It has been pointed out that the antiapoptotic potency of IGF/IGFR-signaling might interfere with strategies that target other tyrosine kinases such as EGFR-TK. Hence, the antineoplastic potency of EGFR blockade may well be underestimated when examined under conditions where IGF-1R is fully functional. IGF-1R is capable of transactivating EGFR-TK and abrogating the antiproliferative effects of EGFR-antibody treatment^[30-32]. As the CRC cell models used in this study were shown to express both IGF-1R and EGFR, we studied the effects of targeting both growth factor receptors by combination treatment. Treating CRC cells with sub-IC₅₀ concentrations of both NVP-AEW541 and humanized anti-EGFR-antibody cetuximab enhanced the antiproliferative effect as compared to the effect of either agent alone. Thus, NVP-AEW541 qualifies as a promising substance for combination treatment strategies to overcome the compensatory effects of mitogenic crosstalks between IGF-1R and EGFR in CRC.

Drug resistance is one of the major problems of chemotherapy. Potential mechanisms of drug resistance include the activation of Ras/Raf/Mek/ERK signal transduction cascade and the increase of cholesterol levels in cancer cells, both being controlled by isoprenoids^[33]. The production of isoprenoids is catalyzed by 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoAR) which may therefore be a rational molecular target for innovative antineoplastic treatment of colorectal cancer. Fluvastatin is an effective inhibitor of HMG-CoAR and has already been shown to inhibit tumor cell growth^[34]. In the present study, we have demonstrated the antineoplastic effect of fluvastatin alone and in combination with NVP-AEW541 in colorectal cancer cells and the antiproliferative effect of NVP-AEW541 augmented by fluvastatin, suggesting that combining NVP-AEW541 and fluvastatin may be a promising approach for dual targeting treatment strategies in colorectal cancer disease.

The mechanisms underlying the antiproliferative action of NVP-AEW541 in colorectal cancer cells were further characterized. NVP-AEW541 induced cell cycle arrest in the G1/G0-phase in both CRC cell lines, suggesting that the drug acts at the G1/S checkpoint. A G1/S cell cycle arrest induced by inhibition of IGFR signaling has been described in other fast growing cancers^[35,36]. Moreover, we observed a definite rise in apoptotic cells after treatment with NVP-AEW541. While the induction of apoptosis

is a well-known effect occurring upon inhibition of IGFR-signaling, the underlying mechanisms have been poorly characterized^[37-39]. Our present results suggest that activation of caspase-3 is involved in NVP-AEW541-induced apoptosis of CRC cells. The proapoptotic protein BAX was upregulated during NVP-AEW541-induced apoptosis, while Bcl-2, the protective and antiapoptotic counterpart of Bax, was downregulated. Our findings suggest that involvement of mitochondrial pathways leads to NVP-AEW541-mediated apoptosis.

As activated IGF-1R induces the Ras-Raf-MEK-ERK signaling pathway with subsequent induction of cyclin D1 expression, we analyzed NVP-AEW541-induced changes of Akt/PKB, ERK1/2 activity and p21^{Waf1/CIP1}, p27^{Kip1} as well as cyclin D1 expression as previously described^[40]. In agreement with previous observations in non-colorectal tumor models^[16], we found that NVP-AEW541 could dephosphorylate IGF-1R as well as ERK1/2 MAPK and AKT/PKB of colorectal cancer cells.

IGF-1R has at least three survival signals that are able to protect cancer cells from apoptosis, namely PI-3K/AKT and MAPK/ERK signaling pathways, and a third one that results in the mitochondrial translocation of Raf 1, the so called 14-3-3 pathway^[41]. Simultaneous inactivation of two of these pathways is required to inhibit IGF-1R capacity of protecting cells from apoptotic injuries^[42]. By showing the simultaneous inactivation of AKT/PKB and ERK1/2 MAPK by NVP-AEW541, we hypothesize that blockade of these two survival pathways is directly involved in the successful inhibition of colorectal cancer cell growth by NVP-AEW541.

Defective function of cell cycle regulators is a main cause for tumor development and progression. For example, the cell cycle promoter cyclin D1 is frequently overexpressed in CRC. Successful therapeutic strategies have to balance or bypass the impaired signaling. In the present study, NVP-AEW541 treatment raised the expression of the cell cycle-inhibiting molecules p21^{Waf1/CIP1} and p27^{Kip1}, while it decreased the expression of cyclin D1. Finally, the expression of COX-2 which is known to be upregulated during colorectal carcinogenesis and plays an important role in colorectal cancer growth, was suppressed by IGFR-TK inhibition as previously described^[43]. Thus, NVP-AEW541-induced COX-2 suppression may well contribute to its antineoplastic potency in colorectal cancer. Since both COX-2 and IGFR are up-regulated during colorectal carcinogenesis, NVP-AEW541 appears to be a promising chemopreventive agent in patients at risk for CRC.

Primary cell cultures of human colorectal cancers were established as a tool to design a rational individual medical treatment of an individual patient. The primary goal was to study NVP-AEW541's antineoplastic potency in a bench to bedside approach, as permanent cell lines may represent well-suited but nevertheless non-representative models of colorectal cancers. Moreover, chemosensitivity testing of primary cultures was performed to establish a new method for predicting the response of an individual patient to a certain drug. Attempts to predict individual responses have already been undertaken for breast cancer and colorectal cancer, respectively^[44,45]. Such an approach

may pave the way to an individualized medical treatment of cancer patients. The importance of predictive testing is further supported by our finding that two out of the tested eight primary cell cultures showed only a weak response to NVP-AEW541 treatment. Nevertheless, NVP-AEW541 is a promising compound for future colorectal cancer treatment, as 75% of the investigated primary colorectal cancers could be effectively treated with the drug.

In conclusion, the IGFR-TK inhibitor NVP-AEW541 potently inhibits the growth of human colorectal cancer cells by inducing both cell cycle arrest and apoptosis without eliciting unspecific cytotoxicity. Furthermore, the compound is well-suited for combination treatment approaches. Thus, inhibition of IGFR-signaling by NVP-AEW541 is a promising targeted anticancer strategy for colorectal carcinoma and should be tested in future clinical trials. Moreover, investigations should be pursued to modulate the IGF/IGFR system as a possible means of chemoprevention of colorectal cancer in patients at risk.

ACKNOWLEDGMENTS

We are indebted to Antje Krahn and Benjamin Becker for expert technical assistance. We thank Novartis for providing us with NVP-AEW541, Dr. Faiss and the nurses of the Central Endoscopy Unit of the Charité-Universitätsmedizin Berlin, Campus Benjamin Franklin for their excellent support of the study. Moreover, we would like to thank the Institute of Physiology, Charité-Universitätsmedizin Berlin, Campus Benjamin Franklin, for its laboratory facilities.

Abstract

AIM: To study whether hemoglobin could amplify colon cancer cell proliferation *via* reactive oxygen species (ROS) production.

METHODS: Colon cancer cell line HT-29 was grown in the conventional method using RPMI1640 media. The viability of the cells was measured using the colorimetric MTT [3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide] assay after adding hemoglobin. We determined reactive oxygen species levels to be indicators of oxidative stress in HT 29 cell lines with and without hemoglobin and/or 5-fluorouracil (5-FU), 5'-deoxy-5-fluorouridine (5-DFUR) using fluorometric dichlorofluorescein diacetate (DCFH-DA) assay.

RESULTS: Cellular proliferation was increased with hemoglobin in a concentration-dependent manner. A significant increment on ROS levels was found in HT 29 cells following hemoglobin incubation. The cytotoxic effects of 5-FU and 5-DFUR were significantly blunted by administration of hemoglobin. There was a slight increase of peroxiredoxin 1, superoxide dismutase 1 concentration according to different hemoglobin concentrations.

CONCLUSION: Hemoglobin has a cellular proliferative effect on HT-29 colon cancer cell line by production of ROS. Also, hemoglobin abates cytotoxic effects of chemotherapeutic agents such as 5-FU and 5-DFUR.

INTRODUCTION

Colon cancer is an important public health issue^[1]. There are nearly one million cases of colon cancer diagnosed worldwide each year. The increasing trend of this cancer is prominent in Asian countries, including Korea^[2,3]. Until the present day, scientists have made an intensive effort to find a provocative factor of this major cancer. Many epidemiologic studies indicate that a western style diet is associated with a high incidence of colon cancer^[4,6]. An especially high protein consumption as in the western-style diet is regarded as a major factor in inducing colon cancer. There is consistent evidence that high meat consumption, in particular red meat, confers an increased risk of this cancer. However, recent large prospective epidemiologic studies that hypothesized a strong relationship between red meat consumption and colorectal cancer development have revealed inconsistent results.

Hemoglobin is a complex of heme and globin, which contribute an important role of oxygen delivery processes to individual tissues^[7]. Intake of these particular molecules contributes nutritional buildup as an iron and protein supplementation. Hemoglobin inside food is already in an oxidized form, and so cannot be used as an oxygen delivery porter. Recently, interesting results about the carcinogenic effects of dietary haemin were reported, documenting that dietary haemin increases the number of aberrant crypt foci in rat colon mucosa^[8-10]. It is important to understand how reactive oxygen species (ROS) are formed in the gut lumen and which biological potency they may have, since intracellular reactions with active oxygen can result in the initiation and progression of carcinogenesis by induction of gene mutations, chromosomal damage and cytotoxic effects^[11-13]. Furthermore, active oxygen regulates expression of genes active during cell differentiation and growth and therefore, probably plays an important role in the promotion phase of tumor generation. In the colon, iron is expected to increase the production of ROS from peroxides via the Fenton reaction, which may be the cause of cellular toxicity and even pro-mutagenic lesions^[14].

The aim of this study was to investigate whether hemoglobin could be classified as a proliferative agent for colon cancer cells by causing reactive oxygen species

release. For this purpose, we have studied the cellular viability of differentiated colon cell line HT29 after administration of hemoglobin at different concentrations. ROS production was investigated in each step. Additionally, we examined the protective effect of hemoglobin on the cytotoxicity of chemotherapeutic agents.

MATERIALS AND METHODS

Reagents and antibodies

Human hemoglobin, 5-fluorouracil (5-FU), 5'-deoxy-5-fluorouridine (5-DFUR) were obtained from Sigma (St. Louis, MO, USA). 2', 7'-Dichlorofluorescein diacetate (DCFH-DA) was purchased from Calbiochem (Meudon, France). Antibodies to human peroxiredoxin 1 and superoxide dismutase 1 were purchased from Labfrontier (Seoul, Korea).

Cell culture

The human colon cancer cell line HT-29 and Lovo was established from Korean Cell Line Bank. To compare the effect on normal fibroblast, we used CCD-33Co normal colonic fibroblast cell line purchased from American Type Culture Collection (Catalog No. CRL-1539). Cells were maintained in stocks of liquid nitrogen, thawed and grown in tissue culture flasks with RPMI 1640 (Gibco BRL, NY, USA) supplemented with 100 mL/L fetal bovine serum and 10 g/L penicillin/streptomycin at 37°C in a 50 mL/L CO₂ incubator. The cultured cells were trypsinized with fresh 2.5 g/L trypsin solution, trypsin was removed and the culture let sit at 37°C until the cells detached (about 5 min). Fresh media was added, aspirated and dispensed into new flasks. Subculture was done every 4-6 d.

MTT assay

A freshly prepared cell suspension was serially diluted in RPMI 1640 containing 100 mL/L FBS to give a cell density ranging 10⁹/L to 10¹¹/L counted by hemocytometer. After 24 h, the culture medium was replaced with a fresh medium containing hemoglobin, 5-FU, 5-DFUR or combination thereof. Six duplicate wells were set up in each sample. The cells not treated with the drugs served as control cells. After incubation time passed, 20 mL dimethylthiazol diphenyl tetrazolium bromide (MTT, 3 g/L) was added to each well and incubated at 37°C for 3 h. After removal of the medium, MTT stabilization solution (DMSO: ethanol = 1:1) was added, then shaken for 10 min until all crystal was dissolved. Then, optical density (OD) was detected in a microplate reader at 550 nm wavelength using an ELISA reader (EMAX ED927, Molecular Devices Inc., USA). The negative control well had no cells and was used as zero point of absorbance. Each assay was performed in triplicate. The following formula was used: cell proliferation inhibited (%) = $[1 - (A \text{ of the experimental samples} / A \text{ of the control})] \times 100\%$. Cell growth curve was completed using time as the abscissa and a value (mean \pm SD) as the ordinate.

Measurement of ROS

Human hemoglobin was dissolved in RPMI 1640. HT 29

cells were incubated with 5-FU or 5'-fluoro-2'-deoxyuridine (5-FDUR) at 37°C in suspension culture at different concentrations 1 to 2 μ g or for different incubation periods. These samples were processed for analysis of ROS by usual flowcytometric techniques. Briefly, cells were harvested, washed twice with PBS and resuspended in serum-free medium. They were incubated with 50 μ mol/L 2',7'-dichlorofluorescein diacetate (Calbiochem, Meudon, France) for 2 h at 37°C and washed with ice-cold HEPES/saline and placed on ice. Fluorescence was measured by flowcytometry (Becton Dickinson, San Jose, USA). As a positive control, cells were separately treated with H₂O₂ and processed for ROS detection.

Immunoblot analysis

Harvested cell line extracts were homogenized with ice-cold lysis buffer (20 mmol/L HEPES pH 7.2, 150 mmol/L sodium chloride, 1% Triton X-100, 1 mmol/L EDTA, 1 mmol/L EGTA, 10 mg/L leupeptin, 10 mg/L aprotinin, 0.1 mmol/L DTT and 1 mmol/L phenylmethylsulfonyl fluoride). For the immunoblot analysis, extracted proteins of 10 μ g were denatured by heating at 95°C for 10 min with Laemmli cooking buffer and separated on 120 g/L SDS polyacrylamide gel electrophoresis. The resolved protein bands were transferred onto a PVDF membrane (Amersham Biosciences, UK) and blocked non-specific binding site by immersing the membrane in 30 mL/L skim milk, 120 g/L Tween 20 in TBS for 2 h. The membrane was incubated with 1:2000 diluted primary antibody for peroxiredoxin I (Difco, USA) and superoxide dismutase 1 for 1 h at room temperature on an orbital shaker. The blotted membrane was then incubated using secondary antibody (anti-rabbit IgG, 1:3000) for 1 h at room temperature on an orbital shaker. Detection was performed with the ECL system.

Statistical analysis

Data shown in figures represent mean \pm SEM. Unless otherwise stated, these means were calculated from the means of triplicate replicates obtained in at least three independent experiments. Statistical evaluation was performed with the Prism program version 6.0. Depending on sample size and type of experiment, repeated measures of ANOVA or one-way ANOVAs were used to determine the significance of the experimental variables.

RESULTS

Proliferation effect of hemoglobin

Cell growth was determined by MTT assay. HT-29 cell line, the main cell of colon cancer, and Lovo cell line and CCL-33Co cell line were objected to confirm the difference in proliferation dependant on the types of cells. It has been verified, as demonstrated in Figure 1, when injected with hemoglobin, proliferation in all three types of cell lines was much greater. We saw the time effects in HT-29 cell line. These effects began to display after 30 min of treatment and were most obvious after approximately 24 h (Figure 1A). After various adjustments of the concentration of the hemoglobin, the results showed that the higher

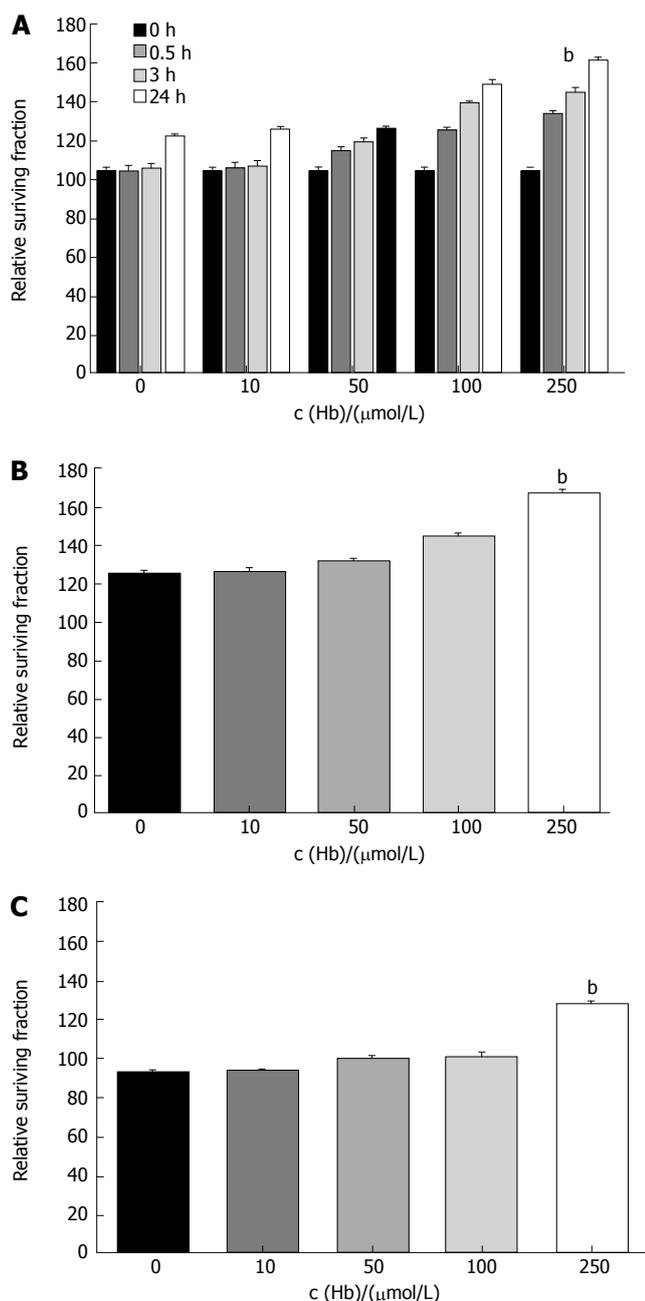

Figure 1 Time-course and dose-response effects of hemoglobin on apoptosis of colorectal cancer cell lines. **A:** HT-29 cell line. ^bP = 0.000 vs 0 μmol/L; **B:** Lovo cell line. ^bP = 0.000 vs 0 μmol/L; **C:** CCL-33Co cell line. ^bP = 0.000 vs 0 μmol/L.

the concentration, the greater the proliferation (Figure 1).

ROS production by hemoglobin

Flowcytometry using DEPC was conducted to measure the total quantity of ROS, which occurs during the administration of hemoglobin. As expected, the amount of ROS production showed a significant increase dependent on the concentration of hemoglobin (Figure 2), and ROS production increased subject to the amount of time following increment.

The restraint of proliferation by anti-cancer medicines

Two drugs (5-FU, an anti-cancer drug most commonly used in treatment of colon cancer, and 5-DFUR, the

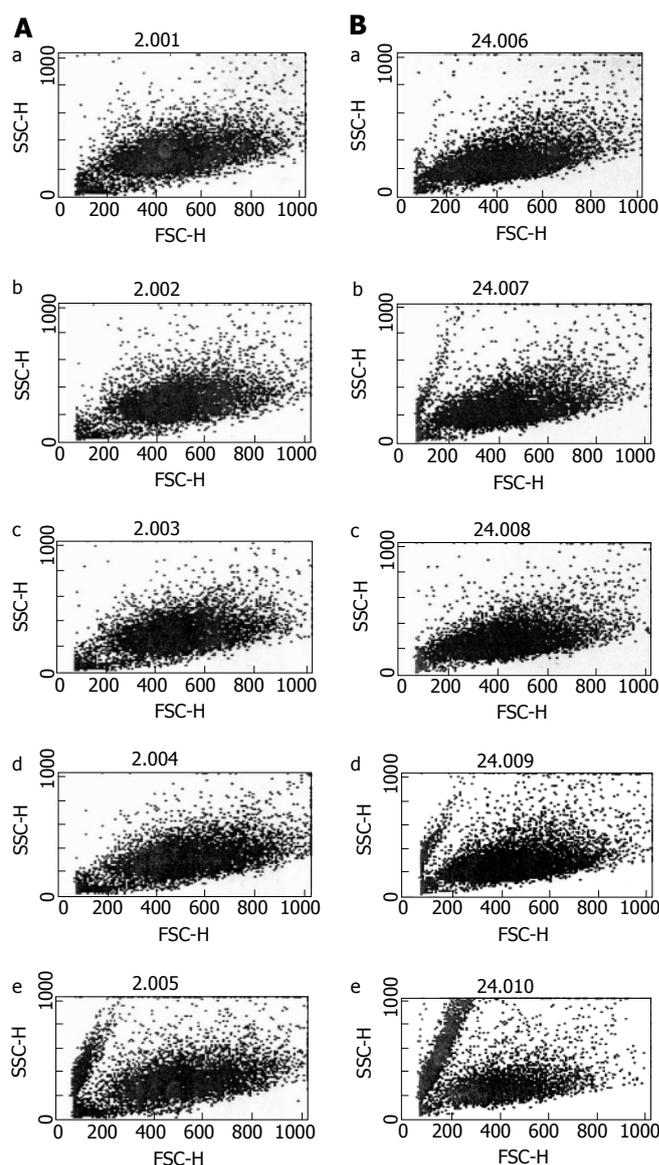

Figure 2 Flowcytometry of reactive oxygen species on HT-29 cells. **A:** After 3 h of hemoglobin administration; **B:** After 24 h of hemoglobin administration. a: Hb 0 μmol/L; b: Hb 10 μmol/L; c: Hb 50 μmol/L; d: Hb 100 μmol/L; e: Hb 250 μmol/L.

activating form of capecitabine which is presently used in metastatic colon cancer) were added to verify the constraint of proliferation effects. Twenty-four hours after drug application at varying concentrations, it was found that the higher the density, the greater was the constraint of proliferation in all three cell types (Figures 3 and 4). Also by flowcytometry, the anti-cancer medication decreases ROS production. Hence, it is believed that administration of anti-cancer drugs is effective in reducing ROS production (Figures 3D and 4D).

Influence of hemoglobin on anti-cancer agents

Twenty-four hours after simultaneously adding 5-FU, 5-DFUR and hemoglobin at various concentrations into three cell lines, results showed evidence of a weakening in the decreased proliferation as compared to using only anti-cancer drugs. Results were proportionate to the given densities of hemoglobin (Figures 5 and 6).

Expression of superoxide dismutase and peroxiredoxin

The occurrence of superoxide dismutase, the most important rate-limiting enzyme in ROS production *in vivo*, and peroxiredoxin, which is a producer of hydrogen peroxide (prominent type of ROS in cancer cells), was compared by the amount of hemoglobin added. Twenty four hours following treatment, the rate of occurrence of the two types of enzymes increased proportionately to the density of hemoglobin. However, the variation was only slight and less than expected (Figures 7 and 8).

DISCUSSION

High intake of meat is believed to be one of the main factors of high incidence of colon cancer among Western countries as compared with Asian countries. There are many reports dealing with which components and nutrients inside meat are considered most risky. There are plenty of reports about nutrients such as iron^[15], folate^[16], cholesterol^[17], calcium^[18], bile salt^[19], heterocyclic amines^[20] and vitamin D^[21] *etc.* related with various gastrointestinal malignancies. It is generally known that red meat has more

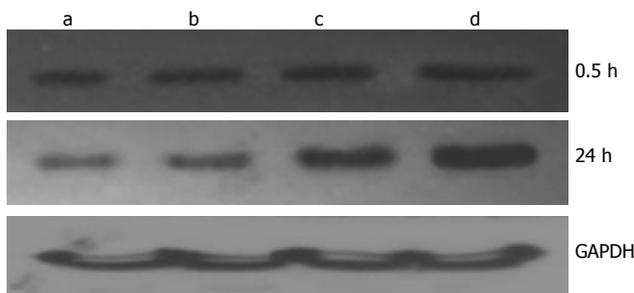

Figure 7 Change of Prx1 expression after administration of hemoglobin. a: Hb 0 $\mu\text{mol/L}$; b: Hb 10 $\mu\text{mol/L}$; c: Hb 100 $\mu\text{mol/L}$; d: Hb 250 $\mu\text{mol/L}$.

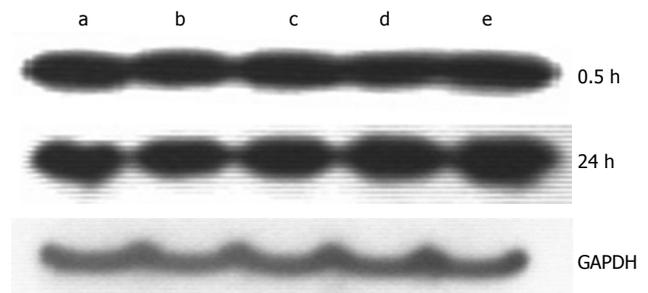

Figure 8 Change of SOD1 expression after administration of hemoglobin. a: Hb 0 $\mu\text{mol/L}$; b: Hb 10 $\mu\text{mol/L}$; c: Hb 50 $\mu\text{mol/L}$; d: Hb 100 $\mu\text{mol/L}$; e: Hb 250 $\mu\text{mol/L}$.

carcinogenic content than white meat. Due to the fact that some cancer patients believe red meat induces cancerous growths or encourages the recurrence thereof, they consume little to no red meats. Occasionally, malnutrition occurs as a result of extreme or reckless diet changes^[22]. However, conclusions about carcinogenic effects of red meat are not confirmed to date, especially the medical basis is insufficient. Therefore, *in vitro* research is required to effectively prove these carcinogenic effects.

The term 'red meat' refers mainly to mammal flesh such as beef, pork and lamb, *etc.* as with most edible meats, whereas the term 'white meat' refers mainly to fowl. The ruddy coloring of red meat reflects the density of myoglobin that is found in muscle tissue and some roles of hemoglobin are also included. Hemoglobin is a tetramer consisting of two alpha chains and two beta chains. Since each unit can combine with oxygen wherein iron is present, 1 hemoglobin can carry 4 oxygen molecules. The main function of hemoglobin is to carry oxygen, in addition to the storage of iron and the place providing globin. This type of function occurs only *in vivo* and exists within the bloodstream. When hemoglobin is inducted into the digestive tract, it is dissolved by digestive enzymes as are other proteins and absorbed as a protein and other nutrients. There are a few reports on the carcinogenic effects of heme or hemoglobin among the components of meat^[10, 23-27]. Sesink *et al.*^[28] stated that dietary heme effects on colon epithelial hyperproliferation are hindered by calcium. They administered pure heme in a meal of an F344 female rat. They announced that the resulting effect of a low calcium and heme containing diet increases colon wall aberrant crypt foci (ACF). Into an experimental model by Pierre *et al.*^[10] heme and hemoglobin were injected and the size and number of ACF were compared and measured with fecal thiobarbituric acid reactive substances (TBAR). In the case of hemoglobin, the number of ACF and the amount of TBAR increased. From these results, hemoglobin was announced as a potent promoter of colorectal carcinogenesis. Gleit *et al.*^[14] observed the increase of DNA strand break after the iron overload injected Fe-NTA (ferric-nitrilotriacetate) which was synthesized from the ferric nitrate and nitrilotriacetic acid into HT29 clone 19A cell line. Also, it was reported that when peroxide was added, more DNA strand breaks occurred with increasing peroxide concentrations. With these findings, iron content within a hemoglobin containing diet increased the DNA genotoxicity. We proceeded with this study under the

assumption that hemoglobin components of dietary red meat affects cell proliferation of the cancerous and normal colonic cells via production of ROS. As expected, the results of this study confirmed the leading effect of hemoglobin. By the amount of hemoglobin dealt with, not only the cellular proliferation increased but also the amount of ROS production increased supporting predictions thereof. The proliferation effect of hemoglobin on normal colonic fibroblast was noted similarly in cancer cell lines. It is assumed that it presents the effect that exposure of hemoglobin leads to normal colon proliferation as well and produces ROS, which forms much more DNA breaks and also helps in becoming susceptible to other carcinogenic stimuli. Enzymes related with ROS production such as peroxiredoxin 1^[29] and superoxide dismutase 1^[30] also increased after hemoglobin application but the effect was minimal compared with expectations. These results suggested that production of enzymes was not a major factor in the process of colon cancer cell proliferation via ROS production.

5-FU and 5-DFUR are major chemotherapeutic agents in the treatment of colorectal cancer^[31,32]. We used these drugs to identify adverse effects of hemoglobin on chemotherapy. Cellular proliferation was decreased 12 h after adding the 5-FU or 5-DFUR and ROS production was decreased as expected. The results with 5-FU was similar with that of 5-DFUR. These reactions were affected by administration of hemoglobin in a concentration-dependent manner in all three cell lines. ROS production was also decreased with hemoglobin. It is interpreted that hemoglobin administration restricted the cytotoxic effect of anti-cancer drugs in colon cancer cells and normal colonic fibroblasts.

In conclusion, hemoglobin inside red meat has a promoting effect on cellular proliferation in cancer cells and in normal colonic fibroblast cells by release of ROS. Furthermore, this phenomenon reduces the cytotoxicity of anticancer drugs, such as 5-FU and 5-DFUR, to colon cancer cells, which could be an adverse factor during chemotherapy in a clinical setting.

Abstract

AIM: To verify the expression and methylation status of the *MAGE-A1* and *MAGE-A3* genes in colorectal cancer tissues and cancer cell lines.

METHODS: We evaluated promoter demethylation status of the *MAGE-A1* and *MAGE-A3* genes by RT-PCR analysis and methylation-specific PCR (MS-PCR), as well as sequencing analysis, after sodium bisulfite modification in 32 colorectal cancer cell lines and 87 cancer tissues.

RESULTS: Of the 32 cell lines, *MAGE-A1* and *MAGE-A3* expressions were observed in 59% and 66%, respectively. Subsequent to sodium bisulfite modification and MS-PCR analysis, the promoter hypomethylation of *MAGE-A1* and *MAGE-A3* was confirmed in both at 81% each. Promoter hypomethylation of *MAGE-A1* and *MAGE-A3* in colorectal cancer tissues was observed in 43% and 77%, respectively. Hypomethylation of *MAGE-A1* and *MAGE-A3* genes in corresponding normal tissues were observed in 2% and 6%, respectively.

CONCLUSION: The promoter hypomethylation of *MAGE* genes up-regulates its expression in colorectal carcinomas as well as in gastric cancers and might play a significant role in the development and progression of human colorectal carcinomas.

INTRODUCTION

Human tumors often display changes in DNA methylation, which include both genome-wide hypomethylation and site-specific hypermethylation. Global hypomethylation and CpG island hypermethylation have been recognized as important contributors to the development of carcinogenesis in humans. Hypermethylation of promoter CpG islands is the signature of transcriptional silencing of their downstream genes, including *RB*, *p16*, *VHL*, *BRCA1*, *E-cadherin*, *APC*, *bMLH1*, *FHIT*, *COX2*, and *CDX1* in various human cancers; and is as effective as inactivation by gene mutation or deletion^[1-6]. Global DNA hypomethylation has been implicated in the activation of oncogenes such as *c-myc*, *k-ras*, and it may also contribute to tumor progression by the induction of genome instability^[7,8].

The *MAGE* family of genes belongs to a group of germ line-specific genes that are activated in different types of tumors. This family of genes was reported to direct the expression of a tumor-specific antigen that was recognized in a melanoma cell by cytolytic T lymphocytes^[9]. The *MAGE-A1* gene has a CpG-rich promoter, which, unlike classical CpG-rich promoters, is methylated in all normal somatic tissues, except for the placenta and testis. In contrast, the promoter region of *MAGE-A1* is completely unmethylated in testicular germ cells and in tumor cells that express the gene^[10]. Demethylation, and therefore, activation of *MAGE-A1* in tumors appears to be a consequence of the genome-wide demethylation process, since the expression of this gene in tumor cells correlates with a decreased level of overall DNA methylation^[11]. A correlation between *MAGE-A1* and *MAGE-A3* expression and genome-wide hypomethylation has been observed in some types of carcinomas^[12,13]. The human *MAGE-A1* and *MAGE-A3* genes, which are located on chromosome X, are expressed in 29% and 66%, respectively, of human gastric cancer cells due to the hypomethylation of the promoter region^[12]. However, it is unknown if this relationship is present in colorectal carcinomas.

In this study, we investigated the promoter methylation

status of *MAGE-A1* and *MAGE-A3* genes. A total of 32 colorectal cancer cell lines were tested for hypomethylation of the *MAGE-A1* and *MAGE-A3* genes promoter. In addition, we screened the methylation status of the *MAGE-A1* and *MAGE-A3* genes promoter in 87 paired colorectal cancers and normal mucosal tissue samples.

MATERIALS AND METHODS

Cell cultures

A total of 32 colorectal cancer cell lines (Table 1) and 2 gastric cancer cell lines (SNU-1 and SNU-5) were obtained from either the Korean Cell Line Bank (KCLB; Seoul, Korea) or the American Type Culture Collection (ATCC; Manassas, VA, USA). Sixteen SNU-colorectal cancer cell lines were established and were reported upon previously by this laboratory^[14,15]. SNU-1 and SNU-5 gastric carcinoma cell lines were used as methylation positive (SNU-1) and negative (SNU-5) controls for *MAGE* gene expression^[12]. All the cell lines were maintained in RPMI1640, which was supplemented with 10% FBS, 100 kU/L penicillin, and 0.1 g/L streptomycin. The cultures were maintained in humidified incubators at 37°C in a 5% CO₂ and 95% ambient air atmosphere.

