for circulating IgG antibodies against *H pylori*, with a mean and median value of 77 U/mL (range 1-476 U/mL) and 15 U/mL, respectively.

Immunohistochemical analysis

TP immunoreactivity was observed in normal epithelial cells, malignant epithelial cells, macrophages and endothelial cells. The usual pattern of positive staining was both cytoplasmic and nuclear. A mean of 5% (range 0%-80%) of cells showed TP positivity.

p53 expression was generally confined to neoplastic tissues, while the normal mucosa was rarely stained. A mean of 3% (range 0%-50%) of cells showed p53 positivity.

CD34 immunostaining was detected in the endothelial cells, especially in the area surrounding the tumor (Figure 1A). In the 'hot spot' tumor area, a mean of 39 vessels (range 0-100 vessels) was found with only 2% of cases not demonstrating any microvessels. VEGF-R1 immunostaining was mainly localized at the membrane and cytoplasm of epithelial and endothelial cells (Figure 1B). By counting only the epithelial component, a mean of 24% (range 0%-100%) of VEGF-R1-immunostained cells was found.

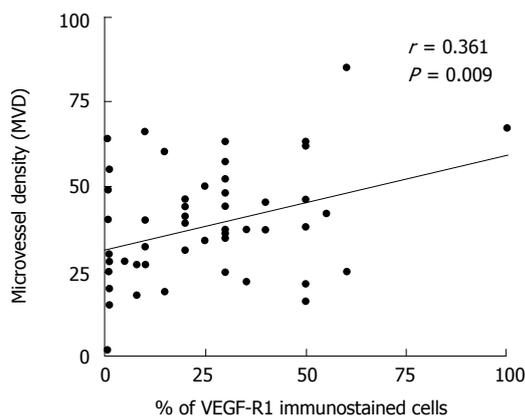

Figure 2 Correlation between percentage of VEGF-R1-immunoreactive cells and microvessel density (MVD) within each tumor.

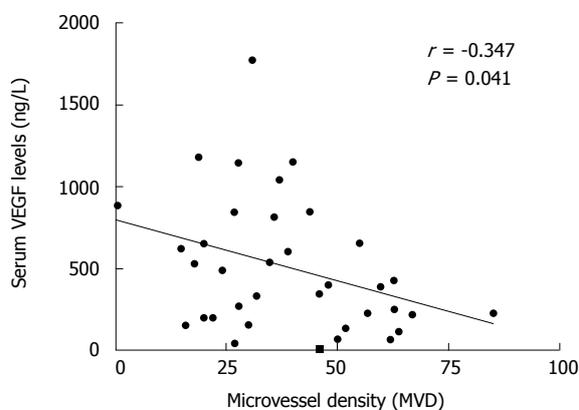

Figure 3 Correlation between serum VEGF levels and microvessel density (MVD) within each tumor.

About 80% of tumors demonstrated VEGF-R1 expression.

Regarding the relationship among the different angiogenic characteristics, only MVD was significantly correlated with both tumor VEGF expression ($r = 0.361$, $P = 0.009$; Figure 2) and serum VEGF levels ($r = -0.347$, $P = 0.041$; Figure 3). Conversely, neither VEGF-R1 expression nor MVD was related to p53 expression.

Table 2 shows the association between the markers of *H pylori* status and angiogenic factors. There was no significant association between markers of *H pylori* status, *cagA*, *vacA* and angiogenic biomarker expression. When the correlation between angiogenesis related-markers and IgG status was analysed a significant correlation between IgG status and plasma VEGF levels was observed ($P = 0.026$). The lack of association between *H pylori* characteristics and biomarkers was also confirmed with multivariate logistic regression analysis.

Angiogenic marker expression and markers of *H pylori* status were analyzed with respect to clinico-pathological features. Plasma VEGF levels and tumor TP expression were both significantly associated with tumor size ($P = 0.030$ and $P = 0.035$, respectively; Table 3). Regarding plasma VEGF levels in particular, T₄ tumors showed a significantly smaller percentage of low IgG cases as compared with T₁₋₃ tumors (31% vs 74%; $P < 0.03$).

Low sVEGF levels (<i>n</i> = 19)	35	67	NS	50	50	NS

NS: Non-significant.

Lastly, p53 expression was significantly associated with metastatic status (*P* = 0.038), as 100% of patients with metastatic disease did not express p53. No association was found between cytohistological tumor grading or *H pylori* infection site and angiogenesis-related markers and *H pylori* characteristics.

DISCUSSION

The role of *H pylori* in gastric cancerogenesis has been extensively investigated; conversely, information is lacking regarding the biological impact of *H pylori* on the progression of gastric cancer. Several factors emphasize the importance that various *H pylori* components can have their roles on the development of pre-neoplastic and neo-

plastic alterations of the gastric mucosa. Specific virulence factors produced by the bacterium, such as the vacuolating cytotoxin (*vacA*) or the cytotoxin-associated protein (*cagA*), contribute to gastroduodenal mucosal injury and impair the healing process of the damaged mucosa^[31,32]. In addition, the host response to the infection and the presence of environmental factors are thought to be involved in the pathogenesis of *H pylori*-related gastroduodenal disease^[33,34]. The vacuolating toxin (*vacA*) is believed to be a major determinant of *H pylori*-associated gastric disease^[35,36]. The vacuolating cytotoxin gene A (*vacA*), which encodes the *vacA* protein, is present in all *H pylori* strains, but its encoded products are associated both with and without *in vitro* vacuolating activity^[37]. It has been suggested that the *vacA* s1a genotype is closely associated with

high cytotoxin production, while the *vacA* s2 allele can demonstrate a negative *in vitro* association with cytotoxin activity. The presence of these virulence factors can be used to identify patients at risk to develop gastric cancer; in fact, patients with neoplastic transformation of the gastric mucosa are more likely to be infected by the *cagA*+ strain^[19,38,39]. However, conflicting results regarding the association between these virulence factors and clinical outcome of gastric cancer are found in the literature^[36,40-43].

p53 mutations and the genotypic characterization of *H pylori* have also been thoroughly studied to identify possible links between *H pylori* infection and p53 alterations without reaching definitive conclusions. Alterations of the *p53* gene and/or its abnormal protein accumulation have both been described during the later stage of gastric carcinogenesis^[44,45] and in precancerous gastric lesions^[46]. As *cagA*+ *H pylori* strains induce particularly severe inflammation in the gastric mucosa^[41,47], it has been hypothesized that gastric tumors from subjects infected with *cagA*+ *H pylori* might have a higher prevalence of p53 mutation than tumors from non-infected subjects.

H pylori infection may also regulate the angiogenesis and invasion of gastric carcinomas^[13,14], but whether *H pylori* exerts its effects to induce neovascularization early in the development of gastric pre-neoplastic lesions or late in clinical phases of the disease is still unknown. However, it is clear that *H pylori* infection can increase the expression of the platelet-derived endothelial cell growth factor by infiltrating interstitial cells in pre-malignant lesions, such as intestinal metaplasia, thereby assisting in creating a favourable environment for tumor development^[48]. Furthermore, it has been demonstrated that *H pylori* is able to up-regulate VEGF expression in gastric epithelial cells determining effects related to *vacA*-expression.

Recently, for the first time, Caputo *et al*^[13] showed that *H pylori* up-regulated VEGF expression in gastric mucosa cells *in vitro* and that this effect was strictly *vacA*-dependent; and, interestingly, this result was not observed when using an isogenic mutant specifically lacking *vacA*. Moreover, *in vitro* and *in vivo* up-regulation of a number of EGF-related growth factors have also been reported^[15,16,49].

In our sufficiently large series of gastric cancer patients, a percentage of *H pylori* infection was demonstrated, either as IgG-circulating level or as *cagA*/*vacA* DNA, which is in agreement with the previous studies^[50,51]. In addition, the neo-angiogenesis characteristics reported did not significantly differ from those of other series of gastric cancers^[7,52,53]. It is also possible to verify a clear relationship between p53, TP, VEGF and the clinicopathological characteristics considered in our series, further stressing the impact that angiogenesis has on tumor aggressiveness^[52,53]. In fact, TP expression and plasma VEGF levels were both associated with tumor size, while p53 expression was associated with metastatic status.

However, when addressing the main objective of our study, it is possible to demonstrate an association only between higher levels of plasma VEGF and high levels of IgG (Table 3). Conversely, *H pylori*-infected tumors did not show p53, MVD, TP, VEGF-R1 characteristics which obviously differed from those without presence of

H pylori infection. These results only partially agree with previous data^[17,54] which, however, were all obtained from experimental *in vitro* models, in some cases referring to mRNA analyses utilizing only quantitative molecular or immuno-enzymatic approaches^[14], therefore not exploiting morphological antigen tissue distribution. Furthermore, the increase of gene expression induced by the co-culture of gastric tumor cells with *H pylori* has been reported to be generally modest with more evident positive modulation for angiogenic factors not investigated in the present study, such as interleukin-8^[14]. Caputo *et al*^[13] also recently suggested that *vacA*-induced up-regulation of VEGF expression could depend on the functionality of epidermal growth factor receptor (EGFR)-, mitogen-activated protein kinase (MAPK)- and COX-2-mediated pathways, the biological targets which are largely heterogeneous in human gastric cancer. In conclusion, our study seems to suggest that the relationship between the *H pylori* toxic effect and angiogenic factors demonstrated *in vitro* could be influenced in human gastric tumor tissues by other key biological factors not considered in the present study.

A last comment regarding IgG and VEGF association concerns the blood of gastric cancer patients. The level of IgG antibodies has been suggested to be useful, not for diagnosis of infection, but for monitoring the outcome of *H pylori* infection over time, and specifically the efficacy of therapies aiming to eradicate *H pylori* infection. Thus, an elevated serum level before primary surgery for gastric cancer could be a signal of long-lasting and probably *H pylori* infection resistant to antimicrobial therapy^[55].

The results of our study indicate that, from the angiogenic point of view, *H pylori*-related gastric cancers do not differ from those in which exposure to the bacterium cannot be demonstrated. Different explanations for these findings can be proposed: an angiogenetic relationship, if any, could be only induced by a long-lasting *H pylori* infection demonstrated by high IgG levels in the plasma; an alternative hypothesis might regard the ability of *H pylori* to modulate angiogenesis only during early phase of disease genesis and progression to be then lost during the clinically evident disease phases. This hypothesis would concord with the presumed role that angiogenesis plays, especially during the extremely early phases of cancer^[9,17,56].

ACKNOWLEDGMENTS

We thank Mr. Baldassarre Stea for statistical analysis, Mr. Cesare Salvatore for technical support and Mrs. Paulene Maselli-Campagna for her help in the elaboration of the manuscript.

Abstract

AIM: To investigate the relationship between the -765G > C COX-2 polymorphism and the development of different gastric lesions: atrophy or intestinal metaplasia and gastric adenocarcinoma.

METHODS: A cross-sectional study was performed involving 320 Portuguese individuals (210 without evidence of neoplastic disease, 73 patients with gastric adenocarcinomas and 37 with atrophy or intestinal metaplasia) using a PCR-RFLP method.

RESULTS: -765C allele was overrepresented in the patients with gastric adenocarcinoma (51%) when compared either with the control group (38%) or patients with atrophy or intestinal metaplasia (27%). C allele was found to be very common in our population (0.22), and a multivariate logistic regression analysis revealed nearly 3-fold increased risk for the progression to gastric adenocarcinoma in patients with atrophy or intestinal metaplasia carrying the -765C allele (OR = 2.67, 95% CI = 1.03-6.93; P = 0.04).

CONCLUSION: -765C carrier status should be

INTRODUCTION

Gastric adenocarcinoma mortality rates have been decreasing in Europe^[1], although, in Portugal it still remains one of the leading causes of cancer-related deaths (third in men and fourth in women). Portugal has one of the highest mortality rates of Europe and the highest in southern Europe, with values of 33.2 and 20.8 per 100 000/year in men and women, respectively^[2].

Cyclooxygenase (COX), also known as prostaglandin endoperoxide synthase, is a rate-limiting enzyme that converts free arachidonic acid into important prostanoids (PGs) and eicosanoids such as prostaglandin H₂^[3]. There are at least two isoforms of COX identified^[4]: COX-1 is expressed constitutively in most cell types and is thought to be responsible for the maintenance of vascular homeostasis and gastroprotection^[3,4]; and, COX-2, the inducible isoform of the enzyme, undetectable in most cells is readily induced by bacterial lipopolysaccharide (LPS), cytokine, growth factors, mitogens and tumor promoters^[5-6].

Enhanced expression of COX-2 has been observed in several forms of cancer^[7-14], including gastric cancer and precancerous tissues^[15-18]. COX-2 over-expression plays an important role in the inhibition of apoptosis, tumor growth, angiogenesis, invasion and metastasis, which are considered to be important steps in cancer development^[3,15,16,19-24].

Single Nucleotide Polymorphisms (SNP) are the most common form of genetic variants of the human genome^[25], some of which might have functional effects on the susceptibility to the development of human cancers^[26-33] by modifying the transcriptional activation.

Several polymorphisms in *COX-2* have been identified so far. However, only a few seemed to have a functional effect on the transcription. Recently, Papafili *et al*^[34] described a new polymorphism in the promoter region of *COX-2*, characterized by a guanine (G) to cytosine (C) transition at position -765 (-765G > C). This polymorphism appears to disrupt a *Stimulatory protein 1* (Sp1) binding site, which is considered to be a positive activator of transcription and leads to a 30% reduction of the *COX-2* promoter activity *in vitro*^[34]. With this evidence, only few investigations have been done involving *COX-2* polymorphisms either in cancer related studies^[25,35-42] or other diseases^[34,43-45].

The aim of this study was to determine the allelic frequencies of the -765G > C *COX-2* polymorphism in a northern Portuguese population and to investigate its association with the development of gastric lesions, such as atrophic gastritis or intestinal metaplasia and gastric adenocarcinoma.

MATERIALS AND METHODS

Subjects

The -765G > C *COX-2* polymorphism was evaluated in a cross-sectional study performed in healthy individuals without clinical evidence of cancer ($n = 210$) and patients with known gastric lesions ($n = 110$), both from the northern region of Portugal attended at the Portuguese Institute of Oncology (Porto, Portugal).

The control group was formed by 75 females and 135 males (64%) with a median age of 51 years old. Patients were divided according to the type of lesion presented upon histopathological diagnosis after endoscopic multiple biopsies. Seventy three patients displayed lesions as severe as high-grade non-invasive neoplasia and intestinal type invasive gastric adenocarcinoma and 37 with lesions, such as atrophy or intestinal metaplasia that belong to a standardized follow-up since 2001^[46]. The three different groups are characterized in Table 1. The group of patients with gastric adenocarcinoma included 27 females and 31 males (53%) with a mean age of 54 years and, and the group of patients with atrophy or intestinal metaplasia included 21 females and 13 males (38%) with a mean age of 61 years.

All samples were obtained with the permissions of the individuals before their inclusion in the study after informed consent according to the Declaration of Helsinki.

Sample DNA extraction

Blood samples were collected with a standard venipuncture technique using EDTA containing tubes. Genomic DNA was extracted from peripheral blood leukocytes by a standard Salting-out protocol^[47].

Genotyping of -765G>C *COX-2* polymorphism

The analysis of the -765G > C polymorphism was

Table 1 Characteristics of the participants: age, gender and type and stage of lesions

	Control $n = 210$	Gastric adenocarcinoma $n = 73$	Atrophy or intestinal metaplasia $n = 37$
Age (mean \pm SD)	49.5 \pm 18.0	54.2 \pm 11.3	60.7 \pm 10.9
Male Gender n (%)	135 (64)	36 (49)	15 (40)
Atrophy n (%)	Na	Na	3 (8)
Complete IM n (%)	Na	Na	4 (11)
Incomplete IM n (%)	Na	Na	30 (81)

Na: Not applicable; Atrophic chronic gastritis without intestinal metaplasia.

performed by PCR-based restriction fragment length polymorphism (PCR-RFLP) as previously described^[43]. The primers used in the amplification were: CX2A (forward): 5'-ATT CTG GCC ATC GCC GCT TC-3' and CX2B (reverse) 5'-CTC CTT GTT TCT TGG AAA GAG ACG-3' (Metabion, Martinsried, Deutschland). The amplification conditions were 95°C during 10 min for the initial denaturation step, followed by 35 cycles of denaturation at 94°C (1 min), annealing at 59°C (1 min) and extension at 72°C (1 min). The final extension step consisted 10 min at 72°C. As a negative control PCR mix without DNA sample was used to ensure contamination free PCR product. Reaction products were digested with *Bsh1236I* restriction endonuclease (Fermentas, Vilnius, Lithuania) during 8 h at 37°C.

Results were observed in 3% agarose gel stained with ethidium bromide (Figure 1). Fragment sizes of 134 + 23 bp indicated a wild-type homozygous -756GG genotype, and an uncut fragment of 157 bp indicated the homozygous -765CC genotype. The presence of all the three bands (23, 134, and 157 bp) indicated a heterozygous -765GC genotype. The 23 bp fragment, resulting from the *Bsh1236I* restriction can not be distinguished from the primer-dimer band in the agarose gel. Analysis of genotypes was independently performed by two of the authors (C.P. and P.F). Cases with nonconcordant results between the two observers, or with the absence of a PCR product were rejected. Also a second PCR-RFLP analysis was performed in ten per cent of all samples to confirm the genotype.

Variables

Individual's age and gender, type of gastric lesion (gastric adenocarcinoma or atrophy or intestinal metaplasia) or its absence, and *COX-2* alleles (G, C).

Statistical analysis

Data analysis was performed using the computer software *Statistical Package for Social Sciences-SPSS* for Windows (version 11.5). Chi-square analysis was used to compare categorical variables, using a 5% level of significance. Multivariate logistic regression analysis was used to estimate odds ratio (OR) and its 95% confidence interval (CI) as a measure of the association between Allele C carrier and the risk for the development of gastric lesion. Gender and age were included in multivariate analysis, and assessment for interaction was considered in the model.

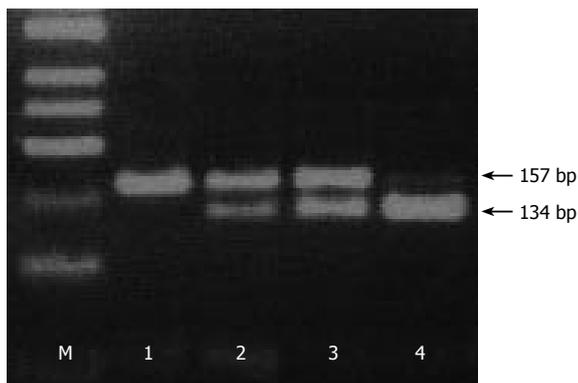

Figure 1 PCR-RFLP analysis of -765G > C *COX-2* polymorphism. M: 50 bp DNA ladder; 1: Homozygous -765CC genotype; 2, 3: Heterozygous -765GC genotype; 4: Homozygous -765GG genotype.

Table 2 Genotype distribution of *COX-2* -765G > C polymorphism

Genotype	Controls (n = 210)		Atrophy or intestinal metaplasia (n = 37)		Gastric adenocarcinoma (n = 73)
	n (%)	P ¹	n (%)	P ²	n (%)
GG	130 (62)	0.197	27 (73)	0.018	36 (49)

CC	13 (6)	0.398	1 (3)	0.339	5 (7)
C carrier	80 (38)	0.197	10 (27)	0.018	37 (51)

¹ vs Atrophy or intestinal metaplasia group (chi-square test); ² vs Gastric adenocarcinoma group (chi-square test).

RESULTS

Allelic distribution of *COX-2* polymorphism

The distribution of -765G > C *COX-2* genotypes is shown in Table 2. The frequency of the -765GG, GC and CC genotypes were 62%, 32% and 6%, respectively in controls, 49%, 44% and 7% in patients with gastric adenocarcinoma and 73%, 24% and 3% in patients with atrophic gastritis or intestinal metaplasia. All genotypic distributions are in Hardy-Weinberg equilibrium ($P > 0.05$). -765C carriers were more frequently found among those with gastric adenocarcinoma ($P = 0.04$) than the other groups.

Risk estimate for associated lesions and invasive gastric adenocarcinoma

Table 3 describes the Odds Ratio for the development of atrophic gastritis or intestinal metaplasia and gastric adenocarcinoma. We found no statistically significant risk for the development of either atrophy or intestinal metaplasia (OR = 0.60, 95% CI = 0.28-1.31; $P = 0.20$) or gastric adenocarcinoma (OR = 1.67, 95% CI = 0.98-2.86; $P = 0.06$). Although the results for the development of gastric lesions were not statistically significant, we observed a possible protective role for -765C carriers, and when the same analysis was adjusted for age and gender by a multivariate logistic regression analysis this protective effect disappeared (OR = 0.95, 95% CI = 0.91-0.99; $P = 0.01$). In contrast, we observed a nearly 3-fold increased risk for the progression of atrophy or intestinal metaplasia

Table 3 Frequency distributions and Odds Ratio for risk of atrophy and intestinal metaplasia or gastric adenocarcinoma in -765 C carriers

Pathology	Genotype n (%)		OR (95% CI)	OR ² (95% CI)	
	GG	C carrier			
Controls	130 (62)	80 (38)	1.00 (Reference)	1.00 (Reference) ¹	
Atrophy or intestinal metaplasia	27 (73)	10 (27)	0.60 (0.28-1.31)	0.95 (0.91-0.99) ¹	1.00 (Reference)
Gastric adenocarcinoma	36 (49)	37 (51)	1.67 (0.98-2.86)	1.45 (0.84-2.64) ¹	2.67 (1.03-6.93)

into gastric adenocarcinoma (OR = 2.67, 95% CI = 1.03-6.93; $P = 0.04$).

Furthermore, when we evaluated the distribution of gender in the two groups, atrophy or intestinal metaplasia and gastric adenocarcinoma, no statistically significant differences were observed ($P = 0.38$).

DISCUSSION

Enhanced expression of *COX-2* gene has been reported in several forms of cancer, including gastric precancerous and adenocarcinoma tissues^[15-18]. This evidence suggests a role of *COX-2* in the carcinogenesis pathway, such as in the inhibition of apoptosis, tumour growth, angiogenesis, invasion and metastasis^[3,15,16,19-24]. A -765G > C polymorphism on the promoter region of *COX-2* gene disrupts the Sp1 binding site^[34] that may alter the susceptibility to develop cancer^[36]. Our results revealed that C allele is extremely common (22%) in our population. Although only a few studies have been developed involving this *COX-2* polymorphism, the frequencies of the polymorphic variant seems to vary, especially among different ethnic populations (Table 4). These studies revealed that the C allele is

more frequent in Western countries, in Europe and America, than in Asian countries. Moreover, our results for the genotype frequencies are in concordance with other previously reported data in Caucasian populations.

-765G > C carriers and development of atrophic gastritis and intestinal metaplasia

In the present study, -765C carriers were slightly overrepresented in the control population (38%) when compared with patients with atrophy or intestinal metaplasia (27%). In fact, although not statistically significant, our results revealed a possible protective role for -765C carriers. Nevertheless, when adjusted for age and gender this protective role disappears (OR = 0.95, 95% CI = 0.91-0.99, $P = 0.01$) suggesting that this variant does not influence the development of gastric lesions such as atrophy or intestinal metaplasia. Although, the protective role is in agreement with previous studies, the small sample size may raise some statistical concerns to this observation. Papafili *et al*^[34] showed that the promoter activity of the -765C allele is reduced to about 30% when compared to the -765G. In addition, Ulrich *et al*^[38] revealed a marginal protection for the development of colorectal adenomatous and hyperplastic polyps when associated with the -765CC genotype. Thus, these results confirm the evidence that the depletion of the Sp1 binding site, considered a positive activator of COX-2 transcription, caused by the -765G > C transition, modifies the transcriptional activation of COX-2^[34].

-765G > C polymorphism and the development of gastric adenocarcinoma in patients with atrophic gastritis and intestinal metaplasia

Gastric cancer developed upon a multistep process from chronic active gastritis, gastric glandular atrophy (GA), intestinal metaplasia (IM), dysplasia and gastric cancer^[46]. In a recent work, it was suggested that COX-2 expression increases as it progresses from initial gastric lesions to gastric cancer, providing evidence that COX-2 might contribute to an early event in gastric carcinogenesis^[48]. Another approach attempt to understand the influence of the COX-2 -765G > C polymorphism has in the progression from atrophy or intestinal metaplasia lesions to gastric adenocarcinoma. We observed a nearly 3-fold increased risk of progression from gastric lesions into gastric cancer (OR = 2.67, 95% CI = 1.03-6.93; $P = 0.04$). This result is consistent with previously cancer-related studies that also revealed that -765C allele carriers had increased risk for the development of those diseases^[36,49]. More recently, Zhang *et al*^[42] described a 2-fold increased risk for the development of esophageal squamous cell carcinoma due to increased expression of COX-2 mRNA in -765G > C heterozygous. Although the exact molecular mechanism by which COX-2 polymorphism may affect the risk of gastric adenocarcinoma development is still unclear, studies in the COX-2 promoter revealed that COX-2 transcription is activated by E2 promoter binding factor 1 (E2F1)^[50], which is dependent on the transactivation and DNA-binding domains of E2F1^[51]. So the ability of this polymorphism to create an E2F binding site, essential for the expression of several genes^[43], might help us to understand why we

observed increased risk.

In conclusion, all these findings suggest that different physiological/pathological conditions, as well as cell type, could determine the influence that -765G > C COX-2 polymorphism has in the development of human diseases, by the modification of the binding sites for the transcription factors^[18]. The contribution of genetic polymorphism to the risk of gastric adenocarcinoma may be dependent on the population in study, as well on several environmental and dietary factors that influence that population. So, we hypothesize that each population has to evaluate its own genetic profile for cancer risk that may help to understand the geographic and racial differences reported for gastric adenocarcinoma^[52]. Furthermore, COX-2 polymorphisms may be involved in different individual drug response^[53,54] and may be explored as for in clinical trials to select those individual to be submitted to COX-2 inhibition. Moreover, the definition of a pharmacogenomic profile using molecular studies may help to the development of a personalized treatment or quimioprevention.

To the best of our knowledge, this is the first report that evaluates the -765G > C COX-2 polymorphisms and gastric adenocarcinoma development worldwide, which also considers the progression from gastric lesions, such as atrophy or intestinal metaplasia, to gastric adenocarcinoma. We theorise that once the lesions are installed, -765C carriers are at risk of progression into gastric adenocarcinoma. However, our results should be cautiously interpreted as they report a cross-sectional design. Therefore, we suggest that -765G > C polymorphism should be used in a large cohort study among patients with atrophy or intestinal metaplasia as a susceptibility marker for gastric adenocarcinoma and to confirm the real meaning of this genetic alteration in gastric adenocarcinoma development.

Abstract

AIM: To describe the frequency of *H pylori* infection among 1000 southern Iranian dyspeptic patients.

METHODS: A prospective study was performed in a referral hospital in south of Iran from 1999 to 2005. One thousand dyspeptic patients (518 males, mean \pm SD age of 49.12 \pm 12.82 years) consecutively underwent upper gastrointestinal endoscopy. Multiple gastric antral biopsy samples were taken from all patients for rapid urease test and histopathologic examination (96.9% satisfactory samples). Patients were considered *H pylori*-infected if one or both tests were positive.

RESULTS: Six hundred and seventy-one patients (67.1%, 95% confidence interval [CI]: 64.2%-70.0%) were *H pylori*-infected. *H pylori* positivity was significantly more frequent in patients with peptic ulcer disease (PUD) than in those with non-ulcer dyspepsia ($P < 0.001$). Male-to-female ratio for duodenal and gastric ulcers was 2.7:1 and 1.5:1, respectively. Moreover, the duodenal-to-gastric ulcer ratio was 1.95:1. The frequency of *H pylori* infection among those with endoscopic diagnosis of gastritis, duodenal ulcer, gastric ulcer, and normal mucosa was 70.1% (398/568), 86.2% (150/174), 71.9% (64/89), and 33.5% (54/161), respectively. *H pylori* infection, male sex, and older age were independently associated with PUD in multivariate analysis. *H pylori* positivity was associated with chronic gastritis, and chronic active gastritis with odds ratios of 34.21 (95% CI: 12.19%-96.03%) and 81.21 (95% CI: 28.85%-228.55%), respectively.

CONCLUSION: *H pylori* and PUD are highly frequent in dyspeptic patients from south of Iran. *H pylori* is a cardinal risk factor for chronic active or inactive gastritis.

INTRODUCTION

H pylori is a major cause of gastritis and peptic ulcer disease (PUD), and has been implicated in the development of gastric malignancy^[1-3]. The prevalence of *H pylori*, a worldwide infection, varies greatly among countries and among population groups within the same country^[4]. *H pylori* is highly prevalent in the developing countries^[5-11] and is common in 57%-91% of Iranian population^[5,12-14]. However, studies regarding *H pylori* prevalence in different regions of Iran, a country with a miscellaneous climate, are limited^[5,12-16]. Thus, we studied the frequency of *H pylori* infection among 1000 southern Iranian dyspeptic patients. Furthermore, we report *H pylori* association with different histopathologic and upper gastrointestinal endoscopy (UGIE) findings in this large number of patients.

MATERIALS AND METHODS

Subjects

A prospective study was performed in the Gastroenterology Division, Shahid-Mohammadi Referral Hospital, Bandarabbas, Iran from October 1999 to August 2005. One thousand consecutive patients (518 males, mean \pm SD age of 49.12 \pm 12.82 years, range 13-89 years) with dyspepsia underwent UGIE. Those with age over 12 years, no prior gastric surgery, no active bleeding, and no consumption of antibiotics, bismuth preparations, or proton pump inhibitors in the 4 wk prior to UGIE were eligible to enter the study. All patients enrolled gave their informed consent and the study was performed according to the Declaration of Helsinki.

Methods

UGIE reported signs of gastritis, PUD, polyp, mucosal atrophy, and tumor. When PUD was present, concomitant gastritis was not mentioned in the study questionnaire. Moreover, when none of the above-mentioned pathologic

NUD	453/732	61.9	58.4-65.4
Tumor	4/5	80.0	40.8-100

PUD: Peptic ulcer disease; NUD: Nonulcer dyspepsia. ^a*P* < 0.05 between groups regarding *H pylori* infection; ^b*P* < 0.001 between PUD and NUD groups regarding *H pylori* infection.

features was present, the UGIE examination was considered normal. During UGIE, at least three biopsy specimens were taken from the antrum lesser curvature mucosa 3-4 cm proximal to the pylorus. One specimen was for rapid urease test (RUT). The RUT was monitored for color change up to 6 h after addition of the gastric tissue. The test was scored as positive if the color changed from yellow to red. The remaining two specimens were fixed in formaldehyde and submitted for histologic examination and HE staining. Nine hundred and sixty-nine antral mucosa biopsies (96.9%) were satisfactory for histopathological examination. One experienced pathologist, blinded to the results of RUT and UGIE, evaluated the coded samples. Thirty percent of coded samples (*n* = 291) were randomly evaluated by a second experienced pathologist. When the results were different (*n* = 11), the slides were discussed in joint sessions where a third pathologist was also present. The slides were observed under an optical microscope at several magnifications (including oil immersion). An increase in lymphocytes and plasma cells in the lamina propria characterized the gastritis as chronic. Activity in the context of chronic gastritis referred to the density of neutrophil polymorphs in the lamina propria, gastric pits, and surface epithelium. The presence of any pathology in at least one biopsy sample was considered a positive finding. The absence of abnormal findings in all specimens was regarded as normal. Detection of any *H pylori* was contemplated evidence of infection. Patients were considered *H pylori* positive if RUT and/or histology were/was positive. When the histologic sample was unsatisfactory, patient's of *H pylori* infection was determined by the RUT.

The frequency of *H pylori* was evaluated by means of cross tables regarding different age, sex, endoscopic and histopathologic diagnoses and tested by chi-square (χ^2) test and Fisher's exact test. Multivariate analysis was performed by entering sex, age groups, and *H pylori* status in a logistic regression model to identify the independent risk factors for endoscopic diagnoses of duodenal ulcer, gastric ulcer, and gastritis (normal endoscopy was set as a reference category). The same model was built to identify the independent risk factors for histopathologic diagnoses (normal mucosa was set as a reference category). For all

Table 2 Histological findings of satisfactory 969 antral biopsies

Histological finding	<i>n</i>	% (95% CI)
Normal mucosa	84	8.7 (6.9-10.4)
Chronic inactive gastritis	365	37.7 (34.6-40.7)
Chronic active gastritis	456	47.1 (43.9-50.2)
Atrophic changes	242	25.0 (23.6-27.7)
Intestinal metaplasia/malignancy	81	8.9 (7.1-10.7)
Glandular dysplasia	1	0.1 (-0.1-0.3)
Adenocarcinoma	4	0.4 (0.0-0.8)

point prevalences, 95% confidence intervals (CI) were calculated. Statistical significance was set at *P* < 0.05.

RESULTS

Six hundred and seventy-one patients (67.1%, Table 1) were *H pylori*-infected. PUD was found in 263 enrolled patients (26.3%, 95% CI: 23.6%-29.0%). Those with PUD were significantly more *H pylori*-infected than those with non-ulcer dyspepsia (NUD) (*P* < 0.001, Table 1). Fisher's exact test displayed that PUD was more frequent in male patients than in female patients (68.8%, 95% CI: 63.2%-74.5%) *vs* 31.2% (95% CI: 25.5%-36.8%) (*P* < 0.001). Male-to-female ratio for duodenal and gastric ulcers was 2.7:1 (127/47) and 1.5:1 (54/35), respectively. While the duodenal-to-gastric ulcer ratio was 1.9:1 (174/89), endoscopic signs of gastritis were evident in 568 (56.8%), polyp in 7 (0.7%), mucosal atrophy in 5 (0.5%), raised/thickened area in 5 (0.5%), and accompanying duodenal and gastric ulcers in 3 (0.3%) patients. Thus, 161 patients (16.1%) had normal endoscopic results. A histologic diagnosis of chronic active gastritis was assigned to 47.1% of biopsy samples. Table 2 summarizes the histopathological findings.

While *H pylori* was frequent in 33.5% of those with normal UGIE, 86.2% of those with duodenal ulcer were *H pylori*-infected (*P* < 0.001, Table 3). Those with histologic diagnosis of chronic active gastritis were significantly more *H pylori*-infected than those with chronic inactive gastritis (*P* < 0.001, Table 3). Table 3 summarizes the frequency of *H pylori* infection regarding different endoscopic and histopathologic findings. Multivariate logistic regression analysis proved *H pylori* positivity, older age, and male gender as predictors of duodenal ulcer, gastric ulcer, and gastritis (Table 4). The second model to identify the risk factors for histopathologic findings, had a 56.1% agreement between predicted and observed results and the amount of variance accounted for 21.4% (Cox & Snell) - 25.3% (Nagelkerke). This model suggested that *H pylori* positivity was associated with chronic gastritis, and chronic active gastritis with odds ratios (OR) of 34.21 (95% CI: 12.19%-96.03%) and 81.21 (95% CI: 28.85%-228.55%), respectively.

DISCUSSION

In the developing world, *H pylori* is a challenging health problem as 20% prevalence of *H pylori* infection among adolescents in the United States pales in comparison with infection rates exceeding 90% by five years of age in parts of the developing world^[17]. One study in northwest of

Table 3 *H pylori* infection regarding endoscopic and histologic diagnoses *n* (%)

Diagnosis	<i>H pylori</i> infection		
	Negative	Positive	Total
Endoscopic findings			
Normal	107 (66.5)	54 (33.5)	161
Gastritis	170 (29.9)	398 (70.1) ^b	568

^b*P* < 0.001 *vs* normal endoscopic findings; ^d*P* < 0.001 *vs* gastritis and gastric ulcer; ^f*P* < 0.001 *vs* normal histopathologic findings; ^b*P* < 0.001 *vs* histopathologic findings and chronic inactive gastritis (Fisher's exact test).

Iran, a region with the highest mortality rate from gastric cancer throughout the country, reported that *H pylori* infection occurs in 89.2% (883/990) of the residents^[5]. Other surveys in different age groups from various regions of the country reported that *H pylori* infection occurs in 57%-91% of the study subjects^[12-14]. In this prospective survey, we report *H pylori* infection in 67.1% of 1000 enrolled dyspeptic patients from south of Iran. Variation in study powers as well as ethnicity, place of birth, socioeconomic factors, diet, occupation, smoking, or alcohol consumption habits among study populations may be the reasons for erratic rates of *H pylori* infection reported from the country^[6,18]. Similarly, *H pylori* seems to be a health problem in the neighboring regions of Iran. In India, *H pylori* is positive in 38 (56.7%) asymptomatic individuals and in 49 (61.3%) symptomatic individuals^[6]. In Saudi-Arabia, *H pylori* is present in 54.9% of gastric biopsies from 488 dyspeptic patients^[7]. In Yemen, 82.2% of 275 dyspeptic patients are *H pylori*-infected^[8]. In Jordan, *H pylori* is frequent in 82% of 197 study subjects^[9]. In United Arab Emirates^[10] and in Kuwait^[11], 90.39% of 437 and 96.6% of 204 studied subjects are infected with *H pylori*, respectively.

About a quarter of dyspeptic patients in this study were proved to have PUD. Nevertheless, in another large cohort of residents in northwest of Iran, the frequency of PUD is just 4.9%^[5]. This relatively low frequency of PUD might be due to the enrollment of unnecessarily dyspeptic subjects in the latter survey. PUD frequencies are divergent in reports from different countries. In a literature review by the American Gastroenterology Association^[19], 19 out of 41 studies report duodenal ulcer in $\geq 10\%$ of dyspeptic patients and the overall prevalence of PUD in these groups of symptomatic patients is $\geq 15\%$ in 21 studies. Duodenal ulcer was approximately twice as common as gastric ulcer in the present survey, which is in quite contrast to the 12:1 ratio reported from India^[6]. Moreover, *H pylori* infection is significantly more frequent in PUD than in NUD patients. Regarding the significantly higher rate of *H pylori* infection in those with duodenal (86.2%) and gastric (71.9%) ulcers in comparison with the subjects with normal endoscopic findings

Table 4 Multivariate logistic regression of selected model variables on endoscopic findings¹

Variable	B	SE	Wald test	<i>P</i>	Odds ratio (95% CI)
Duodenal ulcer					
Sex (male)	1.91	0.26	55.14	< 0.001	6.75 (4.08-11.17)
Age (in three ascending groups)	0.59	0.19	9.211	< 0.01	1.80 (1.23-2.63)
<i>H pylori</i> (+)	2.54	0.28	79.21	< 0.001	12.66 (7.24-22.14)
Constant	-3.75	0.50			
Gastric Ulcer					
Sex (male)	1.34	0.28	22.13	< 0.001	3.83 (2.19-6.69)
Age (in three ascending groups)	0.65	0.22	8.49	< 0.01	1.91 (1.24-2.95)
<i>H pylori</i> (+)	1.63	0.29	30.74	< 0.001	5.12 (2.87-9.11)
Constant	-3.45	0.56

Sex (male)	0.91	0.20	20.15	< 0.001	2.48 (1.67-3.68)
Age (in three ascending groups)	0.65	0.15	18.35	< 0.001	1.92 (1.42-2.58)
<i>H pylori</i> (+)	1.54	0.19	61.81	< 0.001	4.65 (3.17-6.82)
Constant	-1.30	0.361			

¹Normal endoscopy was set as a reference category; agreement between predicted and observed results: 57.2%; the amount of variance accounted for 17.6% (Cox & Snell)- 19.4% (Nagelkerke).

(33.5%) (Table 3), also the significant association of *H pylori* positivity with duodenal (OR: 12.66) as well as gastric ulcers (OR: 5.12) (Table 4), *H pylori* can be introduced as an aetiological agent for PUD, thus strengthening prior findings^[10,20,21]. Furthermore, current evidence shows the cardinal role of *H pylori* in the pathogenesis of PUD^[22-24]. In favor of the results of some studies^[25-27] and against the findings of others^[6,28,29], we found significantly more *H pylori* infections in male than in female PUD subjects, but *H pylori* was not significantly more prevalent in males. Regarding these two latter findings, one may deduce that *H pylori* infection independently results in PUD in males more frequent than in females. The regression model also confirms this judgment as entering both sex and *H pylori* status in the model showed an independent significant role of both factors in prediction of different endoscopic findings (Table 4). Nevertheless, despite more than a 50% agreement between the predicted and observed results of both models in this survey, outcomes should be carefully interpreted due to the limited factors entered into these models as other factors with a possible predictive role were beyond the scope of the current study and thus were not entered into the model.

In the present study, histologic findings of chronic active and inactive gastritis were frequent in about 85% of dyspeptic subjects, which is comparable with the previous 77.8% of chronic active gastritis in northwest of Iran^[5], 80.6% and 67% of chronic gastritis in Saudi-Arabia^[30] and India^[6], respectively. Similarly, *H pylori* with a significantly higher frequency in those with chronic active and inactive gastritis compared to those with normal histology, showed a strong association with chronic active gastritis (OR: 81.21) and chronic inactive (OR: 34.21) gastritis, although more frequent in those with chronic active gastritis, which is suggestive of its causative role in chronic gastritis and gastritis activity. Despite some doubts^[31], *H pylori* is globally believed to have a fundamental role in the pathogenesis of gastric cancer^[3,32,33]. Chronic *H pylori* gastritis leads in more

than half of the affected subjects to a gradual loss of the glandular structures with its specialized cells and a collapse of the reticulin skeleton of the mucosa, a condition of atrophic gastritis^[34]. Indeed, the most common type of gastric cancer, the intestinal type, is preceded by chronic atrophic gastritis, which is 22%-37% prevalent in asymptomatic European adult subjects^[35]. In this survey, a quarter of satisfactory antral biopsies were proved to have atrophic changes in histology, about two thirds of which were associated with *H pylori* infection. Compared to our findings in south of Iran as well as those in the developed world^[35], northwest of Iran with a relatively higher frequency of atrophic changes in the antral biopsies of the sampled population (45.2%)^[5] might be at a higher risk of prevalence of gastric malignancies in the near future, an alarming condition that necessitates further investigations and thoughtful interventions.

In conclusion, *H pylori* and PUD are frequent in dyspeptic patients from south of Iran. *H pylori* infection, male sex, and older age are independently associated with PUD. *H pylori* is associated with chronic gastritis and even more with chronic active gastritis.

Abstract

AIM: To examine the existence of Nitric oxide/cGMP sensitive store-operated Ca^{2+} entry in mouse fibroblast NIH/3T3 cells and its influence on matrix metalloproteinase (MMP) production and adhesion ability of fibroblasts.

METHODS: NIH/3T3 cells were cultured. Confocal laser scanning microscopy was used to examine the existence of thapsigargin-induced store-operated Ca^{2+} entry in fibroblasts. Gelatin zymography and semiquantitative reverse transcriptase-polymerase chain reaction (RT-PCR) were employed to detect the involvement of $[Ca^{2+}]_i$ and NO/cGMP in MMP secretion. The involvement of NO/cGMP-sensitive Ca^{2+} entry in adhesion was determined using matrigel-coated culture plates.

RESULTS: 8-bromo-cGMP inhibited the thapsigargin-induced Ca^{2+} entry in 3T3 cells. The cGMP-induced inhibition was abolished by an inhibitor of protein kinase G, KT5823 (1 μ mol/L). A similar effect on the Ca^{2+} entry was observed in 3T3 cells in response to a NO donor, (\pm)-*S*-nitroso-*N*-acetylpenicillamine (SNAP). The inhibitory effect of SNAP on the thapsigargin-induced Ca^{2+} entry was also observed, indicating NO/cGMP-regulated Ca^{2+} entry in 3T3 cells. Results of gelatin zymography assay showed that addition of extracellular Ca^{2+} concentration induced MMP release and activation in a dose-dependent manner. RT-PCR also showed that cGMP and SNAP reduced the production of MMP mRNA in 3T3 cells. Experiments investigating adhesion potentials demonstrated that cGMP and SNAP could upgrade 3T3 cell attachment rate to the matrigel-coated culture plates.

INTRODUCTION

Members of matrix metalloproteinase (MMP) family have been broadly implicated in both physiological and pathophysiological tissue remodeling^[1], and play a key role in tumor invasion and metastasis. Since degradation of extracellular matrix (ECM) components by MMP is critical for tumor cell invasion and metastasis^[2,3], MMP-2 degrades type IV collagen, a major component of the basement membrane because of its activity. Recent studies have revealed that tumor cells utilize MMP-2 produced by neighboring stromal cells including fibroblasts rather than by tumor cells themselves^[4,5] for tumor progression, invasion, and metastasis, and that tumor cells can stimulate MMP production by stromal cells via soluble factors such as cytokines^[6-9] or through cell-cell interaction mediated by cell adhesion molecules such as CD147^[10,11].

Studies have proved that stromal cells mainly release MMP around tumor cells, and that calcium is a second intracellular messenger which mediates a wide range of cellular responses. These studies aroused our interest in whether calcium ions are involved in MMP secretion. In non-excitabile cells, the influx of Ca^{2+} is a biphasic process, which consists of an initial transient phase followed by a large and sustained phase. Under Ca^{2+} -free conditions, the response is only a small and transient rise in $[Ca^{2+}]_i$, which should reflect the release of intracellular Ca^{2+} stores. When extracellular Ca^{2+} is reintroduced in the absence of the agonist, there is a large rise in $[Ca^{2+}]_i$. Since the depletion of intracellular Ca^{2+} stores is apparently the single

mechanism at work under such a circumstance, it has been hypothesized that the Ca^{2+} entry is activated by the depletion of Ca^{2+} stores and this Ca^{2+} entry is thus called store-operated Ca^{2+} entry (SOC)^[12].

Nitric oxide (NO) is also known to inhibit Ca^{2+} entry through L-type Ca^{2+} channels (LTCC) in SMCs via cGMP-dependent mechanisms or via membrane hyperpolarization due to cGMP-dependent activation of Ca^{2+} -dependent K^+ channels. Besides the direct effects of NO on Ca^{2+} entry, it can also activate heme-containing soluble guanylyl cyclase (sGC) and catalyze the production of cGMP from GTP, thus playing a role in NO/cGMP/protein kinase G (PKG) pathway. Although many reports have described the regulating mechanisms on the calcium channels, they all focused on the end result-- increase in $[\text{Ca}^{2+}]_i$. Thus further investigation is certainly required to clarify the role of NO/cGMP in SOC and MMP secretion.

The aim of the present study was to demonstrate the existence of NO/cGMP-regulated SOC in NIH/3T3 cells and to further explore the influence of store-operated Ca^{2+} entry on MMP secretion and adhesion potential in NIH/3T3 cells.

MATERIALS AND METHODS

Cell culture and reagents

NIH/3T3 cells (CRL-1658, obtained from American Tissue Culture Collection, ATCC) were cultured in Dulbecco's modified Eagle's medium (DMEM) containing 100 mL/L fetal calf serum. Cultures were maintained at 37°C in a humidified incubator under an atmosphere of 950 mL/L air and 50 mL/L CO_2 . 8-bromo-cGMP, (\pm)-*S*-nitroso-*N*-acetylpenicillamine (SNAP), *N*-methyl-(8*R*,9*S*,11*S*)-(-)-9-methoxy-9-methoxycarbonyl-8-methyl-3,10-dihydro-8-11-epoxy-1*H*, 8*H*, 11*H*-2,7*b*, 11*a*-triazadibenzo(a,g)cycloocta(cde)trinden-1-one (KT5823), N^G -nitro-*L*-arginine methyl ester (L-NAME) and thapsigargin were obtained from Calbiochem (La Jolla, CA). DMEM and fetal bovine serum were purchased from Life Technologies, Inc. Fluo3/AM was obtained from Molecular Probes, Inc. (Eugene, OR). One Step RNA PCR kit (AMV) was purchased from TaKaRa Biotechnology (Dalian) Co., Ltd. MMP-2 primers (Accession no. NM008610; 5' ACCATCGAGACCATGCGG3', 5' CTCCCCCAACACCAGTGC3', 334 bp), MMP-9 primers (Accession no. NM013599; 5' TTCTGCCCTACCCGAGTGGGA3', 5' CATAGTGGGAGGTGCTGTCGG3', 426 bp), β -actin primers (5' CTCACCTGCCACCTTCCAG3', 5' CGACCATCCTCCTTAGG3', 494 bp) were obtained from SaiBaiSheng Co. Trizol for total RNA isolation was from Life Technologies, Inc. Matrigel was obtained from Becton Dickinson Laboratory (Bedford, MA). Other reagents were from Sigma-Aldrich (St. Louis, MO).

Measurement of $[\text{Ca}^{2+}]_i$ in single cells by confocal laser scanning microscopy

After an overnight attachment, the cells were rinsed in 0.01 mol/L PBS and loaded with 5 $\mu\text{mol/L}$ Fluo3/AM for 45 min in dark at 37°C in normal PBS (NPBS) containing

2 mmol/L CaCl_2 , pH 7.4. The cells were then washed and resuspended in NPBS. To start the experiment, the cells were pretreated with 4 $\mu\text{mol/L}$ thapsigargin for 2 min. Then the cells were washed with and maintained briefly in PBS containing no Ca^{2+} and 2 mmol/L EGTA. Unless stated otherwise, the cells were pretreated with or without chemicals (i.e. 8-bromo-cGMP, KT5823, SNAP, L-NAME or NiCl_2) for 1-2 min. The fluorescent signal of cytoplasmic calcium ion concentration in 3T3 cells was determined by fluorescence using Bio-Rad MRC 1024 visible light CLSM (Bio-Rad, Hercules, CA) and argon (488/526 nm) laser light.

Gelatin zymography

The conditioned media were collected by centrifugation, concentrated and dialyzed. The dialyzed samples containing an equal amount (20 μg) of total protein were mixed with the sample buffer, incubated in water bath (about 55°C) for 3-5 min and loaded onto the zymographic 100 g/L SDS-polyacrylamide gel containing gelatin (1g/L) and run under standard conditions (2 h at constant voltage of 100V). Afterwards, the gels were washed once with 50 mmol/L Tris (pH 7.4), containing 25 mL/L Triton X-100 for 30 min, and twice with 50 mmol/L Tris (pH 7.4). Gels were then incubated for 16-18 h in 50 mmol/L Tris (pH 7.5), 0.15 NaCl, 10 mmol/L CaCl_2 , 1 mL/L Triton X-100 and 0.2 mg/L sodium azide. Finally, the gels were stained with Coomassie blue and washed with 75 mL/L acetic acid containing 200 mL/L methanol. The gels were subjected to densitometric analysis to quantitate the gelatinase activity by obtaining volumograms on a photo documentation system from UVItect (Cambridge, UK) using the UVIchrom acquisition software.

Semiquantitative reverse transcriptase-polymerase chain reaction

Total RNA was extracted from cGMP-pretreated 3T3 cells using Trizol agents. First-strand cDNA synthesis was performed using 1 μg of total RNA, 40 MU/L of RNase inhibitor, 20 MU/L sense and anti-sense primers of MMP-2, MMP-9 and β -actin, 10 mmol/L dNTP mixture, 25 mmol/L MgCl_2 , 5 MU/L AMV Rtas XL, 5 MU/L AMV-optimized Taq. MMP-2, MMP-9 and β -actin primers were reported in Material section. According to One Step RNA PCR kit (AMV) instructions, the following conditions were used for MMP-2: 28 cycles of PCR amplification, denaturation at 94°C for 1 min, annealing at 60°C for 1 min, extension at 72°C for 1 min; MMP-9: 30 cycles of PCR amplification, denaturation at 94°C for 50 s, annealing at 60°C for 1 min, and extension at 72°C for 2 min; β -actin: 23 cycles of PCR amplification, denaturation at 94°C for 30 s, annealing at 53°C for 30 s, and extension at 72°C for 1 min. Amplification was carried out in a GeneAmp 2400 PCR system (Perkins-Elmer, Foster City, CA). PCR products were resolved on 25 g/L agarose gel in the presence of 0.6 mg/L ethidium bromide. The intensities of the cDNA bands for each protein were normalized to β -actin band intensities. Images of the ethidium bromide (EB)-stained agarose gels were acquired with a digital Kodak camera (Eastman Kodak Company,

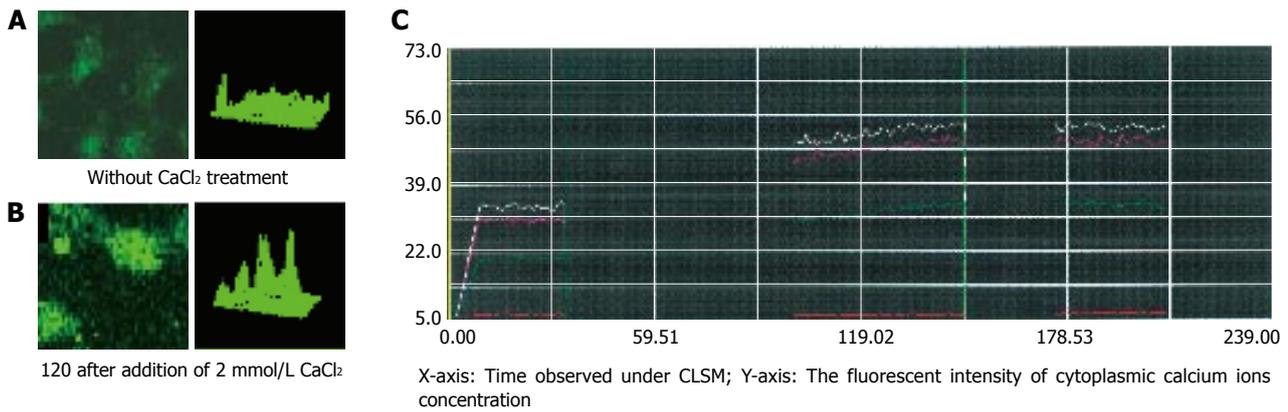

Figure 1 Tg-induced intracellular calcium ion concentration changes in 3T3 cells. **A:** The fluorescent intensity in 3T3 cells was 25-30 in Ca²⁺-free and 2 mmol/L EGTA-containing medium after treatment with 4 μmol/L Tg; **B:** The fluorescent intensity rose to 50-55 in 3T3 cells after adding 2 mmol/L CaCl₂; **C:** Similar intracellular free Ca²⁺ concentration dynamic changes in 3T3 cells and Tg-induced elevation of [Ca²⁺]_i in 3T3 cells 120 min after treatment.

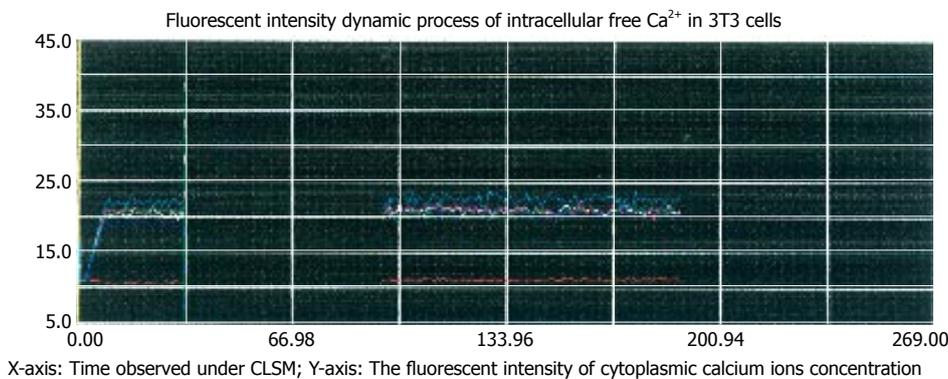

Figure 2 Inhibitory effect of Ni²⁺ on thapsigargin-induced rise in [Ca²⁺]_i. The cells were incubated in NPBS with 4 μmol/L thapsigargin and 3 mmol/L NiCl₂ for 90 s, then the media were replaced with respective media containing 2 mmol/L CaCl₂ without EGTA, no significant change of [Ca²⁺]_i occurred after 120 s.

Rochester, NY, USA) and quantification of the bands was performed by imaging analysis software from Kodak.

Cell adhesion assay

The wells of 96-well culture plates were coated with matrigel at a concentration of 5 mg/L and incubated at 4°C overnight. The coated wells were blocked with PBS containing 20 g/L bovine serum albumin for 30 min and then washed with PBS. Cell suspension in serum-free medium containing 1 g/L bovine serum albumin was added to the wells (2 × 10⁴/well) and incubated at 37°C in 50 mL/L CO₂ for 30-60 min with or without test agents (8-bromo-cGMP or SNAP). After the medium and nonattached cells were removed, 2 g/L crystal violet was added for 10 min. The plate was gently washed with tap water and dried in air for 24 h. Then 0.1 mL of 50 g/L SDS with 500 mL/L ethanol was added for 20 min, the plate was read at 540 nm on an ELISA reader (Microplate Co., EL311SX).

Statistical analysis

Data were expressed as mean ± SD. Intracellular Ca²⁺ fluorescence ratio and percentages of attached cells were estimated with Student's *t*-test or analysis of variance followed by Student-Newman-Keuls test. *P* < 0.05 was considered statistically significant.

RESULTS

Thapsigargin-induced store-operated Ca²⁺ entry in fibroblast NIH/3T3 cells

Thapsigargin was used to deplete intracellular Ca²⁺ stores and induce Ca²⁺ entry from extracellular space. After treatment with 4 μmol/L thapsigargin in Ca²⁺-free and 2 mmol/L EGTA-containing medium for 2 min, the addition of 2 mmol/L CaCl₂ induced a rise in [Ca²⁺]_i about 120 later (Figure 1). The thapsigargin-induced elevation of [Ca²⁺]_i was completely blocked by Ni²⁺ (3 mmol/L), a potent blocker of Ca²⁺ entry that competes for Ca²⁺-binding sites in 3T3 cells (Figure 2), confirming the presence of capacitive Ca²⁺ entry in this cell type.

Effect of NO/cGMP/PKG signal pathway on store-operated Ca²⁺ entry

It has been reported that capacitive Ca²⁺ entry in hepatoma cells could be inhibited by cGMP, an activator of protein kinase G (PKG), and enhanced by KT5823, an inhibitor of PKG^[13-15]. The present study examined the effect of cGMP and KT5823 on the capacitive Ca²⁺ entry in 3T3 cells. The [Ca²⁺]_i fluorescence ratios were obtained in cells without chemical treatment (control) or treated with 2 mmol/L cGMP or 1 μmol/L KT5823, respectively. Results showed that 2 mmol/L cGMP inhibited the Ca²⁺

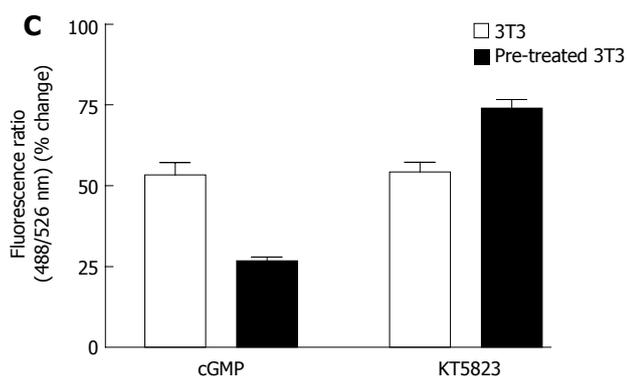

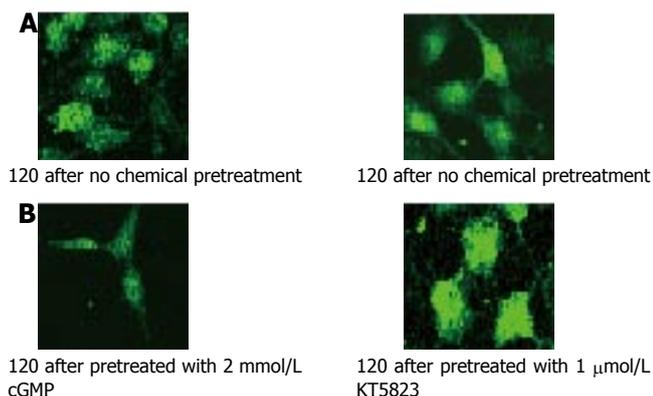

Figure 3 Effect of 8-bromo-cGMP and KT5823 on thapsigargin-induced Ca^{2+} influx. **A:** 3T3 cells were incubated in NPBS with 4 μ mol/L thapsigargin for 2 min, then 2 mmol/L $CaCl_2$ was added into the medium; **B:** 3T3 cells were incubated in NPBS with 4 μ mol/L thapsigargin for 2 min, 8-bromo-cGMP (2 mmol/L) or KT5823 (1 μ mol/L) was introduced 1 min prior to the measurement, then 2 mmol/L $CaCl_2$ was added into the medium; **C:** Effects of cGMP and KT5823 on thapsigargin-induced Ca^{2+} influx. The Ca^{2+} entry fluorescence ratios were obtained in cells without chemical treatment (control) or treated with 2 mmol/L 8-Br-cGMP (cGMP) or 1 μ mol/L KT5823. The cells were incubated in NPBS with 4 μ mol/L thapsigargin for 2 min prior to the chemical treatment. One mmol/L $CaCl_2$ was introduced to the medium to obtain the fluorescent signal of Ca^{2+} entry. The values are the mean \pm SE ($n = 4-6$).

entry with 25.3% \pm 1.3% inhibition compared with 3T3 cells not pretreated (53.0% \pm 4.4%) ($P < 0.05$, Figure 3C). KT5823 (1 μ mmol/L) stimulated the Ca^{2+} entry by 72.3% \pm 3.9% ($P < 0.05$, Figure 3C).

NO is an important intracellular signal molecule that activates soluble guanylylase to synthesize cGMP^[16]. The present study was carried out to investigate the involvement of NO in regulation of the capacitive Ca^{2+} entry using a NO donor (SNAP) and L-NAME (a specific NOS inhibitor) to trigger production of endogenous cGMP. Results showed that SNAP also inhibited the thapsigargin-induced Ca^{2+} influx, 26.7% \pm 6.4% inhibition was observed at 100 μ mol/L SNAP compared with control (48.1% \pm 5.2%) ($P < 0.05$, Figure 4C). L-NAME (200 μ mol/L) could excite the thapsigargin-induced Ca^{2+} influx in 3T3 cells too, 71.6% \pm 3.9% stimulation was observed in 3T3 cells compared with control (49.6% \pm 5.8%) ($P < 0.05$, Figure 4C).

Effect of SOC on MMP mRNA expression

The expression and release of MMPs (such as MMP-2 and MMP-9) work through kinase signaling pathways^[17-19],

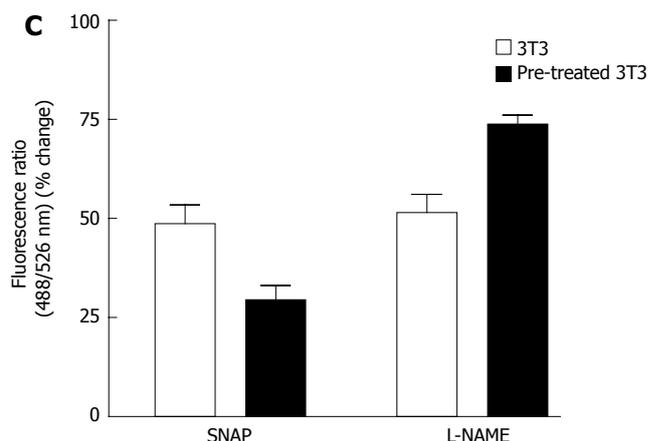

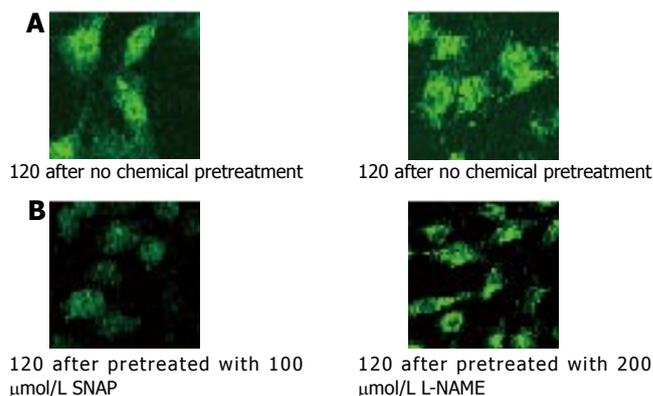

Figure 4 Effect of SNAP and L-NAME on thapsigargin-induced Ca^{2+} influx. **A:** 3T3 cells were incubated in NPBS with 4 μ mol/L thapsigargin for 2 min, then 2 mmol/L $CaCl_2$ was added into the medium; **B:** 3T3 cells were incubated in NPBS with 4 μ mol/L thapsigargin for 2 min, 100 μ mol/L SNAP or 200 μ mol/L L-NAME was introduced 1 min prior to the measurement, then 2 mmol/L $CaCl_2$ was added into the medium; **C:** Ca^{2+} entry fluorescence ratios were obtained in cells without chemical treatment (control) or treated with 100 μ mol/L SNAP or 200 μ mol/L L-NAME. The values are the mean \pm SE ($n = 4-6$).

like NO-cGMP- Ca^{2+} signaling pathway^[20-22]. The present study tested the involvement of SOC in regulating MMP release *in vitro*. RT-PCR showed that synthesis of MMP-2 and MMP-9 mRNA in cGMP-pretreated 3T3 cells was less than that in 3T3 cells not pretreated. Gelatin zymography showed that production of MMP-2 and MMP-9 in 3T3 medium culture was more than that in cGMP- pretreated 3T3 medium culture (Figure 5).

Involvement of $[Ca^{2+}]_i$ and NO/cGMP in MMP secretion

Zymography results showed that the increasing extracellular calcium concentrations (0, 0.09, 0.4, 0.8, 1.2 mmol/L) enhanced MMP-2 and MMP-9 secretion in a dose-dependent manner (Figure 6). In the present study, 4 μ mol/L thapsigargin was used to deplete the intracellular Ca^{2+} store in order to induce Ca^{2+} entry. Zymography results showed pretreatment with 8-bromo-cGMP (2 mmol/L) or SNAP (200 μ mol/L) significantly reduced the production of MMP-2 and MMP-9 in 3T3 cells, and 1 μ mol/L KT5823 or 100 μ mol/L L-NAME enhanced the production of MMP-2 and MMP-9 in 3T3 cells. These results indicated that NO/cGMP sensitive SOC was

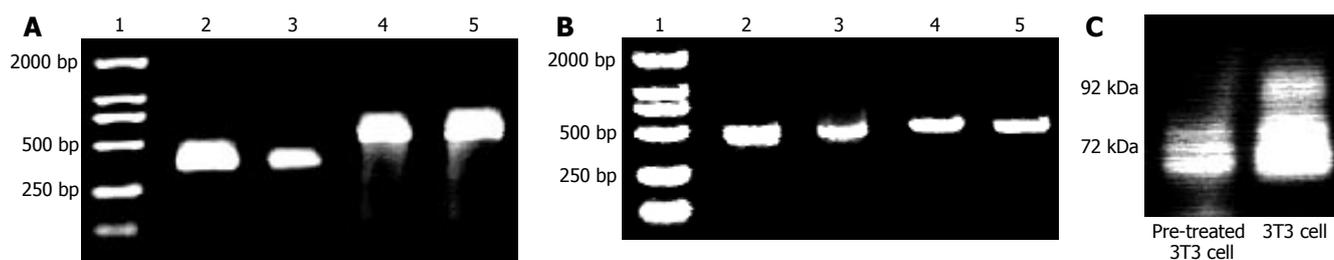

Figure 5 Expression of MMP in pretreated and not pretreated 3T3 cells. **A:** RT-PCR results of MMP-2 mRNA in both cells (1: DL2000 marker; 2: MMP-2 cDNA of 3T3 cells; 3: MMP-2 cDNA of 8-Br-cGMP (2 mmol/L) pre-treated 3T3 cells; 4: β-actin cDNA of 3T3 cells; 5: β-actin cDNA of pre-treated 3T3 cells); **B:** RT-PCR results of MMP-9 mRNA in pretreated and not pretreated 3T3 cells (1: DL2000 marker; 2: MMP-9 cDNA of 3T3 cells; 3: MMP-9 cDNA of 8-Br-cGMP (2 mM) pre-treated 3T3 cells; 4: β-actin cDNA of 3T3 cells; 5: β-actin cDNA of pre-treated 3T3 cells); **C:** Gelatin zymography showing constitutive secretion of MMP-2 (72 kDa) and MMP-9 (92 kDa) into serum-free media by pretreated and not pretreated 3T3 cells.

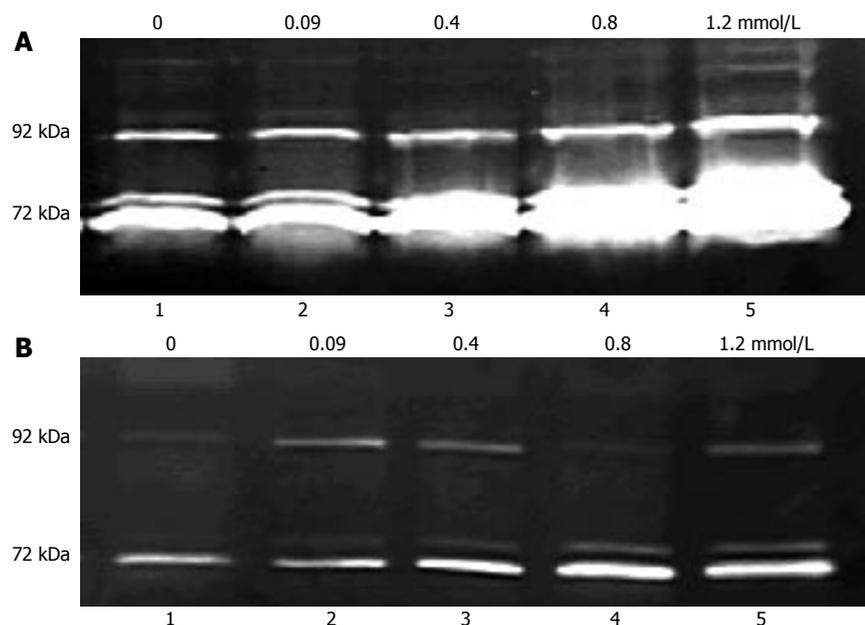

Figure 6 Dose-dependent effect of extracellular Ca²⁺ on MMP release. 8-bromo-cGMP (2 mmol/L) pre-treated and not pretreated 3T3 cells were plated in media with serial doses of Ca²⁺ (0, 0.09, 0.4, 0.8, 1.2 mmol/L) and incubated for 16-18 h, 200 μL conditioned media was used as sample. The 72 kDa gelatinolytic bands corresponded to the MMP-2, the 92 kDa band to MMP-9. **A:** 3T3 cell mean ratio of 72 kDa in groups 1-5 was 0.198 ± 0.094, 0.287 ± 0.114, 0.486 ± 0.079, 1.247 ± 0.089 and 2.487 ± 0.179, respectively (*n* = 4-6); **B:** 8-bromo-cGMP (2 mmol/L) pre-treated 3T3 cell mean ratio of 72 kDa in groups 1-5 was 0.104 ± 0.084, 0.126 ± 0.086, 0.257 ± 0.102, 0.490 ± 0.173 and 0.784 ± 0.187, respectively (*n* = 4-6).

involved in MMP secretion of fibroblasts (Figure 7).

Involvement of NO/cGMP-sensitive Ca²⁺ entry in adhesion

We used matrigel-coated plates as models for investigation of possible signaling pathways involved in extracellular matrix-induced metastasis. Matrigel is a soluble basement membrane preparation containing almost all extracellular matrix components^[23]. The present study was carried out with matrigel as an adhesion substratum. A significant difference in the amount of cells attached to the matrigel-coated plates was observed in 3T3 cells pre-treated and not pre-treated with cGMP (2 mmol/L) for 30 min (71.4% ± 0.5% *vs* 44.7% ± 2.5%) (*P* < 0.05). Pre-treatment with SNAP (200 μmol/L) showed that the percent of attached and non-attached 3T3 cells was 64.7% ± 1.2% and 46.3% ± 2.0%, respectively (*P* < 0.05, Figure 8).

DISCUSSION

Collagenolytic degradation of endothelial and parenchymal basement membranes is a necessary step in the process of tumor invasion and angiogenesis. Neutral MMP-2 and MMP-9 mainly secreted locally by stromal cells, degrade the basement membrane and extracellular matrix collagens.

However, little is known about the signaling pathways that regulate the production of these enzymes. Previous studies have demonstrated that transforming growth factor-β1 (TGF-β1) plays a role in transmembrane signal transduction of MMP-2 regulation^[24]. The present study described a role of calcium mobilization in the regulation of MMP expression.

The present study demonstrated that the existence of NO/cGMP-sensitive store-operated Ca²⁺ entry in mouse fibroblast NIH/3T3 cells, which is allergic to NO/cGMP. The thapsigargin-induced SOC appears to be evidenced by the magnitude of the Ca²⁺ entry and its blockage by Ni²⁺, cGMP or SNAP inhibits the thapsigargin-induced Ca²⁺ entry in 3T3 cells and can be reversed by KT5823 (highly specific PKG inhibitor), indicating a negative regulatory mechanism involving NO/cGMP *via* a PKG-dependent pathway.

Characterization of the regulation of interstitial collagenase (MMP-1) and stromelysin (MMP-3) indicates that there are at least two known regulatory arms for the secretion of these MMPs. Treatment with TGF-β1 inhibits the production of these MMP genes through TIE, a novel CIS-acting transcriptional element^[25,26], whereas phorbol ester-mediated stimulation of transcription is

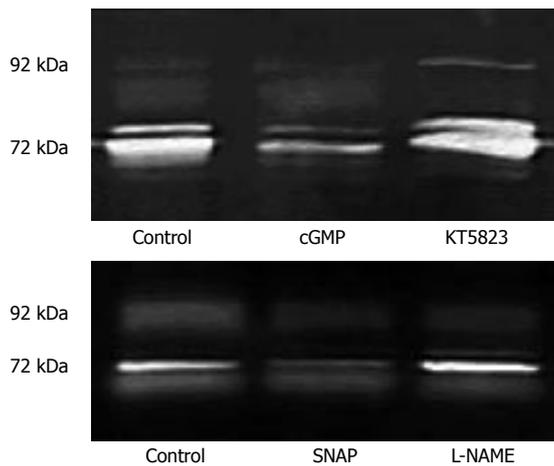

Figure 7 cGMP/KT5823 and SNAP/L-NAME affecting MMP release 3T3 cells via Tg-induced SOC. 3T3 cells were incubated in NPBS with 4 $\mu\text{mol/L}$ thapsigargin for 2 min. Each kind of chemical reagents (2 mmol/L cGMP, 1 $\mu\text{mol/L}$ KT5823, 100 $\mu\text{mol/L}$ SNAP or 200 $\mu\text{mol/L}$ L-NAME) was introduced 1 min prior to the measurement, then 2 mmol/L CaCl_2 was added into each medium and incubated for 16-18 h. The 72 kDa gelatinolytic band (MMP-2) was obtained in cells without chemical treatment (control) or treated with cGMP, KT5823, SNAP, L-NAME.

through phorbol ester-responsive elements (TREs) and AP-1 sites^[27,28]. Regulation of matrix metalloproteinases has also been linked to the second cAMP messenger signal transduction pathway^[29,30]. Several investigators have demonstrated the induction of MMP-1 production in response to cAMP either directly or after cell stimulation with cytokines that signal their effects through cAMP^[29,31]. However, in contrast to MMP-1 and MMP-3, neither MMP-2 nor MMP-9 has TIE or cAMP-regulated elements defined in their 5' sequences^[27,32]. The TRE mechanism has been implicated in the regulation of MMP-9 but not MMP-2^[27]. AP-1 sites have not been documented for MMP-2, although AP-1 and AP-2 sites are in the upstream of MMP-9^[27,32,33]. It was reported that there is a NF- κB binding site in the upstream sequence of MMP-9^[34]. Besides the factors influencing MMP secretion, calcium-activated signal transduction steps are also a common thread underlying important signal transduction pathways, including protein kinase C, phosphoinositide metabolism, and generation of arachidonic acid. However, few calcium-mediated transcriptional pathways have been identified for MMP secretion.

The present study was to identify NO/cGMP-sensitive production and activation of MMP through SOC. In our study, adding extracellular Ca^{2+} concentration induced release and activation of MMP (MMP-2, MMP-9) in a dose-dependent manner, cGMP and SNAP reduced MMP secretion in 3T3 cells. RT-PCR displayed that MMP-2 and MMP-9 mRNA synthesis in cGMP-pretreated 3T3 cells was significantly less than that in non cGMP-pretreated 3T3 cells. Tumor invasion is greatly dependent on the permissive action of the microenvironment. One critical factor is the production of proteolytic enzymes involved in the degradation and remodeling of ECM. Among these enzymes, MMPs represent a large family playing a key role in cell proliferation, angiogenesis, tumor invasion and metastasis^[6]. These enzymes principally degrade the ECM components and attenuate cell-cell adhesion ability so as to

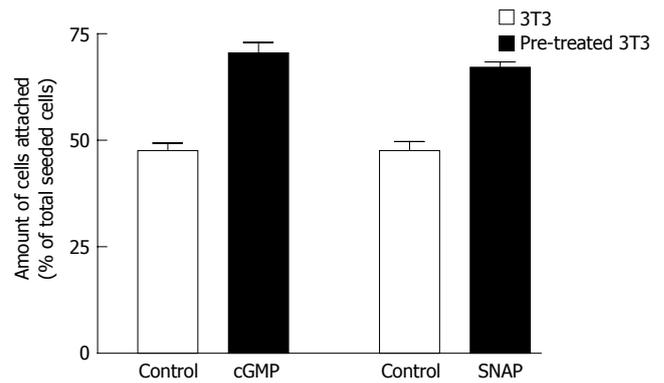

Figure 8 Effects of cGMP or SNAP on adhesion potentials of 3T3 cells to matrigel by adhesion assay. 3T3 cells pretreated with 4 $\mu\text{mol/L}$ Tg were suspended in serum-free medium supplemented with no chemical reagent (control) or cGMP (2 mmol/L) or SNAP (200 $\mu\text{mol/L}$), 2 mmol/L CaCl_2 was added to induce SOC, then seeded into the matrigel (5 mg/L)-coated wells. After incubation for 30 min at 37°C, the percentage of adhered cells was determined using colorimetric crystal violet assay. The values are the mean \pm SE ($n = 6-8$).

promote tumor invasion and metastasis.

Our experiments investigating adhesion potentials demonstrated that the attachment rate of 3T3 cells living in high extracellular Ca^{2+} concentration of the matrigel-coated culture plates was lower than that in low extracellular Ca^{2+} concentration of the matrigel-coated culture plates, suggesting that increased cellular Ca^{2+} concentration attenuates the adhesion potentials in fibroblasts by enhancing MMP secretion. The attachment rate could be upgraded by cGMP and SNAP in 3T3 cells, indicating that interference with NO/cGMP/PKG pathway sensitivity of fibroblasts reduces SOC and inhibits MMP secretion at a considerable level, thus strengthening the adhesion potential of fibroblasts and decreasing the chance of HCC metastasis.

In conclusion, store-operated Ca^{2+} channels exist in mouse fibroblast cells and are involved in MMP secretion. NO/cGMP/PKG pathway negatively regulates this Ca^{2+} entry. Increased extracellular Ca^{2+} concentration may promote degradation of ECM components by increasing MMP secretion and attenuating fibroblast adhesion potential.

Abstract

AIM: To determine circulating and hepatic adiponectin in rodents with fatty liver disease or liver cirrhosis and investigate expression of the adiponectin receptors AdipoR1 on the mRNA and protein level and AdipoR2 on the mRNA level.

METHODS: Fat fed rats were used as a model for fatty liver disease and bile duct ligation in mice to investigate cirrhotic liver. Expression of AdipoR1 and AdipoR2 mRNA was determined by real time RT-PCR. AdipoR1 protein was analysed by immunoblot. Adiponectin was measured by ELISA.

RESULTS: Systemic adiponectin is reduced in fat-fed rats but is elevated in mice after bile duct ligation (BDL). Hepatic adiponectin protein is lower in steatotic liver but not in the liver of BDL-mice when compared to controls. Adiponectin mRNA was not detected in human liver samples or primary human hepatocytes nor in rat liver but recombinant adiponectin is taken up by isolated hepatocytes *in-vitro*. AdipoR1 mRNA and AdipoR1 protein levels are similar in the liver tissue of control and fat fed animals whereas AdipoR2 mRNA is induced. AdipoR2 mRNA and AdipoR1 mRNA and protein is suppressed in the liver of BDL-mice.

CONCLUSION: Our studies show reduced circulating adiponectin in a rat model of fatty liver disease whereas circulating adiponectin is elevated in a mouse model of cirrhosis and similar findings have been described in humans. Diminished hepatic expression of adiponectin

INTRODUCTION

Obesity and especially visceral fat accumulation cause insulin resistance, a common risk factor for hepatic steatosis. Fatty liver is thought to represent the first step towards the subsequent development of liver fibrosis. Impaired mitochondrial function provides the second hit and promotes the generation of reactive oxygen species, which promote lipid peroxidation, the release of inflammatory cytokines, death of hepatocytes and activation of hepatic stellate cells. Non-alcoholic steatohepatitis (NASH) is a progressive disorder that can lead to liver cirrhosis and even hepatocellular carcinoma^[1].

Adiponectin is highly abundant in human serum and is secreted by adipose tissue in inverse proportion to the body mass index^[2]. Adiponectin improves whole body insulin sensitivity and in addition exerts anti-inflammatory effects by reducing NF κ B activation^[3]. Low adiponectin levels are associated with NASH independent of insulin resistance and body mass index indicating a protective effect for adiponectin in liver disease^[4]. This idea is supported by studies in rodents where recombinant adiponectin given to leptin-deficient ob/ob mice ameliorates hepatic steatosis and normalizes alanine aminotransferase levels^[5]. Besides these protective effects on fatty liver disease adiponectin attenuates T-cell mediated hepatic inflammation by reducing the release of proinflammatory cytokines, the activation of hepatic stellate cells and cell death of hepatocytes^[6].

Two 7-transmembrane proteins, AdipoR1 and AdipoR2, have been identified to function as adiponectin receptors^[7]. AdipoR1 mRNA is mainly expressed in the

human heart and skeletal muscle, whereas AdipoR2 was supposed to be the main receptor in the liver^[7]. Recently a prominent protein expression of AdipoR1 in primary hepatocytes was demonstrated indicating that AdipoR1 may also be important in hepatic signal transduction^[8]. Adiponectin activates the AMP-activated protein kinase (AMPK) and PPAR α ^[7] but may also inhibit the binding of growth factors to their corresponding receptors independent of AdipoR1 and AdipoR2^[9].

Although there is a well documented relationship between low adiponectin and liver disease, the role of adiponectin receptors is less clear^[4,6]. In addition, mainly AdipoR2 has been analysed with regard to liver function^[10,11]. Therefore the expression of AdipoR1 was investigated in rodent models of fatty liver disease and liver cirrhosis.

MATERIALS AND METHODS

Subjects

Wistar rats were fed a standard rodent chow (6 animals) or a high fat diet for twelve weeks (six animals) as recently described^[12]. Male C57Bl/6J mice (body weight 25-30 g) underwent common bile duct ligation (BDL) and transection as previously reported^[13]. Another group of animals was sham-operated to serve as a control. For analysis of adiponectin or AdipoR1 protein four control and five BDL mice were used. Analysis of mRNA expression was performed with total RNA isolated from the liver of eight control and four BDL animals. All animal procedures were performed under the guidelines set by The University of Regensburg Institutional Animal Care and Use Committee. Primary hepatocytes from three different donors were isolated and cultivated as described before^[14]. Tissue samples from human liver resection were obtained from patients undergoing partial hepatectomy. Experimental procedures were performed according to the guidelines of the charitable state controlled foundation HTCR (Human Tissue and Cell Research), with the informed patient's consent^[15] approved by the local ethical committee of the University of Regensburg.

Culture media and reagents

RPMI medium was from Biochrom (Southborough, MA, USA), RNeasy Mini Kit from Qiagen (Hilden, Germany) and oligonucleotides were synthesized by Metabion (Planegg-Martinsried, Germany). LightCycler FastStart DNA Master SYBR Green I was purchased from Roche (Mannheim, Germany). AdipoR1 peptide antibody was raised as recently described^[8]. AdipoR2 protein was not analysed because several antibodies investigated did not specifically detect in-vitro translated AdipoR2 by immunoblot (own unpublished results).

ELISAs for human and mouse adiponectin and human recombinant adiponectin were from R&D systems (Wiesbaden-Nordenstadt, Germany). ELISAs for rat adiponectin from BioCat (Heidelberg, Germany). PI3-Kinase p85 antibody was from Upstate (Lake Placid, NY, USA). Recombinant human leptin was from Sigma Chemical (Deisenhofen, Germany) and 100 μ g/L were used.

Monitoring of gene expression by real-time RT-PCR

Real-time RT-PCR was performed as recently described^[16].

Table 1 Oligonucleotides used for real-time RT-PCR

h: Human; m: Mouse; r: Rat.

The primers are listed in Table 1. Amplification in the LightCycler capillaries was done for 45 cycles with initial incubation of ten minutes at 95°C for activation of Taq polymerase. Cycling parameters were 15 s at 95°C, ten seconds 60°C and ten seconds at 72°C. The second derivative method was used for quantification with the LightCycler software. For quantification of the results the standard curve method was used. Normalization was performed by dividing each value calculated for a specific gene by the value of the corresponding housekeeping gene. QuantiTect Primer Assays (Qiagen) for use in real-time RT-PCR with SYBR Green detection were used to determine rat adiponectin mRNA.

SDS-PAGE and immunoblotting

The cells or tissues were solubilized in RIPA buffer. Proteins were separated by SDS-polyacrylamide gel electrophoresis and were transferred to PVDF membranes (Bio-Rad, Germany). Incubations with antibodies were performed in 1% BSA in PBS, 0.1% Tween overnight. Detection of the immune complexes was carried out with the ECL Western blot detection system (Amersham Pharmacia, Deisenhofen, Germany).

Statistical analysis

Data are represented as Box Plots (Sigma Plot) indicating the median, the upper and lower quartile, the largest and the lowest value in the data set. Statistical differences were analysed by Student's *t*-test (MS Excel) and a value of *P* < 0.05 was regarded as statistically significant.

RESULTS

Expression of AdipoR1 was analysed in HepG2 cells treated with insulin or leptin. HepG2 cells were treated

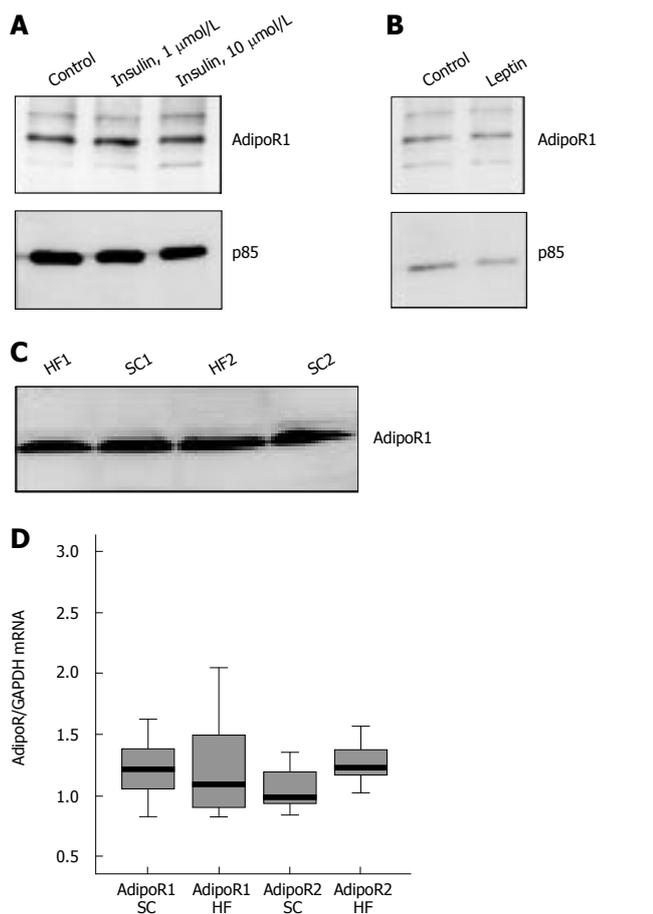

Figure 1 AdipoR1 mRNA and protein and AdipoR2 mRNA in fatty liver disease. **A:** Expression of AdipoR1 in HepG2 incubated with 1 $\mu\text{mol/L}$ or 10 $\mu\text{mol/L}$ insulin for 4 h; **B:** Analysis of AdipoR1 in HepG2 treated with recombinant leptin for 24 h; **C:** AdipoR1 abundance in the liver of rats kept on a standard chow (SC) or a high fat diet (HF); **D:** AdipoR1 and AdipoR2 mRNA expression in the liver of rats kept on a standard chow (SC) or a high fat diet (HF). For normalization GAPDH mRNA levels were determined.

with insulin, 1 $\mu\text{mol/L}$ and 10 $\mu\text{mol/L}$ for four hours (Figure 1A) and six hours (not shown) or leptin for 24 h. AdipoR1 was analyzed by immunoblot and was found not to be regulated by insulin or leptin (Figures 1A and B). AdipoR1 and AdipoR2 mRNA expression was determined in insulin treated cells and was similar in controls and insulin-incubated HepG2 cells (not shown).

AdipoR1 protein and mRNA as well as AdipoR2 mRNA were analysed in the liver of rats on a standard chow (SC) or on a high fat (HF) diet. AdipoR1 protein level is similar in these animals (Figure 1C) and real-time RT-PCR revealed no alterations in the mRNA expression of AdipoR1 whereas AdipoR2 mRNA is induced with a relative expression of 1.0 ± 0.2 in SC and 1.3 ± 0.2 in the HF group ($P = 0.004$) (Figure 1D). RT-PCR data were normalized by the corresponding GAPDH values which were not different between the two groups.

Systemic and liver adiponectin were measured by ELISA. Circulating adiponectin is significantly reduced in fat-fed animals with 4.9 ± 1.1 mg/L adiponectin compared to 6.2 ± 8 mg/L in SC fed rats ($P = 0.02$) (not shown). Liver adiponectin is also lower in fat rats with 8.5 ± 2.4 ng adiponectin in 1 μg liver tissue when compared to controls with 11.9 ± 1.9 ng adiponectin ($P = 0.01$) (Figure 2A).

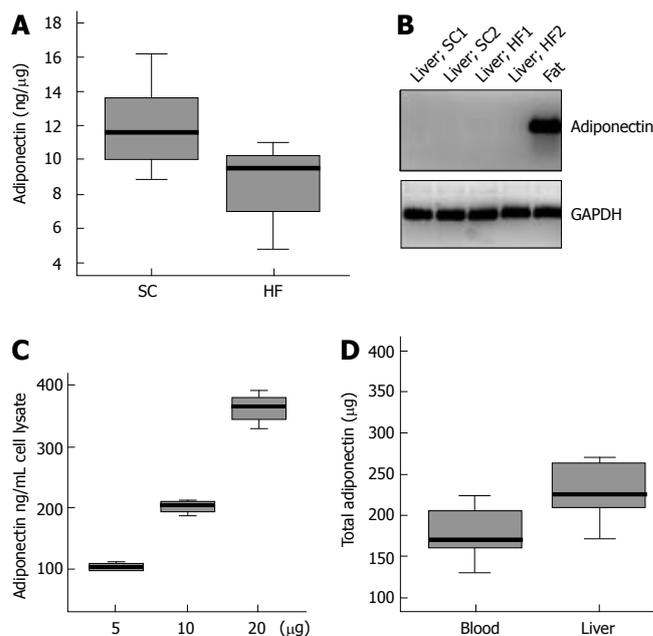

Figure 2 Hepatic adiponectin protein and mRNA in fatty liver disease. **A:** Adiponectin in the liver of standard chow (SC) and high fat diet (HF) animals. Concentration of adiponectin is ng per μg liver tissue; **B:** Adiponectin mRNA in the liver of rats kept on a standard chow (SC) or a high fat diet (HF). Fat tissue was analysed as a positive control; **C:** Primary hepatocytes were incubated with 5, 10 or 20 mg/L adiponectin for 24 h and adiponectin was determined in the cell lysates; **D:** Total systemic and hepatic adiponectin was calculated.

Adiponectin in the liver may be derived from the circulation or originate from liver cells. Adiponectin mRNA was analysed by RT-PCR with total RNA isolated from rat liver of HF and SC animals and rat adipose tissue as a positive control. Adiponectin mRNA was not detected in any RNA isolated from total liver by RT-PCR and 45 cycles of amplification but was easily amplified from adipose tissue RNA (Figure 2B). In addition, adiponectin mRNA was not detected in human liver, in isolated primary human hepatocytes or in HepG2 cells (not shown). Therefore hepatic adiponectin is most likely taken up by liver cells.

To test this hypothesis primary human hepatocytes were incubated with 5, 10 and 20 mg/L recombinant adiponectin for 24 h or PBS as solvent control in serum-free medium. Whereas adiponectin was not detected in the control cells and therefore is below 40 ng/L, adiponectin was found in the cell lysates of hepatocytes incubated with increasing amounts of recombinant protein and was 111 ± 3 $\mu\text{g/L}$, 200 ± 18 $\mu\text{g/L}$ and 360 ± 43 $\mu\text{g/L}$, respectively (Figure 2C). This indicates that about 0.02% of the extracellular adiponectin is taken up by hepatocytes and the uptake correlates to the adiponectin concentration in the medium.

Total circulating adiponectin in rats was calculated and the blood volume was estimated as described (Blood volume (mL) = $0.06 \times \text{body weight} + 0.77$)^[17]. Total liver adiponectin was also calculated by multiplication of hepatic adiponectin concentration with the corresponding weight of the liver. Adiponectin in the blood was 178 ± 31 μg and in the liver 241 ± 59 μg indicating that total liver adiponectin is higher than circulating adiponectin ($P = 0.03$) (Figure 2D). However, this is only a rough estimate because the blood volume of the liver was not included

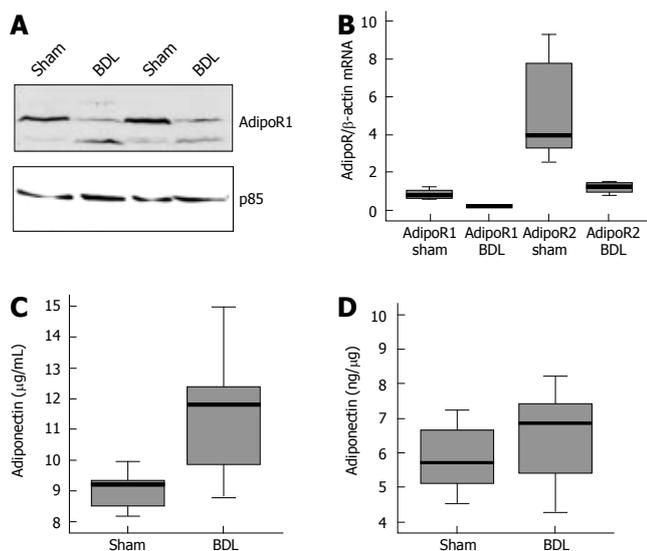

Figure 3 AdipoR1 and adiponectin in liver cirrhosis. **A:** AdipoR1 abundance in the liver of sham-operated or BDL mice; **B:** AdipoR1 and AdipoR2 mRNA expression in the liver of sham-operated or BDL mice. For normalization β -actin levels were determined; **C:** Systemic adiponectin in control and cholestatic animals; **D:** Adiponectin in the liver of sham-operated or BDL mice. Concentration of adiponectin is mg per g liver tissue.

in the calculation. Furthermore, adiponectin may be not equally distributed in the whole liver and levels may vary between different biopsies taken from the same organ.

AdipoR1 and AdipoR2 were also determined in a rodent model of liver cirrhosis. AdipoR1 protein was analysed in the liver of control mice and animals after BDL by immunoblot and was found reduced in all BDL animals investigated (Figure 3A). AdipoR1 and AdipoR2 mRNA were determined by real-time RT-PCR in control and BDL mice. Relative abundance of AdipoR1 mRNA was 0.8 ± 0.3 in sham and 0.2 ± 0.1 in BDL mice ($P = 0.0004$), AdipoR2 mRNA was 5.2 ± 2.6 in controls and 1.2 ± 0.3 in BDL animals ($P = 0.007$) (Figure 3B). Normalization was performed using β -actin as housekeeping gene which was similarly expressed in both groups ($P = 0.14$). Systemic adiponectin was significantly higher in the BDL group with 9.0 ± 0.6 mg/L in the control and 11.1 ± 2.0 mg/L in the BDL animals ($P = 0.03$) (Figure 3C) whereas hepatic adiponectin was similar with 5.8 ± 1.0 mg/g in sham and 6.4 ± 1.5 mg/g in the BDL mice ($P = 0.4$) (Figure 3D).

To identify mediators that are responsible for the suppression of AdipoR1 in liver cirrhosis, primary hepatocytes and HepG2 cells were incubated for 24 h with either LPS (1 and 10 mg/L), TNF (10 $\mu\text{g/L}$), supernatants of activated hepatic stellate cells, CCl₄ (1 mmol/L and 3 mmol/L) or actinomycin D (10 mg/L). AdipoR1 protein was not found reduced in cells treated with these mediators (not shown).

DISCUSSION

Although AdipoR2 has been suggested to represent the main adiponectin receptor in the liver we recently demonstrated significant expression of AdipoR1 mRNA and protein in primary human hepatocytes and HepG2 cells^[8]. In the current study AdipoR1 mRNA and protein,

AdipoR2 mRNA and abundance of circulating and hepatic adiponectin in rodent models of steatotic and cirrhotic liver was investigated.

Rats fed a HF diet develop insulin resistance and fatty liver disease^[12]. AdipoR1 mRNA and protein is similar when total liver tissue isolated from rats on a standard diet or HF animals was analyzed. Furthermore, insulin did not alter AdipoR1 mRNA or protein in HepG2 cell. Leptin deficient ob/ob mice are obese and insulin resistant and hepatic AdipoR1 mRNA was found similarly expressed in these animals when compared to controls^[18]. These data indicate that reduced insulin sensitivity is not associated with reduced AdipoR1 expression in the liver.

AdipoR2 mRNA is about 25% higher in the fatty liver of HF rats whereas in the ob/ob mice AdipoR2 mRNA is not altered^[18]. AdipoR2 mRNA was also investigated in humans and is significantly elevated in fatty liver disease when compared to normal liver^[19] in one study whereas a second study could not detect alterations in AdipoR2 mRNA^[10,20]. However, protein expression has not been investigated so far but is important to clarify abundance of hepatic AdipoR2 in the metabolic syndrome.

Systemic adiponectin is significantly lower in the HF animals and reflects the human situation where circulating adiponectin has an inverse proportion to the body mass index^[2]. In accordance with the lower systemic adiponectin levels, hepatic adiponectin is also reduced in the fat rat. Adiponectin mRNA was not detected in rat liver indicating that hepatic adiponectin may be taken up by the cells. Adiponectin was not found in primary human hepatocytes cultivated *in vitro* for three days but incubation of these cells with 5, 10 or 20 mg/L recombinant adiponectin for 24 h elevated cellular adiponectin in a concentration dependent way. This may indicate that adiponectin is taken up by hepatocytes either from the circulation or the portal vein.

The common and final state of all chronic liver diseases is liver cirrhosis. A well known model of extrahepatic biliary obstruction is common bile duct ligation in mice^[21]. AdipoR1 mRNA and protein and AdipoR2 mRNA were found reduced in the cirrhotic liver of BDL animals. Systemic adiponectin is elevated in animals with liver cirrhosis, a phenomenon also described in a study investigating mice and humans^[22]. However, hepatic adiponectin was similar in sham and BDL mice. It was suggested that adiponectin is excreted via the bile and an impaired liver function in cirrhosis may reduce biliary loss of circulating adiponectin explaining elevated systemic levels^[22]. However, this hypothesis presumes reduced hepatic adiponectin concentrations when compared to control animals and therefore is not supported by our findings.

Although adiponectin was detected in the liver of mice and rats, adiponectin mRNA could not be amplified in rat liver, human liver or isolated human hepatocytes indicating that adiponectin is not produced by hepatocytes or other cells of the liver tissue. These results are in agreement with several studies^[10,20] but contradict the results of other reports^[11,22] and there is currently no explanation for these different findings. However, hepatocytes take up significant amounts of adiponectin and this may explain at least in

part why adiponectin is detected in the liver.

One limitation of the current study is that only four to eight animals could be analyzed per experiment and the investigations would benefit from a higher number of rodents. Nevertheless low circulating adiponectin in obesity^[2] and high levels in liver cirrhosis^[22] have also been reported in human studies and are in accordance with our findings.

All in all, our experiments show reduced circulating adiponectin in a rodent model of fatty liver disease and elevated adiponectin and diminished expression of adiponectin receptors in BDL-induced liver cirrhosis in mice.

Abstract

AIM: To evaluate prognostic indicators for the outcome of patients with perihilar extrahepatic cholangiocarcinoma in an unselected cohort.

METHODS: We retrospectively analyzed 98 patients with perihilar cholangiocarcinoma. Twenty-three patients (23.5%) underwent tumor resection. Patients with non-resectable tumors underwent either transpapillary or percutaneous transhepatic biliary drainage. Additionally, 32 patients (32.7%) received photodynamic therapy (PDT) and 18 patients (18.4%) systemic chemotherapy. Predefined variables at the time of diagnosis and characteristics considering the mode of treatment were entered into a Cox's proportional hazards model. Included in the analysis were age, tumor stage following the modified Bismuth-Corlette classification, bilirubin, prothrombin time (PT), C-reactive protein (CRP), carbohydrate antigen 19-9 (CA19-9), history of weight loss, surgical resection, chemotherapy and PDT.

RESULTS: The Kaplan-Meier estimate of overall median survival was 10.5 (95%CI: 8.4-12.6) mo. In the univariate analysis, low Bismuth stage, low CRP and surgical resection correlated significantly with better survival. In the multivariate analysis, only CRP ($P = 0.005$) and surgical resection ($P = 0.029$) were found to be independently predictive of survival in the cohort. Receiver operating characteristic (ROC) analysis identified a CRP level of 11.75 mg/L as the value associated with the highest sensitivity and specificity predicting a survival > 5 mo. Applying Kaplan-Meier analysis, patients with a CRP < 12 mg/L at the time of diagnosis had a significantly longer median survival than patients with higher values (16.2 vs 7.6 mo; $P = 0.009$).

CONCLUSION: This retrospective analysis identified CRP level at the time of diagnosis as a novel indicator for the prognosis of patients with perihilar cholangiocarcinoma. It should be evaluated in future prospective trials on this entity.

INTRODUCTION

Cholangiocarcinoma is a rare tumor^[1]. The global incidence varies between 0.5 and 1.1 per 100 000^[2]. High-risk groups have been defined. Thus, the life-time risk of intrahepatic and extrahepatic cholangiocarcinoma among patients with primary sclerosing cholangitis (PSC) ranges between 8%-20%^[3]. Further risk factors for the occurrence of cholangiocarcinoma are infections with liver flukes^[4], hepatolithiasis^[5], choledochal cysts^[6] or application of thorotrast^[7]. While recent data show that incidence and mortality rates of intrahepatic cholangiocarcinoma are increasing in several areas in the world, the incidence and mortality rates of extrahepatic carcinoma are declining^[8]. The 5-year survival of patients with extrahepatic cholangiocarcinoma is poor and was found to be less than 20% in a large population-based epidemiological study from the United States^[1].

Perihilar cholangiocarcinoma is mostly diagnosed at an advanced stage. Therefore, more than two-thirds of patients are not suitable for surgery due to either expansion of the tumor or age and comorbidity^[9]. Nevertheless, the prognosis of patients undergoing tumor resection has improved in recent years owing to advancements in surgical techniques resulting in a more aggressive resectional approach^[10,11]. Furthermore, liver transplantation may be an option in highly selected patients after neo-adjuvant

radiochemotherapy and invasive staging^[12,13].

Prognostic factors predicting the outcome of patients undergoing tumor resection have recently been extensively evaluated^[10,14]. In contrast, less attention has been paid to overall outcome and possible prognostic indicators in unselected patients suffering from cholangiocarcinoma. Therefore, we performed a retrospective analysis of 98 consecutive patients with perihilar cholangiocarcinoma treated at a tertiary medical center within a period of 5 years in order to identify the most relevant predictors of outcome.

MATERIALS AND METHODS

Data acquisition

Using our hospital database, we identified the records of 98 consecutive unselected patients with extrahepatic perihilar cholangiocarcinoma type Bismuth I to IV admitted to our hospital between October 1997 and March 2003. Charts were reviewed retrospectively. Data for further analysis were available from all patients.

Diagnostic criteria

Cholangiography showed a perihilar stricture in all patients. Positive histology and/or cytology were present in 68 (69.4%) patients. In the remaining patients, diagnosis was made by the coexistence of a CA19-9 serum level greater than 250 IU/L and typical findings at cholangiography, ultrasound and CT scan.

We recorded patients' age, gender, clinical presentation, tumor stage following the modified Bismuth-Corlette classification^[9], laboratory parameters at presentation (blood count, CRP, bilirubin, alkaline phosphatase, GPT, CA19-9), histology, cytology, type of medical treatment and outcome including date of death.

Statistical analysis

Numeric data were recorded as median and range or 95% confidence intervals (95% CI). To identify prognostic factors, we used the Cox's proportional hazards regression analysis. Survival analysis was performed using the Kaplan-Meier method and comparisons were made employing the log rank test. The Mann-Whitney rank sum test was used for inter-group comparisons. Statistical analysis was performed using the SPSS[®] (SPSS Inc., Chicago, IL, USA) and the StatView 5.0[®]-Software (Version for Windows; SAS Institute Inc., Cary, NC, USA). A *P* value less than 0.05 was considered statistically significant.

RESULTS

Demographics and results of initial evaluation

We conducted this retrospective analysis on 98 consecutive patients (female/male: 48/50) with a median age of 69.5 (range: 35.8-89.9) years. Two patients of the cohort were known to suffer from PSC. Major clinical symptoms at admission were jaundice (73.5%), weight loss (43.9%) and pruritus (33.7%), whereas pain (22.5%), ascites (11.2%) and fever (9.2%) were present in less than one third of patients. The tumors were described as Bismuth types I

Table 1 Laboratory findings at time of diagnosis

Value (normal range)	Median	Range	
Total bilirubin (0.1-1.2 mg/L)	9.1	0.3	38.3
Alkaline phosphatase (50-175 U/L)	375	26	2572
ALT (GPT) (- 19 U/L)	61.5	8	464
Leucocytes (4.3-10.5 G/L)	11	3.6	95
CRP (- 3 mg/L)	8.4	0.06	207
CA19-9 (0.25-20 U/L)	232.9	0.25	24385
PT (70%-130%)	98.5	36	190

ALT: Alanin-Amino-Transferase; GPT: Glutamat-Pyruvat-Transaminase; CRP: C-reactive protein; CA 19-9: Carbohydrate-Antigen 19-9; PT: Prothrombin time.

(*n* = 12), II (*n* = 7), III (*n* = 30) and IV (*n* = 49), respectively. The laboratory findings at time of diagnosis are given in Table 1. CA19-9 levels did not correlate significantly to either serum bilirubin level (*r* = 0.068; *P* = 0.54) or Bismuth stage (*r* = 0.085; *P* = 0.44). Higher CRP-levels correlated significantly to leukocyte count (*r* = 0.569; *P* < 0.0001), but did not depend on bilirubin levels (*r* = 0.153; *P* = 0.16) and tumor extent according to the Bismuth-Corlette classification (*r* = 0.160; *P* = 0.15).

Modality of treatment

Explorative laparotomy was performed in 43 patients (43.9%), and tumor resection could be performed in 23 (23.5%) patients of the cohort. Surgical therapy consisted of resection of the extrahepatic bile-ducts in 9 (39.1%) patients, partial duodenopancreatectomy with hilar resection in 2 (8.7%) patients, hilar resection with right hemihepatectomy in 5 (21.7%) patients, hilar resection with left hemihepatectomy in 4 (17.4%) patients, hilar resection with atypical liver resection in 2 (8.7%) patients and hepatectomy with consecutive liver transplantation in 1 (4.3%) patient. The resected patients were younger, had a lower Bismuth stage and had lower levels of serum bilirubin at diagnosis than the patients who did not undergo surgery, whereas CRP at diagnosis did not differ significantly between both groups (Table 2).

Patients with non-resectable tumors underwent either transpapillary or percutaneous transhepatic biliary drainage. Sixty-two (82.6%) of these patients received unilateral or bilateral plastic stents as biliary endoprosthesis, whereas in 34 (45.3%) patients, metal stents were placed during the course of the disease. In 30 (40%) patients, a percutaneous drainage had to be placed on at least one occasion during their clinical course.

Fifty-one patients received additional therapy. This therapy consisted of intraluminal photodynamic therapy using porfimer sodium (PhotofrinTM, Axcan, Canada) in 32 patients and systemic chemotherapy in 18 patients.

Survival analysis

At the end of observation, 85 of 98 (86.7%) patients had deceased with a median survival of 8.8 (0.8-55.1) mo. Sixteen patients were alive with a median follow-up of 12.3 (1.4-71.7) mo. The Kaplan-Meier estimated overall median survival was 10.5 (95% CI: 8.4-12.6) mo (Figure 1).

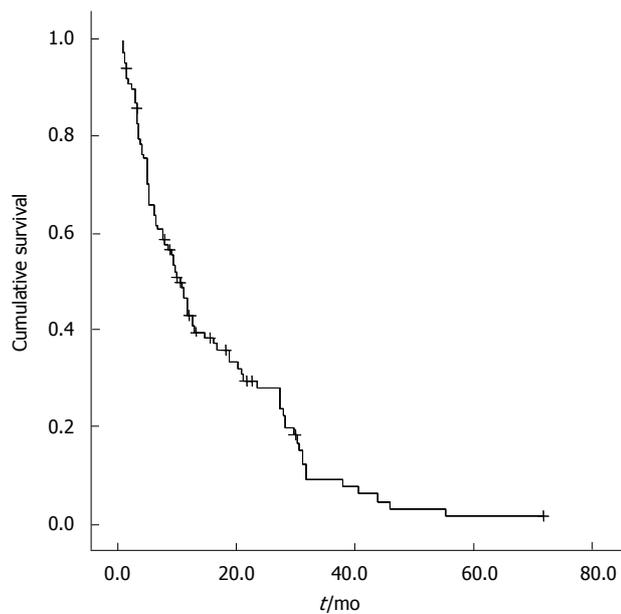

Figure 1 Kaplan-Meier estimate for survival of the whole cohort.

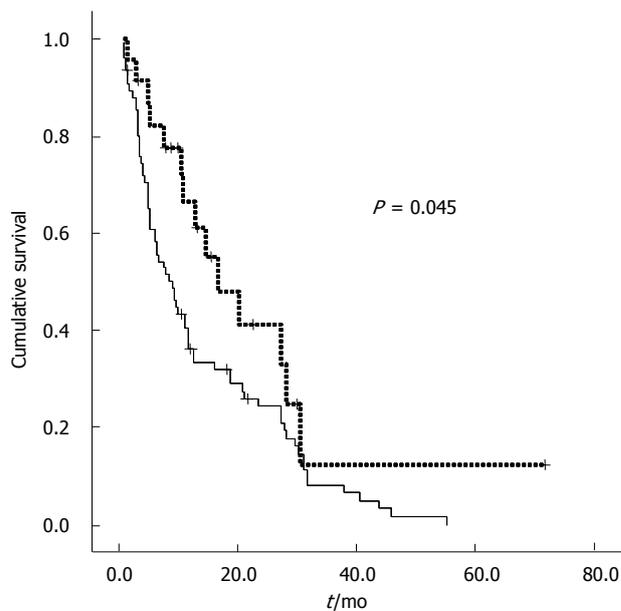

Figure 3 Kaplan-Meier estimate for survival of patients, who underwent resection (dotted line) versus non-resected patients (solid line).

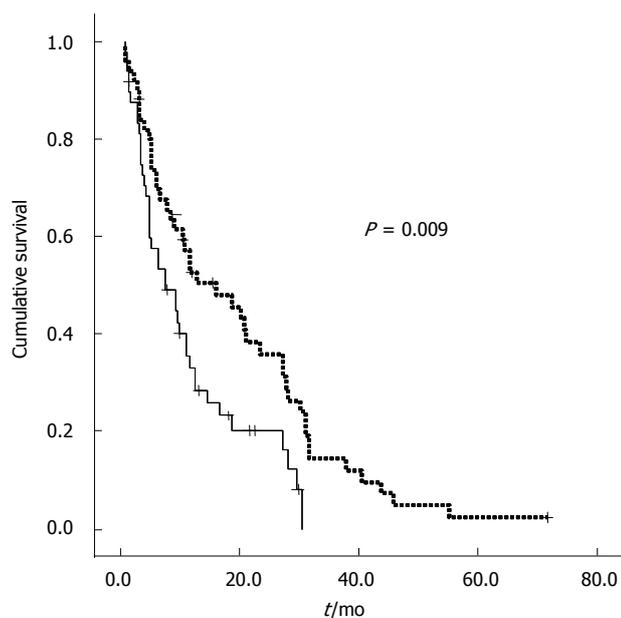

Figure 2 Kaplan-Meier estimate for patients with a serum CRP level < 12 mg/L (dotted line) versus \geq 12 mg/L (solid line).

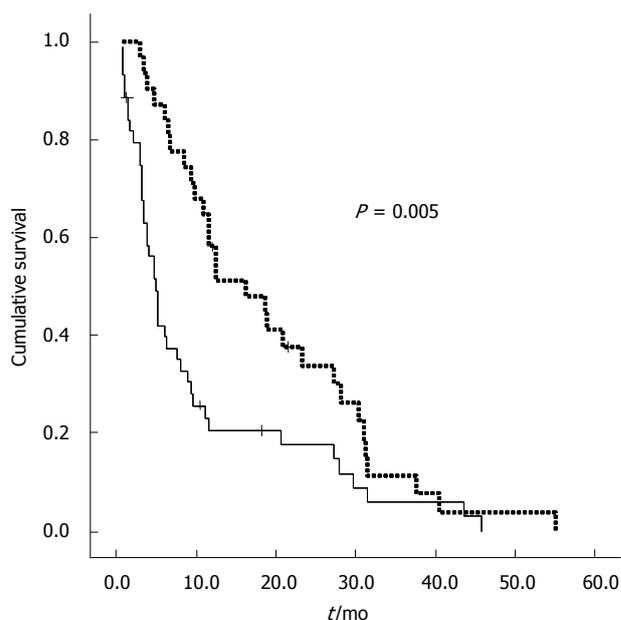

Figure 4 Subgroup analysis of patients without surgical resection: Kaplan-Meier estimate for survival of patients treated with PDT (dotted line) versus non-treated patients (solid line).

Prognostic factors and impact of treatment modality

The parameters examined and the results of the uni- and multivariate analyses are shown in Table 3. In the univariate analysis, low Bismuth stage, low CRP and surgical resection correlated significantly with better survival. In the multivariate analysis, only surgical resection ($P = 0.029$) and CRP ($P = 0.005$) were found to be independently predictive of survival in the cohort. ROC analysis identified a CRP level of 11.75 mg/L as the value associated with the highest sensitivity and specificity to identify patients surviving more than 5 mo.

Patients with a CRP level < 12 mg/L at the time of

diagnosis had a significantly longer median estimated survival than patients with higher CRP values (16.2 *vs* 7.6 mo; $P = 0.009$) (Figure 2). The median survival in the subgroup of patients who underwent resection was significantly longer compared to patients receiving palliative treatment [16.6 (95% CI: 7.7-25.5) *vs* 9.0 (95% CI: 5.6-12.5); $P = 0.045$] (Figure 3). In contrast to the analysis of the whole cohort, in the subgroup of patients with irresectable tumors, PDT was associated with a significant improvement of survival [16.2 (95% CI: 7.0-25.5) *vs* 5.0 (95% CI: 3.8-6.3) mo ($P = 0.005$)] (Figure 4). Systemic chemotherapy was not correlated to a better outcome

Table 2 Inter-group comparison between patients undergoing surgical resection and patients with irresectable tumors

	Resection (n = 23)	No resection (n = 75)	P
Age	65.8 (36.4-74.1)	71.8 (35.8-90)	0.0003
Bismuth	II (I-IV)	IV (I-IV)	0.001
Bilirubin	3.3 (0.3-17.5)	9.6 (0.4-38.3)	0.0026
CRP	15.6 (0.5-101)	9.9 (0.1-207)	0.445
CA19-9	71 (0.3-2910)	322 (0.3-24 385)	0.0098

Data are expressed as median (range).

neither in the multivariate analysis of the whole group nor in the subgroup of non-resected patients [11.6 (95% CI: 0.6-25) with chemotherapy *vs* 8.6 (95% CI: 5.0-12.2) mo without chemotherapy; $P = 0.33$].

DISCUSSION

Our study evaluated outcome and prognostic factors in a large series of unselected patients with perihilar cholangiocarcinoma treated at a tertiary medical center. The prognosis of these patients was poor. The median overall survival in our series was only 10.5 mo. Serum CRP level at diagnosis was identified as a new prognostic indicator for patients with perihilar cholangiocarcinoma. Surgical resection was also associated with prolonged survival. Moreover, in the subgroup of patients with irresectable tumors, additional therapy with PDT apart from biliary drainage, but not chemotherapy, was correlated with a better outcome. Certainly, particularly our data on the impact of treatment modalities on survival are influenced by all the restrictions of a retrospective analysis. There may be biases, such as selection for surgery and less complete follow-up in comparison to a prospective study. Unfortunately, prospective data on the clinical course of non-selected patients with perihilar cholangiocarcinoma are rare. Nevertheless, we were able to analyze a relatively large unselected cohort.

Prognostic factors in patients with cholangiocarcinoma undergoing resection have been extensively evaluated in retrospective series^[11]. In a large series presented by Jarnagin *et al*^[15], negative histologic margins, concomitant partial hepatectomy and a well-differentiated tumor were associated with an improved outcome. Accordingly, residual tumor as well as lymph node involvement were significant prognostic factors in a cohort of long-term-survivors^[14]. Much less is known about the overall outcome of a more heterogeneous non-selected cohort with respect to its possible prognostic factors. Weight loss has previously been reported to be significantly associated with the outcome of patients with malignant strictures of the distal bile duct^[16]. However, this factor could not be confirmed in our cohort of patients with perihilar tumors. Although a retrospective study of 49 cases of resected hilar cholangiocarcinoma identified total bilirubin greater than 10 mg/L to be associated with poorer survival^[17], the bilirubin level was not significantly correlated to the outcome in our study. CRP, on the other hand, was a statistically significant prognostic factor, even in the multivariate analysis. Patients with a CRP <

Table 3 Results of univariate analysis for prognostic factors of survival

PT: Prothrombin time, CRP: C-reactive protein, CA 19-9: Carbohydrate-Antigen 19-9. Significant in the multivariate analysis (^a $P < 0.05$).

12 mg/L at the time of diagnosis had a significantly longer median survival than patients with higher CRP values (16.2 *vs* 7.6 mo; $P = 0.009$). CRP belongs to the family of acute-phase proteins. Its concentration changes in response to injury, infection and neoplasia. It is up-regulated by cytokines, such as interleukin-8 (IL-8), interleukin-6 (IL-6) and tumor necrosis factor α (TNF- α)^[18]. *In vitro* studies have identified IL-6 to be an autocrine growth factor of cholangiocarcinoma (CC) cell lines^[19,20], in which it induces the expression of the anti-apoptotic protein Mcl-1^[21]. Moreover, IL-6 was found to be markedly elevated in the serum of patients with CC and dropped sharply after resection^[22]. Thus, high CRP levels might reflect an increased IL-6 level in patients with advanced cholangiocarcinoma. In this respect, the lack of IL-6 serum level determination displays a limitation of our study. In general, increased CRP levels in malignant disease could also be caused by an inflammatory response to tumor invasion^[23]. Others showed in immunohistochemical studies that neoplastic tissue itself can express CRP^[24]. In cholangiocarcinoma, one might also speculate that elevated CRP serum levels were caused by complicated tumor-induced strictures and subsequent cholangitis. Whereas in our study initial CRP levels correlated to leukocyte count, they were not significantly correlated to tumor size as assessed by the Bismuth-Corlette classification. Interestingly, increased serum CRP levels also correlated with shorter survival in patients with other gastrointestinal malignancies, including pancreatic, esophageal and colorectal cancer^[25-27]. Recently, a CRP level ≤ 1.0 mg/dL was identified as favorable prognostic factor in a group of 65 patients with biliary tract cancers receiving chemotherapy^[28]. However, this cohort consisted of 82% patients with gallbladder carcinoma, an entity with potentially different biological behavior and less frequent occurrence of cholestasis as compared to ours.

CA19-9 has been shown to be useful in the diagnostic evaluation of cholangiocarcinoma^[29,30] and the resectability of intrahepatic and periampullary carcinomas^[31,32]. Those of our patients who underwent resection had significantly lower CA19-9 levels at diagnosis, which might reflect a smaller tumor mass, but yet the marker was not correlated to overall outcome. This is in contrast to patients with

inoperable pancreatic cancer undergoing chemotherapy with gemcitabine, in whom CA 19-9 was prognostic^[33].

The definitive role of chemotherapy and radiotherapy in the treatment of CC has not been fully established, although both options are commonly used^[34]. In our cohort, a small number of patients receiving chemotherapy did not show favorable outcome compared to those without. Also PDT, which had been shown to be a promising palliative approach in several non-randomized and randomized studies on patients with irresectable cholangiocarcinoma, failed to be associated with favorable outcome in the overall analysis. However, it demonstrated a significant influence on survival in the subgroup of non-resected patients. Survival in these patients is comparable to previously published results from prospective trials^[35-37].

In accordance with the literature, somewhat one fourth of our patients (24.8%) underwent surgical resection. In the univariate and the multivariate analyses, resection was significantly associated with a better outcome. Patients undergoing resection of their tumor were significantly younger, although age itself was not an independent prognostic parameter. Conclusions of the influence of tumor resection on the outcome of patients with perihilar CC in comparison to conservative treatment are clearly limited by the retrospective character of this analysis, which implements possible bias by patient selection.

In summary, our study evaluated the outcome of a heterogeneous non-selected cohort of patients with cholangiocarcinoma. In agreement with previous studies, surgical resection was identified as a prognostic factor for prolonged survival. In addition, the serum level of CRP at diagnosis was identified as a novel and independent prognostic indicator in patients suffering from perihilar cholangiocarcinoma and should, therefore, be considered as a prognostic parameter in the design of future prospective studies on this kind of patients.

Abstract

AIM: To evaluate the dosimetry, efficacy and toxicity of intensity-modulated radiation therapy (IMRT) and concurrent chemotherapy for patients with locally advanced cervical and upper thoracic esophageal cancer.

METHODS: A retrospective study was performed on 7 patients who were definitively treated with IMRT and concurrent chemotherapy. Patients who did not receive IMRT radiation and concurrent chemotherapy were not included in this analysis. IMRT plans were evaluated to assess the tumor coverage and normal tissue avoidance. Treatment response was evaluated and toxicities were assessed.

RESULTS: Five- to nine-beam IMRT were used to deliver a total dose of 59.4-66 Gy (median: 64.8 Gy) to the primary tumor with 6-MV photons. The minimum dose received by the planning tumor volume (PTV) of the gross tumor volume boost was 91.2%-98.2% of the prescription dose (standard deviation [SD]: 3.7%-5.7%). The minimum dose received by the PTV of the clinical tumor volume was 93.8%-104.8% (SD: 4.3%-11.1%) of the prescribed dose. With a median follow-up of 15 mo (range: 3-21 mo), all 6 evaluable patients achieved complete response. Of them, 2 developed local

recurrences and 2 had distant metastases, 3 survived with no evidence of disease. After treatment, 2 patients developed esophageal stricture requiring frequent dilation and 1 patient developed tracheal-esophageal fistula.

CONCLUSION: Concurrent IMRT and chemotherapy resulted in an excellent early response in patients with locally advanced cervical and upper thoracic esophageal cancer. However, local and distant recurrence and toxicity remain to be a problem. Innovative approaches are needed to improve the outcome.

INTRODUCTION

Cervical esophageal cancer occurs rarely and accounts for only 2%-10% of all esophageal carcinomas in the United States^[1]. Surgery, an option only for patients with early-stage tumors, generally requires a total laryngopharyngoesophagectomy with reconstruction, an operation often leads to considerable dysfunction. The 5-year overall survival rate was only 16%-28% in two studies of patients treated with curative surgery^[2,3]. Unfortunately, surgical resection is not an appropriate treatment for those with locally advanced tumors, because it is difficult to achieve a clear margin. Radiotherapy alone, which does preserve laryngeal function, produces poor results, as evidenced by two studies of patients treated with definitive radiotherapy alone, showing the 5-year overall survival rate of only 14%-25%^[4,5].

Concurrent chemoradiotherapy is now standard treatment for locally advanced esophageal cancer, based on the results of an intergroup randomized controlled trial

(RTOG 8501)^[6]. Four studies examined the results from RTOG trial among small cohorts of cervical esophageal cancer patients who were treated with concurrent chemoradiotherapy^[7-10]. The 5-year survival rate was 55% in one^[9], and the 10-year survival rate was 27% in another^[8].

As to radiotherapy, treatment planning for cervical esophageal cancer is challenging partly because of the anatomical structures involved. The cervical esophagus lies in a close proximity to the spinal cord, courses through the lower neck and upper thorax with drastic change of contour and diameter of the anatomy; and the lymph nodes at risk must be incorporated into the irregular treatment volume.

Evidence suggested that, in these patients, high-dose radiotherapy results in better local control and survival compared with low-dose radiotherapy^[11]. However, high doses of radiotherapy may be associated with potentially high risk of complication because of the adjacent critical structure involved in the high radiation region, such as spinal cord.

Intensity-modulated radiation therapy (IMRT) is a novel approach to the planning and delivery of radiation therapy. Numerous investigators have demonstrated the benefits of IMRT planning in a variety of tumor sites in terms of the feasibility of normal tissue sparing^[12-14] and the delivery of higher radiation doses than conventional doses^[15,16]. Another advantage of IMRT is its ability to deliver differentiated dose to various structure during same fraction dose irradiation, thus allows to deliver a higher dose to gross tumor and lower dose to subclinical disease during same session of beam deliver, as commonly described as "simultaneous integrated boost (SIB)".

In two recent studies of esophageal cancer, IMRT plans were found to be superior to three-dimensional conformal radiation therapy (3D-CRT) plans in terms of dose conformity, homogeneity, and sparing of critical normal structure, such as the spinal cord and lung^[17,18]. An another study demonstrated that IMRT plans produced better dosimetric results than 3D-CRT in patients with cervical esophageal cancer^[19]. However, there is no clinical treatment result reported on patients with cervical esophageal cancer who were treated with IMRT.

At the University of Texas MD Anderson Cancer Center, we have used IMRT concurrently with chemotherapy for all patients with cervical esophageal cancer and for some with upper thoracic esophageal cancer since August 2002. We performed a retrospective study to evaluate the dosimetric considerations, early response and toxicity of this group of patients.

MATERIALS AND METHODS

Patient population

In this retrospective study, conducted from August 1, 2002 through December 31, 2004, 7 patients were selected according to the following inclusion criteria: newly diagnosed locally advanced cervical and upper thoracic esophageal cancer, definitive concurrent IMRT with chemotherapy treatment at the University of Texas MD Anderson Cancer Center, recoverable treatment plan

available. Patients were excluded if they had a distant metastasis or had esophagectomy or previously had radiotherapy in the neck or thoracic region. This study was approved by our Institutional Review Board, and informed consent for radiation therapy from all patients was taken. HIPPA compliance was enforced.

Pretreatment evaluation

For their pretreatment evaluation, all patients underwent computed tomography (CT) of the neck, chest, and abdomen, positron emission tomography (PET)-CT, and endoscopy and biopsy of the esophagus. Five patients underwent endoscopic sonography of the esophagus; the other 2 patients did not undergo endoscopic ultrasound examination due to severe obstruction of the esophagus by tumor; instead, they underwent bronchoscopy and PET-CT, which confirmed that they had T4N0 and T4N1 disease. In total, 6 of the 7 patients underwent bronchoscopy. The 1997 American Joint Committee on Cancer guidelines for the staging of cancer were used to classify tumor stage. Tumor stage was determined by endoscopic sonography and bronchoscopy findings, nodal stage was determined by endoscopic sonography or PET-CT, and metastasis stage was determined by PET-CT.

Chemotherapy

The induction chemotherapy consisted of two cycles of weekly carboplatin and paclitaxel ($n = 1$), given before chemoradiation. The concurrent chemotherapy consisted of continuous infusion of 5-fluorouracil (5-FU) (1000 mg/m²) on d 1 to 4 and 29 to 32 and cisplatin (75 mg/m²) on d 1 and 29 ($n = 2$), continuous infusion of 5-FU (700 mg/m²) on d 1 to 5 and 29 to 33 and cisplatin (75 mg/m²) on d 1 and 29 ($n = 1$), continuous infusion of 5-FU (300 mg/m²) on Monday to Friday for 5 wk and paclitaxel (45-50 mg/m²) weekly ($n = 2$), carboplatin area under the curve (AUC) 2 twice weekly and paclitaxel (30 mg/m²) weekly for 5 wk ($n = 1$), or carboplatin AUC 1 once weekly and docetaxel (20 mg/m²) weekly and continuous infusion of 5-FU (200 mg/m²) on Monday to Friday for 5 wk ($n = 1$).

Radiotherapy

All patients underwent CT simulation in a supine position with their arms by their sides; the CT images were taken at a 3-mm thickness throughout the entire neck and thorax. Four of the patients were immobilized with a head and neck/upper thoracic thermoplastic mask, and three with a vacuum-locked cradle. The gross tumor volume (GTV), clinical target volume (CTV), planning target volume (PTV), spinal cord, and lung parenchyma were outlined on each image. The GTV was defined as any visible tumor on the image. The CTV was defined as the GTV plus a 2- to 5-cm margin superior to the highest extension of the tumor and a 4- to 5-cm margin inferior to the lowest extension of the tumor with a 2-cm radial margin. Uninvolved bony structure and lung tissue were kept outside the CTV. The PTV was defined as the CTV plus a 5-mm margin. For patients in whom the SIB was used, the GTV boost was defined as the initial GTV plus a 1.5-cm surrounding margin. A 5-mm margin around normal structures, such as

the spinal cord and lung, was also added for the planning organ-at-risk volume (PRV).

The inverse IMRT plans for 4 of the 7 patients were created using Corvus software (v4.0) (Corvus, Nomos Inc., Sewickley, PA) and for the other 3 using Pinnacle (v6.2) software (Philips Radiation Oncology Systems, Andover, MA). All treatment plans used heterogeneity correction and were delivered with 6-MV photons. The mean dose, dose range, and standard deviation (SD) of the PTV (for GTV boost and CTV) were calculated. The minimum dose to the PTV was defined as the dose to the coldest 1% of target volume, and the maximum dose was defined as the dose to the hottest 1% of target volume. The SD percentage of the PTV was the SD dose to the PTV divided by the prescription dose to the PTV. The maximum dose to the spinal cord was defined as that received by 1 cm³ of the volume. The mean dose and the lung V₂₀ (volume of lung receiving ≥ 20 Gy) for the total lung were calculated. The lung V₂₀ < 40% and the maximum spinal cord dose of 45 Gy were considered to be acceptable for the IMRT plan. The pretreatment dosimetric quality assurance procedure and a test run were performed before the start of radiotherapy. Radiotherapy was delivered in a step-and-shoot mode with multi-leaf collimators. Portal films were obtained weekly to ensure the correct set-up.

Toxicity assessment

Acute toxicity levels were assessed weekly with complete blood cell counts and examinations for esophagitis and skin reactions during the concurrent chemoradiotherapy. Esophageal toxicity was defined as late if it occurred more than 90 d after radiotherapy. Radiation pneumonitis was defined as acute if it occurred within 6 mo after radiotherapy. All toxic effects were assessed using RTOG criteria^[20].

Follow-up evaluation

The following evaluations were performed 1 mo after treatment, every 3 mo for the first 2 years, and every 6 mo thereafter: physical examination, complete blood cell count, blood chemistry tests, an endoscopic examination, an esophageal biopsy, and scans of the neck, chest, and abdomen by CT, PET-CT, or both. Endoscopic sonography of the esophagus was performed in two of the patients to evaluate lymph node response.

Response assessment

A complete response (CR) of the primary tumor was defined as: (1) endoscopic examination was negative for all visible tumors and biopsy was negative for tumor cells lasted for ≥ 4 wk, and (2) no evidence of abnormal hypermetabolism on PET-CT scan. The response of the metastatic lymph nodes was assessed by CT, PET-CT, or endoscopic sonography of the esophagus. A CR was defined as the complete disappearance of all measurable and assessable disease for ≥ 4 wk.

Statistical analysis

The survival was calculated from the date of diagnosis.

RESULTS

Patients' characteristics

The median time of follow-up was 15 mo (range: 3-21 mo). Of the 7 patients included in this study, 6 were men. The Karnofsky performance status scores ranged from 70 to 90, and their ages ranged from 52 to 78 years. Six patients had cervical esophageal squamous cell carcinoma, and 1 patient had upper thoracic esophageal adenocarcinoma. At the time of presentation, 2 patients tolerated solid foods, 2 tolerated soft foods, and 3 tolerated only liquid diet. Three patients had lost more than 10% of their weight in the 3 mo before treatment.

Patients had locally advanced disease as follows: 3 patients had biopsy-proven tracheal invasion by tumor through bronchoscopy examination, rendered them as T₄ stage; one of them had 60% tracheal obstruction with a tracheal-esophageal (TE) fistula and had a tracheal stent placement before chemoradiation treatment; 3 patients had T₃ and 1 had T₂N₁ stage tumors. According to the endoscopic and PET-CT findings, the tumor length ranged from 3 to 8 cm. In 6 patients, a percutaneous gastrostomy or jejunostomy feeding tube was placed prior to the start of radiotherapy because of severe dysphagia, poor nutritional status, or a high risk of aspiration. The characteristics of the patients, tumor, and treatment are summarized in Table 1.

Dosimetric considerations

The primary tumor was irradiated with a total dose of 59.4-66 Gy given in 1.8-2.31 Gy/fraction. Three patients with cervical esophageal cancer also received prophylactic irradiation to the bilateral supraclavicular regions to a total dose of 46-60 Gy at 1.36-1.8 Gy/fraction. One patient with cervical esophageal cancer received bilateral supraclavicular and neck irradiation to a total dose of 56 Gy at 1.7 Gy/fraction because of small lymph node metastasis in the bilateral lower neck diagnosed by PET-CT. Three patients with cervical esophageal cancer also received irradiation to the superior mediastinum to a total dose of 56-66 Gy at 1.7-2.0 Gy/fraction. The SIB technique was used in 5 of the 6 patients with cervical esophageal cancer. In the other 2 patients, the GTV and CTV received the same fraction dose and total dose, since lymph node region was not prophylactically treated. Table 1 also shows the radiation treatment characteristics. Five, seven, eight, or nine coplanar beams with different gantry angles were used in the 7 patients. The total number of beam segments and monitor units (MU) was 218-559 and 21 252-40 812 for Corvus plans, and 198-417 and 27 423-42 504 for Pinnacle plans, respectively (Table 2). The daily treatment time was about 10-20 min.

Table 3 summarizes the dosimetric parameters of IMRT plans for the 7 patients. The median GTV was 78 cm³ (range: 17-229 cm³). The median GTV dose was 64.8 Gy (range: 59.4-66 Gy), and the median CTV dose was 56 Gy (range: 50.4-66 Gy). The minimum dose received by the PTV of boost GTV ranged from 91.2 to 98.2% (SD: 3.7%-5.7%) of the prescribed dose. The minimum dose received by the PTV of CTV ranged from 93.8% to 104.8% (SD: 4.3%-11.1%) of the prescribed dose. The V₂₀

Table 1 Patient and treatment characteristics for the 7 patients with cervical and upper thoracic esophageal cancer

Patient No.	Tumor distance from UES (cm)	Stage	Induction chemotherapy	Concurrent chemotherapy	XRT dose (GTV)	XRT dose (CTV)	XRT dose (supraclavical regions)

to the bilateral lung was 10.3%-36.0% in all patients, and the lung mean dose was 6.6-17.6 Gy (median: 12.6 Gy). The maximum dose to the spinal cord ranged from 37.2 to 45.8 Gy. The dose distribution and dose volume histogram (DVH) for patient number 7 are shown in Figures 1 and 2 using pinnacle planning system.

Tumor response and failure

One patient with cervical esophageal cancer, whose general condition gradually deteriorated, experienced excessive mucus production, weight loss and fever, and decided to begin home hospice care after 2 wk of radiotherapy, died of disease 4 mo after diagnosis. Thus, this patient’s response was not evaluable and was not included in this analysis.

The other 6 patients all achieved a CR in the primary tumor and lymph node areas after concurrent chemoradiotherapy. The response was assessed by endoscopic biopsy for all patients, 4 of them also had PET-CT. Two patients had no evidence of disease (NED) at 13 and 17 mo. Two patients developed local recurrence in the esophagus 4 and 6 mo after treatment, one of them was successfully treated with salvage photodynamic therapy and had NED at 21 mo and the other died of disease at 15 mo. One patient had lung metastasis 7 mo after treatment and was alive with disease at 17 mo. One patient had both lymph nodes recurrence in the neck and soft tissue metastasis in the left thigh 11 mo after treatment and died of disease. Table 4 shows the tumor response and failure.

Toxicity

Acute major toxic effects included myelosuppression, dermatitis, and esophagitis. Myelosuppression occurred in 2 patients: 1 had grade 3 and another had grade 4 leukopenia. Three of the patients who had been immobilized with a thermoplastic mask experienced grade 3 skin reactions in the neck, and 1 of these required a 3-d treatment interruption. The patient who had a T4 tumor with a tracheoesophageal (TE) fistula and tracheal stent placement before chemoradiation developed grade 4 esophagitis 1 mo after treatment and had an esophageal stent placed 4 mo after treatment. Another patient experienced grade 4 late esophageal toxicity (TE

fistula) 7 mo after radiotherapy and had an esophageal stent placed. Two patients experienced grade 3 late esophageal toxicity (benign esophageal strictures requiring esophageal dilatation one to four times) 4 mo and 10 mo after radiotherapy. No patient had symptomatic radiation pneumonitis, although 2 patients had radiographic changes in their irradiated lung. No patients lost more than 10% of their weight during chemoradiotherapy. No patient experienced radiation myelitis. All except 1 patient completed radiotherapy without interruption in 37-44 d. Radiotherapy was interrupted for three day in 1 patient due to grade 3 skin toxicity and radiation was completed in 50 d. Table 4 summarizes the toxicity of chemoradiotherapy.

DISCUSSION

No consensus has been reached as to the optimal radiation technique and target volume delineation for treating cervical esophageal cancer, and a survey conducted in Canada has come up with different opinions from radiation oncologists^[21,22]. IMRT has potential benefit for treating cervical esophageal cancer because of the complexity of anatomy in this region. Separate IMRT plans designed for the initial large-field treatment and the subsequent boost

treatment are referred as two-phase IMRT strategies. On the other hand, the term “simultaneous integrated boost” (SIB) is used to define treatment plan that delivers differentiated doses to different targets during a single fraction dose delivery as follows: one IMRT plan simultaneously delivers different dose levels to different

targets in a single treatment session, which results in the primary target (e.g., palpable or visible disease or GTV) and the secondary target (e.g., regions at risk for microscopic disease or CTV) being treated to different dose levels in each and same treatment fraction. Using this approach, the fractional dose delivered to gross tumor

can be increased, while, at the same time, the radiation doses and dose schedules known to be adequate for tumor control in marginal tissues and clinically uninvolved lymph nodes are preserved. Thus, the SIB-IMRT has been considered a novel method for accelerated fractionation therapy in controlling gross disease through dose-per-fraction escalation. It can shorten overall treatment time, which is preferable for treating tumors with rapid repopulation. It has the ability to deliver large IMRT fields, often required for simultaneous treatments of all target volumes, by splitting them and dynamically feathering their junctions for greater accuracy^[23]. Therefore, it is an easy, efficient, and less error-prone method of planning and delivery, because it allows the same plan to be used for the entire course of treatment.

Since the large-field and boost doses are delivered in the same number of fractions, one must consider the radiobiological consequences of different fraction sizes for the gross disease, regions of microscopic spread, and electively treated lymph nodes. One can select the conventional 2 Gy per fraction for the gross disease for an SIB strategy, but that might lead to a significantly lower dose per fraction to volumes of microscopic disease and electively treated lymph nodes. On the other hand, one can choose to deliver 2 Gy per fraction to the lower and intermediate dose volumes, but this would require a high dose per fraction, as much as 2.5 Gy or more per fraction, to the gross disease. The latter scheme may have the advantage of shortening the treatment duration and a potential for improvement in local control but at an increased risk of injury to the embedded normal tissues.

In our study, the IMRT plans showed good homogeneity and conformity and the treatment time was acceptable. SIB-IMRT was used in 5 of 7 patients, which made the treatment course simple. Several researchers reported that SIB-IMRT is superior to two-phase IMRT (sequential IMRT) in terms of conformity of dose distribution within the target volume and the sparing normal tissue for head and neck cancer^[24, 25], lung^[25, 26] and prostate cancers^[25]. The SIB-IMRT also has some advantage over 3-dimensional conformal radiotherapy regarding homogeneity of tumor dose and reduction of the dose to normal tissue for cervical esophageal cancer^[19] and malignant glioma^[27, 28].

Defining target volume delineation for IMRT plan, especially a consistent CTV delineation, is challenging because current imaging techniques are not capable of directly detecting subclinical tumor involvement and also because the patterns of failure is not clear. It is difficult to differentiate if the local tumor recurrence is due to a geographic miss or persistent disease. The tendency for esophageal cancer to be multicentric or to present with submucosal skip metastasis supports the use of generous proximal and distal margins for treatment. In the RTOG 8501 trial^[6], the entire esophagus was included in the radiation portals, but the toxic effects were severe. In the subsequent RTOG 9405 study^[29], 5-cm proximal and distal margins and a 2-cm radial margin were added around the GTV which is effective and has been accepted as a standard in most institutions in the United States.