Nucleic acid isolation and cDNA synthesis from the cell lines

Genomic DNA and total RNA were isolated from washed-cell pellets. Total genomic DNA was extracted in accordance with the standard SDS-proteinase K procedure; and total cellular RNA was extracted based on the manufacturer's instructions (Intron Biotechnology; Seoul, Korea). For cDNA synthesis, 2 µg of total RNA was reverse transcribed with a random hexamer, dNTPs, and 1 µL (200 U) of SuperscriptTM II reverse transcriptase (Life Technologies; Gaithersburg, MD, USA) in a final volume of 20 µL for 1 h and 15 min at 42°C after a 10-min denaturation at 70°C. Eighty microliters of distilled water were added subsequent to the reverse-transcription reaction.

Expression of *MAGE-A1* and *MAGE-A3* genes

For mRNA expression analysis, the cDNA was amplified in 25 µL of a PCR reaction mix with 1 µL of the reverse-transcription reaction, the primers and 0.5 U of Taq DNA polymerase. The PCR conditions consisted of 10 min at 94°C for the initial denaturation, followed by 35 cycles of 94°C for 30 s, 54°C for 60 s, and 72°C for 60 s, and a final elongation of 7 min at 72°C. The primer sequences are as follows. *MAGE-A1* cDNA was amplified by PCR with MG1 RT primers; MG1 RT sense, 5'-TGTGG GCAGGAGCTGGGCAA-3', MG1 RT antisense, 5'-GCCGAAGGAACCTGACCCAG-3'. For the *MAGE-A3* cDNA, the MG3 RT primers were used; MG3 RT sense, 5'-AAGCCGGCCAGGCTCGGT-3', MG3 RT antisense, 5'-GCTGGCAATGGAGACCCAC-3'. PCR amplification was performed in a programmable thermal cycler (PCR System 9700, Applied Biosystems; Foster City, CA, USA). Primers for β -actin were used to confirm RNA integrity. Both *MAGE-A1* and *MAGE-A3* and β -actin RT-PCR reactions used the same cDNA synthesis. The

amplified DNA fragments were fractionated in 2% agarose gel and stained with ethidium bromide.

Tissue sample collection and DNA extraction

A total of 87 paired tumor and normal mucosal tissue samples were obtained from 87 patients, who had primary colorectal adenocarcinoma. The normal mucosal tissue specimens were collected from each patient 10 cm or more away from the tumor areas. Approximately 2 g of the surgically removed tissues were frozen immediately and then stored in liquid nitrogen. The remaining sections of the samples were fixed with formalin and used for further histological examination in order to confirm the diagnosis postoperatively. Genomic DNA was isolated from the frozen-tissue biopsies with the standard SDS-proteinase K procedure.

Methylation specific PCR

With respect to the MS-PCR, the sodium bisulfite modification of genomic DNA was performed as reported previously^[16]. A total of 2 µg of genomic DNA obtained from colorectal cancer cell lines, was denatured with NaOH and hydroquinone. Then, 3 mmol/L sodium bisulfite was added and the mixture was incubated at 55°C for 16 h. Following the bisulfite modification, the DNA was purified with a Wizard DNA purification system (Promega; Madison, WI, USA), ethanol precipitated, dried, and resuspended in 100 µL distilled water. The PCR was performed using the PCR primers that were described previously^[12]. The amplified DNA fragments were fractionated in 2% agarose gel that was stained with ethidium bromide and visualized under UV light.

5-aza-2'-deoxycytidine treatment and RT-PCR

For 5-aza-2'-deoxycytidine treatment, the cells were seeded in two 2 × 10⁵ cells/75 cm² culture flasks on d 0. The cells were treated with and without 1-5 µmol/L of 5-aza-2'-deoxycytidine (Sigma Chemical Co.) for 24 h on d 2 and 5, and the medium was changed 24 h after addition of 5-aza-2'-deoxycytidine. The cells were harvested on d 8 for the analysis of the *MAGEs* expression. Subsequently, the RNA was prepared, and RT-PCR was performed to detect *MAGE-A1* and *MAGE-A3* expression with the *MAGE-A1* and *MAGE-A3* RT-PCR primers as described above.

RESULTS

Expression of *MAGE-A1* and *MAGE-A3* in colorectal cancer cell lines

Expression of *MAGE-A1* and *MAGE-A3* mRNA in 32 colorectal cancer cell lines was analyzed by RT-PCR, and *MAGE-A1* and *MAGE-A3* expressions were observed in 19 (59%) and 21 (66%) of the cell lines, respectively (Figure 1 and Table 1). PCR for β -actin confirmed the integrity of the RNA.

Clinico-pathological features

Of the 87 colorectal carcinomas, 57 (66%) were obtained from the proximal colon (cecum to splenic flexure), and 30 (34%) from the distal colorectum (splenic flexure to

rectum). Randomly selected patients aged 16-81 years, including 55 males and 32 females. Of the 32 colorectal cancer cell lines, 7 originated from the proximal colon and 8 from the distal colorectum. The origin of the remaining 17 colorectal cancer cell lines was unknown.

Analysis of *MAGE-A1* and *MAGE-A3* methylation by MS-PCR

By using primers for unmethylated *MAGE-A1* DNA amplification on bisulfite modified DNA, amplified DNA fragments were observed in 26 (81%) cell lines (SNU-61, SNU-175, SNU-283, SNU-503, SNU-769A, SNU-769B, SNU-1033, SNU-1197A, SNU-C1, SNU-C2A, SNU-C5, Caco2, COLO201, COLO205, COLO320, DLD-1, HCT-15, HCT-116, HT-29, Lovo, LS174T, NCI-H716, SW403, SW480, SW1116, and WiDR) (Figure 2 and Table 1). And by using primers for unmethylated *MAGE-A3* DNA amplification on bisulfite modified DNA, amplified DNA fragments were found also in 26 (81%) cell lines (SNU-61, SNU-175, SNU-407, SNU-503, SNU-769A, SNU-769B, SNU-1033, SNU-1047, SNU-

1197A, SNU-C1, SNU-C2A, SNU-C4, Caco2, COLO201, COLO205, COLO320, DLD-1, HCT-15, HCT-116, HT-29, Lovo, LS174T, NCI-H716, SW403, SW1116, and WiDR) (Figure 2 and Table 1). By using primers for amplification of unmethylated or methylated DNA, amplified DNA fragments were found in all 32 cell lines. *MAGE-A1* unmethylated DNA products were observed in 37 out of 87 tumor tissue samples (43%; Figure 3). In the normal tissue samples, the methylated DNA was amplified in all 87 samples. However, the unmethylated DNA was amplified in 2 normal tissues (2%). *MAGE-A3* unmethylated DNA products were observed in 67 out of 87 tumor tissue samples (77%; Figure 3). In the normal tissue samples, the methylated DNA was amplified in all 87 samples. However, the unmethylated DNA was amplified in 5 normal tissues (6%).

Reexpression of *MAGE-A1* and *MAGE-A3* after treatment with 5-aza-2'-deoxycytidine

We investigated whether *MAGE-A1* mRNA was re-expressed after 5-aza-2'-deoxycytidine treatment in 22 cell

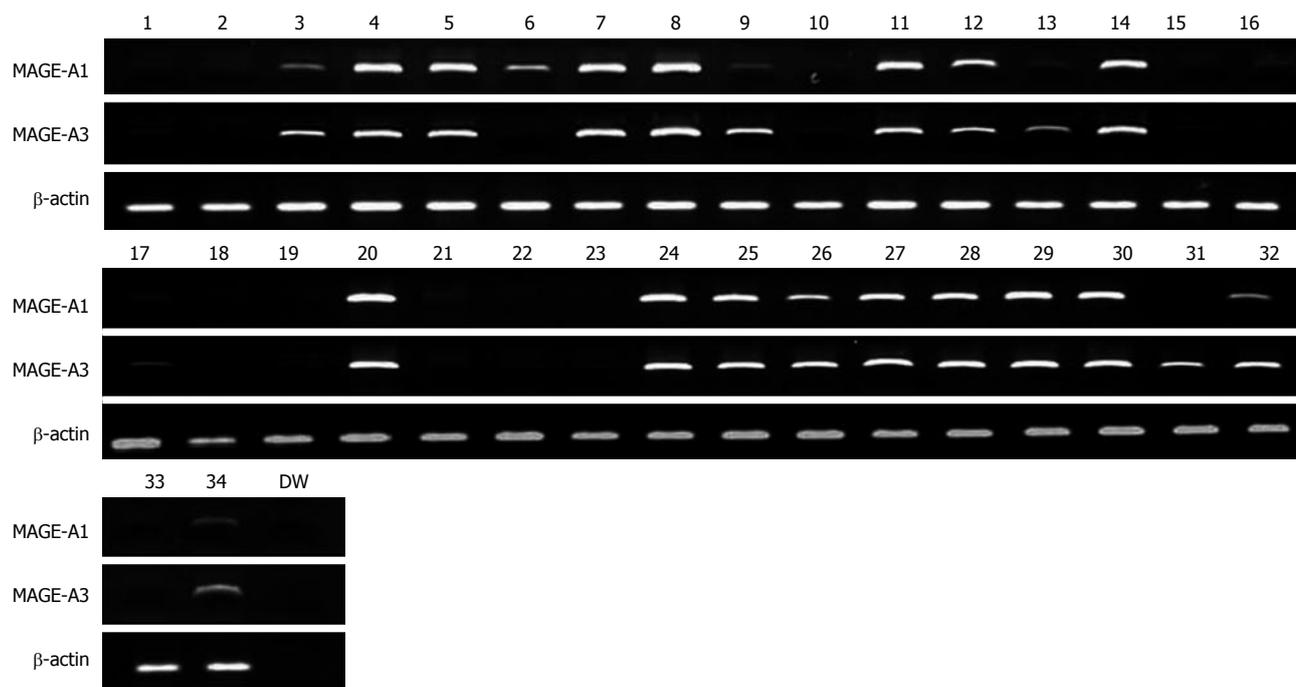

Figure 1 RT-PCR analysis of the *MAGE-A1* and *MAGE-A3* genes in 32 colorectal cancer cell lines. β -actin was amplified as an internal control. The *MAGE-A1* gene was significantly expressed in 19 colorectal cancer cell lines (Lanes, 3, 4, 5, 6, 7, 8, 9, 11, 12, 14, 20, 24, 25, 26, 27, 28, 29, 30 and 32). The *MAGE-A3* gene was expressed in 21 colorectal cancer cell lines (Lanes, 3, 4, 5, 7, 8, 9, 11, 12, 13, 14, 17, 20, 24, 25, 26, 27, 28, 29, 30, 31 and 32). Lane numbers 1 to 34 show cell lines SNU-61, SNU-81, SNU-175, SNU-283, SNU-407, SNU-503, SNU-769A, SNU-769B, SNU-1033, SNU-1040, SNU-1047, SNU-1197, SNU-C1, SNU-C2A, SNU-C4, SNU-C5, Caco-2, COLO201, COLO205, COLO320, DLD1, HCT-8, HCT-15, HCT-116, HT-29, LOVO, LS174T, NCI-H716, SW403, SW480, SW1116, WiDr, SNU-1, and SNU-5 respectively.

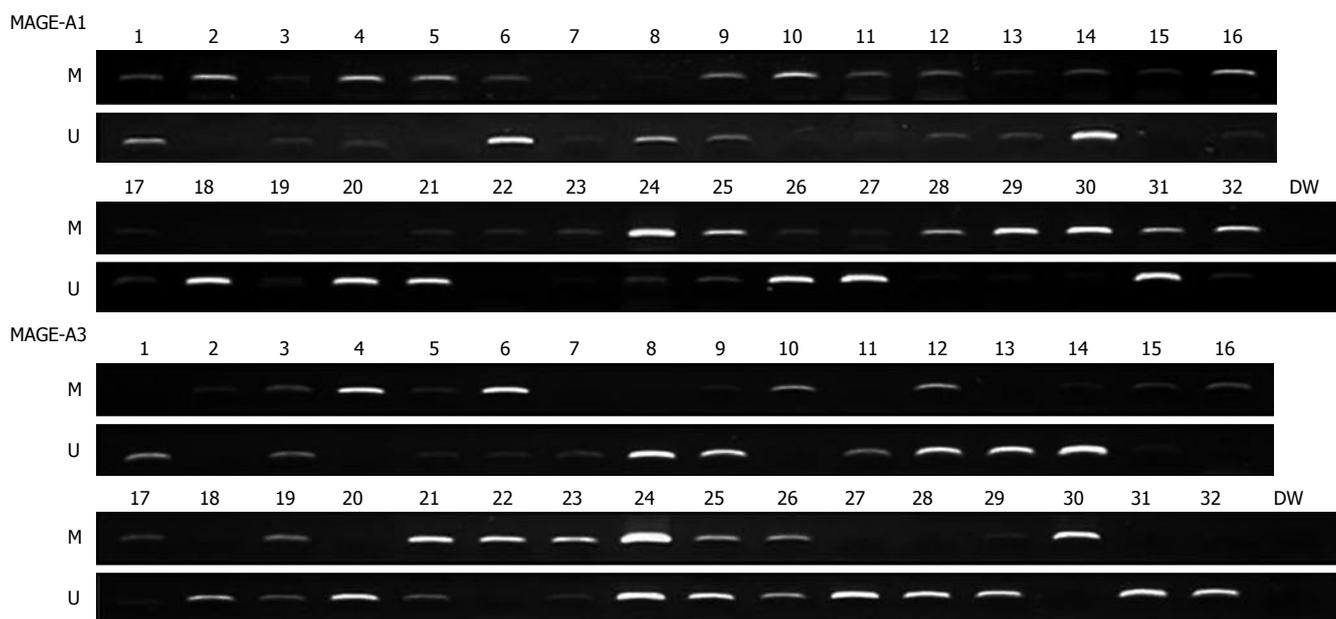

Figure 2 Methylation analysis of the *MAGE-A1* and *MAGE-A3* genes in colorectal cancer cell lines. The promoter region of the *MAGE-A1* gene was unmethylated in 26 cell lines (SNU-61, SNU-175, SNU-283, SNU-503, SNU-769A, SNU-769B, SNU-1033, SNU-1197A, SNU-C1, SNU-C2A, SNU-C5, Caco2, COLO201, COLO205, COLO320, DLD-1, HCT-15, HCT-116, HT-29, Lovo, LS174T, NCI-H716, SW403, SW1116, and WiDR cell lines). Unmethylated *MAGE-A3* DNA amplifications were found in 26 cell lines (SNU-61, SNU-175, SNU-407, SNU-503, SNU-769A, SNU-769B, SNU-1033, SNU-1047, SNU-1197A, SNU-C1, SNU-C2A, SNU-C4, Caco2, COLO201, COLO205, COLO320, DLD-1, HCT-15, HCT-116, HT-29, Lovo, LS174T, NCI-H716, SW403, SW1116, and WiDR cell lines). Lane M denotes product amplified by primers recognizing a methylated sequence and Lane U denotes the product amplified by primers recognizing an unmethylated sequence, respectively.

lines, including 10 cell lines (SNU-61, SNU-81, SNU-1040, SNU-C5, Caco-2, COLO201, COLO205, DLD1, HCT-8, and HCT-15) that did not express *MAGE-A1* mRNA. After an RT-PCR analysis, we observed that all of the *MAGE-A1* mRNAs were re-expressed, except for the SNU-1040 and COLO205 cell lines (Table 1).

This suggested that the inactivation of *MAGE-A1* expression was caused by another mechanism. Further, we investigated whether *MAGE-A3* mRNA was re-expressed after 5-aza-2'-deoxycytidine treatment in 22 cell lines, including 9 cell lines (SNU-61, SNU-81, SNU-1040, SNU-C5, COLO201, COLO205, DLD1, HCT-8, and

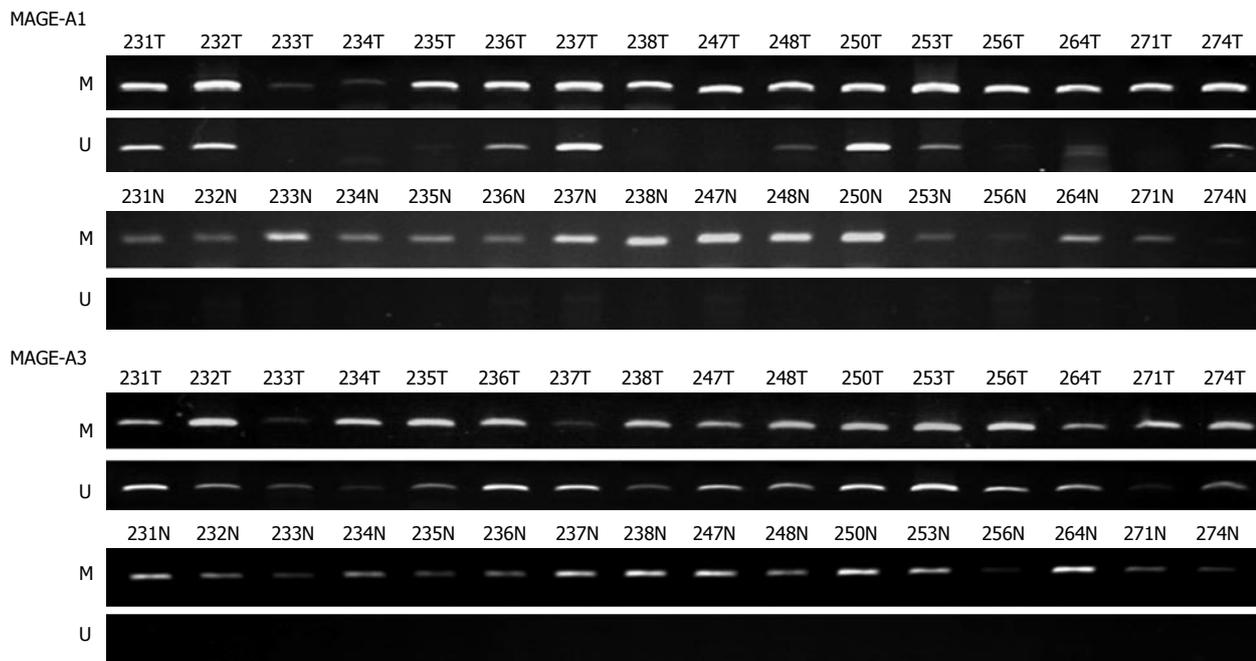

Figure 3 Methylation analysis of the *MAGE-A1* and *MAGE-A3* genes in colorectal cancer tissues and corresponding normal tissues. Methylation-specific PCR product amplified by primers recognizing methylated and unmethylated sequence. The promoter region of the *MAGE-A1* and *MAGE-A3* genes was unmethylated in colorectal cancer tissues, not normal tissues. Numbers represent each colorectal tissue and T denotes colorectal tumor tissues and N denotes corresponding normal tissues.

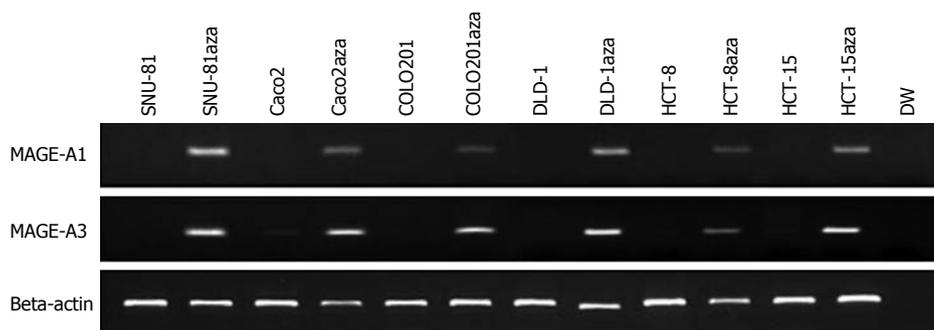

Figure 4 RT-PCR analysis after treatment with 5-aza-2'-deoxycytidine. The *MAGE-A1* and *MAGE-A3* genes were reactivated.

HCT-15) that did not express *MAGE-A3* mRNA. After an RT-PCR analysis, we observed that all of the *MAGE-A3* mRNAs were re-expressed (Table 1 and Figure 4).

DISCUSSION

Genome-wide hypomethylation and site-specific hypermethylation are common features of cancer cells. DNA hypomethylation in cancer cells is accompanied by the activation of germ line-specific genes, such as the *MAGE-A1* gene, the repression of which, in normal somatic tissues, is dependent upon DNA methylation^[17]. Recent studies have reported the presence of very high *MAGE-A1* and *MAGE-A3* expressions in colorectal carcinomas^[18,19]. Although previous reports have shown the expression of *MAGE* genes, the mechanism of *MAGE* genes expression in colorectal carcinomas was unclear. This led us to question whether it could be associated with decreased genomic methylation. It has been reported that *MAGE-A1* and *MAGE-A3* expression was related to gene hypomethylation in gastric carcinoma, hepatocarcinoma, and melanoma^[12,20,21]. However, such a relationship has still not been confirmed in colorectal

carcinoma. Accordingly, we analyzed the methylation status of the promoter region on the *MAGE-A1* and *MAGE-A3* genes in 32 colorectal cancer cell lines and estimated its association with *MAGE-A1* and *MAGE-A3* mRNA expression. We first examined the expression pattern of the *MAGE-A1* and *MAGE-A3* genes in these cell lines by an RT-PCR and observed that *MAGE-A1* and *MAGE-A3* were over-expressed significantly in 19 (59%) and 21 (66%) cell lines, respectively. This expression ratio of *MAGE-A1* and *MAGE-A3*, obtained by an RT-PCR in colorectal cancer cell lines, is similar to that observed in gastric cancer cell lines^[12]. On the other hand, previous reports have revealed a much lower expression of *MAGE* in colorectal carcinomas ranging between 5%-39%^[18,19,22]. In the literature, the expression of the *MAGE* genes was studied in colorectal carcinoma tissues; however, we have tested that in cancer cell lines. We assume that the major discrepancy of expression rates of *MAGE* genes between other reports and our findings might result from this. Since RNA or DNA was extracted from surgically removed frozen tissue biopsies, the tumor tissues may have been contaminated with normal stromal cells, therefore, masking the true levels of hypomethylation or expression

Table 2 Summary of expressions, promoter methylation status and clinical associations of the *MAGE-A1* and *MAGE-A3* genes in 32 colorectal cancer cell lines and 87 colorectal cancer tissues

	% of expression		% of hypomethylation

of the *MAGE* genes in cancer tissues^[6]. For further analysis of the methylation status of the *MAGE* genes in colorectal cancer tissues, laser capture microdissection techniques would allow more precise isolation of cancer cells and normal cells. It has already been reported that cancer cell lines have much higher levels of CpG island hypermethylation than corresponding malignant tissues, which may explain our lower incidence of hypomethylation in tissues *versus* cell lines. Moreover, cancer cells might be clonally selected with growth advantages over cancer cell lines. However, cancer cell lines often preserve hypermethylation or hypomethylation from the tumors they originate, thus they are indeed useful tools to study methylation status.

We analyzed promoter unmethylation of the *MAGE-A1* and *MAGE-A3* genes with a methylation-specific PCR after sodium-bisulfite modification and by direct sequencing analysis. Of the 32 cell lines analyzed, the promoter hypomethylation of *MAGE-A1* and *MAGE-A3* was observed in both at 26 cell lines each. Further, 23 cell lines (SNU-61, SNU-175, SNU-503, SNU-769A, SNU-769B, SNU-1033, SNU-1197A, SNU-C1, SNU-C2A, Caco2, COLO201, COLO205, COLO320, DLD-1, HCT-15, HCT-116, HT-29, Lovo, LS174T, NCI-H716, SW403, SW1116, and WiDR) were simultaneously unmethylated in both the *MAGE-A1* and *MAGE-A3* genes. With exception, there were two cell lines (SNU-61, COLO201) with negative gene expression for either *MAGE-A1* or *MAGE-A3*, but unmethylated *MAGE-A1* or *MAGE-A3* promoter was detected. On the contrary, there were four cell lines (SNU-283, SNU-407, SNU-1047 and SW480) in which *MAGE* genes were strongly expressed, although no unmethylated *MAGE* promoter could be detected, suggesting the activation or inactivation of *MAGE* expression by another mechanism.

In our study, the rates of hypomethylation of the *MAGE-A1* and *MAGE-A3* genes in colorectal cancer cell lines were 81% in both and those in colorectal cancer tissues were 43% and 77%, respectively. The DNA was extracted from the surgically removed frozen-tissues;

however, the tumor tissues might have been contaminated with some normal stromal cells. Therefore, the levels of hypomethylation of *MAGE-A1* and *MAGE-A3* genes in cancer tissues might be affected by the DNA from normal cells. To obtain a better understanding of the promoter hypomethylation status of the *MAGE-A1* and *MAGE-A3* genes in colorectal cancer tissues, expression analysis of *MAGE-A1* and *MAGE-A3* (such as, *in situ* hybridization or immunostaining) and the more precise methylation analysis method (such as, laser capture microdissection techniques) to isolate cancer cells from normal cells need to be performed. The hypomethylation of the *MAGE-A1* and *MAGE-A3* genes in corresponding normal tissues was detected in only 2 and 5 samples (2% and 6%), respectively (Table 2).

To evaluate the association between the clinical parameters and *MAGE* expression, the Pearson χ^2 test was used to evaluate differences in tumor location (proximal or distal) or gender, and significance was determined using 95% confidence intervals. In our study, unmethylated *MAGE-A1* DNA expression was significantly different in respect of tumor location and gender. Unmethylated *MAGE-A1* DNA expression was significantly higher in distal location ($P = 0.028$) and in females ($P = 0.004$). However, unmethylated *MAGE-A3* DNA expression was not significantly associated with tumor location ($P = 0.239$), while it was only related to female gender ($P = 0.021$).

Our results supported the role of the promoter methylation in maintaining a silent phenotype of the *MAGE-A1* and *MAGE-A3* genes, as the *MAGE* gene was re-expressed after treatment with 5-aza-2'-deoxycytidine. This agent reactivates gene expression when methylation of CpG islands is the cause of reduced gene expression. We demonstrated that the *MAGE-A1* and *MAGE-A3* mRNAs were re-expressed after 5-aza-2'-deoxycytidine treatment in all 8 and 9 cell lines that did not express *MAGE-A1* and *MAGE-A3* mRNAs, respectively. However, the SNU-1040 and COLO 205 cell lines did not show re-expression, suggesting the inactivation of *MAGE-A1* expression by another mechanism.

In conclusion, we observed hypomethylation in the promoter region of both the *MAGE-A1* and *MAGE-A3* genes in 23 of 32 colorectal cancer cell lines. This methylation was confirmed by MS-PCR, treatment with 5-aza-2'-deoxycytidine, and bisulfite direct sequencing analysis. Hypomethylation of the promoter region appears to be a frequent phenomenon in human colorectal cancers and upregulates transcription of the *MAGE-A1* and *MAGE-A3* genes in colorectal cancer cells. In addition, out of 87 colorectal cancer tissues, we observed hypomethylation in the promoter regions of the *MAGE-A1* and *MAGE-A3* genes in 37 (43%) and 67 (77%) tissues, respectively. This suggests that promoter hypomethylation of *MAGE-A1* and *MAGE-A3* genes upregulates its expression in colorectal carcinomas as well as in gastric cancers, and might play a significant role in the development and progression of human colorectal carcinomas.

Abstract

AIM: To examine the relationship between *H pylori* and gastro-oesophageal reflux disease (GORD) in Iran.

METHODS: In this study 51 GORD patients (referred to endoscopy at Taleghani hospital) were compared with 49 age-sex matched controls. Diagnosis of *H pylori* was made by gastric mucosal biopsy and rapid urease test (positive if the result of one or both diagnostic methods was positive). Updated Sydney system was used to report histopathological changes.

RESULTS: The frequency of *H pylori* infection based on rapid urease test and histology was 88.2% (45) in patients and 77.6% (38) in controls, which showed no significant difference. The frequency of *H pylori* infection was significantly higher in the antrum than in the corpus and cardia. The mean activity, inflammation, and gastritis scores were also higher in the antrum of patients than in the antrum of controls. The mean scores were significantly higher in the corpus of controls than in the corpus of patients. Diffuse active gastritis was observed in a significantly larger number of controls, while the frequency of diffuse chronic gastritis was higher in patients. There was no significant difference in the frequency of other histological findings between patients and controls.

INTRODUCTION

Heartburn is a common symptom in the general population^[1,2] and is associated with the development of adenocarcinoma of the oesophagus and cardia^[3]. Gastritis-associated hypochlorhydria may protect against gastro-oesophageal reflux disease (GORD)^[4,5]. It has hypothesized that the declined *H pylori* infection results in a decline in peptic ulcer and a concomitant increase in reflux disease and associated oesophageal adenocarcinoma^[6,7]. However, the relationship between *H pylori* infection and GORD has not been established^[8-11]. It was reported that prospective, large studies are needed to explore the *H pylori*-gastro-oesophageal disease relationship further and to avoid confusing potential benefits with known risks^[9-12].

The main of this study was to investigate whether there is a difference between the frequencies of *H pylori* infection in cases and controls, and the possible relationship between *H pylori* infection and GORD.

MATERIALS AND METHODS

Patients

In this study, patients with a history of heartburn, at least two times a week for a period of more than 3 mo, referred for gastrointestinal endoscopy at Taleghani Hospital, Shaheed Beheshti University of Medical Sciences, between March 2001 and February 2002, were enrolled. The reflux oesophagitis group included 51 patients (31 men and 20 women, mean age, 54.1 ± 17.2 years, range 17-80 years) with endoscopically diagnosed erosive reflux oesophagitis.

Table 1 Frequency of *H pylori* infection in two groups *n* (%)

Group	<i>H pylori</i>			Rut	Diagnosis of <i>H pylori</i>	Total
	Cardia	Corpus	Antrum			
Case	27 (52.9)	25 (49.0)	37 (72.5)	23 (45.1)	45 (88.2)	51 (100.0)
L.A. classification						
A	11 (21.6)	8 (15.7)	12 (23.5)	9 (17.7)	16 (31.4)	17 (33.3)
B	11 (21.6)	11 (21.6)	17 (33.4)	12 (23.5)	21 (41.2)	24 (47.1)
C	4 (7.8)	5 (9.8)	7 (13.7)	2 (3.9)	7 (13.7)	9 (17.7)
D	1 (1.9)	1 (1.9)	1 (1.9)	0	1 (1.9)	1 (1.9)
Control	28 (57.1)	27 (55.1)	31 (63.3)	22 (44.9)	38 (77.6)	49 (100.0)
Total	55 (55.0)	52 (52.0)	68 (68.0)	45 (45.0)	83 (83.0)	100 (100.0)

Patients with a history of upper gastrointestinal (GI) surgery, malignancy, oesophageal varices, and antibiotics or bismuth consumption during the last 6 mo, together with those using H₂ blockers, proton pump inhibitors (PPIs), alcohol, or non steroidal anti inflammatory drugs (NSAIDs) during the last 4 wk, were excluded from the study. The control group comprised: 49 asymptomatic patients (29 men and 20 women, mean age, 52.2 ± 17.1 years, range 18-80 years) without reflux oesophagitis, any symptom of upper GI diseases, and any lesion in their endoscopy, which was performed for other reasons (work up for iron deficiency, possible malignancy, and ERCP, sphincterotomy, or stone extraction candidates). Two cases of control group were missed during the study. The cases and controls were sex and age matched with a maximum difference of less than 3 years. Written informed consent was obtained for all upper endoscopy and biopsy procedures. This study was approved by the Ethics Committee of the Research Center of Gastroenterology and Liver Diseases, Shaheed Beheshti University of Medical Sciences.

Endoscopy and gastric biopsies

Endoscopy was performed for both case and control groups, by two endoscopists blinded to the status of the controls and patients. The presence and grading of reflux oesophagitis were determined according to L.A. classification, from A (least severe) to D (most severe)^[13]. During endoscopy, two biopsies were taken from the antrum, corpus, and cardia, and stained with standard haematoxylin/eosin and Geimsa to identify *H pylori* and histopathological changes. Rapid urease test was performed on the biopsy specimens from antrum, corpus, and cardia. The urease test was considered positive when the urea solution changed from yellow to pink at room temperature within 24 h. The diagnosis of *H pylori* infection was made by positive findings on either histology or urease test. Patients were considered to be *H pylori*-positive if the result of one or both diagnostic methods was positive and *H pylori*-negative if both methods revealed negative results.