We used slightly smaller proximal than distal margins in our study, because of our concern about increased

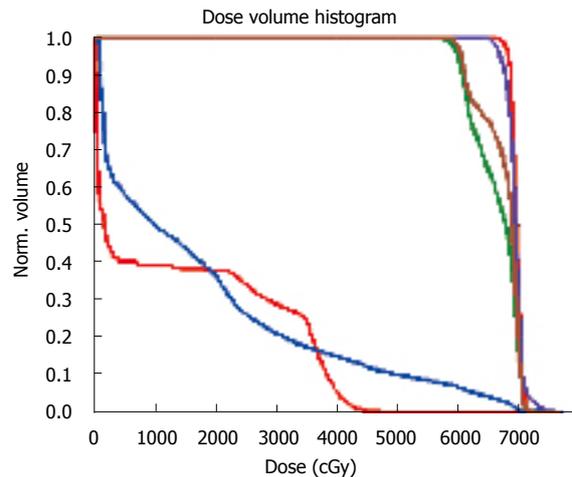

Figure 2 Dose volume histogram (DVH) of the IMRT for patient number 7, showing DVH curves for GTV, boost PTV, CTV, PTV, total lung and spinal cord (from right to left). Norm. Volume = Normalized volume.

toxic effects on the pharynx. Prophylactic irradiation of the supraclavicular and superior mediastinal nodes could decrease the risk of nodal relapse without greatly increasing the toxic effects. In the RTOG 94-05 study^[29], boost GTV was defined as a 2-cm margin around the initial GTV; we used the same boost GTV expansion in our study (1.5-cm margin from GTV to boost GTV and another 5 mm added for PTV).

This is the first study that we are aware of that reported the clinical result for esophageal cancer patients treated with IMRT. In this study, all 6 evaluable patients achieved complete response both in the primary tumor and lymph node sites. Although the early response result was very encouraging for this small group of locally advanced tumors, 2 patients developed local recurrences and another 2 had distant metastases. Only 3 patients survived with no evidence of disease during a median time of 13 mo follow-up. Although some clinical data on cervical and upper thoracic esophageal cancer patients who were treated with concurrent chemotherapy and radiotherapy with conventional or 3-dimensional conformal techniques have been published, the data are sparse because the disease is rare and the published series have consisted of relatively few patients. For example, Ampil *et al*^[7] reported that only 2 of their 6 patients achieved CR when conventional radiation techniques were used to deliver a total dose ranging from 36 to 64 Gy at 2.0 Gy/fraction. Burmeister *et al*^[9] reported that 31 of their 34 patients had CR after a total dose delivered by 3-dimensional conformal radiation that ranged from 50.4 Gy in 20 fractions to 65 Gy in 33 fractions. The 5-year survival rate in this group was 55%. However, only 3 patients in this group had locally advanced disease; most had early disease. Moreover, Bidoli *et al*^[8] reported that 37 of their 58 patients (29 of whom had cervical esophageal cancer) experienced a CR after having been given 50 Gy in 25 fractions with conventional radiation techniques. The 10-year survival rate was 27% for the 29 patients with cervical esophageal cancer. We await the maturity of our study to report the long-term outcome.

Three patients experienced severe skin toxicity, probably caused by the use of the mask and the lack of effort to avoid irradiating the skin during IMRT planning. In a study by Burmeister *et al*^[9] with 3-dimensional conformal radiotherapy, a moderate-to-severe skin reaction occurred in most patients on the neck. IMRT technique has the potential to reduce skin toxicity if skin was defined as an avoidance structure. From our experience, to reduce toxic effects to the skin, we need to use a cradle instead of a mask to immobilize patient, also consider skin as an avoidance structure during IMRT planning.

The development of acute esophagitis during and after radiotherapy is usually unavoidable. Fortunately, no patient lost more than 10% of body weight or had to have treatment interrupted because of esophagitis, probably because of the intensive supportive and nutritional therapy received through a gastrostomy or jejunostomy tube. Therefore, the prophylactic use of such tubes is recommended for patients who have severe dysphagia or poor nutritional status prior to the initiation of chemoradiation.

Development of late esophageal toxic effects is a concern for esophageal cancer survivors. An esophageal stricture caused by fibrosis of the esophagus, usually at the site of tumor, was mainly due to the high total radiation dose delivered^[30]. In this study, 3 of 4 surviving patients had esophageal stricture or fistula. Burmeister *et al*^[9] demonstrated that in 34 patients treated with 3-dimensional conformal radiotherapy, strictures were the most notable late effect of the therapy: 11 patients developed mild strictures that did not require dilation, 4 patients developed strictures requiring repeated dilation, and 1 patient developed a severe stricture that did not respond to dilation. In the patient with a severe stricture, the attempted corrective surgery failed and resulted in death of the patient. In addition, the local tumor recurrence remains to be a concern even though relatively high radiation dose was used for this group of patients. The degree of dose escalation by IMRT was limited by long-term toxicity, such as esophageal strictures and fistula. For patients who had their local diseases well-controlled, development of distant metastases became a major pattern of failure.

Therefore, new approaches besides IMRT are needed. One possible way is to use induction chemotherapy. Theoretically, induction chemotherapy could treat the occult micrometastatic disease upfront and may lead to a decrease in the incidence of distant metastases; in addition, induction chemotherapy could be effective in shrinking the primary tumor so that only moderate radiation dose is required to control the local disease, while reducing the late esophageal toxicity. Stuschke *et al*^[10] reported their results of induction chemotherapy plus concurrent chemoradiotherapy (a total dose of 60 to 65 Gy in 6 wk delivered by 3D-CRT) for 22 patients with upper and midthoracic locally advanced squamous cell carcinomas. Locoregional recurrences as one site of first relapse were observed in 12 patients and distant metastases as one site of first relapse occurred in 4 patients. Seven long-term survivors had a good swallowing function. Induction chemotherapy results in a major response rate of 45%

and response to induction chemotherapy is strongly associated with long-term survival and locoregional tumor control. No long-term survivors are found among non-responders to induction chemotherapy. The criterion good response to induction chemotherapy can be used to select patients for high-dose radiotherapy. Another way is molecular targeting agents. Epidermal growth factor inhibitor (EGFR), such as cetuximab, in combination with radiotherapy yielded positive results in treating head and neck squamous cell carcinoma^[31]. It is perhaps worthwhile to test EGFR in treatment of cervical and upper thoracic esophageal cancer, because squamous cell carcinoma is the major histology.

In conclusion, concurrent IMRT and chemotherapy resulted in an encouraging tumor response in patients with locally advanced cervical and upper thoracic esophageal cancer. However, local and distant recurrence, and late toxicity remain to be a challenge in the management of this disease. Additional innovative treatment modalities are needed to improve the outcome. All patients with cervical and upper esophageal tumor should be registered and treated in a prospective study with consistent chemotherapy and IMRT dose schedule, and possibly target therapy.

Abstract

AIM: To investigate the prevalence of *H pylori* associated corpus-predominant gastritis (CPG) or pangastritis, severe atrophy, and intestinal metaplasia (IM) in patients without any significant abnormal findings during upper-GI endoscopy.

METHODS: Gastric biopsies from 3548 patients were obtained during upper GI-endoscopy in a 4-year period. Two biopsies from antrum and corpus were histologically assessed according to the updated Sydney-System. Eight hundred and forty-five patients (mean age 54.8 ± 2.8 years) with *H pylori* infection and no peptic ulcer or abnormal gross findings in the stomach were identified and analyzed according to gastritis phenotypes using different scoring systems.

RESULTS: The prevalence of severe *H pylori* associated changes like pangastritis, CPG, IM, and severe atrophy increased with age, reaching a level of 20% in patients of the age group over 45 years. No differences in frequencies between genders were observed. The prevalence of IM had the highest increase, being 4-fold higher at the age of 65 years versus in individuals less than 45 years.

CONCLUSION: The prevalence of gastritis featuring at risk for cancer development increases with age. These findings reinforce the necessity for the histological assessment, even in subjects with normal endoscopic appearance. The age-dependent increase in prevalence of severe histopathological changes in gastric mucosa, however, does not allow estimating the individual risk for

INTRODUCTION

H pylori infection is an established risk factor for development of gastric cancer^[1,2]. According to the model of carcinogenesis of the intestinal type adenocarcinoma proposed by Correa, the multi-step development starts from the condition of a chronic active gastritis, followed by glandular atrophy, intestinal metaplasia, dysplasia, and finally gastric adenocarcinoma^[3]. The risk for gastric cancer also increases in the presence of corpus-predominant gastritis as well as a pangastritis^[4]. Since only a small subset of *H pylori* infected subjects will develop gastric cancer, from a clinical point of view it is a major difficulty to identify those patients with *H pylori* infection who are at a higher risk to develop gastric cancer. Therefore there is a need to identify patients, who have these advanced changes in gastric mucosa. The combination of these risk factors (gastric cancer risk index) has been proven to be a simple way to better estimate the risk for gastric cancer development^[5,6]. The gastric cancer risk index has been proven to be independently increased in both histological types of gastric cancer: the intestinal as well as the diffuse type.

The aim of the present study was to estimate the prevalence of advanced histopathological changes in gastric mucosa in patients with normal appearance of gastric mucosa during upper GI-endoscopy.

MATERIALS AND METHODS

A total of 3548 first time upper GI-endoscopies were

Table 1 Age and sex distribution of *H pylori* positive patients without gross pathology of gastric mucosa during upper GI-endoscopy

Endoscopic normal gastric mucosa with <i>H pylori</i> infection	
Number (n)	845
Mean age (yr)	54.8 (18-87)
Sex	
Male	450/845 (53.2%)

55-64	199/845 (23.6%)
65-74	166/845 (19.6%)
> 75	95/845 (11.2%)

performed in the Endoscopic Unit of the University of Magdeburg over a 4-year period. During this period, it was the policy in our department to obtain gastric specimens from all patients regardless of the appearance of the mucosa to establish the pattern of gastritis in those patients. Patients with contraindication to obtain gastric specimens or previous endoscopy with histological investigation were not included.

Around one half of the investigated patients were outpatients, and the other half hospitalized patients. After the investigation, an endoscopic report was entered in a computer-based database. Upper GI-endoscopy was performed by several experienced gastroenterologists. Two gastric specimens from the corpus and antrum, respectively, were taken and analysed histologically according to the Sydney-System in all patients. Histological results were documented in the same computer-based database. Histological examination was performed by different pathologists from the Institute of Pathology at the University of Magdeburg. All slides have been re-evaluated for the needs of this study by a single experienced gastrointestinal pathologist in a blinded way without being aware of clinical or endoscopic diagnoses and prior histological reports. The study was performed according to the guidelines of the Ethics Committee of the Medical Faculty of the University of Magdeburg and all patient data were made anonymous to protect patients' identity.

The database was retrospectively analyzed for those patients who had a normal endoscopic appearance of gastric mucosa or simply signs of gastritis or duodenitis. Thus all patients with gastric or duodenal ulcers, GI-bleeding, and upper GI-malignancy were excluded. The presence of reflux oesophagitis or hiatal hernia was not an exclusion criterion. Furthermore, patients known to be treated with proton-pump inhibitors or with indirect evidence for this treatment by histological observation of parietal cell hypertrophy were excluded. *H pylori* infection was determined by positive culture, rapid urease test and/or histology.

We identified 845 *H pylori* positive patients who fulfilled the predefined criteria. Age distribution and gender are

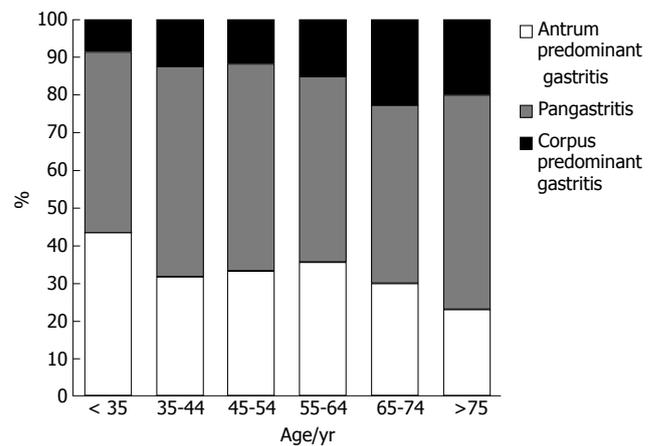

Figure 1 Prevalence of different phenotypes of gastritis in patients with *H pylori* infection in different age groups. With increasing age the number of patients with corpus-predominant gastritis increased significantly, whereas the antrum predominant gastritis decreased (Kruskal Wallis test; $P < 0.01$).

given in Table 1. In these patients the following parameters were calculated according to the histological examination: (1) Corpus-predominant gastritis^[4]: Higher degree of neutrophilic infiltration in the corpus compared to the antrum; (2) Pangastritis^[4]: Equal degree of neutrophilic infiltration in the corpus and in the antrum; (3) Antrum-predominant gastritis^[4]: Higher degree of neutrophilic infiltration in the antrum compared to the corpus; (4) Intestinal metaplasia^[4,7]: Absence or presence in any investigated specimen from antrum or corpus; (5) Severe atrophy^[4,8]: Severe loss of glands; not diagnosed in the antrum when only a few intestinal crypts were observed in the whole specimen; (6) Antrum and corpus gastritis score: Score by total sum of grade of gastritis (mild = 1, moderate = 2, marked = 3 infiltration with lymphocytes and plasma cells) and activity of gastritis (mild = 1, moderate = 2, marked = 3 infiltration with neutrophilic granulocytes) either in the antrum or in the corpus, a maximum of a sum of 6 points in the antrum and in the corpus for each individual person; (7) Gastric cancer risk index^[5,6]: 1 point scored for at least moderate infiltration with lymphocytes and plasma cells in the corpus and less or equal infiltration in the antrum, 1 point scored for at least moderate infiltration with neutrophilic granulocytes in the corpus and less or equal infiltration in the antrum, 1 point scored for the detection of intestinal metaplasia in the antrum or in the corpus, a maximum of 3 points for each individual person.

RESULTS

The frequency of corpus-predominant gastritis was significantly increased with age (Kruskal-Wallis test, $P < 0.01$). While in the group of patients of less than 35 years old only 8.8% had a corpus-predominant gastritis, and the number increased to 22.9% between the ages of 65-75 years (Figure 1). The highest increase was observed between the age groups of 45-54 years (13.8%) and 55-64 years (23.1%). The number of patients with pangastritis remained constant, whereas the frequency of antrum-predominant gastritis declined over time.

Table 2 Frequency of intestinal metaplasia (IM) in the gastric antrum and the corpus in patients without macroscopic pathology during upper GI-endoscopy

Age (yr)	Overall IM	IM only in the antrum	IM only in the corpus	IM in antrum and corpus

55-64	4/199 (2.0%)	3.38 ± 0.94	2.93 ± 1.17
64-75	9/166 (5.4%)	3.20 ± 0.92	2.98 ± 1.08
> 75	9/95 (11.2%)	3.08 ± 0.96	3.06 ± 1.15
Differences between age groups	$P < 0.001$ (χ^2 -test)	NS (ANOVA)	$P < 0.001$ (ANOVA)

The frequencies of intestinal metaplasia in different age groups increased significantly in an almost linear pattern ($r^2 = 0.9585$, $P < 0.001$). The increase rate was 0.71% per year (95% CI 0.51-0.92). Nearly 40% of patients over 65 years had intestinal metaplasia (Table 2). For example, the relative risk for a patient at the age of 64-75 years was 5.0 (95% CI 2.6-9.6) times higher compared to a patient younger than 35 years. Intestinal metaplasia was more frequent in the corpus compared to the antrum (20.7% *vs* 6.7%), and those located only in the antrum were a rare event (3.4%).

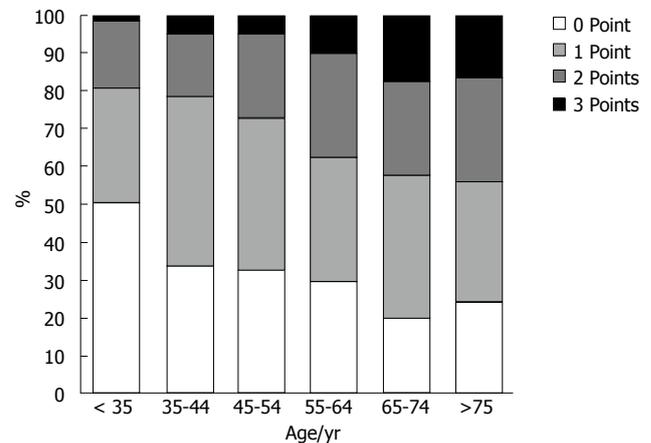

The frequencies of severe atrophy and the antrum/corpus gastritis score in the different age groups are provided in Table 3. Severe atrophy was close to 2% in the group younger than 65 years and increased up to 11.2% at the age over 75 years. The antrum gastritis score was almost equal in all age groups (mean 3.27 ± 0.95). The corpus gastritis score increased significantly with age [increase of 0.01 per year (95% CI 0.006-0.016)].

The gastric cancer risk index showed a significant shift to a higher index with age (Kruskal-Wallis test; $P < 0.0001$; Figure 2). At least 10% of the individuals older than 55 years had a score of 3 points, and more than 25% of them had a score of 2 points.

Comparison of the different scoring systems like gastric cancer index and phenotype of gastritis showed a significant correlation ($P < 0.001$, χ^2 -test; Table 4). This was expected because the phenotype of gastritis was included in the gastric cancer index. Nevertheless, the definitions for predominant gastritis were very different (see

Table 4 Comparison of gastric cancer risk index and phenotype of gastritis in 845 patients with *H pylori* positive gastritis

Phenotype of gastritis	Gastric cancer risk index			
	0 point	1 point	2 points	3 points
Antrum-predominant gastritis	156	104	21	0
Pangastritis	107	178	113	36
Corpus-predominant gastritis	2	22	62	44

**Figure 2** Gastric cancer risk index in patients with *H pylori* infection in different age groups. With increasing age the number of patients with 2 or 3 points increased significantly (Kruskal Wallis test; $P < 0.0001$).

METHODS). The group with the highest risk for gastric cancer according to Uemura *et al*^[4] might be these with the corpus-predominant gastritis ($n = 130$), whereas the risk might be highest for those with a gastric cancer index of 3 ($n = 80$), and the overlapping group contained only 44 patients (26.5%).

DISCUSSION

Histological alterations of the gastric mucosa such as corpus-predominant gastritis, pangastritis, intestinal metaplasia or severe atrophy are proposed to carry an increased risk for gastric cancer in *H pylori* infected individuals. In our study we observed a strong association of intestinal metaplasia, atrophy as well as corpus-predominant gastritis with increasing age. Our results represent the frequency of histopathological changes in a country with a lower gastric cancer prevalence compared to other parts of the world (i.e. China or Japan). This might be of importance for future investigational trials on this topic.

We investigated only patients with normal appearing gastric mucosa or no grossly visible changes at endoscopy. In such a setting, often a rapid urease test would be performed by most investigators to test for *H pylori* only; therefore histopathological changes will not be diagnosed. However, our data clearly indicate that there is a need to obtain gastric specimens in routine endoscopy, even if the macroscopic appearance is to a greater or lesser extent normal. There is much evidence that several phenotypic changes in the gastric mucosa are associated with an

increased risk of gastric cancer. In a large prospective study from Japan^[4] only patients with *H pylori* infection developed gastric cancer. A closer look at the data revealed that certain histopathological findings increased the risk dramatically. In fact, the presence of intestinal metaplasia (RR 6.4), severe atrophy (RR 4.9), pangastritis (RR 15.6), and, most strikingly, corpus-predominant gastritis (RR 34.5) was associated with an increased risk for gastric cancer. An additional aspect in this study was the fact that about 60% of the patients who developed gastric cancer, had no initial pathological findings during upper GI-endoscopy and were classified as non-ulcer dyspepsia. It demonstrates the importance to obtain gastric specimen during upper GI-endoscopy even though the macroscopic findings are normal.

The optimal strategy for patients with risk lesions for gastric cancer has not been established. One option might be to eradicate *H pylori* infection. It is well known that corpus-predominant or pangastritis will be healed after successful eradication therapy; on the other hand, atrophy and intestinal metaplasia will persist constantly according to systematic review of the published literature^[9]. In addition, a large randomized trial from China indicates that the point of no return might be already achieved when atrophy or intestinal metaplasia are observable^[10]. In that trial, performed in more than 1600 healthy volunteers from Fujian Province, a significant reduction of gastric cancer incidence in an 8-year follow-up period by *H pylori* eradication was only observed in those patients without intestinal metaplasia or atrophy in the gastric mucosa in the beginning of the study. One possible conclusion from this study is that patients with those histopathological changes have to be included in an endoscopic surveillance program, but it is unknown which intervals are necessary and how cost-effective such a strategy might be. This will have to be the topic of future investigational trials.

The combination of histopathological features is a promising tool, since there is a clear need to identify those patients at risk for the development of gastric cancer. While the scoring system used in the trial by Ley *et al*^[11] is probably too complex to use in general, the gastric cancer index might be more promising to use in clinical practice. This score includes the type of gastritis as well as the presence of intestinal metaplasia and has been proven to be highly predictive for the presence of gastric carcinoma^[5]. We identified 80 (9.5%) out of 845 patients with normal endoscopic appearance and the highest possible gastric cancer risk score of 3. Especially in those patients an endoscopic surveillance might be necessary; however, the final proof of any improvement for the individual patient is yet missing.

In the trial of Uemura *et al*^[4] the highest risk was found in those patients with a corpus-predominant gastritis; nevertheless, a marked risk was observed in those with pangastritis, also. Pangastritis was very frequently

diagnosed in our population (51.3%). The significance of this finding therefore will have to be verified.

Our results indicate that there is a need to obtain gastric biopsies during upper GI-endoscopy, even if the macroscopic appearance is normal or without any gross pathology. The prevalence of gastritis associated with an increased risk for cancer development increases with age. The individual risks for gastric cancer development remain to be established by the follow-up. *H pylori* eradication therapy alone might not be sufficient enough to prevent gastric cancer in patients with advanced changes in the gastric mucosa. From the actual perspective, and with regard of the literature, interventions have to be implemented earlier, before advanced changes in gastric mucosa caused by *H pylori* occur or, more worthwhile, preventing being infected with *H pylori*.

Abstract

AIM: To report on our large German collective and updated data of 142 patients with autoimmune hepatitis (AIH) type 1.

METHODS: Key investigations performed were liver biopsy, serum autoantibodies as well as serum markers such as IgG and elevated transaminases. Antinuclear antigen (ANA) and smooth muscle antigen (SMA) autoantibodies characterized type 1 AIH. Type 3 (AIH) was solely characterized by the occurrence of soluble liver antigen/liver-pancreas antigen (SLA/LP) autoantibodies either with or without ANA or SMA autoantibodies.

RESULTS: Most prevalent HLAs were A2 (68 patients, 48%), B8 (63 patients, 44%), C7 (90 patients, 63%), DR3 (49 patients, 38%), DR4 (49 patients, 38%) and DQ2 (42 patients, 30%). Compared to the Italian and North American patients, we found fewer patients with a DQ2 subtype. Furthermore, the B8-DR3-DQ2 human leucocyte antigen (HLA) was also less prominent compared to the North American patients. However, prevalences of B8, DR3, DR4, DR7, DR11 and DR13 were comparable to the Italian and North American patients. Furthermore, we report on an additional subgroup of patients with SLA/LP positive AIH. Generally, in this subgroup of patients the same HLA subtypes were favoured as the AIH type 1.

CONCLUSION: Although HLA subtypes were comparable between these three collectives, the German patients were distinct from the Italian and North American patients with respect to DQ2 and from the North American patients with respect to B8-DR3-DQ2

INTRODUCTION

Autoimmune hepatitis (AIH) is characterized by portal lymphatic infiltrates on liver histology and in most patients with the occurrence of autoantibodies such as antinuclear, smooth muscle antibody-positive (ANA/SMA, type 1), liver-kidney microsomal antibody-positive (LKM-1), and soluble liver antigen/liver-pancreas antigen (SLA/LP) antibodies. Untreated, the disease usually runs an unfavorable course with 5 year survival rates of 50% and 10 year survival rates between 10% and 27%^[1,2]. However, in most patients the disease can be controlled with immunosuppressants such as prednisolone and azathioprine, resulting in an almost normal average life expectancy^[3].

Although the pathomechanism of the disease is still unknown, an underlying genetic predisposition has been suggested due to the fact that patients are predominantly of female gender (women to men ratio equals to approximately 6:1) and the association of the disease with certain human leucocyte antigens (HLAs). Muratori *et al*^[4] recently published an extensive study on two large populations, Italian and North American, and demonstrated a distinct genetic association of HLA with the disease. B8-DR3-DQ2 was reported to be the most frequent genotype in Italian patients with AIH type 1 but significantly less frequent in North American patients. In addition, a clear difference in occurrence of the DR4 genotype was demonstrated with fewer patients in Italy presenting with such a genotype. Furthermore, the C7, DR3, DR11, DR13, and DQ2 loci were investigated but no significant differences between

Table 1 Most prevalent HLA subtypes in German patients with autoimmune hepatitis type 1

HLA	AIH type I German patients
C7	90 (63%)
A2	68 (48%)
B8	63 (44%)
DR3	49 (38%)
DR4	49 (38%)
DQ2	42 (41%)

these two populations could be found.

In order to further elucidate these genetic associations and differences, we now report on the HLA antigens in our large German collective of 142 patients with AIH type 1 and compared it to published data, especially in the Italian and North American populations. In addition, we report on our small subgroup of 29 patients with SLA/LP positive AIH.

MATERIALS AND METHODS

Subjects

One hundred and forty-two consecutive patients with definite, autoantibody positive AIH type 1 and 29 consecutive patients with SLA/LP positive AIH, who had been referred to the Department of Internal Medicine I, Mainz University Hospital, were investigated. All patients lacked serological evidence of chronic viral hepatitis B and C by third-generation enzyme-linked immunoassay. There was no evidence for illicit drug abuse, excessive alcohol intake (> 4 oz/wk) or exposure to hepatotoxic drugs. Diagnosis of AIH was established according to the revised Scoring system described previously^[5].

Methods

Key investigations performed were liver biopsy, serum autoantibodies as well as serum markers such as IgG and elevated transaminases. Similar to Muratori's study^[4] and according to international standards, ANA and SMA autoantibodies characterized type 1 AIH. Type 3 (AIH) was solely characterized by the occurrence of SLA/LP autoantibodies either with or without ANA or SMA autoantibodies.

Of our 142 patients with AIH type 1, 119 were women (84%) and 23 were men (16%). Of these patients, 108 (76%) were positive for ANA, 101 (71%) for SMA autoantibodies, and 67 (47%) patients had both ANA and SMA autoantibodies. DR and DQ alleles were not examined in all patients. DR alleles were investigated in 129 patients and DQ in 103 patients. Of the 29 patients with AIH type 3, 22 were women (76%) and 7 were men (24%). Since HLA loci are thought to be genetically fixed and to be independent of age, serum markers or immune globulins, patients were not further characterized in that respect.

RESULTS

The most commonly found HLA subtypes in our patients

with AIH type 1 were C7 (90 patients, 63%), A2 (68 patients, 48%), B8 (63 patients, 44%), DR3 (49 patients, 38%), DR4 (49 patients, 38%) and DQ2 (42 patients, 30%) (Table 1). As significant differences had been demonstrated in the Italian and North American populations regarding the distribution of the B8-DR3-DQ2 and DR4 HLA subtypes, these subtypes were also analysed along with the additionally reported C7, DR7, DR11, DR13, and DQ2 loci. The B8-DR3-DQ2 subtype was identified in 28 (27%) German patients with AIH type 1. And 49 patients (38%) were tested positive for the DR4 locus. In addition, almost half of all patients with AIH type 1 were positive for the HLA subtype B8 (45%) and 38% for DR3 (Table 2). The C7 HLA subtype which was highly prevalent in Italian patients with AIH type 1 was also common in the German population with 90 patients (63%). Further HLA subtypes reported and compared in Italian and North American patients were less prevalent in the German population. DR11 was positive in 17 (13%) of patients. Also DR13 could be identified in 17 (13%) of patients. Compared to the North American and Italian patients the DQ2 allele was also less prominent with 42 (41%) of patients.

For patients with SLA/LP positive AIH, HLA association had previously not been reported. Thus, we assessed the association of HLA of 29 patients with SLA positive, type 3 AIH (Table 3). Given a significantly smaller collective, there seemed to be a trend for SLA/LP positive AIH to be associated with the same HLA as AIH type 1. The most prevalent HLA in our patients with AIH were A2 in 16 patients (55%), B8 in 15 patients (52%), C7 in 22 patients (76%), DR3 in 12 patients (41%), and DQ2 in 13 patients (45%). Interestingly, only 3 patients did not carry either DR3 or DR4.

DISCUSSION

The etiology of AIH is still unknown. However, an underlying genetic predisposition has been suggested due to the fact that patients are predominantly of female gender and the association of the disease with certain HLA. Muratori *et al*^[4] recently published an extensive study on two large populations, Italian and North American, and demonstrated a distinct genetic association of HLA antigens with the disease. Since this study not only investigated the commonly studied HLA antigens type II but also extensively investigated the HLA antigens type I, this study was of significant value. In order to further elucidate HLA association with AIH and to compare our collective of patients with AIH, which is among the largest reported, to published populations in different regions of the world, we here present our data on HLA association in German patients.

Within the Italian population significant association of AIH was demonstrated for HLA antigens B8 (32%), C7 (51%), DQ2 (53%) and for the combined HLA type B8-DR3-DQ2 (30%). The frequencies of B8 and C7 were confirmed by our study (45% and 63%). In addition, an earlier British study had also reported on an association of increased frequency of C7 with AIH type 1^[6]. In contrast, DQ2 was found less prominent in German patients compared to Italian (41% *vs* 53%) and North American

(41% *vs* 57%) patients, but still at a higher frequency compared to the Italian control population (30%). Finally, the combined HLA subtype B8-DR3-DQ2 was less frequent in German patients, especially compared to North American patients (27% *vs* 48%). This may mostly be due to the significant lower frequency of the DQ2 HLA in German patients.

On the contrary, our patients displayed DR4 HLA frequency that was highly similar to the North American patients and significantly higher than the reported Italian HLA associations. An association of DR4 with AIH type 1 had been reported and in other populations, especially in Japan (83%) and Brazil (50%) it had an even higher frequency^[7,8].

Frequency of HLA DR3 was highly similar between German and North American patients (45% and 52%), which were clearly higher than in all other populations reported thus far. Comparable to Italian patients DR3 was found at 31% in Japanese and 32% in Brazilian patients. In smaller populations from Western India, China and Turkey, this HLA antigen was even found at 11% to 17%^[9,11]. Moreover, 49 of all patients carried neither DR3 nor DR4. However, a search for highly prevalent HLA in these patients did not reveal any additional, obvious new association, independent of DR3 or DR4.

All other HLA frequencies, specifically reported and compared by Muratori were comparable between our collective and the Italian and the North American study groups. The results of all three study groups are summarized in Table 2.

To date, most studies on HLA association with AIH mainly focused on AIH type 1 patients and reported only a few AIH type 2 patients. Thus far, HLA association of SLA/LP positive AIH has not been reported in a significant number of patients. Therefore, we extended our analysis of HLA antigen association to SLA/LP positive AIH. Given a smaller group of only 29 patients, HLA frequencies seemed to be similar to patients with AIH type 1. Comparable to AIH type 1, a high frequency of C7 (77%) was found. Frequencies for A2, B8, and DR3 were comparable to those of our German patients with AIH type 1 but also to AIH type 1 patients of the Italian and North American groups, who had not reported data on their AIH type 3 patients. Clearly a higher frequency of

Table 3 Most prevalent HLA subtypes in German patients with SLA/LP positive autoimmune hepatitis

HLA	AIH SLA/LP positive German patients <i>n</i> = 29
A2	16 (55%)
B8	15 (52%)
C7	22 (76%)
DR3	12 (41%)
DQ2	13 (45%)

HLA DQ2 was observed in patients with SLA/LP positive AIH compared to our patients with AIH type 1. However, these higher HLA DQ2 frequencies are comparable to the DQ2 frequencies of the Italian and North American groups. Together, these data suggest a common genetic association and background for AIH types 1 and 3. This is in accordance with the observation that type 1 and SLA/LP positive AIH are also comparable with respect to their clinical course^[2].

In conclusion, German AIH type 1 patients were demonstrated to be genetically distinct from Italian or North American patients and other populations, especially with respect to a significantly lower frequency of HLA DQ2 and a lower occurrence of HLA B8-DR3-DQ2. Other HLAs were found at similar frequencies, suggesting an underlying genetic background of AIH type 1. Analysis of a smaller group of 29 patients with SLA/LP positive AIH pointed towards comparable HLA frequencies in patients with AIH type 1 and SLA/LP positive AIH, which is in accordance with a similar clinical course. The challenge is yet to investigate whether these findings may help to better understand the etiology of AIH, to predict prognosis of the disease, or to further improve therapeutic concepts.

Abstract

AIM: To examine the expression of leptin and its receptor, OB-R, in normal gastric mucosa and neoplasia.

METHODS: By immunohistochemical staining using specific antibodies, we evaluated the expression of leptin and OB-R in 207 gastric carcinomas (100 early and 107 advanced carcinomas) and analyzed their relationship with clinicopathological features.

RESULTS: Both normal gastric epithelium and carcinoma cells expressed a significant level of leptin. In cases with OB-R staining, carcinoma cells showed OB-R-positive expression, but the intensity was weaker than that in normal mucosa. The expression of OB-R showed a significant correlation with the level of leptin expression. The expression levels of both leptin and OB-R tended to increase as the depth of tumor invasion or TMN stage increased ($P < 0.01$). Lymph node metastasis was detected in 49.5% (47/95) of leptin-strong cases and in 50.5% (48/95) of OB-R-positive cases, and the rate was 33% (37/112) in leptin-weak cases and 17% (19/112) in OB-R-negative cases. Both venous and lymphatic invasion also tended to be observed frequently in positive tumors as compared with negative tumors. Interestingly, in the 96 leptin- or OB-R-positive tumors, hematogenous metastasis was detected preoperatively in 3 (3.1%) patients. In contrast, none of the carcinomas that lacked expression of leptin and OB-R showed hematogenous metastasis.

CONCLUSION: Overexpression of leptin and expression of OB-R may play a positive role in the process of progression in gastric cancer. Functional upregulation of leptin/OB-R may have a positive role in the development and initial phase of progression in gastric cancer.

INTRODUCTION

Previous studies have shown a positive association between adiposity and increased risk of cancers of the endometrium, kidney, gallbladder (in women), breast (in postmenopausal women), and colon (particularly in men)^[1-9]. Consistently, a recent large scale cohort study demonstrated that increased body weight is associated with increased mortality for all cancers combined, as well as for cancers at various specific sites^[10].

The adipocyte-derived cytokine, leptin, is thought to play a key role in the control of satiety, energy expenditure, and various reproductive processes^[11-13]. Leptin is a peptide hormone composed of 167 amino acids with a molecular mass of 16 kDa^[14]. Generally, plasma leptin level is representative of body fat mass^[15-18] and increases in a logarithmic fashion with an increase in body mass in mice^[19]. Leptin controls body mass and metabolism by affecting the metabolic, neuroendocrine, reproductive and hematopoietic systems^[20]. In cancer, there is regulatory dysfunction in metabolic, neuroendocrine and other systems. Although initially thought to be exclusively expressed in and secreted by adipocytes, recent studies have shown that leptin expression can be detected in a number of additional tissues, including the placenta^[21], gastric mucosa^[22], pituitary cells^[23] and hepatic stellate cells^[24]. More importantly, leptin has been shown to regulate cell proliferation in diverse normal and malignant tissues and to stimulate the proliferation of certain normal hematopoietic and epithelial cells. Leptin has also been shown to promote the invasiveness of premalignant colon and kidney epithelial cells *in vitro*^[25]. These findings suggest the possibility that leptin may be critically involved in the promotion of cancer.

Leptin exerts its action through the leptin receptor (OB-R), a member of the cytokine family of receptors, which was also detected in both rat and human gastric mucosa. Further studies, however, have shown that leptin receptors are expressed in many other tissues, including

the brain, placenta, pancreas, adrenal gland, hematopoietic cells, liver, lung and heart^[21,24,26-28]. In addition, OB-R has been identified in malignant cells, including lung and gastric carcinoma and leukemic cells^[22,29-32].

In this study, therefore, we used antibodies to leptin and OB-R, and immunohistochemically characterized the expression pattern of these two proteins in gastric carcinoma and evaluated the possible role of leptin in the tumorigenesis and spread of gastric cancer.

MATERIALS AND METHODS

Two hundred and seven carcinomas, which were surgically resected in the Department of Surgery, The University of Tokyo, from 1991 to 2002, were included in this study. In all cases, serial-step sections 3-mm wide were cut, fixed in 10% formalin solution, and then embedded in paraffin. All the resected primary tumors and regional lymph nodes were histologically examined by hematoxylin-eosin staining according to the Japanese Classification of Gastric Carcinoma^[33]. Tumors were histologically classified into two types based on the predominant features: differentiated type (well and moderately differentiated adenocarcinoma) and undifferentiated type (poorly differentiated adenocarcinoma and signet ring cell carcinoma). In addition, we examined several discrete histological parameters, including lymphatic invasion, venous invasion and lymph node metastasis.

Immunohistochemical study of leptin and OB-R

We investigated the expression of OB-R and leptin with immunohistochemical staining using affinity purified rabbit polyclonal antibodies against leptin (Santa Cruz, Biotech, CA, USA) and goat polyclonal antibodies against OB-R (M-18, Santa Cruz Biotech)^[30,32], respectively. Sections (3- μ m thick) were deparaffinized in xylene, hydrated through a graded series of ethanol, and heated in a microwave oven for two 7-min cycles (500 W). After being rinsed in phosphate buffered saline (PBS), endogenous peroxidase activity was inhibited by incubation with 0.3% hydrogen peroxide in 100% methanol for 30 min. After 3 washes in PBS, nonspecific reaction was blocked by incubation with PBS containing 5% skimmed milk for 30 min at room temperature, and then the sections were incubated with normal rabbit or goat serum for 30 min. The sections were incubated overnight at 4°C in humid chambers with the primary antibody to leptin at 1/70 dilution or the primary antibody to OB-R at 1/100. After three washes with PBS, the sections were incubated with biotinylated rabbit anti-goat or anti-rabbit immunoglobulin for 30 min. After washing again with PBS, the slides were treated with peroxidase-conjugated streptavidin for 30 min, and developed by immersion in 0.01% H₂O₂ and 0.05% diaminobenzidine tetrahydrochloride for 3 min. Light counterstaining with Mayer's hematoxylin was performed.

Statistical analysis

All statistical calculations were carried out using Stat View-J 5.0 statistical software (SAS Institute, USA). Student's t-test and Wilcoxon's test were used to analyze data.

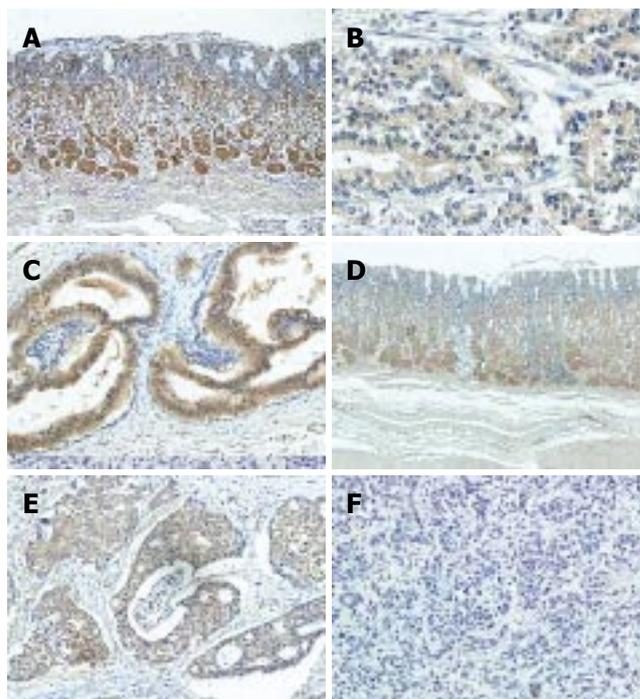

Figure 1 Immunohistochemical staining of leptin and OB-R in normal gastric mucosa and cancer. **A:** Leptin in normal mucosa; **B:** Leptin weak type in gastric cancer; **C:** leptin strong type in gastric cancer; **D:** OB-R in normal mucosa; **E:** OB-R positive type in gastric cancer; **F:** OB-R negative type in gastric cancer.

Differences with a *P* value of less than 0.05 were considered to be statistically significant.

RESULTS

Immunohistochemical detection of leptin and OB-R in normal mucosa and carcinoma

In all cases, the lower part of the fundic glands in the normal part of the mucosa expressed a significant level of leptin, suggesting that leptin is mainly produced in chief and parietal cells (Figure 1A). Leptin could be detected in the cytoplasm as well as the cell membrane, but not in the nucleus. However, the surface epithelium of normal gastric mucosa totally lacked expression of leptin. This staining pattern was similar to that described in the gastric epithelium in a previous report^[22].

Gastric carcinoma cells mostly showed positive immunoreactivity, although the staining intensity varied among the samples. According to the staining pattern, tumors were subdivided into two groups. When investigators agreed that the staining intensity of carcinoma cells was significantly weaker than that of chief and parietal cells in corresponding normal mucosa, those tumors were categorized as having weak expression (Figure 1B). In contrast, when carcinoma cells stained to a similar degree or more strongly than normal gastric mucosa, those tumors were categorized as having strong expression (Figure 1C).

OB-R was also detected in normal mucosa, and the immunostaining pattern was mostly consistent with that of leptin staining (Figure 1D). In cancer tissue, however, some carcinoma cells showed significant expression while

Table 1 Relationship between expression of Ob-R and leptin

	Ob-R expression		P
	Positive (67)	Negative (140)	
Leptin expression			
Strong (74)	45	29	< 0.001
Weak (133)	22	111	

others were mostly negative for OB-R. In tumors positive for OB-R, most of the carcinoma cells were equally stained and heterogeneity was rarely observed in each sample (Figure 1E), while in negative tumors a few carcinoma cells were stained only faintly (Figure 1F).

The relationship between the expression patterns of leptin and OB-R is presented in Table 1. Among 74 carcinomas with strong expression of leptin, 45 (60.8%) also expressed OB-R strongly, while only 29 carcinomas (39.2%) lacked expression of OB-R. In the 133 carcinomas with weak leptin expression, 111 (79.3%) also lacked expression of leptin OB-R. Hence, the expression of leptin and OB-R was significantly correlated in gastric cancer ($P < 0.001$).

Clinicopathological features and relation to expression of leptin and OB-R

Table 2 shows the correlation between leptin and OB-R expression and clinicopathological data in the 207 carcinomas cases. No significant difference was observed in age, preoperative tumor markers or tumor size between the positive and negative groups. Interestingly, positive expression of leptin was found in 64 of 155 male patients (41.3%) versus 10 of 52 female patients (19.2%), and the difference was statistically significant ($P < 0.05$). The relationship of BMI with leptin expression in the two groups did not show a significant association. The stomach is anatomically divided into three portions; upper (U), middle (M), lower (L) parts^[53]. Interestingly, the percentage of tumors with strong expression of leptin was higher in those located in the upper part (23/51; 45.1%) than in those in the middle (36/94; 38.3%) and lower (15/62; 24.2%) parts, and this was statistically significant ($P < 0.05$).

The expression levels of both leptin and OB-R increased as the depth of tumor invasion or TMN stage increased ($P < 0.01$). When leptin expression was compared with histological type, 45 of 88 (51.1%) well differentiated carcinomas expressed leptin strongly, while 90 of 119 (75.6%) undifferentiated carcinomas showed weak staining ($P < 0.001$). Moreover, the percentage of tumors with OB-R-positive expression was significantly higher in differentiated carcinomas (48.9%) than in undifferentiated carcinomas (20.1%) ($P < 0.001$). Thus, both leptin and OB-R were expressed at a higher level in differentiated carcinomas as compared with undifferentiated carcinomas ($P < 0.001$).

Venous as well as lymphatic invasion was more frequently observed in tumors with high leptin and positive OB-R expression. Accordingly, lymph node metastasis was detected in 71.6% (48/67) of OB-R-positive cases, which

was significantly higher than 31.3% (47/150) of OB-R-negative cases. Interestingly, in the 74 tumors with high leptin expression, hematogenous metastasis was detected preoperatively in 3 (4.1%) patients, and peritoneal dissemination was detected intraoperatively in 5 (6.8%) patients. However, in 133 tumors with low leptin expression, only one case showed peritoneal dissemination and none was associated with hematogenous metastasis ($P < 0.05$).

DISCUSSION

Leptin is well known to play a major role in the regulation of weight and adiposity. Recently, many studies have shown that increased body weight is associated with increased risk of cancer and cancer-related mortality, suggesting a possible role of leptin in the pathogenesis of cancer. Leptin is reported to be abundantly produced in the stomach^[34,35]. In gastric carcinoma, some reports have shown that obesity is one of the main risk factors^[36-42]. These findings suggest that leptin may be critically involved in the development and progression of gastric cancer. This idea encouraged us to evaluate the expression of leptin and its receptor in gastric cancer tissues.

In our series, leptin and OB-R were predominantly expressed in chief and parietal cells but not in the surface epithelium in normal parts of the gastric mucosa that were adjacent to cancer tissue, which is mostly consistent with data of previous studies^[22,43,44]. However, carcinoma cells showed a variety of staining patterns for leptin or OB-R. Leptin was detected in all carcinoma cells, although the level of expression could be divided into two categories according to the staining intensity, whereas OB-R was detected in some tumors but not in others, and the level of expression of leptin showed a positive correlation with OB-R expression. This suggests the existence of a common regulatory mechanism in the expression of leptin and its receptor in the gastric epithelium.

The main finding in our study was that the expression levels of both leptin and OB-R tended to increase as the depth of tumor invasion or TMN stage increased ($P < 0.01$). Moreover, nodal and distant metastasis, as well as pathological lymphatic or vascular invasion, was frequently detected in leptin-strong and OB-R-positive tumors as compared with leptin-weak and OB-R-negative tumors. Shuneider *et al.*^[43] reported that leptin led to significantly increased proliferation in AGS cells, and the MAP-kinase-1 specific inhibitor U0126 blocked leptin-induced cell proliferation in a dose-dependent manner. Tessitore reported that in colorectal cancer patients, plasma leptin level in stage IV patients was significantly higher than that in stage I patients. In addition to stimulating proliferation, leptin has been shown to promote invasiveness of renal and colonic epithelial cells via PI3-kinase-, rho- and rac-dependent cascades^[25]. All these findings support that leptin may have a promoting effect on cancer invasion and metastasis. Our findings were consistent with these results and suggest that leptin and OB-R might function as an autocrine growth factor during the development and progression of gastric cancer.

Another interesting finding was that the expression of

Table 2 Expression of leptin and clinicopathologic characteristics of patients

leptin/OB-R was correlated with the differentiation of gastric cancer. In our series, cancers of undifferentiated type tended to have weak expression of leptin as well as negative OB-R expression as compared with differentiated cancers. In each type, expression of leptin/OB-R showed a positive association with stage and metastasis (data not shown). This suggests that the different expression

of leptin/OB-R was determined at the early stage of carcinogenesis. The carcinogenic pathway of differentiated type carcinoma is considered to begin with *H pylori* infection, followed by atrophic gastritis and intestinal metaplasia, and inappropriate activation of gut specific transcription factor CDX2 has an important role in the early stage of carcinogenesis. In contrast, dysfunction

of E-cadherin is considered to have critical roles in the development of undifferentiated carcinoma. The molecular interaction between leptin/OB-R and CDX2 or E-cadherin is an interesting subject for future research^[45].

In conclusion, we confirmed that the expression level of leptin/OB-R showed a positive correlation with the depth of tumor invasion, stage, and metastasis as well as tumor differentiation. Our findings suggest that coexpression of leptin and OB-R may have a positive role in the progression in gastric cancer in an autocrine or paracrine manner. Functional inhibition of leptin/OB-R might effectively suppress the growth and metastasis of gastric cancer.

Abstract

AIM: To investigate the effects of luminal exposure to H₂O₂ and two related thiol oxidizing agents on basal and stimulated chloride secretion in native colon using electrophysiological and pharmacological approaches.

METHODS: Unstripped rat distal colon segments were mounted in Ussing chambers. Potential difference, calculated resistance and short-circuit current across unstripped colon segments were monitored with a dual voltage/current clamp. Paracellular permeability was assessed by measuring the mucosa-to-serosa flux of a fluorescent probe (FITC).

RESULTS: Luminal exposure to hydrogen peroxide transiently stimulated chloride secretion without altering barrier function. This stimulatory effect could be blocked by basolateral atropine but not indomethacin. The cysteine and methionine oxidizing compounds, phenylarsine oxide and chloramine T respectively, mimicked the effect of H₂O₂, except for a drop in transcolonic resistance after 30 min. In contrast to the observed stimulatory effect on basal secretion, cAMP-stimulated electrogenic ion transport was blunted by luminal H₂O₂. However, the Ca²⁺-activated response remained unchanged.

CONCLUSION: H₂O₂ may be an important selective modulator of intestinal ion and water secretion in certain pathologic conditions such as inflammation or ischemia-reperfusion by multiple mechanisms.

INTRODUCTION

The colonic lumen is an extraordinarily aggressive milieu containing high concentrations of oxidizing compounds^[1] as a result of the digestion of nutrients, the presence of dietary oxidants and the metabolic activity of resident colonic flora. Moreover, many gastrointestinal diseases, such as intestinal ischemia, ischemic colitis or inflammatory bowel disease, are associated with an increase in the concentration of both reactive oxygen and nitrogen species in the intestinal mucosa^[2], generated by either activated neutrophils infiltrating the colonic crypts or epithelial cells submitted to ischemia/reperfusion. Therefore, colonic epithelial cells and submucosal tissue are under continuous luminal oxidative stress in states of health and disease, but little is known about the impact of luminal oxidants on mucosal functions in intact native mammalian colon since most studies have been carried out in cell lines.

Oxidants have been shown to interfere with epithelial ion transport and barrier function. In intestinal model cell lines, addition of hydrogen peroxide, either basolaterally or apically, first activates vectorial Cl⁻ transport and then inhibits cAMP-activated anion secretion. The inhibitory effect on the forskolin-stimulated response appears to be the result of the blockade of apical Cl⁻ conductance and the inhibition of Na⁺-K⁺-ATPase activity^[3]. In animal models, serosal application of H₂O₂, at micromolar concentrations, to muscle-stripped rat colon evokes a transient increase in anion secretion^[4]. Yet, the role of luminal oxidants on stimulated transport in intact native colon remains poorly understood. Therefore, our aim was to investigate the effect of luminal H₂O₂ on basal and stimulated electrogenic ion transport in rat distal colon.

MATERIALS AND METHODS

Rat distal colon model in vitro

Male Sprague-Dawley rats weighing 250-350 g were killed by intraperitoneal administration of sodium pentobarbital.

Animals were handled in accordance with the protocols approved by Comisión de Investigación-Hospital Clínico San Carlos, in compliance with both Spain's and European Union's regulations for the use of animals in biomedical research.

The method to obtain samples for electrophysiological studies has been reported elsewhere^[5,6]. In brief, a 5-cm segment of distal colon was surgically removed and placed in iced buffer solution. The specimen was opened along its mesenteric side. Unstripped colonic segments were mounted in modified chambers (Costar, San Diego CA) with a surface area of 0.64 cm². These chambers could provide individualized access to both the luminal and the serosal compartments of the colon. Both chambers were bathed with an identical volume (5 mL) of the buffer solution containing 122.0 mmol/L NaCl, 2.0 mmol/L CaCl₂, 1.3 mmol/L MgSO₄, 5.0 mmol/L KCl, 20.0 mmol/L glucose and 25.0 mmol/L NaHCO₃ (pH 7.4 when gassed with 950 mL/L of O₂ and 50 mL/L CO₂ at 37°C).

Electrophysiology

Two Ag/AgCl electrodes connected to a dual voltage-current clamp (World Precision Instruments ECV 4000, Sarasota-FL, USA) were placed in the apical and basolateral chambers. Spontaneous transepithelial potential difference (E₀; lumen negative, in mV) could therefore be monitored. Potential difference values were corrected for the junction potentials (< 0.1 mV) between the luminal and the serosal solutions. Two additional electrodes were used to apply a 50 μA current through the mounted colon. The resulting potential difference was measured (E₅₀). Transcolonic resistance (TR, in Ω·cm²) was calculated with E₀ and E₅₀ values by Ohm's law, reflecting epithelial viability and intestinal barrier function. Short circuit current (I_{sc}, in μA/cm²) could be obtained with E₀ and TR values by Ohm's law, indicating the amount of electrical current needed to nullify the spontaneous potential difference between the apical and the basolateral surfaces.

Electrophysiological experiments were carried out after the samples were mounted in the modified chambers and bathed in buffer solution until stable electrical activity was reached. The response of rat colon exposed to luminal oxidants to the muscarinic blocker (atropine) was studied after it was added to the basolateral chamber in the continued presence of both compounds. Similarly, the effect of two different secretagogues (forskolin and carbachol) on ion transport was assessed following the same protocol (luminal incubation + continued presence of the oxidant).

Paracellular permeability

Paracellular permeability was assessed by measuring the mucosal-to-serosal flux of fluorescein isothiocyanate (FITC; MW: 376.3) as previously described^[6]. Paired rat distal colon segments were mounted in chambers and bilaterally incubated in regular buffer for 10 min for equilibration. Subsequently, the apical buffer was replaced with a FITC-containing solution (140 μmol/L) with or without hydrogen peroxide. Basolateral buffer aliquots were collected at 0, 5, 15, 30 and 60 min after apical buffer replacement and the

fluorescent emission at 520 nm after excitation at 480 nm was measured with a spectrofluorometer (Bio-Tek FL600 Fluorescence Microplate Reader, Bio-Tek Instruments GmbH, Bad Friedrichshall, Germany). A calibration curve (fluorescence vs FITC concentration) was generated to calculate the concentration of FITC in the serosal chamber. The apparent permeability coefficient (P_{app}) was calculated according to the equation $P_{app} (cm/seg) = (ct2/ct1) \cdot V \cdot A^{-1} \cdot C_0^{-1}$, where (ct2/ct1) is the net increase in FITC concentration in the serosal buffer in a given interval of time (seconds), V is the volume (in milliliters) of the basolateral compartment, A is the surface of the colon segment (in square centimeters) and C₀ is the concentration in the apical chamber.

Materials

Cyclic AMP and Ca²⁺-dependent secretion was stimulated with forskolin (10 μmol/L) and carbachol (100 μmol/L), respectively. Phenylarsine oxide (PAO, 0.2 mmol/L) and chloramine T (CIT, 5 mmol/L) were used as non-physiologic thiol oxidants. For muscarinic receptor inhibition, atropine at a concentration of 1 mg/L was employed. Indomethacin (1-10 μmol/L) was used for blockage of cyclo-oxygenase activity. Forskolin and indomethacin were added to both chambers (luminal and serosal). However, exposition to the muscarinic agonist and its antagonist was only from the serosal side. All the compounds were obtained from Sigma, Madrid-Spain.

Statistical analysis

Results were presented as mean ± SD. Student's *t* and repeated measure ANOVA tests were used for statistical comparisons when indicated. *P* < 0.05 was considered statistically significant.

RESULTS

Luminal exposure to H₂O₂ (up to 10 mmol/L) for 30 min did not alter either transcolonic resistance (TR of H₂O₂-treated samples = 92.2% ± 11.7% of controls; *n* = 6 for each group; NS) or paracellular permeability (P_{app} = 1.24 × 10⁻⁶ ± 0.16 × 10⁻⁶ for control vs 0.95 × 10⁻⁶ ± 0.35 × 10⁻⁶ for 10 mmol/L H₂O₂; *n* = 6 for each group, NS). However, as shown in Figure 1, a transient increase in I_{sc} occurred 5 min after the addition of the oxidant to the apical chamber (peak I_{sc} = 46.7 ± 2.8 μA/cm² for control samples, *n* = 5; vs 85.9 ± 9.6 μA/cm² for 10 mmol/L H₂O₂; *n* = 6, *P* < 0.01). This secretory response was dose-dependent (from 100 μmol/L to 10 mmol/L) and peaked at a concentration of 8 mmol/L (ΔI_{sc} = 32.3 ± 3.4 μA/cm² at 8 mmol/L; *n* = 4 for all groups; *P* < 0.05 for the comparison between controls and oxidant-treated samples). However, it was not specific for H₂O₂ since two widely used cysteine and methionine oxidizing agents, phenylarsine and chloramine T, at concentrations used by other investigators to study epithelial barrier function in cell lines (0.2 mmol/L and 5 mmol/L respectively), generated the same secretory response after 5 min but induced a slight drop in transcolonic resistance 30 min after addition (Table 1).

In order to investigate the implication of different

Table 1 Transcolonic resistance and maximal short circuit current in rat distal colon exposed to phenylarsine oxide (PAO, 0.2 mmol/L) and chloramine T (CIT, 5 mmol/L) for 30 min

Group	n	TR ¹ at 30 min	peak Isc ²
Control	8	113 ± 8.0	66.4 ± 6.8
PAO (0.2 mmol/L)	4	77 ± 14.0 ^a	131.6 ± 16.7 ^a
CIT (5 mmol/L)	4	66.5 ± 4.3 ^a	166.6 ± 27.8 ^a

^aP < 0.05 vs control; ¹Transcolonic resistance; ²Short circuit current.

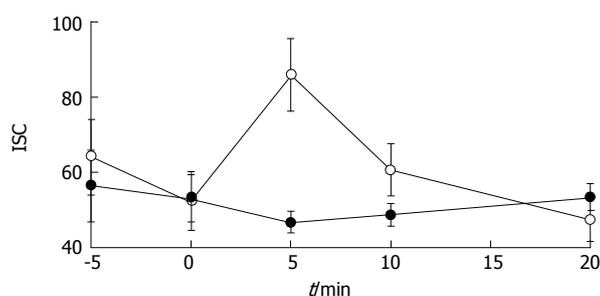

Figure 1 Luminal H₂O₂ transiently stimulates Cl secretion. After the addition of 10 mmol/L H₂O₂ to the apical surface of unstripped rat distal colon segments at time 0 (in white circles, n = 4), basal Isc increased significantly compared to control (black circles, n = 4), with maximal secretion occurring 5 min after the addition of the oxidant (P < 0.001).

secretagogues in H₂O₂-induced secretion, colonic samples were first incubated with varying concentrations of indomethacin (1–10 μmol/L) and subsequently exposed to the three oxidizing compounds. No inhibition of the Isc rise caused by 10 mmol/L H₂O₂ was observed. For example, samples incubated with 2 μmol/L indomethacin after addition of 10 mmol/L H₂O₂ yielded a peak Isc of 110 ± 13.7 μA/cm², whereas for controls the peak Isc was 134 ± 14.2 μA/cm² (n = 9 for each group; NS). The same result was observed with the other two oxidants (data not shown). Since other mediators, such as acetylcholine, might be involved in the observed effect, the response to luminal oxidants after muscarinic receptor blockade was investigated. Interestingly, the secretory response elicited by the three compounds was suppressed by basolateral preincubation with atropine (1 g/L). The ΔIsc in atropine-treated samples after exposure to 10 mmol/L H₂O₂ was -1.3 ± 8.6 μA/cm², whereas in samples incubated in regular buffer the ΔIsc in response to the same concentration of H₂O₂ was 55.2 ± 13.7 μA/cm² (n = 6, P < 0.01). Both PAO and chloramine T displayed a similar behaviour (Figures 2A and B).

Subsequently, the effect of luminal H₂O₂ on stimulated secretion was studied. After 30 min of incubation with 10 mmol/L H₂O₂, when no drop in permeability occurred (TR after incubation for 30 min = 116.6 ± 15.8 Ω · cm² H₂O₂-treated samples vs 87.8 ± 19.7 Ω · cm² for control; n = 6 and n = 5 respectively; NS), forskolin stimulated-secretion was inhibited (Figure 3) (maximal Isc = 69.3 ± 9.4 μA/cm² for H₂O₂-treated samples vs 134.1 ± 23.1 μA/cm² for control (n = 6 and n = 5 respectively; P < 0.01). This inhibitory action was dose-dependent with an IC₅₀-0.7 mmol/L. Since Ca²⁺-dependent agonists could activate

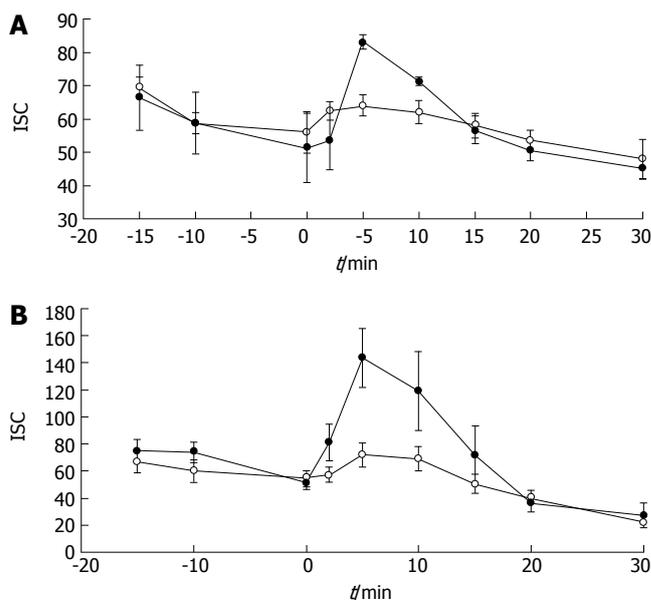

Figure 2 Oxidant-stimulated secretion is sensitive to basolateral atropine. Both phenylarsine oxide (PAO, 0.2 mmol/L) and chloramine T (CIT, 5 mmol/L) showed a similar prosecretory effect when they were added luminally to rat distal colon. **A:** Preincubation of colon segments with basolateral atropine (1 g/L) for ten minutes (added at time -10; in white circles, n = 3) suppressed the increase in Isc induced by luminal cysteine oxidizing agent PAO added at time 0 (control in black circles; n = 3; P < 0.01 between groups); **B:** A similar result was observed with the methionine oxidizing compound chloramine T. Basolateral incubation with 1 g/L of atropine (added at time -10; in white circles, n = 8) suppressed the secretory response caused by CIT added at time 0 (in black circles, n = 8; P < 0.001 between groups).

distinct signaling pathways and membrane transporters to generate electrogenic ion transport, we studied the effect of 10 mmol/L H₂O₂ on the carbachol-stimulated secretory response. In this case, samples exposed to the oxidant luminally or to regular buffer responded to the Ca²⁺ agonist in the same fashion (Figure 4).

DISCUSSION

Even under normal conditions, colonic epithelial cells are continuously exposed to luminal oxidants from different sources^[7,8]. Since these compounds may interfere with epithelial functions, further understanding of the specific effects of reactive oxygen species on ion transport is necessary to design therapeutic strategies to prevent cell dysfunctions, such as hypersecretion and energy depletion, during inflammation or ischemia^[1,2]. In this study, we showed that luminal hydrogen peroxide, within a physiologically relevant concentration range, could transiently activate chloride secretion without altering either electrical resistance or paracellular permeability in rat distal colon. This effect might be due to either direct stimulation of membrane transport proteins or due to the activation of intracellular second messengers in epithelial cells. In fact, mucosal and serosal addition of H₂O₂ could potentiate Cl secretion in a synergistic fashion^[9] in T84 cells previously stimulated with cAMP-agonists, suggesting that the Ca²⁺ signaling pathway might be involved in H₂O₂-triggered secretory response.

However, the maximal Isc induced by H₂O₂ in the T84

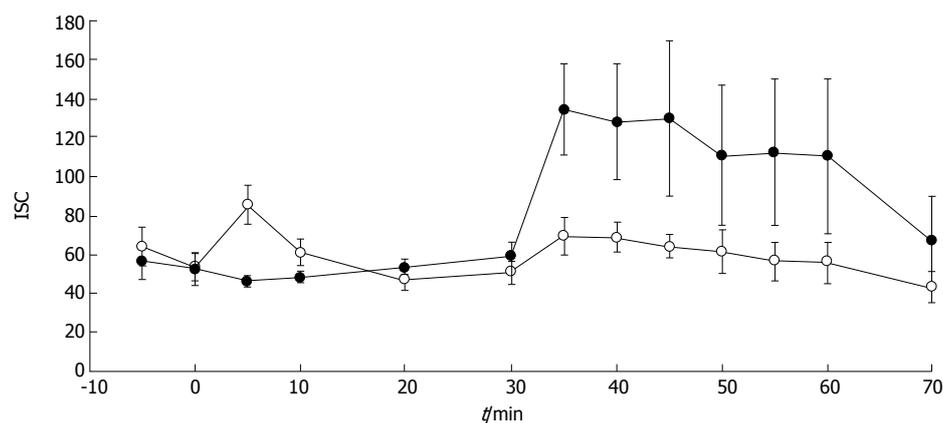

Figure 3 cAMP-activated secretion is blocked by luminal H_2O_2 . Incubation of rat distal colon with 10 mmol/L H_2O_2 for 30 min (white circles; $n = 6$) inhibited the rise in Isc caused by 10 μ mol/L forskolin added at time 0 (control in black circles; $n = 6$; $P < 0.01$) in white circles, $n = 8$) and suppressed the secretory response caused by CIT added at time 0 (in black circles, $n = 8$; $P < 0.001$ between groups).

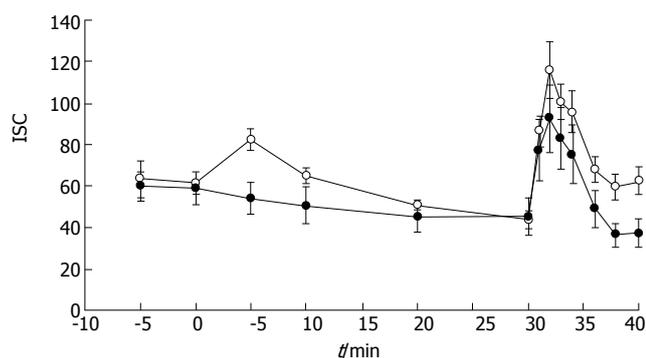

Figure 4 Ca^{2+} -stimulated Cl^- secretion is not affected by luminal H_2O_2 . Incubation of rat distal colon with 10 mmol/L H_2O_2 for 30 min (white circles; $n = 6$) slightly enhanced the response induced by 100 μ mol/L carbachol (control in black circles; $n = 6$; NS).

cell line is rather small compared to that observed in our model. Sugi *et al*^[10] suggested that oxidants might enhance the response to secretagogues by priming of transport proteins in epithelial cell membrane. Interestingly, our results suggest that sudden increases in the concentration of luminal oxidants could activate secretion by releasing acetylcholine rather than by directly stimulating epithelial cells, which is independent from the generation of prostaglandins. This assertion is supported by the fact that the rise in Isc induced by three different oxidants-hydrogen peroxide, phenylarsine oxide and chloramine T, is almost completely suppressed by incubation with basolateral atropine but not with indomethacin at several concentrations. These findings are in contrast with the observations reported by Karayalcin *et al*^[11], who found that basolateral hydrogen peroxide stimulates indomethacin-inhibitable secretion in stripped rat colon, which can be only partially blocked by atropine. Likewise, Tamai *et al*^[4] showed that H_2O_2 increases Isc probably by stimulating release of arachidonate metabolites and neurotransmitters. This divergent finding may be due, at least in part, to the different “*in vitro*” models used. We studied the unstripped rat distal colon^[12,13] because it could more accurately reflect the native tissue “*in vivo*” than the mucosa-submucosa preparations. Furthermore, Tamai *et al*^[4] and Karayalcin *et al*^[11] have used lower H_2O_2 concentrations and applied the oxidant to the serosal aspect of the stripped colonic wall.

An alternate explanation would imply that luminal

H_2O_2 exerts a distinct action on each signaling pathway. That is, it might be priming the Ca^{2+} -dependent pathway while blocking the cAMP-dependent pathway. Thus, the stimulatory action of prostaglandins on colonic epithelial cells would be abolished and therefore, would become “invisible”. To further support this hypothesis, previous studies in T84 cells have shown that incubation with H_2O_2 blocks chloride secretion stimulated by the cAMP agonist forskolin^[3]. Similarly, we found that H_2O_2 could inhibit the cAMP-dependent secretory response, but not the activation of electrogenic ion transport by carbachol. In fact, the response to the Ca^{2+} agonist was slightly augmented. This finding points at a cyclic nucleotide-dependent membrane transport protein as the target for luminal oxidants. From previous studies, one can speculate that apical cAMP-dependent Cl^- channels are the most likely sites of action for these compounds^[3,14]. The Na^+K^+ -ATPase is another potential target for oxidizing agents^[3]. However, the discrepancy between the observed inhibition of the cAMP-dependent increase in vectorial anion transport and the absence of such an action on Ca^{2+} -stimulated secretion renders this explanation unlikely.

In conclusion, our results suggest that H_2O_2 may be an important selective modulator of intestinal ion and water secretion in certain pathologic conditions such as inflammation or ischemia-reperfusion by multiple mechanisms. Irrespective of the underlying mechanism of activation, the fact that an increase in the luminal concentration of reactive oxygen species triggers chloride secretion may be teleologically explained as a defensive mechanism for flushing microorganisms and toxic byproducts of bacterial metabolism away from the colonic lumen to dilute their concentration.

stectomy; Timing

Tzovaras G, Zacharoulis D, Liakou P, Theodoropoulos T, Paroutoglou G, Hatzitheofilou C. Timing of laparoscopic cholecystectomy for acute cholecystitis: A prospective non randomized study. *World J Gastroenterol* 2006; 12(34): 5528-5531

<http://www.wjgnet.com/1007-9327/12/5528.asp>

Abstract

AIM: To study the timing of laparoscopic cholecystectomy for patients with acute cholecystitis.

METHODS: Between January 2002 and December 2005, all American Society of Anesthesiologists classification (ASA) I, II and III patients with acute cholecystitis were treated laparoscopically during the urgent (index) admission. The patients were divided into three groups according to the timing of surgery: (1) within the first 3 d, (2) between 4 and 7 d and (3) beyond 7 d from the onset of symptoms. The impact of timing on the conversion rate, morbidity and postoperative hospital stay was studied.

RESULTS: One hundred and twenty-nine patients underwent laparoscopic cholecystectomy for acute cholecystitis during the index admission. Thirty six were assigned to group 1, 58 to group 2, and 35 to group 3. The conversion rate and morbidity for the whole cohort of patients were 4.6% and 10.8%, respectively. There was no significant difference in the conversion rate, morbidity and postoperative hospital stay between the three groups.

CONCLUSION: Laparoscopic cholecystectomy for acute cholecystitis during the index admission is safe, regardless of the time elapsed from the onset of symptoms. This policy can result in an overall shorter hospitalization.

Key words: Acute cholecystitis; Laparoscopic cholecy-

INTRODUCTION

Laparoscopic cholecystectomy (LC) has been established as the treatment of choice for the management of acute cholecystitis (AC), despite initial reservations, regarding the impact of this policy on the conversion rate and morbidity^[1]. Several prospective randomized trials^[2-4] suggest the superiority of early (within 72 h) over the delayed (after a few weeks interval) intervention. This 72 h limit, however, is difficult to be kept in many cases for a variety of reasons, referring to both patients and physicians. On the other hand, there is a paucity of solid data as to what happens in the period after this 72 h time frame. The speculation of a worse outcome, when attempting LC for AC during the urgent admission beyond this very early phase, is experience rather than evidence-based.

In our daily practice, we have realized that only a small number of patients with AC are managed surgically within this "gold window" of 72 h from the onset of symptoms. If the remaining majority of patients with AC are managed conservatively with interval cholecystectomy to follow, then an increased total hospitalization and subsequently increased cost can be expected. Furthermore, the subgroup of patients who do not respond to conservative treatment, as well as those who relapse while awaiting an interval cholecystectomy should be considered^[5]. For these reasons, we have adopted a policy of performing a LC during the initial emergency/urgent admission for "all comers" with AC, regardless of time delay between its onset of symptoms and surgery.

In view of this policy, we examined prospectively the impact of the duration of symptoms on mortality, morbidity, conversion rate and postoperative hospital stay in patients who underwent LC for AC during the urgent (index) admission.

MATERIALS AND METHODS

Subjects

Between January 2002 and December 2005, all American Society of Anesthesiologists classification (ASA) I, II and III patients admitted or referred to our unit with AC under the care of one consultant surgeon (GT) with a special interest in HPB and laparoscopic surgery, were treated with LC during the index admission, regardless of the time elapsed from the onset of symptoms. ASA IV patients were usually offered ultrasound-guided percutaneous cholecystectomy and therefore, were excluded from the study. Patients were considered having AC when they had five out of the following six positive criteria: persistent right upper quadrant pain, temperature > 37.5°C, WBC > 10 × 10⁹/L, positive Murphy's sign, presence of gallstones on ultrasound in combination with wall thickening and/or fluid at the gallbladder fossa. The diagnosis of AC was confirmed by intraoperative findings and pathologic specimens. Patients with strong evidence of concomitant common bile duct (CBD) stones were not excluded from the study, but were treated initially with preoperative endoscopic retrograde cholangiopancreatography (ERCP), sphincterotomy and CBD clearance, followed by LC after an interval of at least 24 h, in order to assure that no ERCP-related complication occurred. Patients with suspicion of CBD stones had preoperative MRCP, and if stones were detected, they were treated as above. Intraoperative cholangiogram was not performed in any of the cases. There were no other selection criteria and every effort was made to operate on all the patients as soon as theatre time was available, provided that any concomitant medical problem was previously dealt with. The latter resulted sometimes in what is called in the literature "physician delay"^[6]. Laparoscopic cholecystectomy was attempted in all cases under general anesthesia. The usual four-trocar technique was used (10 mm umbilical, 10 mm subxiphoid, 5 mm subcostal midclavicular line, 5 mm anterior axillary line) but additional trocar was used as necessary. The gallbladder was aspirated in most of the cases in order to be grasped, and dissection of the Calot's triangle structures was always performed close to the gallbladder wall. Retrograde dissection was only exceptionally performed, when in doubt about the triangle's structures after the initial dissection.

Methods

The patients were divided in three groups according to the time between onset of symptoms and operation: (1) within 3 d (early group), (2) between 4 to 7 d (intermediate group) and (3) ≥ 8 d (delayed group). All data including demographics, preoperative, operative findings and postoperative information were collected prospectively into a computerized database. The episode of AC was considered simple (oedematous, hydrops) or complicated (emphyema, gangrenous, emphysematous, concomitant choledocholithiasis or pancreatitis). The aim of the study was to detect the impact of the time elapsed from onset of symptoms to operation on the conversion rate, 30-d mortality, 30-d morbidity with special attention to bile duct injury incidence and length of postoperative hospital stay.

Table 1 Impact of delay in laparoscopic cholecystectomy on outcomes

Outcome	I: ≤ 3 d (n = 36)	II: 4-7 d (n = 58)	III: ≥ 8 d (n = 35)	P
Conversion rate	1 (2.8%)	2 (3.4%)	3 (8.5%)	NS
Mortality	0	0	0	NS
Morbidity	3 (8.3%)	6 (10.3%)	5 (14.2%)	NS
Postop hospital stay	2 (1-6) d	2 (1-14) d	2 (1-35) d	NS

NS: no significant difference.

Statistical analysis

Statistical analysis was performed using the Arcus Quickstat biomedical statistical package (Research Solutions, UK) with the median values for continuous variables presented with range in parentheses. Fisher's exact test and Mann Whitney U test were used as appropriate to compare the groups to each other. $P < 0.05$ (two-tailed test) was considered statistically significant.

RESULTS

One hundred and twenty-nine patients underwent LC for AC during the index admission according to the protocol. During the same period some 453 elective laparoscopic cholecystectomies were performed by the same team. Thirty-six of the patients with acute cholecystitis (28%) had their operation within the first 3 d from the onset of their illness, 58 patients (45%) between 4 to 7 d and the other 35 patients (27%) after the first week. None of our patients had a more than 48 h delay due to unavailability of theatre space. Any other delay from the onset of symptoms to operation was attributed to either patients' delayed presentation/referral to our unit or to concomitant medical problems needing to be addressed preoperatively. Special mention should be made of a subgroup of patients with AC whose surgery was delayed due to the intake of anti-coagulants or more often anti-platelet agents, due to the dramatically increased use of these drugs during the last decade.

The impact of timing of LC on outcomes is shown in Table 1. Although the conversion rate was somewhat higher in the "delayed" group, this difference was not significant when this group was compared to either the "early" ($P = 0.35$, Fisher's exact test) or the "intermediate" group ($P = 0.36$, Fisher's exact test). Similarly, there was no significant difference in mortality, morbidity and postoperative hospital stay between the three groups of patients. Interestingly, this was noted despite the fact that a significantly higher number of complicated cases of AC were found among patients of the "intermediate" group, compared to those who underwent earlier operations. This was also reflected on the operative time difference between the groups (Table 2). No major bile duct injuries occurred. Four cases had bile leak, two in the "intermediate" group and two in the "delayed" group. The first was attributed to the gallbladder fossa, the second from an avulsed cystic duct and the remaining two from a friable cystic stump.

The first case eased spontaneously after 48 h, the other three cases with bile leak were treated successfully with ERCP, sphincterotomy and stenting of the common bile duct. Other complications and their treatment are shown in Table 3.

DISCUSSION

Acute cholecystitis which is generally found in approximately 20% of all admissions for gallstone disease^[7] is no longer considered a contraindication for laparoscopic cholecystectomy. In fact, urgent LC is now considered the optimal treatment of patients with AC^[1]. Early LC has been proven superior to delayed interval LC in most of the prospective randomized trials. It results in a shorter hospital stay and a shorter recuperation time while the conversion rate and morbidity remain similar with or even lower than delayed interval LC^[2-4]. How early is “early” is not clear in the literature, as this parameter has not been effectively tested in controlled randomized trials. All these prospective randomized trials comparing early and delayed interval LC, refer to the first 48-72 h for the early group, making this group somewhat highly selected. In daily practice very few patients are able to have surgical treatment during this short period of time, due to either patient or/and physician delay^[6]. Very often patients present with delay or they are referred with delay by their physicians. Others suffer from co-morbidities needing consultation with other specialties preoperatively, while some require other intervention preoperatively, i.e. ERCP. A significant number of patients take oral anti-coagulants or anti-platelet agents requiring reversing before surgery. For all these reasons many patients in reality cannot have surgery within this time frame. In the present series some 72% of patients with acute cholecystitis were treated surgically during the index admission beyond the 72 h boundary, which is not very different from the reported experience by other authors^[8-10]. There were no solid data regarding the optimal policy for this large group of patients treated outside this 72 h boundary. To our knowledge, there is only one small prospective randomized trial designed to address this issue^[11]. Chandler *et al*^[11] found that there is no difference in the conversion rate or morbidity between the early group (n : 21, surgery as soon as theatre schedule allowed) and the delayed group (n : 22, surgery during the index admission, after resolution of symptoms or failure to resolve on 5 d course of conservative treatment). Results from other comparative non-randomized trials of early and delayed LC during the urgent admission for AC are rather conflicting and most of these however indicate a higher conversion rate for the delayed group, but no difference in morbidity^[6,8,9,12-14]. The definition of the so called “early” group among trials is also confusing. Some trials define early group counting from the time of admission or diagnosis rather than the time of onset of symptoms. This could be sometimes misleading, as the onset time of episode could differ significantly from the time of admission. We believe that counting from the onset of symptoms is more representative of the reality. Furthermore, all the studies were designed by using a boundary either of 48, 72 or 96 h from either onset of symptoms or time of admission, in order

Table 2 Demographic and perioperative characteristics of patients with acute cholecystitis

Characteristic	I: \leq 3 d ($n = 36$)	II: 4-7 d ($n = 58$)	III: \geq 8 d ($n = 35$)

^a $P < 0.05$, ^b $P < 0.01$ vs group I.

to compare the two groups of population. They included invariably patients who had surgery within the first 7 d for comparison. In our study, the patients were divided into three groups, including those who were treated surgically during the index admission even beyond one week from the onset of their illness.

Our findings are in accordance with previous studies, suggesting the safety of early LC for AC. The present study, however, does not support the findings of earlier reports, regarding the rising conversion rate, when LC for AC is performed after 72 h^[6,12,15]. Our data have shown that the timing of cholecystectomy does not influence the conversion rate, as recently shown by others^[8,10]. This is probably attributed to the very low conversion rate in the whole group of our patients, making any differences between the subgroups insignificant. Our total conversion rate of 4.6% for LC in AC is one of the lowest in the literature and only slightly higher than that in our team's experience with elective LC for the same period (~1%). Even one week after the onset of symptoms there was nothing to suggest increased risk with regards to the conversion rate and morbidity; this has never been challenged before. Another issue of concern in laparoscopic treatment of AC is the presumed increased risk of bile duct injury when the procedure is performed beyond the early edematous phase of the first 48-72 h. Our data do not support this traditional belief, as there was no major bile duct injury in any of the patients. It is possible that the majority of patients with AC who are deferred for interval LC because they are outside this “early window of chance” are faced with a “difficult” elective cholecystectomy after few weeks^[16]. Waiting for the gallbladder to “cool down” allows maturation of acute inflammation, neovascularization, fibrosis, and contraction, making the dissection more difficult, as it has been proposed by others^[9]. While inflammation in the early stages may not necessarily involve Calot's triangle structures, chronic inflammation may scar and distort it, making dissection in this critical area more difficult and prone to bile duct injuries.

In conclusion, our data show that LC for AC during the index admission is safe and associated with a low morbidity and a low conversion rate. These findings refer not only to those patients who undergo surgical treatment very

Table 3 Complications and their treatment

(1) Bleeding Laparotomy d 1	(1) Subhepatic collections Percutaneous CT guided drainage Laparotomy after failed percutaneous	(1) Bleeding from drain site Drain removal
(1) Wound infection (converted) Wound opening	(1) Re-admission at postop day 15 with cholangitis ERCP & sphincterotomy (1) Chest infection Antibiotics, physiotherapy	(1) Severe pancreatitis ICU admission (1) Readmission at postop d 6 with DVT Heparin

Complications are presented with parentheses to indicate the number of patients suffered the complication; under the complication line the way of management for each case (without numbers) is presented.

early, but also to those treated after the window of the first 3 or 7 d from the onset of symptoms. Further prospective randomized trials focusing on this particular question are required to validate these results. However, it appears reasonable to state that in units with expertise in laparoscopic surgery, every effort should be made to operate on all patients with AC during the index admission as soon as diagnosis is made and co-morbidities are dealt with, regardless of the time delay from the onset of symptoms. This policy is safe, not associated with a higher conversion rate or morbidity and results in an overall shorter hospitalization by avoiding re-admissions.

Abstract

AIM: To assess the clinical, biochemical, and virological outcome during long-term follow-up of chronic hepatitis C patients with sustained virological response following effective antiviral therapy.

METHODS: This study was a retrospective cohort study including 171 sustained responders defined as HCV RNA PCR negative at 6 mo after the end of effective antiviral treatment (SVR-6). Clinical signs and symptoms, biochemical hepatic parameters, ultrasonography and HCV RNA PCR were followed.

RESULTS: Mean follow-up period was 35.38 ± 22.2 mo after the end of treatment. Twenty-seven (15.8%) responders had evidence of cirrhosis before treatment. Forty-eight (28.1%), 107 (62.6%) and 6 (3.5%) patients were genotype 1, 3, and 6 respectively, while 10 patients (5.8%) were unclassified. There were no virological and biochemical relapses during the period of follow-up. None of the patients showed evidence of hepatic decompensation. However, there were 3 patients (1.8%) developing hepatocellular carcinoma at 14, 18, 29 mo after treatment discontinuation, two of whom had evidence of cirrhosis prior to therapy.

CONCLUSION: The study shows that during a follow-up interval for about 3 years in 171 chronic hepatitis C patients with sustained viral response after effective antiviral treatment there were no evident signs of either biochemical or clinical relapse of liver disease in all but three patients who developed hepatocellular carcinoma.

Key words: Chronic hepatitis C; Sustained virological re-

INTRODUCTION

Chronic hepatitis C viral (HCV) infection is well recognized as a major cause of cirrhosis and hepatocellular carcinoma. Spontaneous remission of the disease seems to be rare. After alpha-interferon was used as therapy for HCV infection in 1986^[1], Interferon associated with Ribavirin became the standard treatment for this disease. Sustained virological response, defined as HCV RNA PCR negative at 6 mo after the end of treatment (SVR-6), is considered to be a useful predictor for long term response^[2], since the probability of a late relapse among sustained responders was only 4.7%-8.7%^[2-5], and a sustained response is associated with decreased histological activity on liver biopsy^[6,12]. Moreover, the disappearance of detectable plasma HCV RNA has fostered the notion that sustained responders may be cured of the disease^[4].

From most of the studies, SVR-6 can be obtained in 40%-60% of individuals infected with genotype 1 and in a higher percentage (75%-85%) of subjects with genotypes 2 and 3^[5]. However, there are only few studies reporting long-term outcomes in patients who had SVR-6^[1-4,6-8], especially in Asian population. In this study, we assessed the long-term clinical, biochemical and virological outcome of Thai HCV patients with sustained virological response.

MATERIALS AND METHODS

Study design

Chronic hepatitis C patients with SVR-6 from Hepatology Unit, Faculty of Medicine, Mahidol University (Siriraj Hospital), Bangkok, Thailand from 1995 to 2005 were included in this retrospective cohort study.

Patients

The criteria required for the study included: evidence of

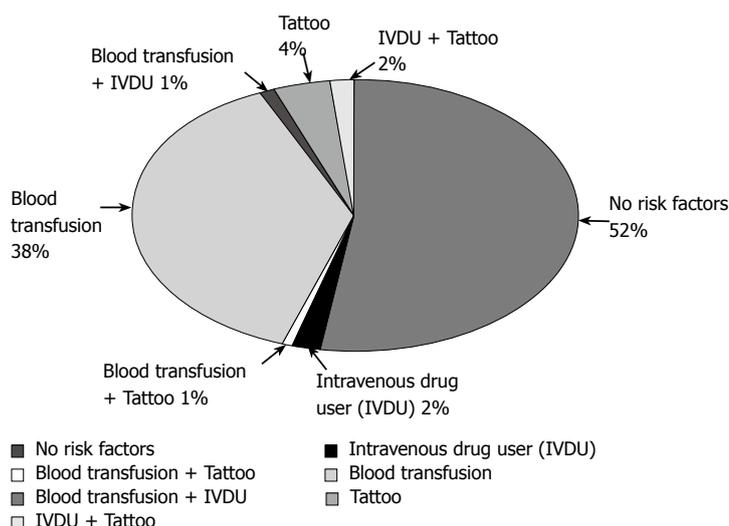

Figure 1 Routes of infection.

chronic HCV infection as defined by HCV RNA PCR positive by Roche AmpliCor HCV Assay[®] (with a detection limit of 100 copies/mL), age of 18 years or older, and sustained virological response after effective antiviral treatment. Patients co-infected by chronic hepatitis B virus and/or human immunodeficiency virus and patients where complete data could not be retrieved were excluded from the analysis.

Data were obtained from 171 chronic hepatitis C patients who responded to interferon therapy. Data were collected from case record forms. Patients treated with conventional interferon, PEG-interferon α -2a and PEG-interferon α -2b were 54.4%, 17% and 28.6% respectively. Twenty-one patients (12.3%) required therapy twice to achieve SVR-6. Duration of therapy was 24 wk for responders with genotype 3 infection, while non-responders and other HCV genotypes patients were treated for 48 wk.

Data recorded

The investigators recorded demographic data, details of treatments (type of interferon used and duration of therapy), virological data (genotypes and viral loads) and biochemical data (bilirubin, transaminases and albumin levels) obtained from certified laboratories. Pre-treatment liver biopsies were done in 105 of the 171 patients using the Histology Activity Index (HAI) score. Mean histological score and fibrosis score were 7.72 ± 4.08 (range 1 to 18) and 1.51 ± 1.3 (range 0 to 4) respectively.

Sustained virological response was defined as no detectable HCV RNA PCR at the end of treatment and after six months of follow up.

Patients were considered to have decompensation if they showed any of the following findings: ascites, bleeding varices, jaundice, or hepatic encephalopathy. Patients were classified as having cirrhosis on the basis of ultrasonography or liver biopsy. Hepatocellular carcinoma was diagnosed from ultrasonography or other imaging

Table 1 Characteristics of 171 HCV infection patients with SVR-6 ($n = 171$)

Characteristics	
Age (yr)

studies.

Sustained virological responders were considered to have a late virological relapse if HCV RNA PCR became detectable on any occasion after six months of follow up, confirmed by HCV viral load study.

Follow-up data was recorded every six or twelve months for clinical, biochemical and virological outcomes.

Statistical analysis

Statistical analyses were performed using SPSS version 10 for Windows. The descriptive statistics and Paired *t*-Test were used to analyse. The Kaplan-Meier method was used to determine the rate of hepatocellular carcinoma occurrence.

RESULTS

Study population

Data were obtained from 171 patients treated for chronic HCV infection who had SVR-6. The ages of the patients were 48 ± 10.5 years. Male to female ratio was 1.12:1. Routes of infection are shown in Figure 1. Characteristics of sustained virological responders are shown in Table 1.

Of 171 sustained responders, 27 patients (15.8%) had compensated cirrhosis (as determined by liver biopsy or imaging study) before the start of treatment.

Clinical, biochemical and virological studies were followed up to 35.38 ± 22.2 mo (range 8 to 134 mo) after the end of treatment.

Clinical outcomes

At the end of follow-up, all patients were fully active and alive. No new cases of cirrhosis appeared. Of the 27 patients with cirrhosis, none developed decompensated liver disease. Hepatocellular carcinoma, as assessed by abdominal ultrasonography every 6 mo were found in three patients at 14, 18 and 29 mo of follow-up. The details of these patients are shown in Table 2. Their HCV RNA values were still undetectable at the time of the diagnosis

Table 2 Features of the three hepatocellular carcinoma patients

	Case 1	Case 2	Case 3
Age (yr)	50	75	63
Sex	Male	Male	Male
Previous cirrhosis	Yes	Yes	No
Onset after the end of treatment (mo)	14	18	29
Alfa-fetoprotein (IU/mL)	433.7	2.09	21.59
Size at first detection	3 cm	1.5 cm	1 cm, 3 lesions

of hepatocellular carcinoma. Two of them had cirrhosis before treatment. From the statistical analysis of this data, it showed that, after a median follow-up period of 31 mo, the incidence of developing hepatocellular carcinoma in SVR-6 patients was no more than 1.8%.

Biochemical and virological outcomes

There was a significant reduction of aminotransferase levels after SVR-6. The pre-treatment and post-treatment values of AST were 84.3 ± 48.9 and 27.7 ± 12.9 , while ALT were 120.4 ± 81.2 and 25.2 ± 15.3 U/L (the normal values of AST: 0-37 and ALT 0-40 U/L).

No late virological relapse was found. Four (2.3%) of the 171 sustained responders had false positive HCV RNA PCR (confirmed by HCV RNA viral load less than 50 IU/mL).

DISCUSSION

We assessed the long term outcome of 171 patients with chronic hepatitis C who achieved sustained virological response by effective antiviral treatment. Our result demonstrated that SVR-6 was associated with a permanent absence of HCV viremia during the long-term follow-up in all cases. However, this finding showed better result than previous reports which had a late virological relapse between 4.7%-8.7%^[2,3]. The reasons may due to: (1) the smaller number of patients included compared to previous studied; (2) fewer HCV genotype 1 included compared; (3) more than half of our patients were infected by genotype 3 (this type is known to have a more favorable prognosis), and (4), the low sensitivity of HCV RNA PCR tests used in the studies before 2000 that may potentially account for few apparent early virological responses.

Disease progression such as development of cirrhosis seems to arrest after the stage of SVR-6, but a risk of developing hepatocellular carcinoma is still remaining. The incidence of hepatocellular carcinoma from our study at a mean follow-up period about 3 years is 1.8% which is slightly higher than the previous results reported from Japan (0.02%-0.5% per year)^[3,9,10], while the incidence of hepatocellular carcinoma in western countries seems to be rare after SVR and limited only to patients with cirrhosis^[4,11]. Therefore, regular ultrasonography should not be discarded for the management of cirrhotic patients, even in those showing persistently normal aminotransferase, alfa-fetoprotein and undetectable HCV RNA levels after interferon treatment.

In summary, this long-term study shows that in chronic

HCV infection, sustained responders to interferon attain remarkable improvement of clinical outcomes. This supports the hypothesis that persons with sustained responses to interferon-therapy show a low risk for further relapse of HCV infection, development of cirrhosis and hepatocellular carcinoma^[3,4,6,7,12]. However, the follow-up period of these patients was too short to allow a definite conclusion about the potential effect of the sustained response to interferon therapy for prevention of progressive liver disease.

Abstract

AIM: To compare the efficacy and acceptance of senna tablet and sodium phosphate solution for bowel preparation before colonoscopy.

METHODS: One hundred and thirty four patients, who needed elective colonoscopy, were randomly allocated to take 180 mg senna tablet or 95 mL sodium phosphate solution on the day before colonoscopy. The efficacies of both laxatives were compared using the mean difference of colon-cleanliness score of the rectum, sigmoid segments, descending colon, transverse colon and cecum. The scores were rated by two observers who were blinded to the laxatives administered. The higher score means that the colon is cleaner. The efficacy of both laxatives were equivalent if the 95% confidence interval of the mean difference of the score of colon lie within -1 to +1.

RESULTS: On intention-to-treat analysis, the mean cleanliness scores in the four segments of colon except the cecum were higher in the sodium phosphate group than those in senna group (7.9 ± 1.7 vs 8.3 ± 1.5 , 8.0 ± 1.8 vs 8.5 ± 1.4 , 7.9 ± 2.0 vs 8.5 ± 1.3 , 7.9 ± 2.0 vs 8.2 ± 1.4 and 7.2 ± 1.7 vs 6.9 ± 1.4 , respectively). The 95% confidence intervals (95% CI) of mean difference in each segment of colon were not found to lie within 1 point which indicated that their efficacies were not equivalent. The taste of senna was better than sodium phosphate solution. Also, senna had fewer side effects.

CONCLUSION: The efficacy of senna is not equivalent

INTRODUCTION

Adequately cleansed colon is essential for colonoscopy. Inadequate bowel preparation might lead to missed diagnosis, increasing the time of colonoscopy by 7.5%-10.3% and increasing cost 12%-22%^[1]. Ness *et al*^[2] reported that the incidence of inadequate bowel preparation was 21.7% and 5.4% had poor preparation leading to cancellation or abortion of procedure. Currently, the laxatives of choice for bowel preparation are sodium phosphate solution (NaP) and polyethylene glycol solution (PEG). Despite its efficacy^[3-5], phosphate solution has poor taste. It may cause electrolyte imbalance, severe nausea and vomiting. The advantage of PEG is its minimal effect on intravascular volume and serum electrolyte balance, but this large-volume laxative is difficult for many patients to tolerate. Although PEG and NaP are equally effective in colonic cleansing^[6], NaP is better tolerated. However, NaP may be contraindicated in certain patient populations. The selection of a colonoscopy preparation requires clinical judgment, cost and informed patient preference^[7,8].

Senna (*Cassia angustifolia* Vahl, *Leguminosae*, Indian senna, Tinnevely senna) is a laxative that stimulates the intestinal motility and affects epithelial transport of water and electrolytes. The main advantages of senna are low cost, safety and ease of ingestion. It had been combined with other laxatives for bowel preparation, and their efficacy ranged from 70% to 85%^[9-12]. There are few studies on the efficacy of high-dose senna tablet alone. The aim of

this study was to compare the efficacy and acceptance of senna tablet and sodium phosphate solution for bowel preparation before colonoscopy.

MATERIALS AND METHODS

The study was carried out as a randomized, controlled (equivalent), single-blind trial from June to November 2003. The study population consisted of adult patients who required elective colonoscopy. The exclusion criteria were: (1) known allergy to senna or sodium phosphate solution; (2) presence of severe metabolic, renal and cardiac conditions; (3) bed-ridden or psychotic patient; (4) pregnancy; (5) patient taking laxatives within one week prior to enrollment; and (6) patients who had previous colonic resection surgery. The study was approved by the Ethical Committee Board of the hospital.

The patients were allocated into two groups and they were advised to take full liquid diet two days before colonoscopy. The control group took sodium phosphate solution (Swift® 90 mL, Berlin Pharmaceutical Industry Co. Ltd., Thailand). The experimental group took senna tablet, 180 mg (24 tablets of 7.5 mg /tab, Senokot®, Reckitt Benckiser, Thailand). The patients took the laxatives in divided doses at 14.00 pm and 16.00 pm on the day before colonoscopy. Since the duration of action of NaP is within 6 h, so the laxatives should not interfere the patient's sleeping time.

Data collection

Shortly before colonoscopy, nurses interviewed each patient to assess compliance, acceptance and side effects of laxatives by using visual analog scale. The colonoscopist and his assistant independently rated the quality of bowel cleansing, using visual analog score (VAS) as followed: 0-2 = numerous solid feces, 3-5 = semi-solid feces, 6-7 large volume of liquid feces, 8-10 = small volume of clear liquid or no feces. In an equivalent trial^[13], it was important to pre-specified that (1) the mean score should lie above seven to assure that both laxatives were effective, and (2) the 95% confidence intervals of the mean difference lie between -1 and +1 VAS score in all segments of colon. The sample size calculation was based on testing equivalence with power 0.8 and 10% drop out^[14]. The variance of VAS score from our pilot study was 2.93.

Before data analysis, the 95% limit of agreement^[15] of cleansing score between two colonoscopists will be calculated to confirm the agreement on the assumption that the mean score difference between them should lie within two points. The score used for analysis were the average score from two colonoscopists. The VAS score for acceptance and side effects of the two laxatives were analyzed using Student's *t* test. The outcome variables of accepted and side effects of laxatives were also measured using VAS score. The patients were asked to grade the taste of the laxative as follows: 0-2 = hard to ingest, 3-5 = ingested with very bad feelings, 6-7 = easily ingested, and 8-10 = easily ingested with good feelings. The scores of the side effects (nausea and vomiting, abdominal pain, vertigo and sleeplessness) were rated as follows: 0-2 = no symptom, 3-5 = mild symptom, 6-7 = moderate symp-

Table 1 Demographic and baseline colonoscopic data of the patients (n = 67)

Characteristics of patients	Senna	NaP
Sex (M/F)	22 : 45	30 : 37
Age (yr, mean ± SD)	54.3 ± 12.7	51.6 ± 12.6

Sleeplessness	1.2 ± 2.7	1.4 ± 2.5	<i>P</i> = 0.65
Adverse event	2:67	2:64	

tom, and 8-10 = severe symptom.

RESULTS

Patient's flow in this study is shown in Figure 1. One hundred and seventy patients were enrolled, but thirty patients did not meet eligibility criteria. One hundred and thirty-six patients were randomly allocated to take senna tablet or NaP solution. Two patients did not take laxatives due to error in packaging. Among the 134 patients who took a laxative, 3 patients did not attend colonoscopy and 10 patients did not have complete colonoscopy for various reasons.

Both groups of patients were comparable with regard to demographic data, diagnosis and other colonoscopic data (Table 1). However, the efficacy of senna tablet was not equivalent to NaP solution (Table 2). The mean

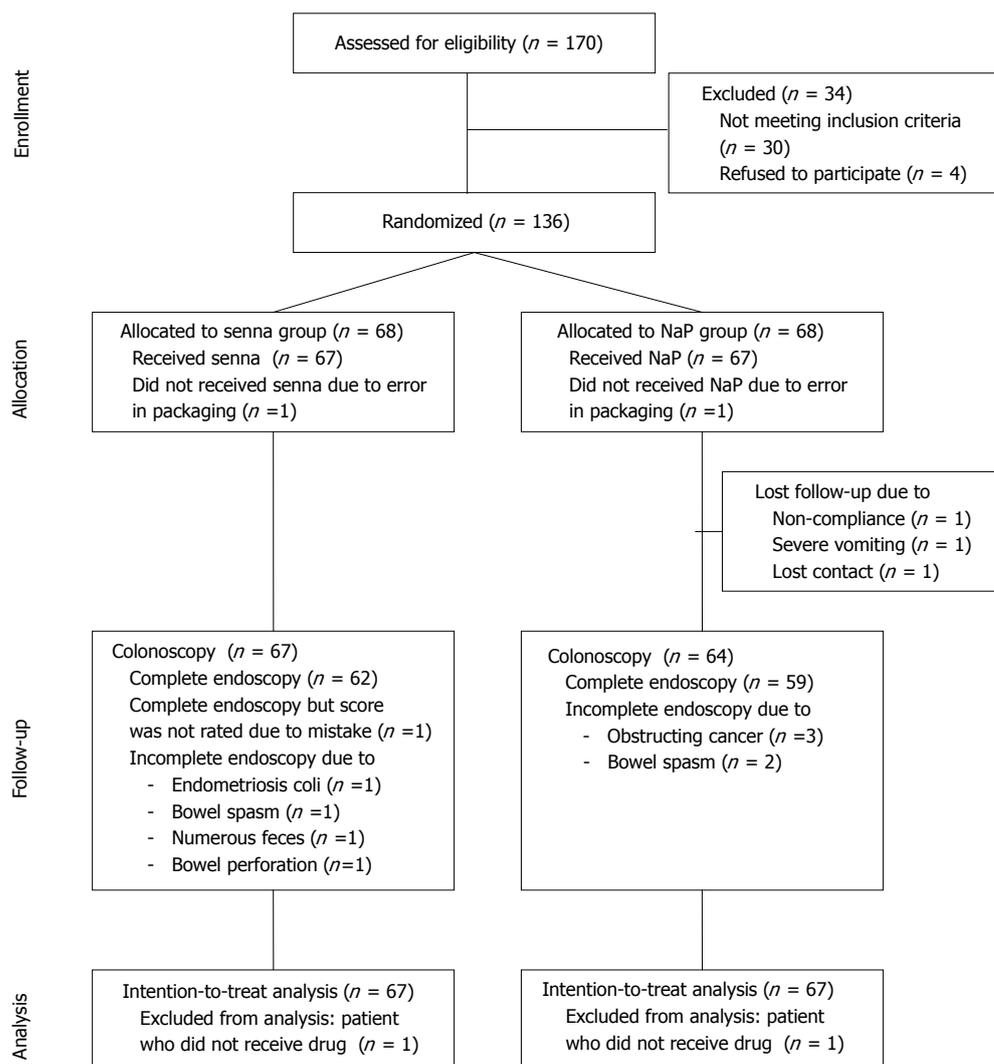

Figure 1 Flow diagram of patients progress through the phases of a randomized trial.

cleansing scores of NaP solution were higher than senna tablet in four segments of the colon except in the ascending colon and the cecum. The 95% CI of the mean difference exceeded 1 point in three segments of the colon. In the other two segments of the colon, they lied nearly over 1 point. By intention-to-treat analysis, we included all patients who had taken the laxatives whether they had complete or incomplete colonoscopy. For the missing data in both groups, we assigned the lowest score in each group (worst-case approach). For example, the lowest cleansing score in senna group was two, while that in NaP group was four.

The cleansing score, acceptance score and side effects of the two laxatives are shown in Table 2. The patients accepted senna tablets more than NaP solution and those patients who took senna tablets had less nausea and vomiting. There were four adverse events in this study. In the senna group, 1 patient had post-polypectomy bleeding which ceased spontaneously, and 1 patient had sigmoid perforation during colonoscopy due to fixation of the sigmoid colon; this patient had received long-term steroid treatment of myasthenia gravis and also had previous left hip surgery. In the NaP group, 2 patients had broncho-

spasm after colonoscopy and both recovered after 24 h.

DISCUSSION

NaP solution and PEG had widely been used for bowel preparation because of their similar efficacy, Hwang *et al*^[16] claimed that NaP group had higher completion rate than PEG group (84.2% *vs* 27.5%, $P < 0.001$) and NaP appeared to be more cost-effective^[16]. In contrast, senna was not popular for bowel preparation. Fear of adverse effects might responsible for its underuse. Serious adverse effects of senna, such as asthma, hepatitis, hypertrophic osteoarthropathy, cachexia, hypo-gammaglobulinemia, finger clubbing and tetany, had been reported^[17-21]. However, these adverse effects were uncommon and resulted from long-term and large amount used. There are no epidemiologic data to support neoplastic potential of senna compound^[22]. The inconsistent efficacy of senna might be another reason for its underuse. Two studies by Chilton *et al*^[11] and Valverde *et al*^[23] showed that senna (X-prep) solution alone or senna in combination with other laxatives were better than PEG or NaP solution. On contrary, two other studies by Dahshan *et al*^[24] and Arezzo *et al*^[12] showed that

those standard laxatives were better than senna. Moreover, Hangartner *et al*^[9] and Borkje *et al*^[10] concluded that senna has no clinical difference compared with those laxatives. Radaelli *et al*^[25,26] had claimed that high-dose senna had 97.3% efficacy in bowel cleansing, and that 288 mg of senna was better than 4 L of PEG-ES (90.6% *vs* 79.7% efficacy, $P = 0.003$). In contrast, our study showed that 180 mg of senna tablets did not have equivalent efficacy as NaP solution. The inconsistencies of these results were hardly explained. Bowel cleansing may be affected by other factors, such as gender, age, obesity, race, constipation, previous abdominal surgery and associated complicated diverticular disease^[27]. In addition, the mean score of senna group was also above seven points and we imply that senna has some effect in bowel cleansing and it may be alternative laxative for bowel preparation.

In addition, we noticed that the mean cleansing score of cecum in the senna group was higher than that in the NaP group. This phenomenon might be related to timing of laxative intake. Church *et al*^[28] suggested that the patients who took laxatives 5 h before colonoscopy had better result than patients who took laxative 1 d before colonoscopy. The VAS scores of taste, nausea and vomiting in the senna group were significantly better compared with the NaP group (Table 2). However, in term of pain symptom, senna was not found to be better than NaP. These findings confirmed our rational background knowledge that senna had more palatability and less nausea and vomiting than NaP solution. The adverse events occurred in 4 patients were not related to laxatives but were related to colonoscopy or anesthetic procedure.

In conclusion, senna does not have the same efficacy as oral NaP solution. However, senna has better compliance and fewer side effects than NaP. Senna may be prescribed as an alternative laxative for bowel preparation in patients who have contraindications to NaP solution.

Abstract

AIM: To ultrasonographically evaluate the acute effects of smoking on gallbladder contraction and refilling in chronic smokers and nonsmokers.

METHODS: Fifteen chronic smokers (21-30 years old) and fifteen nonsmokers (21-35 years old) participated in this study. Chronic smokers were selected among the volunteers who had been smoking for at least 5 years and 10 cigarettes per day (mean 17.5/d). Examinations were performed in two separate days. In the first day, basal gallbladder (GB) volumes of volunteers were measured after 8-h fasting. After the examinations, participants had a meal containing at least 30-40 gram fat. Gallbladder volume was assessed at 5, 15, 30, 60, 120 and 180 min after the meal. In the second day, participants smoked 2 cigarettes after 8-h fasting. Then, they had the same meal, and gallbladder measurements were repeated at the same time points. Same procedures were applied to both groups.

RESULTS: The mean starving GB volumes were 23.3 ± 3.3 mL in the first day, 21.9 ± 3.0 mL in the second day in nonsmoker group and 18.3 ± 3.0 mL in the first day, 19.5 ± 2.8 mL in second day in smoker group. There was no significant difference between starving GB volumes. We did not find any significant difference between the GB volumes measured at 5, 15, 30, 60, 120 and 180 min in the first and second days in nonsmoker group. In smokers, post cigarette GB volume was found significantly higher at 5, 15 and 30 min which corresponded to GB contraction phase ($P < 0.05$). Control GB volume measurements were not significantly different between the two groups. Post-smoking GB volumes were also not significantly different between the two groups.

CONCLUSION: Smoking prolongs the maximal GB emptying time both in smokers and in nonsmokers though it is not significant. It delays GB contraction in

chronic smokers and causes a significant decrease in GB emptying volume. Smoking causes no significant delay in GB refilling in both smokers and nonsmokers. These effects of smoking observed in acute phase result in bile stasis in GB. Bile stasis is the underlying cause of most GB disorders in chronic process.

INTRODUCTION

Smoking is still widespread in many societies despite the recognized relationship of it with many diseases. It is one of the risk factors for lung, stomach, larynx, esophagus, and some other cancers. Its association with lung cancer has been well described. Besides, smoking carries an important risk of developing cardiovascular diseases^[1]. Chronic pulmonary diseases, gastric ulcers, and many other diseases are increased among smokers. Some reports showed that smoking increases the risk of gallbladder cancer^[2]. Many prospective studies have found an association between smoking and clinical gallbladder disease^[3-6]. On the other hand, no relation has been found between smoking and gallstone formation in some other reports^[7,8]. A population-based study reported that sonographically detected gallbladder diseases are associated with smoking and are moderately increased in smokers^[9]. Some epidemiologic researches focused on the relation of smoking and gallbladder diseases, but they have not found any positive relation^[10,11]. There are a limited number of studies in the literature evaluating the effect of smoking on gallbladder motility by ultrasonography. Janderko *et al.*^[12] evaluated gallbladder contraction and refilling in chronic smokers by ultrasonography and found that refilling is delayed. In our study, we evaluated the gallbladder volume changes in contraction and refilling periods in both smokers and nonsmokers by

ultrasonography. We compared the obtained data of both groups. To our knowledge, there is no other study in the literature evaluating the effects of smoking on gallbladder in the acute period in smokers and nonsmokers by ultrasonography.

MATERIALS AND METHODS

Subjects

Fifteen smoker (10 women and 5 men) and 15 nonsmoker volunteers (9 men and 6 women) were included in the study. The mean age of smokers was 24.2 years (21-30 years), and the mean age of nonsmokers was 28.1 years (21-34 years). Volunteers having smoked for at least 5 years were included in group of smokers. The mean smoking rate in this group was 17.5 cigarettes per day (10-25). None of the volunteers had gastrointestinal disorder, gallbladder disease, any disease like diabetes mellitus that could affect gallbladder, or any previous surgery of gastrointestinal tract. Prior to 48-h and during the study, no medicine or smoking was allowed. A preliminary gallbladder sonography was performed and only the volunteers without any gallbladder abnormality were included in the study. All participants gave their informed consent.

Study design

Gallbladder volumes of all volunteers were measured twice in two separate days. At least 8 h after the last meal, participants were taken into the dimly lighted sonography room at a temperature of 22-24°C. A 3.5 6 MHz convex broadband (tissue harmonic) abdominal transducer (Toshiba, Nemio, Tokyo-Japan) was established for the measurements. All measurements were performed in supine, left lateral, and lateral decubit positions in which gallbladder cross-sectional and longitudinal diameters were best visualized. The best imaging position of gallbladder was recorded for each participant and used in following measurements. The most appropriate transducer position was noted for each volunteer and marked on the skin. Cross-sectional diameters were calculated from the widest diameters measured during sonography. The longest axis of the gallbladder was established as the longitudinal diameter. The distance between internal margins of each opposite wall was used for the measurement of diameters. The subjects with significant folding of gallbladder or the subjects whose longitudinal diameter could not be viewed in a single frame were excluded from the study.

Longitudinal and cross-sectional diameter measurements were repeated three times and the mean of these three measurements was established. Gallbladder volume was calculated with the formula $V = (\pi/6) \times L \times W \times H$, where V = GB volume, L = GB length, W = GB width, H = GB height, as previously described^[13].

Study methods

Gallbladder volumes of all volunteers were measured twice in two separate days. In the first day (control examination) after 8-h (at least) overnight fasting, basal GB volumes were measured. Then, 30-40 g fat-containing meal was given to the volunteers and participants were told to eat the

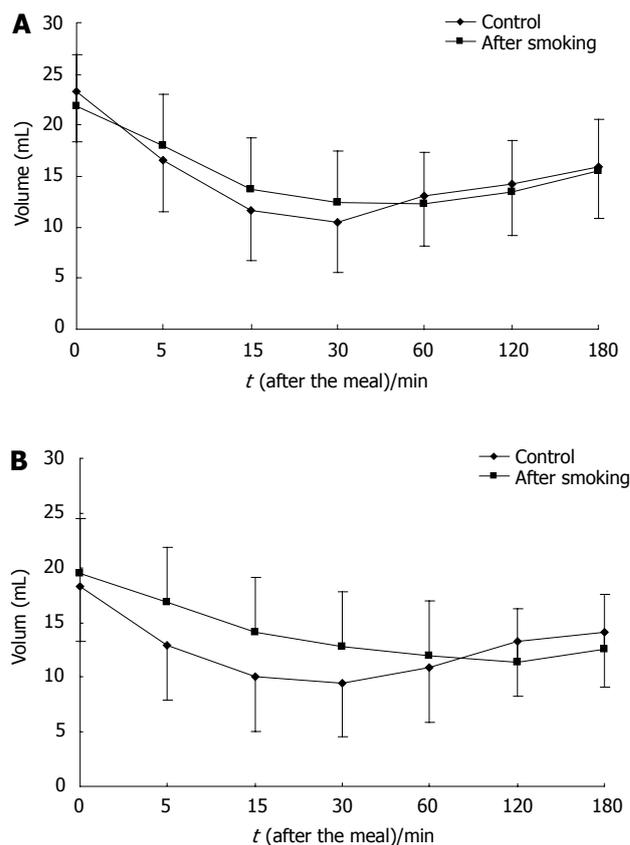

Figure 1 Effect of smoking on gallbladder emptying and refilling in nonsmokers (A) and smokers (B).

meal up in 2 min. After that, GB volumes were measured at 5, 15, 30, 60, 120 and 180 min. Contraction phase as the measurements till 60 min, and refilling phase was presumed as the measurements at 120 and 180 min. To avoid the start of cephalic phase of digestion, volunteers and meals were kept in separate rooms until the examinations. In the second day (study examination), after an overnight fasting, two cigarettes were given to the participants who were encouraged to consume the cigarettes in 5-10 min with deep inhalations. Approximately 3 min after the smoking, a meal containing 30-40 g fat, was given to the volunteers. Then, GB volumes were measured at 5, 15, 30, 60, 120 and 180 min. The same procedures were repeated in smoker and nonsmoker groups.

GB volume changes versus time were presented graphically for both two groups using the pre- and post-smoking values (Figure 1A and B). Acquired data are shown on Tables 1 and 2 by comparing them between the two groups and within each group.

Statistical analysis

Values are presented as mean \pm SD. The paired and two-tailed Student's *t* tests were used. $P < 0.05$ was considered statistical significant.

RESULTS

There was no difference in body mass index and age between smokers and nonsmokers. The mean fasting GB

	Control	After smoking	<i>P</i>	Control	After smoking	<i>P</i>
0	23.3 \pm 3.3	21.9 \pm 3.0	0.175	18.3 \pm 3.0	19.5 \pm 2.8	0.371
5	16.5 \pm 2.9	18.0 \pm 2.8	0.174	12.9 \pm 2.1	16.9 \pm 2.5	0.022
15	11.7 \pm 2.5	13.7 \pm 2.6	0.080	10.0 \pm 1.5	14.1 \pm 1.6	0.011
30	10.5 \pm 1.9	12.4 \pm 2.1	0.432	9.5 \pm 1.6	12.8 \pm 1.7	0.042
60	13.1 \pm 2.4	12.3 \pm 2.0	0.756	10.9 \pm 1.5	12.0 \pm 1.6	0.359
120	14.2 \pm 2.5	13.5 \pm 1.8	0.859	13.3 \pm 2.9	11.3 \pm 1.5	0.398
180	15.9 \pm 2.5	15.5 \pm 1.9	0.508	14.1 \pm 2.9	12.6 \pm 1.7	0.449

volume in nonsmoker group was 23.3 \pm 3.3 mL in the first day and 21.9 \pm 3.0 mL in the second day, and was 18.3 \pm 3.0 mL in the first day and 19.5 \pm 2.8 mL in the second day in smoker group. Although the fasting GB volumes did not differ significantly, these values were lower in smoker group. In the first day, minimum GB volumes (in other words, maximal GB emptying) were measured at 30 min in both groups.

However, the post-smoking measurements in the second day were performed at 60 postprandial minute in nonsmoker group, and at 120 min in smoker group (Figures 1A and 1B). Smoking delayed the maximal GB emptying in both smokers and nonsmokers. Besides, in both groups, GB refilling was faster in the first day and slowed down in the second day (Figure 1A and B). In nonsmoker group, GB volumes measured at 5, 15, 30, 60, 120 and 180 min in the first and second days were not significantly different (Table 1). GB volume was significantly higher in smoker group at GB contraction phase (5, 15 and 30 min) after the two cigarettes were smoked ($P < 0.05$, Table 1). There was no significant difference between two groups both in basal GB volume measurements and in post-smoking measurements between the two groups (Table 2).

DISCUSSION

In this study, we showed the disrupted GB contractility in smokers and delayed maximal GB emptying both in smokers and nonsmokers just after smoking. Although our study group was small in size, basal GB volume had a tendency to be lower in smokers than in nonsmokers. However, this difference was not statistically significant. Many epidemiologic studies have reported a mild or moderate association between smoking and gallstone or postcholecystectomy state^[4,6,10,11]. On the other hand, no association has been detected between smoking and gall stone formation^[7,8,14]. It is not clear which biologic mechanism is mediated in the predisposition of smoking to gallstone formation. Some authors suggested that smoking lowers the plasma high-density lipoprotein cholesterol level which increases risk of gall stone formation by decreasing hepatic excretion of the bile acids^[15]. Estrogen is blamed for gall stone formation because of high incidence of gallstone in women. In respect to this, some studies have shown high plasma estrogen level in smokers^[16], while some others have not found any significant difference^[17]. Cholecystokinin, a proximal gut hormone, is a well

known mediator of GB contraction^[18]. It is the main determining factor for the postprandial GB discharge. Cholecystokinin starts GB contraction by affecting the pre-ganglionic cholinergic nerves. Cholecystokinin is released from mucosa cells by the arrival of stomach content that is rich in fat and protein to the small intestine^[19]. Smoking exerts an inhibitory effect on intestinal and gastric motility^[20-22]. As a result of decreased gut motility and delayed gastric emptying, cholecystokinin release is also decreased or delayed. Therefore, decreased GB contractility can be expected. However, in our study, smoking caused a nonsignificant and minimal decrease of GB contractility in nonsmoker volunteers. In addition, GB volume was slightly increased in post-smoking contraction phase in this group (Figure 1A). Previous studies have also reported similar results^[23]. On the other hand, we showed a significant difference of GB volume in post-smoking early contraction phase (postprandial 5, 15 and 30 min) of smokers (Table 2). It was also significantly higher in post-smoking 5, 15 and 30 min (Figure 1B). To the best of our knowledge, no data are available on whether this delay of GB contraction in smokers results from a disruption in the smooth muscle contraction mechanism of GB wall or from the delay of the blood cholecystokinin increase due to delayed gastric emptying. One of the limitations of this study is that the blood levels of cholecystokinin were not measured. According to Jonderko *et al*^[12], smoking delays GB refilling at acute phase in chronic smokers. Our results also showed that GB refilling was delayed after smoking both in smokers and in nonsmokers although not significant. Smoking suppresses pancreatic polypeptide release which plays an important role in GB refilling^[24,25].

In humans, disruption of GB emptying is associated with gallstone formation^[26]. Bile stasis and disrupted GB motility are important factors for gallstone formation^[27,28]. Delayed gallbladder emptying and reduced muscle contractility occur in chronic calculus, or in gallstone, cholecystitis^[29,30]. It was reported that acalculous cholecystitis is formed after inhalation of intense cigarette smoke in dogs^[31]. Impairment of gallbladder contractility may contribute to the clinicopathology of acalculous cholecystitis^[32].

In our study, smoking caused a nonsignificant prolongation of the maximal GB emptying time both in smokers and in nonsmokers at acute phase, delayed GB contraction in smokers, and decreased the GB emptying volume. Besides, smoking did not delay GB refilling

significantly in both groups. Because of all these acute effects, smoking comprises a risk for GB diseases. In the chronic process, smoking may have these effects by affecting GB smooth muscle contraction or by decreasing cholecystokinin release *via* the inhibition of intestinal motility, or by both. *In vitro* studies are needed to evaluate the effects of smoking on gallbladder smooth muscles and laboratory studies are required to show its effects on cholecystokinin release.

Abstract

AIM: To evaluate the furazolidone-based triple therapy in children with symptomatic *H pylori* gastritis.

METHODS: A prospective and consecutive open trial was carried out. The study included 38 patients with upper digestive symptoms sufficiently severe to warrant endoscopic investigation. *H pylori* status was defined based both on histology and on positive ¹³C-urea breath test. Drug regimen was a seven-day course of omeprazole, clarithromycin and furazolidone (100 mg, 200 mg if over 30 kg) twice daily. Eradication of *H pylori* was assessed two months after treatment by histology and ¹³C-urea breath test. Further clinical evaluation was performed 7 d, 2 and 6 mo after the treatment.

RESULTS: Thirty-eight patients (24 females, 14 males) were included. Their age ranged from 4 to 17.8 (mean 10.9 ± 3.7) years. On intent-to-treat analysis ($n = 38$), the eradication rate of *H pylori* was 73.7% (95% CI, 65.2%-82%) whereas in per-protocol analysis ($n = 33$) it was 84.8% (95% CI, 78.5%-91%). All the patients with duodenal ulcer ($n = 7$) were successfully treated (100% vs 56.2% with antral nodularity). Side effects were reported in 26 patients (68.4%), mainly vomiting (14/26) and abdominal pain ($n = 13$). Successfully treated dyspeptic patients showed improvement in 78.9% of *H pylori*-negative patients after six months and in 50% of *H pylori*-positive patients after six months of treatment.

CONCLUSION: Triple therapy with furazolidone achieves moderate efficacy in *H pylori* treatment. The eradication

INTRODUCTION

Available treatment regimens for gastritis due to *H pylori* show a lower success rate in children than in adult patients in the same geographic region. Several factors influence *H pylori* eradication rate, such as compliance with treatment, mutations generating resistances, sanctuaries (sites where there is no contact between the bacterium and antimicrobial drugs), deficiency in immunity of the host, low gastric pH, large infecting load, dormant forms and reinfection^[1]. *H pylori* treatment in children has specific difficulties and the success rate of the current options is worse than that in adults. It is speculated that in children there is less compliance with treatment and the prevalence of resistant strains is higher due to the greater exposure to antibiotics because of common childhood diseases. In addition, patients without peptic ulcer seem to present a lower success rate^[2].

The ideal treatment regimen for *H pylori* eradication should present a higher than 80% cure index on intention-to-treat analysis. Antimicrobial resistance is a major concern and in the past decade there was the emergence of clarithromycin-resistant strains, reaching 34.7% of isolates in some, mainly developed countries^[3-5]. Resistance occurs due to punctual mutations in the 23S rRNA^[5]. Nevertheless, in developing countries, resistance to metronidazole is highly prevalent, possibly due to overuse of this antimicrobial drug in gynecology and parasite treatment; thus this drug is not a viable alternative^[6]. Although amoxicillin resistance is regarded a rare phenomenon, recently there are an increasing number of

reports on resistant strains^[7].

Furazolidone emerges as an alternative for therapeutic regimens in developing countries due to its low cost and prevalence of resistant strains. This antimicrobial is a monoamine oxidase inhibitor usually utilized in the treatment of giardiasis. There are studies demonstrating its efficacy and safety in several developing countries^[8-12]. The drug has been used in *H pylori* treatment regimens since 1990, initially tested in China with a reasonable success rate and constitutes an alternative in situations where there is high resistance prevalence to nitroimidazoles. In our country a triple regimen with furazolidone, clarithromycin and omeprazole can attain a 90% cure in adult patients on intention-to-treat analysis^[13] while with furazolidone, levofloxacin and rabeprazole can reach 83% eradication as a third-line regimen^[14]. Consensus statements providing guidelines for the management of *H pylori* infection in children have made recommendations for therapy based on data derived from adult trials but have not provided suggestions on therapeutic options^[15,16]. The present study was to evaluate the triple regimen with omeprazole, clarithromycin and furazolidone for 7 d in children with *H pylori* gastritis, being the first study in children.

MATERIALS AND METHODS

Subjects

To warrant *H pylori* eradication, patients meeting the following criteria were included: (1) duodenal ulcer or erosive duodenitis ($n = 7$); (2) ulcer-like functional dyspepsia, according to the Rome II criteria, sufficiently severe to justify upper gastrointestinal endoscopy and without major mucosal abnormalities ($n = 29$)^[17]; (3) upper gastrointestinal bleeding ($n = 1$); (4) iron-deficiency anemia refractory to standard treatment ($n = 1$). Patients with former unsuccessful treatment for *H pylori* or with other organic diseases that could explain the symptoms were excluded. The study was approved by the Ethics Committee of the "Universidade Federal de São Paulo/Escola Paulista de Medicina". On inclusion of the patients in the study, the responsible person(s) received written information about the patients and signed a free and informed consent.

Diagnosis of infection

Endoscopic examination was performed by our team, under deep sedation or general anesthesia supervised by an anesthetist. Four biopsy specimens were collected from the gastric antrum at approximately 2 cm from the pylorus, two for rapid urease test and two for histological analysis. The latter two were fixed in 100 mL/L formol, placed on filter paper and stained with hematoxylin-eosin and modified Giemsa. The findings were described according to modified Sydney criteria^[18]. The histological diagnosis of the infection was established by an experienced pathologist, based on the typical appearance of the bacterium along the mucus layer covering the gastric mucous membrane. Rapid urease test was performed with a non-commercial solution (100 mg/mL aqueous urea solution with 10 mg/mL phenol red) as previously described^[19]. The patient

Table 1 Endoscopic findings

Endoscopic findings	n	%
Nodular gastritis	16	42.1
Normal	13	34.2
Duodenal ulcer or erosive bulbitis	4	10.5
Erosive duodenitis and nodular gastritis	1	2.6
Erosive gastritis	1	2.6
Nodular gastritis and esophagitis	1	2.6
Duodenal ulcer and esophagitis	1	2.6
Erosive duodenitis, esophagitis and nodular gastritis	1	2.6

was considered infected when both tests were positive and non-infected when both were negative.

H pylori treatment

The triple regimen was administered twice daily for seven days: 100 mg furazolidone or 200 mg furazolidone (> 30 kg), 250 mg clarithromycin or 500 mg clarithromycin (> 30 kg), 10 mg omeprazole or 20 mg omeprazole (> 30 kg). Antibiotics were prescribed after meals whereas omeprazole was administered before the first meal. Patients and their responsible persons were advised to maintain the treatment even with minor adverse effects. On the last day of the treatment, a complete physical examination was performed to evaluate the clinical conditions of patients. During this examination the patients were asked about adverse effects, and compliance was controlled by return of empty medication blisters. Compliance with treatment was defined by over 75% intake of the prescribed doses.

H pylori eradication

A renewed clinical and endoscopic evaluation was performed two months after the treatment, with collection of antrum and corpus biopsies for histology and rapid urease test. Patients whose responsible persons did not give consent to another endoscopy were evaluated using the ¹³C-urea breath test. This test was performed as previously described^[20]. The cutoff value of breath test was delta over baseline 4‰. The patients were submitted to a new clinical evaluation two and six months after treatment and asked about the progress of symptoms and the frequency and intensity of epigastric pain in those with dyspepsia.

Statistical analysis

Continuous variables were expressed by calculation of the mean and standard deviation. The eradication rates were expressed by calculation of the proportion with an 85% confidence interval (95% CI). Treatment groups were compared using Pearson's chi-square test with Fisher's exact test when necessary. Factors associated with treatment success were evaluated by estimation of the odds ratio with 95% confidence interval. $P < 0.05$ was considered statistically significant.

RESULTS

Thirty-eight patients were included (24 females) with their

Table 2 Adverse effects reported by 26 of the 38 patients

Adverse effect	n	%
Vomiting	14	36.8
Abdominal pain	13	34.2
Metallic taste	6	15.8
Diarrhea	5	13.2
Nausea	5	13.2
Dizziness	2	5.3
Headache	2	5.3
Asthenia	1	2.6
Skin rash	1	2.6

age ranging from 4 to 17.8 (mean 10.9 ± 3.7) years. Results of the endoscopic examinations are shown in Table 1. The histological analysis showed active chronic gastritis in all patients. Intensity of the neutrophil infiltrate was low in 9 patients (23.7%), moderate in 19 (50%) and intense in 10 (26.3%). Intensity of bacterial density on histology was low in 11 patients (28.9%), moderate in 19 (50%) and intense in 8 (21.1%).

Slight side effects were reported in 26 patients (68.4%), disappearing with the interruption of the treatment (Table 2). Compliance with the protocol occurred in 33/38 patients (86.6%), intake of medications was not correct in 4 patients and control of treatment was very late in one. The eradication rate of infection was 84.8% in 28/33 patients treated according to the protocol (95% CI: 78.5%-91%), and 73.7% by intent-to-treat analysis in 28/38 patients (95% CI: 65.4%-82%). Influence of demographic, clinical and histologic data on the success of treatment is shown in Table 3. The infection was eradicated in all the 7 patients with erosive duodenitis or duodenal ulcer, while only 9/16 (56.2%) patients with nodular antrum gastritis as a single alteration were successfully treated ($P = 0.08$).

Evaluation of *H pylori* eradication was performed through histology and ¹³C-urea breath test in 26 patients who were successfully treated and breath test in 2 patients who were successfully treated. *H pylori* eradication evaluation was not performed in 4 patients whose medication intake was less than 25% of that prescribed. Results of endoscopy were normal in 21 (65.6%), nodular antrum gastritis in 9 (28.1%) and erosive gastritis in 1 (6.5%). Cure of infection was achieved in two patients with erosive gastritis. After the treatment, among the 26 cured patients, 9 (34.6%) had normal histology, 7 (26.9%) inactive chronic gastritis, 9 (34.6%) low neutrophil infiltrate and 1 (3.8%) moderate neutrophil infiltrate. Among the 6 patients remaining infected, a second endoscopy revealed low neutrophil infiltrate in 4 (67%) and moderate neutrophil infiltrate in 2 (33%), decreased neutrophil infiltrate in 3 (50%). Gastritis activity did not worsen in any of the patients.

Clinical progress

Success treatment of *H pylori* infection in patients with functional dyspepsia is shown in Figure 1. After two months of treatment, 63% of the eradicated dyspeptic patients and 60% of the non-eradicated patients reported

¹ for therapeutic success; ² without duodenal ulcer or erosive duodenitis.

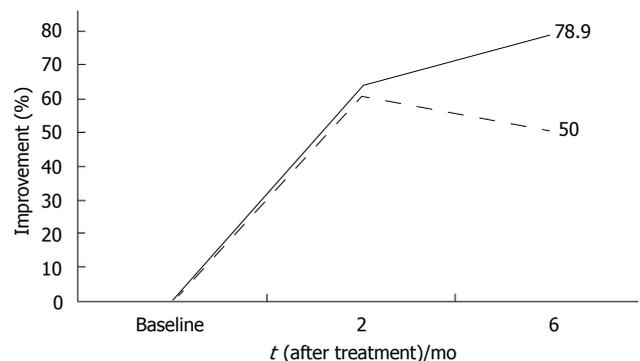

Figure 1 Patients with non-ulcer dyspepsia reporting symptom improvement after treatment according to *H pylori* infection eradication in 2- and 6-mo follow-up. Continuous line: successfully eradicated patients; Dashed line: not eradicated patients. P (2 mo) = 1, P (6 mo) = 0.2.

improvement of symptoms ($P = 1$), while at 6-mo follow-up 78.9% successfully treated patients and 50% of the non-eradicated patients reported improvement of symptoms ($P = 0.2$). The hematological parameters of the patients with refractory iron deficiency anemia returned to normal after treatment and all patients with duodenal ulcer or erosive duodenitis were asymptomatic.

DISCUSSION

The attained success rate (73.3% by intent-to-treat analysis) was higher than that observed by a former study with amoxicillin, clarithromycin and omeprazole for 7 d (50%, 95% CI: 19%-81%) in our service, but similar to that for 10 d (73%, 95% CI: 51%-95%)^[21]. There is no other study

comparing triple therapy for 7 d with a longer treatment period. Other studies with clarithromycin, amoxicillin and proton pump inhibitor reported that the eradication rate of *H pylori* is 54%-77.8% in children^[6,22,23]. At present, the first-line regimen recommended by Brazilian consensus for the treatment of adults is the triple treatment with clarithromycin, amoxicillin (or furazolidone) and proton pump inhibitor for 7-14 d^[24]. A seven-day treatment period was chosen in our study because it is as effective as a ten-day period. The efficiency of a longer treatment period (14 d) is only 9% higher with a significant cost increase^[25]. In Brazil there are 16% clarithromycin-resistant and 55% metronidazole-resistant strains, thus requiring alternative regimens for classical compositions^[25,26]. Recently a sequential therapy has been described, consisting of two treatment regimens for five consecutive days. In these studies, amoxicillin and proton pump inhibitor (PPI) are used for five days followed by PPI, clarithromycin and tinidazole for another five days^[27]. In children the regimen is more efficient than the traditional treatment with amoxicillin, metronidazole and PPI for 10 d (97.3%, 95% CI: 86.2%-99.5% *vs* 75.5%, 95% CI: 59.8%-86.7%), and has no more side effects (global rate 12%)^[28]. A sequential regimen exposes the patients to three different drug classes as a first line treatment, which may make the choice of a second-line treatment difficult in eventual therapeutic failures.

There are no clinical or laboratory factors associated with a better result of the treatment (Table 3). The eradication rate of *H pylori* observed in our study in patients with duodenal ulcer is similar to that observed by Dani and coworkers^[13] in adults with ulcer disease, but the difference in the eradication rate of *H pylori* in patients with functional non-ulcer dyspepsia did not reach statistical significance, perhaps due to the small number of patients with ulcer included in our study ($P = 0.08$). A recent study has shown a lower eradication rate of *H pylori* in patients with non-ulcer dyspepsia^[2]. Justifying factors include clarithromycin susceptibility to strains in patients with dyspepsia, less strain virulence (CagA negative) and differences in compliance with treatment. The lowest eradication index of *H pylori* observed in children may be due to the low prevalence of duodenal ulcer^[29]. On the other hand, patients with antral nodularity present a lower eradication rate of *H pylori* (56.2%), but lymphoid follicles are found to be associated with treatment failure in adult patients^[30]. Antral nodularity may be related to a higher inflammation intensity and more aggressive strains. However, it seems more difficult to eradicate infection with a CagA negative strain^[31]. The high incidence of side effects (67.6%), although slight and self-limited, constitutes an inconvenience for the studied regimen. The reported side effects are slight and do not compromise the success treatment (Table 3). The reported symptoms may be attributed to clarithromycin or to furazolidone. Furazolidone is a nitrofurantoin compound which has been used in the treatment of giardiasis since the 1950s. The drug has minimal adverse effects, mostly nausea, vomiting and diarrhea. Other side effects include brown discoloration of urine and hemolysis in glucose-6-phosphate dehydrogenase deficient patients and infants

younger than 1-year old^[32]. Treatment regimens with furazolidone usually present a higher incidence of side effects than traditional alternatives^[9]. Lower furazolidone doses neither affect the success treatment rate, nor decrease the frequency of adverse effects^[11].

The omeprazole dose used may be considered small in view of recent evidence that some patients need higher doses^[33]. The importance of antisecretory drugs in the eradication regimen is their direct effect on the bacterium and the better antibiotic activity at high pH^[1]. Cytochrome P2C19 is responsible for hepatic metabolism of some proton pump inhibitors, such as omeprazole, and the CYP2C19 genotype, an isoform, is associated with more rapid metabolism, constituting another risk factor for unsuccessful eradication treatment of *H pylori*^[34]. However, there are no studies describing the prevalent genotypes. Finally, some of our patients used generic omeprazole. The efficacy of *H pylori* eradication regimen with generic medication is lower than that with proprietary drugs in adult patients in Russia^[35]. Omeprazole bioavailability depends on its presentation

Most of our patients presented non-ulcer dyspepsia, a situation in which treatment of *H pylori* infection is still controversial. The treatment seems to be beneficial to some adult patients and it is estimated that 1 in 18 patients improves after the treatment^[36]. There are still important limitations in therapeutic trials for dyspepsia in children. There are no criteria for the selection of patients and no validated diagnostic and functional dyspepsia severity scores in children, which makes the generalization of results difficult. Over 50% of physicians in USA treat *H pylori* in children with dyspeptic symptoms without endoscopy^[37]. In spite of the higher symptom improvement proportion among the successfully treated patients (78.9% *vs* 50%), the study could not draw a conclusion about the clinical validity of the treatment because of the small number of studied patients (Figure 1). Other studies have reported a similar response rate in children with recurrent chronic abdominal pain^[6,38]. Long-term symptom resolution in patients with severe symptoms requiring endoscopy shows differences in epigastric pain resolution between *H pylori*-negative (3/26) and positive (7/10) patients ($P = 0.001$) after one to two years^[38]. Early clinical evaluation may underestimate the beneficial effects of the treatment and longer follow-up periods may show effective *H pylori* eradication and symptom resolution.

The tested regimen may be superior to the regimen with clarithromycin, amoxicillin and omeprazole, and can be used in the treatment of infection in patients with duodenal ulcer. Its success rate is lower in non-ulcer dyspepsia. Treatment regimens with a longer time should be tested in children.

CONCLUSION: The frequency of the NOD2/CARD15 susceptibility variants in the Hungarian pediatric CD population is high and the profile differs from the adult CD patients, whereas the results for SLC22A4 and SLC22A5 mutation screening do not confirm the assumption that the carriage of these genotypes means an obligatory susceptibility to CD.

Abstract

AIM: To investigate the frequency of the common NOD2/CARD15 susceptibility variants and two functional polymorphisms of OCTN cation transporter genes in Hungarian pediatric patients with Crohn's disease (CD).

METHODS: A cohort of 19 unrelated pediatric and 55 unrelated adult patients with Crohn's disease and 49 healthy controls were studied. Genotyping of the three common CD-associated CARD15 variants (Arg702Trp, Gly908Arg and 1007finsC changes) with the SLC22A4 1672C→T, and SLC22A5 -207G→C mutations was performed by direct sequencing of the specific regions of these genes.

RESULTS: At least one CARD15 mutation was present in 52.6% of the children and in 34.5% of the adults compared to 14.3% in controls. Surprisingly, strongly different mutation profile was detected in the pediatric *versus* adult patients. While the G908R and 1007finsC variants were 18.4% and 21.1% in the pediatric group, they were 1.82% and 11.8% in the adults, and were 1.02% and 3.06% in the controls, respectively. The R702W allele was increased approximately two-fold in the adult subjects, while in the pediatric group it was only approximately 64% of the controls (9.09% in the adults, 2.63% in pediatric patients, and 4.08% in the controls). No accumulation of the OCTN variants was observed in any patient group *versus* the controls.

INTRODUCTION

Crohn's disease (CD) is a chronic inflammatory disorder of the gastrointestinal tract. Although the peak onset of the disease typically occurs in the second and third decades of life^[1], the incidence of pediatric cases has been strongly increasing recently^[2]. Despite the comprehensive research that has been made to discover the background of the disease, the etiology is still unknown. Besides the environmental effects, it is supposed that genetic susceptibility plays a crucial role in the development of the disease^[3,4].

Genome-wide linkage analyses have resulted in identification of several loci of potential CD susceptibility genes^[5-11]. CARD15 (NOD2) gene, which is located at the pericentromeric region of chromosome 16, was the first gene to be identified as CD gene^[12-14]. NOD2 is an intracellular protein expressed in peripheral blood monocytes, Paneth and intestinal epithelial cells; and it is important for inflammatory signal transduction *via* activation of the transcription factor, nuclear factor kappa-B (NF-κB)^[15]. Several studies on Caucasian populations have reported an association between CARD mutations and CD. Three coding variants (R702W, G908R

and 1007finsC) have been identified as independent risk factors for development of CD.

Recently two polymorphisms in the carnitine/organic cation transporter gene cluster (SLC22A4 and SLC22A5, encoding OCTN1 and OCTN2, respectively) have been found to confer risk for CD^[16]. The aim of the present study was to investigate the prevalence of these two functional variants of the SLC22A4 and SLC22A5 genes and the three CARD15 mutations in Hungarian pediatric population with CD.

MATERIALS AND METHODS

Patients

We examined 19 pediatric (14 males and 5 females; mean age: 13.4 years) and 55 adult (27 male and 28 female with real maturity onset disease; mean age: 42.3 years) patients with CD. This cohort was compared with 49 age- and sex-matched healthy controls (28 males and 21 females; mean age: 14.4 years). Both the pediatric and adult CD patients exhibited different clinical manifestations, therefore they represented mixed clinical CD populations. The diagnosis was confirmed by clinical, radiological, endoscopic and histological findings. Informed consent was obtained from each participant of the study and the study design was approved by the Local Ethics Committee.

Methods

Genomic DNA from the patients and the controls was isolated from peripheral blood using standard desalting procedure.

The presence of the NOD2 and OCTN variants was detected by direct sequencing using the primers designed in our laboratory. The primers' sequences for the PCR amplification as well as for the sequencing and annealing temperatures are listed in Table 1. The PCR was carried out in a final volume of 50 μ L containing 200 μ mol/L of each dNTP, 2 units of Taq polymerase, 5 μ L of reaction buffer [100 mmol/L Tris HCl (pH 9.0), 500 mmol/L KCl, 15 mmol/L MgCl₂, 0.2 μ mol/L of each primer and 1 μ g of DNA to be amplified. The amplification was performed for a total of 35 cycles in an MJ Research PTC-200 thermal cyler. The amplification conditions were: pre-denaturation at 95°C for 2 min, denaturation at 95°C for 30 s, annealing for 30 s at the temperatures listed in Table 1 for the different SNP, primer extension at 72°C for 30 s, and the final extension at 72°C for 5 min. For DNA sequencing, a BigDye Terminator labeling was used and the analysis was performed in an ABI 3100 automatic sequencer.

Statistical analysis

Chi-square test (cross-table analysis) was used to analyze the possible associations with mutations in comparison of either the susceptibility variants and/or the normal haplotypes. $P < 0.05$ was considered statistically significant.