For histopathological analysis, biopsy specimens were fixed in 40 g/L neutral-buffered formaldehyde and embedded in paraffin. Five-micron thick sections were cut from each paraffin block and stained with haematoxylin and eosin for routine histology. Two pathologists blinded to the clinical information of subjects assessed the histopathological changes independently. Updated Sydney

system was used to report histopathological changes^[14]. The degrees of inflammation and activity were scored from 0 (absent) to 3 (most severe). The inflammation score and activity score were summed and expressed as the gastritis score. The predominance for the anatomic regions in gastritis was determined based on the degree of inflammation in the different anatomic parts of the stomach. If the degree of inflammation was higher, the anatomic place with a higher grade of inflammation was stated as the predominant region. For the diagnosis of multifocal atrophic gastritis, we determined intestinal metaplasia or significant mucosal atrophy. Because of the low reproducibility for routine grading of mucosal atrophy, atrophy score was not used as a marker for grading^[14].

Statistical analysis

Results were expressed as mean ± SD. Odd's ratios (95% CI) were calculated to evaluate the differences in the frequency of *H pylori* infection and other histological findings between patient and control groups. Cochran's Q test was used to compare the frequency of *H pylori* infection in the cardia, corpus, and antrum. Mann-Whitney *U* test was used to analyze the differences in activity, inflammation, and gastritis scores between the two groups and Friedman test was used to analyze the different scores in the cardia, corpus, and antrum. *P* < 0.05 was considered statistically significant.

A sample size of about 50 for patient and control groups was considered to have an 80% detecting rate (at the two-sided 5% level) with at least a 25% difference in the prevalence of *H pylori* between the two groups.

RESULTS

Among the 51 reflux oesophagitis patients, 17 (33.3%) were in grade A, 24 (47.1%) in grade B, 9 (17.6%) in grade C, and 1 (1.9%) in grade D (Table 1). Hiatal hernia was observed in 30 (58.8%) patients. The prevalence of *H pylori* infection is shown in Table 1. The frequency of *H pylori* in the antrum was significantly higher than that in the corpus and cardia of the patients (*P* < 0.01), while the differences were not significant in different regions of stomach of the controls, which might be due to the inadequate sample size. We were not able to find any significant difference in the frequency of *H pylori* infection between the two groups (OR: 2.2, 95% CI: 0.7-7.4) as shown in Table 2.

The different histological findings in patients and

Normal	20 (39.2)	11 (22.4)	31 (31.0)	2.2 (0.9-5.8)
Total	51 (100.0)	49 (100.0)	100 (100.0)	-

¹Based on histology and rapid urease test.

controls are shown in Table 2. The frequency of chronic inflammation in the corpus was significantly higher in controls than in patients (OR: 0.2, 95% CI: 0.1-0.6). Diffuse active gastritis was also observed in controls (OR: 0.4, 95% CI: 0.2-0.9), while diffuse chronic gastritis was observed in patients (OR: 5.7, 95% CI: 1.1-40.4). The frequency of intestinal metaplasia and mucosal atrophy was not significantly different between the two groups (Table 2).

The inflammation, activity, and gastritis scores in both groups are depicted in Table 3 and Figure 1. The mean activity score in the cardia, corpus, and antrum of controls was significantly higher than that of patients ($P < 0.01$ or $P < 0.001$, Figure 1A). The inflammation score was higher in the corpus of controls than that in patients ($P < 0.01$, Figure 1B), while the inflammation score of the cardia and antrum was not significantly different between the two groups. Similarly gastritis score was significantly higher in controls than in patients ($P < 0.01$ and $P < 0.05$, Figure 1C).

The mean activity score was significantly higher in the antrum than in the corpus and cardia of controls ($P < 0.001$, Table 3), while the differences were not significant in patients probably due to the inadequate sample size. The mean inflammation and gastritis scores were also significantly higher in antrum than in corpus and cardia of both patients and controls ($P < 0.001$, Table 3). These findings together with the higher frequency of *H pylori* infection in the antrum indicated that *H pylori* in antrum could induce inflammation.

DISCUSSION

Increasing attention has been paid to the relationship between *H pylori* infection and reflux oesophagitis in recent years. GORD is a common condition affecting 25%-40% of the population^[2]. The presence of hiatal hernia^[15], transient relaxation of the lower oesophageal sphincter^[16,17], and impaired clearance of regurgitated gastric contents in the oesophagus^[18] are considered possible causative factors for GORD.

There is evidence that infection with *H pylori* is the principal cause of peptic ulcer disease^[10]. However, there

is uncertainty about the role of this organism in GORD and the available data do not demonstrate an evident association between these two factors, although an etiologic link has been found between *H pylori* infection and GORD or peptic oesophagitis^[10]. The prevalence of *H pylori* infection in patients with GORD in our study (88.2%) was higher than that reported in other studies^[9], suggesting that *H pylori* infection is more frequent in developing countries than in industrialized countries^[19].

No difference was found in the prevalence of *H pylori* between patients with reflux oesophagitis and controls in this study. Conflicting evidence about the association of *H pylori* infection with GORD has been reported and geographical location is an important determinant^[9]. The pathogenic role of *H pylori* in reflux oesophagitis is suspected in earlier studies^[20] while other studies have found no relationship between *H pylori* prevalence in GORD patients with that reported in other patients^[10,21-34]. In contrast, the possible protective role of *H pylori* in reflux oesophagitis and other GORD-related diseases such as Barrett's oesophagus and oesophageal adenocarcinoma has recently been suggested^[35-39]. *H pylori* can cause chronic gastritis in virtually all infected people. This persistent inflammation ultimately leads to loss of the normal architecture of gastric mucosa, disappearance of gastric

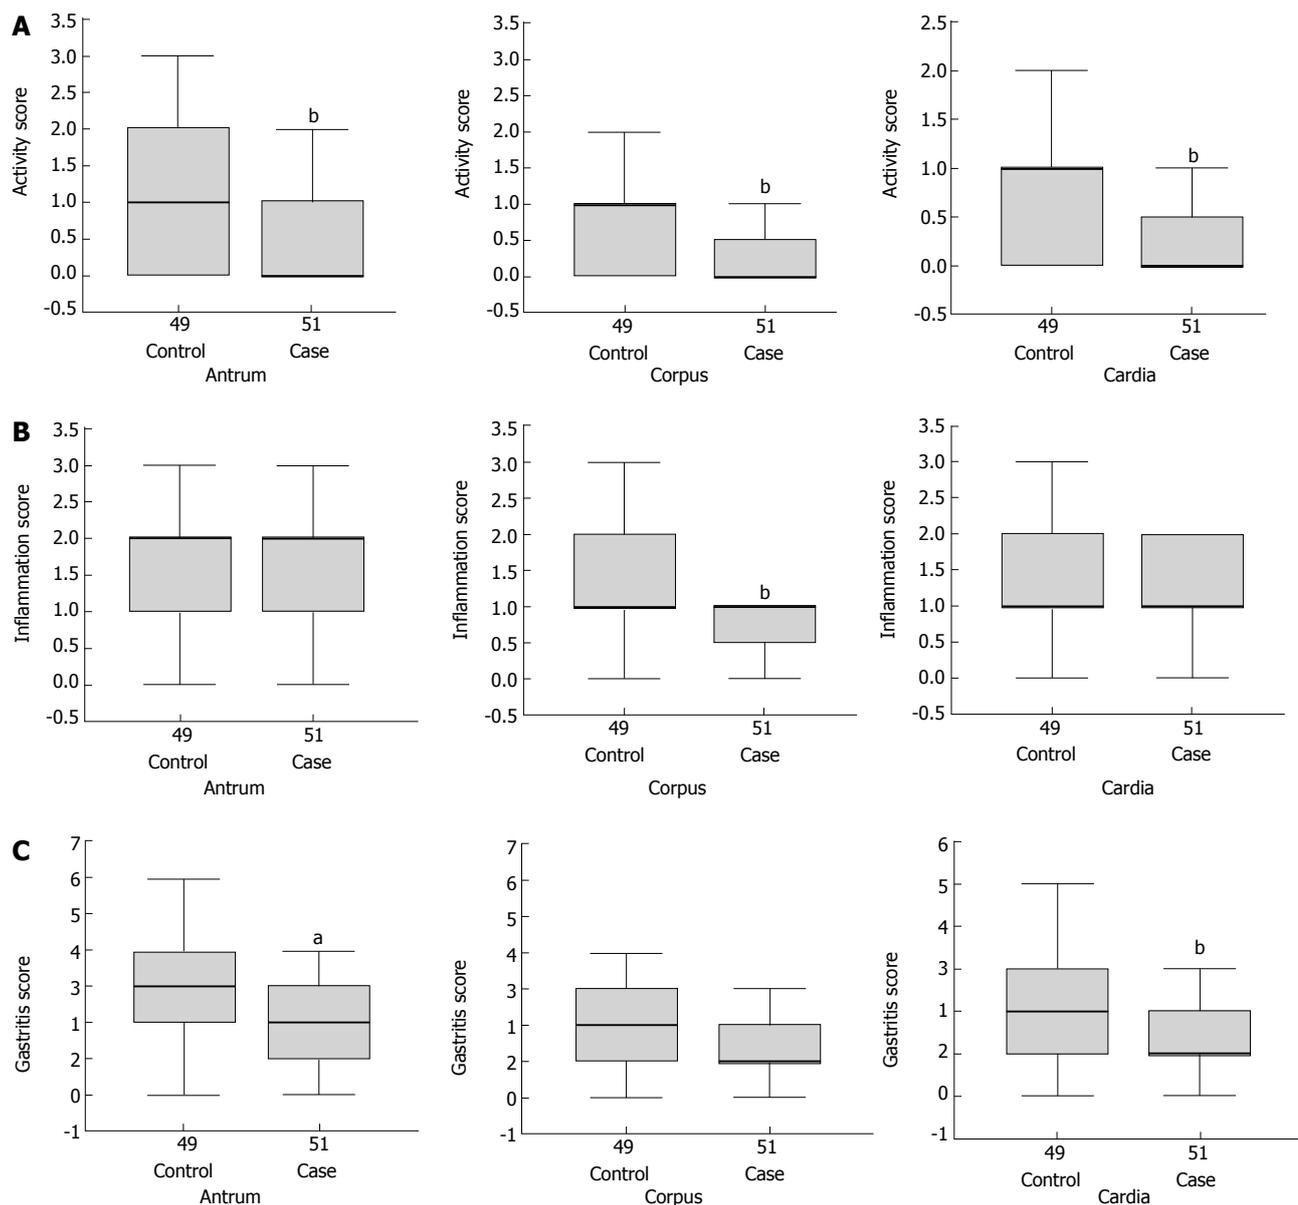

Figure 1 Scores of activity (A), inflammation (B), and gastritis (C) in the antrum and corpus of patients and controls. ^a $P < 0.05$, ^b $P < 0.01$ vs controls.

glands and specialized cells^[40]. Diffuse active gastritis was observed in controls while diffuse chronic gastritis was observed in patients in the present study, suggesting that active inflammation might play a protective role in GORD. Chronic antrum-predominant gastritis has been shown to be associated with secretion of acid and formation of duodenal ulcer^[8,41]. In patients otherwise predisposed to reflux disease, antrum-predominant gastritis may therefore increase acid production and reflux disease development^[8]. On the other hand, atrophy induced by chronic *H pylori* infection (chronic corpus gastritis) with decreased gastric acid production can protect against reflux oesophagitis^[8,11,42]. As a consequence, the antrum predominant inflammation might be considered a factor for *H pylori* infection.

In conclusion, *H pylori* infection is not associated with DORD. Multicentre prospective studies with a larger sample size are needed to explore the relationship between *H pylori* infection and DORD.

Abstract

AIM: To investigate maternal *H pylori* infection status to determine the potential of maternal transmission.

METHODS: In the present study, we examined these issues in an experimental murine model, which is a Mongolian gerbil model that has been reported as an optimal laboratory animal model to study *H pylori*. Pregnant Mongolian gerbils, infected experimentally with *H pylori*, were divided into as four groups. Following the experimental design, the stomachs of the mother and litters were isolated and assessed for transmission of *H pylori* at the prenatal period, parturition day, 1-wk old and 3-wk old respectively. Bacterial culture and polymerase chain reaction (PCR) were used to examine the presence of transmitted *H pylori*.

RESULTS: All litters showed no transmission of *H pylori* during pregnancy and at parturition day. However, they revealed 33.3% and 69.6% at 1-wk and 3-wk of age respectively by PCR.

CONCLUSION: These results suggested that vertical infection during the prenatal period or delivery procedure is unlikely as a route of mother-to-child *H pylori* infection. It may be that *H pylori* is acquired through breastfeeding, contaminated saliva and fecal-oral transmission during co-habitation.

INTRODUCTION

H pylori is a gram-negative, spiral-shaped, microaerophilic bacterium that infects the human gastric mucosa^[1]. Chronic infection is thought to be associated with chronic active gastritis, peptic ulcer and gastric malignancies, such as mucosa-associated B cell lymphoma and adenocarcinoma^[2-4]. In particular, this organism has been categorized as a class I carcinogen by the World Health Organization^[5] and previous studies have confirmed that long-term infection with *H pylori* induces adenocarcinoma in Mongolian gerbils^[6,7]. In-depth knowledge of the transmission patterns may constitute important information for future intervention strategies. In the absence of consistent and verified environmental reservoirs, a predominantly person-to-person transmission has been postulated. *H pylori* infection is associated with poor living conditions, and possible transmission routes are fecal-oral, oral-oral, or gastro-oral, but firm evidence is lacking^[8-11]. Young children are particularly vulnerable to infection by transmission of *H pylori* from their infected parents, especially infected mothers^[12-15], and it is generally believed that such transmission is influenced by socio-economic status^[16,17]. However, little is known about how and when maternal transmission occurs during the perinatal period, especially whether this occurs before or after parturition. In the present study, we examined these issues in an experimental murine model, which is a Mongolian gerbil model that has been reported as an optimal laboratory animal model to study *H pylori in vivo*^[18].

The present study was designed to examine the incidence of vertical transmission of *H pylori* from their infected mother during the perinatal period in an experimental murine model.

MATERIALS AND METHODS

Experimental design

The experimental scheme of this study was summarized in Figure 1. Pregnant Mongolian gerbils were infected experimentally with *H pylori*. The stomachs of the litters were isolated and assessed for transmission of *H pylori* during pregnancy and at parturition day, 1 wk and 3 wk after delivery respectively. Their mother was also evaluated for the infectious status of *H pylori*. To determine the vertical transmission of *H pylori*, bacterial culture assay and polymerase chain reaction (PCR) were conducted with each sample.

Animals

Specific pathogen-free (SPF) 3-mo-old male and female

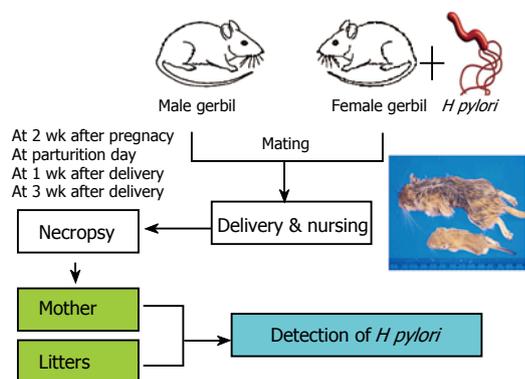

Figure 1 Scheme of experimental vertical transmission.

Mongolian gerbils (*Meriones unguiculatus*) were obtained from the SPF Animal Facilities of College of Medicine, Seoul National University, South Korea. All animals were kept in the inspecting facility of Wonkwang University (Iksan, South Korea) for 1 wk before experimentation to allow acclimation. Thereafter, they were kept in an isolated SPF barrier room with regulated temperature ($23^{\circ}\text{C} \pm 1^{\circ}\text{C}$), humidity ($50\% \pm 5\%$) and light/dark cycle (12/12 h). The animals were fed a sterilized pellet diet by 2 M rad radiation (Purina, Korea) and sterilized water *ad libitum*. All studies were performed in accordance with the Guide for Animal Experimentation by Wonkwang University and approved by the Institutional Animal Care and Use Committee of Wonkwang University (Iksan, South Korea). All efforts were made to minimize pain or discomfort of animals used.

Preparation of *H pylori* & inoculation

H pylori (ATCC 43504; American Type Culture Collection, USA) was incubated in a brain-heart infusion broth containing 10% fetal bovine serum at 37°C overnight under a microaerophilic atmosphere and allowed to grow to a density of 2.0×10^9 colony-forming units (CFU) per 1 mL of culture broth. Animals were inoculated twice at 3-d intervals by oral administration of 1.0×10^9 CFU of *H pylori* suspended in 0.5 mL of broth. The challenged animals were confirmed to be *H pylori*-positive by PCR of their fecal samples as described previously^[19]. *H pylori*-negative animals were excluded from the following study.

Maternal transmission of *H pylori*

One week after the challenge with *H pylori*, the infected females and males were transferred to separate cages for mating. As soon as a female was confirmed to be pregnant, she was separated from the group and cared for until delivery. Twelve infected pregnant females were used to determine maternal transmission. Three mothers were sacrificed at 2 wk after pregnancy. The gastric samples of mother and fetuses were isolated and submitted to determine *H pylori* infection. Also, another nine pregnant gerbils were cared for until delivery and the mother and her litters were housed in one cage per family. For 12 h before their sacrifice, they were housed in a grated cage and deprived diet (Figure 2). The stomachs of the mother and litters were isolated and assessed for transmission of

Figure 2 The mother and her litters were housed in one cage per family. For 12 h before their sacrifice, they were housed in grated cage and deprived diet.

H pylori at parturition day, 1 wk and 3 wk after delivery respectively. For the negative control, an uninfected female and her litters were sacrificed at 2 wk after pregnancy, parturition day, 1 wk and 3 wk after delivery respectively. Thereafter their gastric samples were submitted to examine *H pylori* infection.

Isolation of *H pylori*

Aliquots of homogenate were cultured on M-BHM *pylori* agar medium plates and the plates were incubated under the previous described condition^[19]. To confirm *H pylori* infection, the remainder of the homogenate was used for the following PCR procedure.

Polymerase Chain Reaction

Bacterial DNAs were extracted from the above homogenate by bead beater-phenol extraction method^[19]. Each sample homogenate was suspended in 200 μL of Tris-EDTA-NaCl buffer [10 mmol/L Tris-HCl, 1 mmol/L EDTA, and 100 mmol/L NaCl (pH 8.0)]. A bacterial suspension was placed in a 2.0-mL screw-cap microcentrifuge tube filled with 100 μL (packed volume) of glass beads (diameter, 0.1 mm; Biospec Products, USA) and 100 μL of phenol-chloroform-isoamyl alcohol (25:24:1) (Sigma Chemical Co., USA). The tube was oscillated on a Mini-Bead Beater (Biospec Products) for 1 min and was centrifuged ($12000 \times g$, 5 min) to separate the phases. The aqueous phase was subsequently transferred into another clean tube; 10 μL of 3 mol/L sodium acetate and 250 μL of ice-cold absolute ethanol were added. To precipitate the DNA, the mixture was kept at -20°C for 10 min. The harvested DNA pellets were dissolved in 60 μL of Tris-EDTA buffer [10 mmol/L Tris-HCl and 1 mmol/L EDTA (pH 8.0)] and were used as a template DNA for PCR. A set of primers (HF, 5'-ACTTTAAACGCATGAA GATAT-3'; and HR, 5'-ATATTTTGACCTTCTGGGGT-3') was used to detect specific nucleic acid of *H pylori*^[19]. The template DNA (50 ng) and 20 pmol of each primer were added to a PCR mixture tube (Maxime PCR PreMix; iNtRON Biotechnology, Korea) containing 1 U of Taq DNA polymerase, 250 $\mu\text{mol/L}$ each deoxynucleoside triphosphate, 50 mmol/L Tris-HCl (pH 8.3), 40 mmol/L KCl, 1.5 mmol/L MgCl_2 , and the gel loading dye. The volume was adjusted with distilled water to 20 μL . The

reaction mixture was subjected to 30 amplification cycles (5 min at 95°C, 30 s at 94°C, 30 s at 52°C, 45 s at 72°C, and 5 min at 75°C) followed by a 5-min extension at 72°C (model 9600 Thermocycler; Perkin-Elmer Cetus, USA). The PCR products were electrophoresed on a 1.2% agarose gel.

RESULTS

While culture of the bacterium is one of the gold standards in the diagnosis of *H pylori* infection, in the present study, we also used the PCR with the culture method to detect *H pylori*. The culture method was not considered to be ideal for determination of *H pylori* transmission because only small amounts of bacteria were suspected to colonize the stomach and the detection limit of the quantitative culture assay was 1×10^2 CFU/g gastric tissue^[20]. The sensitivity of the PCR was 1 CFU/g feces and higher than those of other assays^[19]. Vertical transmission was examined at 2 wk after pregnancy and at parturition day (corresponding to the transplacental or intrauterine transmission during prenatal period and the delivery transmission during birth canal passage, respectively). Each stage group was composed of three pregnant females and their litters.

As the results of assessment performed at 2 wk after pregnancy, the mothers revealed *H pylori* infected status by culture assay and PCR (Table 1). However, their fetuses were not infected with *H pylori* (Figure 3). For the evaluation of delivery transmission during birth canal passage, all litters showed no transmission of *H pylori* (Figure 4) although the mothers were identified *H pylori* infected by culture assay and PCR (Table 1). However, their fetuses were not infected with *H pylori* (Table 1). *H pylori* was not detected in any litters and their mothers of the negative control group (Table 1).

Maternal transmission was examined at 1 wk and 3 wk postpartum (corresponding to the transitional milk and

weaning stage, respectively). Each stage group was composed of three families. At 1 wk and 3 wk postpartum, the mothers revealed *H pylori* infected status by culture assay and PCR and some of their litters were infected with *H pylori* (Figure 5). The frequency of maternal transmission was increased during the nursing period. The transmission rate at 3 wk postpartum was significantly higher than at 1 wk postpartum (Table 1). *H pylori* was not detected in any litters of the negative control group.

DISCUSSION

Half of the world's population is estimated to be infected with *H pylori* and the infection is mainly acquired in early childhood but the exact routes of transmission remain elusive. Infected mothers are generally considered to be the main source of the pathogen^[15,21,22]. The epidemiology of *H pylori* infection is variable, with prevalence being significantly higher and incident infection occurring earlier in developing countries compared with developed countries^[17,23,24]. There is an obvious public health impact of *H pylori* infection and thus, to design targeted and cost-effective prevention strategies, elucidation of the mode of transmission for this bacterium is crucial^[25]. It

is known that *H pylori* infection is typically acquired in early childhood and usually persists throughout life unless specific treatment is applied^[12,14,26]. Definitive modes of transmission have not yet been characterized and the principal reservoir appears to be humans. Person-to-person transmission via fecal-oral, oral-oral and gastro-oral routes have been proposed^[8-11]. Numerous studies also indicate low socioeconomic status, including domestic overcrowding in childhood, as major risk factors for higher infection prevalence rates^[16,17,23,27,28]. Little is known about when and how often maternal transmission of *H pylori* occurs during the perinatal stage. In the present study, we examined these issues in an experimental murine model.

The results of the vertical-transmission experiment indicated that vertical transmission of *H pylori* did not occur at the pregnant and delivery stage. However, they revealed 33.3% and 69.6% at the lactating and weaning stage respectively. Recent epidemiological studies in humans suggest that acquisition of *H pylori* occur during childhood. For example, Rothenbacher *et al*^[29] reported that *H pylori* acquisition seems to occur mainly between the first and second year of life: that is, after the age of weaning. Our results are in agreement with this report. Also, Rothenbacher *et al*^[22] reported that infected parents, especially infected mothers, play a key role in the transmission of *H pylori* within families. Maternal contact behaviour during the breastfeeding period may be responsible for the high frequency of maternal transmission^[30]. Our results also showed that the maternal-transmission of *H pylori* was not observed during pregnancy and delivery stage, but detected at lactating and weaning stage. On the basis of these findings, vertical infection during pregnancy or at delivery is unlikely as a route of mother-to-child *H pylori* infection. We suggested that *H pylori* infection by the transplacental route during pregnancy does not occur and that *H pylori* transmission by discharges of the uterine or vagina, obstetric delivery tract, during parturition does not occur. *H pylori* might be acquired through breast-feeding, contaminated saliva and fecal-oral transmission during co-habitation.

In conclusion, the present study provides new and important information on maternal transmission of *H pylori*. This study implied that maternal transmission of *H pylori* might be developed during latency or a later postpartum stage. Data from human children are limited, because most *H pylori*-infected children have no symptoms and it is difficult for a paediatrician to examine such asymptomatic children invasively. In the present study, we examined these issues in an experimental murine model, the Mongolian gerbil model that has been reported as an optimal laboratory animal model to study *H pylori in vivo*^[18]. We analysed the stomachs of many infant Mongolian gerbils directly and we believe that it is meaningful to use our results to speculate when *H pylori* infection occurs in human children. The acquisition of *H pylori* infection during childhood seems to be a critical risk factor for the later development of gastric cancer. The prevention of transmission of *H pylori* during childhood could provide an effective strategy to decrease *H pylori* infection and gastric cancer.

Abstract

AIM: To determine the mechanical properties of anastomotic colonic tissue in experimental settings and therefore give a measure of wound healing.

METHODS: Thirty-six male Wistar rats were used as experimental models of anastomotic tissue integrity. On the 5th post-operative day, the tensile strength was measured by application of an axial force, providing a quantitative measure of anastomotic dehiscence and leakage.

RESULTS: Diagrams of the load as a function of the time [$P = P(t)$] and of the displacement also as a function of time [$\Delta s = \Delta s(t)$] were recorded for each test, permitting the design of the load versus the displacement diagram and thus providing significant data about the critical values of anastomotic failure. Quantitative data were obtained concerning the anastomotic strength of both control specimens (healthy rats), as well as specimens from non-healthy rats for comparison.

CONCLUSION: This experimental model provides an excellent method of measuring anastomotic strength. Despite the relative small number of specimens used, this method provides an accurate way of measuring wound repair. More experimental measurements need to be performed to correlate emerging tensile strength val-

ues to anastomotic failure.

INTRODUCTION

Investigating wound healing and attempting to improve its outcome necessitates process quantification^[1]. Parameters for anastomotic repair and adhesion formation^[2] may be mechanical, biochemical, or histological. Histology is not a primary tool for quantification when comparing various series of experimental anastomoses. Certainly it is very useful to describe the course and eventual result of the healing sequence at the tissue level. Also, the successive infiltration of various cells into the wound area may be followed, and obvious differences between anastomoses (e.g, ileal and colonic) will certainly be demonstrated this way. However, the measurement of choice to evaluate anastomotic repair and the effects of variations in surgical techniques, administration of drugs, or of any other modification to establish procedures, will mostly be either mechanical or biochemical or both.

The developing mechanical strength is, without doubt, a meaningful parameter to follow while investigating anastomotic healing. For this purpose, two fundamentally different approaches can be chosen. First, one can choose bursting strength, which is expressed either as bursting pressure or bursting wall tension, which is the measure of the resistance of the intestinal wall to increasing intraluminal pressure. Second, one can choose breaking strength, which reflects the resistance of the intestinal wall to forces exerted in a longitudinal direction^[3-5].

While both of these methods used to evaluate anastomotic healing have been investigated in the international literature, no paper has so far described

in detail the process itself, analyzing its advantages, disadvantages and parameters taken into consideration, therefore establishing the need for an in-depth presentation of the mechanical apparatus used and presenting not only the theoretical background behind the measurements but also the technical difficulties that arise.

MATERIALS AND METHODS

Thirty-six male Wistar rats weighing 300-350 g were used, and were housed two per cage. They were fed a standard diet and water *ad libitum*. All experiments were approved by the Athens Prefecture, Directorate of Veterinary Services (License No. K/355/27-1-2005), according to the Presidential Decree No. 160/1991 (Governmental Gazette A' 64), with which Greece has conformed to the 86/609/EEC directive. Laparotomy^[6] was performed through a midline 2 cm incision under anesthesia induced by ketamine (80 mg/kg) and xylazine (3 mg/kg). A colonic segment, 1 cm in length, 5 cm distal to the ileocecal junction was transected and the colon was re-anastomosed end-to-end using 5-0 Vicryl (Ethicon) sutures in single-layer interrupted fashion^[7]. About 10 sutures were placed for each anastomosis to secure an inverted anastomosis without mucosal protrusion, which is regarded as a major cause of perianastomotic adhesions. The abdominal muscle wall was then closed with 5-0 Vicryl (Ethicon) sutures, followed by skin closure with 4-0 Silk (Medipac) sutures.

To obtain the test specimen, the rats were sacrificed with an overdose of ether, on the 5th post-operative day. The previous abdominal incision was reopened, and the anastomotic site identified and inspected for possible adhesions and leakage. An 8 cm segment of the colon with the anastomosis in the middle was resected. Care was taken not to detach adhesions from the anastomosis, but to dissect the surrounding tissues. The resected specimen was gently irrigated with saline to remove feces and was mounted on a table.

The basic purpose of the present experimental protocol is the determination of the mechanical behavior of intestinal anastomoses and more specifically the response to tensile loading and the determination of the respective tensile strength. One can define the ratio of the applied force at the moment of failure, F_{cr} , over the surface, A , upon which the force acts normally^[8], as tensile strength (Figure 1). The ratio of the force over the respective area is known in engineering science as stress and therefore the tensile strength is the respective tensile stress at the moment of failure.

In the international scientific literature the mechanical behavior under tension, of specimens like the ones of the present protocol, has been studied in two ways: (1) By applying an internal hydraulic pressure, p ,^[9-12]. In this case (and for points relatively far from the borders of the specimens) a stress state equivalent to the so-called biaxial tension appears on the surface of the concave cylindrical specimen. Assuming that the thickness of the specimens is much smaller in comparison to its diameter, the principal tensile stresses at the moment of failure are given by the

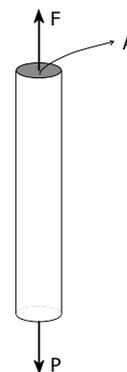

Figure 1 Typical forces applied on a standard specimen.

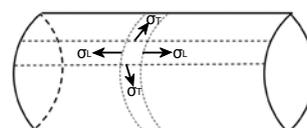

Figure 2 The application of hydraulic pressure creating a two-dimensional stress field.

relations (Figure 2)^[13]:

$$\sigma_L = \frac{p_{cr}r}{2t}, \quad \sigma_T = \frac{p_{cr}r}{t}$$

where p_{cr} is the value of the hydraulic pressure at the moment of the first failure, r the radius of the intestine and t its wall thickness. The stress system is characterized as principal since no shear stresses can be generated by a pure hydraulic pressure.

(2) By applying directly an axial force, F ,^[14,15]. In this case the critical value of the tensile strength is expressed as:

$$\sigma_{cr} = \frac{F_{cr}}{2\pi r t}$$

The procedures described above present both advantages and disadvantages. More specifically, the application of hydraulic pressure, although relatively easily realizable in the laboratory, creates a two-dimensional stress field, as shown in Figure 2. Therefore the conclusions drawn are not directly comparable to the respective ones of the experiments with uniaxial loading. Especially in the case of anisotropic materials (like the ones of the present study), it is impossible to define which one of the two stresses is responsible for the failure and therefore it is not possible to determine the critical value, since the direction at which failure will appear is not *a priori* known.

On the contrary, the application of an axial force is especially difficult from a practical point of view (as it will be seen in the next paragraph), but the results obtained are directly usable without reductions and additional assumptions.

Experimental difficulties of the direct tension experiment

In the present study the second procedure (direct tension) was adopted. The most important difficulties stated above

are summarized as following: (1) The nature of the materials under study renders the gripping of the specimens, with the aid of conventional friction grips through compression loads, extremely difficult. In fact, since it is impossible to form “gripping heads” to the specimens (“dog-bone” specimens), it is given that the failure will appear in the portion of the specimen which is inside the grips or in their immediate vicinity. However, in this area the stress field is strongly triaxial and therefore the results obtained are invalid and should be rejected. On the other hand, the limited chances to obtain long specimens in combination with the low friction coefficient between the external surfaces of the specimens (intestines) do not allow the use of pulley-shaped grips, in which the holding force emanates from the friction of a number of successive layers of the material rolled around the periphery of the pulley. (2) The extremely low force which is necessary for the fracture of even intact and healthy specimens, which according to international literature is estimated at the value of a few tenths of Newton^[14], renders the conventional arrangements of applying axial tension practically useless. (3) The nature of the specimens under study, which are twisted and bended around different axes, due to adhesion formation around the anastomotic area, renders the measurements of length changes and therefore of reduced deformations (strains, ϵ) almost impossible. (4) Finally, the nature of the intestines once again, which under torsion are “self-configured” into the form of plane plates, results in an interaction between the walls of the specimens, making difficult the reduction of the external loads into stresses (σ). Another factor making the situation more difficult is the non-constant thickness of the specimens throughout their length and their perimeter, which does not allow us to calculate the effective area of the loaded intestine.

In order to confront these difficulties in the present experimental study, the following procedures were adopted.

Gripping the specimens

A specific gripping system was designed, consisting of a pair of light metallic pins of cylindrical cross-section of diameter equal to 5 mm, with rounded head which permits easy entrance of the intestine in the pin, without injuring the specimen walls, reducing thus the time required for the in-situ preparation of the specimens (Figure 3). The pins are grooved at their mid-length and a suture which holds the specimens in place is rolled up in this groove. The upper part of the pins is drilled through the thickness and the specimen is suspended through this hole from the upper plate of the loading frame. At the same time, the second pin is fixed to the immobile plate of the frame.