RESULTS

The allele frequencies are shown in Table 2. A total of

	GC	7 (36.8)	31 (56.4)	26 (53.1)
	CC	9 (47.4)	10 (18.1)	13 (26.5)
	C allele frequency (%)	65.8	46.4	53.1

52.6% of pediatric patients with Crohn's disease carried at least one NOD2 mutation compared to 34.5% of adult patients and to 14.3% of the controls (pediatric patients *vs* controls $P < 0.05$).

While the T allele frequency, leading to heterozygous and homozygous R702W mutation, was increased approximately two-fold in the adult CD population (9.09%) compared to the controls (4.08%), it was only 2.63% in the pediatric CD patients (Table 2; $P < 0.05$ comparing the pediatric susceptibility and/or normal variants *versus*

the same values of the adult patients or the controls). By contrast, the C allele frequency, encoding the G908R variant, was found highly elevated (18.4%) in pediatric patients, and was only 1.82% in adult CD patients, and 1.02% in the controls ($P < 0.05$). For the 1007finsC variant, a significantly increased prevalence was found both in pediatric (21.1%) and in adult CD (11.8%) patients as compared with the controls (3.06%) ($P < 0.05$).

There were no significant differences in the allele frequencies of SLC22A4 C1672T and SLC22A5 G-207C mutations when compared either the results of the pediatric or the adult CD populations to the results of the controls (Table 2).

DISCUSSION

The carriage rate for the three common CD-associated CARD15 mutations was reported 31% in a pediatric CD population in North America^[17], 60% in Germany^[18], 51.5% in the Israeli Jewish patients^[19] and 40.7% in an Italian cohort^[20]. In two studies, the cytosine insertion mutation 3020insC was significantly more common in the pediatric CD population^[18,21], whereas among the Jewish patients G908R missense mutation was the most frequent variant^[19,22].

An association of the three CARD15 mutations R702W, G908R and 1007finsC with CD has been confirmed in several studies^[17,18,23], although different allele frequencies have been observed. While the allele frequencies of the three mutations were almost the same (8.3%, 8.3% and 7.4%) in the Italian pediatric patients^[20], the G908R variant was the most frequent among Jewish children^[19] and 1007finsC was more common in Germany^[18] and in the USA^[21]. An earlier onset of disease was found in the presence of a CARD15 mutation in three additional studies^[23-25]. These findings suggest that CARD15 mutations may be more frequent in pediatric CD.

To our surprise, in our study groups, two mutations, G908R and 1007finsC, were significantly more frequent in the pediatric population with the allele frequencies of 18.42% in children *versus* 1.02% in controls and of 21.05% in children *versus* 3.06% in controls, respectively. The genotyping results for the adult population are in agreement with previous Hungarian findings^[26,27].

The OCTN1 and OCTN2 transporters mediate the transport of carnitine and a wide range of organic cations^[28-30] and have an important role in the energy supply of epithelial cells. Recently, it has become clear that the OCTN1 also transports the ergothioneine^[31], and the affinity parameters make it almost unquestionable that the carnitine transport function is secondary. A C1672T missense substitution in exon 9 of the SLC22A4 gene results in marked changes in OCTN1 transporter activity, whereas G-207C transversion in the SLC22A5 promoter region causes OCTN2 promoter function impairment.

By resequencing the five genes in the IBD5 interval, which harbors the cytokine gene cluster, and, therefore, is an attractive candidate region for IBD, Peltekova *et al*^[16] identified 2 novel polymorphisms in the SLC22A4 and SLC22A5 genes. These two mutations (SLC22A4 C1672T and SLC22A5 G-207C) form a two-allele risk haplotype

(OCTN-TC) which was associated with CD and showed significant interactions with CD-associated CARD15 mutations. This observation has been repeatedly confirmed^[32-34], although, in the absence of the IBD5 risk haplotype, no association of OCTN1/2 variants with CD was reported in two studies^[33,34]. While a Belgian group^[35] found that the OCTN did not play a role in the susceptibility to CD, the two functional variants in the SLC22A4 and SLC22A5 genes were completely absent in Japanese^[36].

In our study, which is probably the first in the international literature for pediatric population, we could not find accumulation of any of the susceptibility haplotypes either in the pediatric or in the adult CD subjects, thereby not supporting the susceptibility role of the above haplotypes in the development of CD.

In conclusion, we observed an accumulation of CARD15 mutations in pediatric cases, whereas the results for SLC22A4 and SLC22A5 mutation screening do not confirm the assumption that the carriage of these genotypes means significant susceptibility to CD. However, for genotype-phenotype correlations, further studies are needed with larger study populations.

ACKNOWLEDGMENTS

We thank Judit Oksai and Edit Papp for their help in the technical management of the study.

Abstract

AIM: To assess the efficacy of peginterferon alpha 2b at doses of 50 µg weekly and 80 µg weekly (based on body weight) plus ribavirin in HCV genotype 2 and genotype 3 chronic hepatitis C patients.

METHODS: During the study period of Jan 2002 to Dec 2003, all patients diagnosed as chronic hepatitis C or HCV related compensated cirrhosis were treated with peginterferon alpha 2b 50 µg S/C weekly (body weight < 60 kg) or 80 µg S/C weekly (body weight > 60 kg) plus ribavirin 800 mg/d for 24 wk.

RESULTS: Overall 28 patients, 14 patients in each group (based on body weight) were treated during the period. Out of 28 patients, 75% were genotype 3, 18% were genotype 2 and 7% were genotype 1. The mean dose of peginterferon alpha 2b was 0.91 µg/kg in group 1 and 1.23 µg/kg in group 2 respectively. The end of treatment and sustained virologic response rates were 82% and 78% respectively. Serious adverse effects were seen in 3.5% patients.

CONCLUSION: Low dose peginterferon alpha 2b in combination with ribavirin for 24 wk is effective in HCV genotype 2 and 3 chronic hepatitis C patients.

INTRODUCTION

The hepatitis C virus is a major cause of liver diseases affecting 170 million people worldwide^[1]. In India, the estimated prevalence of hepatitis C virus infection is 1.8%. Genotypes 2 and 3 are predominant in Indian population^[2].

Therapy for chronic hepatitis C has greatly improved over the last decade and is still evolving^[3-8]. The introduction of pegylated form of interferons and addition of ribavirin have further improved the efficacy of therapy in chronic hepatitis C. Higher sustained virological response (SVR) rates in patients with chronic hepatitis C have been reported with pegylated form of interferons compared with standard interferons both as monotherapy as well as in combination with ribavirin^[9-13].

Peginterferon alpha-2b is recommended at a dose of 1.5 µg/kg body weight in combination with ribavirin for treatment of chronic hepatitis C. An earlier study has reported similar efficacy of peginterferon alpha-2b at doses of 1 µg/kg and 1.5 µg/kg body weight in treatment of chronic hepatitis C as monotherapy^[9]. Recent studies have shown that 82%-90% SVR could be achieved in HCV genotype 2 and 3 patients using peginterferon and ribavirin combination^[13,14].

Interferon-based regimens are associated with significant side effects and costs. The cost of therapy in developing countries is a major limiting factor in initiating treatment. There is limited data on efficacy of low dose peginterferon alpha 2b plus ribavirin on chronic hepatitis C. It would be worthwhile to study whether the dose of peginterferon alpha-2b could be lowered from 1.5 µg/kg body weight to 1 µg/kg body weight in combination with standard dose of ribavirin without compromising the efficacy of therapy in HCV genotype 2 and 3 chronic hepatitis C patients.

Therefore, we conducted a non-randomized pilot study to assess the efficacy of peginterferon alpha-2b, at doses of 50 µg and 80 µg (based on body weight) plus ribavirin at standard dose in HCV genotype 2 and 3 related chronic hepatitis and compensated cirrhotic patients.

MATERIALS AND METHODS

Subjects

All patients with chronic liver disease attending our hospital from Jan 2002 to Dec 2003 were evaluated for HCV infection. After detailed history and clinical examination, patients underwent routine hematological investigations, liver function test, abdominal ultrasound

and upper GI endoscopy. All patients were tested for the presence of anti-HCV antibodies with Abbott diagnostic test kit according to the manufacturer's instructions. Those patients who tested positive for anti-HCV were further investigated for HCV RNA. HCV RNA was tested by RT-PCR (SDS) using 30 base pair long dual labeled oligonucleotide TaqMan probe (Rotorgene from Corbett research Australia). HCV genotype was tested by molecular based linear array system using COBAS AMPLICOR.

All patients diagnosed with chronic hepatitis C and compensated cirrhosis were eligible for study. Patients meeting with the following criteria were excluded: Presence of decompensated cirrhosis, hepatitis B coinfection, HIV co-infection, renal failure, concomitant malignancy, co-morbid serious cardiac and respiratory diseases, neuropsychiatric disorders, pregnancy, lactating mothers and alcohol abuse.

Study protocol

All eligible patients who gave informed consent were included in the study. Patients were treated with either 50 µg or 80 µg subcutaneous (s/c) weekly dose of pegylated interferon alpha 2b based on body weight plus 800 mg daily dose of ribavirin. Those patients who weighed less than 60 kg were administered a dose of 50 µg per week of pegylated interferon alpha 2b while those weighing more than 60 kg received 80 µg S/C per week. All patients were evaluated as outpatients weekly for 4 wk, then at wk 8, 12, 16 and 24 during treatment. Following the completion of treatment, patients were evaluated at wk 4, 12 and 24. On each visit during follow-up, routine hematological workup was done. Besides, relevant investigations were performed as and when necessary. Qualitative HCV RNA was tested after 12 wk of treatment, at end of treatment (24 wk) and 6 mo after completion of treatment. Liver biopsy was not considered mandatory in study protocol and was done in those patients who agreed to undergo the procedure. Side effects of the therapy were carefully recorded during follow-up. Sustained virologic response was defined as normalization of ALT and negative HCV-RNA 6 mo after completion of therapy.

Informed, written consent was taken from all the patients. Our hospital ethics committee approved the study protocol.

Statistical analysis

The quantitative values were expressed as mean \pm SD. Fisher's exact test was used for statistical comparison of the data. $P < 0.05$ was considered as significant.

RESULTS

Overall 28 patients (25 males and 3 females) were included in the study. The demographic profile and clinical characteristics of the patients are shown in Table 1.

Fifteen out of 28 patients (54%) were chronic hepatitis and the remaining 13 (46%) were compensated cirrhosis (Child A). Eighteen (64%) of 28 patients had elevated ALT > 1.5 times the upper limit. The pretreatment ALT levels were 89 IU/L \pm 28 IU/L. Out of 28 patients, 75%, 18% and 7% were genotype 3, 2 and 1 respectively. Fourteen

Table 1 Demographic, clinical, biochemical and molecular profiles of patients (mean \pm SD, $n = 28$)

Demographic profile	
M/F	25:3
Age (yr)	47.5 \pm 13.2
Body weight (kg)	60.6 \pm 9.18
Clinical profile	
Chronic hepatitis C (n)	15
Compensated cirrhosis (n)	13
ALT (> 40 IU/L)	18
ALT (< 40 IU/L)	10
Molecular profile	
Genotype 3 (n)	21
Genotype 2 (n)	5
Genotype 1 (n)	2
Follow-up (mo)	18.1 \pm 6.7

patients (mass < 60 kg) were administered 50 µg S/C weekly dose of peginterferon alpha 2b plus 800 mg oral daily dose of ribavirin. The mean dose of peginterferon alpha 2b was 0.91 µg/kg body weight (0.6 µg/kg \pm 1.22 µg/kg) in this group.

The second group of 14 patients (mass > 60 kg) received 80 µg S/C weekly dose of peginterferon alpha 2b with daily oral dose of 800 mg ribavirin. The mean dose of peginterferon alpha 2b in this group was 1.23 µg/kg (1.03 µg/kg \pm 1.33 µg/kg). One patient discontinued treatment due to severe side effects and another patient lost to follow up after 2 wk. Twenty-six out of 28 patients completed the 24 wk treatment. At the end of 24 wk treatment, 23 patients were negative for HCV RNA and 3 patients tested positive for HCV RNA. On further follow up, one patient tested positive for HCV RNA 6 mo after completion of therapy. Overall, at the end of treatment, 23 (82%) of 28 patients showed response to therapy. The SVR was achieved in 22 (78%) out of 28 patients. Though the dose per kg body weight of peginterferon alpha 2b was significantly different in two groups ($P < 0.002$), there was no difference in response to therapy with respect to dose or genotype (Table 2). During the follow-up of 18.1 \pm 6.7 mo, one non-responder patient developed hepatocarcinoma (HCC) and died of liver failure following variceal bleeding.

One patient (3.5%) developed unbearable weakness and burning in urethra and discontinued the treatment. Seven (25%) of 28 patients developed mild leucopenia and thrombocytopenia which required temporary interruption of treatment for 1-2 wk. However, none of these 7 patients discontinued treatment any more and completed the 24 wk treatment.

DISCUSSION

The combination of peginterferon and ribavirin is the mainstay of treatment in chronic hepatitis C. Both forms of peginterferon alpha 2a and alpha 2b in combination with ribavirin have shown SVR rates from 79%-93% in genotype 2 and 3 chronic hepatitis C patients, making it a potentially curable disease^[14,15]. In our study, end of treatment response (ETR) and SVR rates were 82%

Table 2 Response of therapy with respect to dose and genotype

Patients (n = 28)	Response to peginterferon alpha 2b Dose 50 mcg (n = 14)		Response to peginterferon alpha 2b Dose 80 mcg (n = 12) ¹	
	Yes	No	Yes	No
Genotype 1 (n = 2)	-	1	1	-
Genotype 2 (n = 5)	3	-	2	-
Genotype 3 (n = 21)	8	2	8	1

¹Two patients in group 2 did not complete therapy.

and 78% respectively. The mean dose per kg body weight of peginterferon alpha 2b was 0.9 µg/kg and 1.23 µg/kg in the two groups, respectively. Lindsay *et al*^[9] have shown similar SVR rates with 1.5 µg/kg and 1 µg/kg of peginterferon alpha 2b as monotherapy.

In a recent study, Zeuzem *et al*^[14] have shown SVR rates of 79% and 93% in genotype 3 and genotype 2 chronic hepatitis C patients respectively when treated with peginterferon alpha 2b 1.5 µg/kg S/C weekly plus ribavirin 800-1400 mg/d based on body weight. In the same study, higher virologic response rate was observed in HCV genotype 3 patients with baseline HCV RNA concentration of < 600 IU/L compared to those with baseline HCV RNA > 600 IU/L (85% *vs* 59%). In our study, quantitative HCV RNA assay was not included in the study protocol, hence data could not be analysed based on HCV RNA levels. However, our results are comparable with those reported by Zeuzem *et al*^[14], albeit at a much lower dose. One patient (3.5%) reported serious side effects resulting in discontinuation of treatment. The remaining patients tolerated the treatment well. The overall safety profile was much improved compared with earlier studies^[16]. One patient who was a non-responder to treatment died during follow-up due to HCC related decompensation, suggestive of progressive disease.

HCV genotypes 1b and 2a are common in China^[15]. In Japan, genotypes 1b, 2a and 2b are prevalent. Genotype 3 is also observed in Southeast Asian countries. In India, genotypes 2 and 3 are predominant HCV genotypes^[2]. These genotypes 2 and 3 respond well to treatment^[11,13,14]. But the cost of the treatment is a major limiting factor in developing countries. Our study has shown that > 80% SVR rates could be achieved in HCV genotype 2 and 3 infected chronic hepatitis C patients with lower than recommended dose of pegylated interferon alpha 2b. In light of encouraging results of our study, a randomized controlled trial is needed to compare the efficacy of lower doses of pegylated interferon alpha 2b, ie, with 1.5 µg/kg body weight of peginterferon alpha 2b in combination with standard dose of ribavirin with specific reference to Asian population.

In conclusion, the present study shows that lower than recommended dose of peginterferon alpha 2b in combination with ribavirin for 24 wk is effective in HCV genotype 2 and 3 chronic hepatitis C patients.

Abstract

AIM: To investigate the effect of serum derived from rats treated with electroacupuncture at stomach meridian acupoints on the expression of epidermal growth factor receptor (EGFR) gene in gastric mucosal cells.

METHODS: The stress-induced gastric mucosal injury in rat model was established by water-immersion and restrained stress methods. 52 rats were randomly divided into: normal group ($n = 8$), model group ($n = 8$), model serum group ($n = 12$), stomach serum group ($n = 12$), and gallbladder serum group ($n = 12$). The gastric mucosal cells were separated by pronase-EDTA digestion method and incubated with serum. The EGFR gene expression in gastric mucosal cells was detected by reverse transcription-polymerase chain reaction (RT-PCR) method.

RESULTS: Compared with normal group (0.6860 ± 0.0594), the serum derived from rats of the stomach group (1.2272 ± 0.0813 , $P = 0.00 < 0.01$) and gallbladder group (0.9640 ± 0.0387 , $P = 0.00 < 0.01$) had a tendency to enhance the EGFR gene expression in gastric mucosal cells. Such tendency existed in the model group (0.7104 ± 0.0457) but with no significant difference ($P = 0.495 > 0.05$) and in model serum group (0.8516 ± 0.0409) with an extremely obvious difference ($P = 0.001 < 0.01$). Furthermore, the EGFR gene expression in stomach serum group was significantly higher than that in gallbladder serum group ($P = 0.00 < 0.01$).

CONCLUSION: The present study shows that serum

derived from rats treated with electroacupuncture at stomach meridian acupoints can distinctly increase the EGFR gene expression of gastric mucosal cells. Therefore, there is certain meridian specificity in the serum, which could provide a proof for the TCM theory "particular relation between meridian and internal organ".

INTRODUCTION

Gastric mucosal damage is a common pathological reaction in the diseases of the digestive system. The acupuncture and moxibustion are very effective cure for this damage^[1,2]. Previous experimental studies demonstrated that epidermal growth factor (EGF) and transforming growth factor- α (TGF- α) were the most important peptides for the repair of the gastric mucosal injury^[3]. Acupuncture at gastric meridian acupoint could alter gastric motility and secretion and also the content of gastrin, substance P, EGF and TGF- α in serum and gastric mucosa^[4,5]. Recent research indicated that EGFR was closely related to the healing of impaired gastric mucosa, which was of great importance to the gastric mucosal protection and repair after damage^[6]. The EGFR belongs to the family of trans-membrane tyrosine protein kinase (TPK). Activation of EGFR stimulates cell proliferation, differentiation, adhesion, and migration^[7,8]. The aim of this study was to examine the effect of serum derived from rats treated with electroacupuncture at stomach meridian acupoints on the expression of EGFR gene in gastric mucosal cells. This would hopefully clarify the humoral

mechanism of acupuncture effect on gastric mucosal cells and the essential correlation of the meridian acupoints and internal organs.

MATERIALS AND METHODS

Reagents

Pronase and dithiothreitol (DTT) were purchased from MERK. Bovine serum albumin (BSA) was obtained from Biosharp. Percoll was purchased from Pharmacia, Dulbecco's Modified Eagle Medium (DMEM) from Hyclone, 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) from Biosource, Trizol reagent was obtained from Invitrogen. AMV reverse transcriptase, ribonuclease inhibitor (RNasin), dNTPs, Taq DNA polymerase, 100 bp DNA ladder, diethylpyrocarbonate (DEPC), oligodT18 primer, and gelose were purchased from Promega. Tyrosine kinase inhibitor (PD153035) was purchased from Calbiochem. EGFR and the internal control, glyceraldehyde-3-phosphate dehydrogenase (GAPDH) were obtained from Invitrogen. All other reagents were analytically pure.

The stress-induced gastric mucosal injury in rats

Water-immersion and restrained stress methods were adopted^[9]. Before modelling, the experimental rats were fasted for 24 h and had free access to water only. Rats were fixed on boards and were immersed vertically in a homeostatic bath at $23 \pm 1^\circ\text{C}$ for 10 h, with the liquid surface up to the level of the xiphoid process of the sternum.

Experimental design

Sprague-Dawley (SD) male and female rats, with an average weight of 200 ± 30 gm, were supplied by the Experimental Animal Center at Hunan Agriculture University (Permission number: 20030316) 2 wk before the experiment. During this period, they had access to Purina rat chow and water. Animals were fasted overnight before the experiments. Fifty-two rats were randomly divided into normal group, model group, model serum group, stomach serum group and gallbladder serum group. 8 rats were in the normal group and model group. Each of the model serum group, stomach serum group and gallbladder serum group included 12 rats.

Four rats of each of the model serum group, stomach serum group, and gallbladder serum group were selected at random for deriving serum, and the remaining 8 rats were used for isolating gastric mucosal cells. Acupoints location was defined by reference of rat-acupoint-atlas and analogy to human body^[10]. According to the induction stated above, three pairs of acupoints consisting of Sibai (ST 2), Liangmen (ST 21), and Zusanli (ST36) in the stomach Meridian, were designed, which represent acupoints of different level (head, trunk, and limb). Also, 3 pairs of acupoints of the gallbladder Meridian in the same horizontal level were selected: Yangbai (GB 14), Riyue (GB24), and Yanglingquan (GB 34).

Pairs of stainless-steel needles of 0.25 mm in diameter were inserted into the acupoints stated above in experimental rats. The needles were connected to

the output of an electronic pulse generator, a medical electroacupuncture stimulator (Model G6805-1, made by Shanghai Medical Electro-apparatus Factory, China), which achieves intermittent-and-irregular wave (intermittent wave: 4 Hz, irregular wave: 20 Hz), constant time of 30 min per day, ten days, while there was a light vibration in the lower limbs of rats.

Isolation of gastric mucosal cells

Animals were fasted overnight before the experiments. All experiments were performed using freshly isolated gastric mucosal cells. The contents of the stomach were washed out with phosphate-buffered saline (PBS). The stomach was then ligated at the base of the forestomach and the proximal end of the antrum to obtain mucosal cells primarily from the oxyntic region. After being transformed into inside-out gastric bags, they were filled with 2.5 mL of 1 mg/mL pronase solution in buffer A (0.5 mmol/L NaH_2PO_4 , 1.0 mmol/L Na_2HPO_4 , 20 mmol/L NaHCO_3 , 80 mmol/L NaCl, 5.0 mmol/L KCl, 50 mmol/L HEPES, 11 mmol/L glucose, 0.02 mmol/L BSA, 2 mmol/L EDTA, pH 7.4). The filled gastric bags were incubated in pronase-free buffer A at 37°C for 30 min. The gastric bags were then transferred into buffer B (0.5 mmol/L NaH_2PO_4 , 1.0 mmol/L Na_2HPO_4 , 20 mmol/L NaHCO_3 , 80 mmol/L NaCl, 5.0 mmol/L KCl, 50 mmol/L HEPES, 11 mmol/L glucose, 0.01 mmol/L BSA, 1 mmol/L CaCl, 1.5 mmol/L MgCl, pH7.4) and gently agitated by a magnetic stirrer at room temperature for 1h. The gastric mucosal cells dispersed in buffer B were collected by centrifuging at 3000 rpm for 5 min and subsequently resuspended in serum-free DMEM^[11,12].

Serum collection

The blood was sampled from carotid artery after rats were treated according to the requirement of experimental procedures. Then the blood was transferred into centrifuge tubes and placed steadily for 2 h at 37°C . Tubes were centrifuged at 2500 rpm for 10 min. The serum was carefully sucked and frozen at -20°C . The gastric mucosal cells were incubated with 100 mL/L serum at 37°C for 30 min in the experiment^[13,14].

RNA extraction

Following the treatment stated above, gastric mucosal cells obtained from each rat were collected in Eppendorf tubes and kept in the -80°C . Eight samples from each group were selected randomly for RNA extraction. Total RNA was isolated from samples of gastric mucosal cells by using a guanidium isothiocyanate/phenol chloroform single step extraction kit from Stratagene. Total RNA was precipitated in ethanol and resuspended in sterile RNAase-free water for storage at -80°C until use. Total RNA was quantified spectrometrically at 260 nm, and the quality of isolated RNA was analyzed on agarose gels under standard conditions.

Reverse transcription reaction

Total RNA (10 μL , about 0.5 μg /sample) was reverse transcribed (RT) using oligo (dT) 18 primers 1 μL , $5 \times$

Table 2 The EGFR gene expression in gastric mucosal cells (mean \pm SD, $n = 8$)

Group	EGFR mRNA/GAPDH mRNA
Normal group	0.6860 \pm 0.0594
Model group	0.7104 \pm 0.0457 ^d
Model serum group	0.8516 \pm 0.0409 ^{b,d}
Stomach serum group	1.2272 \pm 0.0813 ^b
Gallbladder serum group	0.9640 \pm 0.0387 ^{b,d}

^b $P < 0.01$ vs Model group; ^d $P < 0.01$ vs Stomach serum group.

RT-buffer 4 μ L, dNTPs (10 mmol/L) 1 μ L, RNasin (20 MU/ μ L) 0.5 μ L, M-MULV reverse transcriptase (200 MU/ μ L) 1 μ L, and DEPC-treated water 2.5 μ L in a 20 μ L reverse transcription reaction system. The reaction was performed at 42°C for 30-60 min so that target mRNA was transcribed into cDNA. The tubes were cooled and centrifuged for several seconds.

Polymerase chain reaction (PCR)

An aliquot of the RT product of each sample (1/20 of the total volume) was used in the PCR amplification reactions for EGFR and GAPDH. The PCR reaction contained 4 μ L cDNA, 10 \times PCR buffer 5 μ L, dNTPS (10 mmol/L) 1 μ L, oligonucleotide primers sense/antisense (10 mmol/L) 1 μ L (primer sequences are stated below), Taqase 1 μ L, ddH₂O 32 μ L in a total volume of 50 μ L. Reaction mixtures were incubated for predenaturation at 94°C for 2 min, followed by 38 cycles for EGFR (denaturation at 94°C for 30 s, annealing at 53°C for 1 min, and extension at 72°C for 1 min) and 25 cycles for GAPDH (denaturation at 94°C for 30 s, annealing at 56°C for 30 s, and extension at 72°C for 30 s), and a final extension at 72°C for 5 min.

Primer design and the RT-PCR product electrophoresis

To use of the relatively quantitative method to measure EGFR gene expression, rat GAPDH was selected as internal control substance. The primer sequences and sizes of amplification products are as shown in Table 1. Five microliter PCR products were analyzed on 10 g/L agarose gel containing ethidiumbromide with TBE buffer at 80 V for 40 min and photographed under UV illumination. The band intensities were quantified by densitometry. EGFR and GAPDH PCR products were, respectively, 664 and 426 base pairs (Table 1). EGFR and GAPDH were determined by computer-assisted densitometric scanning. Signals were quantified by density analysis of the digital images using Eagle Eye II image software (Stratagene) and EGFR/GAPDH quotient indicated the relative expression of EGFR. Experiments were performed in triplicate.

Statistical analysis

The data for each group were expressed as mean \pm SD.

Comparison between groups was assessed using one-way analysis of variance (ANOVA). Differences were considered statistically significant if the P value was less than 0.05. Software SPSS 13.0 was used in all statistical tests.

RESULTS

Expression of EGFR gene in gastric mucosal cells

By using RT-PCR, the EGFR gene expression in gastric mucosal cells were detected in rats of normal group and model group as a weak signal but it was well-defined among other groups: model serum group, stomach serum group and gallbladder serum group. Compared with Model serum group, the serum in stomach serum group and gallbladder serum group appeared to up-regulate significantly the EGFR gene expression in gastric mucosal cells, $P < 0.01$, and obvious difference between stomach serum group and gallbladder serum group was found ($P < 0.01$). However, there was no difference between normal group and model group, $P > 0.05$ (Table 2; Figure 1).

DISCUSSION

According to the classical Traditional Chinese Medicine (TCM) theory, there is a particular relation between meridian acupoints and viscera and the functional activities of the organism can be regulated by acupuncture at the meridian acupoints. However, it is still unknown how the acupuncture regulates the functional activities of the organism, and what is essential for the relationship between meridian acupoints and viscera. The present study proved that the acupuncture at the stomach meridian acupoints could improve gastric mucosal protection mechanism and that it is a very effective cure for gastrointestinal diseases^[15,16]. Acupuncture at acupoints of Sibai (ST2), Liangmen (ST21), and Zusanli (ST36), could produce certain ameliorative effect through the following mechanisms: augmentation of the gastric antrum, reinforcement of pressure on gastric pyloric sphincter, stimulation or inhibition of related gastrointestinal peptide secretion^[17,18]. All of these have provided experimental

evidence for the theory of "Particular relationship between gastric meridian and the stomach". However, the functional mechanism of the repair of gastric mucosal lesion is not entirely clear, and the humoral factor of acupuncture and moxibustion effect is still unknown.

The mucosal lining of the gastrointestinal tract, especially the stomach, is easily exposed to a variety of exogenous injurious agents, including non-steroidal anti-inflammatory drugs and ethanol. Each of these agents either alone or in combination with others may induce mucosal injury. However, a number of *in vivo* and *in vitro* studies have demonstrated that the gastric mucosa of animals possesses the inherent capacity to repair after mild injury^[19]. The cellular protective functions against damage maybe accomplished in several ways. There are evidences for participation of both the early phase of epithelial repair, known as restitution, marked by increased cell migration but no proliferation, and the delayed phase of cell renewal, marked by proliferation, differentiation and migration^[20,21].

In general, EGFR is one of the recently described members of cell membrane proteins. It is made of 1186 amino acids. As a trans-membrane receptor of tyrosine protein kinase family, EGFR plays a very important role in regulating healing process of damaged gastric mucosa, and regulates cell metabolism, proliferation, differentiation, migration and other biological phenomena. Many studies indicated that there was an elevated EGFR expression during the healing course of damaged gastric mucosa. Therefore, EGFR is of a great importance to the gastric mucosal protection and injury healing^[22,23]. The relationship between EGFR and its downstream signal transduction pathway and the healing of gastric mucosal injury is increasingly becoming a focus of researchers' attention. This study assessed, by RT-PCR methods, the EGFR mRNA expression in gastric mucosal cells of the rat after incubation with 10% serum for 30 min. The data showed that EGFR mRNA expression in gastric mucosal cells was enhanced shortly after incubation with the serum derived from the rats. Meanwhile, it was proved that the serum derived from the rats treated with electroacupuncture had an obvious tendency to stimulate the EGFR mRNA expression in gastric mucosal cells. In addition, EGFR mRNA expression in stomach serum group was much higher than that in model serum group and gallbladder serum group. Therefore, we hypothesize that the serum derived from rats treated with electroacupuncture contains many kinds of active substances that stimulated the EGFR gene in the gastric mucosal cells. This study also indicated that the discrepancy in the expression of EGFR gene may be the underlying mechanism of different effect of electroacupuncture at acupoints of gastric meridian and that of gallbladder meridian. Thus, this could be a proof for the TCM theory "particular relation between SMFY and the stomach". The active substance (s) in the serum derived from the rats treated with electroacupuncture at stomach meridian acupoints is (are) unknown, and therefore, more research using proteomic technology is needed.

Abstract

Arteroportal fistula is a rare cause of prehepatic portal hypertension. A 44-year-old male with hepatitis virus C infection was admitted for acute variceal bleeding. Endoscopy showed the presence of large esophageal varices. The ultrasound revealed a mass near the head of pancreas, which was characterized at the color-Doppler by a turbulent flow, and arterialization of portal vein flow. CT scan of abdomen showed a large aneurysm of the gastroduodenal artery communicating into the superior mesenteric vein. The sinusoidal portal pressure measured as hepatic vein pressure gradient was normal, confirming the pre-hepatic origin of portal hypertension. The diagnosis of extrahepatic portal hypertension secondary to arteroportal fistula was established, and the percutaneous embolization was performed. Three months later, the endoscopy showed absence of esophageal varices and ascites. At the moment, the patient is in good clinical condition, without signs of portal hypertension.

INTRODUCTION

Extrahepatic arteroportal fistula is a rare disorder

of hepatic vasculature characterized by anomalous communication between arteries and portal vein system most commonly caused by abdominal trauma, and iatrogenic damage induced by procedures such as liver biopsies, tumors and congenital vascular malformations^[1]. Arteroportal fistula may cause severe portal hypertension which leads to gastroesophageal variceal bleeding, refractory ascites, diarrhea, and hepatic encephalopathy. The recent progress in computed tomography and magnetic resonance technology with no invasive angiography imaging, makes it possible to confirm the suspicious arteroportal fistula at the Doppler ultrasonography and guide the choice of the treatment. The hepatic vein portal pressure gradient (HVPG) measurement may verify the diagnosis of extrahepatic portal hypertension.

CASE REPORT

A 44-year-old male was admitted to our Institution because of acute variceal bleeding and a clinical diagnosis of cirrhosis. The patient underwent a total gastrectomy in 1984 for gastroduodenal ulcer. In December 2000, there was a biopsy-proven chronic active hepatitis secondary to hepatitis virus C infection; and a long-term biochemical and virological response was obtained with a 12-mo course of combined antiviral treatment with PEG-IFN plus Ribavirin. Upon admission, the liver function tests were made and the results were: AST 34 U/L, ALT 61 U/L, INR 1.2, PT 63%, serum albumin 33 g/L, serum bilirubin 1.1 mg/dL, and platelets count $15 \times 10^3 \mu\text{L}$.

The endoscopy showed the presence of large esophageal varices with cherry red spots, localized in the medial and lower third of the esophagus and extended into the subcardial tract; the varix actively bleeding was treated with banding legations. Two days later, the ultrasonography showed homogeneous liver texture, enlarged spleen (a longitudinal diameter of 16.3 cm) and absence of ascites. However, an anechoic mass 2.5 cm in diameter was detected next to the head of the pancreas. The color-Doppler demonstrated turbulent flow, and arterialization of portal vein flow, with an increased peak velocity (83 cm/sec) (Figure 1). All these findings were suggestive for extrahepatic arteroportal fistula. A 16 slices-MDCT scan of the abdomen was performed, using 150 mL of isosmolate iodate contrast media (1.8 mL/kg), injection-velocity of 5 mL/sec, pitch 1, thickness of 2.5 mm, interval reconstruction of 0.6 mm, and triple-phase acquisition. Maximum Intensity Projection

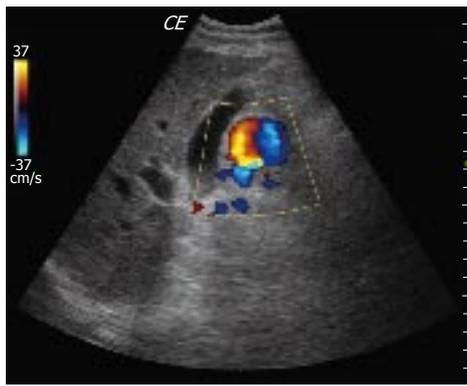

Figure 1 Color–Doppler US showed an anechoic mass, 2.5 cm in diameter, next to the head of the pancreas with turbulent flow inside.

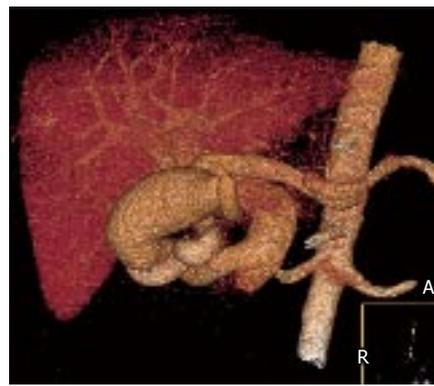

Figure 2 MDCT 3D reconstruction showed the presence of a large aneurysm filled with a dilated gastroduodenal artery and draining into the superior mesenteric vein.

Figure 3 Celiac axis arteriogram confirmed a large aneurysm of gastro-duodenal artery and a fistulous communication with the main portal vein.

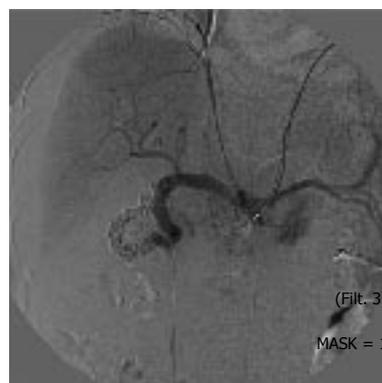

Figure 4 Arteriogram performed after coils embolization showed complete occlusion of the fistula.

(MIP) and Volume Rendering (VR) 3D angiography reconstructions clearly confirmed the presence of a large aneurysm filled by a dilated gastroduodenal artery, draining into the superior mesenteric vein (Figure 2). Other CT findings were normal liver, presence of esophageal varices and splenomegaly (volume of 910 mL). The HVPG was normal (5 mmHg), confirming the extrahepatic origin of portal hypertension. The diagnosis of extrahepatic portal hypertension secondary to arteroportal fistula was established. However, the patient refused the percutaneous arterial embolization of the fistula.

Seven months later a clinical examination revealed the presence of ascites. The MRI confirmed the presence of free fluid into the abdomen, bilateral pleural effusion and no changes in the aneurysm. The percutaneous embolization was then accepted. The initial angiogram of the celiac axis confirmed the large aneurysm of the gastroduodenal artery and a fistulous communication with the main portal vein (Figure 3). After selective catheterization of the aneurysm, several metallic coils (8 mm in diameter) were placed in both the aneurysm and the fistula. The post-procedure arteriogram showed the complete occlusion of the fistula (Figure 4).

One month later, the endoscopy demonstrated the absence of esophageal varices. Three months later, a CT scan showed a complete thrombosis of the arteroportal fistula, the absence of ascites and pleural effusion, and a significant reduction of the spleen volume (689 mL). Now, the patient is free of symptoms with normal liver function

tests: AST 34 U/L, ALT 32 U/L, serum bilirubin 0.8 mg/dL, albumin 3.9 g/dL, PT 98%, INR 0.8, and platelets count $22 \times 10^3 \mu\text{L}$.

DISCUSSION

The arteroportal fistula is a rare disorder of hepatic vasculature characterized by anomalous communication between the arteries and portal venous system. Extrahepatic arteroportal fistulas are less common than the intrahepatic ones. The most common causes of arteroportal venous fistula are traumas, iatrogenic damage and congenital vascular malformations^[1]. In our patient there was no history of traumas or other vascular malformations, suggesting that the previous gastrectomy might be the most likely cause of arteroportal fistula. It is known that this vascular disorder may cause portal hypertension in non-cirrhotic liver^[2,3], due to an increased arterial blood flow. In addition, the nodular regenerative hyperplasia and hepatoportal sclerosis with fibrosis may develop during the follow-up period and worsen portal hypertension^[5].

In our case, the arteroportal venous fistula was well detected by Doppler ultrasonography, and confirmed by computed tomography and magnetic resonance angiography.

Severe portal hypertension with large esophageal varices, ascites and pleural effusion was maintained by the increased portal venous inflow. This is confirmed by a

normal value of HVPG that rules out the hepatic origin of portal hypertension. The arteroportal venous fistula can be treated with percutaneous arterial occlusion^[4]. Notably, esophageal varices and ascites disappeared after the embolization, which further confirmed the role of increased portal blood inflow.

In conclusion, arteroportal fistula is a rare cause of portal hypertension in non-cirrhotic liver and may cause variceal bleeding and ascites. Imaging studies are useful to detect it and the HVPG measurement is useful in confirming the extrahepatic origin of portal hypertension. The percutaneous arterial embolization is an effective therapy for these patients.

Abstract

Esophageal cancer (EC) is a highly lethal disease. Approximately 50% of patients present with metastatic EC and most patients with localized EC will have local recurrence or develop metastases, despite potentially curative local therapy. The most common sites of distant recurrence are represented by lung, liver and bone while brain and breast metastases are rare. Usually patients with advanced disease are not treated aggressively and their median survival is six months. We report a woman patient who developed breast and brain metastases after curative surgery. We treated her with a highly aggressive chemotherapeutic and surgical combination resulting in a complete remission of the disease even after 11-year follow-up. We think that in super selected patients with more than one metastasis, when functional status is good and metastases are technically resectable, a surgical excision may be considered as a salvage option and chemotherapy should be delivered to allow a systemic control.

INTRODUCTION

Esophageal cancer (EC) is a highly lethal disease, with an estimated annual incidence of 14 550 new cases and 13 770 related deaths in 2006 in the USA^[1]. Approximately 50% of patients present with metastatic disease and most patients with localized EC will have local recurrence or develop metastases, despite potentially curative local therapy^[2].

The most common sites of distant recurrence are represented by lung, liver and bone^[3] while brain and breast metastases are rare. Brain metastases have been reported only in 3.6% of all resected patients^[4] but their incidence in all patients with EC is higher^[5].

Extra mammary malignancies rarely metastasize to the breast, usually in patients with disseminated neoplasms^[6] and according to literature data, only few cases of breast metastases from EC have been reported so far^[7-9].

The case presented here is a woman with EC who underwent surgery and later developed synchronous solitary breast and brain metastases. She showed uncommon sites of recurrence of the disease. Generally, patients with EC are not treated aggressively in the presence of advanced diseases. Nevertheless, we performed a highly combined aggressive chemotherapeutic and surgical approach resulting in a complete remission of the disease even after 11-year follow-up. Together with the clinical case description, considering the rarity of the event, we discussed the features connected with the diagnosis and management of such an uncommon presentation of the metastatic disease.

CASE REPORT

In June 1995 a 51-year-old white woman patient with EC was admitted to our hospital. She complained of severe dysphagia and dyspeptic disorders associated with a weight loss. Her history revealed recent onset of dysphagia,

Figure 1 Barium swallow shows the presence of a stenotic trait in the middle thoracic esophagus.

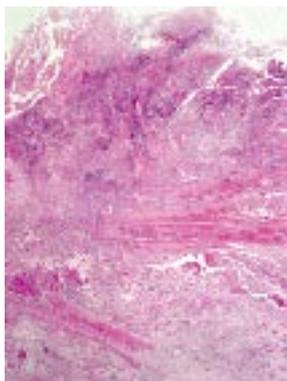

Figure 2 Esophageal histological sample (haematoxylin-eosin stain 20 x) shows the presence of squamous cell carcinoma with involvement of muscular tunic.

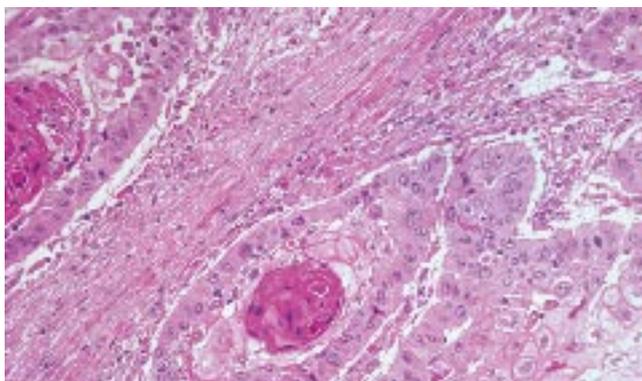

Figure 3 A squamous pearl at a higher magnification (haematoxylin-eosin stain 200 x).

present at first due to solid foods and then due to fluids as well. The difficult food intake caused a subsequent 5 kg weight loss during the five months prior to our observation. Since she had no other specific complaints, we decided to submit our patient to instrumental checks.

Barium swallow showed the presence of a 4 cm stenotic trait in the middle thoracic esophagus (Figure 1) and a next esophagogastroduodenoscopy revealed a vegetant mass in the esophageal lumen causing the stenosis. A biopsy of the mass was performed and histologic examination revealed a squamous esophageal carcinoma (Figures 2 and 3). The tumor marker values were increased and carbohydrate antigen 19-9 (CA19-9) was 250 U/mL (normal < 40 U/mL) while carcinoembryonic antigen (CEA) was 24

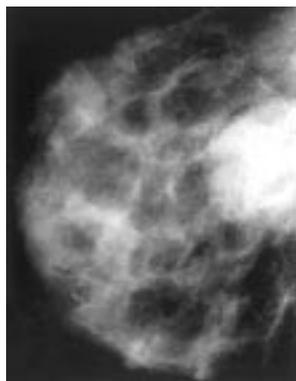

Figure 4 Mammography shows a well-defined nodule without calcification.

µg/L (normal < 3 µg/L). Other laboratory findings were normal.

Total body CT scan, abdominal ultrasonography and bone scintigraphy revealed that the disease was at stage IIa, we therefore decided to treat the patient surgically. In July 1995, subtotal esophagectomy was performed with dissection of lymph nodes and retrosternal reconstruction using tubulized gastric stump. Surgical operation was radical and the lymph nodes were negative for metastases. Histological examination confirmed the presence of squamous carcinoma and pathological stage of the disease was T₂ N₀ M₀. The woman underwent periodical clinical checks.

In November 1995, the patient noted the presence of an approximately 3 cm × 3 cm nodule in the upper lateral quadrant of the left breast. At clinical examination, it appeared as a hard mass not fixed to the surrounding structures. The tumor marker carbohydrate antigen 15-3 (CA15-3) was normal. A mammography confirmed the presence of the nodule (Figure 4) and fine-needle aspiration cytology under ultrasound guidance was performed, indicating the presence of squamous carcinoma cells.

Total body CT scan requested for restaging showed also a 1 cm × 1 cm focal lesion in the frontal right lobe of the brain. Therefore, we treated the woman with a palliative chemotherapy schedule based on cisplatin (25 mg/m² iv a day) from d 1 to d 5, and 5-fluorouracil (1000 mg/m² iv a day) from day 1 to day 5 by continuous infusion every four weeks^[10]. After the first cycle administration we observed remarkable reduction of the breast metastasis at clinical examination.

Taking into account either the palliative medical treatment or her relatively young age and good general conditions, we decided to perform surgical excision of both metastases followed by chemotherapy. In the following ten days, either tumorectomy or brain metastasectomy of the breast lesion was performed. Histological examination (Figures 5 and 6) revealed the presence of esophageal metastatic tumor. No surgical complication occurred. One month later, we resumed chemotherapy and further five courses of treatment were delivered.

In the following time the patient began to start again her daily activities and underwent periodical clinical and instrumental checks, which were always negative. The woman enjoyed good health after eleven years.

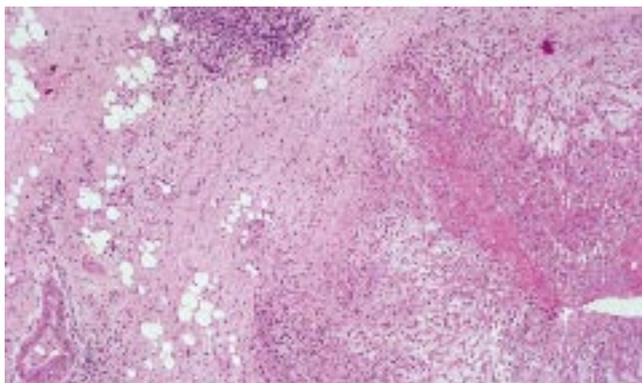

Figure 5 The right side of breast histological sample shows an infiltrating squamous carcinoma's focus with peritumoral inflammation while the left side shows a normal mammary duct section (haematoxylin-eosin stain 40 x).

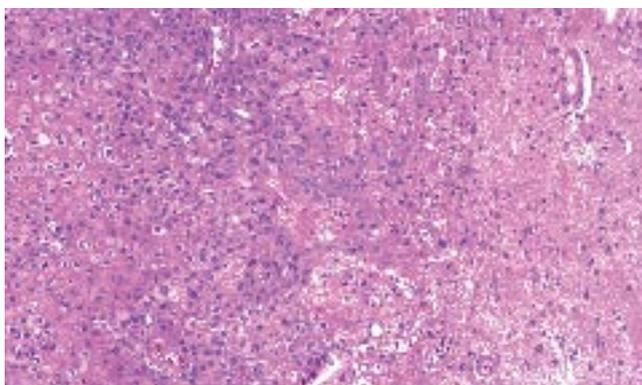

Figure 6 Squamous carcinoma infiltrating the cerebral parenchyma (haematoxylin-eosin stain 100 x).

DISCUSSION

EC is treatable but rarely curable. Patients with metastatic EC have a median survival time of six months^[11]. Moreover the reported 5-year survival rate ranges from 20% to 36% after intentionally curative surgery^[12] due to a high rate of either local or distant recurrence. Distant metastasis rate is reported to be 26% within 20 mo after radical surgery^[13]. Early metastatic relapse after complete resection of any apparently localized primary tumor indicates that micrometastatic tumor cell spread at the time of surgery is undetectable by current staging methods and routine histopathology^[14].

Commonly EC metastasizes to the lungs, liver and bone^[3] but rarely to the brain^[4] and exceptionally to the breast^[7-9]. We observed an unusual metastatic pattern with both solitary breast and brain single metastases in our patient. Breast metastases from non-mammary malignancies are very rare and their incidence ranges from 0.5% to 5.1% of all breast tumors^[7]. They usually occur in the upper outer quadrant^[6] and their prognosis is poor^[8,9].

Clinical and radiological aspects of secondary breast tumors are heterogeneous, though in most cases they appear as a solitary palpable, usually mobile mass. Mammographic finding consists of a round, dense and well-circumscribed mass, without spiculation, microcalcification or skin thickening. Furthermore, growth

is usually rapid^[15]. However, differential diagnosis is needed for correct treatment choice and it is reasonable to obtain a histological or cytological sample of the lesion.

The presence of metastatic lesions in any patient is an indication for a systemic treatment of primary cancer. Anyhow it has been reported that curative surgery for breast metastasis is a correct choice of treatment if metastases in other sites are controlled by other modalities^[7].

For the case reported here, we made a disease restaging which showed concomitant presence of a brain metastasis because of the detection of her breast metastasis. This feature represents a further worsening of the prognosis of our patient. As a matter of fact patients with brain metastases from EC have a median survival time of 3.9 mo^[16]. However it has been reported that an intensive brain tumor treatment may result in a longer survival time of selected patients with good Karnofsky performance status (KPS)^[17] after excision of a single brain metastasis from EC^[18]. Even the presence of multiple or recurrent brain metastases does not automatically contraindicate surgery because it can prolong survival and enhance the quality of life^[19]. Currently surgery followed by whole brain radiation therapy (WBRT) is considered the standard treatment^[20] for a single brain metastasis.

For the case reported here, we began chemotherapy in order to obtain a systemic control of the disease. Since we observed a remarkable reduction of the breast lesion after only one course of chemotherapy, we modified our treatment plan. Since the patient was relatively young and in good functional status, we decided to perform radical excision of her metastatic EC followed by chemotherapy. Brain radiotherapy was not performed. This combined aggressive chemotherapeutic and surgical approach resulted in a complete remission of the disease even after 11-year follow-up.

Generally, the prognosis of patients with recurrent EC is poor, but in some cases surgical resection, chemotherapy or radiotherapy has been proven effective^[21].

Our experience suggests that when functional status is good and metastases are technically resectable, surgical excision may be considered in selected patients with more than one metastasis and chemotherapy should be delivered to allow a systemic control.

Abstract

Collision tumors are thought to arise from the accidental meeting and interpenetration of two independent tumors. We report here a highly unusual case of a 61-year old man who had a unique tumor that was composed of a metastatic adenocarcinoma from the stomach to the rectum, which harbored a collision tumor of primary rectal adenocarcinoma. The clonalities of the two histologically distinct lesions of the rectal mass were confirmed by immunohistochemical and molecular analysis. Although histologic examination is the cornerstone in pathology, immunohistochemical and molecular analysis can provide evidence regarding whether tumors originate from the same clone or different clones. To the best of our knowledge, this is the first reported case of such an occurrence.

INTRODUCTION

The term collision tumor refers to two coexisting, but independent tumors^[1]. Malignant neoplasms originating from two or more distinct topographic organs may form a collision tumor. A possible explanation for this is field cancerization, which occurs due to long-term exposure to carcinogens, whereby multiple carcinogenic transformations give rise to genetically unrelated secondary primary tumors with independent mutations^[2,3] and thus, the chance of tumor collision may be increased. However, there is no explanation for the occurrence of many collision tumors. As most diagnoses are made based on the histology alone, the question is whether histologic classification can accurately reflect the molecular findings in these tumors. If two tumors arise independently and are associated with coincidence only, the genetic alterations are expected to be different from each other because of the different tumor origins. We report here a rare collision tumor of the rectum that was composed of a rectal adenocarcinoma within the metastatic gastric adenocarcinoma. Furthermore, in an effort to find the molecular evidence both for the histologic diagnosis of this collision tumor and for the clonality of the two separate components, we characterized the molecular alterations of each tumor component by examining the microsatellite instability (MSI) and loss of heterozygosity (LOH), and performed an immunohistochemical analysis as well. The findings of this tumor represent an entity that has never been described at this location.

CASE REPORT

A 61-year old man presented with postprandial epigastric pain for 5 mo. Upper gastrointestinal endoscopy suggested an ulcerofungating tumor spreading from the gastric body and antrum to near the esophagogastric junction, and biopsy revealed a poorly differentiated adenocarcinoma. The patient underwent radical total gastrectomy for the gastric cancer with regional lymph node dissection. During the operation, the rectum showed a tumor that was considered to be a distant metastasis from the gastric cancer. So, low anterior resection of the rectum with regional lymph node dissection was also performed for the distant metastasis of the gastric carcinoma.

The resected rectum revealed a relatively ill-defined ulcerofungating mass measuring 7 cm × 6 cm. Sectioning

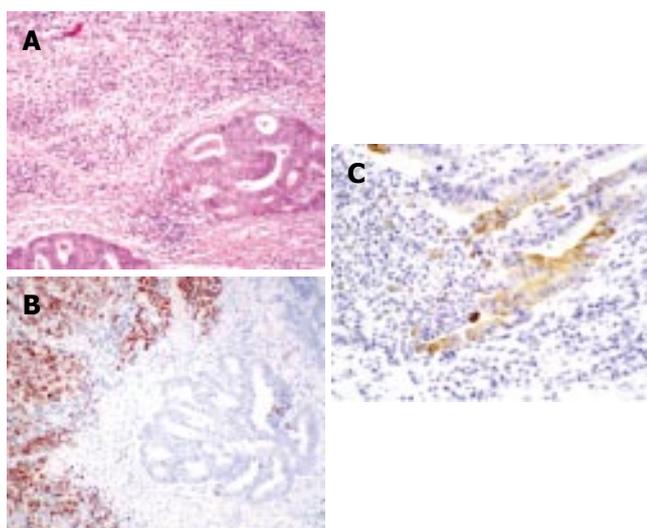

Figure 1 Histological features of rectal tumor showing the interface of a tubular adenocarcinoma component of primary rectal cancer (right) and a poorly-differentiated adenocarcinoma component metastasized from the stomach (left) (hematoxylin and eosin; $\times 40$) (A), immunohistochemical analysis showing positive MUC2 in metastatic gastric carcinoma and negative MUC2 in primary rectal carcinoma ($\times 200$) (B), and negative CK7 in metastatic gastric carcinoma and positive CK7 in primary rectal carcinoma ($\times 200$) (C).

revealed a whitish granular infiltrating tumor with extension into the perirectal soft tissue. Any regional differences of the tumor were not grossly identified. The resected stomach revealed a Borrmann type IV mass, measuring 14 cm \times 14 cm, at nearly the entire gastric wall. Microscopically, the rectum showed a larger component of poorly differentiated adenocarcinoma with a focal signet-ring cell appearance involving the entire rectal wall. A smaller component of well-differentiated tubular adenocarcinoma invading into the perirectal soft tissue was noted within the poorly differentiated adenocarcinoma. Both components collided with each other with no intermingling at their interface (Figure 1A). The surgical margins were tumor-free. Multiple regional lymph nodes ($n = 28$) showed metastatic adenocarcinoma ($n = 26$), of which two revealed feature of well-differentiated tubular adenocarcinoma and 24 revealed poorly-differentiated adenocarcinoma. The stomach mass was an invasive, poorly-differentiated adenocarcinoma invading into the perigastric soft tissue and showing the same histologic features as the larger component of the rectal tumor. The

well-differentiated tubular adenocarcinoma cells seen in the rectal wall were not found in the gastric wall. The proximal resection margin was tumor-involved, but the distal resection margin was tumor-free. Multiple regional lymph nodes ($n = 60$) showed poorly-differentiated metastatic adenocarcinoma ($n = 47$).

Immunohistochemical staining was performed to distinguish the two components of the rectal tumor. The characteristics of the antibodies used in this study and the results are presented in Table 1 as well as in Figure 1B and C. In summary, the primary gastric carcinoma as well as the metastatic gastric carcinoma in the rectum displayed both strong and diffuse staining for MUC2, but negative staining for cytokeratin 7 (CK7), whereas the primary rectal carcinoma component showed focal positive immunoreactivity for CK7, but negative staining for MUC2. The distribution of immunostaining was well correlated with the histologic distinction between metastatic gastric and primary rectal carcinoma components in the collision tumor.

The tissue of both tumors and their non-tumor counterparts were scraped from 10 μ m-thick formalin-fixed, paraffin-embedded sections, and then genomic DNA was extracted using the DNeasy tissue kit (Qiagen, Hilden, Germany). DNA sample pairs were amplified using the microsatellite instability MSI/LOH starter kit (Applied Biosystems, Foster City, CA, USA). Genetic stability was analyzed using the Bethesda reference panel that includes BAT25, BAT26, D2S123, D5S346 and D17S250^[4]. Both the primary and metastatic gastric carcinoma components as well as the primary rectal carcinoma component showed microsatellite stability (Figure 2). LOH analysis was carried out using 3 polymorphic microsatellite repeat markers including D2S123, D5S346 and D17S250. A value below 0.6 or above 1.6 was interpreted as evidence of LOH, whereas values between these figures were considered retention of heterozygosity. LOH was found in both primary and metastatic gastric carcinoma components, but not in primary rectal carcinoma component (Table 2). Eight months after surgery, the patient died of recurrent gastric cancer.

DISCUSSION

Collision tumor is considered as a double tumor showing a 'side by side' or 'one upon another' pattern. It can

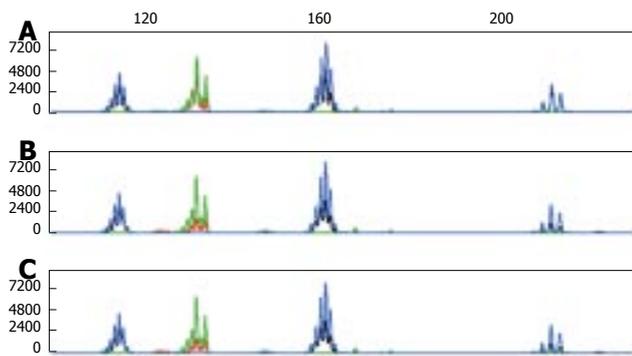

Figure 2 Microsatellite instability phenotype analysis showing no microsatellite instability in the primary rectal tumor (A), the metastatic gastric tumor (B) and the primary gastric tumor (C). Blue and green line: Normal tissue; Black and red line: Tumor tissue.

Table 2 Results of loss of heterozygosity analysis for primary rectal carcinoma component and both primary and metastatic carcinoma components of the stomach

Microsatellite marker	Chromosomal region	Tumor suppressor gene	Loss of heterozygosity		
			Rectal tumor		Primary stomach
			Primary rectum	Metastatic stomach	
D2S123	2p16	hMSH2	No (0.95)	No (0.93)	No (1.03)
D5S346	5q21	APC	No (1.31)	Yes (0.50)	Yes (0.54)

occur within the same organ, or in adjacent organs, or in conjunction with systemic malignancy^[5]. Several hypotheses have been suggested as the mechanisms for collision tumor. The simplest is that two primary tumors occur in continuity by an accidental “meeting”. Two different tumors may also contiguously develop because the region is altered by the same carcinogenic stimuli. Another hypothesis is that the presence of the first tumor alters the microenvironment, making the development of the second adjacent tumor more likely^[5]. In our case, because the primary rectal cancer occupied a smaller portion of the lesion within the larger portion of metastatic gastric cancer, suggesting that metastatic gastric carcinoma to the rectum probably makes some changes in microenvironment and metabolic condition of the rectum, in which a second primary rectal cancer may have developed in association with a previous metastatic focus rather than a metastasis harboring rectal adenocarcinoma. Therefore, we can postulate that substances produced by gastric adenocarcinoma stimulate the immediate adjacent mucosa to undergo increased proliferation and neoplastic transformation.

Collision tumor needs to be distinguished from composite tumor, which is characterized by two divergent lineages originating from the same neoplastic clonal proliferation^[1], because different treatments are warranted depending on the type of collision tumor encountered^[6]. The behavior of collision tumor depends on the individual elements. Definitive conclusion could not be drawn with regard to the prognosis of this type of collision tumor

in our case. However, it is important to differentiate between a case with rectal carcinoma coincidentally having a metastatic gastric carcinoma component and a case with only a primary rectal carcinoma component because of the difference in prognosis. The prognosis of patients with only primary rectal carcinoma is determined by the staging at diagnosis and it is likely to be more favorable than that of patients with an additional metastatic gastric adenocarcinoma in the rectum.

Genetic analysis provides evidence regarding whether the tumors originate from the same clone or from different clones. The panels for each anatomically different site of tumor are then compared to identify the conserved and unique mutations. If the mutational profiles are predominantly unmatched, the diagnosis of a second primary tumor can be established. In an effort to determine the clonality of the two separate components in this patient’s rectal tumor, we characterized the molecular alterations of each tumor component, by MSI and LOH analysis. It has been recently reported that the pattern of MSI findings is a useful tool in determining whether a patient has double primary tumors or a single clonal tumor with metastasis^[7]. Kim *et al.*^[8] reported that high coincident MSI is observed in 17.7% of patients with colon and stomach cancers, suggesting that a genetic defect of mismatch repair deficiency may be responsible for a small subset of double primary cancers of the colorectum and stomach. In this case, we could not find any discriminating pattern of MSI in both primary and metastatic gastric carcinoma components, as well as in primary rectal carcinoma component. The clonal evolution of cancer can be followed up by using markers that identify LOH. However, carcinogenesis is most often not a single event, but rather the result of many mutations that accumulate over time. Blaker *et al.*^[9] reported that LOH patterns of primary colon cancer and metastatic tumors are different in about half of the cases. In our case, LOH analysis showed that the two components of rectal tumor were collision tumor.

The mucin gene family consists of at least nine MUC genes whose tissue distribution has mainly been studied with antibodies that recognize the core protein of different mucins. At immunohistochemical level, the expressed main mucin types are MUC1 for the intestinal type, MUC5AC for the diffuse type, and MUC2 for the mucinous type in gastric cancer^[10]. MUC2 expression has been shown to be significantly lower in non-mucinous colorectal cancer^[11]. Different expressions of various types of CK in tumors at different primary sites can be a clue to the origin of a neoplasm. It has been reported that carcinomas of the colon generally express CK20, whereas the CK7 expression is usually negative, and the expressions of CK7 and CK20 in carcinomas of the stomach have yielded more variable results^[12]. However, carcinomas of a gastrointestinal origin exhibit overlapping and heterogeneous expressions of each mucin and also CK, and there is no definitively consistent immunoreactivity pattern. In this study, primary gastric carcinoma as well as metastatic gastric carcinoma in the rectum displayed strong and diffuse staining for MUC2, but negative staining for CK7, whereas the primary rectal carcinoma component showed focal

positive immunoreactivity for CK7, but negative staining for MUC2. The distribution of immunostaining was significantly correlated with the histologic distinction between metastatic gastric and primary rectal carcinoma components in collision tumor.

To the best of our knowledge, although one of the tumors with a significantly elevated risk is colorectal cancer after the diagnosis of stomach cancer, rectal collision tumor with primary rectal adenocarcinoma and metastatic gastric adenocarcinoma is an entity that has not been previously described at this location. Our immunohistochemical and molecular approach clearly demonstrates that the two components of adenocarcinoma of the rectum have a different clonality.

Abstract

We herein present a case of a 75-year-old female with mucosa-associated lymphoid tissue (MALT) lymphoma of the transverse colon with the stage IE (Ann Arbor classification). Colonoscopy revealed the tumor's appearance as a IIa plus IIc-like early colon cancer as defined according to the macroscopic classification of the Japanese Research Society for Cancer of Colon, Rectum and Anus, measuring less than 2 cm in diameter. Histologically, the tumor was diagnosed as MALT lymphoma because of the presence of lymphoepithelial lesions consisting of diffuse proliferation of atypical lymphocytes and glandular destruction. The majority of these lymphocytes immunohistochemically stained for the B-lymphocyte marker. The patient first underwent *H pylori* eradication therapy with Lansap[®]. However, the tumor size gradually increased over the next 4 mo and the patient eventually underwent surgical resection. The operative procedure included a partial colectomy with dissection of the paracolic lymph nodes. The tumor measured 45 mm x 30 mm in diameter and histological examination showed that the lymphoma cells had infiltrated the muscle layer of the colon without nodal involvement. The patient has had no recurrence postoperatively without any chemotherapy.

INTRODUCTION

The term mucosa-associated lymphoid tissue (MALT) lymphoma was first introduced by Isaacson and Wright^[1] in 1983. This entity includes low-grade gastric B-cell lymphoma and immunoproliferative small intestinal disease. MALT lymphomas occur in a variety of extranodal organs, such as the gastrointestinal (GI) tract and the non-GI tract, in which the stomach is the most common site^[2,3]. Since convincing evidence has been presented showing the relationship between *H pylori* and gastric MALT lymphoma, the therapeutic strategy has been altered for patients with gastric MALT lymphoma in the early stages^[4-8]. In contrast, a treatment for colonic MALT lymphoma has not yet been established. In the present report, we describe a case of colonic MALT lymphoma which did not respond to *H pylori* eradication treatment and, therefore, underwent a surgical resection, and also provide a literature review on this rare entity.

CASE REPORT

A 75-year-old female was admitted to Nagasaki Prefectural Shimabara Hospital for surgical treatment of MALT lymphoma of the transverse colon on June 21, 2005. The patient had shown a positive fecal occult blood test on January 20, 2005 without any clinical symptoms and signs. Her past histories included hypertension, diabetes mellitus, and cholecystolithiasis. The results of complete blood counts, blood chemistries and tumor markers, such as carcinoembryonic antigen, were all within the normal limits. Colonoscopy revealed the tumor's appearance as IIa plus IIc-like early colon cancer^[9], measuring less than 2 cm in diameter, in the transverse colon (Figure 1). Biopsy specimens histologically showed lymphoepithelial lesions with diffuse proliferation of atypical small lymphocytes and some glandular destruction. These lymphocytes immunohistochemically showed diffusely positive staining for L-26 (Figure 2) and bcl-2, but negative staining for CD3, CD5, CD10, CD79a, UCHL-1 and cyclin D1. These findings were compatible with MALT lymphoma of the colon. Barium enema showed a flat-elevated lesion in the transverse colon (Figure 3). Abdominal and chest CT demonstrated neither abnormal lesions nor

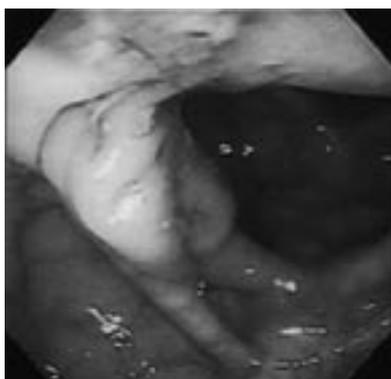

Figure 1 Colonofiberscopy showing the tumor's appearance as a IIa plus IIc-like early colon cancer.

Figure 3 Barium enema showing a flat and well-circumscribed tumor in the transverse colon (arrows).

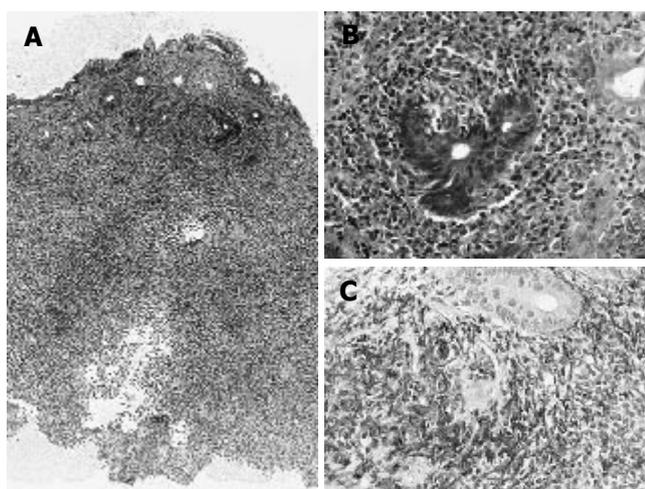

Figure 2 Biopsy specimens histologically showing diffuse proliferation of atypical small lymphocytes in the mucosal layer (A: x 40 magnification, HE) and glandular destruction (B: x 200 magnification, HE). These lymphocytes immunohistochemically showing diffusely positive staining for L-26 (C: x 200 magnification, ABC method).

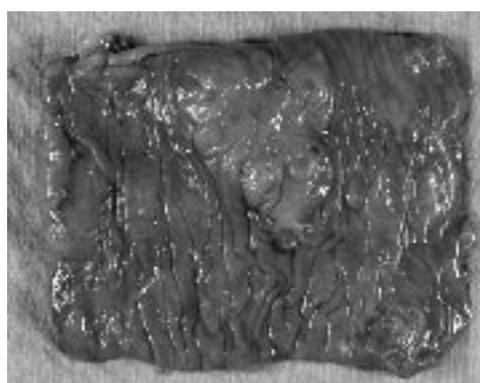

Figure 4 Resected specimens showing a flat-elevated tumor with slight depression, measuring 45 mm x 30 mm in diameter.

enlargement of lymph node. According to the Ann Arbor classification, this MALT lymphoma belonged to the stage IE. The patient first underwent *H pylori* eradication therapy with Lansap[®] because of positive reaction to a urea breath test (UBT). However, over the course of 4 mo, the tumor gradually increased in size, although *H pylori* were eradicated. The patient was considered to be a non-responder to eradication therapy, and was indicated for surgical resection. A partial colectomy with dissection of the paracolic lymph nodes was performed on June 23, 2005 (Figure 4). The tumor grossly appeared to be a IIa plus IIc-like early colon cancer, measuring 45 mm × 30 mm in diameter. Resected specimens were histologically and immunohistochemically reconfirmed to be MALT lymphoma without nodal involvement. The lymphoma cells infiltrated mainly into the mucosa and submucosal layer, and partly infiltrated into the muscular layer of the colon (Figure 5). The patient has had no recurrence postoperatively without any chemotherapy.

Figure 5 The lymphoma cells mainly infiltrated into the mucosal and submucosal layers, and partly infiltrated into the muscular layer of the colon (x 20 magnification, HE).

DISCUSSION

MALT lymphoma is defined as extra-nodal marginal zone B-cell lymphoma of MALT type in peripheral

B-cell lymphoma according to morphologic features, immunophenotype, genetic features, postulated normal counterpart, and clinical features^[10,11].

H pylori eradication therapy is currently widely recognized as an initial therapy in cases with low-grade (stage I) gastric MALT lymphoma^[12-14]. In contrast, it has not yet been clarified whether *H pylori* eradication, or chemotherapy, or surgery should be performed in colonic MALT lymphoma compared with gastric MALT lymphoma, because the colorectal MALT lymphomas are rare. The individual clinical details of colorectal MALT lymphoma are summarized in Table 1^[15-27]. Some reports have

Location; R: Rectum, S: Sigmoid colon; D: Descending colon; T: Transverse colon; C: Cecum; ND: Not described; NED: No evidence of disease. ¹This patient had MALT lymphomas in the stomach and the descending colon, simultaneously. ²These patients performed laparoscopy-assisted colon resection. ³This patient has received repeated eradication.

described the successful regression of colorectal MALT lymphoma by means of eradication therapy in *H pylori*-positive patients^[16,20]. Even in cases with colorectal MALT lymphoma negative for *H pylori*, the regression of the tumor was also recognized as a result of *H pylori* eradication therapy^[19,23,24,27]. In prospective studies of gastric MALT lymphoma, eradication therapy was not effective in patients negative for *H pylori*^[28,29]. Grunberger *et al.*^[30] reported that antibiotic eradication therapy was not effective in patients infected with *H pylori* suffering from extra-gastric MALT lymphoma. Therefore, they suggested that *H pylori* did not play a role in the development of extra-gastric MALT lymphomas. Similarly, antibiotic eradication therapy was not effective in our present case. These results may suggest that colorectal MALT lymphomas are not directly related to *H pylori* infection, while gastric MALT lymphomas are strongly associated with *H pylori* infection. In the future, a definite pathogenesis of colorectal MALT lymphoma should be clarified when cases of colorectal MALT lymphomas have accumulated. As a speculation, colorectal MALT lymphomas may be caused by unknown antibiotic-sensitive microorganisms other than *H pylori*, although that is not clear. In gastric MALT lymphoma, indeed, *Helicobacter heilmannii*-associated MALT lymphoma other than *H pylori* has been reported to be completely regressed by eradication therapy^[31].

Surgical resection is mandatory when a colorectal MALT lymphoma does not respond to eradication therapy or chemotherapy, and it is localized without dissemination.

In conclusion, the present case with colonic MALT lymphoma eventually underwent surgical resection of the colon after the failure of eradication therapy. Surgical intervention is now the procedure of choice for colorectal MALT lymphoma because its pathogenesis and therapeutic strategy have not yet been established.

Abstract

A case of a large multiplex recurrent hydatid cyst involving the left gluteal muscle and the left iliopsoas, accompanied with degeneration of the musculature of the left upper leg is presented along with a review of the relevant literature. Very few such cases have been reported worldwide. The presented case is also distinguished by the involvement of muscles of distant anatomic areas.

INTRODUCTION

Echinococcosis is a zoonotic infection caused by tapeworms of the genus *Echinococcus* which inhabits in the small intestine of carnivores. The adult worms produce eggs that are released with the feces and spread in various ways, such as through the wind, water or flies^[2]. After ingestion by the host, the embryos migrate through the intestinal wall and are either arrested in the capillary bed of the liver developing into liver cysts, or manage to penetrate into systemic circulation thus ending up in remote organs. The lung, the brain, and the muscles or

bones are the more frequently involved distant organs. Due to their physiologic role as capillary filters and their vast capillary volume, the liver and lung are most often affected. Other manifestations are found in 15% of the patients, with the skeletal system making up for 1%-4% of all cases^[7]. Voluntary muscles are a very rare site of infection, counting for less than 1% of total^[5].

In this report, we present a case of a large multiplex recurrent hydatid cyst involving the left gluteal muscle and the left iliopsoas, accompanied with degeneration of the musculature of the left upper leg. To our knowledge, less than 50 such cases have been reported in the literature worldwide. The presented case is also distinguished by the involvement of muscles of distant anatomic areas, while no liver, lung or bone lesions were identified.

CASE REPORT

A 78-year-old Caucasian male was admitted to our clinic, with a swelling of the waist and the left upper leg. The patient had been operated four times over the past 18 years for echinococcosis of the musculature of the left upper leg. During this period, he suffered recurrent swellings of the thigh that were treated as abscesses. His past medical record was otherwise unremarkable.

On physical examination, a mass was located in the left waist and the upper part of the left gluteus muscle. A communicating fistula with a daughter cyst was identified in the median part of the left gluteus muscle. Another communicating fistula extended from the daughter cyst to 5 cm above the knee joint where a third cyst was palpable. The aforementioned findings were also visible on ultrasound (US) and MRI studies. The lesions of the primary and daughter cyst in the waist and the communicating fistula were located superficially at the fascia of the left gluteus muscle (maximum diameter 10 cm).

There were no signs of calcification in any of these cysts. No liver or lung manifestations were present. Anti-echinococcal IgG was positive for infection (title 2,2, positive if > 1.1, ELISA).

The patient was submitted to perform a complete cystopericystectomy of both primary and daughter cysts and radical excision of the fistula. The overlying skin was excised and the surgical wound was primarily closed. The lesions were easily dissected from the underlying fascia that did not need removal. The cysts contained purulent material. The wound was drained for 24 h. The surgical

Figure 1 Preoperative appearance of the lesion, where primary cyst, communicating fistulas and daughter cysts are discernible.

specimen was submitted for histopathological examination which confirmed the diagnosis. The postoperative course was uneventful and the patient was discharged on the 6th postoperative day. He has been followed up for 16 mo and no recurrent cyst was evident on CT and MRI scan.

DISCUSSION

Soft tissue hydatid disease is rare even in endemic areas, such as the Mediterranean. Intramuscular lesions in the absence of liver, lung or bone manifestations are most uncommon^[1,4]. In our case, we encountered an extended soft tissue disease with no signs of systemic infection but a history of multiple recurrences. To our knowledge, very few similar cases have been reported in the literature worldwide (Table 1). Recurrences had developed in the form of abscess-like lesions in multiple sites of the leg which is also uncommon in intramuscular infections. Quality of life of this patient was poor due to constant symptomatic hyeminitis, possibly a result of chronic local inflammation. He also experienced mobilization difficulties (Figure 1).

Determining the ideal therapeutic approach for a recurrent musculoskeletal hydatid cyst can be quite challenging for the general surgeon. Moreover, the rarity of the disease renders the decision making on the favorable treatment quite difficult. Conservative treatment, complete excision and simple drainage have all been suggested as adequate^[10]. Hydatid disease progresses slowly and is rarely life-threatening, especially when located in the soft tissue or muscles, thus supporting a more conservative therapeutic approach. Additionally, co-morbid conditions and advanced age of the patient as well as the surgeon's experience are of great importance for the final decision. However, in case the disease causes profound disabilities or mobilization problems, complete cystopericystectomy should always be considered.

The nature of the lesion should be well documented and evaluated. Radical surgical therapy is especially indicated in cases of unilocular manifestations as only this method offers hope of permanent cure^[9]. Therapeutic dilemmas could arise in cases of extended disease with many muscles or muscle layers in different sites of the body which are communicating *via* fistulas. Communication between lesions should always be suspected and revealed, even if primary and daughter cysts are distant. Complete surgical treatment should include the primary lesion, the daughter cysts and the communicating fistulas as a whole specimen.

Hydatid disease may occur anywhere in the musculo-

skeletal system, from the big toe to the crown of the head^[5,6,8]. In endemic areas, echinococcosis should be always suspected and bared in mind in the differential diagnosis of cystic lesions in soft tissue, even if the radiological appearance is not typical. Once the diagnosis is established, the surgeon should consider performing a radical procedure aiming in minimizing the possibility of a recurrence.

Abstract

Mirizzi syndrome (MS) is an uncommon complication of gallstone disease and occurs in approximately 1% of all patients suffering from cholelithiasis. The syndrome is characterized by extrinsic compression of the common hepatic duct frequently resulting in clinical presentation of intermittent or constant jaundice. Most cases are not identified preoperatively. Surgery is the indicated treatment for patients with MS. We report here a 71-year-old male patient referred to the surgical outpatient department for diffuse upper abdominal pain and mild jaundice (bilirubin rate: 4.2 mg/dL). Ultrasound examination revealed a stone in the cystic duct compressing the common hepatic duct. The patient had a history of gastrectomy for gastric ulcer 30 years ago. MRCP revealed a stone impacted in the cystic duct causing obstruction of the common hepatic duct by extrinsic compression. With these findings the preoperative diagnosis was indicative of MS. At laparotomy a moderately shrunken gallbladder was found embedded in adhesions containing a large stone which was palpable in the common bile duct. The anterior wall of the body of the gallbladder was opened by an incision which extended longitudinally along the gallbladder towards the common bile duct. The stone measuring 3.0 cm in diameter, was then removed setting astride a large communication with the common bile duct. A Roux-en-Y cholecysto-cholecho-jejunostomy was performed. The subhepatic region was drained. The patient had an uneventful recovery. He was discharged eleven days after operation and remained well after a 30-mo follow-up.

Key words: Benign jaundice; Hepatic duct obstruction; Impacted gallstone; Cholecystobiliary fistula

INTRODUCTION

Mirizzi syndrome (MS) is a rare complication of long-standing cholelithiasis, which results from impaction of a large calculus or multiple small stones in the cystic duct or in the neck of the gallbladder causing extrinsic narrowing of the common hepatic duct. This condition may result in the clinical presentation of intermittent or constant jaundice. MS occurs in approximately 1% of all patients with cholelithiasis. Although modern imaging techniques are available, the majority of cases are identified during surgery. During the last two decades, 27 patients suffering from MS have been treated in our department^[1,2], we present here a case of a 71-year-old male patient with MS and a literature review.

CASE REPORT

A 71-year-old male patient was referred to the surgical outpatient department for diffuse upper abdominal pain and mild jaundice (bilirubin rate: 4.2 mg/dL). Ultrasound examination revealed a stone in the cystic duct compressing the common hepatic duct (Figure 1). The patient had a history of gastrectomy for gastric ulcer 30 years ago, thus ERCP was not feasible. MRCP revealed a stone impacted in the cystic duct causing obstruction of the common hepatic duct by extrinsic compression. With these findings the preoperative diagnosis was indicative of MS. At laparotomy a moderately shrunken gallbladder was found embedded in adhesions containing a large stone which was palpable in the common bile duct (Figure 2A). It was obvious that the local operative circumstances required great surgical care. Therefore the anterior wall of the body of the gallbladder was opened by an incision which extended longitudinally along the gallbladder towards the common bile duct. The cystic duct could not be identified. The stone measuring 3.0 cm in diameter was then removed setting astride a large

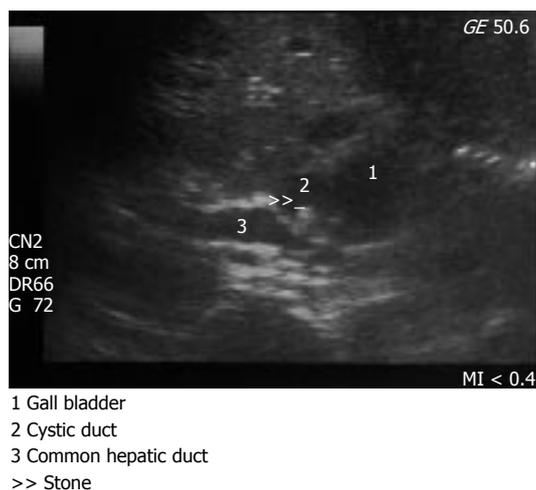

Figure 1 Ultrasound showing a stone compressing the common hepatic duct.

communication with the common bile duct (Figure 2B). Based on this finding and because the risk of stricture at the site of fistulae was significant, we decided to bypass the cholecystocholedochal fistula defect rather than to close it directly or by using a gallbladder flap for closing the opening of the common bile duct around a T-tube. A Roux-en-Y cholecysto-choledocho-jejunostomy was performed (Figure 2C). The subhepatic region was drained. The patient had an uneventful recovery. He was discharged on the 11th postoperative day and remained well after a 30-mo follow-up.

DISCUSSION

MS was first described in 1948 as obstructive jaundice due to a gallstone impacted in the cystic duct or Hartmann's pouch compressing the common hepatic duct^[3].

McSherry *et al*^[4] in 1982 suggested a subclassification of MS into two types. The first type concerns the external compression of the common hepatic duct by a calculus in the cystic duct or Hartmann's pouch, whereas in the second type the stone has entered partly or completely into the common bile duct, resulting in a cholecystocholedochal fistula. Furthermore, in 1989 a new classification of patients with MS and cholecystobiliary fistulae was presented by Csendes *et al*^[5], which includes four types: type I lesion includes those with external compression of the common bile duct; type II lesion is a cholecystobiliary fistula present with erosion of less than one third of the circumference of the bile duct; type III lesion is a fistula involving up to two-thirds of the duct circumference; type IV lesion is a complete destruction of the bile duct.

MS and cholecystobiliary fistulae therefore appear to be different, evolving stages of the same pathological condition, thus it is reasonable that Lubbers^[6] proposes that the term MS can now be abandoned, since it is only the first stage of a more complex process.

Gallstone erosion into the common duct is nevertheless a rare complication of cholelithiasis with an incidence rate ranging from 0.7% to 1.4% of all patients undergoing

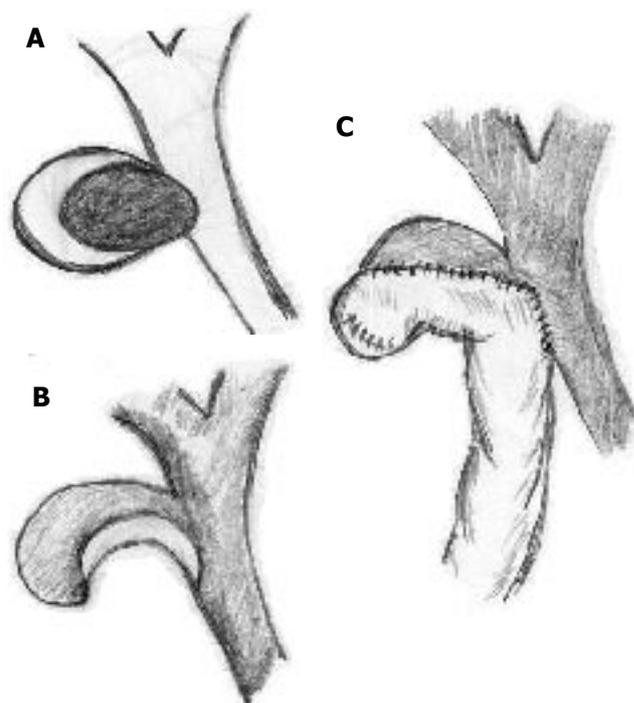

Figure 2 Schematic representation of the described technique during laparotomy (A, B) and Roux-en-Y cholecysto-choledocho-jejunostomy (C).

cholecystectomy^[7].

The clinical diagnosis of MS is difficult, since there are no pathognomonic patterns of presentation. Ultrasound is diagnostically the best screening method, with ERCP and/or MRCP to confirm the diagnosis. MRCP can be as good as ERCP in the diagnosis and its ability to delineate details of biliary structures, but its disadvantage compared to ERCP is its inability to confirm the presence of fistulae and does not afford therapeutic stenting. On the other hand, T₂ weighted sections can differentiate a neoplastic mass from an inflammatory one, that cannot be detected by ultrasonogram or CT scan^[8]. Finally intraductal ultrasound, as an adjunct to ERCP, can also be of help^[9]. Despite of all these modern diagnostic tools, the problem may become apparent only during surgery.

Surgical treatment for type I MS is partial cholecystectomy leaving the neck of the gallbladder in place^[10]. In some cases, open or laparoscopic total cholecystectomy may be performed^[11]. However some authors consider this a contraindication for laparoscopic cholecystectomy^[12-14].

Surgical treatment of type II MS is less clearly defined. Corlette and Bismuth^[15] have recommended partial cholecystectomy, oversuturing of the gallbladder cuff and insertion of a T-tube through the fistula as an adequate treatment for type II MS.

Choledochoplasty is an acceptable therapeutic approach but the amount of gallbladder tissue employed for this has not yet been standardized^[16].

Furthermore, cholecystoduodenostomy has been described^[17] and hepaticojejunostomy^[18] can also be used if complete destruction of the common hepatic duct occurs.

Reconstruction of the extrahepatic biliary tree in case of MS type II with bypass of the lesion using a Roux-

en-Y cholecysto-choledochal-jejunostomy as in our case can be carried out. To our knowledge, this is the first case described in the literature.

In conclusion, since the preoperative diagnosis of MS cannot be achieved, an awarded suspicion is necessary to avoid a lesion of the biliary tree if firm adherence around Carlot's triangle is found. The success of treatment is related to a precocious recognition of the condition even at the time of surgery when the individual characteristics of each case are considered^[18].

Abstract

Ever since its earliest reports, portal venous gas (PVG) has been associated with numerous intraabdominal catastrophes and has served as an indication for urgent surgical exploration. It is traditionally regarded to be an ominous finding of impending death, with highest mortality reported in patients with underlying bowel ischemia. Today, computed tomography has demonstrated a wider range of clinical conditions associated with PVG, some of which are 'benign' and do not necessarily require surgery, unless when there are signs of intraabdominal catastrophe or systemic toxicity. One of these 'benign' conditions is Crohn's disease. The present report describes a 19-year-old Chinese boy with Crohn's pancolitis who presented with septic shock associated with PVG and portal vein thrombosis, and was successfully managed surgically. To our knowledge, this is the first report of PVG and portal vein thrombosis associated with Crohn's disease in a Chinese patient. In addition, we have also reviewed the reports of another 18 Crohn's patients with PVG previously described in the English literature. Specific predisposing factors for PVG were identified in 8 patients, including barium enema, colonoscopy, blunt abdominal trauma, and enterovenous fistula. The patients who developed PVG following barium enema and blunt trauma were all asymptomatic and no specific treatment was necessary. Eleven patients (58%) who presented with signs of intraabdominal catastrophe or systemic toxicity required either immediate or eventual surgery. The overall mortality rate among the 19 patients was only 11%. The present literature review has shown that the finding of PVG associated with Crohn's disease does not always mandate surgical intervention. It is the clinical features and the related complications that ultimately determine the treatment approaches. The overall outcome of PVG associated with Crohn's disease has been favourable.

INTRODUCTION

Portal venous gas (PVG) is a rare radiological finding that occurs when intraluminal gas from the gastrointestinal tract or gas-forming bacteria enters the portal venous circulation^[1]. Factors predisposing to PVG include bowel mucosal injury, bowel distension, and sepsis^[2]. Ever since its earliest reports^[3,4], PVG has been associated with numerous intraabdominal catastrophes and has served as an indication for urgent surgical exploration. It is traditionally regarded to be an ominous finding of impending death, with highest mortality reported in patients with underlying bowel ischemia^[2]. However, it is becoming apparent that there are conditions in which the finding of PVG is relatively 'benign' and does not always indicate surgery, and these conditions include digestive tract dilatation, ulcerative colitis, Crohn's disease, and complications of iatrogenic and endoscopic procedures^[5]. Remarkably, there are reports of PVG occurring in patients with uncomplicated Crohn's disease after blunt trauma^[6,7] or colonic diagnostic procedures^[8,9], which resolves spontaneously without treatment. On the other hand, when PVG occurs in Crohn's patients with signs of intraabdominal catastrophe or systemic toxicity, urgent surgery is warranted, and the final outcome has mostly been favourable^[10-18]. The present report describes a 19-year-old Chinese boy with Crohn's pancolitis who presented with septic shock associated with PVG and portal vein thrombosis, and was successfully managed surgically. To our knowledge, this is the first report of PVG and portal vein thrombosis associated with Crohn's disease in a Chinese patient. The literature of PVG associated with Crohn's disease is also reviewed, with special emphasis on the clinical features, the various predisposing factors, and the treatment approaches.

Figure 2 Photograph of the total colectomy specimen showing the classical features of Crohn's colitis: cobblestone mucosa with skipped lesions.

CASE REPORT

A 19-year-old Chinese boy presented to the Accident and Emergency Department of our hospital with fever, hypotension, and abdominal distension. He had been diagnosed with Crohn's pancolitis a year ago and had been treated with mesalazine, but the drug compliance was poor. One month prior to this hospitalization, he had been admitted to another hospital because of fever and bloody diarrhoea. He was treated as a flare-up of Crohn's disease with intravenous steroid and antibiotics. However, his condition remained static despite a week of medical treatment, and he insisted to be discharged against medical advice. He consulted a Chinese herbalist and consumed some Chinese herbal medicines, but his condition continued to deteriorate. He became so ill that his parents finally brought him to our hospital to seek for further medical treatment.

On arrival, his temperature was 38°C, blood pressure 86/40 mmHg and heart rate 153 beats/min respectively. The abdomen was grossly distended and tense, although no frank peritoneal sign could be elicited. Initial blood tests showed leukocytosis, coagulopathy, and metabolic acidosis. He was immediately admitted to the Intensive Care Unit (ICU); aggressive fluid resuscitation and antibiotics were given. After initial stabilization, an urgent computed tomography (CT) of the abdomen and pelvis was performed, which showed evidence of portal venous gas, portal vein thrombosis, gross ascites, and pneumoperitoneum (Figure 1). The small bowel appeared thickened and inflamed, but the large bowels were not clearly demonstrated. The diagnosis was compatible with Crohn's disease with bowel perforation and septic shock, and hence an emergency laparotomy was arranged.

Intraoperatively, generalized peritonitis with 2-3 L of faeculent fluid and pus was noted throughout the peritoneal cavity. The small and large bowels were densely matted together by inflammatory adhesions. The large bowel appeared shrunken and chronically diseased, but no perforated site was identified. No obvious stricture or perforation was noted along the small bowel. The adhesions between the bowels were removed, and this already resulted in a blood loss of 9 L because of severe coagulopathy. Damage control surgery with packing of all the raw areas was done and the patient was sent back to the ICU for

Figure 3 Computed tomography of the abdomen showing evidence of partial recanalization of the portal vein (long arrow) with increasing surrounding collaterals (short arrow).

further stabilization. NovoSeven (recombinant coagulation factor VIIa) and blood products were given to correct the coagulopathy. A second-look laparotomy performed 24 h later showed no more active bleeding from the raw areas. No obvious perforated site was identified along the gastrointestinal tract. The small bowel appeared edematous but viable, while the large bowel appeared shrunken and unhealthy. Thus a total colectomy was performed to remove the diseased large bowel (Figure 2). The abdomen was temporarily closed using a sterile plastic bag to avoid abdominal compartment syndrome. The abdomen was subsequently closed at a 3rd laparotomy 48 h later and an end ileostomy was fashioned. Pathological examination of the resected colon showed severe Crohn's colitis with multiple ulcerations and deep fissures but without perforation.

The postoperative course was very stormy and the patient had prolonged stay in the ICU. Peritoneal swab cultures and blood cultures grew *Enterococcus* and Methicillin-resistant *Staphylococcus aureus* and so vancomycin was added to the treatment regimen. For the portal vein thrombosis, anticoagulation therapy was not started initially because of coagulopathy. Nevertheless, partial recanalization of the portal vein with increasing collaterals was evident on follow-up CT a few weeks later (Figure 3). One month after the 3rd surgery, he developed an episode of massive intraabdominal haemorrhage secondary to erosion of a

mesenteric vessel by an infected collection and required a 4th laparotomy for haemostasis. Fortunately, he recovered quite uneventfully thereafter and was subsequently discharged home 2 mo after the first surgery.

The patient was put on maintenance mesalazine and azathioprine and remained well and asymptomatic 14 mo after the surgery. A CT enteroclysis was performed later and showed no evidence of small bowel involvement.

DISCUSSION

Portal venous gas was first described by Wolfe and Evans

in 1955 in 6 neonates with fatal necrotizing enterocolitis^[3]. In 1960, Susman and Senturia reported the similar finding in an adult, critically ill with small bowel infarction^[4]. Since then, PVG has been reported with increasing frequency in the literature. One of the first reviews by Liebman *et al* evaluated 64 patients with PVG on plain X-ray reported in the literature before 1977^[2]. According to that review, although PVG was observed in association with various clinical conditions, it was mostly (72%) found among patients seriously ill with necrotic bowel. The overall mortality was 75%, and this led the authors to recommend urgent surgical exploration for PVG except for patients with stable

ulcerative colitis who had undergone barium enemas, because 5 such patients survived with conservative treatment. Over the last 2 to 3 decades, advances in diagnostic radiology, including the development of ultrasonography and CT, have increased the sensitivity of imaging PVG. Brandon *et al* suggested that early recognition using CT, with appropriate surgical intervention, improves the chance for patient survival when PVG is identified^[17]. Moreover, PVG on CT has been found to be associated with a wider range of clinical conditions, some of which are 'benign' and do not necessarily require surgical intervention, especially when there are no signs of intraabdominal catastrophe or systemic toxicity^[19]. A recent study of 17 patients with PVG detected by CT has actually reported a mortality rate as low as 29%^[20]. Today, PVG is recognized as a mere diagnostic clue in patients with suspected acute abdominal pathology and is not itself a predictor of mortality. The more relevant prognosticator is the clinical condition in which PVG occurs.

One of the relatively 'benign' conditions that are associated with PVG is Crohn's disease. Including the present case, 19 cases of PVG associated with Crohn's disease were reported in the English literature (Table 1)^[6-18,21-23]. In 4 of these patients, PVG was iatrogenic in origin, resulting from barium enema^[8,9,21] or colonoscopy^[12]. Two patients developed PVG after blunt abdominal trauma^[6,7]. It has been postulated that elevated intraluminal pressure (during colonic diagnostic procedures) or intraperitoneal pressure (associated with blunt trauma) can permit bowel gas or gas-forming bacteria to gain access to the portal venous circulation through microscopic mucosal injury. Another factor predisposing to PVG is the development of entero-venous fistula between the bowel lumen and the mesenteric venous system, which is an extremely rare complication reported in 2 patients with Crohn's disease^[10,13]. In the remaining 11 patients, no specific predisposing factors could be identified. PVG in these patients is thought to be the result of mucosal injury and sepsis^[2] associated with bowel inflammation and portal pyaemia. The occurrence of PVG does not seem to be associated with the anatomical location of Crohn's disease involvement. Both ileal and colonic diseases can develop PVG.

The finding of PVG associated with Crohn's disease does not always mandate surgical intervention. It is the clinical features and the related complications that ultimately determine the treatment approaches. The presentation of PVG following blunt trauma^[6,7] and barium enema^[8,9,21] is remarkably innocuous; all the 5 reported patients were asymptomatic and no specific treatment was necessary (except in 1 patient who was given 'prophylactic antibiotics' for 48 h^[21]). Intravenous antibiotics were administered to patients who developed fever, and 3 of them had complete resolution of symptoms with this simple medical treatment^[16,22,23]. Eleven patients (58%) who presented with signs of intraabdominal catastrophe or systemic toxicity required either immediate or eventual surgery. All these patients underwent resection of the inflamed small and large bowels. The overall mortality rate among the 19 patients was only 11%; a patient with entero-venous fistula died of sepsis and liver failure 1 mo after surgery^[13], while another patient who underwent surgery for ischemic and perforated

small bowel finally died of disseminated cytomegalovirus infection^[16].

The combination of extensive pylephlebitis (or septic thrombosis of the portal vein) and PVG that occurs in our case is an extremely rare complication among patients with Crohn's disease; only 1 similar case was reported in the German literature^[24]. Severe active Crohn's disease and sepsis are the 2 predisposing factors^[25]. Although PVG itself is not a predictor of mortality, the finding of PVG combined with pylephlebitis is generally regarded as an ominous prognostic sign^[26]. Nevertheless, as illustrated in our case, favourable clinical outcome in these patients can still be achieved with early CT diagnosis, maximal organ support in the ICU, aggressive medical treatment, and prompt surgical intervention.

In conclusion, the finding of PVG associated with Crohn's disease does not always mandate surgical intervention. It is the clinical features and the related complications that ultimately determine the treatment approaches. The overall outcome of PVG associated with Crohn's disease has been favourable.

Imazu H, Kojima K, Katsumura M, Omar S. Is there an alternative therapy to cyanoacrylate injection for safe and effective obliteration of bleeding gastric varices? *World J Gastroenterol* 2006; 12(34): 5587

<http://www.wjgnet.com/1007-9327/12/5587.asp>

TO THE EDITOR

We read with interest the article entitled "Bleeding gastric varices: Results of endoscopic injection with cyanoacrylate at King Chulalongkorn Memorial Hospital" by Noophun *et al*^[1]. They performed n-butyl-2-cyanoacrylate (CA) injection therapy for bleeding gastric varices in twenty-four patients, and hemostasis was achieved in seventeen (71%) patients. They concluded that CA injection therapy was effective and safe for bleeding gastric varices. However, we disagreed with the author's conclusion. Their hemostasis rate was relatively low, and two of the 24 patients developed serious complications as a result of glue embolism. Although CA injection therapy has been accepted as the first line treatment especially in Europe and Asia, hemostasis and obliteration of gastric varices are still a therapeutic challenge and many serious complications as a result of CA injection have been reported^[2]. In addition, there is no reimbursement from the insurance companies in Japan if CA is used for obliterating varices and therefore this therapeutic option is not widely practised there. Although conventional endoscopic injection sclerotherapy using ethanolamine oleate has been reported to be ineffective for bleeding gastric varices^[3], we conducted endoscopic injection sclerotherapy combined

with a vasoactive drug for bleeding gastric fundal varices. We have reported a series of thirty patients with bleeding gastric fundal varices treated with endoscopic injection sclerotherapy using 5% ethanolamine oleate plus infusion of vasopressin^[4]. With our method, continuous injection of 5% ethanolamine oleate mixed with contrast medium through a double lumen catheter was performed under fluoroscopic guidance until it filled the varices and their feeder veins, and thrombin glue was sprayed at the puncture site during withdrawal of the injector needle to prevent bleeding. We have achieved a high rate of hemostasis (93%) with a relatively low rebleeding rate (19%) over follow-up period of up to 5 years without any serious complications^[4]. We would like to recommend our sclerotherapy under fluoroscopic guidance method combined with medical therapy as an alternative to CA injection therapy for bleeding gastric varices, although randomized trials with a larger number of patients are warranted. If CA is to be used, aliquots of 1.0 mL CA per injection must be strictly enforced to prevent any embolic complications. Injections can be repeated if bleeding continues, as long as only 1.0 mL CA is injected each time^[5]. Fluoroscopic guidance might also be useful in minimizing this complication^[6].

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents/Clinical Medicine and Science Citation Index-Expanded, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, Nature Clinical Practice Gastroenterology and Hepatology, CAB Abstracts and Global Health.ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology

Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
<http://www.wjgnet.com>
Telephone: +86-10-85381901
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is

Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

Key words

Please list 6-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P*<0.05, ^b*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, ^c*P*<0.05 and ^d*P*<0.01 are used. Third series of *P* values can be expressed as ^e*P*<0.05 and ^f*P*<0.01. Other notes in tables or under illustrations should be expressed as ¹*F*, ²*F*, ³*F*; or some other symbols with

a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (<http://www.wjgnet.com/cgi-bin/index.pl>), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 µg/L; CO₂ volume fraction, 50 mL/L CO₂ not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please download CAF from <http://www.wjgnet.com/wjg/help/9.doc>.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to *WJG* all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The *WJG* requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1) direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3) supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The *WJG* does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to *WJG* if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Abstract

The gastric mucosa separates the underlying tissue from the vast array of antigens that traffic through the stomach lumen. While the extreme pH of this environment is essential in aiding the activation of enzymes and food digestion, it also renders the gastric epithelium free from bacterial colonization, with the exception of one important human pathogen, *H pylori*. This bacterium has developed mechanisms to survive the harsh environment of the stomach, actively move through the mucosal layer, attach to the epithelium, evade immune responses, and achieve persistent colonization. While a hallmark of this infection is a marked inflammatory response with the infiltration of various immune cells into the infected gastric mucosa, the host immune response is unable to clear the infection and may actually contribute to the associated pathogenesis. Here, we review the host responses involved during infection with *H pylori* and how they are influenced by this bacterium.

INTRODUCTION

H pylori is one of the most common human pathogens, since it infects the gastric mucosa of about 50% of the world's

population. The majority of infections are asymptomatic, making the infection lifelong without effective bacterial eradication. The clinical magnitude of this bacterium has become accepted rather recently. *H pylori* has been recognized as the causal agent for chronic gastritis and gastric and duodenal ulcers. Additionally, epidemiological and statistical studies associated the infection with a higher risk of gastric malignancy leading the World Health Organization International Agency for Research in Cancer to categorize *H pylori* as a class I carcinogen.

The bacteria induce a host immune response, but the persistence of the infection suggests that the response is not effective in eliminating the infection. Furthermore, multiple lines of evidence suggest that the immune response contributes to the pathogenesis associated with the infection. As a result, the immune response induced by *H pylori* is a subject of continuous study that has encouraged numerous questions. The inability of the host response to clear infections with *H pylori* could reflect down-regulatory mechanisms that limit the resulting immune responses to prevent harmful inflammation as a means to protect the host. Consequently, the chronic immune response induced may be inadequate or misdirected, and could thus afford a colonization advantage for the bacteria by providing improved availability of adhesion places. An example of this is the resulting increase in class II major histocompatibility complex (MHC) and CD74, induced by IFN- γ and IL-8, that are used as receptors by *H pylori*^[1-3].

H pylori has been shown to employ multiple mechanisms to antagonize, impair, or subvert host responses^[4]. For instance, *H pylori* has been noted to inhibit macrophage nitric oxide production and phagocytosis^[5]. Another mechanism where *H pylori* can down-regulate the immune response is through its VacA virulence factor. This cytotoxin can interfere with the processing and presentation of antigens by antigen-presenting cells (APCs)^[6], and can also inhibit T cell activation through interference of the calcineurin-associated IL-2 signaling pathway^[7]. These and multiple other observations on the nature of the immune response during *H pylori* infection have led to models that help explain how the bacteria could persist in the gastric environment by generating a non-effective immune response. The ineffective response, together with the host factors, determines the severity of the disease.

HUMORAL RESPONSE

Nearly everyone infected with *H pylori* develops specific antibodies, which are found in serum and in gastric

aspirates or extracts of stomach. Accordingly, elevated titers of IgG and IgA antibodies directed at membrane proteins (MP), flagelin, urease, lipopolysaccharide (LPS) and *H pylori* adhesin A (HpaA) have been reported in patients infected with *H pylori*^{48,91}. Yet, those titers do not differ between asymptomatic patients and patients with duodenal ulcers. IgM- and IgA-producing cells in biopsies from the antral region of the *H pylori*-infected patients' stomachs were 40- to 50-fold higher in frequency than in non-infected subjects. However, IgG-producing cell numbers are the same for non-infected and infected *H pylori* subjects. Those results suggest that the infection induces a large recruitment of immune cells into the gastric mucosa, particularly IgA-producing cells. A recent immunoproteome analysis compared individual sera from *H pylori*-positive patients suffering from gastric adenocarcinoma or duodenal ulcer with a pool of five sera from *H pylori*-negative patients to detect antigenic proteins from three separate *H pylori* strains¹¹⁰. That study recognized 30 antigens detected by *H pylori* positive sera, nine of these were newly identified and 21 established previously. The study established the presence of antigens related to specific disease. Interestingly, cancer sera provided stronger immunoreactivity while a similar study suggested that sera from ulcer patients have more anti-*H pylori* antibodies than sera from gastritis patients¹¹¹.

Due to the plasticity of the *H pylori* genome as well as the phase variation that the bacteria present in its LPS, specifically mimic Lewis antigens, 20% to 30% of the people infected with *H pylori* develop autoantibodies, with most of them specific to the gastric proton pump located in the parietal cells. These antibodies may block pump function, leading to achlorhydria associated with the infection, which contributes to the gastric damage seen during infection.

T-CELL RESPONSE

H pylori induce the recruitment of CD4⁺ and CD8⁺ T-cells into the gastric mucosa, but there appears to be preferential activation of CD4⁺ cells rather than CD8⁺ cells¹². Several studies have noted that the T helper cell response to *H pylori* is polarized, since CD4⁺ T cells in the gastric mucosa of infected individuals produce the Th1 cytokines, interleukin (IL)-12 and interferon (IFN)- γ , whereas IL-4, a Th2 cytokine, production by these T cells is absent^{13,14}. A recent study by Amedei *et al*¹⁵ suggested that *H pylori* neutrophil-activating protein (HP-NAP) contributes to this Th1-polarized T cell response in the gastric mucosa of *H pylori*-infected patients. In that study, addition of HP-NAP to antigen-induced T cell lines in culture resulted in a shift from a predominant Th2 to a Th1 phenotype of specific T cells.

Another subset of CD4⁺ T cells are T regulatory cells, which produce IL-10 and transforming growth factor (TGF)- β ¹⁶. While there is a demonstrated infiltration of T cells in the gastric mucosa and most of those are CD4⁺ T cells with markers of activation, various studies have tried to address the inefficiency of the host response in clearing the infection. Different studies have demonstrated that *H pylori* infection can decrease T cell responses as well as

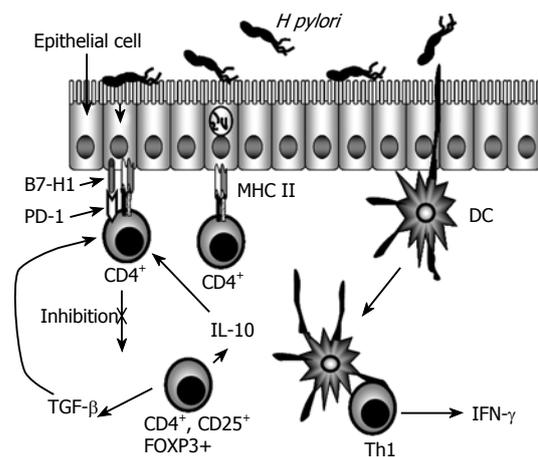

Figure 1 Regulation of CD4⁺ T Cells During *H pylori* Infection. CD4⁺ T cell numbers increase in the gastric lamina propria of individuals infected with *H pylori*. These cells are predominantly Th1 cells characterized by their production of IFN- γ . Because the epithelium separates *H pylori* from CD4⁺ T cells, and also expresses key proteins associated with antigen presenting cells, the gastric epithelium, in addition to dendritic cells, could be involved in the presentation of antigens to these CD4⁺ T cells. The expression of inhibitory B7 related molecules along with CD4⁺ T cells with a regulatory T cell phenotype could be playing a role in limiting the function of effector CD4⁺ T cells.

induce T cell energy¹². CD45RO⁺ memory T cells as well as activated CD69⁺ and CD25⁺ T cells are increased in the antral lamina propria of infected subjects¹⁷. Memory T cells isolated from peripheral blood from infected people responded less to stimulation with *H pylori* antigens than cells isolated from non-infected subjects^{12,18,19}. These results suggested the presence of regulatory T (T reg) cells, CD4⁺ and CD25⁺ in the peripheral blood of *H pylori* infected individuals, which could inhibit the response of CD4⁺ T cells to *H pylori*. This notion was supported by observations that a higher responsiveness was obtained after depletion of *H pylori*-specific T reg cells^{20,21}. Hence, these observations may help explain the inability of the host response to eliminate the infection due to the activation of T reg cells, which were recently reported to be increased in the gastric mucosa of *H pylori*-infected individuals and were described as CD4⁺, CD25^{high} and FOXP3⁺. Such cells may simultaneously reduce mucosal damage mediated by T cells as well as reduce specific T cell responses, possibly by reducing activation of IFN- γ -producing CD4⁺ T cells that can be effective in protection against the infection with these bacteria. Figure 1 illustrates the presence of the various T cell populations in the infected gastric mucosa and how they may interact with one another and with other resident cells.

The role of CD8⁺ T cells in the gastric mucosa of *H pylori*-infected individuals is less clear than that of the CD4⁺ T cells. Although their numbers are also increased, the CD8⁺ T cells that are found in the infected tissue are thought to be intraepithelial lymphocytes. Their contribution to the local response is in the form of IFN- γ production, which in turn helps increase class II MHC molecule expression on adjacent cells. A recent report by Azem and colleagues showed that *H pylori*-reactive CD8⁺ T cells can be efficiently stimulated by *H pylori* antigen-pulsed B cells and DCs, and that most of the CD8⁺ T cells in the infected gastric mucosa are memory T cells²¹.

ANTIGEN PRESENTING CELLS IN THE GASTRIC MUCOSA

The activation of CD4⁺ T cells requires their effective cross talk with cells that express class II MHC molecules, which are classically referred to as antigen presenting cells (APC). Conventional APC include macrophages, dendritic cells and B cells. The role of these cells in the adaptive response is to internalize foreign antigens and present them in the form of peptides bound to class II MHC molecules to the T cells. The infected gastric mucosa contains a significant macrophage population that produces nitric oxide, IL-6, IL-1 β , TNF- α , and IL-12 that help drive a T helper 1 response responsible for the production of IFN- γ , and little or no IL-4 and IL-5^[22,23]. Although in smaller numbers, dendritic cells are also present and respond to *H pylori* with the production of IL-6, IL-8, IL-10 and IL-12, and have increased expression of CD80, CD83, CD86, and HLA-DR as a result of their stimulation with *H pylori*^[24].

For efficient T cell activation, T cells require not only the T cell antigen receptor (TCR)-mediated signaling, but also costimulatory signals provided by APC^[25]. The B7 family of molecules provides signals that are critical for both stimulating and inhibiting T cell activation. Engagement of CD28 by CD80 (B7-1) and CD86 (B7-2) stimulates and sustains T cell responses, whereas engagement of CTLA-4 by the same ligand inhibits T cell responses^[26]. Recently, several new members of the B7 family have been identified. B7-H2 (homologue 2 also known as GL50, B7h, B7RP-1 and LICOS) has been identified as a ligand for the CD28 family member ICOS (inducible T-cell co-stimulator). Two additional B7 family members, Programmed Death-Ligand 1, PD-L1 (B7-H1) and PD-L2 (B7-DC) bind to the receptor Programmed Death-1 (PD-1) and their interaction down regulates T cell activation^[27]. PD-1 is a type I transmembrane receptor expressed on activated T and B cells. Like CTLA-4, PD-1 contains an immunoreceptor tyrosine based inhibitory (ITIM) motif in its cytoplasmic region and acts as a negative regulator of lymphocyte function via multiple mechanisms, including cell-cycle inhibition and apoptosis. The literature suggests that there is another unidentified receptor for B7-H1 and B7-DC whose function has yet to be determined. Two other receptors of the B7 family are B7-H3 and B7-H4 (also known as B7S1 and B7x); however, their receptors and functions are still unclear^[28-30]. In an attempt to examine whether changes in the expression of these novel B7 family members could contribute to the hyporesponsiveness of T cells in the infected gastric mucosa, we examined by real-time PCR the expression of the message for these molecules in gastric biopsies and observed the expression of B7-H1, B7-DC, and B7-H3. Since, as discussed below, the epithelium is exposed to both *H pylori* and T cells in the lamina propria, we examined the epithelium for these molecules and detected their expression by PCR and by Western blot analysis. B7-H1 was the most prominent coinhibitory molecule of the B7 family whose expression was induced following *H pylori* infection. More interesting, epithelial cells in gastric biopsies infected with *H pylori* showed higher B7-H1

expression compared with uninfected samples^[31]. Gastric epithelial cells were found to constitutively express B7-H1, and the level of expression increased significantly during infection. T cells cocultured with gastric epithelial cells exposed to *H pylori* had a lower proliferation index, IL-2 secretion, and CD69 expression in response to activation via CD3. However, blockage of B7-H1 with specific anti-B7-H1 antibodies restored the responses to levels close to those of T cells not cocultured with gastric epithelial cells. This may represent a novel mechanism of immune avoidance used by *H pylori*, which involves the induction of coinhibitory molecule expression on gastric epithelial cells by the bacterium.

Recent elegant studies by Anderson and colleagues showed the importance of CTLA-4 in establishing T cell anergy during *H pylori* infection in a murine model. In this model of *H pylori* infection, the mice that received anti-CTLA-4 Fabs responded to an *H pylori* challenge with much greater inflammation and drastically decreased bacterial numbers. Their results suggested that CTLA-4 engagement may represent yet another mechanism of inactivation of *H pylori*-specific T cells during *H pylori* infection, which could in turn contribute to the chronicity of this infection^[32].

While direct interaction between APC and T cells represent the traditional mechanism leading to T cell activation, another mechanism that is under active investigation involves exosomes secreted by APC. Exosomes are small membrane vesicles derived from late endosomes, which are released into the extracellular membrane and interact with membranes of other cells at a relative distance. Exosomes secreted by APC carry class I and II MHC molecules, costimulatory molecules, and adhesins. Thus, they have immunomodulatory capacity, such as in the activation of naïve T cells^[33]. They have been shown to stimulate T cells *in vitro* and to induce anti-tumor responses *in vivo*^[34,35]. While they are not yet characterized in the context of the T cell response to *H pylori*, their contribution in modulating the local response has to be considered.

Human dendritic cells have been shown to produce IL-8, IL-10, and IL-12 in response to *H pylori* as well as to purified *H pylori* antigens^[36,37]. Thus, *H pylori* can bind to the dendritic cell receptor DC-specific ICAM-3-grabbing nonintegrin (SIGN) through the blood group Lewis X antigen present in its LPS^[38]. This interaction can alter the T helper balance and favor pathogen persistence. Also, in monocytes, urease and HSP60 have been shown to be potent activators of proinflammatory cytokines via NF- κ B activation^[39,40].

THE GASTRIC EPITHELIUM AS AN ACTIVE PLAYER IN THE MUCOSAL RESPONSE

In terms of providing protection, the gastric epithelium has typically been regarded as a physical barrier; however, multiple studies have provided evidence to suggest that the gastric epithelium plays a key role in the inflammatory and immune responses induced by *H pylori*. The epithelium is the only cell phenotype in the gastric mucosa that is in direct contact with the pathogen. This feature places the

epithelium in a strategic situation to interact with *H pylori* and with the immune elements in the lamina propria. There is strong evidence to suggest that the gastric epithelium is an active player in the response while performing functions associated with antigen presenting cells^[41,42]. In addition, it is well documented that the epithelium has the ability to produce cytokines that trigger the recruitment of inflammatory cells into the gastric lamina propria^[1]. The production of IL-8 in response to *H pylori* infection is one of the first epithelial responses. This chemokine recruits immunological components into the gastric mucosa from the periphery, particularly polymorphonuclear cells, which contribute to epithelial damage^[43]. Macrophages also contribute to epithelial damage by producing nitric oxide in response to *H pylori* urease leading to the induction of additional inflammatory mediators^[44]. However, the bacteria produce an arginase encoded by the gene *rocF* that competes with the NOS for L-arginine and converts this to urea and L-ornithine rather than NO^[45].

One of the major mechanisms of IL-8 induction by epithelial cells is through the injection of CagA into gastric epithelial cells by a type IV secretion system^[46]. This system releases CagA into the epithelial cells cytosol inducing cell proliferation and IL-8 production^[47]. Our group has recently described the interaction of *H pylori* with CD74 on gastric epithelial cells (GEC) leading to the production of IL-8, *via* NF- κ B activation^[1]. Interestingly, IL-8 induced by *H pylori*, in addition to its effect in the recruitment of inflammatory cells, also acts in an autocrine manner and induces further expression of CD74^[2]. This, in turn, suggests that *H pylori* has the ability to induce the increased expression of receptors on the host epithelium to enhance colonization and the stimulation of proinflammatory responses. As part of the inflammatory response, we noted that the *H pylori*-infected gastric epithelial cells produce macrophage migration inhibitory factor (MIF), which is an important cytokine that bridges the innate and adaptive immune responses^[48]. The production of MIF was found to be dependent on CagA, since CagA-deficient mutant *H pylori* strains had a significantly reduced ability to stimulate MIF production.

Some of the interactions of the epithelium with *H pylori* can be detrimental to the integrity of the epithelium. For instance, we have shown that *H pylori* use class II MHC as receptors on GECs, and this interaction leads to apoptosis^[3]. This interaction is mediated *via* *H pylori* urease. It has also been reported that *cag* genes may up-regulate Fas ligand (FasL) expression leading T cells to undergo apoptosis^[49]. Thus, the contribution of the gastric epithelium in influencing the adaptive response by expressing molecules that either directly or indirectly limit T cell activity has to be considered in our ongoing efforts to understand the host response to *H pylori*.

THE INNATE RESPONSE TO *H PYLORI*

Other potential interactions that lead to production of pro-inflammatory cytokines include that of *H pylori* with toll-like receptors (TLR) expressed by epithelial cells. It has been reported that gastric epithelial cells express TLR2, TLR4, TLR5, and TLR9^[50-53] that

interact respectively with lipoproteins, LPS, flagellin, and CpG motifs. The expression of those receptors by epithelial cells is of importance in innate immunity against *H pylori*. Since these innate receptors may elicit cytokine secretion when they bind their ligands, they may have an indirect effect in the subsequent adaptive response through the enhancement of processing and presentation of antigen by host cells. However, it has been demonstrated that *H pylori* LPS has a 500-1000 fold lower endotoxigenic activity than LPS from *S. typhimurium* and *E. coli*^[54,55]. This low stimulatory potential can be attributed to the phosphorylation pattern and the LPS' lipid A acylation^[55]. In addition, *H pylori* LPS has low binding affinity to LPS-binding protein (LBP) and in consequence, has a lower transfer rate to CD14 present in macrophages and monocytes^[56].

Another ligand for TLR receptors on the epithelium is *H pylori* flagellin. This flagellin contains different amino acids than that of other bacteria in the TLR5 recognition site, as well as having a compensatory mutation that preserves bacterial motility. Those differences avoid the recognition of flagellin by TLR5^[57]. *H pylori* also avoids recognition by TLR9, which is the receptor for unmethylated CpG motif present in bacteria and viruses. Since *H pylori* DNA shows a high rate of methylation, it can evade the recognition of its DNA by TLR9.

Mast cells represent another innate cell phenotype that is found within the *H pylori*-infected gastric mucosa of humans and mice^[58]. These cells represent an innate defense component that may kill bacteria through the release of proteases and other mediators. Additionally, an interesting observation was made in a recent study that showed that these cells can mediate bacterial clearance in vaccinated mice, and were suggested to do so *via* a cross talk with CD4⁺ T cells^[59].

In parallel with CagA, peptidoglycan (PGN) is also translocated into the epithelial cells by the *cag pathogenicity island* (PAI)-encoded type IV secretion system. Cag-PAI positive bacteria can induce the production of IL-8 *via* NF- κ B in a manner that is CagA-independent by signaling through Nod1. Thus, *H pylori* PGN can interact with Nod1 and induce the activation of NF- κ B^[60].

CONCLUDING REMARKS

Infection with *H pylori* results in robust innate and acquired immune responses by the host, where the gastric epithelium represents a central player. Interaction of *H pylori* with the host epithelium results in the release of an array of chemokines and cytokines. Some of these factors are stimulated *via* the engagement of toll-like receptors or cell surface receptors, such as CD74. Also, injection of CagA *via* the bacterial type IV secretion system leads to NF- κ B activation and the ensuing release of cytokines. The infected gastric mucosa is infiltrated by neutrophils and mononuclear cells as well as components of the acquired response, such as lymphocytes. A specific humoral response is also triggered during infection, as well as a T cell response that is skewed toward a Th1 cell response. In spite of these immune mechanisms, *H pylori* is not cleared because the bacteria seem to be equipped

with an array of mechanisms that allows them to evade or downregulate the host responses. Understanding these multiple mechanisms is a required step toward the development of any immune intervention strategies to protect from initial infection and to eliminate infections that are already established.

Abstract

H pylori is probably the most prevalent human pathogen worldwide. Since it was initially suggested in 1983 by Marshall and Warren to be implicated in gastritis and peptic ulcer disease, *H pylori* has also been implicated in gastric carcinoma and was classified as a class I carcinogen. In the last two decades, a noteworthy body of research has revealed the multiple processes that this gram negative bacterium activates to cause gastroduodenal disease in humans. Most infections are acquired early in life and may persist for the life of the individual. While infected individuals mount an inflammatory response that becomes chronic, along with a detectable adaptive immune response, these responses are ineffective in clearing the infection. *H pylori* has unique features that allow it to reside within the harsh conditions of the gastric environment, and also to evade the host immune response. In this review, we discuss the various virulence factors expressed by this bacterium and how they interact with the host epithelium to influence pathogenesis.

H PYLORI INFECTION AND DISEASES ASSOCIATED WITH THE INFECTION

H pylori is one of the most common pathogens affecting humankind, infecting approximately 50% of the world's population. This pathogen is a gram-negative spiral shaped bacterium that has the unique ability to colonize the human gastric mucosa. The infection is usually acquired early in life and may persist a lifetime, unless treated. Of those infected, many will develop asymptomatic gastritis, but 10% develop gastric or duodenal ulcers, and approximately 1% develop gastric carcinoma. The outcome of the infection may involve a combination of the bacterial factors, host factors, as well as environmental factors. Ulceration and carcinogenesis are mutually exclusive outcomes of this infection. *H pylori* infection is a very persistent infection, and in areas of high prevalence, reinfection is also very common.

A very high percentage of gastric and duodenal ulcers (up to 85%) are attributable to *H pylori* infection. Patients in the United States who are infected with *H pylori* have a 3.5 times increased risk of developing peptic ulcer disease than uninfected persons^[1]. A hallmark feature of infection with *H pylori* is a pronounced inflammatory response and the inability of the host to clear the infection, which results in a persistent infection, increased acid production, and tissue damage.

It is now well accepted that chronic infection with *H pylori* is a major risk factor in the development of gastric cancer. *H pylori* has been shown to induce changes in the gastric mucosa that could contribute to the development of cancer. Given the strength of the evidence supporting an association between adenocarcinomas of the gastric mucosa and *H pylori* infection, *H pylori* has become classified as a class I carcinogen by the International Agency for Research on Cancer in affiliation with the World Health Organization^[2]. Gastric cancer remains the second deadliest cancer worldwide. On a global scale, gastric cancer accounts for approximately 700 000 deaths annually. In the US there are 24 000 new cases and 14 000 deaths annually^[3].

Infection with *H pylori* also plays a critical role in the development of mucosa-associated lymphoid tissue (MALT) lymphoma. *H pylori* is present in the gastric mucosa of most cases of MALT lymphoma, and 75% of these cases regress after eradication of *H pylori*^[4,5]. Interestingly, gastric MALT lymphoma is the only known

Table 1 *H pylori* adhesins and the gastric epithelial receptor for each

?	Phospholipids
?	Trefoil Factor 1

malignancy whose course can be directly changed by the removal of a pathogen. Thus, *H pylori*-associated diseases are a significant global problem and result in considerable morbidity, mortality, and societal costs.

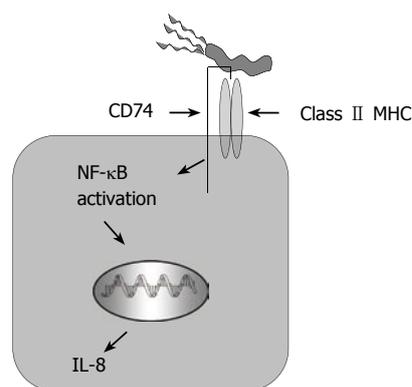

H pylori virulence factors and pathogenesis

H pylori colonizes the gastric epithelial apical surface, but the precise mechanisms of adherence and pathogenesis are still being elucidated. Adherent strains are able to survive in the gastric mucosa, colonize at high densities, and are able to re-colonize, while non-adherent strains are readily removed^[6]. Thus, adhesion is crucial in the ability of *H pylori* to persist and cause disease. In addition to contributing to colonization, adherence results in signal transduction, activation of NF- κ B and subsequent secretion of interleukin-8, which is important in the inflammatory response during infection.

Adhesins

An assortment of molecules on gastric epithelial cells (GECs) have been proposed as receptors for *H pylori* adherence, as well as multiple adhesins that have been identified on the outer membrane of *H pylori*, but those responsible for pathogenic events are still being investigated (Table 1). Several well known adhesins are BabA, SabA, and AlpAB. BabA and SabA bind to fucosylated and sialylated blood group antigens, respectively. There are clearly multiple adhesins and receptors for *H pylori* because only half of the strains in the U.S. have detectable BabA^[7]. While the attachment of *H pylori* using BabA as an adhesin does not appear to induce signaling or immune responses from host cells, SabA appears to be required for activation of neutrophils and the resulting oxidative burst by binding to sialylated neutrophil receptors^[8]. Although the AlpAB receptor is unknown, it may be even more important as an adhesin because studies with knockout strains dramatically reduced adherence of the bacteria to some cells^[9]. HopZ, another adhesin being investigated, also showed decreased adherence when a knockout strain was utilized^[10], but not as dramatically as the AlpAB knockout strain. *H pylori* urease can also act as a bacterial adhesin^[11]. Urease present on the bacterial surface due to bacterial lysis or release^[12,13] binds to class II MHC molecules on host cells, and may induce their apoptosis^[11].

Other studies from this group also suggest that the

**Figure 1** *H pylori* binds to CD74 on gastric epithelial cells and induces NF- κ B activation and IL-8 production.

urease B subunit binds to CD74, which is expressed in polarized fashion on the luminal side of the epithelium^[14], and in doing so stimulates gastric epithelial IL-8 release^[15] (Figure 1). A recent study by O'Brien and colleagues showed that, similar to other pathogens, *H pylori* uses decay accelerating factor (DAF aka CD55) as a receptor for binding to the gastric epithelium^[16]. Since there have been multiple *H pylori* adhesins described, bacterial adhesion is clearly a complex mechanism with multiple outcomes depending on the host cell receptor engaged.

Cytotoxicity associated pathogenicity island

Following colonization and attachment, various virulence factors expressed by certain *H pylori* strains appear to promote disease. For instance, the expression of *cagA* and *vacA* genes by strains of *H pylori* is highly associated with disease^[17]. These *cagA* gene-expressing strains have also been associated with peptic ulcer and patients infected with these strains have an increased risk of gastric cancer^[18]. The *cagA* gene is considered a marker for a cluster of genes referred to as pathogenicity island (PAI). *cagPAI* is known to encode for a type IV secretion system that allows CagA, and possibly peptidoglycan, to be delivered into epithelial cells (Figure 2). CagA is tyrosine phosphorylated by Src family kinases^[19], and has differing numbers of tyrosine phosphorylation motifs (EPIYA motifs), which determine the virulence of the *H pylori* strain and host cell response to it. The amount of EPIYA motifs is directly related to the levels of phosphorylation and cytoskeletal rearrangement seen in epithelial cells^[20]. Phosphorylated CagA interacts with a protein tyrosine phosphatase, SHP-2 inducing its phosphatase activity. Upon activation of SHP-2, it is able to induce host cells signaling, such as MAP kinase/MEK/ERK1/2 signaling through Ras/Raf. Dysregulation in this pathway is responsible for increased cell proliferation and moving of gastric epithelial cells (cell spreading) and cell elongation (hummingbird phenotype)^[21]. Interaction of CagA with other signaling molecules such as growth factor receptor-binding protein-2 (Grb-2), hepatocyte growth factor scatter factor receptor (c-Met), and phospholipase C gamma (PLC- γ) can induce similar phenotypes in gastric epithelial cells^[22,23]. Phosphorylated CagA inhibits the activity of Src kinases in a negative feedback loop^[19]. Thus, the inhibition on Src kinases activity also results in dephosphorylation of a set

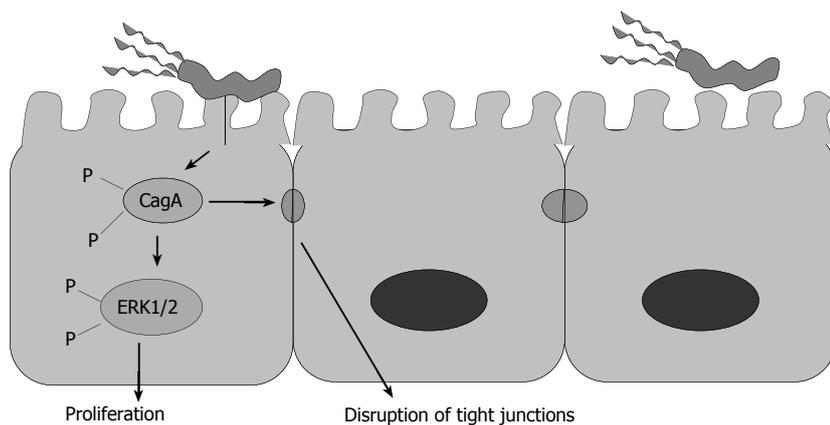

Figure 2 CagA is injected into the cell by a type IV secretion system where it is phosphorylated and induces ERK1/2 phosphorylation and increased cell proliferation. CagA also induces disruption of the tight junctions between adjacent cells.

of host cell proteins, including the actin-binding protein cortactin. In parallel to ERK1/2 signaling, NF- κ B may also be activated, and upregulation of pro-inflammatory cytokines may also ensue^[24]. While it was initially thought that the CagA injection was not responsible for the production of proinflammatory cytokines, but other proteins of the *cagPAI* were thought to play a crucial role, it has more recently been shown that CagA injection into the host gastric epithelial cell can induce NF- κ B activation and IL-8 production^[24]. In fact, independent studies showed that transfection of *cagA* into gastric epithelial cells induced IL-8 production^[25]. The activation of the Ras/MEK/ERK pathway occurs following the interaction of CagA with Grb2. Because CagA interacts with important signaling mediators in the host cells, it is considered responsible for changes in cell morphology, adhesion and turnover. CagA also induces the recruitment of ZO-1 and junctional adhesion molecule (JAM) to the site of bacterial attachment causing disruption of the epithelial barrier and dysplastic alterations in epithelial cell morphology. This effect is phosphorylation independent^[26]. The delivery of *H. pylori* peptidoglycan via the *cagPAI*-encoded type IV secretion system results in the intracellular binding of peptidoglycan by Nod1, an intracellular pathogen-recognition molecule, and this may also contribute to the induction of gastric epithelial responses^[27]. The *H. pylori* Type IV secretion system (T4SS) stimulates the Rho family GTPases Rac1 and Cdc42 in gastric epithelial cells in an independent CagA translocation mechanism^[28]. Thus, Rac1 and Cdc42 are recruited to the membrane at sites of infection activating p21-activated kinase (PAK1) and rearrangements of the cytoskeleton^[29]. The T4SS can also activate the receptor tyrosine kinase, epidermal growth factor receptor (EGFR), regulating the ERK1/2 pathway *via* Ras phosphorylation^[30]. Furthermore, CagA can inhibit B-cell proliferation by suppressing the JAK-STAT signaling pathway. Hence CagA, in a phosphorylation-independent pathway, can diminish the immune response against *H. pylori* and play a role in the development of MALT lymphoma by impairing p53-dependent apoptosis pathway^[31].

Vacuolating cytotoxin

The vacuolating toxin, or VacA, is a pore forming toxin that has the ability to induce vacuole formation in cells and disrupt normal membrane trafficking. VacA, is expressed

by about half of all *H. pylori* strains. Like CagA, VacA appears to be unique to *H. pylori* since no other species have a homologue. VacA has effects on many cell types, including gastric epithelial cells, antigen presenting cells, mast cells, and lymphocytes, which makes it an important virulence factor. This toxin is secreted by *H. pylori*, and it binds to the plasma membrane of host cells where it forms anion-selective channels. The receptors for VacA are EGFR and RPTP- α and - β ^[32]. However, VacA also binds to detergent-resistant microdomains (lipid rafts) and GPI-APs^[33,34]. This process results in the release of nutrients from the cell, and the bacteria may use these for survival^[35]. As the anion concentration becomes higher inside the cell through these pores, proton pumping also increases, as does an influx of weak bases. The weak bases are protonated and trapped inside, causing osmotic swelling, and the formation of a vacuole^[36]. VacA can also disrupt mitochondrial membrane potential and affect cellular ATP concentrations, which disrupt the cell cycle progression and lead to apoptosis^[37,38]. Another significant way in which VacA contributes to pathogenesis is by inhibiting the processing of antigens by B-cells and their presentation to CD4+ T-cells^[39], as well as the T cell activation and proliferation. When mixed with T cells, VacA suppresses NFAT^[40,41,42], IL-2 production, and surface expression of IL-2 receptors, which are required for T cell proliferation and viability^[36]. Multiple signaling pathways of T cell activation are also affected by VacA exposure, which is one mechanism *H. pylori* may use to evade immune responses. In gastric epithelial cells, VacA activates the p38 and ERK-1/2 MAP kinases, thereby contributing to the induction of immune responses by these cells^[43]. In fact, the *vacA* gene product has been shown to cause in mice, some of the tissue damage observed in *H. pylori*-infected patients^[44].

Urease

Another major virulence factor of *H. pylori* is urease, which is expressed by all strains. Urease is composed of two subunits, α , which is approximately 24 kDa, and β , which is approximately 68 kDa. *H. pylori* produces a large amount of urease, representing 5% to 10% of the total protein content of the bacteria. This enzyme is essential for the survival and pathogenesis of the bacteria. Perhaps the most important role urease plays is to hydrolyze urea into CO₂ and NH₃, which aids in buffering the bacteria from

the acidic conditions it may encounter in the stomach. Urease is crucial for *H pylori* colonization, as shown by studies where urease negative strains were not able to colonize in multiple animal studies^[45,46]. The inability of urease negative strains to colonize was initially assumed to be due to their inability to buffer their niche. However, similar studies under hypoacidic conditions also led to the same results, where urease negative mutants of *H pylori* could not colonize in an animal model. These observations suggested a role for urease beyond its enzymatic function. Although much urease is located intracellularly, there is some present on the bacterial surface^[47,13]. *H pylori* surface-associated urease can act as an adhesin for the bacteria, which induces the production of inflammatory cytokines from both gastric epithelial cells and macrophages^[48,49], along with apoptosis of some cells^[111]. While the mechanism of action associated with these responses elevated by urease is not entirely clear, the induction of apoptosis may result as a consequence of binding to class II MHC^[50]. The urease B subunit can also bind to CD74 and induce IL-8 production by gastric epithelial cells^[51]. Both of these responses are important in the overall pathogenesis seen during *H pylori* infection.

Other factors

Another important disease-associated virulence factor of *H pylori* is the outer inflammatory protein A (OipA). OipA is part of a family of 32 outer membrane proteins characterized as part of the *H pylori* genome. This protein has been suggested to induce pro-inflammatory responses from gastric epithelial cell lines. In one study with *H pylori* clinical isolates, those isolates expressing OipA, but not the *cag* pathogenicity island proteins were able to induce IL-8 production from gastric epithelial cell lines at 3 times the level of strains that did not express either^[52]. Isolates from Japan all expressed OipA, while isolates from the U.S. did not, and thus it is thought that the presence of OipA may make Japanese strains more virulent. When the signaling induced by *cag*PAI proteins was compared to OipA, OipA was found to induce phosphorylation of Stat1, while the *cag*PAI proteins induced NF- κ B activation^[52]. Both of these signaling pathways contribute to induction of IL-8 production, but act in conjunction with one another to fully activate the IL-8 promoter.

Some other virulence factors expressed by *H pylori* include neutrophil-activating protein (NAP) and heat shock protein 60 (Hsp60)^[53,54]. NAP has been shown to be a chemoattractant for both monocytes and neutrophils during *H pylori* infection^[55]. Hsp60 has been shown to induce proinflammatory cytokines by macrophages and gastric epithelial cells^[56,57], which appears to be mediated by Toll-like receptors (TLRs). Lipopolysaccharide expressed by *H pylori* is a very weak immunogen compared to that of other gram negative bacteria, but it has been shown to induce some proinflammatory cytokines^[58]. Although the interactions that initiate epithelial cell signals following bacterial adherence are critical in pathogenesis, they are not well understood, nor are the responses of the gastric epithelium that contribute to chronicity of the infection.

In a VacA paralogue mechanism *H pylori* can secrete collagenase, which can degrade collagen present in the

extracellular matrix to supply the bacteria with essential amino acids. During chronic infections, collagenase can exacerbate ulcer development and deter the process of ulcer healing^[59].

VIRULENCE FACTORS AND INFLAMMATION

Perhaps the most important response for the pathogenesis associated with infection is inflammation. Both antigen specific and non-specific responses contribute to inflammation during infection. These responses contribute to fighting infection, but are also responsible for mucosal damage. Adhesion of *H pylori* to the host epithelium, or bacterial factors such as urease or the *cag*PAI proteins, induce signaling that upregulates proinflammatory cytokines and chemokines such as IL-8 and GRO- α . In a recent study, we showed that CagA is important in the induction of macrophage migration inhibitory factor (MIF) production by the gastric epithelium^[60]. This cytokine has significant importance in the innate and adaptive host responses. Although the *cag*PAI proteins are the most recognized factor inducing inflammatory responses, there are several other interactions known to upregulate these responses. We have recently discovered that through *H pylori* attachment to CD74, or crosslinking CD74 on gastric epithelial cells, NF- κ B activation occurs leading to IL-8 production^[15]. Blocking this interaction with monoclonal antibodies resulted in a substantial decrease in the amount of IL-8 produced in response to *H pylori*. Other bacterial factors that induce inflammatory responses are HSP60, which was shown to induce IL-8 through Toll-like receptor pathways^[57], and urease, which induced responses from both gastric epithelial cells and peripheral blood mononuclear cells^[49]. The cytokine responses, in turn, recruit other immune cells to the site of infection such as IL-8, which is one of the initial chemokines that recruits neutrophils to the site of infection. Neutrophils are then activated by *H pylori* or its soluble products, and proceed to release reactive oxygen species (ROS) and more IL-8^[61], which lead to tissue damage associated with infection.

THE IMPACT OF *H PYLORI* ON THE GASTRIC EPITHELIUM

Cell turnover rate

Another response of GECs to infection is enhanced proliferation. In order to balance the increased growth of epithelial cells, the host must compensate by increasing epithelial cell turnover. One mechanism to account for epithelial cell turnover is increased cell death. Apoptosis provides a highly regulated mechanism for cell loss in both healthy and inflamed tissue. In the digestive tract, apoptosis has been described as being important in the control of normal epithelial cell turnover while it is increased in the gastric epithelium during infection with *H pylori*^[62,63]. The rate of apoptosis induction may be regulated by exogenous cytokines and growth factors. For example, we have shown that IFN- γ can directly augment the ability of *H pylori* to induce apoptosis of GECs^[50]. An indirect effect of IFN- γ is its ability to induce an increased expression of putative receptors (i.e., class II MHC and CD74) for *H pylori*. Our

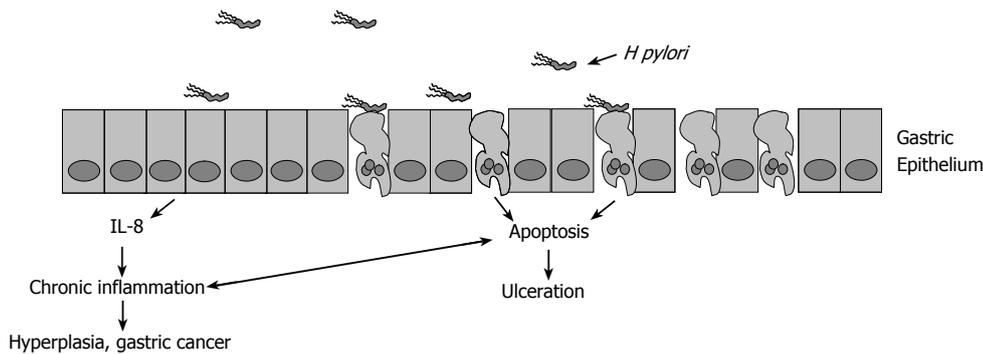

Figure 3 *H pylori* induces chronic inflammation leading to either ulceration or malignant outgrowths.

studies have shown that *H pylori* induces the expression of class II MHC and CD74^[50,64], and another study showed that *H pylori* induces yet another receptor, sialyl-Le^x, on GEC^[65].