The suspension and fixing of the pins is achieved with the aid of circular rings. In this way the maximum possible number of degrees of freedom is given to the specimen making possible the self-alignment and the “untwisting” of the intestine during tension without external limitations and therefore without, as much as possible, the development of parasitic tensions and disfigurements.

Despite the low total weight of the specimens gripping system (about 0.12 N), it was deemed appropriate to add the weight of the lower half, which is suspended

Figure 3 The gripping system consisting of a pair of light metallic pins. The grooves at which the intestine is gripped are indicated by the arrows.

and therefore sustained by the specimen, at the value of the final failure load, taken into consideration that these values are relatively comparable (the mean value of the failure load, as it was obtained from a series of preliminary experiments is equal to about ranges between 1.00 N and 2.20 N).

The load application system

After the rejection of loading through the application of dead weights (water or lead grains), due to the induction of vibrations and oscillations, a special load cell of capacity of 5 N and sensitivity of 10^{-3} N was used attached in a stiff electrical loading frame (Instron). This frame was selected, apart from its robustness, because it provides the ability of choosing the load application speed between wide ranges (from 0.5 mm/min to 500 mm/min). This characteristic of the frame is very important in case biological materials are to be studied, since their mechanical behavior exhibits viscoelastic nature, which is strongly dependent on the strain rate induced (de/dt).

In the first phase of the experimental project an especially low tension speed (1 mm/min) was selected, and therefore the loading can be considered as static or at least quasi-static. As a result the overall duration of each test usually exceeds 10 min. It is planned, in a second phase, to study the effect of loading rate by employing dynamic or quasi-dynamic protocols.

Calibration of the apparatus

Before starting the main series of experiments, a number of preliminary tests were carried out, in order to define the range of the expected values of both the failure load and the elongation of typical specimens, and to calibrate the apparatus in the specific range of values.

The calibration of the loads was achieved with the safest method of the suspension of standardized (certified) weights from the load cell. Both the absolute reading values of the load cell as well as their linearity at the range of the expected loads were checked. The deviations detected for the absolute values of the loads did not exceed in any case the limit of 0.2% set by the “Quality Assurance System” of the Laboratory of Testing and

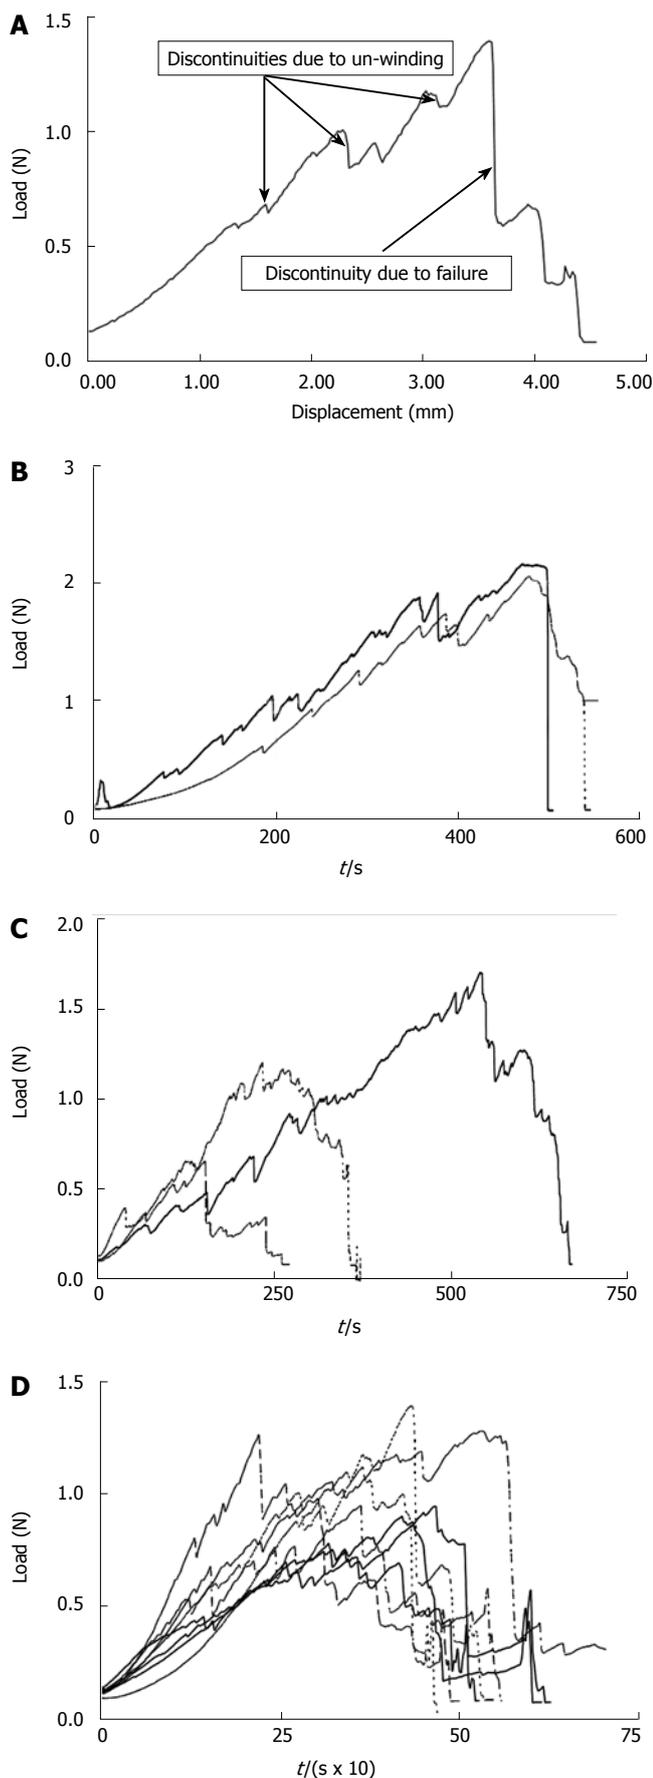

Figure 4 Load versus time and displacement diagrams for characteristic tests. **A:** Load versus displacement for a typical test of the preliminary series; **B:** Load versus time using intact specimens from healthy rats; **C:** Load versus time using specimens from healthy rats after colonic anastomosis; **D:** Load versus time using specimens from non-healthy rats after colonic anastomosis.

Materials of the National Technical University of Athens (NTUA/LTM), as it is described in the respective “Quality Assurance Manual” according to ISO9000/2000 system.

On the other hand, the linearity of the values of the loading cell in relation to the respective ones of the standard weights exceeded 99.8% for the whole range of interest, as it was concluded from a linear interpolation in the experimental data, using the least square method.

The calibration of the readings of the load frame for the displacements was achieved with the aid of three LVDT’s (Linear Voltage Displacement Transducers), which have been verified with a standard micrometric vernier of an accuracy of 1 μm . Apart from the absolute values of the displacements, the parallel of the motion of the loading frame was also checked. The deviations detected did not exceed in any case the limits set by “Quality Assurance System” of the NTUA/LTM. Finally, the time recording device of the data acquisition and storage system was also calibrated with the aid of a prototype chronometer. The deviations were not measurable.

Data acquisition and storage system

The data to be recorded during the experiments include the values of the load as a function of the time [$P = P(t)$] and the values of the displacement of the moving plate of the loading frame also as a function of time [$\Delta s = \Delta s(t)$]. The data acquisition system includes a special multi channel “bridge” (National Instruments, type SCXI-1000), with the ability of adjusting the sampling rate. The system includes, also, a personal computer with suitable commercial software (LabVIEW-8). From the functions $F = F(t)$ and $\Delta s = \Delta s(t)$ recorded, one can eliminate the time obtaining the function of the applied force as a function of the displacement induced and therefore as a function of the elongation of the intestine, i.e. $F = F(\Delta s)$.

After the preliminary experiments, it was deemed appropriate to add to the data acquisition system a video device, in order to monitor the specimen during the experiment in a mode synchronous to the recording of the values of the load and the displacement. This was considered necessary, since the records of the load versus presented oscillations, due to two different reasons: (1) The “un-twisting” of the twisted parts or the “un-folding” of the folded parts of the intestine, which lead to a sudden length increase of the specimen, and therefore to instantaneous unloading, that is to a fall in the recorded load, as it is shown characteristically in the diagram of Figure 4A. (2) Local failures of parts of the specimen and especially in the case of anastomosed intestines failure of the anastomotic area itself or of directly neighboring areas, due to the tearing of the material from the anastomotic suture.

Since one cannot distinguish between these two discontinuities of the $F = F(t)$ diagram, the synchronous video-recording of the experiment was considered necessary. In this way it is possible to locate the discontinuities of the diagram due to the “un-twisting” or to the “un-folding” of the specimen, until the discontinuity due to the anastomotic failure or failure of its immediate neighboring area. Therefore the loading corresponding to this discontinuity can be safely considered as the crucial anastomotic failure load.

RESULTS

Three different classes of specimens were tested using the system described in the previous paragraphs.

The first one included a number of “intact” specimens, i.e. specimens from healthy rats without anastomoses. The results of these tests are to be used as a measure that will permit the characterization of the quality of the anastomosis, at least from the point of view of mechanical strength. Two characteristic examples of these tests are shown in Figure 4B. The data obtained from these tests for the failure force exhibited very small scattering (as it was perhaps expected) and the average value was of the order of:

$$F_{cr}^{intact} = 2.09 \text{ N} \pm 0.6 \text{ N}$$

Taking into account that the thickness of the wall of the intestine of the rats after the 8th week of their life is stabilized to about 1.1 mm while its perimeter varies in the range 9-12 mm^[16], it is concluded that the tensile failure strength of the “intact” specimens ranges between:

$$160 \text{ kPa} \leq \sigma_{fail}^{intact} \leq 210 \text{ kPa}$$

The second class of experiments included the control tests, namely it was carried out using specimens obtained from healthy rats but after having been subjected to colon anastomoses. The scattering of this series of tests was obviously higher compared to that of the “intact” specimens and it was considered necessary to study the acceptability of the results based on statistical experiments. The Chauvenet criterion was adopted and a number of tests were excluded from the analysis. In Figure 4C the results of three tests of this series are shown, corresponding to the ones with the lowest and highest acceptable failure forces and to a third one with failure force almost equal to the average value. The average value for the failure force was determined equal to:

$$F_{fail}^{control} = 1.35 \text{ N} \pm 0.42 \text{ N}$$

Similarly the failure strength ranges between:

$$100 \text{ kPa} \leq \sigma_{fail}^{control} \leq 135 \text{ kPa}$$

It can be concluded that the present procedure for the anastomotic operation results in a decrease of the mechanical strength of the colonic segments under study of the order of only 35% in comparison to the intact specimens.

As a final step, a third series of tests was carried out with specimens obtained from non-healthy rats after having been subjected to colon anastomotic surgery. It was strange to observe that the scattering of the results was rather lower in this case and the application of the Chauvenet criterion yielded the exemption of only one test. A number of characteristic tests of this class experiments is shown in Figure 4D. The average value for the failure force, for this series of tests was determined equal to:

$$F_{fail}^{non-healthy} = 1.09 \text{ N} \pm 0.19 \text{ N}$$

In this case failure strength ranges between:

$$82 \text{ kPa} \leq \sigma_{fail}^{non-healthy} \leq 110 \text{ kPa}$$

The decrease of the mechanical strength compared to the intact specimens is of the order of about 50%, while if the comparison is carried out on the basis of the results of the control tests, is of the order of about 19%.

DISCUSSION

Wound leakage, the major concern for every surgeon performing intestinal anastomosis, is considered a multifactorial process, upon which many factors act, accelerating or inhibiting its metabolic pathway^[17,18]. Numerous clinical entities and metabolic abnormalities can alter the course of tissue repair. Amongst them diabetes mellitus, hypothyroidism, immunocompetence, infection and other diseases are proven to be detrimental to anastomotic healing, while other factors like the surgical technique, advanced age, malnutrition, obesity, inadequate perfusion and/or oxygenation are considered risk factors for impaired wound healing^[19-22].

Taking the 5th post-operative day as a crucial time point upon which anastomotic failure is mostly recognized in clinical practice, the authors tried to give a measure of the anastomotic strength by taking advantage of its mechanical behavior. While both bursting pressure and tensile strength are used to describe the mechanical properties of viscoelastic materials like the ones under study, the authors preferred to evaluate the second and correlate it to the healing of colonic anastomosis. This is because tensile strength appears to be a better standard to evaluate the biological aspects of healing. Tensile strength is an important determinant of anastomotic strength, in contrast to the bursting pressure, which can evaluate the overall anastomotic integrity, but may reflect healing less accurately.

The authors in this paper described not only a system for gripping the specimens, the load application, the data acquisition and storage system, but also a detailed view of the theoretical background behind the forces applied in the tissues under study, as well as the experimental difficulties of the direct tension experiment.

The values of the load as a function of the time [$P = P(t)$] and the values of the displacement of the moving plate of the loading frame also as a function of time [$\Delta s = \Delta s(t)$] were recorded, giving the load versus the displacement curve for each measurement and therefore providing the recorded discontinuities due to the anastomotic failure.

While the tests performed were used only for a preliminary series of measurements, since the number of specimens was relatively small, significant conclusions can be made regarding wound strength and tissue regeneration. The decrease of the axial force required causing mechanical failure from 2.09 N in case of the “intact” specimens to about 1.35 N for the control tests and to 1.09 N for the specimens from non-healthy rats is an excellent index of the quality of the anastomotic operation. Of course, a larger number of measurements need to be carried out, so as to provide a more rigid approach to tissue leakage, its quantitative expression through the tensile strength experiments, and its clinical correlations with pathological entities that delay wound healing or with factors that promote anastomotic integrity and repair.

Abstract

AIM: To study the morphological positive expression of atrial natriuretic peptide (ANP)-synthesizing cells and ultrastructural localization and the relationship between ANP-synthesizing cells and microvessel density in the stomach of rats and to analyze the distribution of the three histologically distinct regions of ANP-synthesizing cells.

METHODS: Using immunohistochemical techniques, we studied positive expression of ANP-synthesizing cells in rat stomach. A postembedding immunogold microscopy technique was used for ultrastructural localization of ANP-synthesizing cells. Microvessel density in the rat stomach was estimated using tannic acid-ferric chloride (TAFC) method staining. Distribution of ANP-synthesizing cells were studied in different regions of rat stomach histochemically.

RESULTS: Positive expression of ANP-synthesizing cells were localized in the gastric mucosa of rats. Localization of ANP-synthesizing cells identified them to be enterochromaffin cells (EC) by using a postembedding immunogold electron microscopy technique. EC cells were in the basal third of the cardiac mucosa region. ANP-synthesizing cells existed in different regions of rat stomach and its density was largest in the gastric cardiac region, and the distribution order of ANP-synthesizing cells in density was cardiac region, pyloric region and fundic region in mucosa layer. We have also found a close relationship between ANP-synthesizing cells and microvessel density in gastric mucosa of rats using TAFC staining.

CONCLUSION: ANP-synthesizing cells are expressed

INTRODUCTION

Since atrial natriuretic peptide (ANP) was isolated from atrium by de Bold *et al* in 1981^[1-3], brain natriuretic peptide (BNP), C-type natriuretic peptide (CNP), dendroaspis (DNP), micrurus natriuretic peptide (MNP), and ventricular natriuretic peptide (VNP) have been found in succession. They distribute not only in the heart but all over the body^[4-10]. ANP regulates a variety of physiological functions, including natriuresis, diuresis and vasodilation. Three types of natriuretic peptide receptors for ANP, BNP and CNP have been identified, for example, natriuretic peptide receptor type A (NPR-A), type B (NPR-B) and type C (NPR-C). NPR-A has guanylate cyclase activity and mediates the biological functions of ANP through the synthesis of cGMP^[2]. NPR-A preferentially binds ANP and BNP, but has a low affinity for CNP. Although ANP is synthesized primarily in the heart as a cardiac hormone, in fact ANP and its receptor are expressed in numerous extracardiac tissues, e.g., lung, thymus, gastrointestinal tract, suggesting a possible role as a regional regulator acting as an autocrine and/or paracrine regulatory peptide^[11,12]. Our previous study indicated that NPR existed in different regions of gastric mucosa and its density was the largest in rat gastric antrum, and NPR significantly inhibited spontaneous contraction of gastric smooth muscles in rats, guinea-pigs and humans^[13-16]. However, the distribution of ANP-synthesizing cells and the relationship between the distribution of ANP-synthesizing cells and microvessel density in gastric tissues have not been identified. It is also not clear about the ultrastructural localization of ANP-synthesizing cells in rat stomach. Therefore, in the present

study, the morphological distribution and ultrastructural localization of ANP-synthesizing cells were identified under postembedding immunoelectron microscopy. The relationship between distribution of ANP-synthesizing cells and microvessel density was investigated using histochemical techniques in rat stomach.

MATERIALS AND METHODS

Animals

Wistar rats (obtained from the Experimental Animal Center of Yanbian University College of Medicine) of either sex weighing 300-350 g were anaesthetized by a lethal dose of abdominal cavity injection of pentobarbital sodium (30 mg/kg), and the abdomen of each rat was opened along the midline. Because the rat stomach demonstrates significant regional differences in structure, we separated the stomach into three regions: the fundic or fundus, the cardiac, and the pyloric region or antrum (Figure 1).

Immunohistochemistry

Freshly excised atria and stomach were fixed in 40 g/L formaldehyde fixative and embedded in paraffin. Sections (5 μ m) were deparaffinated, rehydrated and incubated with 3 mL/L hydrogen peroxide in methanol for 15 min at room temperature to block endogenous peroxidase activity. After washing twice with phosphate-buffered saline (PBS) for 5 min, tissue sections were incubated at 37°C for 20 min with blocking solution. Sections were incubated at 37°C for 2 h with primary antibody: rabbit anti-rat ANP (sc-20158, Santa Cruz Biotechnology, Inc) 1:100. After washing twice with PBS (0.01 mol/L, pH7.4) for 10 min, tissue sections were incubated at 37°C for 30 min with biotin-anti-rabbit IgG. After washing two times in PBS for 5 min, the sections were incubated with streptavidin-HRP for 30 min. Then the sections were washed two times in PBS for 5 min, and they were incubated with metal-enhanced 3,3-diaminobenzidine solution for 15 min, then they were washed two times in distilled water and counterstained with hematoxylin. Negative control sections were incubated with normal rabbit serum instead of primary antibody. The positive staining for ANP-synthesizing cells was expressed as red brown granules, which were mainly located in cell cytoplasm under microscopy. At least 5 high-power (\times 400 field) fields were chosen randomly for cell counting. The ratio of the positive distribution of ANP-synthesizing cells was calculated by dividing the number of positive cells over the total number of cells, and was expressed as percentage, counted, analyzed under the CMIAS image analysis system (Beihang, China), and photomicrographed (Olympus PM-10AD).

Immunoelectron microscopy

Freshly excised stomach mucosal and atrial myocyte blocks of 1 mm³ were fixed in 100 mL/L paraform fixative, then dehydrated and embedded in Epon-812 resin. Sections (70 nm) were incubated with 100 mL/L hydrogen peroxide in methanol for 30 min at room temperature. After washing

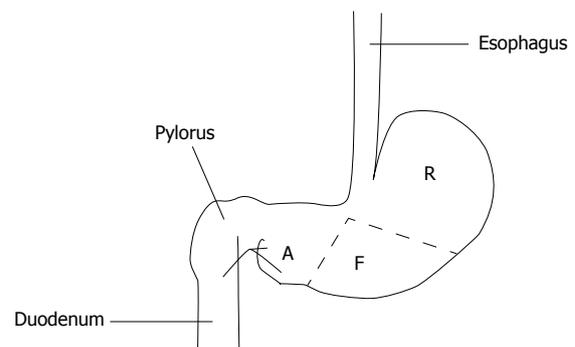

Figure 1 Different histological regions of rat stomach. R: Cardiac region or cardia; F: Fundic region or fundus; A: Pyloric region or antrum.

twice with distilled water for 10 min, tissue sections were incubated at room temperature for 1h with blocking solution, then tissue sections were incubated at 4°C for 36 h with primary antibody: rabbit anti-rat ANP (sc-20158, Santa Cruz Biotechnology, Inc) 1:90. Negative control sections were incubated with normal rabbit serum instead of primary antibody. After washing twice with PBS for 5 min, tissue sections were incubated at room temperature for 1h with protein A-10 nm colloidal gold labeled (Product Number P 6730, Sigma). After washing twice with distilled water for 5 min, sections were stained with urenyl acetate and lead citrate each for 5 min and were observed under a JEM-1200EX, 80 kv electron microscope (JEOL, Japan).

Histochemistry

Freshly excised rat stomach tissues were fixed with paraformaldehyde fixative (formaldehyde: potassium = 1:4) for 36 h at 4°C. The tissues were then fixed in 3% potassium bichromate fixative for 12 h at room temperature, and embedded in paraffin. Histochemical staining for ANP-synthesizing cells were performed by the chromaffin staining method. After washing twice with distilled water for 20 min, the tissues were stained at room temperature for 20 min with 10 g/L toluidine solution, and after washing twice with distilled water for 10 min, the sections were stained at room temperature for 15 min with 1% saffron solution. Chromaffin staining was made for enterochromaffin cells. The positive cells were expressed as brown granules, which were mainly located in cell cytoplasm under microscopy. At least 5 high-power (\times 400 field) fields were chosen randomly for cell observation. The area density of the distribution of positive cells was calculated under light microscopy (Olympus BH-2, Japan) and with CMIAS image analysis system (Beihang, China).

Tannic acid-ferric chloride method

The gastric microvessels in density and distribution were investigated in different regions of stomach. After the experimental rats (Wistar rats) were perfused with 20 g/L compound fixative tannic acid solution, the stomachs were taken out and cut into frozen sections, then these sections were immersed in 20 g/L ferric chloride solution at room temperature for 20 min to reveal the microvessels. The blood vessels were revealed distinctively by TA-Fe staining

method, and observed under the light microscope, the density and distribution of the vessels were measured and analyzed by CMIAS image analysis system. Density and distribution of microvessels in rat stomach was determined according to the KONG Xiang-yu *et al* method^[13], and was photomicrographed (Olympus PM-10AD, Japan).

Statistical analysis

Data were expressed as mean \pm SD. The two-tailed χ^2 test was used to examine the correlation between ANP-synthesizing cells and microvessel density. Statistical significance was estimated by *t* test. Differences were considered significant when $P < 0.05$. All the calculations were performed using SPSS11.0.

RESULTS

Expression of ANP-synthesizing cells in rat stomach

Immunohistochemical positive expressions of ANP-synthesizing cells were exhibited in paraffin sections of atria and stomach. As a positive control, ANP-synthesizing cells showed intense positive expression in atrial myocytes cytoplasm (as red brown granules, Figure 2A). ANP-synthesizing cells also were positively expressed in gastric mucosa and the positive granules localized to cytoplasm in the basal portion of cardiac region glands (Figure 2B and C). In negative controls, complete absence of positive staining for ANP-synthesizing cells was observed when normal rabbit serum was substituted for primary antiserum (Figure 2D). The morphological shape of the individual ANP-synthesizing cells was variable, exhibiting round, pyramidal, flask shapes, etc. The general epithelial morphology of these cells was typically endocrine in appearance, and most immunoreactivity was localized to the basal portion of the stomach of rats. Negative staining for ANP-synthesizing cells was detected in the lamina propria, submucosa, and smooth muscle. Expression of ANP-synthesizing cells was exhibited in different regions, and its density was the largest in gastric cardiac region, and the density order of ANP-synthesizing cells was cardiac region (cardia) > pyloric region (antrum) > fundic region (fundus) in mucosal layer.

Identification of ANP-synthesizing cells in rat stomach

The gastric mucosa was cut into ultra-thin sections, and situs ultrastructural detection of ANP-synthesizing cells was carried out using a post-embedding immunogold labeling technique under electron microscope. The localization of immunogold labeling was displayed in the endocrine granule of the enterochromaffin (EC) cell of DNES (disperse or diffuse neuroendocrine system, DNES) in gastric gland of rat (Figure 3A). These results indicate that the EC cell synthesizes and secretes ANP in gastric mucosa of rat. In negative control, complete absence of positive staining was observed when normal rabbit serum was substituted for anti-ANP antiserum (Figure 3B and C).

Distribution of ANP-synthesizing cells in rat gastric mucosa

The distribution of ANP-synthesizing cells (enterochromaffin cell, EC cells) in the different regions of gastric mucosa was detected using a histochemical

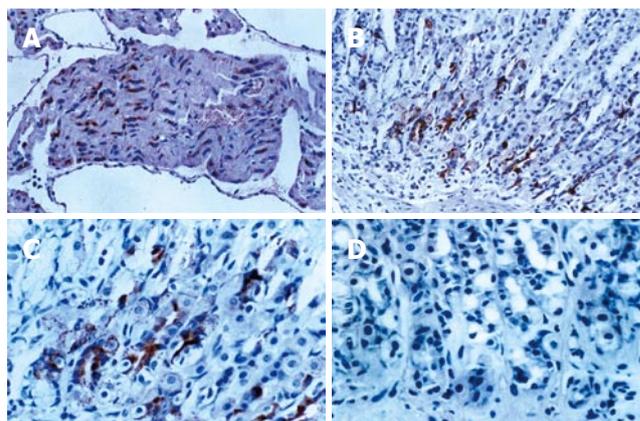

Figure 2 A: As a positive control, atrial myocytes show intense positive cytoplasmic staining for ANP (IHC \times 200); B: Positive staining for ANP is localized to cytoplasm of mucosal cells in cardiac glands (IHC \times 200); C: Positive staining for ANP is localized to cytoplasm of mucosal cells in cardiac glands (IHC \times 400); D: As a negative control, complete absence of staining is observed when normal rabbit serum is substituted for ANP (IHC \times 400).

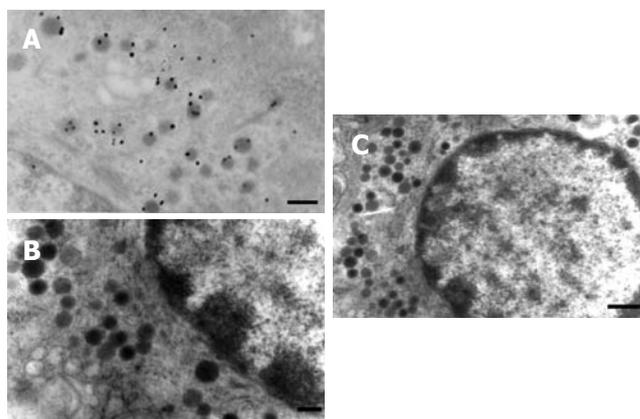

Figure 3 A: localization of immunogold labeled in the endocrine granule of the enterochromaffin cell (TEM \times 20 000, bar = 200 nm); B: Negative control, complete absence of immunogold labeled in the endocrine granule of enterochromaffin cells when normal rabbit serum was substituted for anti-ANP antiserum (TEM \times 20 000, Bar = 200 nm); C: Normal enterochromaffin cells in gastric mucosa (TEM \times 15 000, Bar = 500 nm).

technique in rats. It has been identified that EC cell is only a chromaffin cell in the rat gastric mucosa. Consecutive serial sections were stained for chromaffin and the chromaffin granules (brown granules) were localized in EC cell cytoplasm. Negative staining for chromaffin granules were detected in the lamina propria, submucosa, smooth muscle and in negative control. The distribution of EC cells in gastric mucosa was further examined using chromaffin staining. There were three histologically distinct regions (cardia, fundus and antrum) in the distribution of EC cells in rats. EC cells existed in mucosal layer, and its density was the largest in gastric cardia, and the density order of EC cells (mean \pm SD) was cardiac region > pyloric region > fundic region in mucosal layer (Figure 4, $n = 18$).

Relationship between ANP-synthesizing cells and microvessel density

The microvessels were stained successfully with tannic acid-ferric chloride^[13,14]. Microvessel of gastric mucous

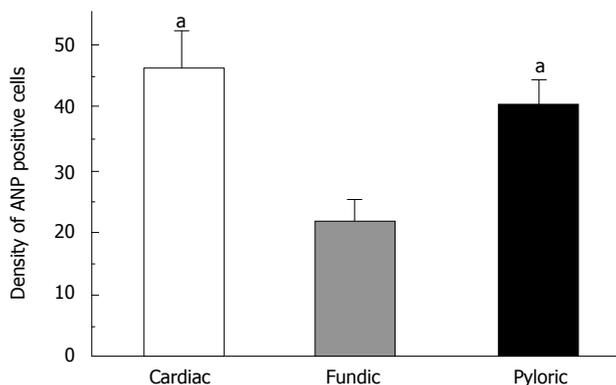

Figure 4 The distribution of ANP synthesizing cells in different regions of stomach in rats. Mean ± SD. ^a*P* < 0.05 vs fundic region.

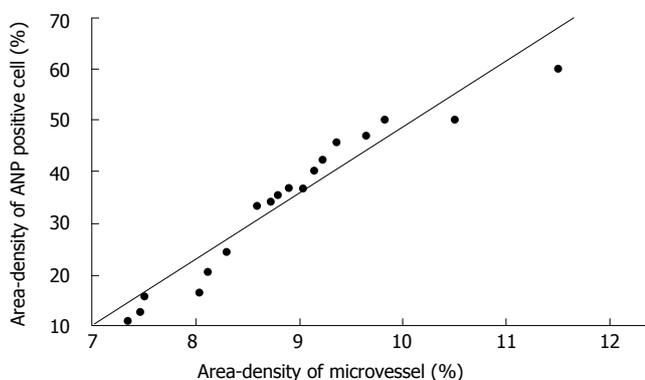

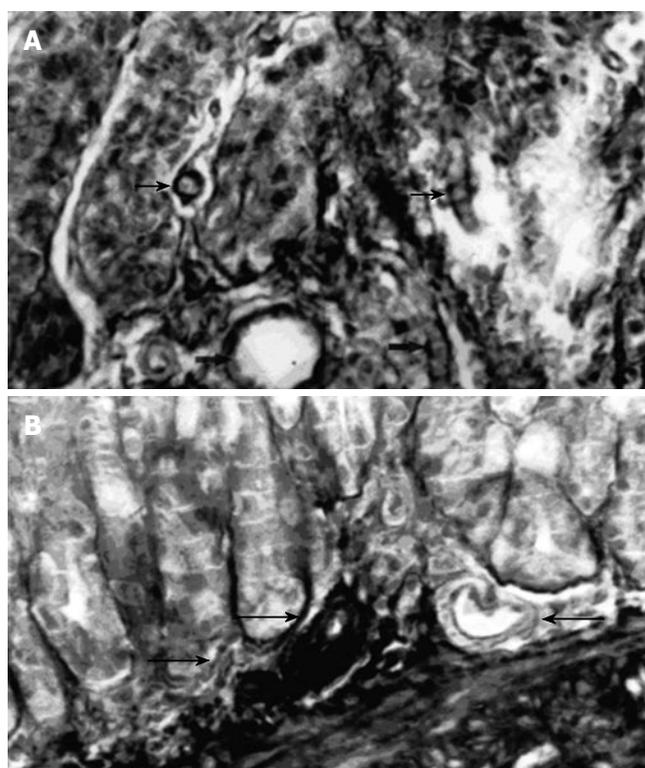

Figure 5 **A:** Microvessels of gastric mucous were in wiggled way and cut into different cross-sections, it could be clearly observed in distinct three-dimensions (arrow) (TA-Fe × 400); **B:** Some branch arteries from the large vessels run into the basal glands of the gastric mucosa (arrow) (TA-Fe × 400); **C:** There is positive significant relationship between the positive rate (%) of ANP-synthesizing cells and microvessel density (%) in cardiac region mucosa of rats (*r* = 0.53, *P* < 0.05, *n* = 18).

were in wiggled way and cut into different cross-sections, it could be clearly observed in distinct three-dimensions (Figure 5A). Some microvessels could be found scattering among antral mucosa, some branch arteries from the large vessels ran into the basal glands of the gastric mucosa (Figure 5B). The density of microvessels varies from position to position, the more basal glands were found, the more microvessel were distributed in rat gastric mucous. In order to study the relationship between the positive rate of ANP-synthesizing cells and microvessel density in rat gastric mucosa, the data were analyzed by statistical analysis system of SPSS11.0. There was a positive significant relationship between the positive rate of ANP-synthesizing cells and microvessel density in antral mucosa of rats (*r* = 0.53, *P* < 0.05, Figure 5C).

DISCUSSION

In the present study, the ANP-expressing myoendocrine cells are most concentrated in the right atrium, to a lesser extent in the left atrium, and almost absent in the left ventricle^[15,16]. We have demonstrated that morphological distribution and ultrastructural localization of ANP-synthesizing cells in rat stomach. ANP may have tissue-specific functions within the stomach. Gower *et al*^[17-19] and Vuolteenaho *et al*^[20-24] earlier found that the rat antrum contains ANP-synthesizing cells coupled with our present results that similar immunostaining patterns are produced when antibodies are directed to antral mucosal cells, however we have also found positive cells in cardiac and fundus. EC cells are an abundant type of enteroendocrine cells that contain serotonin and occur throughout the gastrointestinal tract^[25-28]. On the basis of differences in the ultrastructural appearance of the secretory granules, it has been suggested that EC cells are comprised of several subpopulations and store different peptides. Three types of EC cells for EC₁, EC₂, and EC_n have been identified. EC cells have two types of open-type enterochromaffin cell and close-type enterochromaffin cell. Open-type enterochromaffin cells have a large basolateral compartment in contact with the basal lamina and a narrow apical process that allows access to the lumen. Results from our present immunohistochemical studies demonstrate that at least some of the ANP-synthesizing cells in the gastric mucosa are exposed to both basal lamina and lumen, and under immunoelectron microscopy they were identified as EC cells that synthesized ANP.

Guo HS *et al*^[29] using a radioautograph technique, detected the distribution of NPR (NPR-A) in different regions of rat stomach. NPR-A existed in both the mucosal layer and muscle layer, and the distribution order of NPR-A in density being antrum > body > fundus in muscle layer. Rambotti *et al*^[30] found that NPR-A extensively distributed in many tissues, for example, the bladder of the toad, bullfrog brain, in fetal ovine pulmonary vascular and in the porcine coronary. The present study confirmed that NPR-A also existed in the stomach of rat and the density was largest in gastric antrum in rats, demonstrating the presence of NPR-A transcripts in the extracts of gastric fundus and natriuretic peptide-induced cGMP production

localized to the parietal, mucus secreting cells in the fundus, and pyloric glands, as well as gastric smooth muscle cells^[29]. Because ANP is known to stimulate gastric acid secretion and relaxes gastric smooth muscle, the effect of atrial natriuretic factor (ANF) on exocrine pancreatic secretion and the possible receptors and pathways involved were studied *in vivo*^[29,31]. These findings suggest that these effects of ANP may be direct. Rambotti *et al*^[31] demonstrated the presence of ANP-induced guanylate cyclase activity on both apical and basolateral surfaces of mucosal cells within the pyloric glands of rat stomach, ANP released locally into the gastric lumen could target lumenally directed receptors, suggesting that ANP may help control a “negative feedback” system within the stomach of increasing acid secretion and simultaneously enhance mucus production to protect the lining of the stomach from the effects of acid. This would provide for a regulatory mechanism to ensure that the acid produced after a meal does not injure the mucosal surface of the stomach. Previous studies also indicated that vagus nerve regulated many functions of NP, for example, ANP promoted gastric acid secretion^[32], ANP and endothelin-1 (ET-1) might prevent renal dysfunction during the progression of congestive heart failure(CHF) through the cGMP pathway in dogs^[33,34], ANP can reduce the pre-load and after-load in normal and failing hearts^[35-37]. ANP each inhibited the growth of the human pancreatic adenocarcinomas *in vivo* and three of the four peptide hormones of the tumors (up to 49%)^[10,38,39]. The intestinal tract is a target organ for ANP, characterized by various biologic activities, immunoreactivity, as well as specific binding sites for ANP^[40,41].

In conclusion, our result demonstrated that ANP-synthesizing cells exist in gastric mucosa of rats, and its density was largest in gastric cardiac region, and the distribution order of ANP-synthesizing cells in density was cardiac region > antrum > fundic region in mucosa layer. This result shows that it is the EC cells in the gastric mucosa that synthesize ANP. This basolateral plasma membrane is juxtaposed to microvessel *via* ANP which could enter the circulation from the stomach. The density of microvessel varies from position to position at the EC cell concentrating area, and the relationship between distribution of ANP-synthesizing cells and microvessel density was investigated in the stomach of rats.

Abstract

AIM: To determine the prevalence of osteoporosis in a cohort of patients with Crohn's disease (CD) and to identify the relative significance of risk factors for osteoporosis.

METHODS: Two hundred and fifty-eight unselected patients (92 M, 166 F) with CD were studied. Bone mineral density (BMD) was measured at the lumbar spine and hip by dual X-ray absorptiometry. Bone formation was assessed by measuring bone specific alkaline phosphatase (BSAP) and bone resorption by measuring urinary excretion of deoxypyridinoline (DPD) and N-telopeptide (NTX).

RESULTS: Between 11.6%-13.6% patients were osteoporotic (T score < -2.5) at the lumbar spine and/or hip. NTX levels were significantly higher in the patients with osteoporosis ($P < 0.05$) but BSAP and DPD levels were not significantly different. Independent risk factors for osteoporosis at either the lumbar spine or hip were a low body mass index ($P < 0.001$), increasing corticosteroid use ($P < 0.005$), and male sex ($P < 0.01$). These factors combined accounted for 23% and 37% of the reduction in BMD at the lumbar spine and hip respectively.

CONCLUSION: Our results confirm that osteoporosis is common in patients with CD and suggest that increased bone resorption is the mechanism responsible for the

INTRODUCTION

Osteoporosis is now recognised as a common complication of inflammatory bowel disease (IBD) and in particular Crohn's disease (CD). Estimates of prevalence vary but those studies employing the World Health Organisation^[1] diagnostic criteria (a bone density 2.5 or more standard deviation units below the mean value for young adults) report rates of 13%-42%^[2-4]. The pathogenesis of osteoporosis in patients with CD is likely to be multifactorial. Most, but not all studies, have found an association with current or cumulative corticosteroid use^[5-11] but other factors such as disease duration^[3,4,12] low body weight or body mass index^[4,10,13] calcium and vitamin D deficiency^[12,14] small bowel involvement or resection^[10] smoking^[13] gender and increasing age^[13] have been implicated. At the molecular level *in vitro* studies have demonstrated that serum from children with CD can inhibit bone formation suggesting that pro-inflammatory cytokines such as IL-6 may be involved^[16].

The mechanism of bone loss is poorly understood. Normal bone in healthy adults is in a state of equilibrium, the rate of osteoblastic bone formation equaling the rate of bone resorption by osteoclasts. Biochemical markers of bone turnover such as deoxypyridinoline (DPD) and cross-linked N-telopeptides of type 1 collagen (Ntx), both markers of bone resorption, and osteocalcin and bone specific alkaline phosphatase (BSAP), markers of bone formation, are now available and have been used in several studies examining the possible mechanisms of bone loss in patients with IBD. Consistent findings are raised levels

of either DPD or Ntx^[2,4,12,17,18] suggesting increase in bone resorption, although there is also evidence that bone formation is reduced^[7].

The aim of this cross sectional study was to determine the prevalence of osteoporosis in an unselected group of patients with CD and to identify the relative importance of possible risk factors and the mechanism of bone loss.

MATERIALS AND METHODS

Patients were recruited from the IBD register at the Freeman Hospital and additionally from the Royal Victoria Infirmary, also in Newcastle-upon-Tyne, and the Queen Elizabeth Hospital, Gateshead. Patients were under the care of either surgical or medical gastroenterologists and all fulfilled at least two of four diagnostic criteria (histological, radiographic, endoscopic and surgical)^[19]. Patients were contacted by letter inviting them to participate in the study and were then seen at the Freeman Hospital by either SB or NT. Those who did not attend were sent one further letter reminding them to do so. We included patients aged between 25 and 70 years only and excluded women who were pregnant or planning a pregnancy because of the potential risk from exposure to ionizing radiation during bone densitometry.

A questionnaire was completed with the patient detailing age, tobacco and alcohol consumption, fracture history, and in women, reproductive and menstrual history. Details of duration and site of disease, corticosteroid use (expressed as number of months on corticosteroids), relevant surgical history and drug history were obtained at interview and by careful scrutiny of the medical notes. Height and weight was measured immediately prior to bone densitometry and these figures were used to calculate body mass index [weight/height², (kg/m²)]. The study was approved by the Newcastle-upon-Tyne Joint Ethics Committee.

Bone mineral density measurements

Bone mineral density (BMD) was measured at the lumbar spine (L1-L4) and left hip (total hip) by dual X-ray absorptiometry (Hologic Inc. QDR 2000, Waltham, MA.). The coefficient of variation (CV) is 0.7% at the lumbar spine and 1.0% at the hip^[20]. BMD results are expressed as an areal density in g/cm², but have been compared with the manufacturer's mean value for young adults and for normal people of the same age and sex to give T scores and Z scores respectively. The T score is the number of standard deviation units above or below the mean value for young adults of the same sex, whilst the Z score is the number of standard deviation units above or below the age related mean value. The WHO has defined osteopenia as a T score of < -1 but > -2.5, whilst osteoporosis is defined as a T score of -2.5 or lower. These diagnostic criteria are not necessarily thresholds for intervention, particularly for patients on oral corticosteroids, where a higher T score of -1.5 would be more appropriate^[21].

Biochemical measurements

Serum and urine samples were taken between 2 pm

and 4 pm. The serum was immediately centrifuged and all samples were stored at -30°C. Serum calcium and phosphate levels were measured using standard methods on an Olympus 600 automated system, (interassay CVs for calcium and phosphate are < 1% and < 2% respectively).

Bone resorption was assessed by measurement of the urinary excretion of free DPD and Ntx with values expressed as a fraction of urinary creatinine excretion. Free DPD was measured by competitive immunoassay (Chiron Diagnostics Corporation, MA) (interassay CV < 8%). The reference range (manufacturer's data), is 3.0-7.4 nmol DPD/mmol creatinine for females aged 25-44 years and 2.3-5.4 nmol DPD/mmol creatinine for males aged 25-55 years. Ntx was measured by enzyme-linked immunoabsorbant assay ("Osteomark", Ostex International, Seattle, WA) with results expressed as bone collagen equivalents (BCE). The reference ranges for men and women (manufacturer's data) are 3-51 and 5-65 nm/mmol creatinine respectively (interassay CVs < 9%). Bone formation was assessed by measurement of serum BSAP using enzyme-linked immunoabsorbant assay (Metra BioSystems, Southampton, UK) (interassay CV < 6%).

Patients with a T score of -1.5 or less at either the lumbar spine were investigated further to look for other secondary causes of osteoporosis, such as vitamin D deficiency with secondary hyperparathyroidism, thyroid disease and, in men, hypogonadism.

Intact parathyroid hormone (PTH) levels, reference range 12-72 ng/L, were measured by immunometric assay (Immulite Intact PTH, Diagnostics Products Corporation, Los Angeles, CA.) (interassay CV < 5%). Vitamin D levels (25 OH Cholecalciferol and 25 OH Ergocalciferol), normal range 10-50 nmol/L, were assayed by high performance liquid chromatography performed at the Department of Clinical Biochemistry, Royal Victoria Infirmary, Newcastle-upon-Tyne (interassay CV < 12%). Thyroid stimulating hormone (TSH), reference range 0.3-4.1 Mu/L, was measured with a two site immunoassay using direct chemiluminometric detection and monoclonal/polyclonal antibodies (interassay CV < 4.0%). Testosterone, reference range 9-20 nmol/L, was measured with a competitive immunoassay using direct chemiluminometric detection and a polyclonal antibody (interassay CV < 5.2%) and Sex Hormone Binding Globulin (SHBG) was measured with a non-competitive immunoradiometric assay (interassay CV < 5%). The free androgen index (FAI), reference range > 3 nmol/nmol, was calculated after dividing the total serum testosterone by the SHBG level.

Statistical analysis

The results are expressed as means \pm SD. Comparison between group means was analysed using Student's unpaired *t*-test or, where data was not normally distributed, the Mann-Whitney *U*-test. Multiple regression analysis was performed to determine independent risk factors for osteoporosis and the adjusted χ^2 value was calculated to determine the proportion of the variability in BMD attributable to these factors. The chi-squared test was used to compare incidences. A *P* value of < 0.05 was taken to be statistically significant. Analyses were made with

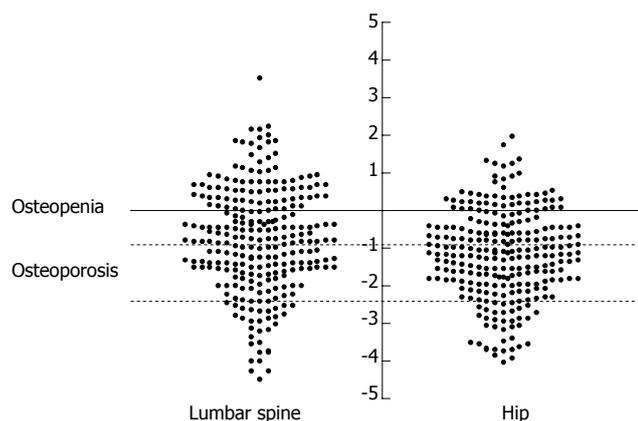

Figure 1 Scatterplot of T score values at the lumbar spine and hip. Dotted lines represent thresholds for diagnosis of osteopenia and osteoporosis.

GraphPad Prism (GraphPad Software Inc) and Minitab (Version 12.1, Minitab Inc).

RESULTS

Two hundred and sixty five patients responded to the correspondence inviting them to participate in the study, 7 of whom subsequently declined a DXA scan and were excluded from the study. The remaining 258 patients who completed the study comprised 92 men and 166 women. One patient was of Asian descent, the remainder were white. Table 1 summarizes the clinical characteristics of the group.

Fractures

Twenty-eight patients (10.9%) reported a low trauma fracture in adulthood, 12 of whom had osteoporosis. The fractures comprised wrist^[9], forearm^[5] and vertebral^[3] fractures, and 2 each of metatarsal, rib and ankle fractures, 1 patella fracture and 1 femoral fracture. Two patients had more than 1 fracture and in 5 cases the fracture site was not documented.

Site of disease

One hundred and ninety two (74.4%) had small bowel disease, of which 70 (27.1%) had small bowel involvement alone and 88 (34.1%) had small bowel involvement with colonic disease. Forty-nine (18.9%) had isolated colonic disease. At least one partial small bowel resection had been performed in 135 (52.3%) of the study group, whilst 92 (35.7%) had undergone partial or total resection of their large bowel.

Drug treatment

Seventy-seven patients (29.8%) were currently taking oral corticosteroids and 152 (58.9%) had previously taken corticosteroids to treat complications of their Crohn's disease. Forty-five patients (17.4%) were currently taking bone active treatment (calcium supplementation with or without vitamin D, bisphosphonates or hormone replacement therapy).

Table 1 Patient characteristics (means \pm SD)

<i>n</i>	258 (166 F, 92 M)
Age (yr)	44.5 (\pm 11.5)
Postmenopausal women	67 (25.9%)
Fractures	28 (10.8%)
BMI (kg/m ²)	24.7 (\pm 4.6)
Disease duration (yr)	14.3 (\pm 9.5)
Small bowel involvement	192 (74.4%)
Small bowel resection	135 (52.3%)
Large bowel involvement	173 (67.1%)
Current CS use	77 (29.8%)
Previous CS use	152 (58.9%)
Duration CS use (mo)	51.0 (\pm 68.4)
Current smokers	83 (32.2%)

CS: Corticosteroids.

Table 2 Bone mineral density measurements (means \pm SD)

Site	BMD (g/cm ²)	Z score	T score	Osteopenia	Osteoporosis
Lumbar spine	0.975 \pm 0.15	-0.308 \pm 1.39	-0.795 \pm 1.39	77 (29.8%)	30 (11.6%)
Total hip	0.860 \pm 0.15	-0.675 \pm 1.19	-1.181 \pm 1.21	67 (25.9%)	35 (13.6%)

Osteopenia defined as a T score of < -1 but > -2.5 ; Osteoporosis defined as a T score of < -2.5 .

Tobacco and alcohol consumption

Eighty-three patients (32.2%) were current cigarette smokers and 78 (30.2%) previous smokers. The mean alcohol intake was 8.8 units/week among the 160 patients who drank alcohol.

Bone mineral density measurements

Measurements at the lumbar spine were available in 257 patients, one was excluded because of the presence of surgical metal rods. Measurements at the hip were available in all 258 patients. Details of the mean BMD measurements, mean Z and T scores and numbers with osteopenia or osteoporosis are presented in Table 2 and Figure 1. Employing the WHO definitions for osteoporosis 18 (6.9%) were osteoporotic at both the lumbar spine and hip. Considering each site separately, 30 (11.6%) patients were osteoporotic at the lumbar spine (16 men, 14 women) and 35 (13.6%) were osteoporotic at the hip (15 men, 20 women) whilst a further 77 (29.8%) and 67 (25.9%) fulfilled the criteria for osteopenia at the lumbar spine and hip respectively.

Risk factors

Table 3 shows the characteristics of those patients with and without osteoporosis. At the lumbar spine patients with osteoporosis had a significantly lower BMI and had taken corticosteroids for longer, there was a trend towards longer disease duration although this did not achieve statistical significance. Patients with osteoporosis at the hip were also likely to have a lower BMI, a longer disease duration and have taken corticosteroids for longer. Gender, small bowel resection and current tobacco use were not

Table 3 Comparison of those patients with and without osteoporosis and the presence of risk factors (mean \pm SD)

Risk factor	Osteoporosis at lumbar spine and/or hip (<i>n</i> = 47)	Osteopenia/normal bone mineral density (<i>n</i> = 211)	<i>P</i>
BMI (kg/m ²)	22.3 \pm 0.6	25.2 \pm 0.3	< 0.0001
Corticosteroid use (mo)	92.3 \pm 16.7	34.9 \pm 3.2	< 0.0001
Disease duration (yr)	18.9 \pm 1.5	13.2 \pm 0.6	< 0.005
Age (yr)	46.8 \pm 11.4	44.1 \pm 11.5	NS
Small bowel resection (Y/N)	10/37	105/106	NS
Current smokers (Y/N)	11/36	72/139	NS
Gender (M/F)	22/25	69/142	NS

Analysis was made using Student's unpaired *t*-test or the chi-squared test where appropriate; NS: not significant.

significant factors at either site. One hundred and fifteen patients (44.6%) had T scores < -1.5 at the lumbar spine and/or hip respectively. The T score within individual patients was significantly lower at the hip compared with the lumbar spine (-0.80 \pm 1.4 *vs* -1.19 \pm 1.2, *P* < 0.0001).

Postmenopausal women had significantly lower T scores at the lumbar spine and hip compared to the rest of the study group (-1.30 \pm 0.16 *vs* -0.63 \pm 0.10 and -1.5 \pm 0.14 *vs* -1.09 \pm 0.09 respectively, *P* < 0.0001). This group accounted for 11/29 patients with osteoporosis at the spine and 12/34 at the hip.

Multivariate analysis was used to determine independent predictors for the presence of osteoporosis. Variables included in the analysis were age, sex, disease duration, BMI, length of corticosteroid use and small bowel resection. Of these, decreasing BMI (*P* < 0.001), length of corticosteroid use (*P* = 0.003) and male sex (*P* = 0.009) were the significant predictors at the lumbar spine whilst at the hip decreasing BMI (*P* < 0.001), number of months treatment with corticosteroids (*P* < 0.001), increasing age (*P* = 0.003) and male sex (*P* = 0.005) were significant. The adjusted *r*² value was calculated using sex, age, sex-age interaction, corticosteroid use, BMI, disease duration and small bowel resection (Yes/No) as variables. These factors accounted for 22.9% and 37.2% in the variability in BMD at the lumbar spine and hip respectively.

Biochemical measurements

The mean levels of total calcium and phosphate were normal (Table 4). There was no difference in the means between those with and those without osteoporosis. Patients with a T score < -1.5 at either site (*n* = 115) were investigated further and in these patients mean levels of TSH and 25 OHD were normal (Table 5). Five patients had abnormal thyroid function tests. Two patients had low TSH levels, one of these patients was on thyroid replacement therapy. Of the three with above normal TSH levels, none had abnormal tri-iodothyronine or thyroxine levels. Two patients had biochemically low 25 OHD levels (defined as < 10 mol/L) but neither was associated with a secondary hyperparathyroidism or with small bowel resection. Mean PTH levels were normal. PTH levels were raised (defined as twice the upper limit

Table 4 Biochemistry and markers of bone formation and resorption in patients with osteoporosis at either the lumbar spine and/or hip compared with those patients with osteopenia or normal bone density (mean \pm SD)

BSAP (11.6-30.6 μ g/L)	19.7 \pm 1.4	18.6 \pm 0.6	NS
DPD/creat (2.3-7.4 nmol/mmol)	5.8 \pm 1.0	5.6 \pm 0.4	NS
Ntx/creat (3.0-65.0 BCE)	63.7 \pm 9.5	40.6 \pm 3.6	<i>P</i> < 0.05

BSAP: Bone specific alkaline phosphatase; DPD: Deoxypyridinoline; Ntx: N-telopeptides of type 1 collagen; BCE: Bone collagen equivalents; NS: not significant.

Table 5 Results of further bone biochemistry carried out in patients with a T score of -1.5 or less at either the lumbar spine and/or hip (*n* = 115) (mean \pm SD)

Biochemistry (normal range)	T score < -1.5 at lumbar spine and/or hip (<i>n</i> = 115)
TSH (0.3-4.1 Mu/L)	1.7 \pm 1.1
25 OHD (10-75 nmol/L)	45.1 \pm 22.3
PTH (10-72 ng/L)	46.9 \pm 62.7
¹ Testosterone (9-20 nmol/L)	13.5 \pm 6.7
² FAI (> 0.3 nmol/nmol)	0.4 \pm 0.1

¹Testosterone and SHBG only measured in men (*n* = 46). ²Free Androgen Index (Testosterone/SHBG).

of normal) in 4 patients (range 153-613 ng/L) including one patient with severe nutritional deficiency (BMI < 19, anaemia, hypoalbuminaemia) and severe osteoporosis who nevertheless had normal 25 OHD levels because of treatment with vitamin D metabolites prior to inclusion into the study. Three men (6.5%) were hypogonadal (FAI < 3 nmol/nmol).

Markers of bone formation and bone resorption

Mean levels of BSAP and DPD were normal, there was no significant difference between those with and without osteoporosis (Table 4). Ntx levels, although also within the normal range, were significantly higher in patients with osteoporosis.

DISCUSSION

We have shown that between 11%-13% of a large group of unselected patients with CD are osteoporotic. A low BMI, increasing exposure to corticosteroids and male sex appear to be the main predictors of osteoporosis which, however, only explain between 23%-37% of the variability in BMD described. Biochemical abnormalities such as 25 OHD deficiency and secondary hyperparathyroidism,

thyroid disease and male hypogonadism are unusual but our results suggest that increased bone resorption, assessed by measuring urinary excretion of DPD and Ntx, may be the mechanism responsible for the accelerated bone loss.

As far as we are aware this is the largest and most complete study to date of the prevalence of osteoporosis in patients with CD. Our group of patients are unselected and we consider a reasonable representation of the larger population with CD in terms of age and sex composition, duration and site of disease and disease management. Between 11%-13% of our patients are osteoporotic. This is perhaps lower than we expected given the unselected nature of our patient group, although broadly in keeping with other studies using the same diagnostic criteria. However, there is considerable discrepancy among prevalence rates reported. This may be accounted for by differences in the site and the methods used to measure BMD and in the patient groups studied, some for example including those not only with CD but also ulcerative colitis (UC), where there is evidence that osteoporosis is less common^[9,22]. Other groups have studied patients with CD only and have selected further to exclude for example those currently taking corticosteroids or at risk of metabolic bone disease^[2].

We found that the BMD at the hip was significantly lower compared with the lumbar spine. This has previously been reported in other studies of patients with IBD^[2-4,8,23] and is also the pattern of bone loss seen in other chronic inflammatory conditions such as rheumatoid arthritis. It may reflect a degree of degenerative change at the lumbar spine in some of the older patients which would spuriously elevate the density at that site, however we attempted to minimise this effect by excluding patients over the age of 70.

The clinical significance of osteoporosis is the increased susceptibility to fracture and the resulting morbidity and mortality. Eleven percent of our patients reported low trauma fractures, mostly of the upper limb. We did not perform radiography in our patients and, as many vertebral fractures are asymptomatic, the true prevalence is likely to be higher. Relatively few studies have examined fracture incidence and prevalence in adult patients with CD. In retrospective studies, fracture prevalence, calculated from plain radiography of symptomatic areas or self reported fracture, varies between 7% and 27%^[7,9,12]. Vestergaard *et al*, in a study of over 800 patients with IBD^[24] conducted *via* a postal questionnaire, reported an increased relative risk of low trauma fractures in women with CD of 2.5. The increase in fracture risk was seen mostly in premenopausal women but men with CD or patients of either sex with UC were not at increased risk of fracture. The authors speculated that their findings were due to a number of factors including the increased use of continuous corticosteroids and more severe systemic inflammation in CD compared to UC, and possible hypogonadism in the female patients.

A low BMI, increasing corticosteroid use, male sex and increasing age were independent risk factors in predicting those with osteoporosis although these factors together only accounted for between 20%-40% of the variability in BMD. Low body weight or a low BMI have been reported

in other studies of patients with IBD to be significant risk factors for osteoporosis, particularly at the peripheral sites^[4-6,9-11]. Within the context of IBD a low BMI may merely reflect severe inflammatory disease and/or malabsorption although there is also good evidence that low body mass *per se* is a significant factor in determining BMD^[25,26].

In our study male sex was a significant independent risk factor for osteoporosis at both sites. Most groups have reported no significant differences between the sexes and only one study has looked specifically at men with IBD. Robinson *et al* studied the hormone profile of 48 men with CD^[27] and found biochemical evidence of hypogonadism in only 3 patients, 2 of whom had osteopenia. Three of our male patients (6.5%) with reduced BMD were hypogonadal. This is lower than we might expect given the number of our patients taking corticosteroids which might lead to suppression of gonadotrophin, testosterone and SHBG levels.

The role of corticosteroids in the pathogenesis of osteoporosis in patients with IBD is complex. Whilst some studies have shown a clear relationship between lifetime corticosteroid dose and vertebral fracture rate^[5] or low BMD other studies have suggested that BMD is unrelated to corticosteroid use^[2,3,6,10]. There have been several prospective studies examining the role of corticosteroids in the rate of bone loss^[22,28,29]. The largest of these^[28], a longitudinal study of over 100 patients with IBD and bowel resection who were followed up for a mean period of over 5 years found no relationship between bone loss and corticosteroid use. The conflicting results are probably a reflection of the heterogeneity of patient groups studied and the complex relationship between disease severity, systemic inflammation and treatment with corticosteroids.

We found a very low prevalence of biochemical abnormalities in our patients and in particular no evidence of 25 OHD deficiency and secondary hyperparathyroidism or of a correlation with small bowel resection. The relationship between 25 OHD levels and BMD in patients with IBD is not clear cut. Andreassen^[14] reporting one of the higher prevalences of 25 OHD deficiency (44%) in a study of 115 patients with CD nevertheless found that this, in combination with PTH levels, only accounted for 4% of the variation in BMD. Croucher^[30] described the histomorphometric findings in a study of 19 patients with IBD, all of whom had osteoporosis and 16 of whom had undergone bowel resection. Despite only one patient having a low 25 OHD level, there was evidence of a mild mineralisation defect in the patient group compared with the control group, although none had the classical changes associated with osteomalacia.

Biochemical markers of bone formation and resorption are now widely available and have been used to predict bone loss^[31,32] and response to treatment of osteoporosis with bisphosphonates and hormone replacement therapy (HRT) in postmenopausal women^[33,34]. Several studies have now used these markers in exploring the mechanisms of bone loss in patients with IBD. Most studies have demonstrated an increase in bone resorption without a corresponding increase in bone formation^[2,4,12,17,18]. Our results, which show that patients with osteoporosis

have significantly higher levels of Ntx (but not DPD), would support the results of these studies. It should be noted however that the mean value, even in patients with osteoporosis, was within the normal range and their role in predicting those patients with IBD at risk of losing bone is not clear. Pollak *et al* has reported that increased levels of Ntx predicted rates of bone loss in a prospective study of 36 patients with IBD over a period of 2 years^[35] whilst Schulte^[29] found that they did not discriminate between those with accelerated bone loss and those without. Despite this they may be useful in targeting those patients to treat more aggressively with anti-resorptive agents such as HRT and the bisphosphonates.

Management of patients with IBD and osteoporosis remains problematic although recent guidelines for the management and prevention of osteoporosis in IBD have been published in the United Kingdom^[36]. The guidelines recommend, amongst other measures, that all patients currently taking corticosteroids and with a T score of < -1.5 should be prescribed a bisphosphonate in addition to vitamin D supplementation. This study highlights the potential clinical implications of this strategy, as approximately 20% of our patients would require bisphosphonates if these guidelines were implemented.

We have also established that although there are several significant risk factors for osteoporosis, these combined explain less than 40% of the variability in BMD. A genetic predisposition to osteoporosis complicating other chronic conditions such as rheumatoid arthritis has been described^[37]. This may be of significance in our population and merits further investigation.

ACKNOWLEDGMENTS

We would also like to acknowledge the following consultant staff who gave permission for their patients to be involved in the study: Dr. R Lendrum, Dr. M Hudson, Dr. J Mansfield, Dr. K Oppong, Dr. C Record, Mr. P Wright and Mr. P Hainsworth as well as the patients who participated in the study.

Abstract

AIM: To investigate the role that the hedgehog (Hh) signaling pathway, which includes sonic hedgehog (Shh), Patched (Ptc), Smoothed (Smo) and Gli-1, plays in human gastrointestinal stromal tumors (GISTs).

METHODS: Surgically resected specimens from patients with GISTs, leiomyomas and schwannomas were examined by immunohistochemical staining for aberrant expression of hedgehog signaling components, Shh, Ptc, Smo and Gli-1, respectively.

RESULTS: In GISTs, 58.1% (18 of 31), 77.4% (24 of 31), 80.6% (25 of 31) and 58.1% (18 of 31) of the specimens stained positive for Shh, Ptc, Smo and Gli-1, respectively. In leiomyomas, 92.3% (12 of 13), 92.3% (12 of 13), 69.2% (9 of 13) and 92.3% (12 of 13) stained positive for Shh, Ptc, Smo and Gli-1, respectively. In schwannomas, 83.3% (5 of 6), 83.3% (5 of 6), 83.3% (5 of 6) and 100% (6 of 6) stained positive for Shh, Ptc, Smo and Gli-1, respectively. Immunohistochemistry revealed that the expressions of Shh and Gli-1 were significantly higher in leiomyomas than in GISTs ($P < 0.05$, respectively). Shh expression strongly correlated with the grade of tumor risk category and with tumor size ($P < 0.05$, respectively). However, the expressions of Ptc and Smo did not correlate with histopathological differentiation.

CONCLUSION: These results suggest that the Hh signaling pathway may play an important role in myogenic differentiation and the malignant potential of human in-

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are rare mesenchymal tumors of the gastrointestinal tract that occur from the esophagus to the anus, including in the omentum, mesentery and retroperitoneum^[1]. Small GISTs are often detected during surgery for other conditions, gastroscopy or routine X-ray^[1,2]. Some GISTs present with bleeding, perforation, pain, obstruction or a combination of these symptoms^[3,4]. These tumors have a wide clinical spectrum from benign, incidentally detected nodules to malignant tumors^[1] categorized into four risk groups: very low, low, intermediate and high^[5]. Traditionally, primary mesenchymal spindle cell tumors of the gastrointestinal (GI) tract have been uniformly classified as smooth muscle tumors (e.g., leiomyomas, cellular leiomyomas, or leiomyosarcomas). Tumors with epithelioid cytologic features have been designated as leiomyoblastomas or epithelioid leiomyosarcomas^[6]. Recently it has been postulated that GISTs originate from Cajal cells in the gastrointestinal tract, which are thought to be pacemaker cells that regulate intestinal motility^[7,8]. Thus, GISTs differ from leiomyomas and schwannomas, which are of mesenchymal cell origin. Further, GISTs are characterized by the frequent expression of the bone marrow leukocytic progenitor cell antigen CD34^[9] and c-kit proto-oncogene^[8]. They also show a remarkable variability in their differentiation, and can be roughly divided into four major categories according to the phenotypic features of the tumors: smooth muscle type, neural type, combined

type and uncommitted type^[10]. Although there are many studies about GISTs, their mechanisms of tumorigenesis, progression and differentiation remain unknown.

The Hedgehog (Hh) gene was initially isolated from *Drosophila* embryonic segments, and it controls patterning of imaginal disc-derived adult structures such as the eye, the appendage and the abdominal cuticle^[11-13]. The mammalian Hh gene, Sonic hedgehog (Shh), is important in the patterning of many tissues and structures such as gastrointestinal epithelium, neurons, smooth muscle tissue, and bone^[14-16]. Shh also plays a role in the development of the endoderm, mesoderm and ectoderm^[17,18]. The response to the Hh signal is controlled by two transmembrane proteins, the tumor-suppressor Patched (Ptc) and the proto-oncogene Smoothed (Smo)^[13]. Smo is a member of the seven transmembrane-receptor family^[11] and its activity is suppressed by the twelve-span transmembrane Ptc. Hh stimulation releases this inhibition, leading to Smo activation of a transcriptional response^[13]. Downstream targets of the pathway in vertebrates include Gli-1, which is associated with development of basal cell carcinomas and medulloblastomas^[19].