Other cytokines and chemokines induced by *H pylori* may also play a role in inducing GEC proliferation. MIF, which is produced by GEC in response to CagA injection^[60], and may be produced by macrophages and T cells during infection^[66] can induce GEC proliferation. MIF affects proliferation by inactivating p53 tumor suppressor gene and inducing proliferative signaling such as ERK1/2 activation. Additionally, IL-8 has recently been shown to promote GEC proliferation by accelerating the processing of EGFR ligands, which bind and induce transactivation of the receptor^[67]. In one study administering nonsteroidal anti-inflammatory drugs was capable of decreasing GEC proliferation in the mouse model^[68], further suggesting a role for pro-inflammatory cytokines in cell turnover during *H pylori* infection.

ROS and DNA damage

The prevalence of IL-8 produced by the gastric epithelium at the site of infection results in the infiltration of neutrophils. *H pylori* soluble factors activate neutrophils^[69], which go on to produce reactive oxygen species (ROS). Gastric epithelial cells have also been shown to produce ROS in response to *H pylori*^[70]. Interestingly, *H pylori* appear to be resistant to the antimicrobial action of ROS. However, ROS may also induce DNA damage in the epithelium, which leads to apoptosis. Since ROS production appears to be dependant on bacterial load^[71], it also may be correlated to the amount of damage to the epithelium. When there is a lower bacterial load, the balance between oxidants and antioxidants in the gastric mucosa is disrupted at levels not high enough to induce apoptosis. The risk of DNA damage from ROS is high, and thereby may lead to pro-carcinogenic events.

Overview of the impact of *H pylori* on pathogenesis

The interactions of *H pylori* with the host are a complex series of events that induce pathogenesis while allowing the bacterium to persist. Only about 20% of the bacteria are bound to the epithelium *via* multiple adhesions at any given time^[72]. Attachment to the epithelium, along with multiple virulence factors, induce proinflammatory immune responses. These responses can affect host cell viability and lead to one of two mutually exclusive events. Either excess gastric acid is produced leading to ulceration,

or chronic inflammation induces atrophy of the stomach wall and malignant outgrowths (Figure 3). The unique and persistent interactions of *H pylori* with the host, along with 50% worldwide infection rates, make it a significant pathogen that induces considerable disease.

SUMMARY

While a significant volume of knowledge has been acquired during the last decade to help us understand how *H pylori* causes disease, there is still no available vaccine that is effective against this pathogen. *H pylori*'s ability to maintain its long-term residence in a broad segment of humankind is in large part due to the subversion of common structures on the host cells for its interactions. As with most infectious agents, adhesion to host cells is a crucial step in colonization. Attachment is facilitated by various structures or adhesins on the bacteria which include BabA, SabA, HopZ, AlpA/B, and urease. These adhesins bind to carbohydrate moieties on blood group antigens, as is the case of BabA and SabA binding to Lewis antigen, or to proteins of central importance to the host response, such as urease binding to class II MHC and CD74. These interactions are important to characterize in detail as they may offer insights into novel prophylactic or therapeutic agents directed at *H pylori*-associated diseases.

Following colonization, *H pylori* employs virulence factors, such as the cagPAI type IV secretion system and a vacuolating cytotoxin to exert damage on the host epithelium and to alter the host immune response. The ability of VacA to disrupt endosomal traffic and thus alter antigen presentation, together with its ability to arrest T cell cycle progression, makes VacA an important virulence factor that could contribute to the establishment of chronic infection. As we understand the mechanisms that contribute to the long term residence of *H pylori* in the human stomach, we will be better able to prevent the chronicity that underlies the development of the serious diseases associated with this infection.

Abstract

Crohn's disease (CD) and ulcerative colitis (UC) are chronic inflammatory disorders of the gastrointestinal tract that share clinical and pathological characteristics. The most accredited hypothesis is that both CD and UC result from a deregulated mucosal immune response to normal constituents of the gut microflora. Evidence, however, indicates that the main pathological processes in these two diseases are distinct. In CD, the tissue-damaging inflammatory reaction is driven by activated type 1 helper T-cell (Th1), whereas a humoral response predominates in UC. Consistently, a marked accumulation of macrophages making interleukin (IL)-12, the major Th1-inducing factor, is seen in CD but not in UC mucosa. Preliminary studies also indicate that administration of a monoclonal antibody blocking the IL-12/p40 subunit can be useful to induce and maintain clinical remission in CD patients. Notably, the recently described IL-23 shares the p40 subunit with IL-12, raising the possibility that the clinical benefit of the anti-IL-12/p40 antibody in CD may also be due to the neutralization of IL-23 activity. This review summarizes the current information on the expression and functional role of IL-12 and IL-12-associated signaling pathways both in patients with CD and experimental models of colitis, thus emphasizing major differences between IL-12 and IL-23 activity on the development of intestinal inflammation.

INTRODUCTION

Inflammatory bowel disease (IBD) is the general term indicating Crohn's disease (CD) and ulcerative colitis (UC), two chronic inflammatory disorders of the intestine that have different morphological, immunological and clinical characteristics. The etiology of IBD is unknown, but evidence has been accumulated to show that the liability to develop CD or UC is influenced by a wide range of genetic and environmental factors, which have been only in part characterized. Over the last recent years, it has also become evident that both CD and UC are caused by excessive immune reactivity in the gut wall, and that this is directed against normal constituents of the luminal flora. However, CD and UC are immunologically different diseases, even though they share end-stage effector pathways of tissue damage. These advances led to the development of novel therapeutic agents that are currently being studied for their capacity to specifically target the mucosal inflammatory pathways occurring in IBD patients.

IL-12 AND TH1 CYTOKINES IN CD

In both CD and UC, the inflamed tissue is heavily infiltrated with leukocytes, mostly T lymphocytes. These cells are activated and make increased amounts of cytokines, which are thought to have a primary role in promoting the disease process. Using sensitive assays, several authors have shown that CD and UC have distinct profiles of cytokine production. While in CD there is a predominant synthesis of type 1 helper T-cell (Th1) cytokines, including IFN- γ and TNF- α , Th2 cytokines, such as IL-5 and IL-13, are considered to have a more prominent role in UC^[1,2]. T-lamina propria lymphocytes (T-LPL) isolated from the inflamed colon of UC patients also make more IFN- γ than normal T-LPL following *in vitro* activation with anti-CD3/CD28 antibodies^[1]. Therefore, the classic Th1-Th2 paradigm seems to be overly simplistic, and there is now sufficient evidence to believe that these two pathways can co-exist rather than being mutually exclusive in the human gut.

The discovery that IFN- γ -secreting T-LPL are abundant in CD mucosa has paved the way for studies in which the switch that controls the differentiation of such cell type was investigated. This research led to the demonstration that in CD mucosa there is increased production of IL-12, the major Th1-inducing factor in man^[3,4]. IL-12 is a heterodimeric cytokine composed

of two covalently linked subunits (p40 and p35) and synthesized by monocytes/macrophages/dendritic cells^[5]. Transcripts for both IL-12 subunits have been detected in gastric and intestinal mucosa of patients with CD^[3,6]. In addition, it was shown that lamina propria mononuclear cells isolated from intestinal mucosal areas of CD, but not UC, patients released *in vitro* functionally active IL-12, and that neutralization of endogenous IL-12, in CD mucosal cell cultures, resulted in a significant decrease in the number of IFN- γ -producing cells^[3,4].

IL-12 mediates its biological activities through a receptor composed of two subunits, $\beta 1$ and $\beta 2$ ^[5]. Although both subunits are required to form a functional receptor, $\beta 2$ appears to be crucial in controlling Th1 cell lineage commitment^[7,8]. Consistently, high expression of IL-12R $\beta 2$ has been described in various Th1-mediated diseases, as well as in CD T-lamina propria lymphocytes (T-LPL)^[9-11]. Additionally, CD mucosal lymphocytes express high levels of active STAT-4, a transcription factor that is activated by IL-12R signals and is necessary to promote the induction of IL-12-driven Th1-associated genes^[11]. Notably, T cells from STAT-4-deficient mice manifest impaired IFN- γ production in response to IL-12 and are unable to efficiently promote the development of colitis when transferred in immunodeficient mice^[12]. On the other hand, studies in mice over-expressing STAT-4 revealed that such animals developed colitis that is characterized by the presence of a diffuse infiltration of Th1 cytokine-secreting cells in the intestinal wall^[13].

While IL-12 appears to be sufficient to trigger the Th1 cell program in naïve T cells, the expansion and maintenance of Th1 cell response in the gut would require additional signals (Figure 1). Indeed, the IL-12-induced synthesis of IFN- γ by intestinal lamina propria T lymphocytes can be enhanced by cytokines that signal through the common γ -chain receptor, such as IL-7, IL-15 and IL-21^[14,15]. Additionally, in CD mucosa, there is an enhanced production of biologically active IL-18, a cytokine involved in perpetuating Th1 cell responses^[16,17]. Immunohistochemical analysis has localized IL-18 to both lamina propria mononuclear cells and intestinal epithelial cells. In these cells, the expression of IL-18 is invariably associated with active subunits of IL-1 β -converting enzyme, a molecule capable of cleaving the precursor form of IL-18 to the active protein^[16,17]. Moreover, functional studies showed that down-regulation of IL-18 expression in cultures of CD lamina propria mononuclear cells by specific IL-18 antisense oligonucleotides significantly inhibited IFN- γ synthesis, further supporting the concept that IL-18 serves as a strong costimulatory factor of IL-12-driven Th1 responses^[16]. A newly discovered TNF-superfamily cytokine (TL1A) has also been involved in initiating or promoting the Th1 response in CD as well as in experimental models of IBD^[18,19]. Another protein that could contribute to the ongoing Th1 immune response in CD is osteopontin, a 60 kDa phosphoprotein, that is highly expressed in epithelial cells and macrophages in CD and shown to increase IL-12 production in CD mucosal cells^[20].

An analysis of transcription factors expressed in Th1 vs Th2 cells led to the discovery of T-bet, a novel

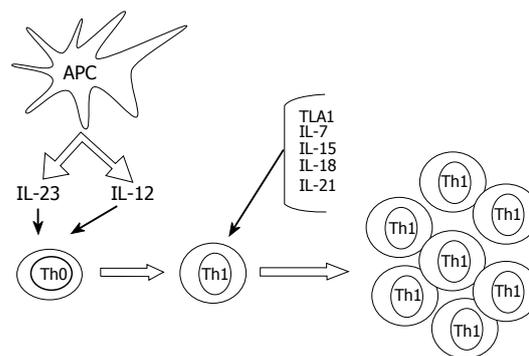

Figure 1 Some putative mechanisms implicated in the induction and expansion of Th1 cells in the gut of patients with Crohn's disease. Cytokines produced by antigen presenting cells, such as IL-23 and IL-12, promote the differentiation of Th1 cells. The expansion and mucosal accumulation of this cell subtype are then sustained by additional molecules, such as IL-18, IL-7, IL-15, IL-21 and TL1A.

member of the T-box family of transcription factors. T-bet drives chromatin remodelling of the IFN- γ locus and up-regulates IL-12R $\beta 2$ chain. Therefore, its expression strictly correlates with the differentiation of Th1 cells^[21]. As expected, T-bet is markedly over-expressed in CD4+ T-LPL of patients with CD and it associates with a reduced expression of GATA-3, a transcription factor that governs Th2 cell polarization^[22].

The molecular mechanisms underlying T-bet induction are not fully understood, even though there is evidence that cytokines that activate STAT1, such as IFN- γ and IL-21, may positively regulate T-bet expression. In line with these observations, neutralization of IL-21 in cultures of CD mucosal T cells is followed by a decreased expression of T-bet and secretion of IFN- γ ^[15].

REGULATION OF IL-12 PRODUCTION

A critical question remains as to what induces IL-12 in CD gut and which mechanisms are in place to regulate IL-12 production. IL-12 is produced by antigen-presenting cells mostly in response to bacteria or bacterial products/components^[5]. Since the development of Th1-mediated colitis both in humans and mice requires the presence of gut microbiota, it is conceivable that IL-12 production is driven by luminal bacteria. Indeed, it was shown that LPMC isolated from the inflamed intestine of CD patients are hyper-responsive to sonicates of bacteria from autologous intestine (BsA), and this phenomenon associates with increased expression of activation markers on both CD4+ and CD8+ lymphocyte subsets and production of IL-12 and IFN- γ ^[23]. Consistently, both local and systemic tolerance to BsA is broken in a murine model of chronic intestinal inflammation induced by the hapten reagent 2, 4, 6-trinitrobenzene sulfonic acid (TNBS), which mimics several important characteristics of CD. Tolerance to BsA is, however, restored in mice systemically treated with antibodies to IL-12^[24].

The reason why CD LPMC would respond to luminal bacteria with enhanced production of IL-12 remains, however, unclear. One possibility is that, in CD, LPMC are primed to synthesize high levels of IL-12 by specific stimuli. This hypothesis is suggested by the recent

observation that flagellin, a major antigenic target of immune response associated with CD^[25], can activate innate immunity *via* Toll-like receptor 5 (TLR5), and instruct dendritic cells to promote Th1 responses *via* IL-12p70 production^[26]. Another possibility is that CD LPMC lack negative regulators of bacteria-driven intracellular signals, and therefore would respond to bacterial stimulation with enhanced IL-12 synthesis. In line with this, it has recently been shown that splenocytes of mice carrying on deletions of CARD15, a gene whose mutations are associated with CD, and encoding NOD2, respond to peptidoglycan (PGN) stimulation with exaggerated activation of NF- κ B and production of IL-12 and IL-18^[27]. According to these data, NOD2 would function as a negative regulator of IL-12 production mediated by PGN. Therefore, in the absence of this negative regulation, PGN could elicit an excessive NF- κ B-dependent IL-12 response by mucosal cells^[28]. In the gut, NOD2 also regulates the production of anti-bacterial peptides, such as defensin-5, by Paneth cells^[29]. Consistently, epithelial cells expressing mutated NOD2 have a reduced capacity to restrict proliferation of bacterial pathogens in monolayer cultures^[30], raising the possibility that CARD15 mutations could facilitate the colonization of the intestine with bacteria that eventually sustain macrophage/dendritic cell activation and enhance IL-12-driven Th1 cell responses. Whether this explanation really fits with the mucosal IL-12 synthesis in CD patients with mutations remains, however, unknown, as no study has yet analyzed whether intestinal mucosal cells of CD patients with CARD15 mutations make *in vivo* more IL-12 than those of CD patients without CARD15 mutations.

IL-12-INDUCED T CELL RESPONSE LEADS TO MUCOSAL DESTRUCTION IN HUMAN FETAL GUT

Taken together, the above data suggest that the IL-12-driven Th1 signaling pathway can be important in immune-mediated injury in the gut. This is also substantiated by observations made in *ex vivo* models of T cell-mediated gut inflammation. By using human fetal gut explants, we previously showed that activation of T-LPL by anti-CD3 and IL-12 resulted in a strongly Th1-biased response that was followed by severe tissue injury, with destruction of the mucosa. Furthermore, analysis of explants culture supernatants revealed that stimulation of fetal gut tissues with anti-CD3 and IL-12 increased the production of matrix metalloproteinase 1 (MMP-1, collagenase) and MMP-3 (stromelysin 1), while the synthesis of tissue inhibitors of MMP-1 and 2 remained unchanged^[31]. Stromelysin 1 has a broad substrate specificity, being capable of degrading proteoglycans, laminin, fibronectin, collagen core protein, and non-helical cross-linked regions of type IV collagen. Stromelysin 1 has, therefore, the potential to destroy the structure of the intestinal lamina propria, thereby removing the scaffolding on which the epithelium lies. Indeed, abundant stromelysin 1 has been found in the mucosa of patients with CD, particularly near ulcers^[32]. Notably, the addition of a stromelysin 1 inhibitor to the IL-12-stimulated fetal gut organ culture prevented

the tissue damage without altering T cell activation. Similarly, a p55 TNF receptor human IgG fusion protein was able to prevent the mucosal degradation and inhibit stromelysin 1 production, thus suggesting that TNF- α is a key mediator of the IL-12-induced tissue damage^[31].

BLOCKADE OF IL-12 FACILITATES THE RESOLUTION OF TH1-MEDIATED INFLAMMATION IN THE GUT

The role of IL-12 in the mucosal inflammation in patients with CD is also supported by the demonstration that this cytokine is produced in excess in experimental models of Th1-induced colitis, such as the TNBS-induced colitis. Importantly, treatment of mice with antibodies to IL-12/p40 abrogates the TNBS-induced colitis, and the beneficial effect of such a treatment has been linked to the capacity of the blocking antibody to enhance mucosal T cell apoptosis through a FAS-dependent mechanism^[33,34].

Consistently, a randomized controlled study of 79 CD patients receiving 1 or 3 mg of an anti-IL-12p40 monoclonal antibody *versus* placebo demonstrated a response in 75% of CD patients compared with 25% in the placebo group. These responses paralleled a decrease in downstream cytokines, including IFN- γ and TNF- α ^[35]. In subsequent studies, it was also shown that patients with CD manifested both increased IL-12p70 and IL-23 secretion before anti-IL-12p40 mAb treatment and normal levels of secretion of these cytokines following cessation of treatment. Moreover, IL-23-induced T cell production of IL-17 and IL-6 was greatly reduced after IL-12 antibody treatment^[36]. More recently, it has been shown that treatment of active CD patients with two doses of Fontolizumab, an anti-IFN- γ antibody, which interferes with Th1 polarization as well as activation of macrophages, monocytes and natural killer cells, resulted in increased rates of clinical response and induction of remission compared with placebo^[37].

THE EMERGING ROLE OF IL-23 IN GUT INFLAMMATION

Whereas the central role of IL-12 in the generation of IFN- γ -secreting cells has long been appreciated, recent studies have shown that Th1 cell responses can also be regulated by IL-23. Importantly, IL-23 shares with IL-12 the p40 subunit^[38], and therefore, IL-23 biological activity is fully inhibitable by neutralising IL-12p40 antibodies. This fact and the demonstration that IL-23 is up-regulated in CD mucosa^[39] raise the question whether the beneficial effect of the blocking IL-12p40 antibody observed in CD patients is due to the neutralization of IL-12 and/or IL-23. Results from studies in mice with targeted deletion of either the IL-12/p35 or IL-23/p19 subunit suggest the possibility that IL-23 and not IL-12 is essential for manifestation of intestinal inflammation occurring in IL-10-deficient mice. The IL-23-driven intestinal inflammation appears to be mediated by the production of IL-17 and IL-6. Moreover, administration of recombinant IL-23 acceler-

ates the development of colitis in lymphocyte-deficient recombinase-activating genes-knockout (RAG-KO) mice after reconstitution with CD4+ T cells from interleukin-10-knockout (IL-10-KO) mice^[40]. Whether IL-23 plays a similar role in other models of Th1-mediated colitis, such as the TNBS-colitis, remains however unknown. Similarly, it remains to be ascertained whether the deleterious effect of IL-23 on the ongoing mucosal inflammation occurs only in the absence of IL-10-related regulatory effects.

In conclusion, human IBD are thought to be caused by a dysregulated T cell response directed against constituents of the intestinal bacterial microflora. In CD, such a response is associated with an exaggerated production of IL-12 and IFN- γ . There is also evidence that the recently described IL-23 may drive the intestinal inflammation in murine models of IBD, thus suggesting that strategies aimed at specifically inhibiting the p19 subunit of IL-23 could be therapeutically useful in CD. Some observations made in cell systems, however, suggest to be cautious before drawing any conclusion. In fact, it has been reported that T-bet negatively regulates IL-17 production, thus promoting the shift of IL-17-producing cells towards a classical Th1 phenotype characterized by high IFN- γ ^[41]. Based on these findings, it is conceivable that IL-23 may play a determinant role in the early phase of T cell-mediated immune responses, thus leaving the place to IL-12/IFN- γ /T-bet pathway in the late phase.

Abstract

Recent evidence has highlighted the impact of glycemic control on the incidence and progression of diabetic micro- and macrovascular complications, and on cardiovascular risk in the non-diabetic population. Postprandial blood glucose concentrations make a major contribution to overall glycemic control, and are determined in part by upper gastrointestinal function. Conversely, poor glycemic control has an acute, reversible effect on gastrointestinal motility. Insights into the mechanisms by which the gut contributes to glycemia have given rise to a number of novel dietary and pharmacological strategies designed to lower postprandial blood glucose concentrations.

INTRODUCTION

Diabetes and its long-term complications, which include cardiovascular, renal, neurologic, and ophthalmic disease, represent a major cause of morbidity and mortality throughout the world^[1]. The prevalence of both type 1 (insulin-dependant) and type 2 (non insulin-dependant) diabetes is increasing, the latter as a consequence of obesity. In the US, 29 million people and 14% of adults have diabetes or impaired fasting glucose, of whom about a third are undiagnosed^[2]. Similar figures are evident throughout the developed world^[3].

Hyperglycemia is central to the pathogenesis of diabetic micro- and macrovascular complications^[4]. There is increasing evidence that postprandial hyperglycemia is the major determinant of "average" glycemic control, and represents an independent risk factor for macrovascular disease, even in people without diabetes^[5]. While the relative importance of individual determinants of the blood glucose response to a meal remain to be clarified precisely, it is clear that upper gastrointestinal motility has a major impact that has generally been overlooked. Moreover, postprandial glycemic control in turn has a profound effect on the motor function of the upper gut. Hence, blood glucose concentration is determined by, as well as a determinant of, gastric and small intestinal motility^[6].

The aims of this review are to examine (1) evidence relating to the importance of postprandial, as opposed to fasting, glycemia in the development and progression of diabetic complications, (2) the contribution of upper gastrointestinal function to postprandial blood glucose concentrations, (3) the impact of variations in glycemia on gastric and small intestinal motility, and (4) the therapeutic strategies suggested by these insights.

IMPACT OF POSTPRANDIAL GLYCEMIA ON COMPLICATIONS OF DIABETES

The DCCT/EDIC and UKPDS trials established that the onset and progression of microvascular, and probably macrovascular complications of diabetes, are related to "average" glycemic control, as assessed by glycated hemoglobin^[4,7,8]. This provides a rationale for the widespread use of intensive therapy directed at the normalisation of glycemia. In the recently reported DCCT/EDIC study, a period of intensive, as opposed to conventional, therapy for a period of 6.5 years between 1983 and 1993 was shown to be associated with a reduction in the risk of a subsequent cardiovascular event by 42%^[4]. Glycated hemoglobin is potentially influenced by both fasting and postprandial blood glucose concentrations. However, given that the stomach empties ingested nutrients at a closely regulated overall rate of 2-3 kcal per minute^[9,10] and humans ingest around 2500 kcal daily, it is clear that most individuals spend the majority of each day in either the postprandial or post-absorptive phase with a limited duration of true "fasting" for perhaps three or four hours before breakfast^[11]. Hence, the traditional focus on the control of "fasting" blood glucose in diabetes management appears inappropriate.

It is well established that postprandial hyperglycemia precedes elevation of fasting blood glucose in the

evolution of diabetes^[12]. Furthermore, it appears to be the better predictor of coronary artery^[13] and cerebrovascular^[14] complications, and predicts all-cause and cardiovascular mortality, even in the general population without known diabetes^[15]. Blood glucose values at two hours during an oral glucose tolerance test are a better predictor of mortality than fasting blood glucose^[16], and reduction in cardiovascular risk in patients with type 2 diabetes is associated with control of postprandial, as opposed to fasting, glycemia^[17]. For example, patients with impaired glucose tolerance who were treated with the α -glucosidase inhibitor acarbose, to reduce postprandial glycemia, experienced a reduction in cardiovascular risk of about a third compared to placebo during a mean of three years follow-up^[18]. Postprandial blood glucose concentrations correlate well with glycated hemoglobin in the setting of mild to moderate hyperglycemia^[19], with fasting blood glucose only assuming greater importance at higher HbA1c values^[20]. There is also evidence that therapy directed towards lowering postprandial blood glucose concentrations may have a greater impact on HbA1c than attention to fasting blood glucose^[21].

Hyperglycemia potentially has diverse effects on blood vessels. In the short term, hyperglycemia is associated with activation of protein kinase C, which affects endothelial permeability, cell adhesion, and proliferation in the vessel wall. Over the longer term, non-enzymatic glycosylation of proteins results in atherosclerosis^[22]. Elevated postprandial blood glucose concentrations are associated with an increase in plasma biochemical markers of oxidative stress^[23,24]. However, to what degree hyperglycemia *per se* accounts for this effect, as opposed to concurrent elevations of non-esterified fatty acids and triglycerides, remains to be elucidated^[25].

CONTRIBUTION OF UPPER GASTROINTESTINAL FUNCTION TO POSTPRANDIAL GLYCEMIA

Postprandial blood glucose levels are potentially affected by a number of factors, including pre-prandial blood glucose concentration, food properties such as viscosity, fibre content, and quantity and type of carbohydrate, gastric emptying, small intestinal delivery and absorption of nutrients, insulin secretion, hepatic glucose metabolism, and peripheral insulin sensitivity^[26]. The relative importance of these factors is likely to vary with time after a meal, and between healthy subjects and patients with type 1 or type 2 diabetes. While it is logical that the gastrointestinal tract, which controls the rate at which ingested carbohydrate is absorbed and releases peptides that stimulate insulin secretion, should have a major impact on postprandial glycemia, its role has frequently been overlooked and generally underestimated in the past. The rate of gastric emptying is now established as a major contributor to variations in glycemia, while the influence of small intestinal motor function represents a current research focus.

Gastric emptying

Gastric emptying accounts for at least 35% of the variance

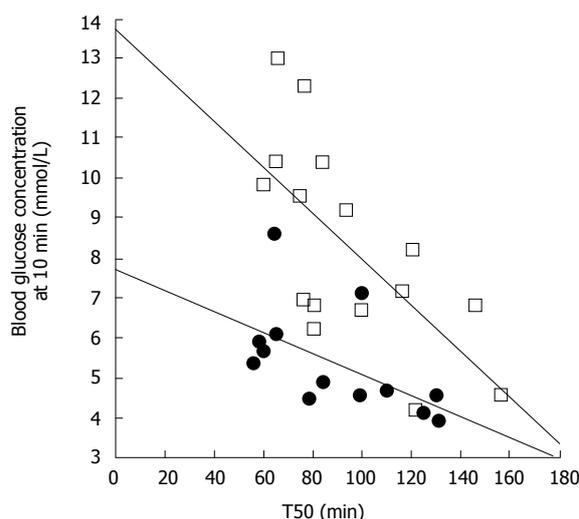

Figure 1 Relationship between the blood glucose concentration 10 min after consuming 75 g glucose in 300 mL water, and the gastric half-emptying time (T50) in patients with type 2 diabetes (open squares, $r = -0.67$, $P < 0.005$) and healthy subjects (filled circles, $r = -0.56$, $P < 0.05$). Adapted from Jones *et al* 1996^[28].

in the initial rise as well as the peak blood glucose levels after an oral glucose load in both healthy individuals^[27] and patients with type 2 diabetes^[28] (Figure 1). Pharmacological slowing of gastric emptying by morphine reduces the postprandial glycemic response to a mixed meal in type 2 patients, whilst acceleration of gastric emptying by erythromycin (a motilin agonist) increases postprandial blood glucose concentrations (Figure 2). Here, differences in peak blood glucose values are more marked than those in the area under the blood glucose curve^[29]. In type 1 patients the glycemic response to a meal, and therefore the requirement for exogenous insulin, is also critically dependent on the rate of gastric emptying. Here, when emptying is slower, the insulin requirement to achieve euglycemia is less^[30].

In health, gastric emptying is modulated by feedback arising from the interaction of nutrients with the small intestine, so that the overall rate of gastric emptying is closely regulated at about 2-3 kcal per minute^[9]. Infusion of a caloric load directly into the small intestine slows gastric emptying by a mechanism that includes relaxation of the gastric fundus, suppression of antral motility, and stimulation of phasic and tonic pressures in the pylorus^[31,32]; the latter acts as a brake to gastric outflow. The length of small intestine exposed to nutrient appears to be the primary determinant of the magnitude of the feedback response^[33,34]. Both transection of duodenal intramural nerves^[35], and suppression of the release of small intestinal peptides by the somatostatin agonist, octreotide^[36], accelerate the emptying of nutrient liquids, indicating the involvement of both neural and humoral mechanisms in mediating feedback from the small intestine. Glucagon like peptide-1 (GLP-1), which suppresses antral and duodenal motility and stimulates pyloric contractions^[37-39], probably represents one such humoral mediator, and the slowing of gastric emptying by this peptide appears likely to be the major mechanism by which its administration improves postprandial glycemia in patients with type 2 diabetes^[40]. While the contribution of endogenous GLP-1 in regulating gastric emptying

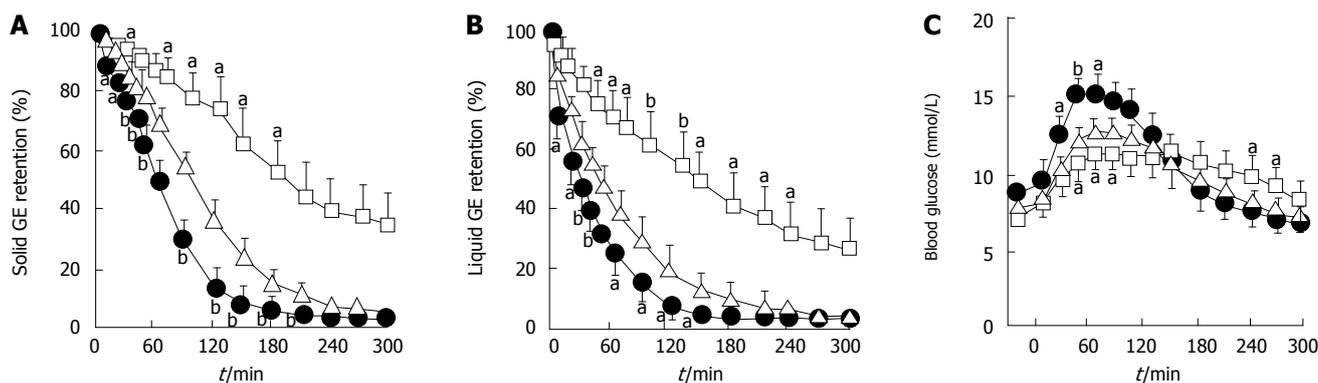

Figure 2 Effects of erythromycin (200 mg iv, filled circles) and morphine (8 mg iv, open squares) compared to placebo (open triangles) on (A) solid and (B) liquid gastric emptying and (C) blood glucose concentration in 9 patients with type 2 diabetes. ^a $P < 0.05$, ^b $P < 0.01$ vs placebo. Adapted from Gonlachanvit *et al* 2003^[29].

remains to be clarified (i.e. the “physiological” as opposed to “pharmacological” action), a recent study using the GLP-1 antagonist, exendin (9-39) amide, confirmed that endogenous GLP-1 mediates the suppression of antral motility and stimulation of pyloric pressures induced by the presence of glucose in the small intestine^[38].

It has long been recognised that oral or enteral administration of glucose results in a much greater insulin response than an equivalent intravenous glucose load^[41-44], a phenomenon referred to as the “incretin” effect. The putative incretin peptides, GLP-1 and glucose-dependent insulinotropic polypeptide (GIP), are released from the small intestine in response to nutrients^[45], apparently in a load-dependent fashion^[46]. Therefore, the rate of delivery of carbohydrate from the stomach into the small intestine is likely to be critical in determining not only the rate of glucose absorption, but also the incretin response. Although GIP is the more potent of the two hormones in healthy individuals^[47], the insulinotropic effect of GIP appears to be markedly diminished in patients with type 2 diabetes, while the insulin response to GLP-1 is retained^[45]. This forms a rationale for the therapeutic use of GLP-1 and its analogs in the management of type 2 diabetes (to be discussed). There is limited evidence that type 2 diabetes is associated with an impaired GLP-1 response to oral glucose^[48], but to what degree delayed gastric emptying, which occurs frequently in type 2 patients^[49], accounts for this decrease in GLP-1 has not been evaluated.

In considering the potential impact of gastric emptying on postprandial glycemia, the initial rate of glucose entry into the small intestine (“early phase” of gastric emptying) may be particularly important^[50]. Type 2 diabetes is characterised by a reduced “early”, and frequently increased “late”, postprandial insulin response. Studies in rodents have established the importance of “early” insulin release as a determinant of postprandial glucose excursions, in that a small “early” increase in portal vein/peripheral blood insulin is more effective than a larger, “later” increase at reducing blood glucose levels^[51]. A recent study involving both healthy subjects and type 2 patients, established that modest physiological variations in the initial rate of small intestinal glucose entry have major effects on the subsequent glycemic, insulin and incretin responses (Figure 3)^[52]. Nevertheless, while initially rapid, and subsequently slower, duodenal glucose delivery can boost incretin and insulin responses when compared to

constant delivery of an identical glucose load, the overall glycemic excursion is, if anything, greater^[52], and certainly not improved^[53]. This evidence adds to the rationale for the use of dietary and pharmacological strategies designed to reduce postprandial glycemic excursions by slowing gastric emptying, rather than initially accelerating it. However, the “dose-response” relationship between duodenal glucose delivery and glycemia remains to be clearly determined.

Small intestinal glucose absorption

The gut lumen is the site of absorption of glucose from the external environment into the body, as well as being the source of the incretin peptides that drive much of the postprandial insulin response. Thus, it is logical that variations in small intestinal function should be a major determinant of postprandial glycemia. Nevertheless, there is little information about the impact of small intestinal motility and absorptive function on glycemia, at least in part because of the technical demands in studying this region of gastrointestinal tract^[6,54].

The large surface area of the small intestine is well suited to absorption of water and solutes. Perfusion studies in healthy humans have established that the proximal jejunum has a maximal absorptive capacity for glucose of approximately 0.5 g per minute per 30 cm^[55-57]. Small intestinal mucosal hypertrophy occurs in animal models of diabetes, with concomitant increases in glucose absorption, but this is rapidly reversed by insulin treatment^[58]. However, acute hyperglycemia does result in transient increases in intestinal glucose absorption in rodents^[59-61]. The few studies performed in humans with type 1^[62] “insulin-requiring”^[63], or type 2^[64] diabetes have not demonstrated increased small intestinal glucose absorption, other than one report of increased absorption at high luminal glucose concentrations^[65]. Attention was paid to maintaining euglycemia in at least one of these studies^[63]. However, there is a recent report of increased expression of monosaccharide transporters in humans with type 2 diabetes^[66], the clinical significance of which remains to be clarified. One human study failed to demonstrate an effect of marked hyperglycemia (14 mmol/L) on jejunal glucose absorption in healthy subjects^[63], although a relationship has been observed between more physiological postprandial blood glucose concentrations (less than 10 mmol/L) and the absorption of the glucose analog, 3-O-methylglucose, in healthy

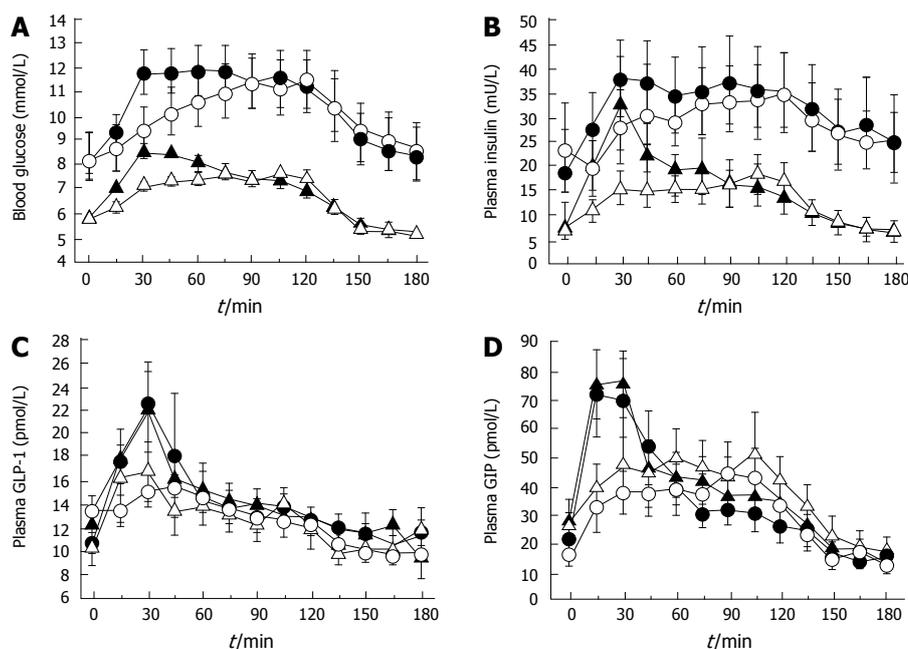

Figure 3 Effect of initially more rapid intraduodenal glucose infusion (3 kcal/min between $t = 0$ and 15 min and 0.71 kcal/min between $t = 15$ and 120 min) (closed symbols) compared to constant infusion (1 kcal/min between $t = 0$ and 120 min) (open symbols) in healthy subjects (triangles) and patients with type 2 diabetes (circles) on (A) blood glucose, (B) plasma insulin, (C) plasma GLP-1, and (D) plasma GIP. Each pair of curves differs between 0 and 30 min for variable vs constant intraduodenal infusion ($P < 0.05$). Adapted from O'Donovan *et al* 2004^[52].

subjects and patients with type 1 diabetes^[67]. Hence, the effect of transient hyperglycemia on small intestinal glucose absorption remains uncertain.

Given that an upper limit exists for absorption of glucose across the small intestinal mucosa, it is logical that patterns of intestinal motility which serve to spread luminal glucose over a large surface area could promote glucose absorption. Furthermore, certain motor patterns could facilitate mixing of complex carbohydrates with digestive enzymes, and their exposure to brush border disaccharidases. Thus, when glucose is infused directly into the duodenum, its rate of absorption increases with the number of duodenal pressure waves and propagated pressure wave sequences^[54,67]. Further insights into the effects of luminal flow on glucose absorption are likely to require additional techniques, such as intraluminal impedance measurement, in which inferences can be made regarding movement of fluid boluses by measuring changes in electrical impedance between sequential pairs of intraluminal electrodes. A preliminary study in healthy humans using this technique indicates that pharmacological suppression of intraduodenal flow with an anticholinergic agent is associated with delayed absorption of luminal glucose^[68]. These observations are likely to be of relevance to patients with type 1 diabetes mellitus, who demonstrate an increased frequency of small intestinal pressure waves in the postprandial state^[67].

The region of small intestine that is exposed to carbohydrate is also likely to be a determinant of the glycemic response. GLP-1 is released from intestinal L cells, whose concentration is greatest in the distal jejunum, with fewer L cells located in the proximal jejunum, ileum, and colon^[69]. In humans, it is unclear whether nutrients must interact directly with L cells to stimulate GLP-1 release. A neural or endocrine loop between the duodenum and the more distal small bowel has been postulated^[70], but remains unproven. The lack of a GLP-1 response when glucose is infused into the duodenum below a certain dose (1.4 kcal/min)^[71] would be consistent with the concept of complete absorption of the glucose load high

in the small intestine, precluding significant interaction with L cells, although other investigators have reported a GLP-1 response even with 1 kcal/min intraduodenal glucose infusion^[52]. Nevertheless, GLP-1 responses to meals are enhanced following intestinal bypass procedures that promote access of nutrients to more distal small intestine^[72-75], while inhibition of sucrose digestion in the proximal small intestine with acarbose increases the GLP-1 response^[76], presumably by facilitating more distal interaction of the intestine with glucose. It follows that dietary modifications that favor exposure of more distal small intestinal segments to glucose could reduce glycemic excursions by stimulating GLP-1 release. Furthermore, a major action of both GLP-1 and peptide YY, which is also released from L cells, is to retard gastric emptying, thus slowing any further entry of carbohydrate to the small intestine^[77].

IMPACT OF VARIATIONS IN GLYCEMIA ON UPPER GUT MOTILITY

Acute changes in the blood glucose concentration are now recognised to have a major, reversible impact on the motor function of every region of the gastrointestinal tract. This may in part account for the poor correlation of upper gastrointestinal dysfunction in diabetes with evidence of irreversible autonomic neuropathy, to which it has traditionally been attributed^[78]. When compared to euglycemia (4-6 mmol/L), gut motility is modulated through the range of blood glucose concentrations from marked hyperglycemia (greater than 12 mmol/L), through "physiological" blood glucose elevation (8-10 mmol/L), to insulin-induced hypoglycemia (less than 2.5 mmol/L), and effects are observed rapidly (within minutes), although the thresholds of response may differ between gut regions^[6]. The mechanisms mediating the effects of acute changes in the blood glucose concentration are poorly defined, and the potential impact of chronic, as opposed to acute, variations in glycemia on gastrointestinal motility has hitherto received little attention. Nevertheless, it is clear

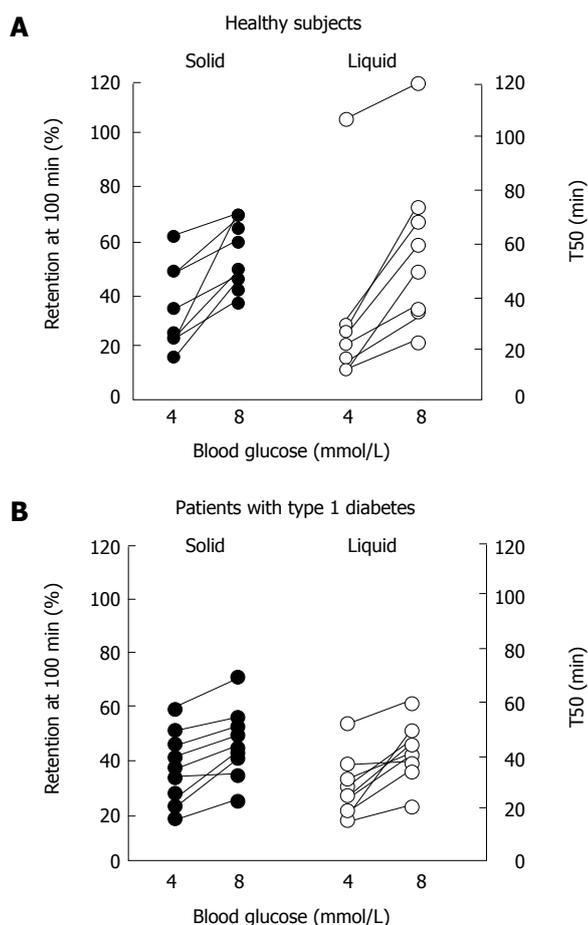

Figure 4 Solid and liquid gastric emptying in (A) healthy subjects and (B) patients with type 1 diabetes mellitus during euglycemia (blood glucose 4 mmol/L) and "physiological" hyperglycemia (blood glucose 8 mmol/L). Adapted from Schvarcz *et al* 1997^[82].

that gut motor function and postprandial glycemia are highly interdependent variables.

Gastric motility

Marked hyperglycemia (16–20 mmol/L) slows both solid and nutrient liquid emptying in patients with type 1 diabetes when compared to euglycemia (5–8 mmol/L)^[79]; in type 2 patients, cross-sectional data also indicate an inverse relationship between the blood glucose concentration and the rate of gastric emptying^[49]. Conversely, gastric emptying is accelerated by acute hypoglycemia induced by insulin (2.6 mmol/L) in healthy subjects^[80] and type 1 patients, even when emptying is slower than normal during euglycemia^[81]. In type 1 diabetes, as well as healthy volunteers, elevation of blood glucose to "physiological" postprandial levels (8 mmol/L) also slows gastric emptying when compared to euglycemia (4 mmol/L)^[82] (Figure 4). The magnitude of the effects of glycemia on the rate of gastric emptying is substantial, and has implications for absorption of orally administered medications, including oral hypoglycemic agents^[83], as well as impacting on carbohydrate absorption.

The rate of gastric emptying is determined by the coordinated activity of various regions of the stomach and proximal small intestine^[84]. The proximal stomach acts as a reservoir for solids and generates tonic pressure to facilitate liquid emptying. The distal stomach grinds

and sieves solids and pumps chyme across the pylorus, predominantly in a pulsatile manner, while phasic and tonic pyloric pressures, and duodenal contractile activity act as a brake to gastric outflow. The timing of antral contractions is controlled by an electrical slow wave, with a frequency of about 3 per minute, generated by the interstitial cells of Cajal^[85]. During fasting, cyclical activity of gastric motility is observed, with a periodicity of about 90 min, characterised by irregular contractions of increasing frequency (phase II), and a brief (5–10 min) period of regular contractions at the rate of 3 per minute (phase III) during which indigestible solids empty from the stomach, followed by motor quiescence (phase I). Acute hyperglycemia is associated with diminished proximal gastric tone^[86–88], suppression of both the frequency and propagation of antral pressure waves^[89–92], and stimulation of pyloric contractions^[93]—a motor pattern associated with slowing of gastric emptying. The frequency of the gastric slow wave is also disturbed^[94]. The suppression of antral motility is observed at blood glucose concentrations as low as 8 mmol/L^[89,91]; the threshold appears higher in the proximal stomach^[95]. Hyperglycemia also attenuates the prokinetic effects of erythromycin in both healthy subjects and type 1 patients^[96,97], at least in part by inhibiting the stimulation of antral waves and coordinated antroduodenal pressure sequences^[98]. This effect is of considerable importance, since the action of other prokinetic drugs is also likely to be impaired during hyperglycemia, although this issue has not been specifically examined.

Small intestinal motility

As in the stomach, fasting small intestinal motility is cyclical, and characterised by phases I to III, the latter with a frequency of 9 to 12 per minute. This "migrating motor complex" (MMC) propagates aborally along the small intestine, and serves to "sweep" the lumen of indigestible debris. After a meal, the MMC is interrupted by irregular contractions propagated over short distances, which facilitate digestion and absorption of nutrients.

In healthy subjects during hyperglycemia (10 mmol/L), the duodenum becomes less compliant (more "stiff") to balloon distension, while distension stimulates a greater number of phasic pressure waves, when compared to euglycemia^[99]. Both phenomena could contribute to a duodenal "brake" to gastric emptying. More marked hyperglycemia (12–15 mmol/L) reduces the cycle length of the MMC^[100], the frequency of duodenal and jejunal pressure waves, and the duration of the postprandial period (early return of phase III activity), and slows small intestinal transit^[101]. These alterations in function could have implications for absorption of nutrients and medications, alteration in bowel habit, and the occurrence of small intestinal bacterial overgrowth in diabetes^[102]. However, other than suppression of proximal duodenal wave frequency^[103], there is limited information about the effects of hyperglycemia on small intestinal motor function in patients, as opposed to healthy volunteers.

Mechanisms mediating the effects of hyperglycemia on gastric and small intestinal motility

Most information about the etiology of gastrointestinal dysfunction in diabetes relates to the effects of

longstanding diabetes rather than acute, reversible changes that could relate to transient hyperglycemia^[104]. Rodent models of diabetes have demonstrated marked apoptosis of enteric neurons^[105], affecting nitrergic (inhibitory) neurons in particular^[106], and loss of interstitial cells of Cajal^[107]. The latter are also deficient in humans with diabetes and severe gut symptoms^[108]. Hyperglycemia appears to be responsible for apoptosis of enteric neurons^[109], but the latter would seem unlikely to mediate changes that are evident within minutes, rather than days or weeks. Enteric neurons sensitive to changes in glucose have been identified^[110], although their responsiveness to systemic, as opposed to luminal glucose remains unclear. Vagal nerve function is reversibly inhibited by acute hyperglycemia^[111,112], and this may account for some of the observed phenomena. Hyperinsulinemia is unlikely to explain the observed effects, particularly as they are seen in type 1 (insulin deficient) as well as type 2 and healthy subjects. Studies are indicated to determine whether reversible changes in nitrergic or serotonergic neurotransmission occur with variations in glycemia.

THERAPEUTIC STRATEGIES DIRECTED AT MINIMISING POSTPRANDIAL GLYCEMIA

The major impact of gastrointestinal function on the glycemic response to meals, as outlined above, suggests a number of logical, and in many cases complimentary, strategies to lower postprandial blood glucose concentrations (Table 1). These include (1) minimising the carbohydrate content, or substituting low- for high-glycemic index foods in meals, (2) slowing gastric emptying, even in individuals with modest delays in emptying provided they remain free of symptoms, (3) inhibiting the absorption of carbohydrate from the small intestine, or delaying its absorption to more distal small intestinal segments, and (4) augmenting the incretin response. Many approaches fulfill a number of these aims concurrently. Most studies relating elevated postprandial glycemia with cardiovascular risk have evaluated blood glucose 2 h after a meal^[113], suggesting that lowering peak blood glucose may be an appropriate target. Nevertheless, the glycated hemoglobin relates closely to the integrated mean blood glucose (i.e. area under the curve) over 24 h, albeit with a curvilinear rather than linear relationship^[114], so reducing the total area under the blood glucose excursion over several hours after a meal may also be an important goal. It should be noted that strategies for individuals with impaired glucose tolerance or type 2 diabetes managed without exogenous insulin, particularly those involving slowing of gastric emptying, may not be applicable to type 1 and insulin-requiring type 2 patients, in whom the goal should be to coordinate the absorption of carbohydrate with the action of exogenous insulin, which in some cases may involve accelerating gastric emptying, if it is already delayed^[115].

Carbohydrate content and glycemic index

Low-carbohydrate diets were the mainstay of treatment for diabetes in the pre-insulin era^[116]. The outcome of the Nurses' Health Study is indicative of a relationship between both cardiovascular risk and the incidence of diabetes with dietary glycemic load^[117]. Short-term

Table 1 Therapeutic strategies directed at minimizing postprandial glycemia

Strategy	Examples
Alter carbohydrate in diet	Low-carbohydrate diets Low glycemic index carbohydrates
Slow gastric emptying	High fiber diets Fat "preloads" Low glycemic index carbohydrates Acarbose GLP-1 analogs and DPP-IV inhibitors Pramlintide
Inhibit small intestinal carbohydrate absorption	Acarbose High fiber diets Low glycemic index carbohydrates
Augment the incretin response	GLP-1 analogs and DPP-IV inhibitors Acarbose Fat "preloads" ? Low glycemic index carbohydrates

studies indicate the potential for low-carbohydrate diets to improve 24 h glycemia and glycated hemoglobin in patients with type 2 diabetes^[118], including those failing conventional treatment with diet and a sulfonylurea^[119]. In medium- to long-term studies, substituting protein for carbohydrate improved glycemia in overweight hyperinsulinemic subjects^[120], while a low-carbohydrate diet improved fasting glucose over 6 mo in type 2 patients, with glycemic benefits maintained at 1 year, when compared to a low-fat diet^[121,122]. The magnitude of the decrease in glycated hemoglobin was small (mean 0.6% in the latter study), but likely to be clinically significant. In addition to the reduction in carbohydrate load, protein itself might improve glycemia by stimulating insulin release^[123], although this phenomenon is less apparent in medium-versus short-term studies^[124].

Rather than trading carbohydrates for alternative macronutrients, another approach is to substitute low- for high-glycemic index carbohydrates. The glycemic index (GI) compares the blood glucose response of a test food with that of a standard carbohydrate, either glucose or white bread^[125]. Foods may be low GI by virtue of a relative delay in gastric emptying and/or small intestinal glucose absorption^[126,127]. For example, spaghetti (low GI) empties from the stomach much slower than potato (high GI) from about 60 min after the meal, although their glycemic profiles diverge earlier^[128], indicating that slowing of small intestinal glucose absorption is important. Both the physical properties of the carbohydrate (such as enclosed kernels) and its chemical composition (such as a high amylose:amylopectin ratio) influence small intestinal carbohydrate digestion and absorption^[127,129]. Glycemic index tends to vary inversely with the content of dietary fiber in meals^[130]; dietary fiber *per se* potentially slows gastric emptying^[131] and small intestinal carbohydrate absorption^[132], the latter by a mechanism that includes modification of small intestinal motility from a stationary (favoring mixing), to a propulsive pattern. The beneficial effect on the glycemic response of adding guar gum to an oral glucose load appears to be achieved mainly by slowing gastric emptying^[133,134]. Nevertheless, guar also slows

small intestinal glucose absorption, probably by inhibiting diffusion of glucose out of the luminal contents^[135]; this is reflected in the observation that both GLP-1 and insulin responses are less than with guar-free glucose^[136].

Low GI foods may also stimulate insulin release through the incretin effect, or other mechanisms^[137]. Furthermore, they may enhance satiety and reduce energy intake at a subsequent meal^[138,139]. Additional information about the potential for these beneficial effects from different classes of low GI foods is needed. Fructose has been advocated as a low GI substitute for glucose in the diabetic diet, since it results in a much lower glycemic excursion than an equivalent glucose load^[140], while retaining the capacity to stimulate insulin secretion^[141]. In addition, some investigators have found that fructose ingestion suppresses food intake more than glucose^[140,142], although this issue is controversial^[141], and probably depends on the load and timing of fructose ingestion in relation to the subsequent meal.

Most medium- to long-term studies of low GI diets indicate a benefit for glycemic control^[143], typically the effect is modest^[144], but is still likely to be clinically meaningful, and in many cases is of similar magnitude to the improvement in glycemic control achieved by pharmacological agents^[145].

Slowing gastric emptying

Given the relationship between the degree of postprandial glycemia and the rate of gastric emptying in both healthy subjects^[27] and type 2 patients^[28], it is logical that dietary and/or pharmacological interventions which slow gastric emptying should be effective in lowering postprandial glycemia in type 2 diabetes. In addition to the effects of dietary fiber in retarding gastric emptying, slowing of emptying by either an oral proteinase inhibitor^[146], adding a solid non-carbohydrate meal to an oral glucose load^[147], or combining fat (the most potent macronutrient for slowing gastric emptying^[148]) with carbohydrate^[149], all reduce postprandial blood glucose and insulin responses. The underlying concept is that the presence of nutrients in the small intestine both delays gastric emptying and stimulates GLP-1 and GIP. Hence, consumption of oil as a “preload” before a mashed potato meal markedly delays the subsequent rise in blood glucose, and stimulates GLP-1 release in patients with type 2 diabetes^[150]. This approach requires further refinement to determine the optimum load, timing, and macronutrient content of the “preload”, but has the potential advantage of simplicity when compared to pharmacological strategies, which also appear to act predominantly by slowing gastric emptying. For example, the improvement in postprandial glycemia associated with GLP-1 and its analogs is related to slowing of gastric emptying rather than enhancement of insulin secretion^[40]; the latter is in fact reduced due to a decrease in the rate of entry of carbohydrate into the small intestine. The amylin analog, pramlintide, also slows gastric emptying^[151], and its use is associated with an improvement in overall glycemic control, as assessed by glycated hemoglobin, with medium-term use in type 1 and type 2 patients^[152-155]. Pramlintide has the additional advantage of promoting weight loss, probably by suppressing appetite^[156].

Inhibiting absorption of glucose

The α -glucosidase inhibitors, including acarbose, delay absorption of carbohydrates in the proximal small intestine^[157]. The resultant exposure of more distal intestinal segments to glucose results in enhanced and prolonged GLP-1 secretion in healthy subjects^[76,158], with subsequent slowing of gastric emptying^[159]. The magnitude of these effects is likely to depend on meal content (ie. disaccharide load). Moreover, acarbose fails to stimulate GLP-1 release or delay gastric emptying in patients with type 2 diabetes, although it is still beneficial for reducing postprandial glycemia in this group^[160], presumably by impairing carbohydrate absorption. Inhibition of glucose entry into enterocytes might represent an additional mode of action of acarbose^[161]. Again, it is clear that the mechanisms by which postprandial glycemia is improved frequently overlap. For example, slowed absorption of glucose, as discussed, is also a feature of low GI and high fiber diets.

Augmenting the incretin response

The effect on GLP-1 concentrations of the dietary strategies already discussed, and the observed potentiation of GLP-1 secretion and associated improvement in glycemic control after bariatric surgery^[162], point to the value of augmenting the incretin response in optimising postprandial glycemia. GLP-1 is metabolised rapidly by the enzyme dipeptidyl peptidase IV (DPP-IV), and therefore is not a suitable agent for therapeutic administration. Instead, longer lasting agonists have been developed, including both albumin-bound analogs of GLP-1, and exendin-4, a peptide derived from the saliva of the Gila monster lizard, which is structurally similar to GLP-1 and shares several biological properties, but may be a more potent insulinotropic agent than GLP-1^[26]. Subcutaneous administration has been shown to reduce postprandial glycemia in type 2 patients^[163]. Resistant analogs of GLP-1, along with DPP-IV inhibitors, appear to have a promising role in the therapy of diabetes^[164].

CONCLUSION

Upper gastrointestinal function plays a major, though often overlooked, role in determining postprandial glycemia. Recent insights into the mechanisms by which variations in gut function alter the blood glucose concentration have suggested a number of potential therapeutic strategies that require further evaluation for their utility in achieving good glycemic control.

Abstract

Although the Sydney Systems (original and updated) for the classification of gastritis have contributed substantially to the uniformity of the reporting of gastric conditions, they lack immediacy in conveying to the user information about gastric cancer risk. In this review, we summarize the current understanding of the gastric lesions associated with an increased risk for cancer, and present the rationale for a proposal for new ways of reporting gastritis. In addition to the traditional histopathological data gathered and evaluated according to the Sydney System rules, pathologists could add an assessment expressed as grading and staging of the gastric inflammatory and atrophic lesions and integrate these findings with pertinent laboratory information on pepsinogens and gastrin levels. Such an integrated report could facilitate clinicians' approach to the management of patients with gastric conditions.

INTRODUCTION

Chronic gastritis is an inflammatory condition of the gastric mucosa characterized by elementary lesions whose type, extent, and distribution are related to their etiology and modulated by host responses and environmental factors^[1]. Infection with *H pylori*, which affects an estimated three to four billion persons worldwide, is by far the most

common cause of chronic active gastritis; chemical agents, autoimmune phenomena, and other infections account for a very small proportion of chronic, usually non-active gastritides. *H pylori*-gastritis is epidemiologically and biologically linked to the development of gastric cancer^[2] and *H pylori* has been listed as a class I carcinogen^[3]. Epidemiological and pathological data suggest that extent, intensity, and distribution patterns of gastric inflammation and atrophy are consistently related to the incidence of gastric cancer in a population^[4-7]. Although odd-ratios for gastric cancer and peptic ulcer risk in relationship with the type of gastritis have been estimated, most often retrospectively, only in small series and in few populations^[5,8-10], it is widely accepted that the accurate histopathological assessment of the gastric mucosa could serve as a reasonably good predictor of cancer risk in an individual patient. In fact, most recent classifications of gastritis have contained the implicit aim of providing a clinico-pathological correlation that could be both synchronous (that is, at the time of the sampling) and, more usefully, diachronic.

When appropriate sampling is available, the histopathological features of the gastric mucosa recognized as being part of the neoplastic process and broadly referred to as "pre-neoplastic lesions" (atrophy, pyloric and intestinal metaplasia, epithelial dysplasia) can be accurately evaluated by the microscopic examination of mucosal biopsies. Although classification systems such as the Sydney System^[11], its Houston-updated version^[12], and the more recent guidelines for the evaluation of atrophy^[13] suggest strategies for the formulation of histopathological reports, we still lack a way to translate the pathological information into a standardized report that would convey comprehensive information on the gastric condition while lending itself to a straightforward analysis of cancer risk.

The purpose of this article is to explore ways for pathologists to maximize the predictive value of the gastric evaluation by: (1) streamlining the histopathological report of gastric biopsies, and (2) integrating relevant laboratory information with pathological data.

GASTRIC MUCOSAL CHANGES RELATED TO GASTRIC CANCER

As a result of seminal field studies conducted by Max Siurala in Finland and Estonia^[14-17] and Pelayo Correa in Colombia^[4,18-19], as well as the crucial body of knowledge derived from decades of Japanese studies^[20,21], the separate entities of chronic superficial gastritis, atrophy, metaplasia, dysplasia and carcinoma were integrated into a hypothetical

sequence known as Correa's cascade^[22]. Increasingly well-documented by patho-epidemiological studies, the 1984 multi-step hypothesis of gastric carcinogenesis still lacked an etiological initiator. The missing first step was discovered in the same year^[23] and *H pylori* found its place at the top of the cascade^[24].

The histopathological lesions broadly regarded as preneoplastic are chronic gastritis, atrophy, intestinal metaplasia, dysplasia, and neoplasia. Their evolution in a cohort can be viewed as a pyramid with a very large base representing the entire *H pylori*-infected population; a segment of these subjects (generally larger in developing than in industrialized areas) will progress to atrophic gastritis, mostly accompanied by intestinal metaplasia. A very small minority will progress further to dysplasia with some eventually developing adenocarcinoma. The closer a lesion is to neoplasia, the more likely it will progress into it. Thus, whereas chronic gastritis is a remote and uncertain precursor of gastric cancer that could be better called a "predisposing condition," high-grade dysplasia is considered already a neoplastic lesion^[25,26]. If pathologists could make a reliable assessment of the risk that each patient has, based on a staging of the disease, effective strategies could be developed to detect the early, curable phase of gastric cancer and prevent its progression.

Chronic gastritis

The risk of gastric cancer for a patient with simple, non-atrophic *H pylori* gastritis is negligible, thus, the decision to treat the infection is based, in most cases, on other considerations. There is, however, one exception. Gastric cancer and atrophic gastritis associated with it have at least some familial predisposition^[27-30]; therefore, it would seem wise to treat *H pylori* infection as early as possible in direct relatives of patients with gastric cancer. This is one of the rare circumstances in which *H pylori* would be eradicated for the specific purpose of preventing gastric carcinoma in an individual patient.

Atrophy

Gastric atrophy is defined as the loss of appropriate glands in a given gastric compartment^[13,31]. This purely histopathological definition indicates that the glands expected to be present in the portion of gastric mucosa under examination (for example, oxyntic glands in the mucosa of the corpus) are no longer there, and have been replaced by something else that does not belong to that area. This "something else" may be extracellular matrix, fibroblasts and collagen, or other glands that normally are not there (e.g., intestinal-type glands or pseudo-pyloric glands). Any of these replacements prevents that portion of gastric mucosa from performing its normal functions (e.g., to secrete acid). Thus, the functional correlate of atrophy is strictly related to its extension.

Atrophic gastritis is a condition characterized by the presence of significant areas of atrophy. Its two most common underlying causes are chronic infection with *H pylori* and the autoimmune gastritis that may become associated with pernicious anemia. In the Updated Sydney System, the term "atrophic gastritis" is used in contrast to

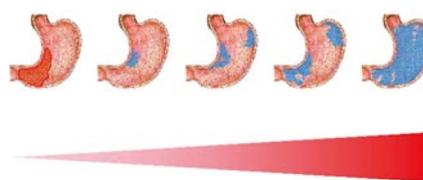

Figure 1 Schematic representation of the progression of atrophy, from absent in the case of antrum-predominant non-atrophic gastritis depicted on the left to the almost generalized metaplastic atrophy depicted on the right. The increased extension of atrophy corresponds to an increased cancer risk, indicated as an expanding triangle. The extension of atrophy can also be reported as a stage from 0 to 4.

"non-atrophic gastritis" or simply "gastritis," a condition usually more severe in the antrum (hence the term "antral-predominant") found in most subjects infected with *H pylori* in the Western industrialized world.

The stomach affected by atrophic gastritis shows a decrease or absence of appropriate glands, an expansion of the antral-type mucosa into the corpus ("antralization" or pseudo-pyloric metaplasia) and usually extensive areas of intestinal metaplasia. This condition has been known for several decades to represent a significant epidemiological risk factor for gastric adenocarcinoma^[14,17,24,32-36]; as schematically depicted in Figure 1, its prognostic implications in the individual patient seem to be related to the extent and distribution of the atrophic areas^[10,37].

Intestinal metaplasia

Intestinal metaplasia is the replacement of the normal gastric mucosa with an epithelium similar to that of the intestine. Attempts to classify the different types of intestinal metaplasia have resulted in a confusing terminology (complete *vs* incomplete, type 1, 2a and 2b, *etc.*); the classification currently used was proposed by Jass and Filipe^[38,39]: Type I (brush border and no sulfomucins); Type II (no brush border, rare sulfomucins); and Type III (no brush border, cellular disarray, abundant sulfomucins). Type I intestinal metaplasia has been often said to pose little increased risk of developing carcinoma, whereas type III has been considered as an already dysplastic lesion^[10,40-42]. The classification of the three types of metaplasia requires relatively sophisticated histochemical techniques and is far from being standardized. Furthermore, the data suggesting different cancer risks for the different types of intestinal metaplasia are not unequivocal^[43]. Therefore, immunohistochemical sub-typing of intestinal metaplasia should be limited to the clinical research setting and not a part of the routine evaluation of patients with intestinal metaplasia.

Dysplasia

Malignancy is the final step of progressive genetic and phenotypic changes that modify the original cellular morphology, eventually generating a biologically new cell characterized by uncontrolled growth and the potential to migrate and implant in locations beyond its original fixed

site. This biological process has been called multi-step or step-wise oncogenesis. In epithelial tissues (for example, the squamous lining of the uterine cervix or the columnar lining of the colon) the first of step visible to an observer using a light microscope is a change in the morphology of the cells that form the epithelium. Nuclei are larger, nucleoli may be prominent and the chromatin may be clumped or granular; compared to the larger nucleus, the cytoplasm appear smaller, a phenomenon referred to as "increased nucleo-cytoplasmic ratio". Various degrees of disarray of the orderly structure of the normal epithelium usually accompanying these changes. Epithelial alterations of this kind occur in two situations: when the epithelium has been injured and is undergoing repair, and when genetic alterations have transformed the cells in a neoplastic growth. It is generally agreed by pathologists that in the former instance one refers to the phenomenon as "regenerative atypia", whereas in the latter case the term "dysplasia" is used^[44].

The importance of recognizing and correctly identifying dysplasia is self-evident: while regenerative atypia is the desired response to epithelial injury and an essential part of an organism's homeostasis, dysplasia is the harbinger of cancer and requires immediate action. However, the morphological differences between atypia and dysplasia are not always apparent, and significant areas of phenotypic overlap exist between the two. Pathologists have tried for years to standardize the criteria for the diagnosis and grading of dysplasia in tissues accessible to biopsy sampling. Without getting into the complex historical details of the process, for the purpose of this review we say only that, through the efforts of pioneers such as the late Rodger Haggitt, Robert Riddell, Brian Reid, and others, a satisfactory level of agreement has been reached for dysplasia of the colon and of Barrett's epithelium^[44-46]. Gastric dysplasia has received less attention in the past, with only one major consensus article addressing the issue before 1996^[47].

In the last decade, the discovery of *H pylori* and its relationship with gastric cancer has stimulated increasing attention to the preneoplastic lesions of the stomach. The possibility that curing this infection could prevent or even cause the regression of such lesions has highlighted the need for uniform and rigorous definitions and diagnostic criteria. However, unlike metaplasia, whose recognition has always been largely free of major disputes, or atrophy, which has been the focus of major conceptual disagreements among pathologists, dysplasia exposed a novel angle of controversy: a pathological schism between East and West, or, more accurately, between Japan and the West^[48].

Japan is one of the countries with the highest incidence of adenocarcinoma of the stomach in the world; at the same time, it also has the world's best survival rates for gastric cancer. Although the effective early detection programs, innovative endoscopic techniques, and daring and successful therapeutic endoscopists have been invoked to explain the Japanese success in this area, another explanation has been suggested, mostly in a veiled or oblique manner. To state it simply, it has been implied that, to have such good survival rates the Japanese must

call cancer what others call dysplasia. The question has been propelled into the international scientific forum only recently, through the efforts of RJ Schlemper, who in 1996 organized a workshop to address the issue. This workshop resulted in a seminal paper entitled "Differences in diagnostic criteria for gastric carcinoma between Japanese and Western pathologists," published in the Lancet in 1997^[49]. Following the workshop and publication of its findings, several other groups have formed to tackle the problem in the traditional pathologists' fashion: by trying to measure the level of agreement (or disagreement) amongst observers. These groups included various proportions of Japanese and Western pathologists, and the ultimate aim was to reach a consensus that classification, if used globally, would allow comparative studies performed in different countries. As a result, new issues have emerged and new classifications have been proposed. The classification currently accepted by the World Health Organization^[50] is largely modeled on the consensus agreement reached in Padua, Italy, in 1998^[20], and summarizes one of the most recent proposals for an integrated therapeutic and pathological approach^[51].

The Padova model is based: (1) on the definition of dysplasia as pre-invasive neoplasia; and (2) on a five-category classification of gastric neoplasia which includes: 1, negative for dysplasia; 2, indefinite for dysplasia; 3, non-invasive neoplasia; 4, suspicious for invasive cancer; 5, gastric cancer. The numerical prefix assigned to each diagnostic category essentially corresponds to the diagnostic categories of the Japanese Classification for Gastric Cancer^[52]. Within each category one or more sub-categories are hierarchically ordered to cover the spectrum of epithelial alterations.

THE IMPORTANCE OF GOOD SAMPLING

The topographic distribution of inflammatory infiltrates, lymphoid follicles, atrophy, and metaplasia is an essential determinant used for all classifications of gastritis. These changes may be patchily distributed and their relative intensity in different parts of the stomach may be highly variable. Furthermore, the inflammatory and atrophic processes have different phenotypical expressions in different regions of the stomach. Therefore, to obtain an accurate picture of gastritis, pathologists must have a set of specimens representative of each gastric compartment. Each specimen is examined according to uniform criteria, a general impression of the intensity of the features of gastritis is extrapolated from the various specimens from each compartment, and finally this information is amalgamated in a topographical diagnosis. The location of the biopsy specimens recommended by the Updated Sydney System^[12] is depicted in the left panel of Figure 2. A suggestion has been made to replace the original sites with others, purportedly more likely to yield information about the extension of intestinal metaplasia^[53], but in the absence of independent testing no proposal in this sense has been presented.

Irrespective of the protocol used, gastroenterologists must keep in mind that the predictive information they can get from their pathologist is only as good as the

biopsy sampling submitted for examination. The Sydney System 5-biopsy protocol is a compromise between what is practically doable in routine practice and the ideal need for maximal topographic information. As depicted in Figure 2, right panel, in special situations such as the diagnosis and follow-up of gastric mucosa-associated lymphoid tissue B-cell lymphomas or the diachronic investigation of dysplasia much more extensive sampling protocols need to be applied^[48,54-56].

VIRTUAL HISTOPATHOLOGY

The determination of serum pepsinogens I (PG I) and II (PG II), gastrin-17 (G-17) and IgG anti-*H. pylori* antibodies by ELISA has been proposed as an array of non-invasive markers for the assessment of both morphological and functional status of the gastric mucosa^[57]. The rationale for this approach, described by its enthusiastic supporters as the “serological biopsy,” rests on the fact that PG I is exclusively secreted by oxyntic glands and represents an excellent marker of the secretory ability of the gastric corpus. In contrast, PG II is produced by all types of gastric and duodenal glands and its production is influenced by gastric inflammation^[58,59]. Although these molecules are secreted into the gastric lumen, small amounts seep out into the bloodstream and can be measured. Gastrin-17 (G-17), produced in the antrum and secreted directly into the blood, is a specific marker of G cell function^[60]. Several studies have now shown that serum levels of PG I, PG II and G-17 are high in subjects with *H. pylori* non-atrophic chronic gastritis^[61]. Both PG I and PG II concentrations are found to decrease significantly two months after the eradication of *H. pylori*^[62,63]. Furthermore, the ratio of PG I and G-17 levels have been found to correlate well with the histopathological diagnosis of atrophic body gastritis and, in some studies, to be associated with the presence of gastric cancer^[64-66].