There is ample evidence suggesting that the Hh signaling pathway is involved in tumor growth and differentiation. However, there are no studies that examine the expression of Hh pathway components in stromal tumors of the GI tract or the role of the Hh signaling pathway in the etiology of these tumors. Therefore, the purpose of this study is to investigate the expression of Hh pathway signaling proteins in intestinal stromal tumors.

MATERIALS AND METHODS

Tumor classification and selection

A total of 31 GISTs (all cases of stomach), 13 leiomyomas (5 cases of oesophagus, 6 of stomach and 2 of large intestine), and 6 schwannomas (5 cases of stomach and 1 of large intestine) were obtained from patients at Nagasaki University Hospital between 1997 and 2004. The tumor sizes of GISTs were 0.8-8.0 cm in diameter, leiomyomas were 0.1-2.5 cm, and schwannomas were 0.6-4.0 cm. In this study, GISTs were defined and selected as those tumors expressing both c-kit and CD34 surface antigens. Further, we classified smooth muscle actin expressing tumors into smooth muscle (M) type GISTs, S-100 protein expressing tumors into neurogenic (N) type GISTs, both smooth muscle actin and S-100 protein expressing tumors into committed type GISTs, and those expressing only c-kit and CD34 into uncommitted (UN) type GISTs^[10]. And we classified histomorphologically tumors with epithelioid cell form into epithelioid cell (EP) type GISTs, spindle cell form into spindle cell (SP) type GISTs, both epithelioid and spindle cell form tumors into mixed (MIX) type GISTs^[20].

We also categorized GISTs into four groups according to their malignant potential^[5]. The number of mitoses was determined by counting 50 high-power fields ($\times 400$) under Nikon (Tokyo, Japan) E400 microscope. Leiomyomas were defined and selected as tumors expressing smooth muscle actin and not expressing c-kit

and CD34. Schwannomas were defined and selected as tumors expressing S-100 protein and not expressing c-kit and CD34. Tumor identification and classification were determined by two independent pathologists (T. Nakayama and I. Sekine), and cases of questionable diagnosis were omitted from this study.

Immunohistochemical staining

Formalin-fixed paraffin-embedded tissues were cut into 4- μ m sections, deparaffinized in xylene, and rehydrated in PBS. Deparaffinized sections were preincubated with normal bovine serum to prevent non-specific binding and then incubated overnight at 4°C with an optimal dilution (0.1 mg/L) of a primary polyclonal goat antibody against human Shh (N-19), Ptc (C-20), Smo (N-19) and Gli-1 (C-18). Each antibody was from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA, USA). The slides for Shh, Ptc, Smo and Gli-1 were then sequentially incubated with an alkaline phosphatase-conjugated donkey anti-goat immunoglobulin antibody, and the reaction products were visualized using a mixture of 5-bromo-4-chloro-3-indolyl phosphate and nitroblue tetrazolium chloride (BCIP/NBT; BRL, Gaithersburg, MD, USA). Primary antibodies preabsorbed with excess antigen peptides or recombinant protein were used as negative controls. Basal cell carcinoma tissue served as the internal positive control for Shh, Ptc, Smo and Gli-1 immunoreactivity. Immunohistochemical analyses were performed independently by two investigators (T. Nakayama and A. Yoshizaki). Shh, Ptc, Smo and Gli-1 expression was classified into two categories depending on the percentage of cells stained: -, 0%-15% positive tumor cells; +, > 15% positive tumor cells.

Statistical analysis

The Stat View II program (Abacus Concepts, Inc., Berkeley, CA, USA) was used for statistical analyses. Analyses comparing the levels of Shh, Ptc, Smo and Gli-1 expression were performed using the Mann-Whitney, Kruskal-Wallis and Spearman's tests. $P < 0.05$ was taken as significant.

RESULTS

The results from the immunohistochemical analysis of Hh pathway components in human intestinal stromal tumors are summarized in Table 1. Shh expression was heterogenous and localized to the cytoplasm of cells in GISTs (Figure 1A). Ptc and Smo were localized to the cytoplasm and cell membrane, and Gli-1 was localized to the cytoplasm and nucleus of GIST tumor cells (Figure 1B-D). Immunohistochemical stainings of Hh pathway components in leiomyomas and schwannomas are shown in Figures 2 and 3, respectively. The four proteins of the Hh pathway that we examined showed patterns of expression similar to that observed in GISTs. While only 58.1% (18 of 31) of the GISTs were positive for Shh, nearly all leiomyomas and schwannomas were positive (92.3%, 12 of 13, $P < 0.05$). The following results were observed for the other proteins: 77.4% (24 of 31), 92.3% (12 of 13), 83.3% (5 of 6) of the GISTs, leiomyomas

ponents in GISTs classified by cellular differentiation are shown in Table 1. In this study there was no case where a GIST was composed of combined types of cellular differentiation. The following results were observed: Shh was detected in 56.3% (9 of 16), 57.1% (4 of 7) and 62.5% (5 of 8) of UN, M and N type of GISTs; Ptc was detected in 87.5% (14 of 16), 71.4% (5 of 7) and 62.5% (5 of 8), respectively; Smo was detected in 93.8% (15 of 16), 85.7% (6 of 7) and 50.0% (4 of 8), respectively; and Gli-1 was detected in 68.8% (11 of 16), 57.1% (4 of 7) and 37.5% (3 of 8), respectively. The expression of Smo was significantly lower in UN type than in N type of GISTs (*P* < 0.05). And immunohistochemical analyses of Hh pathway components in GISTs classified histomorphologically by cellular form are shown in Table 1, also. In all GISTs, 16.1% (5 of 31) of EP cell type, 9.7% (3 of 31) of MIX cell type and 74.2% (23 of 31) of SP cell type were included, respectively. Each Hh pathway component was detected variably in different cellular type of GISTs. However, there was no correlation between the expression of Hh pathway components and cellular subtype of GISTs.

The results from immunohistochemical analysis of Hh pathway components with regard to the malignant potential of GISTs are summarized in Table 2. There were no correlations between mitosis counts and the expression levels of Hh pathway components. In contrast, the results suggested that lower levels of Shh expression correlated with lower risk GIST categories (*P* < 0.05) and smaller tumor sizes (*P* < 0.05).

DISCUSSION

Recent studies have shown that the Hh pathway plays important roles in cell differentiation, tissue patterning and embryonic development^[16,19,21]. However, the role of the Hh pathway in human intestinal stromal tumors is still unclear. We investigated the expression of Shh, Ptc, Smo and Gli-1 in three types of intestinal stromal tumors (GISTs, leiomyomas and schwannomas) using immunohistochemical techniques. Our data demonstrated

that Shh and Gli-1 were expressed at higher levels in leiomyomas than in GISTs. It suggested that Shh and Gli-1 expressions were correlated with myogenic differentiation. However, in the subclassification of GISTs, myogenic differentiation did not show expression of Shh or Gli-1. Moreover, the consequence of low expression of Smo in neuronal GISTs is not clear yet. Thus, future studies will address the role of the Hh pathway in the differentiation of intestinal stromal tumors.

Abrogation of the Hh pathway can also lead to tumorigenesis. In this pathway, Gli-1, which is involved in controlling cell proliferation and angiogenesis, is a key target of oncogenic action^[3,13,22]. Loss of function Ptc mutations and gain of function Smo mutations are mechanisms of tumorigenesis in many types of tumors such as basal cell carcinomas, medulloblastomas, astrocytomas, small cell lung carcinomas and pancreatic cancers^[19,23-25].

In this study, the expression of Shh correlated with low risk categories and small tumor sizes. It suggests that expression of Shh reduces the risk of malignant GISTs. Normally, Shh releases Smo from Ptc suppression to induce Gli-1 expression and activation^[11,13,19]. Then by a negative feedback mechanism, Gli-1 suppresses the expression of Shh, which results in decrease of Gli-1. However, our data did not show a concomitant decrease in Gli-1 expression in tumors that expressed low levels of Shh. In fact, we observed high Gli-1 levels in larger tumors of high risk categories when Shh expression was low. We hypothesize that Gli-1 may be up-regulated by pathways other than the Hh pathway, or mutation of an Hh pathway component could disrupt the feedback mechanism in high risk GISTs. Thus, future studies will examine Hh pathway components in high risk GIST tumors. In conclusion, our study suggests that the Hh pathway may play important roles in myogenic differentiation and the malignant potential of human intestinal stromal tumors.

In recent studies, mutations affecting c-kit that cause constitutive tyrosine kinase activation have been shown to be important for the pathogenesis of GIST^[26,27]. Joensuu

et al.^[28] reported a patient in whom Imatinib (STI-571, Gleevec), a tyrosine kinase inhibitor, was effective against a GIST. And Imatinib has been proven to be remarkably efficacious in heavily pretreated GISTs patients with advanced disease in phase III clinical trials^[29]. The expression of the Hh pathway is upregulated by the activation of tyrosine kinase through the epidermal growth factor pathway^[30], and may be upregulated by the c-kit/tyrosine kinase pathway.

ACKNOWLEDGMENTS

We are grateful to Mr. Toshiyuki Kawada (Nagasaki University Graduate School of Biomedical Sciences, Molecular Pathology) for his excellent immunohistochemical assistance.

Abstract

AIM: To evaluate pegylated interferon alpha2a (PegIFN- α 2a) in Egyptian patients with HCV genotype 4, and the impact of pretreatment viral load, co-existent bilharziasis and histological liver changes on response rate.

METHODS: A total of 73 naïve patients (61 with history of bilharziasis) with compensated chronic HCV genotype 4 were enrolled into: group A (38 patients) who received 180 mg PegIFN-alpha2a subcutaneously once weekly for a year and group B (35 patients) received IFN alpha-2a 3 MU 3 times weekly. Ribavirin was added to each regimen at a dose of 1200 mg. Patients were followed for 72 wk and sustained response was assessed.

RESULTS: Significant improvement in both end of treatment response (ETR) ($P < 0.002$) and sustained response (SR) ($P < 0.05$) was noted with pegylated interferon, where ETR was achieved in 29 (76.3%) and 14 patients (40%) in both groups respectively, and 25 patients in group A (65.8%) and 9 (25.7%) in group B could retain negative viraemia by the end of follow up period. Sustained virological response (SVR) showed a significant negative correlation with age and positive correlation with pretreatment inflammation in patients receiving PegIFN. Viral clearance after 3 mo of therapy was associated with high incidence of ETR and SR ($P < 0.001$), but without significant difference between both forms of interferon. Significant improvement in response was achieved in patients with high grade fibrosis (grade 3 and 4) with PegIFN- α 2a, where SR was seen in 5 out of 13 patients in group A, but none in group B. There was no significant difference in response between

INTRODUCTION

Hepatitis C is comparable to a 'viral time bomb'. The WHO estimates that about 200 million people, 3% of the world's population, are infected with hepatitis C virus (HCV) and 3 to 4 million persons are newly infected each year. The striking genetic heterogeneity of RNA genome of HCV is well recognized. Six major genotypes and over 50 subtypes and minor variants referred to as "quasispecies" are described^[1]. HCV genotype differences seem to be of considerable clinical significance because they affect the responses to antiviral therapy^[2]. HCV genotype 4 appears to be prevalent in the Middle East and Central Africa, where almost 13% of HCV carriers around the world live in the Eastern Mediterranean region. Prevalence rates of HCV genotype 4 ranges from 60% in Saudi Arabia to 90% in Egypt where it has been reported to be frequently associated with cirrhosis and a poor response to interferon (IFN)^[3,4].

Concurrent HCV-genotype 4 infection and schistosomiasis result in a much more severe liver disease than that seen with either disease alone. Luckily, the activity of HCV infection seems to be partially suppressed in such patients^[5]. The effect of such co-infection on hepatic fibrosis and in turn on response to treatment in HCV patients is however, conflicting. While Helal *et al* in 1989^[6] and Shiha *et al* in 2002^[7] reported a lack of enhancement

of hepatic pathology in the schistosomal patients, Hassan *et al* in 2002^[8] suggested that schistosomiasis is an important risk factor involved in enhancement of nitric oxide levels and virus replication, which in turn may aggravate liver cell injury and hence the development of cirrhosis.

It has been reported that treatment with conventional IFN is less effective in patients with genotypes 1 and 4 than in patients with genotypes 2 and 3^[9]. The high rate of HCV turnover coupled with the short half-life of the drug, limits the efficacy of conventional IFN therapy^[10]. Pegylated IFN- α 2a [Peg-IFN- α 2a (40 kDa); Pegasys, Hoffmann-La Roche] is produced by attachment of a 40 kDa branched polyethylene glycol moiety to IFN- α 2a by a stable amide bond. It is characterized by prolonged absorption half-life, restricted volume distribution, and decreased clearance compared to standard interferon, which thus increase its therapeutic efficacy with less frequent doses^[11]. Recent clinical trials have shown that the response to pegylated interferon α 2a plus ribavirin (RBV) therapy for chronic HCV infection is superior to that achieved with standard interferon α 2a plus ribavirin therapy or peginterferon- α 2a alone with a rapid decline in viral load in the first 12 wk, for all HCV genotypes^[12]. Hematological adverse effects in the form of anaemia, neutropenia and thrombocytopenia are the primary laboratory abnormalities experienced during IFN plus RBV combination therapy and may necessitate dose modification and thus potentially impact outcome. This anemia is attributed to both ribavirin dose-dependent hemolysis and direct suppressive effect of interferon on erythropoiesis^[13]. Hematopoietic growth factors may be useful in the management of these side effects.

The purpose of this prospective analysis is to compare the effectiveness and safety of Pegasys (40 kDa) IFN- α 2a once weekly with IFN- α 2a, in compensated HCV genotype 4, in combination with ribavirin. The effect of pretreatment viral load, histological liver changes and schistosomiasis co-infection on response to treatment is also assessed.

MATERIALS AND METHODS

Patients

Adult patients with chronic active hepatitis C as evidenced by positive serological test for HCV-Ab using enzyme linked immunosorbent assay (ELISA) (Ortho Diagnostics, Neckargmun, Germany), detectable serum HCV-RNA by RT-PCR (Amplicor Molecular System, Hoffmann-La Roche, Basel, Switzerland), elevated serum alanine transaminases (ALT) activity more than twice the normal value and histopathological criteria of chronic active hepatitis. Liver histology was classified according to Scheuer score system from 0-4 for both grades (necroinflammation) and stage (degree of fibrosis). Hepatocellular carcinoma was excluded by testing of α -fetoprotein and by ultrasound scanning. None of the female patients was pregnant as evidenced by negative serum pregnancy test. Breast feeders were excluded. All patients had normal serum direct and indirect bilirubin, albumin and creatinine. All patients were genotype 4

detected by the Inno LiPA HCV II assay (Innogenetics Inc., GA, USA). Patients were excluded if co-infected with HBV, HIV. Hemochromatosis, Wilson disease or other causes for chronic liver disease were also ruled out. Other exclusion criteria included neutrophil count $< 1.5 \times 10^9$ /L, platelet count $< 90 \times 10^9$ /L or haemoglobin (Hb) < 100 g/L for female and < 110 g/L for male, positive auto-antibodies including antinuclear antibody (ANA), antimitochondrial antibody (AMA), anti-smooth muscle autoantibody (ASMA), patients with a history of severe psychiatric disease, seizure disorder, organ transplantation, or severe cardiac or pulmonary disease. All patients had normal thyroid function prior to the study and all were either non-diabetics or with controlled blood glucose level with hemoglobin A_{1c} $< 8.5\%$. Patients were excluded if they had clinically significant retinal abnormalities, clinical gout, were a substance abuser (alcohol or I.V. drugs) or showed any medical condition requiring systemic steroids.

Safety assessment

Patients were reviewed in the Hepatology Outpatient Clinic weekly during the first month and monthly thereafter along the course of therapy to check for safety, and then followed for at least 6 mo after discontinuation of treatment to assess for sustained response. Epoetin beta (Recormon[®], Roche) at a dose of 4000 U/weekly for 2 wk was given when Hb level decrease > 30 mg/L or $> 25\%$ from baseline levels. Also Filgrastim (Neupogen[®], Amgen, Inc. F. Hoffmann-La Roche Ltd. Basel) 5 μ g/kg was given once or twice weekly if neutrophils $< 0.7 \times 10^3$ / μ L, while drug was discontinued completely for any patient showing Hb level < 85 g/L, neutrophils $< 0.5 \times 10^9$ /L, platelet $< 50 \times 10^9$ /L, abnormal thyroid function tests, creatinine > 177 μ mol/L or ALT/AST double baseline levels. Patients requiring modification of more than 4 doses were excluded.

Efficacy assessment

The primary efficacy end point was sustained response (SR), defined as undetectable HCV RNA and normal ALT level at the end of follow up (24 wk after discontinuation of treatment). The relapse rate was calculated as percentage of patients with an end-of-treatment response in whom HCV RNA was detectable at wk 72. End of treatment response (ETR) was defined as normalization of ALT and loss of detectable serum HCV RNA at the end of treatment.

Study design

This randomized, controlled clinical trial was conducted from February 2002 to November 2004. The study consisted of a screening phase, which began 2 mo prior to the first dose of the drug under evaluation. Examination established eligibility of patients according to inclusion/exclusion criteria. After a written informed consent was obtained in accordance with the Helsinki Declaration of 1979, 80 patients were randomly assigned at a 1:1 ratio to receive either, subcutaneously, once weekly 180 μ g of peginterferon- α 2a (Pegasys, Hoffmann-LaRoche) or IFN α 2a (Roferon[®], Hoffmann-LaRoche) 3 MU 3 times. Ribavirin 1200 mg at a daily oral dose was added to both

regimens. Throughout the study, patients were monitored for vital signs, weight, adverse events, medication compliance, thyroid function, haematologic parameters, blood chemistry and serum HCV- RNA levels.

Statistical analysis

The data were coded, and processed on an IBM-PC compatible computer using Statistical Packages for Social Sciences (SPSS). Data were expressed as mean and standard deviation (SD) unless otherwise stated. Student-t-test was used to ascertain the significance of difference between mean values of two continuous variables and Mann-Whitney test was used for non-parametric distribution. Chi-Square analysis was performed to test for differences in proportions of categorical variables between 2 or more groups. In 2 × 2 tables, the Fisher exact test (two-tailed) was used instead of Chi-Square, in particular, when sample size was small. One-way analysis of variance (ANOVA) and non-parametric Kruskal Wallis one-way analysis of variance (ANOVA) was employed for comparison of several group means and to determine the presence of significant differences between group means. The Pearson's correlation coefficient was used to evaluate the strength association between two variables. The level $P < 0.05$ was considered as the cut-off value for significance. Multivariate logistic regression analysis was performed.

RESULTS

Seventy-three patients out of 80 completed the study and follow up periods, and were classified into 2 groups: 38 patients received pegylated IFN and ribavirin (group A) and 35 received non-pegylated IFN and ribavirin (group B). Seven patients (2 in group A and 5 in group B) could not continue the study because of severe side effects or intolerability to treatment. Thyroid dysfunction in one patient in each group, intolerability of the drug's side effect in another one in group A and in 2 patients from

group B, in addition to increase of transaminases and thrombocytopenia in 2 patients with cirrhosis in group B were the causes of drug discontinuation. Male gender was predominant in both groups, 31 and 33 respectively. Baseline demographic data and disease characteristics were similar in both groups (Table 1). Thirty-one patients in group A and 30 in group B had a history of bilharziasis treated with either tarter emetic (44 patients) or praziquentel (17 patients). Among these, one had histological pattern of bilharzial granuloma in liver tissue, but none had active bilharziasis prior to treatment.

Patients who received pegylated IFN (29, 76.3%) showed a significant ETR in comparison to those receiving non-peg-IFN (14, 40%) ($P < 0.002$). A significant ($P < 0.05$) improvement in SR was noticed with Peg-IFN, where 25 patients in group A (65.8% of total number of patients who completed the study) and 9 (25.7 %) in group B could retain negative viraemia at the end of follow up period (Table 2). A significant negative correlation between age and sustained response was noted in both groups ($P = 0.015$) without a significant difference between both drugs. There was no correlation between gender, pre-treatment, viraemia or body weight and response rate (Table 3). There was a significant positive correlation between pre-treatment ALT and ETR in patients receiving Peg-IFN but not in patients receiving IFN. Also, a significant positive correlation ($P < 0.05$) was found between stage of hepatic inflammation and response rate in patients treated with peg-IFN, but not with IFN (Table 3). Intent to treat (ITT) analysis showed significant improvement in both of ETR and SR with peg-IFN therapy, where ETR was 72.5% and 35%, respectively, while SR was 62.5% and 22.5% ($P < 0.002$).

Regarding viraemia, there was no significant difference between responders and non-responders in both groups and within the same group. Viral clearance after 12 wk of therapy was associated with high incidence of ETR and SR ($P < 0.001$), but also, without significant difference between both groups. By studying the relation between histopathological activity and response, treatment with peg-IFN showed a significant improvement in response and sustained response in patients with severe fibrosis (grade 3 and 4). Only one patient out of 11 with severe fibrosis showed ETR with conventional IFN therapy and unfortunately relapsed after discontinuation of treatment, while 8 patients out of 13 showed ETR with peg-IFN therapy and 5 of them could retain negative viremia at

¹Group A = PEG-IFN+RBV; ²Group B = IFN + RBV.

72 wk (Table 4). There was no significant difference in response in bilharzial and non-bilharzial patients in both groups, where SR was achieved in 27 patients co-infected with bilharziasis (60.7%) and in 7 cases of HCV alone (58.3%) (Table 5).

With respect to safety and tolerability, peg-IFN was comparable to conventional IFN. Weight reduction was similar in both groups, where the mean reduction was 2.9 \pm 4.3 kg and 2.6 \pm 2.7 kg respectively. After flu-like picture, hematological side effects represented the commonest encountered problem (Table 6). Although anemia was seen in 71.1% and 65.7% in both groups respectively, only 39.5% and 37.1% in both groups developed Hb drop more than 30 mg/L or > 30% of baseline level and required growth stimulating factors (These figures were related only to those patients who completed the study). Two patients from group B with cirrhotic changes were withdrawn because of thrombocytopenia. The proportions of patients withdrawn from treatment because of laboratory abnormalities or other adverse effects were similar in both groups and no new or unexpected adverse effects specific to peginterferon were presented. On multivariate logistic regression analysis, no significant predictive values were noted.

DISCUSSION

Hepatitis genotype is now recognized as the most

important baseline characteristic determining treatment regimen and the most useful predictor of response^[14]. Slow viral dynamics, particularly second-phase decay^[15] and limited effectiveness of IFN in blocking the virion have been implicated in poor response to IFN therapy in hepatitis C genotype 4 patients^[16], which genotype has been described as a difficult-to-treat one. Unfortunately, this is the predominant genotype in the Middle East where large numbers of affected individuals are reported. A great improvement in response has recently been noted in all genotypes after the introduction of pegylated forms of IFN, whether as monotherapy or combined with ribavirin. Data presented in this study further reinforce the superior efficacy of PegIFN/Ribavirin combination therapy in terms of ETR and SVR in HCV genotype 4 infection. This is in accordance with earlier reports (Thakeb *et al* 2004^[17]; Shobokshi *et al* 2004^[18]; and Diago *et al* 2004^[19]). The lower SR noted compared to that reported by Diago *et al*^[19] for western genotype 4 cases (65.8% *vs* 79%) may reflect a difference in sensitivity of genotype 4 subtypes to PegIFN- α 2a. The improved response to PegIFN- α 2a in genotype 4 compared to conventional IFN and PegIFN- α 2a previously reported by us^[20,21] can be attributed, at least in part, to a high and persistent trough serum level of PegIFN- α 2a in the first 4 wk of treatment which led to rapid viral eradication^[22,23], or the recently reported third phase decay with PegIFN- α 2a in the first 1-4 wk of therapy^[24]. Other causes also include

the improved patients' adherence to treatment and the use of erythropoietin and G-CSF, thus overcoming anaemia and neutropenia that have commonly led to halting therapy.

The significant correlation noted in the present study between viral clearance at wk 12 and SVR, regardless of the type of IFN used, confirms a consistent relationship between the rapidity of HCV-RNA suppression and the likelihood of achieving SR^[25,26]. Conversely, patients showing positive PCR at wk 12, all failed to achieve SR regardless of ETR seen in 2 of them. This suggests that a positive PCR at wk 12 in genotype 4 cases might be considered as a strong negative predictor of response.

In terms of pretreatment predictors, only patient's age showed a negative correlation with response rate. This is probably not related to age *per se*, but rather to the age of infection, or in other words, the duration of infection, since older patients are known to develop a higher rate of liver fibrosis^[27]. The presence of cirrhosis has been shown to be independently associated with decreased SVR in HCV infected patients^[28]. In this respect we could demonstrate a superior SR with PegIFN- α 2a over non-pegylated IFN (25.7% *vs* 0%) in both advanced fibrosis and compensated cirrhosis genotype 4 patients. Similar results were reported by Heathcote *et al* in 2000^[29] and Marcellin *et al* in 2004^[30].

In agreement with Tsubota *et al*^[31] and contrary to Picciotto *et al*^[32], we could not find any correlation between pretreatment viral load and SR, which implies that HCV-

RNA levels *per se* are less influential compared to the major impact of genotype that generally determines the rate of SR.

HCV patients co-infected with schistosomiasis exhibited a unique clinical, virological and histological pattern manifested by an increased incidence of viral persistence with high HCV-RNA titers and accelerated fibrosis. This may be attributed to the fact that patients with schistosomiasis have a down regulated immune response to HCV in the form of reduced IFN γ , IL-4 and IL-10 secreted by HCV-specific T cells^[33]. In spite of this, we did not find any significant difference in response to either IFN forms in cases of combined infections. This might be explained by the recent observation of El Rafei and colleagues^[34] that *Schistosoma mansoni* by targeting a specific subset of memory CD8 cells, reduces the late differentiated memory T cell population in HCV co-infected individuals. This implies that patients infected with the genotype 4 can still mount HCV-specific T cell responses, despite the prevalence of concomitant schistosomiasis.

As for safety and tolerability, both IFN forms were comparable. As in previous reports, anemia and thrombocytopenia were the commonest hematological adverse events of the combination therapy^[35]. Nevertheless, none of our patients experienced bleeding tendency or uncontrolled infection throughout the study period. The use of Epoietin α and G-CSF helped improve patients' adherence to treatment, and minimize dose reduction and discontinuation of treatment in the first 12 wk. Adherence to therapy is increasingly recognized as a key determinant in the outcome of antiviral therapy in chronic hepatitis^[36] and although erythropoietin stimulates both erythropoiesis and thrombopoiesis^[37], the latter effect was not demonstrated in our patients and 4 had to discontinue treatment because of thrombocytopenia.

We can conclude that concomitant HCV-genotype 4 and bilharzial infections do not seem to affect the improved responses achieved with pegylated interferon α 2a plus ribavirin combination therapy. Also, in spite of the improved response in advanced fibrosis and compensated cirrhosis, advanced histopathological changes, coupled with positive viremia after 12 wk of

therapy, still remain the most important negative predictive factor for response in genotype 4 patients. A non-stop and extensive work is still needed to win the battle against HCV. Each new pharmacological modification carries with it more hope for better control of this complicated disease and tells that the difficult to treat genotype 4 will eventually be conquered.

Abstract

AIM: To report the endoscopic treatment of large hyperplastic polyps of the esophagus and esophago-gastric junction (EGJ) associated with Barrett's esophagus (BE) with low-grade dysplasia (LGD), by endoscopic mucosal resection (EMR).

METHODS: Cap fitted EMR (EMR-C) was performed in 3 patients with hyperplastic-inflammatory polyps (HIPs) and BE.

RESULTS: The polyps were successfully removed in the 3 patients. In two patients, with short segment BE (SSBE) (≤ 3 cm), the metaplastic tissue was completely excised. A 2 cm circumferential EMR was performed in one patient with a polyp involving the whole EGJ. A simultaneous EMR-C of a BE-associated polypoid dysplastic lesion measuring 1 cm x 10 cm, was also carried out. In the two patients, histologic assessment detected LGD in BE. No complications occurred. Complete neosquamous re-epithelialization occurred in the two patients with SSBE. An esophageal recurrence occurred in the remaining one and was successfully retreated by EMR.

CONCLUSION: EMR-C appears to be a safe and effective method for treating benign esophageal mucosal lesions, allowing also the complete removal of SSBE.

Key words: Hyperplastic polyps; Endoscopic mucosal resection; Barrett's esophagus

INTRODUCTION

Benign esophageal tumors are rare, representing less than 1% of all esophageal tumors^[1]. They are usually asymptomatic and often discovered incidentally^[2]. Many classifications have been proposed for benign esophageal tumors: by histological cell types, which are divided into epithelial and non-epithelial tumors, or by the location in the esophageal wall, categorized as intramural and extramural tumors^[3,4].

Epithelial polypoid lesions of the esophagus and esophagogastric junction (EGJ) are uncommon^[5-8]. Among them, hyperplastic-inflammatory polyps (HIPs) often occur in combination with gastroesophageal reflux disease (GERD)^[9-13]. Endoscopic mucosal resection (EMR) is a promising therapeutic option for the removal of superficial carcinomas throughout the gastrointestinal tract. This technique permits resection of the mucosa and submucosa, exposing the muscularis propria^[14]. The authors report the outcome of EMR in three patients with large hyperplastic polyps of the EGJ associated with Barrett's esophagus (BE).

MATERIALS AND METHODS

Endoscopy

Upper gastrointestinal endoscopy (UGIE) was performed with standard forward-viewing videoendoscope (GIF-Q145, Olympus Optical Co. Ltd., Tokyo, Japan).

Before EMR, endoscopic ultrasonography (EUS) (GF-UMQ 130, 7.5-20 MHz, Olympus Optical Co. Ltd., Tokyo, Japan) was performed to assess lesion depth and lymph node status.

Endoscopic resection technique

EMR was performed with the "cap" technique (EMR-C). A 13 mm diameter transparent plastic cap (MH-594, Olympus Co. Ltd., Tokyo, Japan) was preloaded on the tip of a standard diagnostic forward-viewing endoscope

Figure 1 A sessile villous-like polyp extending for the whole length of BE.

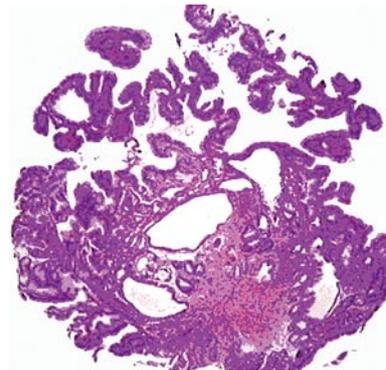

Figure 2 Hyperplastic polyp from the gastroesophageal junction was comprised of cardiac type mucosa with foveolar hyperplasia and cystic dilatation of gastric pits (HE x 100).

(GIF-Q145, Olympus Optical Co. Ltd., Tokyo, Japan). Inside the distal end of the cap is a gutter that positions the opened monofilament polypectomy snare (SD-221U-25, Olympus Co. Ltd., Tokyo, Japan). After submucosal injection of diluted epinephrine (1:200 000), with methylene blue, the cap was pressed against the mucosa and suction applied. The polypectomy snare was closed around the tissue and resection performed by endocut mode only, using the ERBE-ICC 200 cautery device (ERBE Elektromedizin Gmgh, Tubingen, Germany).

After each resection the endoscope was withdrawn to collect the tissue specimen.

Deep sedation with propofol was used to perform the endoscopic procedures.

RESULTS

All resected fragments were fixed in 40 g/L neutral formaldehyde, embedded in paraffin and serially sectioned. The sections were stained with hematoxylin and eosin; in addition all specimens were stained with periodic acid-Schiff/Alcian blue stain at pH 2.5 for evaluation of intestinal metaplasia (IM).

Immunohistochemical staining for p53 was performed in all cases (clone DO-7, BioGenex, San Ramon, CA; final dilution 1:20 000).

Case 1

A 72-year old man complained of gastroesophageal reflux symptoms since the age of 25, which became worse in the last five years, occurring also during the night. He was taking over-the-counter drugs (ranitidine) for his reflux symptoms, with poor control. He never complained of dysphagia. The past medical history of the patient was unremarkable. Endoscopy showed a 3 cm hiatal hernia, and a circumferential BE 10 cm long. A sessile villous-like polyp, 10 mm wide, extending for the whole length of BE, was observed (Figure 1). The colour of the lesion was similar to BE, and at the EGJ became wider, involving the entire circumference of the junction for a length of 15 mm.

EUS demonstrated a lesion confined to the mucosa. No pathologic lymph nodes were detected. Multiple biopsies from BE showed incomplete IM with low-grade epithelial dysplasia (LGD), rare pancreatic pits and positivity for p53; biopsies from the EGJ polyp showed proliferation

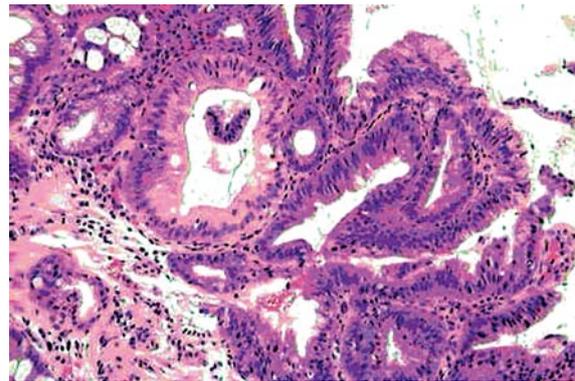

Figure 3 Sessile lesion arising in the Barrett's esophagus: the adenomatous villous-type polyp is composed of low grade dysplastic epithelium (HE x 250).

of hyperplastic cardiac-type epithelium with some cystic dilatation of gastric pits, rare goblet cells, rare parietal cells (Figure 2) and some groups of cells with LGD. Additional features included oedema and inflammation in the lamina propria.

Biopsies from the sessile lesion in BE showed fragments of adenomatous villous-type with incomplete IM, epithelial LGD (Figure 3) and over expression of p53.

The patient was hospitalised and EMR-C performed. Both lesions (the long esophageal one, 1 cm × 10 cm, and its 2 cm of circumferential expansion at the EGJ), were completely removed in one endoscopic session. No intraprocedural or delayed complications occurred. On histology, the EGJ lesion was a hyperplastic polyp, and the lesion arising in BE was a villous adenomatous polyp with LGD (also named BE-associated polypoid dysplastic lesion).

Intravenous omeprazole was administered during the following 24 h. Then 40 mg of rabeprazole were given. The patient was kept fasting for 24 h. Then a liquid diet was started, and solid foods were reintroduced five days later. He was dismissed after four days on long term rabeprazole 40 mg.

UGIE was not repeated until 18 mo later, as the patient refused earlier endoscopic examinations. He was asymptomatic, and still taking 40 mg of rabeprazole. Endoscopy showed a 10 cm long area of neosquamous re-epithelialization where EMR had been performed. Three areas of mucosal abnormality (average size: 12 mm) were detected in the lower esophagus (Figure 4), and EMR was repeated, with resection of larger areas of metaplastic epithelium to favour neosquamous re-epithelialization. No

Figure 4 Areas of neosquamous re-epithelialization coexisting with tiny mucosal abnormalities.

complications occurred and the patient left the hospital three days later. Histology showed both hyperplastic cardiac-type and cystic hyperplastic gastric fundic polyps. The resected associated BE showed incomplete IM without dysplasia.

A further endoscopy performed 3 mo later, revealed large areas of re-epithelialization and no mucosal abnormalities in the residual BE. Multiple biopsies were taken from the residual BE, that showed IM without dysplasia.

Case 2

A 66-year old woman underwent endoscopy for recurrent mild epigastric pain during the previous three months, without gastroesophageal reflux symptoms. The past medical history was unremarkable. Endoscopy showed a 3 cm hiatal hernia, a short segment BE (SSBE-20 mm), and a 25 mm sessile polyp at the EGJ. Multiple biopsies showed hyperplastic squamous epithelium. EUS showed a lesion confined to the mucosa, without lymph node involvement. Biopsies of the BE showed incomplete IM with LGD, and p53 negativity.

The patient was hospitalised and EMR-C performed. The polyp and BE were both excised. No early or delayed complications occurred. The patient left the hospital three days later, and rabeprazole 40 mg was advised. The first repeat endoscopy was scheduled after 3 mo, when histology revealed proliferative hyperplastic squamous epithelium and chronic inflammatory cells in the lamina propria. Endoscopy 3 and 6 mo later showed complete neosquamous re-epithelialization of the lower esophagus, without stricture.

Case 3

A 72-year old man underwent endoscopy for recurrent epigastric pain occurring over the previous five years, without reflux symptoms. Endoscopy showed a 30 mm tongue of metaplastic epithelium in the distal esophagus, a 3 cm hiatal hernia, and a 30 mm sessile polyp at the EGJ. Biopsies from the BE and polyp showed incomplete IM and squamous epithelial hyperplasia. EUS showed a lesion confined to the mucosa. No pathologic lymph nodes were detected.

Both polyp and BE were completely removed by EMR-C. No complications occurred and the patient left

the hospital three days later. He was advised to assume 40 mg of rabeprazole indefinitely. Histology confirmed that the polyp consisted of hyperplastic squamous epithelium and inflammatory infiltrate. The resected BE showed incomplete IM without dysplasia. Immunohistochemical stain for p53 was negative. Endoscopy 3 and 6 mo later showed complete neosquamous re-epithelialization of the lower esophagus, with minimal scarring.

DISCUSSION

We were able to remove large polyps of the esophagus and EGJ by EMR in 3 patients with BE, without complications. In the two patients with a SSBE, the metaplastic tissue was completely removed, allowing complete neosquamous re-epithelialization.

At histology, inflammatory polyps are characterized by hyperplastic epithelium with variable amounts of inflamed stroma^[5]. Occasionally, esophageal polyps containing stroma and granulation tissue, without an epithelial component, have been reported^[5-7]. Other types of polyps are the inflammatory pseudotumors, also known as inflammatory polyps with pseudomalignant erosion. They usually occur in the distal esophagus, arise from the mucosal layer and contain inflamed granulation tissue with bizarre stromal cells. Pseudomalignant erosion has been found in 14.3% of inflammatory polyps of the EGJ^[15]. Inflammatory esophagogastric polyps are thought to be a complication of gastroesophageal reflux^[6,16]. They have also been reported in patients with hiatal hernia (88%) and/or reflux esophagitis (91%)^[6,17]. The association of hyperplastic polyps and BE is infrequent, and to our knowledge, only Abraham *et al*^[5] has reported it previously. In fact, adenoma is more frequently associated with BE. It has been suggested that the use of the term “adenoma” in BE may be misleading, because it carries a “benign” connotation^[18]. The appropriate term for these lesions should be “BE-associated polypoid dysplastic lesion”, because they share similar clinical, pathological and molecular features as those of flat dysplasia^[19].

In a series of 27 patients with a total of 30 hyperplastic esophageal and EGJ polyps, 80% of them were composed of cardiac-type mucosa, 17% of squamous mucosa, and 3% contained both cardiac and squamous mucosa. IM was present in only two polyps (7%)^[5]. The location of HIPs was the EGJ region (67%), distal esophagus (30%) and mid-esophagus (3%), in accordance with other data reported in the literature^[16,17].

Only four cases of hyperplastic polyps in the cervical esophagus have been reported^[20-23], all arising from ectopic gastric mucosa^[24,25].

Less often, polyps are located at the end of a prominent inflamed gastric fold very close to the squamocolumnar junction, also known as “the sentinel fold”, seen in reflux esophagitis^[26].

Histologically similar polyps have been reported in von Recklinghausen's^[27], and Crohn's disease^[28,29], protracted vomiting^[5,30], and infectious esophagitis (Candida, Cytomegalovirus, Herpes simplex virus)^[5]. Other esophageal injuries, due to drugs (K-dur, alendronate sodium and ibuprofen)^[5], sclerotherapy for esophageal

varices^[12], polypectomy, and photodynamic therapy^[5], can result in hyperplastic polyp occurrence. Their pathogenesis is similar to that of gastric and colonic hyperplastic polyps that frequently seem to occur in response to mucosal injury^[31,32]. However, there are cases in which the etiology cannot be defined^[5,33]. Malignant transformation has been occasionally reported in gastric and colonic hyperplastic polyps^[32,34], but not in those arising in the esophagus or EGJ.

In the study of Abraham *et al*^[5], 4 of 27 patients with esophageal hyperplastic polyps also had BE. IM within cardiac-type mucosa was present in two polyps (6.7%): one contained goblet cells, and the other one was surrounded by Barrett's mucosa. Only the latter polyp (3%) showed LGD. Three out of 4 patients with BE had previous, concomitant, or subsequent development of dysplasia in the non-polypoid esophagus. Furthermore, the frequency of dysplasia within esophageal hyperplastic polyps is low and it has been reported only in those cases associated with dysplastic Barrett's esophagus^[5].

In our patients, histological evaluation showed hyperplastic epithelium and inflamed stroma in the polyps located at EGJ. Histological assessment of the 10 cm long polyp arising in BE showed a "BE-associated polypoid dysplastic lesion". The treatment of HIPs of the esophagus and EGJ has changed over the years. In the past open surgical resection was considered standard care in the management of all significant esophageal lesions^[2,33]. Transabdominal Nissen fundoplication operation to prevent reflux has also been used in cases where the correlation between HIPs and GERD was documented^[11].

More recently thoracoscopic approaches have been performed for mucosal or submucosal lesions > 30 mm^[2]. Endoscopic polypectomy for HIPs is the current treatment for lesions ≤ 30 mm^[15,16,27]. Oguma *et al*^[21] reported the successful removal of a pedunculated hyperplastic polyp (size: 9.0 mm × 4.5 mm × 4.0 mm) arising in the ectopic gastric mucosa in the cervical esophagus^[23]. Two of our patients had LGD in the BE. In patients with BE, cancer can develop through several steps encompassing LGD, high-grade dysplasia (HGD) and invasive adenocarcinoma^[35]. However, adenocarcinomas have also been detected in patients whose previous biopsies revealed only low-grade or even no dysplasia^[36-39]. The information on the natural history of LGD is limited. Moreover, the diagnosis of LGD is highly subjective and associated with interobserver variability^[40]. In three articles, the reported rate of progression from LGD to HGD or adenocarcinoma was 10%^[41], 12%^[42], and 28%^[37]. In these studies the agreement among pathologists in diagnosing LGD was associated with an increased risk of progression to HGD or cancer.

At present, patients with HGD are advised to undergo surgical treatment due to the reported frequency of undetected synchronous cancers^[43,44]. However, surgery carries substantial morbidity and mortality^[45]. EMR could become a therapeutic alternative to esophagectomy in selected patients^[46-50].

Some authors suggest EMR in patients with BE and LGD to improve the histologic accuracy^[46,51]. However, complications can occur during this procedure. Bleeding

and perforation have been reported in a median 10% of patients and less than 1% of cases, respectively^[50]. Esophageal stenosis is a late complication, and may occur in 0%-30% of cases^[50]. Larger EMR resections may increase the risk of stenosis. In a study encompassing 137 patients, stenosis occurred only when EMR involved more than two-thirds of the esophageal circumference^[52]. However, in one report of circumferential EMR, only two of 12 patients developed stenosis^[53]. Overall, complications seem fewer for EMR than for surgical resection^[54].

We were able to remove the large sessile lesions with EMR-C, in one session, without complications. In two of our patients, with non-circumferential SSBE, the metaplastic epithelium was completely removed. The patient with a 10 cm long BE showed a large neosquamous re-epithelialization, involving half of the BE surface. In the same patient the 20 mm circumferential EMR at the EGJ level did not cause any stricture.

In conclusion, our experience indicates that esophageal and EGJ hyperplastic polyps could represent an exuberant epithelial regeneration following mucosal injury, particularly GERD. The presence of BE in all of them seems to confirm the hypothesis of GERD in causing inflammatory reaction. The malignant transformation of these polyps is rare, but possible^[5]. Also, the presence of dysplasia within a segment of BE is patchy, and random biopsies may fail to detect it^[55].

We performed EMR to remove the large hyperplastic polyps and the surrounding areas of BE, as EMR provides greater diagnostic precision than endoscopic biopsy. In the study of Conio *et al*^[50] reclassification of the histology after EMR occurred in 26% in a series of 39 patients with BE. Other authors have reported reclassification of the histologic diagnosis after EMR in 0% to 75% of cases^[53,56]. We can conclude that EMR is minimally invasive and a low risk method in treating large benign esophageal mucosal lesions.

Abstract

AIM: To assess the levels of antioxidant capacity and oxidative damage in blood of chronic pancreatitis (CP) patients in comparison with those in healthy control subjects, by using several different analytical techniques.

METHODS: Thirty-five CP patients and 35 healthy control subjects were investigated prospectively with respect to plasma levels of thiols, ferric reducing ability of plasma (FRAP, i.e. antioxidant capacity), levels of protein carbonyls and thiobarbituric acid reactive substances (TBARS). Additionally, we evaluated the production of reactive oxygen species (ROS) in whole blood.

RESULTS: The antioxidative thiols including cysteine, cysteinylglycine and glutathione were significantly lower in CP patients. In addition, the non-enzymatic antioxidant capacity was significantly lower in CP patients, which correlated with the amount of oxidative protein (protein carbonyls) and the extent of lipid damage (TBARS), both were significantly higher in CP patients. The ROS production in whole blood after stimulation with phorbol 12-myristate 13-acetate, demonstrated a strong tendency to produce more ROS in CP patients.

CONCLUSION: Oxidative stress may contribute to the pathogenesis of chronic pancreatitis by decreasing antioxidant capacity and increasing oxidative damage in CP patients may be a rationale for intervention with antioxidant therapy.

INTRODUCTION

Chronic pancreatitis (CP) is a progressive irreversible inflammatory disease that eventually leads to an impaired exocrine and/or endocrine function of the pancreas^[1-4]. Although most cases have been attributed to alcohol abuse, the underlying causes of CP appear to be multi-faceted, including environmental as well as genetic factors. Chronic pancreatitis shares risk factors with pancreatic cancer such as smoking and alcohol abuse, but itself is also a risk factor for pancreatic adenocarcinoma^[5]. A genetic predisposition to pancreatitis is supported by the identification of sequence alterations in the genes encoding cationic trypsinogen (PRSS1), the cystic fibrosis transmembrane conductance regulator (CFTR), and the serine protease inhibitor, Kazal type 1 (SPINK1) in patients with hereditary or idiopathic chronic pancreatitis^[1,6-8]. Additionally, an increased frequency of SPINK1 mutations been reported in patients with alcohol-related chronic pancreatitis^[5,9]. So far we have not completely understood the pathogenesis of CP^[10]. Different hypotheses have been proposed, including the contribution of oxidative stress of endogenous origin or chemical stress by environmental or lifestyle-related xenobiotics^[11-15]. There is growing recognition that an imbalance between reactive oxygen species (ROS) producing and ROS scavenging processes leads to the damage of pancreatic acinar cells, initiating auto-digestion of the entire pancreas. This insight is suggested by data from experimental and clinical studies^[16-19]. Oxidative stress may be important in the pathogenesis of ethanol-induced pancreatic injury, although radiation, exposure to cigarette smoke, medication or trauma may stimulate the generation of free radicals, which subsequently may result in damage of lipids, proteins or nucleic acids. Activation of (enzymatic) antioxidative defence has been described in pancreatic disease independent of its origin^[20]. Glutathione and cysteine are important mediators in the defence against oxidative stress and both molecules play a key role in the maintenance of cellular thiol redox status. Therefore, in the present study the concentrations of glutathione, cysteine and other thiols were measured in blood plasma of patients with CP

and healthy control subjects. In addition, we also measured the non-enzymatic antioxidant capacity by applying the ferric reducing ability of plasma (FRAP) assay in patients with CP and healthy controls. Further assessment of the level of oxidative stress was performed by measuring the concentrations of protein carbonyls in plasma in order to determine the amount of oxidative protein damage. As an indicator of lipid peroxidation we established the concentrations of thiobarbituric acid-reactive substances (TBARS). Finally, we investigated the generation of ROS by chemiluminescence in whole blood of both patients and controls.

MATERIALS AND METHODS

Subjects

The study was approved by the local medical ethical review committee and all subjects gave their written informed consent. This study was conducted at the Department of Gastroenterology of the University Medical Centre Nijmegen, the Netherlands and all subjects studied were Caucasians of Dutch extraction. A total of 35 consecutive CP patients were recruited between January 2004 and June 2004 at the out-patient clinic of the department. In 29 patients an alcohol-related etiology was indicated (ACP), the remaining 6 CP patients had a family history of CP (HCP). The clinical diagnosis of CP was based on one or more of the following criteria: presence of typical complaints (recurrent upper abdominal pain, radiating to the back, relieved by leaning forward or sitting upright and increased after eating), suggestive radiological findings such as pancreatic calcifications or pseudocysts, and pathological findings (pancreatic ductal irregularities and dilatations) revealed by endoscopic retrograde pancreatography or magnetic resonance imaging of the pancreas before and after stimulation with secretin. ACP was diagnosed in patients who consumed more than 60 g (females) or 80 g (males) of ethanol per day for more than two years before they were diagnosed, during their treatment they all gave up drinking alcohol. HCP was diagnosed based on the presence of two first-degree relatives or three or more second-degree relatives in two or more generations, suffering from recurrent acute pancreatitis or chronic pancreatitis for which there was no precipitating factor. For comparison, we collected a control group consisting of 35 healthy subjects. We recruited our healthy controls by advertisement in a local paper and did not apply any monetary incentive for the controls to participate.

Analysis of thiols

Samples of blood were taken by venapuncture into EDTA tubes. Whole blood was centrifuged at $1500 \times g$ for 10 min within 1 h after collection and plasma was stored at -30°C until analysis. Concentrations of the thiols including cysteine, homocysteine, cysteinylglycine and glutathione (the sum of reduced-, oxidised- and protein-bound thiols) in plasma were quantified using high performance liquid chromatography (HPLC) with fluorescent detection, essentially as described by Fortin *et al*^[21] and modified by Rajmakers *et al*^[22]. Thiol levels were calculated using four-point calibration curves for each thiol, which were run in

parallel with the samples, and values were expressed in $\mu\text{mol/L}$.

Analysis of FRAP

The antioxidant capacity in blood plasma was measured using the ferric reducing ability of plasma (FRAP) assay, according to the method of Benzie and Strain^[23]. The reduction of ferric to ferrous ion at low pH formed a coloured ferrous-tripyridyltriazine complex. Absorbance changes were linear over a wide concentration range with antioxidant mixtures, including plasma. FRAP values were obtained using a seven-point calibration curve of known amounts of Fe^{2+} and expressed in $\text{mmol Fe}^{2+}/\text{L}$.

Analysis of protein carbonyls

The amount of oxidative protein damage, as a marker for oxidative stress, was determined using an enzyme linked immunosorbent assay (ELISA) for estimation of protein carbonyls in body fluids, as essentially described by Buss *et al*^[24] and adapted by Zusterzeel *et al*^[25]. Samples were incubated with dinitrophenylhydrazine and then adsorbed to wells of an ELISA plate before probing with a commercial antibody raised against protein-conjugated dinitrophenylhydrazine. The binding of biotin-conjugated primary antibody was then quantified after incubation with streptavidin-biotinylated horseradish peroxidase and staining with o-phenylenediamine. Calibration took place using oxidised and fully reduced albumin, and carbonyl levels were expressed in $\mu\text{mol/g}$ protein.

Analysis of TBARS

Thiobarbituric acid-reactive substances (TBARS), mainly malondialdehyde (MDA) in plasma were evaluated by recording the fluorescence spectrum between 500 and 600 nm on a Shimadzu RFF-5000 spectrofluorometer, of the thiobarbituric acid-malonaldehyde complex, as described by Conti *et al*^[26]. Levels of TBARS were expressed in $\mu\text{mol MDA/L}$.

Analysis of ROS

ROS production in whole blood was evaluated using luminol-enhanced chemiluminescence, as measured in an automated LB96V Microlumat Plus Luminometer (EG & G Berthold, Belgium). Briefly, the signal-amplifying molecule luminol reacts with oxygen species (mainly superoxide anion) generated by neutrophils in whole blood, to produce an excited state intermediate that emits light as it returns to its ground state. ROS production was determined in the absence of a cellular stimulator, as well as in the presence of either a receptor-dependent (serum-treated zymosan, STZ) or a receptor-independent stimulus (phorbol 12-myristate 13-acetate, PMA). Freshly obtained heparinized blood was 1:100 diluted in HBSS containing 1 mmol/L calcium. Two hundred μL of this diluted blood was added to each well of a 96-well plate. In addition, reaction mixtures contained 0.45 g/L bovine serum albumin (BSA), 0.83 mmol/L luminol and either 1 g/L STZ, 0.4 mg/L PMA or no stimulating agents. As an internal positive control for the luminescence process, samples of 1 g/L ammonium persulphate (APS) in phosphate-buffered

solution (PBS) were run simultaneously. Chemiluminescence was monitored every 60 s for 1 h. EDTA blood, taken together with the heparinized blood samples, was tested for leukocyte counts and differentiation, in order to adjust the chemiluminescence produced during one hour ('area under the curve') in relative light units (RLU) per cell for neutrophil counts. All measurements were performed in quadruplicate and corrected for background values (absence of a stimulus). Opsonized zymosan particles were prepared by incubation of STZ with pooled human serum for 30 min at 37°C, as previously described^[27]. These particles were then washed twice in PBS and finally suspended at 12.5 g/L in PBS.

Statistical analysis

Data were analysed using SPSS version 12.0. Differences in the baseline characteristics of patients and controls were estimated with Fisher's exact test and Student's *t*-test. The Mann-Whitney U-test was used to estimate differences in biochemical parameters between the patient and control population in a non-parametrical manner. Differences were considered significant if $P < 0.05$. Finally, we examined the correlation between the non-enzymatic antioxidant capacity with the amount of oxidative protein and lipid damage in CP patients, using Spearman rank correlation test.

RESULTS

The characteristics of patients with CP and healthy controls are denoted in Table 1. The mean age of the CP patients was 51 years (range 25 to 74 years) and was not significantly different from that of the healthy controls (45 years; range 27 to 68 years). There was no significant difference in the distribution of gender between CP patients and healthy control subjects. Smoking habits between CP patients and healthy controls were not different; 66% of the patients and 63% of the control subjects smoked or stopped smoking within the last 5 years.

The oxidative stress was measured in CP patients and healthy controls. The plasma concentrations of cysteine (Cys), homocysteine (Hcys), cysteinylglycine (CGS) and glutathione (GSH), the plasma antioxidant capacity (FRAP) as well as the plasma levels of protein carbonyls and TBARS and chemoluminescence in whole blood are depicted in Table 2.

The plasma concentrations of antioxidative thiols including cysteine, cysteinylglycine and glutathione were significantly lower in the CP patients than in the controls ($P = 0.021$, $P = 0.003$ and $P = 0.048$, respectively). The plasma levels of homocysteine were similar in both groups. The antioxidant capacity as measured by the FRAP assay was also significantly lower in the CP patients than in the healthy control subjects ($P < 0.001$). The levels of both carbonyls and TBARS were significantly higher in the CP patients than in the healthy controls ($P < 0.001$). The chemiluminescence of diluted whole blood of CP patients and controls was not different, although there was a strong trend towards an increased ROS production after stimulation with PMA ($P = 0.058$). As expected, spontaneous generation of ROS in the absence of a stimulus was less

than 10% of the amount of ROS measured in response to the stimuli of PMA and STZ. The leukocyte counts and differentiation within the ranges were considered normal at our hospital. The values obtained with either assay were not different in patients with ACP and HCP.

In addition, the correlation between the non-enzymatic antioxidant capacity with the amount of oxidative protein and lipid damage in CP patients was examined and a negative correlation was found between the non-enzymatic antioxidant capacity and the amount of oxidative protein damage ($r_s = -0.44$, $P = 0.013$), as well as between the non-enzymatic antioxidant capacity and the amount of lipid damage ($r_s = -0.39$, $P = 0.004$). Finally, we found a positive correlation between oxidative protein and lipid damage ($r_s = 0.67$, $P = 0.001$).

DISCUSSION

Alcohol abuse is regarded as a major risk factor for the development of CP. However, the exact mechanism behind the effect of alcohol remains unknown. Some evidence obtained by animal studies, suggests that metabolism of ethanol catalysed by cytochrome P4502E1 (CYP2E1) may contribute to oxidative stress in the pancreas during chronic alcohol consumption^[19]. Trauma, exposure to radiation, cigarette smoke, medication or other toxins generating free

radicals also may increase the amount of oxidants. In the present study, we assessed the antioxidant capacity and levels of oxidative damage in CP patients as compared with healthy controls by means of several analytical techniques that are known to measure various components that together constitute oxidative stress. The major observations were that plasma concentrations of some thiols, having antioxidant properties, were significantly lower in CP patients. Likewise the non-enzymatic antioxidant capacity as measured by the FRAP assay, was significantly lower in CP patients than in healthy control subjects. This inferior antioxidant capacity in CP patients parallels significantly increased amounts of oxidative protein and lipid damage, whereas the generation of ROS in whole blood did not show a statistically significant difference between CP patients and healthy control subjects, with a similar age and gender distribution and smoking habits. Our results clearly indicate that oxidative stress is present in patients with CP and that this eventually might contribute to the initiation and maintenance of inflammation in CP patients, as has been previously suggested^[17,19,28-31]. Thiols such as cysteine and glutathione play an essential role as antioxidants, and are involved in protein synthesis, redox sensitive transduction signalling, cell growth and proliferation, xenobiotic metabolism and immune regulation^[32]. Glutathione is conjugated to many xenobiotics and essential for the optimal functioning of numerous enzymes and hence crucial for cell viability. Decreased levels of glutathione in plasma have been reported, but paradoxically also increased glutathione levels may be found as a result of overshoot after enhanced synthesis due to oxidative stress or conjugation of toxic compounds, as has been shown in different disorders^[33-35]. We found significantly lower plasma concentrations of cysteine, cysteinylglycine and glutathione in CP patients as compared to healthy controls, whereas the control values measured here can be considered normal for the Dutch population^[36]. We found no elevated concentrations of homocysteine in CP patients, however homocysteine does not always act as an antioxidant, moreover elevated plasma concentrations of homocysteine are positively associated with an increased risk of cerebral, coronary or peripheral vascular diseases^[36]. In parallel with the lower plasma concentrations of the antioxidative thiols, the FRAP assay also demonstrated a significantly lower antioxidant capacity in CP patients. Since the FRAP assay does not measure sulfhydryl (SH)-containing antioxidants such as the thiols glutathione and cysteine, this indicates that other non-thiol related antioxidants are decreased in CP patients also. In patients with acute pancreatitis very low ascorbate concentrations in plasma have been described before^[37,38].

Protein carbonyl derivatives are generated by direct oxidative attack of proteins or by indirect lipid peroxidation products and therefore represent a good biomarker for general oxidative stress^[39,40]. The lower FRAP levels in CP patients are accompanied with high protein carbonyl concentrations, indicating that increased oxidative damage occurs as a result of the lower protective capacity as measured by FRAP. Former studies have demonstrated

elevated plasma protein carbonyls in experimental animal models^[41,42] and humans with acute pancreatitis^[43]. Unless properly scavenged, ROS may lead to lipid peroxidation, which represents an important manifestation of oxidative stress. Lipid peroxidation is initiated when free radicals interact with polyunsaturated fatty acids. For instance, in cell membranes this may result in a chain reaction forming lipid hydroperoxides. Analysis of TBARS in plasma is a widely used method for the estimation of lipid peroxidation. In accordance with the elevated levels of protein carbonyls and lower antioxidant capacity, we found significantly increased plasma concentrations of TBARS in CP patients. The production of ROS, as measured in whole blood by chemiluminescence assay, was not significantly higher in CP patients than in healthy controls, although there was a strong trend to generate higher amounts of ROS after stimulation with PMA. We used luminol-enhanced chemiluminescence assay in 100-fold diluted whole blood to study ROS generation of peripheral blood cells in a non-disturbed system. As expected, ROS generation in the absence of a stimulus in CP patients was low, and not significantly different from the values in the healthy control group. Chemiluminescence measurements did not demonstrate a significantly increased ROS generation in CP patients, while the other analytical techniques applied here showed increased oxidative stress and damage in CP patients as compared to healthy control subjects, demonstrating that the oxidative damage in CP patients is caused by other reactive (oxygen) species rather than by leucocytes. Since most of the CP patients included in this study were alcoholics, the cause of oxidative damage might be mainly of exogenous origin. However, a contribution of oxidative stress of endogenous origin might also be possible, since we detected a strong tendency to produce ROS in CP patients after stimulation with PMA. This PMA-induced respiratory burst is receptor-independent and not absolutely dependent on priming^[44], whereas priming does moderately influence the STZ-induced respiratory burst^[45]. We measured the ROS production in whole blood and it is known that during isolation of neutrophils, these cells often become primed^[46]. The clinical importance of oxidative stress in human pancreatic disease was first suggested by Braganza *et al*^[47], and subsequently supported by data from other groups, showing increased levels of lipid hydroperoxides in pancreatic juice^[14] and increased spontaneous production of ROS by neutrophils^[27,48]. The assessment of oxidative stress in CP patients corroborates the hypothesis that oxidative stress leads to damage of pancreatic acinar cells, initiating auto-digestion of the entire pancreas as has been shown in the present study.

In summary, significantly higher levels of products of oxidative damage (protein carbonyls and TBARS), correlating with decreased levels of cysteine, cysteinylglycine, glutathione and non-enzymatic antioxidant capacity (FRAP) can be found in CP patients. Oxidative stress, defined as the imbalance between prooxidant and antioxidant capacity, is higher in CP patients, which may justify further studies on intervention with antioxidant therapies for this serious disease.

Abstract

AIM: To investigate reactivated Epstein-Barr virus (EBV) infection as a cause for chronic hepatitis.

METHODS: Patients with occasionally established elevated serum aminotransferases were studied. HIV, HBV and HCV-infections were excluded as well as any other immunosuppressive factors, metabolic or toxic disorders. EBV viral capsid antigen (VCA) IgG and IgM, EA-R and EA-D IgG and Epstein-Barr nuclear antigen (EBNA) were measured using IFA kits. Immunophenotyping of whole blood was performed by multicolor flow cytometry. CD8⁺ T cell responses to EBV and PHA were determined according to the intracellular expression of IFN- γ .

RESULTS: The mean alanine aminotransferase (ALT) and gamma glutamyl transpeptidase (GGTP) values exceeded twice the upper normal limit, AST/ALT ratio < 1. Serology tests showed reactivated EBV infection in all patients. Absolute number and percentages of T, B and NK cells were within the reference ranges. Fine subset analysis, in comparison to EBV⁺ healthy carriers, revealed a significant decrease of naive T cells ($P < 0.001$), accompanied by increased percentage of CD45RA⁺ ($P < 0.0001$), and terminally differentiated CD28⁺CD27⁻ CD8⁺ T cells ($P < 0.01$). Moderately elevated numbers of CD38 molecules on CD8⁺ T cells ($P < 0.05$) proposed a low viral burden. A significantly increased percentage of CD8⁺ T cells expressing IFN- γ in response to EBV and PHA stimulation was registered in patients, as compared to controls ($P < 0.05$). Liver biopsy specimens from 5 patients revealed nonspecific features of low-grade hepatitis.

CONCLUSION: Chronic hepatitis might be a manifestation of chronic EBV infection in the lack of detectable immune deficiency; the expansion of CD28⁺CD27⁻ and increase of functional EBV-specific CD8⁺ T cells being the only surrogate markers of viral activity.

INTRODUCTION

Epstein-Barr virus (EBV) infects more than 90% of humans by the time of adulthood and persists as a life-long latency, suggesting sophisticated mechanisms for effective immune evasion. Primary EBV infection is usually asymptomatic or results in infectious mononucleosis, which resolves spontaneously after the emergence of EBV-specific immunity. Similar to other herpes viruses, EBV persists in the infected immunocompetent organism, without causing apparent disease. CD8⁺ T cell-mediated responses control the virus both during primary infection and the following carrier state^[1,2].

So far, studies on the interaction between the immune system and EBV have focused mostly on congenital or acquired immune deficiency states, which can lead to viral reactivation. Rare cases of fulminant chronic EBV infection have been described and termed severe chronic active EBV infection (SCAEBV or CAEBV)^[3,4]. Criteria of CAEBV include severe infection lasting more than 6 mo, histologic evidence of major organ involvement, abnormal EBV antibody titers, and increased quantities of EBV in affected tissues in apparently immunocompetent hosts^[5]. However, congenital or acquired defects of cell-mediated immune mechanisms in CAEBV patients are very probable, associated with signalling defects, reduced T-cell or NK cell activity, or reduced perforin levels^[6].

While hepatitis is a common feature of primary EBV infection^[7,8], the role of EBV in chronic liver disease is less obvious. Bertolini *et al* showed typical histopathological lesions of chronic hepatitis without involvement of other organs after inoculation of normal human bone marrow-derived B cell, carrying an endogenous EBV line *in vivo* in nu/nu mice^[9]. Single cases of persistent hepatitis related to EBV infection were reported in immunocompromised persons^[10]. Liver injury may be one of the manifestations of CAEBV^[11-13]. However, only limited knowledge exists about EBV-related hepatitis in immunocompetent patients. We analyzed the clinical and laboratory findings in 15 patients with chronic hepatitis and no data of immune deficiency. Based on the serological profile of reactivated EBV infection and the absence of other major etiological agents, we propose reactivated EBV infection as a cause for the chronic liver disease. Furthermore, we demonstrate that the only significant changes at the level of peripheral blood lymphocytes were the prevalence of CD45RA⁻ T cells, combined with expansion of CD8⁺ T cells lacking CD27 and CD28 expression, and an increased percentage of lytic EBV epitope-specific CTL.