In a recent study, De Mario and his colleagues^[67] demonstrated that the analysis of serum pepsinogens, G-17 and anti-*H. pylori* IgG levels provide consistent and reproducible information regarding gastric atrophy and its association with *H. pylori*. The authors suggest that dyspeptic patients with normal PG I, PG II, G-17 and a negative serological test for *H. pylori* can be reassured that they are unlikely to have peptic ulcer disease and can be treated symptomatically. In contrast, patients with panel test results indicating *H. pylori*-related chronic gastritis, with or without atrophy, could either be treated for *H. pylori* or referred for endoscopy, depending on the type and severity of their manifestations.

GENERATING A CLINICALLY USEFUL HISTOPATHOLOGY REPORT

The article reporting the Updated Sydney System, published in October 1996, has recently passed the 1000-citation milestone^[68], suggesting that the semi-quantitative scoring system it advocated remains a useful tool for clinical research. Nevertheless, the same pathologists who use it when assessing biopsies for clinical studies find it too cumbersome to use in their routine

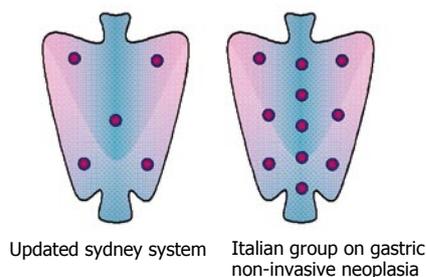

Figure 2 Two different biopsy protocols.

diagnostic activities.

Using the framework provided by the Sydney System's and the Atrophy Club's analytic approach, we have recently put forward a proposal for a grading and staging scheme that integrates the relevant histopathological data gathered and interpreted by the pathologist and delivers them in the form of a simple, yet information-rich report^[69]. We have suggested that the method is both feasible and practical, and that staging and grading (preceded by a description of the histological findings in the biopsy samples) could represent the concluding message of the histological report. This scheme could be done for chronic gastritis what the grading and staging system introduced by the International Group of Hepatologists in 1995 did for chronic hepatitis: make prognostically significant and reproducible information immediately available in the clinical practice^[70,71].

Briefly, the proposal consists of summarizing the combined intensity of mononuclear and scoring granulocytic inflammation in both antral and oxyntic biopsy samples in a grade from 0 (no inflammation) to 4 (a very dense infiltrate in all the biopsy samples). The extent of atrophy, with or without intestinal metaplasia, would be reported as a stage from 0 (no atrophy) to 4 (pan-atrophy involving all antral and oxyntic samples). The latter would convey information on the anatomical extent of the atrophic-metaplastic changes related to cancer risk. Figure 1 shows the progression from stage 0 (left) to stage 4 (right).

A pathologist who had access to the results of the “serological biopsy” and applied the grading and staging principles outlined in this scheme could generate a comprehensive informative integrated report that could be used by clinicians as a solid base for the management of patients with gastric conditions.

This proposal has been discussed at an international consensus group of gastroenterologists and pathologists (Operative Link for Gastritis Assessment-OLGA) that gathered in Parma, Italy, in April 2005. The group included Massimo Rugge, Padova, Italy; Pelayo Correa, New Orleans, Louisiana, USA; Francesco Di Mario, Parma, Italy; Emad El-Omar, Aberdeen, Scotland, UK; Roberto Fiocca, Genova, Italy; Karel Geboes, Leuven, Belgium; David Y Graham, Houston, Texas, USA; Takanori Hattori, Shiga, Japan; Peter Malfertheiner, Magdeburg, Germany; Pentti Sipponen, Espoo, Finland; Joseph Sung, Hong Kong, China; Wilfred Weinstein, Los Angeles, California,

USA; Michael Vieth, Bayreuth, Germany; and Robert M Genta, Geneva, Switzerland.

After deliberations that led to a number of modifications of the original proposal, the OLGA group has agreed that an international staging method is needed to advance research in gastritis and is preparing to test its feasibility and reproducibility both in retrospective and prospective multi-center studies.

Abstract

AIM: To investigate the intracellular apoptotic signals engaged by resveratrol in three gastric adenocarcinoma cancer cell lines, two of which (AGS and SNU-1) express p53 and one (KATO-III) with deleted p53.

METHODS: Nuclear fragmentation was used to quantify apoptotic cells; caspase activity was determined by photometric detection of cleaved substrates; formation of oxidized cytochrome C was used to measure cytochrome C activity, and Western blot analysis was used to determine protein expression.

RESULTS: Gastric cancer cells, irrespective of their p53 status, responded to resveratrol with fragmentation of DNA and cleavage of nuclear lamins A and B and PARP. Resveratrol, however, has no effect on mitochondria-associated apoptotic proteins Bcl-2, Bcl-xl, Bax, Bid or Smac/Diablo, and did not promote subcellular redistribution of cytochrome C, indicating that resveratrol-induced apoptosis of gastric carcinoma cells does not require breakdown of mitochondrial membrane integrity. Resveratrol up-regulated p53 protein in SNU-1 and AGS cells but there was a difference in response of intracellular apoptotic signals between these cell lines. SNU-1 cells responded to resveratrol treatment with down-regulation of survivin, whereas in AGS and KATO-III cells resveratrol stimulated caspase 3 and cytochrome C oxidase activities.

CONCLUSION: These findings indicate that even within a specific cancer the intracellular apoptotic signals engaged by resveratrol are cell type dependent and suggest that such differences may be related to differentiation or lack of differentiation of these cells.

INTRODUCTION

Gastric cancer is a major cause of mortality both in developed and underdeveloped countries because currently available chemotherapeutic regimens are not very effective, resulting in high recurrence rates and poor survival. There is strong evidence that the predominant etiological factors contributing to development of gastric cancer are infections with *H pylori* during early years of life and/or exposure to chemical carcinogens such as those in cigarettes and cured meat^[1]. Identification and eradication of *H pylori* in the world population would be an economically prohibitive undertaking because more than 50% of population over the age of 50 are infected with the bacterium, and eradication would not benefit those with pre-malignant gastric mucosal alterations. However, given the epigenetic origin and prolonged onset of gastric cancer development, the concept of cancer chemoprevention presents an attractive hypothesis to reduce the risk of gastric cancer.

Since apoptosis-inducing compounds control cancer cell proliferation, it is feasible that cancer development may be arrested through molecular intervention with compounds that retard cellular proliferation and induce apoptosis. Trans-resveratrol, a polyphenol found in grapes, wine and peanuts, presents itself as a dietary chemopreventive because numerous studies have demonstrated its ability to suppress proliferation and induce apoptosis in a variety of transformed cells^[2]. We have shown that gastric adenocarcinoma cells respond to resveratrol with inhibition of DNA synthesis, cell cycle arrest, suppressed proliferation, and induction of apoptosis^[3,4], and there is evidence that resveratrol inhibits the growth of transplanted gastric tumor^[5].

There are two major pathways for induction of apoptosis: (1) the extrinsic pathway activated when

extracellular ligands interact with receptors of the TNF family (TNF, FAS, and TRAIL) and (2) the intrinsic pathway, induced by destabilization of mitochondria. Resveratrol up-regulates Fas and Fas-L in gastric adenocarcinoma cells that express p53, whereas only Fas-L becomes up-regulated in cells whose p53 is deleted^[6], suggesting that apoptotic signals engaged by resveratrol within individual gastric carcinoma cell lines may be dependent on p53 status of the cell. Here we explore the action of resveratrol on intracellular apoptotic signals in three different gastric adenocarcinoma cell lines.

MATERIALS AND METHODS

Materials

Resveratrol is a kind gift from Pharmascience, Montreal, Quebec, Canada. The following caspase substrates were purchased from Calbiochem, EMD Biosciences, Inc., San Diego, CA: caspase 1 substrate (Ac-WEHD-pNA), caspase 3 substrate (Ac-DEVD-pNA), caspase 6 substrate (Ac-VEID-pNA), caspase 8 substrate (Ac-IETD-pNA), and caspase 9 substrate (Ac-LEHD-pNA). Cytochrome C Oxidase Assay Kit (CYTOC-OX1) was purchased from Sigma-Aldrich, St. Louis, MO. Antibodies to cytochrome C and lamin B were obtained from Santa Cruz Biotechnology, Inc., Santa Cruz, CA; antibodies to PARP, Bcl-xl, Bax, Bid, and cleaved Lamin A were from Cell Signaling Biotechnology, Beverly, MA; antibody to survivin was from Novus Biologicals, Inc., Littleton, CO; p53 antibody was from PharMingen, Inc./BD Biosciences, San Diego, CA; antibody to β -actin was from Sigma-Aldrich, St. Louis, MO, and antibodies to Bcl-2 and Smac/DIABLO were from Calbiochem/EMD Biosciences, Inc., La Jolla, CA. Chemiluminescence detection system (ECL Western Blotting System) was from Amersham/Pharmacia Biotech, Piscataway, NJ.

Cell culture and cell treatment

Human gastric adenocarcinoma cell lines AGS (ATCC: CLR-1739), SNU-1 (ATCC: CRL-5971) and KATO-III (ATCC: HTB 103) were routinely cultured in RPMI-1640 media supplemented with 100 mL/L fetal bovine serum (FBS), 10 U/mL of streptomycin and 0.25 mg/L of amphotericin B at 37°C in humidified air with 50 mL/L CO₂. Cells were allowed to equilibrate in fresh media for 2-3 h prior to addition of resveratrol which was dissolved in 950 mL/L ethanol. The concentration of ethanol was always maintained at 0.1% in both treated and untreated cells. A stock solution of 100 mmol/L resveratrol was prepared weekly and stored in the dark at -20°C.

Determination of apoptosis

Percent of apoptotic cells was determined using Cell Death Detection ELISA^{PLUS} kit from Roche Applied Science, Indianapolis, IN. Cells (1×10^4 cells/200 μ L) were incubated for designated times with or without 100 μ mol/L resveratrol, and percent of apoptotic cells was calculated based on 100% apoptosis obtained after 48 h of cell exposure to 50 μ mol/L camptothecin.

Caspase activity measurements

Cells were plated in fresh media at 1×10^6 cells/5 mL in 6 well plates, allowed to equilibrate for 3 h, and treated with 100 μ mol/L resveratrol for 24 or 48 h. Vehicle was added to untreated controls that were also cultured for 24 or 48 h. At the end of the specified incubation time, cells were harvested, washed once with 5 mL of PBS and lysed for 30 min at 4°C in lysis buffer A (10 mmol/L Tris pH 7.4, 150 mmol/L NaCl, 1 mmol/L EDTA, 1 mmol/L LEGTA, 1% Triton X-100, 0.2 mmol/L sodium vanadate, 2 mmol/L phenylmethyl-sulfonyl fluoride, 0.5% NP-40, and 20 mmol/L NaF). The caspase assay was performed in 96 well plates in a total volume of 100 μ L as follows: to 32 μ L of assay buffer (312.5 mmol/L HEPES, 31.25% glucose, 0.3125% CHAPS) were added 2 μ L of DMSO, 10 μ L of 100 mmol/L DTT, 30 μ g of cell lysate protein, and the volume adjusted with deionized water to 98 μ L. Following addition of 2 μ L of 10 mmol/L fluorogenic peptide substrate, specific for each caspase, the reaction was incubated at 25°C for 4 h after which time absorbance measured at 405 nm on a microplate reader (Molecular Devices Corporation, Sunnyvale, CA). Activity of each caspase activity was calculated from a standard curve of p-nitroaniline (pNA) absorbance at 405 nm and values are expressed as pmoles of pNA generated per mg lysate protein. Protein content of cell lysates was determined by the method of Lowry^[7].

Western blot analysis

Cellular levels of cytochrome C, p53, survivin, Bax, Bcl-2, Bcl-xl, Bid, Smac/DIABLO, cleaved lamin A, lamin B, PARP, and β -actin (used as control for equal protein loading) were determined in untreated and resveratrol treated cell fractions by Western blot detection. To test the action of resveratrol, cells (0.2×10^9 cells/L of media) were treated with 100 μ mol/L resveratrol for 24 or 48 h, after which time they were harvested, washed with PBS, suspended in 0.5 mL of lysis buffer B (10 mmol/L Tris pH 7.4, 150 mmol/L NaCl, 1 mmol/L EDTA, 1 mmol/L EGTA, 1% Triton X-100, 0.2 mmol/L sodium vanadate, 2 mmol/L phenylmethyl-sulfonyl fluoride, 0.5% NP-40, 20 mmol/L NaF, and 2 mg/L leupeptin), and rapidly frozen in liquid nitrogen. Cells were lysed by a freeze-thaw cycle in liquid nitrogen followed by 30 min at 4°C and cell cytosol was prepared from cell lysates by centrifugation at $10\,000 \times g$ for 20 min. Mitochondria were prepared from whole cells by a subcellular fractionation protocol^[8] and protein content of each fraction determined by the Lowry method^[7]. Equal amounts of protein were separated by SDS-PAGE on either 15% resolving Tris-HCl gels for detection of cytochrome C, survivin, Bcl-2, Bcl-xl, Bax, Bid, and Smac/DIABLO or 12% gels for detection of p53, PARP, cleaved lamin A, lamin B, β -actin, followed by transfer to PVDF membranes, and antigen detected by chemiluminescence. Depicted results are representative of at least two individual experiments.

Measurement of cytochrome C oxidase activity

Cytochrome C oxidase activity was measured in cell

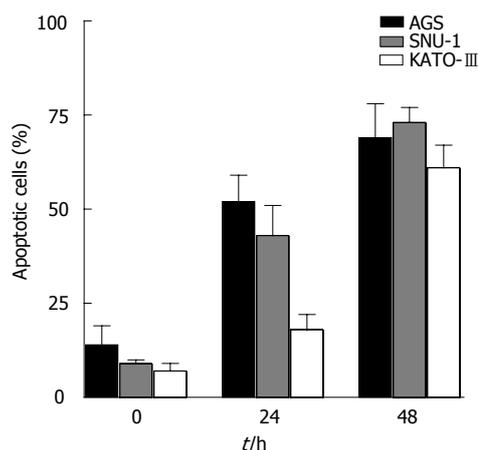

Figure 1 Effect of resveratrol on apoptosis of gastric adenocarcinoma cells.

lysates from untreated and resveratrol treated cells using a commercially available kit from Sigma-Aldrich. Activity of cytochrome C oxidase was determined by measuring the conversion of reduced cytochrome C, which absorbs light at 450, to its oxidized form that does not absorb light at this wavelength, and values are expressed as ΔA_{550} generated by 35 μg of lysate protein.

Statistical analysis

Numerical data were analyzed for statistical significance by Student's *t* test, and Results are expressed as the mean \pm SE. Statistical significance is denoted as $P < 0.01$ and $P < 0.05$.

RESULTS

Effect of resveratrol on apoptosis of SNU-1 cells

Gastric adenocarcinoma SNU-1 cells (expressing p53) and Kato-III cells (p53 deleted) respond to resveratrol treatment with decreased proliferation, concentration dependent inhibition of DNA synthesis and cell cycle arrest^[3,4]. To determine whether p53 status of the cell regulates the action of resveratrol on apoptosis, we measured the extent of apoptosis in three gastric adenocarcinoma cells lines: AGS (expressing wild type p53), SNU-1 (expressing p53) and KATO-III. Results show that cell treatment with 100 $\mu\text{mol/L}$ resveratrol induces a time dependent apoptosis in all three cell lines (Figure 1). Although a small percentage of apoptotic cells was present in the absence of resveratrol, treatment with 100 $\mu\text{mol/L}$ resveratrol for 24 h resulted in significantly increased accumulation of apoptotic cells, and treatment for 48 h further increasing the percentage of apoptotic cells. After 48 h of treatment with 100 $\mu\text{mol/L}$ resveratrol nearly 70% of AGS cells, 75% of SNU-1 cells and 62% of Kato-III cells became apoptotic.

Action of resveratrol on nuclear targets of apoptosis

Apoptosis is characterized by loss of nuclear integrity and degradation of DNA and we previously demonstrated that exposure of gastric adenocarcinoma cells to resveratrol results in DNA fragmentation^[3,4]. Here we determined the action of resveratrol on nuclear proteins PARP, lamin

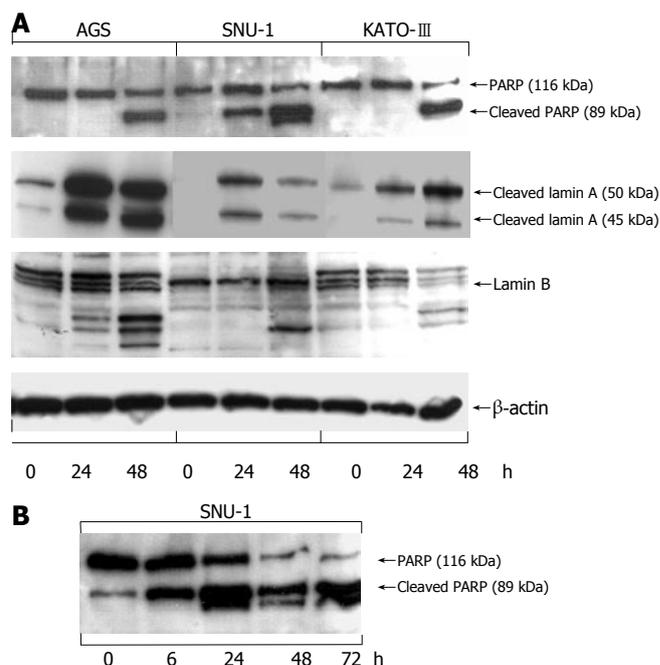

Figure 2 Effect of resveratrol on lamin A, lamin B (A) and PARP (B).

A and lamin B (Figure 2A), and show that resveratrol promotes their cleavage in all three cell lines. Increased levels of lamin A cleavage products were seen in all cells within 24 h of resveratrol treatment, whereas lamin B cleavage products were seen in AGS cells after 24 h, while SNU-1 and Kato-III cells required 48 h of exposure to 100 $\mu\text{mol/L}$ resveratrol to induce lamin B cleavage. Resveratrol treatment caused cleavage of the 116 kDa PARP to an 89 kDa fragment in all three cell lines although there was a time difference among the individual cell lines. In SNU-1 cells the 89 kDa breakdown product of PARP was detected after 24 h while in AGS and KATO-III cells PARP breakdown product was seen after 48 h. Closer analysis of PARP in SNU-1 cells revealed presence of the 89 kDa fragment within 6 h after cell exposure to resveratrol with further breakdown of the 89 kDa band to a smaller fragment after prolonged treatment and nearly total loss of the 116 kDa PARP protein after 72 h of cell exposure to 100 $\mu\text{mol/L}$ (Figure 2B).

Action of resveratrol on caspases

Because nuclear proteins become cleaved during resveratrol-induced apoptosis, we investigated whether this action of resveratrol results from activation of caspases. Activities of caspases 1, 3, 6, 8, and 9 were measured in untreated cells and in cells treated for 24 or 48 h with 100 $\mu\text{mol/L}$ resveratrol. Results show that 100 $\mu\text{mol/L}$ resveratrol had no effect on caspases 1, 8, and 9, but significantly stimulated caspase 3 activity in AGS and KATO-III cells and caused some activation of caspase 6 in AGS cells after 24 h. Caspase 3 activity in AGS cells was increased after 24 h of treatment and remained elevated after 48 h, whereas in KATO-III cells caspase 3 activity responded to resveratrol only after 48 h. Resveratrol, however, had no effect on caspase 3 activity in SNU-1 cells (Figure 3).

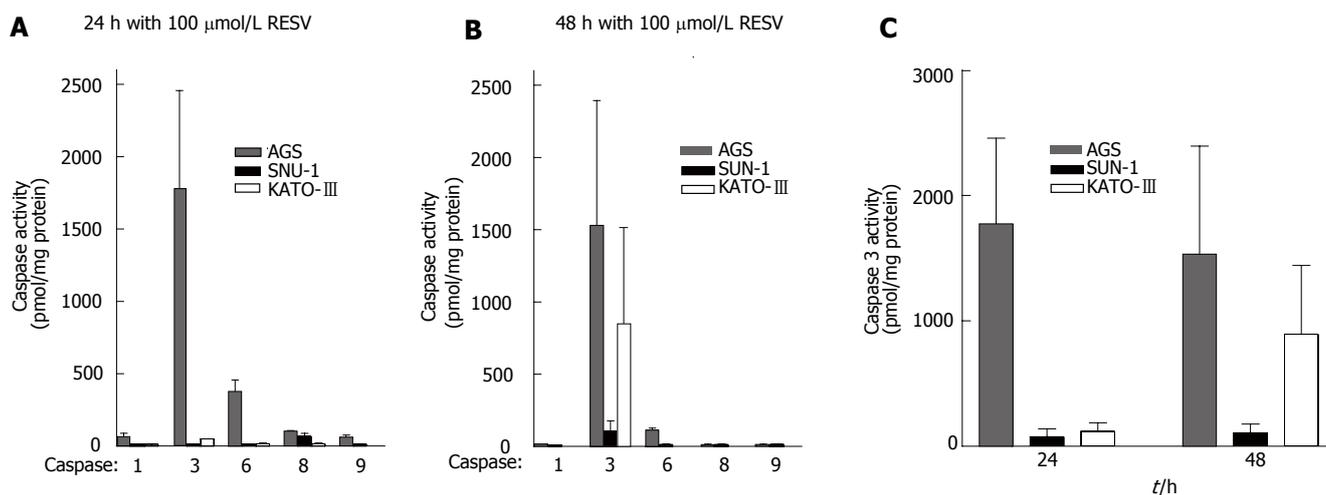

Figure 3 Effect of resveratrol on caspase activity.

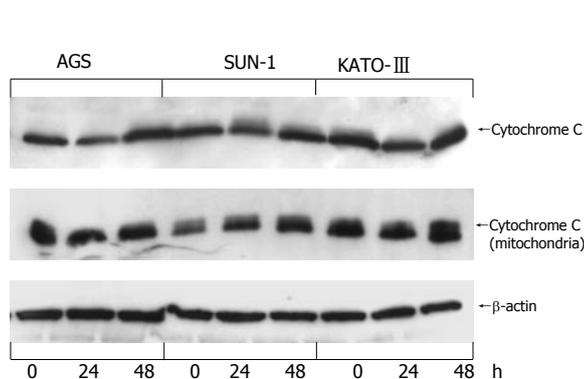

Figure 4 Effect of resveratrol on subcellular distribution of cytochrome C.

Action of resveratrol on subcellular distribution of cytochrome C

Numerous cytotoxic reagents, radiation, and growth factor withdrawal induce apoptosis by promoting release of mitochondrial cytochrome C into cell cytosol. To determine whether resveratrol targets mitochondrial permeability in gastric adenocarcinoma cells we measured distribution of cytochrome C protein between cell cytosol and mitochondria after 24 and 48 h of cell treatment with 100 μmol/L resveratrol. Results indicate that cytochrome C was found to be present in both mitochondria and cytosol of each cell line prior to treatment with resveratrol, and resveratrol treatment had no further effect on redistribution of cytochrome C protein between these two compartments (Figure 4).

Action of resveratrol on cytochrome C oxidase activity

In addition to its role in apoptosis, cytochrome C functions in the respiratory chain as carrier of electrons from flavoproteins to cytochrome oxidase. Since resveratrol is a known antioxidant and inhibits mitochondrial respiratory chain^[9], we inquired whether cytochrome C contributes to the antioxidant potential of resveratrol by measuring cytochrome C oxidase activity in untreated as well as resveratrol treated cells. Results show that resveratrol had a significant stimulatory effect on cytochrome C oxidase activity in KATO-III cells after 24 h of cell treatment, and

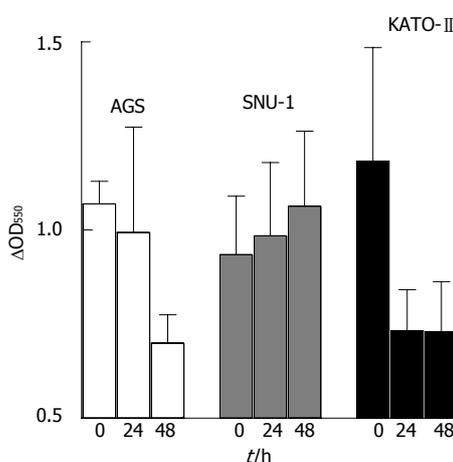

Figure 5 Action of resveratrol on cytochrome C oxidase activity.

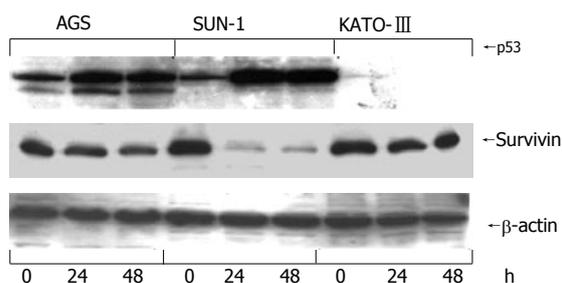

Figure 6 Effect of resveratrol on p53 and survivin.

in AGS cells after 48 of treatment, but had no effect on cytochrome C oxidase activity in SNU-1 cells (Figure 5).

Action of resveratrol on p53 and survivin levels

Cellular levels of survivin, an inhibitor of apoptosis, have been shown to correlate inversely with expression of the p53 tumor suppressor^[10-12], and we determined the action of resveratrol on survivin and p53 protein levels in AGS, SNU-1 and Kato-III cells. Results presented in Figure 6 indicate that resveratrol up-regulates p53 protein in AGS and SNU-1 cells but has no effect on the p53 status in Kato-III cells. Within 24 h after exposure to 100 μmol/L

resveratrol survivin levels in SNU-1 cells became down-regulated. Although AGS cells express p53 and its p53 is up-regulated by resveratrol, levels of survivin in AGS cells were not altered by resveratrol, and resveratrol had no effect on survivin in KATO-III cells.

Action of resveratrol on Bcl-2 proteins

To evaluate the contribution of pro- and anti-apoptotic Bcl-2 proteins in the response of gastric carcinoma cells to resveratrol we measured protein levels of anti-apoptotic Bcl-2 and Bcl-xl and pro-apoptotic Bax, as well as Bid and Smac/DIABLO. Cells were treated with 100 $\mu\text{mol/L}$ resveratrol for 24 or 48 h, sub-cellular fractions prepared as described in Methods, and protein levels determined by Western blotting. Isolated mitochondria were used to determine Bcl-2 and Bcl-xl levels, whereas Bax, Bid and Smac/DIABLO were measured in cell cytosol. Results presented in Figure 7 show that cell treatment with 100 $\mu\text{mol/L}$ resveratrol for up to 48 h had no effect on Bax, Bcl-2, Bcl-xl, and Smac/DIABLO, and did not promote cleavage of cytosolic 22 kDa Bid to the active 15-17 kDa form.

DISCUSSION

A common feature of malignant cells is their ability to proliferate without restraint and, therefore, apoptosis is considered the predominant pathway for elimination of malignant cells with the signals engaged by an apoptotic agent determining its efficacy as a chemopreventive or as an adjuvant to chemotherapy. Previous work from this laboratory has shown that resveratrol-induced engagement of Fas receptor is dependent on the p53 status of the cells. The aim of the present investigation was to determine whether intracellular apoptotic signals engaged by resveratrol are also regulated to some extent by p53. To enhance the signaling response to resveratrol all experiments were performed using 100 $\mu\text{mol/L}$ because this concentration has been repeatedly shown to promote significant apoptotic response in human gastric adenocarcinoma cells^[3-5] and in other malignant cells^[13-15].

One of the differences among the three gastric carcinoma cell lines used in this study is their p53 status: Kato-III cells do not express p53, whereas p53 is present in both AGS and SNU-1 cells. Resveratrol induced a time-dependent apoptotic response in all three cell lines irrespective of their p53 status, and in each cell line resveratrol-induced apoptosis was associated with cleavage of PARP, lamin A and lamin B. Other studies investigating the involvement of p53 in cellular response to resveratrol have also shown that resveratrol induces apoptosis and up-regulates p53 in cells that express this tumor suppressor^[16,17], and that it induces apoptosis in p53 deficient cells^[18,19]. Tumor suppressor p53 exerts control over proliferation and apoptosis by initiating transcriptional activation of specific genes, among them the gene for survivin^[10-12], an inhibitor of apoptosis found to be expressed in all types of malignancies but not in normal, differentiated cells. Patients with gastric cancer express increased abundance of survivin^[20] and survivin expression correlates with p53 accumulation^[18], whereas

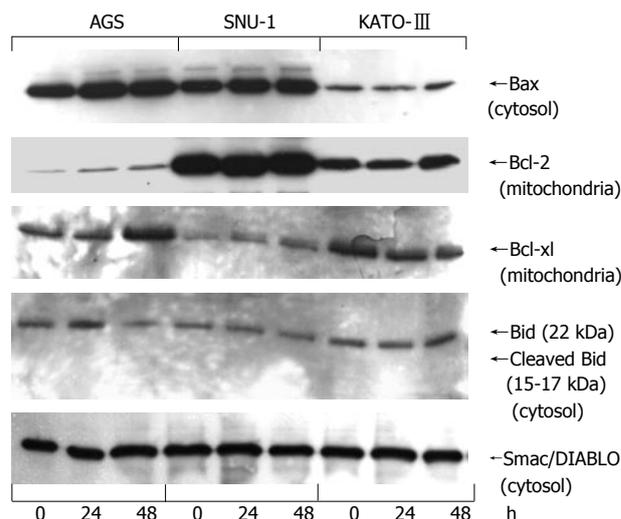

Figure 7 Effect of resveratrol on Bax, Bcl-2, Bcl-xl, Bid and Smac/DIABLO.

suppression of survivin inhibits growth of gastric cancer cells and decreases tumorigenesis^[21]. In our study resveratrol increased p53 levels in both AGS and SNU-1 cells, but only p53-expressing SNU-1 cells responded to resveratrol treatment with loss of survivin suggesting that p53 in AGS cells may have mutations, a common finding in tumor cells.

Since resveratrol is a small, lipophilic molecule it can intercalate within the mitochondrial membrane and directly induce apoptosis through destabilization of mitochondrial membrane. To address this question we determined action of resveratrol action on Bcl-2 family of apoptotic regulators. These proteins control mitochondrial permeability and promote release of mitochondrial cytochrome C. Our findings revealed that resveratrol had no effect on either anti-apoptotic Bax or pro-apoptotic Bcl-2 and Bcl-xl, did not promote cleavage of Bid and had no effect on subcellular redistribution of cytochrome C. On the basis of these results we conclude that resveratrol-induced apoptosis of gastric cancer cells in culture is not an outcome of mitochondrial integrity breakdown. The action of resveratrol on Bcl-2 proteins has been investigated in a number of cells with results supporting a cell type-dependent response. Human leukemia U937 cells readily succumbed to apoptosis after treatment with 100 $\mu\text{mol/L}$ resveratrol, whereas apoptosis was significantly inhibited when these cells were modified to over-express Bcl-2^[22]. In non-Hodgkin's lymphoma and multiple myeloma cell lines Bcl-xl expression was down-regulated by resveratrol^[23], but resveratrol had no effect on Bcl-xl, Bcl-2 nor Bax in other malignant cells^[24], and Bax levels remained unchanged in colorectal carcinoma cells after 24 h of treatment with 40 $\mu\text{mol/L}$ resveratrol^[25]. Since resveratrol caused a decrease in the ratio of Bcl-2/Bax in transplanted gastric tumors and we can only conclude that cells in culture respond differently to resveratrol from primary gastric cancer cells transplanted into nude mice.

Destabilization of mitochondria usually results in release of mitochondrial cytochrome C into cells cytosol, but we found no evidence of involvement of

mitochondria destabilizing Bcl-2 proteins in resveratrol-induced apoptosis of gastric carcinoma cells. However, we did observe presence of cytochrome C in cytosol of untreated as well as resveratrol treated cells. Cytosolic cytochrome C has also been identified within secretory granules of normal rat pancreas and anterior pituitary^[26], and because secretory granules are present in gastric carcinoma cells^[27,28], we addressed the possible role of cytosolic cytochrome C by determining cytochrome C oxidase activity. Our data revealed that resveratrol stimulates cytochrome C oxidase activity in AGS and KATO-III cells, an action that would contribute to the antioxidant potential of these cells. Since transformed cells generate low levels of reactive oxygen that activate gene transcription and stimulate their proliferation^[29,30], antioxidants suppress generation of endogenous reactive oxygen and are considered antiproliferative. We previously demonstrated that resveratrol is antiproliferative and behaves as an antioxidant in gastric adenocarcinoma cells^[3,4]. Our current finding that resveratrol stimulates cytochrome C oxidase is a feasible mechanism for its antioxidant and antiproliferative action toward these. Inhibition of proliferation and induction of apoptosis are known to be closely related events, and when activation of cytochrome C oxidase is coupled with increased caspase 3 activity, as was seen in AGS and KATO-III cells, these events might provide sufficient stimuli to inhibit cellular proliferation and induce apoptosis. Although resveratrol had no effect on either cytochrome C oxidase or caspase 3 in SNU-1 cells, apoptosis in SNU-1 cells probably results from down-regulation of survivin and removal of its protective mechanisms, as was demonstrated for human bladder cells^[31].

In summary, our results reveal that individual gastric carcinoma cell lines respond to resveratrol with engagement of individual apoptotic signals. In p53 expressing SNU-1 cells resveratrol up-regulated p53 and down-regulated survivin, whereas in KATO-III cells and in AGS cells resveratrol stimulated caspase 3 and cytochrome C oxidase activities, enabling suppression of proliferation while stimulating breakdown of nuclear proteins. These findings indicate that even within a specific disease resveratrol can engage alternate apoptotic targets thus providing further evidence that resveratrol can be considered a versatile chemopreventive agent.

Abstract

AIM: To investigate the antineoplastic potency of the novel insulin-like growth factor 1 receptor (IGF-1R) tyrosine kinase inhibitor (TKI) NVP-AEW541 in cell lines and primary cell cultures of human colorectal cancer (CRC).

METHODS: Cells of primary colorectal carcinomas were from 8 patients. Immunostaining and crystal violet staining were used for analysis of growth factor receptor protein expression and detection of cell number changes, respectively. Cytotoxicity was determined by measuring the release of the cytoplasmic enzyme lactate dehydrogenase (LDH). The proportion of apoptotic cells was determined by quantifying the percentage of sub-G1 (hypodiploid) cells. Cell cycle status reflected by the DNA content of the nuclei was detected by flow cytometry.

RESULTS: NVP-AEW541 dose-dependently inhibited the proliferation of colorectal carcinoma cell lines and primary cell cultures by inducing apoptosis and cell cycle arrest. Apoptosis was characterized by caspase-3 activation and nuclear degradation. Cell cycle was arrested at the G1/S checkpoint. The NVP-AEW541-mediated cell cycle-related signaling involved the inactivation of Akt and extracellular signal-regulated kinase (ERK) 1/2, the upregulation of the cyclin-dependent kinase inhibitors p21^{Waf1/Cip1} and p27^{Kip1}, and the downregulation of the cell cycle promoter cyclin D1. Moreover, BAX was upregulated during NVP-AEW541-induced apoptosis, whereas Bcl-2 was downregulated. Measurement of LDH release showed that the antineoplastic effect of NVP-AEW541 was not due to general cytotoxicity of the compound. However, augmented antineoplastic effects were ob-

served in combination treatments of NVP-AEW541 with either 5-FU, or the EGFR-antibody cetuximab, or the HMG-CoA-reductase inhibitor fluvastatin.

CONCLUSION: IGF-1R-TK inhibition is a promising novel approach for either mono- or combination treatment strategies of colorectal carcinoma and even for CRC chemoprevention.

INTRODUCTION

Colorectal cancer (CRC) is the third most common cancer and the fourth most frequent cause of cancer-related deaths worldwide. Long-term survival of colorectal cancer is related to the stage of disease. Once distal metastases develop the prognosis is poor^[1]. At least 40% of patients with colorectal cancer develop distal metastases and most of them die thereof^[2]. Hence, innovative approaches are urgently needed to improve the treatment of advanced colorectal cancer.

There is evidence that insulin-like growth factor 1 receptor (IGF-1R) may be a promising protein for specific and targeted therapeutic approaches^[3]. Several reports indicate that IGF-1R is overexpressed in the majority (> 90%) of colorectal carcinomas, most likely contributing to the aggressive growth characteristics of these tumors and the poor prognosis^[4,5]. IGF-1R is a tetrameric transmembrane receptor tyrosine kinase (TK) composed of two α and two β subunits. The extracellular α subunit is responsible for ligand binding, whereas the β subunit consists of a transmembrane domain and a cytoplasmic tyrosine kinase domain^[6,7]. The receptor is predominantly activated by IGF-I and II but can also be activated by insulin at a much lower affinity (500-1000 fold less). Ligand binding activates in-

trinsic tyrosine kinase activity, resulting in trans- β subunit autophosphorylation and stimulation of signaling cascades that include IRS-1/PI-3K/PKB/S6K and Grb2/Sos/Ras/MAPK pathways^[8,9].

In general, both IGFs and IGF-1R are involved in the development and progression of several cancers^[8-10]. Activation of IGF-1R by its ligands results in proliferation, survival, transformation, metastasis, and angiogenesis. Hence, abnormal or enhanced expression of IGFs and IGF-1R has been correlated with disease stage, reduced survival, metastasis development and de-differentiation of a broad variety of tumors. Obesity and diabetes are associated with an increased risk of colorectal cancer^[11]. This effect seems to be due to alterations in the metabolism of endogenous hormones, including sex steroids, insulin and also activation of the IGF/IGF-receptor system which further supports the idea of the IGF/IGF-receptor system to be a promising target for colorectal cancer treatment and chemoprevention. Several studies have demonstrated the therapeutic potential of interfering with IGF-1R-mediated signaling in cancer cells *in vitro* and *in vivo*. These approaches include the use of antagonistic IGF-1R antibodies, IGF-1R antisense oligonucleotides, or IGF-1R siRNA^[12-14]. Specific inhibition of IGF-1R TK activity appears to be another promising principle.

Recently, NVP-AEW541, an orally available low-molecular-weight pyrolo [2, 3-d] pyrimidine derivative, has been introduced as a potent and reversible inhibitor of IGF-1R tyrosine kinase activity^[15]. NVP-AEW541 has been shown to be highly selective for IGF-1R-TK, as compared to both the closely related insulin receptor (InsR) and other tyrosine or serine/threonine kinases. Antitumor activity of NVP-AEW541 has already been demonstrated in fibrosarcomas and breast cancer^[16]. IGFR-TK inhibition has not been evaluated for the treatment of colorectal cancer. Hence, in the present study we examined the antineoplastic potency of NVP-AEW541 both in human colorectal carcinoma cell lines and in primary cell cultures of human CRC, which shows that NVP-AEW541 potently inhibits colorectal cancer growth by inducing apoptosis and cell cycle arrest in human colorectal carcinoma cells.

MATERIALS AND METHODS

Cell lines and drugs

The human colorectal adenocarcinoma cell line HT29 was cultured in RPMI 1640 medium supplemented with 100 g/L fetal bovine serum, penicillin (100 kU/L), and streptomycin (100 mg/L). The human colorectal adenocarcinoma cell line HCT116 was grown in Dulbecco's minimal essential medium containing 100 g/L fetal bovine serum, penicillin (100 kU/L), and streptomycin (100 mg/L). Cells were kept in a humidified atmosphere (50 mL/L CO₂) at 37°C. Cells were incubated with culture medium containing NVP-AEW541 (Novartis, Basel, Switzerland). For combination treatment, cells were incubated simultaneously with NVP-AEW541 and one of the following drugs: 5-fluorouracil (Sigma, Deisenhofen, Germany), SN-38 (Rhone-Poulenc Rorer, Antony, France), cetuximab (Merck KgaA, Darmstadt,

Germany) or fluvastatin (Calbiochem-Novabiochem, Bad Soden, Germany). Stock solutions (in DMSO, stored at -20°C) were diluted to the final concentration in fresh media before each experiment. In all experiments, the final DMSO concentration did not exceed 1 mL/L.

Isolation and establishment of primary cell cultures from human colorectal cancers

Cells of primary colorectal carcinomas from 8 patients (5 males, 3 females, age range 74 \pm 14 years) were isolated from endoscopically taken biopsies as previously described^[17]. The human tumor material was used according to the standards set by the Ethical Committee of the Charité-Universitätsmedizin Berlin, Campus Benjamin Franklin, Berlin, Germany. Cell preparation was performed by incubation (30 min/RT) with a solution containing 0.5 g/L trypsin, 0.2 g/L EDTA and 1 g/L collagenase. The isolated human colorectal carcinoma cells were maintained in Earle's 199 medium supplemented with 200 g/L FBS, 2 mmol/L L-glutamine, 20 g/L Biotect protective medium, penicillin (100 kU/L), streptomycin (100 mg/L), 10 g/L amphotericin B, and incubated at 37°C in a humidified atmosphere (50 mL/L CO₂).

Analysis of growth factor receptor expression

For analysis of growth factor receptor protein expression, cells were immunostained as previously described^[18,19]. In brief, samples were fixed, permeabilized, and subsequently incubated with a polyclonal anti-EGFR or IGF-1R antibody (5 mg/L, Santa Cruz Biotechnology, Palo Alto, CA), or isotypic control rabbit IgG1 (DAKO, Hamburg, Germany). Cells were then incubated with a secondary FITC-labeled goat-anti rabbit IgG antibody (5 mg/L, BD Pharmingen, Heidelberg, Germany). Fluorescence was detected by flow cytometry on a FACSCalibur (Becton Dickinson, Heidelberg, Germany) and analyzed using CellQuest software.

Determination of cell number

Cell number was evaluated by crystal violet staining as previously described^[20]. In brief, cells in 96-well plates were fixed with 10 mL/L glutaraldehyde and then stained with 1 g/L crystal violet. The unbound dye was removed by washing with water. Bound crystal violet was solubilized with 2 g/L Triton X-100. Light extinction increasing linearly with the cell number was analyzed at 570 nm using an ELISA reader.

Determination of cytotoxicity

Cells were incubated with 0-10 μ mol/L NVP-AEW541 for 1, 6, 12 and 24 h. Release of the cytoplasmic enzyme lactate dehydrogenase (LDH), indicating cytotoxicity, was measured using a colorimetric kit from Roche (Roche Diagnostics, Mannheim, Germany) as described previously^[21,22]. Background release from untreated cells was subtracted. Maximum release was measured after adding 2 g/L Triton X-100 to untreated cells. For determinations, LDH assay reagent was added to sample supernatants and incubated for 30 min at room temperature in dark. Absorbance was measured at 490 nm (reference wavelength 690 nm).

Detection of apoptosis

Preparation of cell lysates and determination of caspase-3 activity were performed as previously described^[23]. The activity of caspase-3 was calculated from the cleavage of the fluorogenic substrate DEVD-AMC (Calbiochem-Novabiochem, Bad Soden, Germany). The proportion of apoptotic cells was determined by quantifying the percentage of sub-G1 (hypodiploid) cells after flow cytometric analysis of isolated propidium iodide-stained nuclei^[24].

Cell cycle analysis

Cell cycle analysis was performed by the method of Vindelov and Christensen^[25]. Cells were trypsinized, washed, and the nuclei were isolated using CycleTest PLUS DNA Reagent Kit (Becton Dickinson). DNA was stained with propidium iodide according to the manufacturer's instructions. DNA content of the nuclei was detected by flow cytometry and analyzed using CellFit software (Becton Dickinson).

Western blotting

Western blotting was performed as previously described^[23]. Blots were blocked in 50 g/L non-fat dry milk for 1 h, and then incubated at 4°C overnight with anti-phospho-Akt, Akt (both 1:1000, Cell Signaling, Beverly, MA), Bax (1:1000, Santa Cruz Biotechnology, CA), Bcl-2 (1:200, Novo Castra Laboratories, Newcastle upon Tyne, UK), COX-2 (1:200), cyclin D1 (1:100), p21^{Waf1/Cip1} (1:200), IGF-1R (1:200), phospho-ERK1/2, ERK1/2 (1:1000, Santa Cruz Biotechnology, CA), or p27^{Kip1} (1:2500, Becton Dickinson). β -actin (1:5000, Sigma) served as a loading control.

Statistical analysis

If not stated otherwise, means of four independent experiments \pm SE were shown. Individual drug treatment was compared by the unpaired, two-tailed Mann-Whitney *U*-test. $P < 0.05$ was considered statistically significant.

RESULTS

Expression of IGF-1R in colorectal carcinoma cells

Expression of IGF-1R and epidermal growth factor receptor (EGFR) was investigated in human colorectal carcinoma cells. Protein expression of IGF-1R was detected in both cell lines. In addition, expression of EGFR protein was detected in both cell lines (Figure 1A). IGF-1R protein expression of NVP-AEW541-treated colorectal cancer cells was determined by Western blotting. HT-29 cells incubated with NVP-AEW541 (0–10 μ mol/L) for 48 h did not abolish the expression of IGF-1R. By contrast even after treatment with 10 μ mol/L of NVP-AEW541, a robust expression of IGF-1R protein could still be observed (Figure 1B). IGF-1R and EGFR expression was confirmed in the investigated 8 primary colorectal cancer cultures by RT-PCR using established primers (not shown)^[18,22].

NVP-AEW541-induced growth inhibition of colorectal carcinoma cells

Cell number changes caused by IGF-1R-TK inhibition

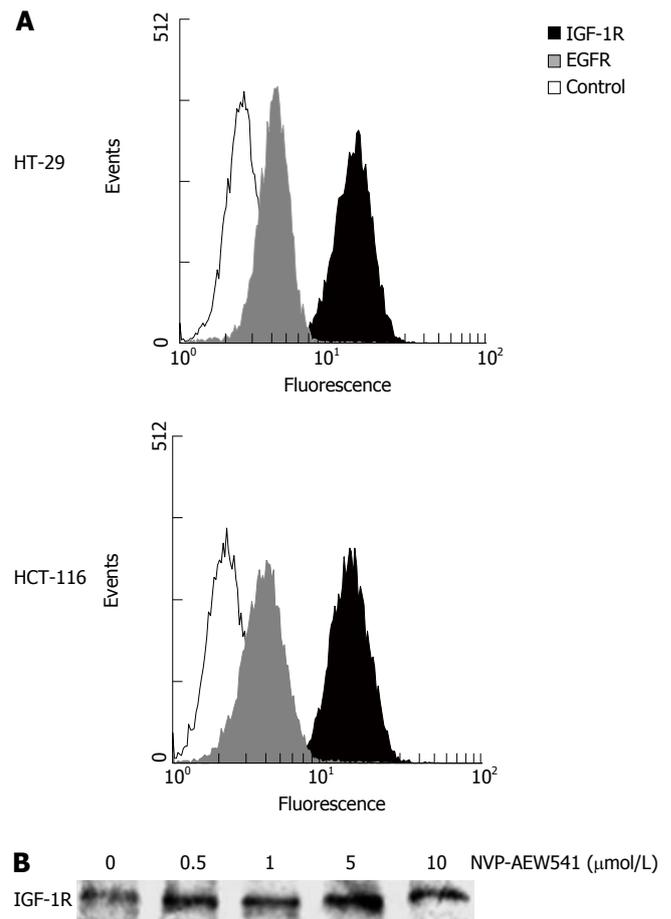

Figure 1 Flow cytometric analysis of IGF-1R and EGFR protein expression in HT-29 (A) and HCT-116 (B) cells. Cells were stained with antibodies against either IGF-1R (black areas) or EGFR (grey areas). Black lines: isotypic controls.

with NVP-AEW541 were studied by crystal violet assays. NVP-AEW541 time- and dose-dependently inhibited the growth of HT-29 and HCT-116 cells (Figure 2A and B). The IC₅₀ values of NVP-AEW541 were 1.7 ± 0.4 μ mol/L (HT-29) and 2.5 ± 0.4 μ mol/L (HCT-116), as determined after 4 d of incubation.

In line with our findings in permanent cell lines, NVP-AEW541 treatment (0–5 μ mol/L) reduced the cell number of primary cultures of human colorectal carcinomas in a dose-dependent manner. After 3 d of incubation a cell number reduction of $47.3\% \pm 2.4\%$ was detected by direct cell counting in six NVP-AEW541-sensitive primary culture preparations. Two out of the investigated 8 primary cultures displayed only a weak growth inhibition of $12\% \pm 4\%$. In treatment-sensitive primary cultures NVP-AEW541 also altered the morphology of the remaining cells, which appeared shrunken and flat. Propidium iodide-positive staining of primary culture cells revealed that NVP-AEW541 treatment led to a loss of cell membrane integrity indicating cell death or that these cells were in the process of dying, respectively (Figure 2C).

Antineoplastic potency of NVP-AEW541 in combination with cytostatics, cetuximab or the HMG-CoA reductase inhibitor fluvastatin

To test whether combination treatment of NVP-AEW541

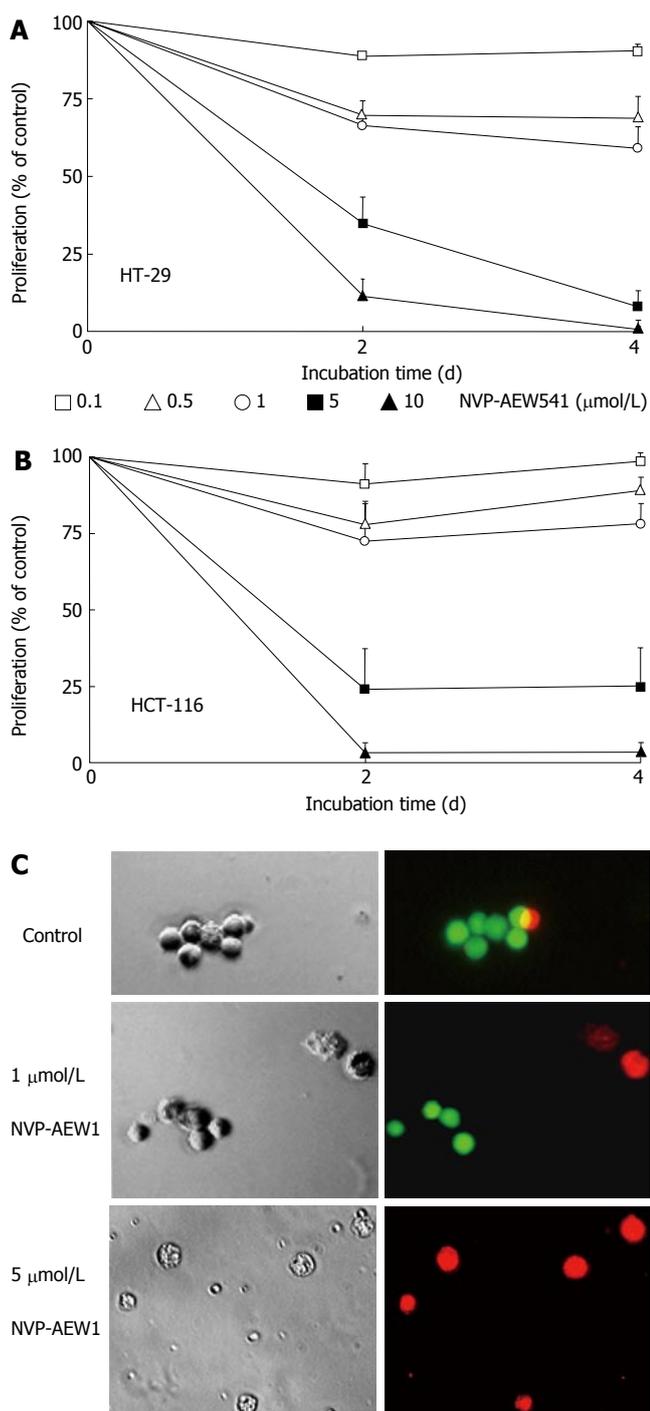

Figure 2 Effects of NVP-AEW541 on HT-29 (A) and HCT-116 (B) cell growth as well as induction of cell death and morphological changes of isolated primary colorectal cancer cells (C). After 4 d of incubation with rising concentrations of NVP-AEW541, the number of HT-29 (A) and HCT-116 (B) cells decreased by > 95%, as determined by crystal violet staining (mean ± SE, *n* = 4). In both cell lines statistical significance (*P* < 0.05) of growth inhibition by NVP-AEW541 was shown for concentrations of 0.5-10 μmol/L. After 3 d of incubation with 0-5 μmol/L NVP-AEW541, the induction of cell death and morphological changes of isolated primary colorectal cancer cells was determined by Live/Dead-fluorescence microscopy (C). Viable cells are stained green, while cells with impaired cell membrane appear red. Phase-contrast images and corresponding fluorescence micrographs of a representative preparation (out of 6 NVP-AEW541-sensitive primary cell cultures) are depicted.

with either 5-fluorouracil (5-FU), SN-38, or whether the humanized monoclonal anti-EGFR antibody cetuximab may lead to additive antiproliferative effects, HT29 and

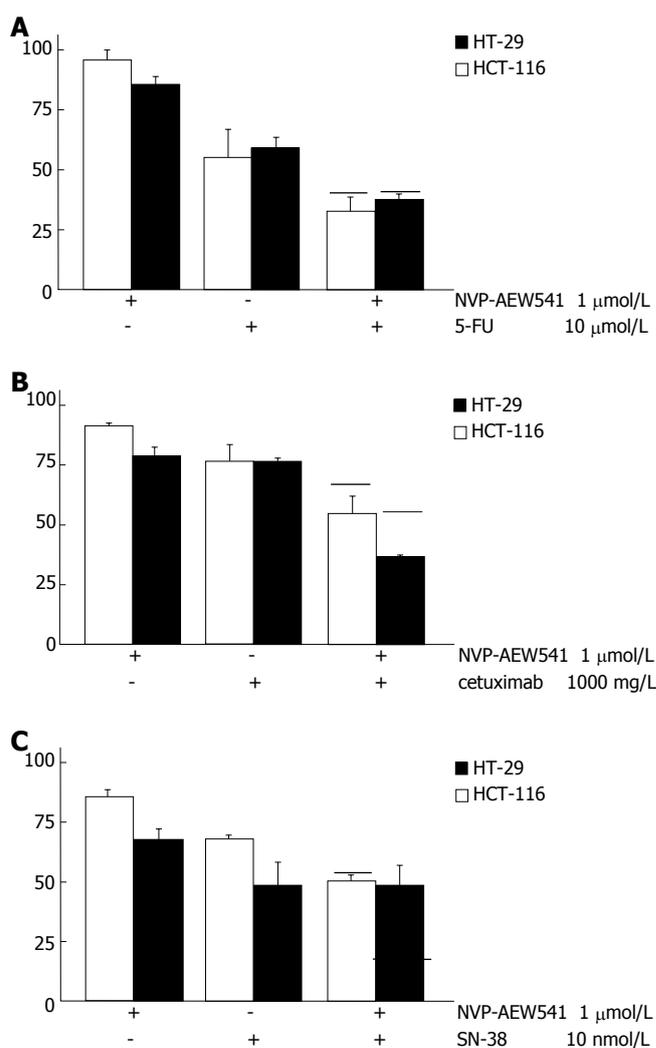

Figure 3 Augmented growth inhibition of combination treatment with NVP-AEW541 plus either 5-FU (A), or SN-38 (B) or cetuximab (C) (mean ± SE, *n* = 4-6). A: Combination treatment with sub-IC₅₀ concentrations of NVP-AEW541 plus 5-FU led to synergistic growth inhibition of colorectal cancer cells; B: Combination treatment with sub-IC₅₀ concentrations of NVP-AEW541 plus the humanized EGFR-antibody cetuximab resulted in slightly over-additive antiproliferative effects; C: Co-treatment with sub-IC₅₀ concentrations of NVP-AEW541 and SN-38 resulted in additive growth inhibition of HCT-116 cells, while no additive growth inhibition was detected in HT-29 cells. Black bars indicate the values of the calculated additive growth inhibition. Data are given as percentage of untreated controls.

HCT-116 cells were co-treated for 96 h with sub-IC₅₀ concentrations of NVP-AEW541 (1 μmol/L) plus either 5-FU (10 μmol/L), or cetuximab (1000 mg/L), or SN-38 (10 nmol/L). In both colorectal carcinoma cell models combination treatment with NVP-AEW541 plus either 5-FU (Figure 3A) or cetuximab (Figure 3B) resulted in additive or even over-additive growth inhibitory effects. When NVP-AEW541 was combined with SN-38, additive antiproliferative effects were only observed in HCT-116 cells (Figure 3C). We additionally investigated the antiproliferative potency of the HMG-CoAR inhibitor fluvastatin, either alone or in combination with NVP-AEW541 in colorectal carcinoma cells (Figure 4). Fluvastatin (0-50 μmol/L) caused a dose-dependent growth inhibition of more than 80% both in HCT-116 cells and in HT-29 cells. Combinations of sub-IC₅₀ concentrations of fluvastatin and NVP-AEW541 resulted in an additive growth inhibi-

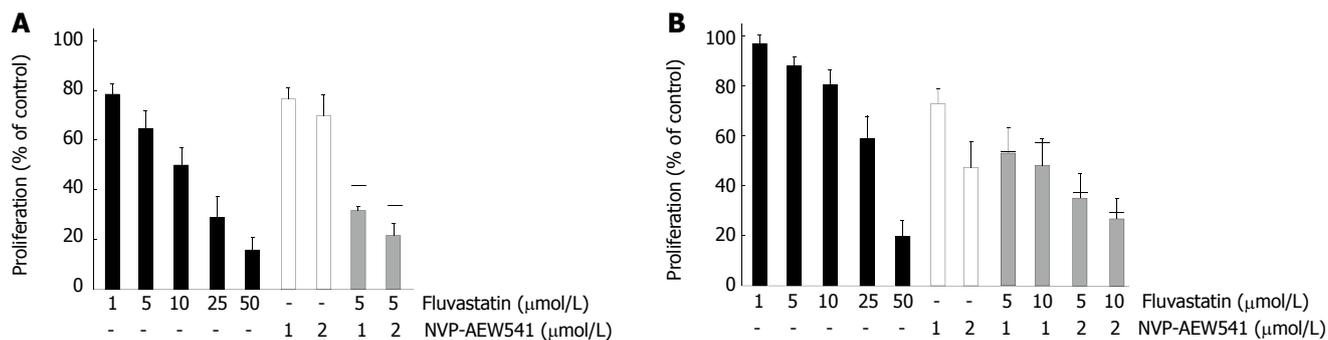

Figure 4 Additive growth inhibition by NVP-AEW541 plus fluvastatin (mean \pm SE, $n = 3-5$). Fluvastatin (1-50 $\mu\text{mol/L}$) induced a dose-dependent growth inhibition of HCT-116 (A) and HT-29 (B) cells by $> 80\%$ when applied for 3 d. Moreover, combination treatment with sub- IC_{50} concentrations of fluvastatin and NVP-AEW541 led to (over-)additive growth inhibition after 3 d of treatment. Black bars indicate the values of the calculated additive growth inhibition.

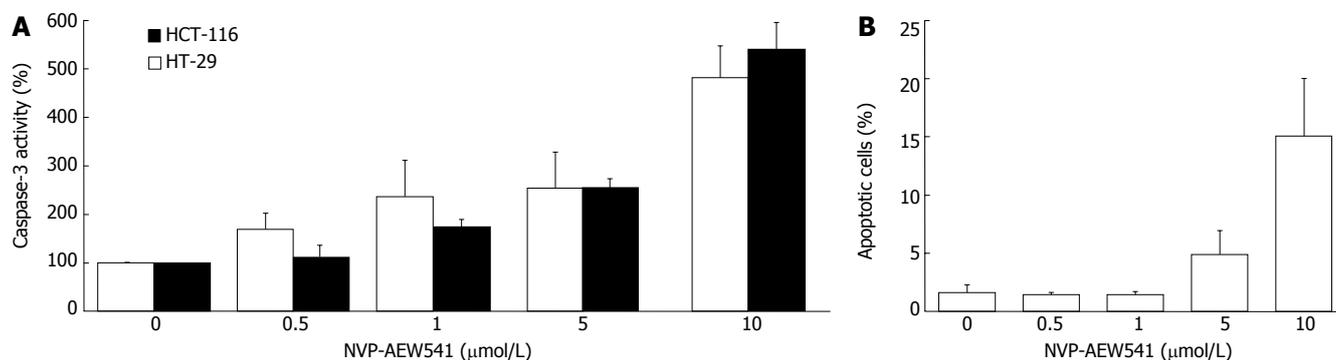

Figure 5 Apoptosis induction by NVP-AEW541 (mean \pm SE, $n = 4$). **A:** After HT-29 and HCT-116 cells were incubated with 0.5-10 $\mu\text{mol/L}$ NVP-AEW541 for 24 h, a dose-dependent induction in caspase-3 activation was observed; **B:** After 72 h of NVP-AEW541 treatment an increased proportion of apoptotic cells measured as subdiploidy was observed in HT-29 cells. $^{\ast}P < 0.05$ vs untreated controls.

tion of either colorectal cancer model.

NVP-AEW541-induced apoptosis in colorectal cancer cells

NVP-AEW541 dose-dependently induced a significant increase of caspase-3 activity after 24 h of incubation (Figure 5A). Compared to control cells, an increase of up to 500% was observed. The dose-dependent induction of apoptosis by NVP-AEW541 became also apparent by flow cytometrically monitoring nuclear degradation after 72 h of treatment (Figure 5B).

NVP-AEW541-induced cell cycle arrest in colorectal carcinoma cells.

To test whether an induction of cell cycle arrest contributed to the antiproliferative potency of NVP-AEW541 in colorectal carcinoma cells, we performed cell cycle analyses. NVP-AEW541 dose-dependently arrested HT-29 and HCT-116 cells in the G₁/G₀ phase of the cell cycle after 24 h of treatment, thereby decreasing the proportion of cells in the S and G₂/M phases (Figure 6).

Cytotoxicity of NVP-AEW541

Cytotoxicity of NVP-AEW541 was determined by measuring LDH release. HT29 and HCT-116 cells incubated with 1-10 $\mu\text{mol/L}$ NVP-AEW541 for 1, 6 or 12 h did not result in a measurable increase in LDH release, indicating that NVP-AEW541 did not directly affect cell membrane

integrity. After 24 h of incubation a slight but not significant increase in LDH-release of about 3% was observed at 10 $\mu\text{mol/L}$ NVP-AEW541, indicating that even at high concentrations NVP-AEW541 did not cause immediate necrotic/cytotoxic effects in colorectal cancer cells (data not shown).

NVP-AEW541-induced modulation of cell cycle and apoptosis-related signaling molecules

The effects of NVP-AEW541 on the phosphorylation of both ERK1/2 and its upstream regulator Akt/PKB were investigated to elucidate the signaling pathways modulated by IGF-1R-TK inhibition. NVP-AEW541 treatment dose-dependently decreased the phosphorylation of both mitogenic and antiapoptotic ERK1/2 MAPK as well as Akt/PKB (Figure 7A). Next, the expression of cell cycle-related proteins was investigated to explore the pathway downstream of NVP-AEW541-induced dephosphorylation of Akt/PKB and ERK1/2, known to be causative for cell cycle arrest. NVP-AEW541 decreased the expression of cyclin D1 but increased the expression of the CDK inhibitors p21^{Waf1/CIP1} and p27^{Kip1}. These data suggest that NVP-AEW541-induced cell cycle arrest was mediated by p21^{Waf1/CIP1} and p27^{Kip1} induction, resulting in a decrease of cyclin D1.

To survey the proapoptotic signaling pathways modulated by IGF-1R-TK inhibition with NVP-AEW541 in CRC

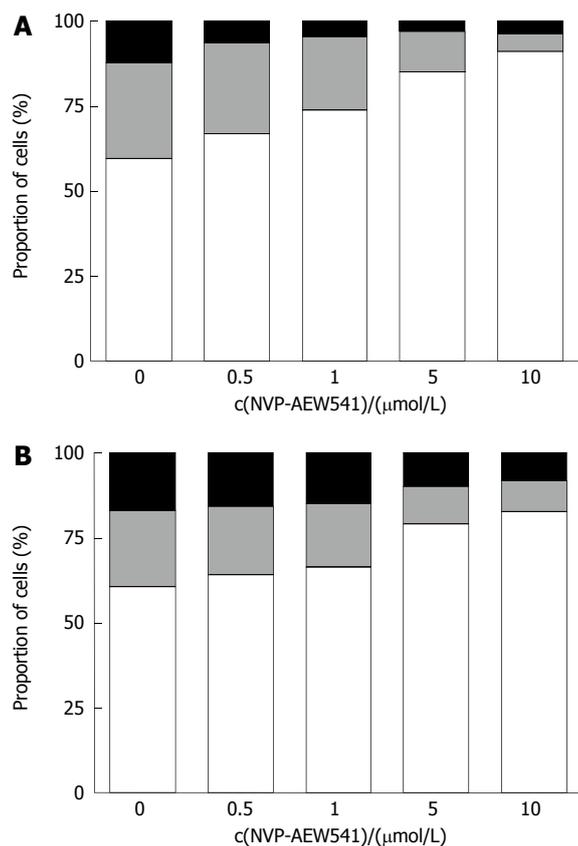

Figure 6 Effects of NVP-AEW541 on the cell cycle of colorectal carcinoma cells (means \pm SE, $n = 4$). After 24 h incubation with NVP-AEW541, a dose-dependent accumulation of HT-29 (A) and HCT-116 (B) cells was observed in the G0/G1 phase of the cell cycle (white bars). Proportion of cells in the S and G2/M phase (grey and black bars) decreased. $^{\ast}P < 0.05$ vs untreated controls.

cells, we also investigated the effects of NVP-AEW541 on the expression pattern of Bcl-2 and Bax. Treatment with NVP-AEW541 dose-dependently increased the expression of the proapoptotic Bax protein, while the expression of the antiapoptotic protein Bcl-2 slightly decreased. Finally, it was proved that NVP-AEW541 could downregulate the expression of cyclooxygenase 2 (COX-2) in colorectal cancer cells (Figure 7B).

DISCUSSION

Treatment options for advanced colorectal cancer (CRC) are unsatisfactory. Thus, there is a strong need for effective novel treatment strategies of CRC. A novel approach for CRC treatment may be the interruption of IGF/IGF-receptor signaling system, which is known to have strong stimulatory effects on cancer cell growth. The protective and mitogenic effects of the IGF/IGF-receptor system involve the constitutive activation of antiapoptotic proteins as well as cell cycle promoting signaling. A tight association between IGF-receptor signaling and regulation of cell growth and apoptosis in CRCs which commonly overexpress IGF-receptors has been described^[4,5,26].

Most fast growing cancers produce and release growth factors and thereby auto-stimulate their growth. This also holds true for CRC in which epidermal growth factor (EGF), transforming growth factor α (TGF- α), insulin-like growth factor (IGF) and vascular endothelial growth

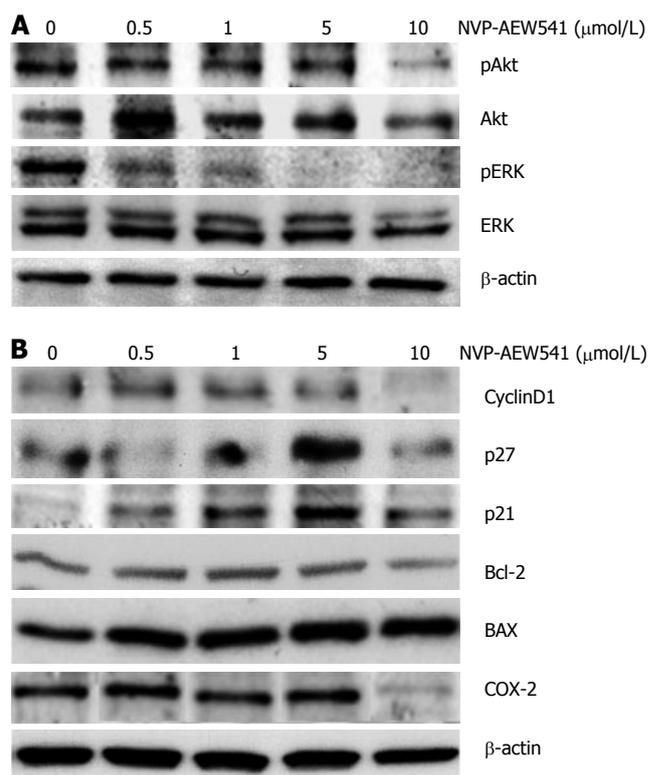

Figure 7 Effects of NVP-AEW541 on the expression and phosphorylation of apoptosis- and cell cycle-related proteins. Modulation of protein phosphorylation or protein expression by NVP-AEW541 treatment was analyzed by Western blotting. **A:** NVP-AEW541 treatment (24 h) induced a dose-dependent dephosphorylation of mitogenic ERK1/2; **B:** NVP-AEW541 dose-dependently increased the expression of the proapoptotic Bax protein, while the expression of the antiapoptotic protein Bcl-2 slightly decreased. The cell cycle promoter cyclin D1 was down-regulated by NVP-AEW541 treatment, while the cell cycle inhibitors p21^{Waf1/CIP1} and p27^{Kip1} were up-regulated. Moreover, COX-2 expression was down-regulated by NVP-AEW541. Expression of β -actin was used as a loading control.

factor (VEGF) are produced and secreted to promote CRC growth^[27]. Therefore, the antiproliferative effects of the novel IGF-1R tyrosine kinase inhibitor NVP-AEW541 were investigated under serum-containing conditions (e.g. in the presence of growth factors like EGF, IGF and TGF- α). Our study demonstrated that inhibition of IGF-1R tyrosine kinase activity by NVP-AEW541 might be suitable for novel targeted therapy of CRC. By abrogating the protective and mitogenic effects of IGF-R signaling, CRC cell growth was potently inhibited by NVP-AEW541. The antineoplastic effects of NVP-AEW541 were based on a pronounced induction of cell cycle arrest and apoptosis. Accompanying or dose-limiting cytotoxicity was not observed, underlining the specific mode of action of the drug. Our findings are in line with recent observations on IGF-R inhibition in other cancer models. Although applying other approaches for IGF-R inhibition, these studies have also shown the strong antineoplastic potency of the interruption of IGF-R signaling without dose-limiting toxicity in several other cancer models^[16,28,29].

Re-initialisation of apoptosis and induction of cell cycle arrest are valuable features for a successful anti-cancer agent. On the one hand, apoptotic cell death is not accompanied with undesired immunological reactions, which occur upon treatment with unspecific and cytotoxic

agents. On the other hand, apoptosis-sensitization and cell cycle arresting effects offer possibilities for powerful combination treatments. In this respect, we investigated combination treatments of NVP-AEW541 and clinically relevant cytostatics with different modes of action. The tested combinations of DNA strand-breaking pyrimidine analog 5-fluorouracil (5-FU) and topoisomerase-I inhibitor SN-38, except for the combination of NVP-AEW541 and SN-38 in HT29 cells, resulted in additive antiproliferative effects. The additive antineoplastic potency appeared to be independent of the mode of action of the respective cytostatic drug. Our data support the notion that NVP-AEW541 is a promising new agent for potentiation of antitumor efficacy of the established cytostatic CRC treatment.