MATERIALS AND METHODS

Patients

Fifteen Caucasian HLA-A2+ patients (11 males, 4 females, mean age 40.6 years (range 19-55) with chronic hepatitis, referred to the Clinic of Gastroenterology, Medical Institute, Ministry of Interior, Sofia between Sep 2004 and Mar 2005, were included in this study. Chronic liver injury was detected during routine prophylactic examination and was defined as an elevation of serum aminotransferases of more than 6 mo duration. All patients were HIV-1, HBV and HCV-negative, had normal serum protein levels, and had no evidence of metabolic, or alcohol-related disorders, or drug toxicity (Table 1). Furthermore, they had no history of prior immune deficiency or of any other recent, recurring or chronic infection, or immunosuppressive factors that might explain the observed pathological changes.

A control group included 15 HLA-A2⁺ EBV⁺ sex- and age-matched healthy volunteers with normal aminotransferase levels. All samples were obtained after informed consent.

Serological and routine laboratory tests

EBV viral capsid antigen (VCA) IgG and IgM, EA-R and EA-D IgG and Epstein-Barr nuclear antigen (EBNA) were measured, using immunofluorescent assay (IFA FDA Atlanta kits). HIV-1, HBsAg, anti-HBc and anti-HCV were tested with ELISA method. Serum aspartate aminotransferase (AST), alanine aminotransferase (ALT), gamma-glutamyl transpeptidase (gamma-GT, GGTP), creatinine, bilirubin, glucose levels, serum proteins and coagulation were measured according to standard laboratory procedures.

Immunophenotypic studies

Whole blood was obtained in heparinized vacutainer tubes. Lymphocyte subset absolute counts were determined

Table 1 Exclusion criteria

Alcohol consumption > 40 mL per day
Diabetes or impaired glucose tolerance (including hyperinsulinaemia, OGTT and fasting blood glucose)
Under- or overweight (BMI < 18 or > 26 kg/m ²)
Dyslipidaemia
Hyper- or hypothyroidism
Gluten enteropathy
Autoimmune hepatitis or PBC/PSH
Viral hepatitis B or C
Hereditary hemochromatosis or Iron overload
Wilson disease
Anamnesis for hepatotoxic drugs use (including herbal and over-the-counters in the last 12 mo)
Hereditary muscular disorders

Table 2 T cell subsets analyzed in this study

mAb combination	Subset	Phenotype
CCR7/CD45RA/ CD8/CD4	Naïve CD8	CD8 ⁺ CD45RA ⁺ CCR7 ⁺
	Antigen-primed/memory CD8	CD8 ⁺ CD45RA ⁻
	Effector CD8	CD8 ⁺ CD45RA ⁺ CCR7 ⁻
	Naïve CD4	CD4 ⁺ CD45RA ⁺ CCR7 ⁺
CD27/CD28/CD8	Antigen-primed/memory CD4	CD4 ⁺ CD45RA ⁻
	Early CD8	
	Intermediate CD8	CD8 ⁺ CD27 ⁺ CD28 ⁺
	Terminally differentiated CD8	CD8 ⁺ CD27 ⁻ CD28 ⁻

by a lysis/no wash procedure with TruCOUNT tubes and CD3/CD4/CD45/CD8 MultiTest; T cell subsets were evaluated by multicolor immunophenotyping and a standard lysis/wash technique (Table 2). The quantitative expression of CD38 on CD8⁺ T cells (CD38 ABC) was assessed by the QUANTIBRITE PE fluorescence quantitation kit, according to the manufacturer's instructions and analyzed with QUANTIBRITE software. All reagents were products of BD Biosciences (B-D, San Jose, CA). At least 5000 lymphocytes were collected per sample and analysed using FACSCalibur flow cytometer and CellQuest software (B-D).

Intracellular cytokine analysis

The HLA-A2 restricted epitope GLCTLVAML from the EBV lytic cycle protein BMLF1 was synthesized according to the standard Fmoc protocol^[14]. EBV peptide (10 mg/L) or PHA (Sigma) were used for overnight stimulation of 250 µL whole blood (at 37°C and humidified 5% CO₂ atmosphere). Two hours later 12.5 mg/L Brefeldin A (BD) was added. Cells were further washed in cold phosphate buffered saline (PBS), incubated with EDTA for 10 min, washed again and processed according to the protocol for surface and intracellular staining. For intracellular staining, 100 µL of stimulated blood was lysed with 1 mL FACS™ Lysing solution (BD) followed by permeabilization with 0.5 mL 1 × FACS permeabilizing solution (BD) for 10 min. After washing with PBS containing 0.5% BSA, a simultaneous staining for IFN-γ/CD69/CD8/CD4 was performed for 30 min at room temperature in the dark.

Table 3 Characteristics of the patients with chronic hepatitis related to Epstein-Barr virus infection

Pt No.	Age (yr)	Sex	Duration of illness (mo)	AST	ALT	ALP	GGT	Serology EBV (IFA)				
								VCA IgG	VCA IgM	EA-R IgG	EA-D IgG	EBNA

8	38	m	12	60	60	150	130	640	0	80	80	20
9	30	m	6	50	125	250	180	640	0	80	80	20
10	25	m	6	20	60	225	90	160	0	80	80	20
11	35	m	6	40	80	136	180	160	0	80	80	40
12	31	m	6	50	80	310	80	320	0	160	160	40
13	43	m	10	60	100	300	100	320	10	160	160	0
14	50	f	6	100	200	130	200	640	0	160	160	40
15	50	f	6	80	120	400	200	320	0	160	160	40

For analysis of intracellular staining at least 25 000 CD8^{high} cells were collected. Detection of at least 0.05% IFN- γ ⁺CD69⁺CD8^{high} cells, after subtraction of non-stimulated control values was considered as significant response.

Liver biopsy and imaging

All patients underwent conventional abdominal ultrasonography. Liver biopsy specimens were obtained from 5 patients.

Statistical analysis

Man-Witney non-parametric test was used to evaluate differences between patient and control groups. *P* values less than 0.05 were considered statistically significant.

RESULTS

Clinical findings

The clinical characteristics of each patient are summarized in Table 3. The estimated mean disease duration before the prophylactic examination was 10.8 (min 6, max 36) mo. At the time of diagnosis of the chronic liver disease none of the 15 patients had an infectious mononucleosis-like illness or any other significant complaints except for one, who reported periods of sub-febrile temperature. None of the patients reported previous opportunistic infections or other significant chronic diseases, or congenital immunodeficiency, or immunosuppressive treatment. The average score of Karnofski performance status was 95%^[15].

Laboratory tests showed normal blood counts. Mean values (95% CI) are as follows: white blood cell count, $6.61 \times 10^9/L$ (5.945 to 7.281); red blood cells $5.08 \times 10^6/L$ (4.7893 to 5.3707); platelets, $243 \times 10^9/L$ (207.31 to 277.89). The mean range of serum ALT at the time of diagnosis was 103 UI/mL (UNL = 40) (SD 40.9, SE 10.57), AST/ALT ratio < 1, gamma-GT 122 UI/mL (UNL = 48) (SD 62.41, SE 16.12). Normal serum protein and albumin levels were established in all patients, and

no hyperbilirubinaemia or coagulation disturbances were found. Fasting glucose levels, as well as the glucose load test were within the reference ranges. A serum insulin level in 12 patients was below upper limit, while 3 patients were not tested. The abdominal ultrasonography series revealed normal liver and spleen image.

EBV-serology at the time of diagnosis

The EBV-specific antibody titers of each patient are shown in Table 2. Serology tests indicated a reactivated EBV infection in all 15 patients. The average EBV VCA IgG titer was 320 UA/mL (160-640), EBNA average titer was 20 UA/mL (10-40), and EA-R and EA-D were elevated (80-160). EBV VCA IgM was not detected in any patient. All controls were EBV VCA IgM-negative.

Lymphocyte subset analysis

The percentage and absolute counts of total lymphocytes, T, B and NK cells, CD4⁺ T cells as well as the CD4/CD8 ratio were within the established reference ranges for healthy age-matched controls. Using the mAb combinations CD45RA/CCR7/CD8/CD4 and CD27/CD8/CD28, naïve, central and effector memory, as well as terminally differentiated effector T cells (CTL) were defined (Table 2). The fine subset analysis of T cells revealed a significant decrease of naïve (CD45RA⁺CCR7⁺) CD4⁺ ($P < 0.05$) and CD8⁺ ($P < 0.01$) T cells accompanied by an increased percentage of memory (CD45RA⁻) CD4⁺ ($P < 0.01$) and CD8⁺ T cells ($P < 0.001$), as well as of the terminally differentiated (CD28⁻CD27⁻) CTL subset ($P < 0.01$) (Figure 1A-E). A moderately increased number of CD38 molecules on CD8⁺ T cells was established (mean, 2150; min, 1090; max, 4413) as compared to controls (mean, 1522; min, 510; max, 2210; $P < 0.05$), most probably corresponding to a low level viral replication.

Circulating CD8⁺ T cells, expressing IFN- γ in response to the lytic BMLF1 epitope were registered in all patients, and their percentage was significantly increased (15/15; mean, 0.39%), as compared to EBV-seropositive donors

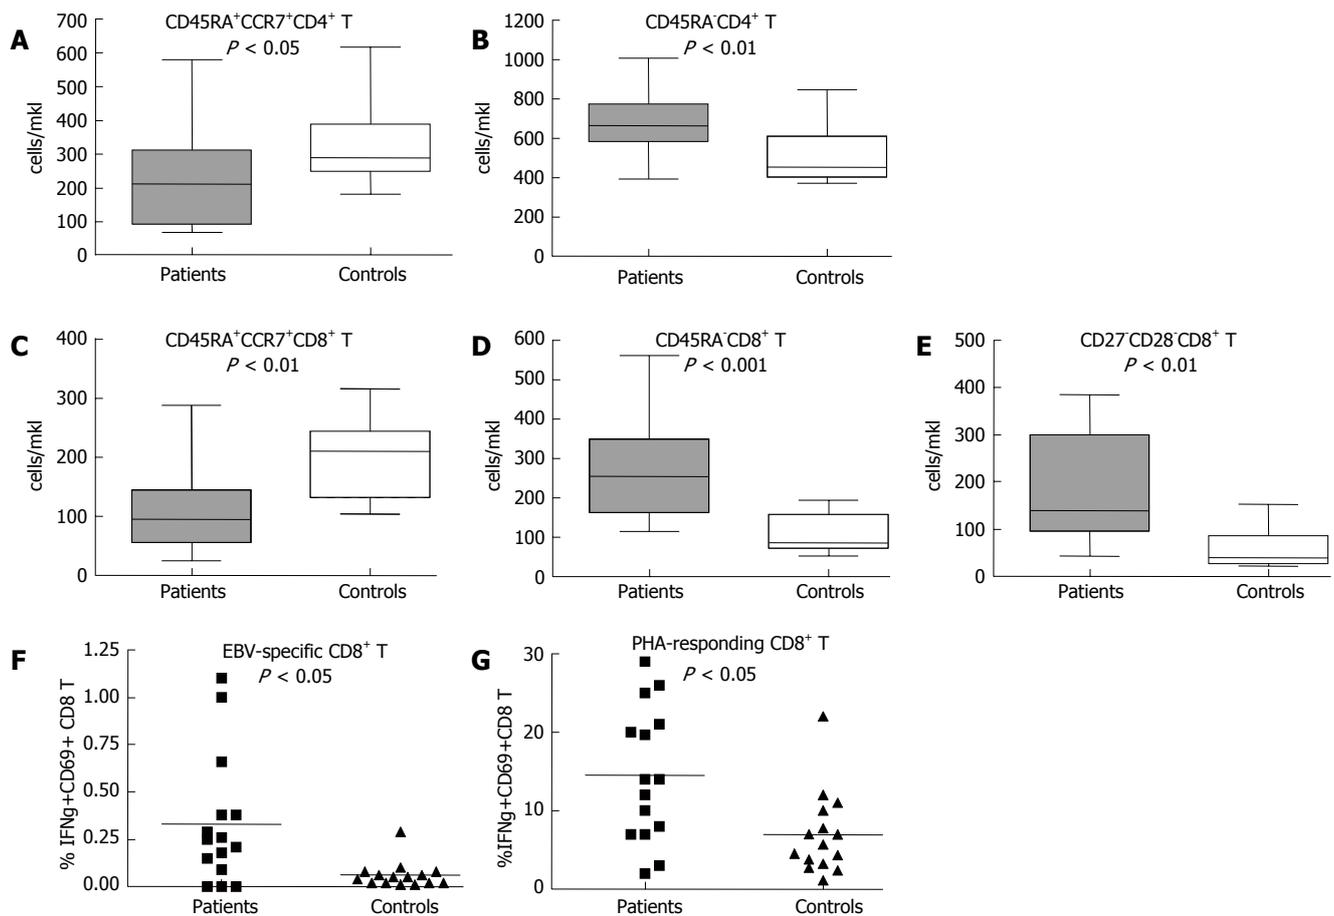

Figure 1 Significant differences detected between patients and control group by immunophenotyping. Patients were characterized by a decreased absolute number of naive CCR7⁺CD45RA⁺CD4⁺ (A) and CD8⁺ (C) T cells, increased absolute number of memory CD45RA⁺CD4⁺ (B) and CD8⁺ (D) T cells, increased absolute number of effector CD28⁺CD27⁺CD8⁺ T cells (E), as well as by increased percentage of IFN γ ⁺CD69⁺CD8⁺ T cells after stimulation with EBV peptide GLCTMVL (F) and with PHA (G). Box-and-whiskers indicate the 25-75 percentile and min-max values for each group. Mean values are designated on all plots by a horizontal line. Man-Witney. P values are indicated for each comparison.

(6/15; mean, 0.06%; $P < 0.05$). The percentage of PHA-responding CD8⁺ T cells was also significantly increased in the patients group in comparison to controls (14.5% *vs* 7.8%, $P < 0.05$) (Figure 1F and G).

Histopathology

Liver biopsy specimens revealed non-specific histopathologic features of low-grade hepatitis. On routine HE slides mild portal and periportal mononuclear infiltrates were seen, composed of small lymphocytes lacking significant cytologic atypia. According to the METAVIR system all patients were staged as A2. No fibrosis was found in any patient except in one which was graded F1 (Figure 2).

DISCUSSION

EBV infects the majority of the human population and persists in the host organism for life. CD8⁺ T lymphocytes specific for lytic and latent EBV antigens control the virus both during primary infection and the long-term carrier state and almost no symptoms indicate these events^[2,16]. Therefore, the development of cellular immune deficiency, related to HIV-infection, transplantation, prolonged immunosuppressive therapy, or even psychological/physical stress is often combined with complications

due to EBV reactivation^[17]. A broad array of clinical entities has, therefore, been related to EBV infection in immunocompromised host, including persistent and necrotizing hepatitis^[18,19]. CAEBV, characterized by a specific pattern of serological and clinical findings, may also induce liver injury^[11,12].

We reported the clinical and laboratory features of 15 Caucasian non-related patients with chronic hepatitis in the settings of reactivated EBV infection that had no apparent immune deficiency and did not meet the classical criteria for CAEBV infection. The serological evidence for EBV reactivation was the presence of EBV-NA and EA-R antibodies, combined with elevated but not extreme titers of IgG anti-VCA^[20]. None of the patients had significant clinical manifestation of the infection, except for one. Although we did not determine plasma and tissue viral load, the moderately elevated CD38 expression on CD8⁺ T cells suggested rather a low-level of viral replication^[21]. In fact, reactivated EBV infection cases have been reported with mild to moderate clinical presentation, and without extreme EBV-specific Ab titers or viral load^[3]. Our data further suggest that the reactivation of EBV infection in the settings of a functional immune system may be more frequent than previously assessed.

Since the latency of EBV infection depends almost entirely on efficient cellular immune responses, phenotypic

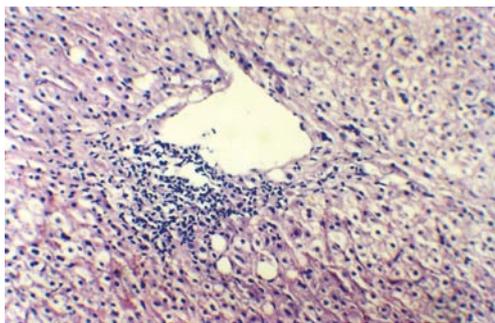

Figure 2 Liver biopsy, showing lymphocyte infiltrate within the lobule and some hepatocyte injury, with mild steatosis displayed in some cells.

and functional changes in the lymphocyte compartment might be expected in case of reactivation. CAEBV is usually characterized by oligoclonal expansions of either T or NK cells^[22,23]. Although we detected no significant changes in the main circulating lymphocyte populations, the fine subset analysis revealed a significant prevalence of antigen-primed (CD45RA⁺) over naïve (CD45RA⁺CCR7⁺) CD4⁺ and CD8⁺ T cells, combined with increased percentage of terminally differentiated (CD28⁻CD27⁻) CD8⁺ T cells. In general, the activation and differentiation state of the circulating T cell pool reflects any major antigen-driven process in the organism. T-cell activation induces a shift from CD45RA to CD45RO expression, while long-lasting chronic viral infections like HIV-1 or CMV are characterized with prevalence of terminally differentiated non-proliferating effectors in the CD8⁺ T cell compartment^[24,25], similar to the natural age-related senescence of cellular immunity^[26]. Moreover, particular viruses may be associated with specific phenotypic changes in latency, as the CMV-driven expansion of CD45RA⁺CD27⁻CD8⁺ T cells^[27]. Logically, such a phenotypic shift must involve both virus-specific and non-specific by-stander activation and differentiation.

The EBV-specific memory pool in asymptomatic carriers is reported to be heterogeneous: CD8⁺ T cells specific for latent epitopes being mostly CD45RA⁻CD28⁺, while those, specific for lytic epitopes, CD45RA⁺/CD45RA⁻CD28⁻CD27⁺^[28]. CD27 is a co-stimulatory molecule promoting the survival of activated CD8⁺ T cells in the absence of CD28^[29], with a limited reexpression capacity. CD27 probably enhances EBV-specific responses, as most of the EBV-specific cytotoxic activity was reported in the CD27⁺ subpopulation^[30]. In our patients group we established a significant expansion of CD8⁺ T cells lacking both CD28 and CD27. We may speculate that in case of long lasting or repeated low-level EBV reactivation, the CD27⁺ pool would be gradually replaced by CD27⁻ CD8⁺ T cells, less efficient in controlling the persistent EBV infection.

EBV-specific cells detected by tetramer staining in latency account for 1%-3% of the circulating CD8⁺ T cell pool^[31]. Again by tetramer staining, a similar detection rate of lytic epitope-specific CD8⁺ T cells has been reported in CAEBV and asymptomatic EBV carriers^[16]. In our series, patients with EBV-related hepatitis had a significantly higher lytic epitope-specific CTL response, as compared to

controls, combined with a higher response to non-specific stimulation, as estimated by IFN- γ expression. These results indicate that the identification of functional EBV-specific CD8⁺ T cells may better differentiate between asymptomatic carriers and clinically unapparent but active infection.

Several viruses have been implicated in the development of chronic liver disease, either as single agents or *via* cross-activation of T cells. A close association between liver lesions and a previous EBV infection has been demonstrated, as well as the presence of EBV-positive cells in affected livers in the settings of continuous low level EBV replication^[32,33]. Sugawara *et al.*^[34-36] linked EBV to HCV-related hepatocellular cancerogenesis, supporting the EBNA-1 promoted HCV replication hypothesis. EBV was suggested to be involved in the hepatocellular carcinogenesis, although this role is still controversial^[37]. Our patients had serological evidence for EBV reactivation and, on the other hand, immunophenotypic evidence for persisting low-level cellular immunity activation and chronic liver inflammation. As the mechanism of EBV-related liver damage remains unclear, indirect, cytokine-induced hepatocellular injury is being discussed^[38,39]. Despite the lack of typical mononucleosis characteristics, liver lymphocyte infiltrates in our cases might be involved in the EBV-provoked immune response.

Although based mostly on exclusion criteria, our data suggest that chronic liver disease could be a manifestation of chronic EBV infection, with persistent low-level virus replication or in case of frequent reactivations. It remains to elucidate the underlying mechanisms of inefficient viral control in these immunocompetent patients and whether such patients may further revert to a fulminant course of the infection.

In conclusion, a reactivated EBV infection might be the possible reason for a chronic elevation of serum aminotransferases without a detectable immune deficiency. The prevalence of memory (CD45RA⁺) and terminally differentiated (CD28⁻CD27⁻) CD8⁺ T cells together with the increased frequency of functionally active EBV-specific CD8⁺ T cells in the circulating CD8⁺ T cell compartment might be the only surrogate markers of reactivated viral infection. The identification and follow-up of such patients may help the prevention of classic CAEBV or other severe manifestations of chronic EBV infection.

Abstract

AIM: To investigate whether single-nucleotide polymorphisms in the promoter regions of endotoxin-responsive genes CD14 C (-159) T is associated with chronic hepatitis B.

METHODS: We obtained genomic DNA from 80 patients with established diagnosis of chronic hepatitis B and 126 healthy subjects served as a control population. The CD 14 C (-159) T polymorphism was investigated using an allele specific PCR method.

RESULTS: Twenty seven percent of chronic hepatitis B patients and 75% of controls were heterozygous for CT genotype. The difference between the chronic hepatitis B and control groups was statistically significant [$P < 0.0001$; Odds ratio (OR) = 2.887; 95% CI: 1.609-5.178]. Twenty four point six percent of chronic hepatitis B and patients 12.3% of the control group were heterozygous for TT genotype. The difference between groups was not statistically significant ($P = 0.256$; OR = 0.658; 95% CI: 0.319-1.358). Forty eight point four percent of chronic hepatitis B patients and 12.7% of control were homozygote for CC genotype ($P < 0.004$; OR = 0.416; 95% CI: 0.229-0.755). The frequency of allele C was 61.9% and allele T was 38.1% in hepatitis B patients group. The frequency of allele C was 55.2% and allele T was 44.8% for the control group ($P = 0.179$; OR = 1.319; 95% CI: 0.881-1.977).

CONCLUSION: The TT heterozygous genotype was not a risk factor for chronic hepatitis B. CC homozygote genotype is protective for hepatitis B. Lack of heterozygosis of genotype CT is a risk factor for chronic hepatitis B. Alleles C or T were not risk factors for chronic hepatitis B.

These findings show the role of a single-nucleotide polymorphism at CD14/-159 on the development of

INTRODUCTION

An estimated 350 million persons worldwide are infected with hepatitis B virus (HBV). Hepatitis B carriers are at risk for development of cirrhosis and hepatocellular carcinoma. Persons with chronic hepatitis B infection need life-long monitoring to determine when intervention with antiviral therapy is needed and to observe for serious sequels^[1].

The mechanism by which HBV establishes a persistent infection is at present still unclear. Evidence suggests that the clinical manifestations and outcomes after acute liver injury associated with viral hepatitis are determined by the immunologic responses of the host^[2]. CD14, a key gene of the innate immune system, functions as a receptor for lipopolysaccharide (LPS), a constitutive element of the bacterial cell wall. CD14 cannot bind to LPS directly. A protein termed LBP (lipopolysaccharide binding protein) must first bind to LPS. The LPS-LBP complex then binds to CD14 and the receptor-ligand complex is internalized. In addition, CD14 is associated with a protein known as Toll-like receptor 4 (TLR-4). As a consequence of the CD14-LPB/LPS interaction at the level of the membrane, TLR-4 becomes activated. TLR-4 plays an important role in signal transduction. Importantly, TLR-4 is now known to activate a transcription factor known as NF κ B. Viruses have targeted cellular cytokine production and cytokine receptor-signaling pathways, apoptotic pathways, cell growth and activation pathways, MHC-restricted antigen presentation pathways and humoral immune responses^[3].

This study tested whether genetic factors, CD14 C (-159) T, has any role in molecular pathogenesis of chronic

hepatitis B and influences the individual susceptibility for chronic hepatitis B.

MATERIALS AND METHODS

Subjects

We analyzed 80 Iranian patients with chronic hepatitis B and 126 sex-matched control subjects. All chronic hepatitis B patients had visited at a liver clinic in Tehran for regular follow-up examinations. All participants signed the informed consent.

Chronic hepatitis B was based upon biochemical, virologic, histological activity and included patients still on interferon or lamivudine treatment; those who finished treatment course and nonresponders to treatment (lack of virologic and or histologic response by first treatment course in which sustained response was unlikely). Asymptomatic carrier state defined as: chronically HBsAg positive patients who have anti-HBc in serum, anti-HBs is either undetected or detected at low titer against the opposite subtype specificity of the antigen regarded as inactive or asymptomatic carriers, HBV DNA load less than 10^5 copies/mL, HBeAg (+, -), serum liver transaminases of normal range. Inactive hepatitis B surface antigen (HBsAg) carriers were monitored with periodic liver chemistries as liver disease may become active even after many years of quiescence. Controlled subjects had no evidence of hepatitis B infection. The serum of control subjects were evaluated for HBsAg, HBsAb, AST and ALT. Those who had negative HBsAg and HBsAb as well as normal AST and ALT were selected for control groups.

CD14 C (-159) T Genotype Determination

Ten milliliters were collected from each subject into tubes containing 50 mmol/L EDTA, and genomic DNA was isolated from anti-coagulated peripheral blood Buffy coat using Miller's salting-out method^[4].

Total genomic DNA from peripheral blood leukocytes was extracted by standard methods. The CD14 C (-159) T polymorphism was investigated using an allele specific PCR method^[5]. PCR products were visualized by electrophoresis in 2% (w/v) agarose gel stained with ethidium bromide. The assay thus yields a 381-bp band for T allele and 227-bp band for C allele.

Statistical analysis

The differences in the frequencies of the CD14 genotypes and alleles and other risk factors were analyzed by the χ^2 test. For comparing mean stage of liver pathology in different genotypes, Kruskal-Wallis test was used. Associations and differences with probability value less than 0.05 were considered significant. Statistical data was expressed as mean \pm SD. All statistical analyses were performed with the use of SPSS software, version 11.05.

RESULTS

The mean age in hepatitis B group was 36.10 ± 13.78 and in control group was 43.60 ± 16.47 . In the hepatitis B group 71.3% of patients were male and 28.8% were

female. In the control group 62.7% were male and 37.3% were female. The two groups were matched by sex. In the hepatitis B group, 12% were HBeAg positive, 85% were HBeAg negative, 85% were HBeAb positive and 15% were HBeAb negative. Serum aspartate aminotransferase (AST) levels in 75.9% of hepatitis B patients were < 40 IU/mL and in 24.1% were ≥ 40 IU/mL. Serum alanine aminotransferase (ALT) in 68.4% of hepatitis B patients was < 40 IU/mL and in 31.6% was ≥ 40 IU/mL. The state of hepatitis B disease at the time of sampling was as follows: 53.8% were asymptomatic carriers, 31.3% were still on antiviral treatment, 6.3% again returned to treatment, 7.5% were in chronic state and 1.3% were cirrhotics. Liver biopsy was performed in 36 patients of hepatitis B group. Histological classification was measured by Modified Histological activity index (HAI) by Ishak score^[6]. Mean stage, grade and pathologic score were 1.85 ± 0.97 , 5.28 ± 1.84 , and 7.17 ± 2.58 , respectively.

Twenty seven percent of hepatitis and 75% of control subjects were heterozygous for CT genotype. The difference between CT genotype was statistically significant ($P < 0.0001$; OR = 2.887; 95% CI: 1.609-5.178). The lack of heterozygosity for genotype CT was a risk factor for hepatitis B. 24.6% of hepatitis and 12.3% of control group subjects were heterozygous for the TT genotype. The difference between groups was not statistically significant ($P = 0.256$; OR = 0.658; 95% CI: 0.319-1.358). The TT homozygote genotype was not a risk factor for hepatitis B. 48.6% of hepatitis and 12.7% of control group subjects were heterozygous for the CC genotype ($P < 0.004$; OR = 0.416; 95% CI: 0.229-0.755). The CC homozygote genotype was protective for hepatitis B.

The frequency of allele C was 61.9% and allele T was 38.1% in the hepatitis B group.

The frequency of allele C was 55.2% and allele T was 44.8% for control group ($P = 0.179$; OR = 1.319; 95% CI: 0.881-1.977). So alleles were not a risk factor for hepatitis B. There were no statistically significant associations between allele frequencies and genotypes frequencies in the hepatitis B group with state of disease; ALT (< 40 , ≥ 40) IU/mL, mean stage of liver pathology, HBeAg (+, -). Mean stage of liver pathology was not statistically significant in different genotypes (CC, CT, CT) by Kruskal-Wallis test.

DISCUSSION

In a previous study^[7], the effect of recombinant HBsAg (rHBsAg) on LPS- and IL-2-induced activation of monocytes was investigated. It showed that recombinant HBsAg particles, which contain the S protein only, bind almost exclusively to monocytes. Further it showed that recombinant HBsAg (rHBsAg) particles not only inhibit LPS-induced secretion of IL-1 β and TNF α , but also inhibit IL-2-induced secretion of IL-8. Their results suggested that monocytes express a receptor that is recognized by HBsAg and that HBV produces HBsAg in excess amounts to interfere with the normal function of antigen-presenting cells.

In our population, HBeAg negative chronic hepatitis B is more common than HBeAg positive. But difference

in associations of frequency of alleles and genotypes in HBeAg negative versus positive chronic hepatitis B patients were not statistically significant. Besides the viral role, we aimed to investigate the CD14 C (-159) T polymorphism as a host factor, which deteriorates the hepatitis course and outcome in our population.

The CD14 promoter genotype may affect inflammatory processes and be involved in atherogenesis, and it is therefore possible that this genotype might also be associated with other major forms of thrombotic disease, such as ischemic cerebrovascular disease, coronary artery disease. LPS is a structural component of gram-negative bacteria and is bound in plasma by the LPS binding protein^[8]. The LPS binding protein complex then binds to a glycosylphosphatidylinositol-anchored membrane protein, membranous CD14 (mCD14), on monocytes and macrophages and activates these cells. The activated phagocytes in turn secrete inflammatory cytokines through which LPS indirectly activates endothelial cells. Soluble CD14 (sCD14), which lacks a glycosylphosphatidylinositol anchor, can also be found in plasma. Endothelial cells and smooth muscle cells, lacking their own mCD14, are directly activated by LPS-sCD14 complex^[9,10]. Directly and indirectly activated endothelial cells express cell adhesion molecules and increased procoagulant activity, and they release free radicals, thereby mediating the initiation and development of atherosclerosis.

A previous study^[11], demonstrated T allele frequency was significantly higher in myocardial infarction survivors and that the density of monocyte mCD14 was higher in T/T homozygotes than in other genotypes.

In another study^[12], the possible association between the C (-260)→T polymorphism in the CD14 promoter and the occurrence of symptomatic ischemic cerebrovascular disease (CVD) was tested. They concluded that the C (-260)→T polymorphism in the CD14 promoter is not associated with an increased risk for CVD.

A previous study^[13] mentioned activated Kupffer cells release proinflammatory cytokines, a process that is regulated by the CD14 endotoxin receptor (CD14). Also, both clinical and experimental data suggest that Kupffer cell activation by gut-derived endotoxins and other bacterial products is an important pathogenic factor. In that study, the association of CD14 promoter polymorphism with different forms of alcoholic liver damage (ALD) was examined in 3 separate autopsy series. The overall age-adjusted risk for cirrhosis was 3.08 for the carriers of the CT genotype, and 4.17 for the homozygous TT genotype. Their results suggested that in the relatively isolated Finnish population, the T allele and in particular, TT homozygotes confers increased risk of alcoholic liver damage and are at a high risk to develop cirrhosis.

Another study^[14] investigated whether single-nucleotide polymorphisms in the promoter regions of endotoxin-responsive genes CD14 and tumor necrosis factor- α (TNF- α) were associated with biliary atresia (BA) and idiopathic neonatal cholestasis (INC) in 90 patients with established diagnosis of BA and 28 patients with INC. Also, forty-two adult patients with hepatitis B-related cirrhosis and 143 healthy children served as control populations. According to that study the single-nucleotide polymorphism at

CD14/-159 is associated with the development of BA and INC. They concluded that endotoxin susceptibility might play a role in the pathogenesis of infantile cholestasis.

In the present study, we did not compare risk factors of hepatitis B infection, its routes of exposure and transmission in hepatitis B and control groups. Although determining the exact time of hepatitis B infection was impossible. Whether specific polymorphisms of CD14 C (-159) T has any correlation with progression of liver pathology or whether it indirectly produces needs further study and a larger sample size.

CONCLUSIONS

Our study demonstrated that the role for CD14 C (-159) T polymorphism on the development of chronic hepatitis B. Although the number of subjects in the chronic hepatitis B subtypes was relatively small, differences in the genotype distributions for chronic hepatitis B subtypes was significant.

Lack of heterozygosis of genotype CT is a risk factor for chronic hepatitis B.

TT homozygote genotype was not a risk factor for chronic hepatitis B. CC homozygote genotype is protective for chronic hepatitis B.

These findings show a role for single-nucleotide polymorphisms at CD14/-159 C (-159) T on development of chronic hepatitis B. Endotoxin susceptibility may play a role in the pathogenesis of chronic hepatitis B.

Abstract

AIM: To explore the anti-hepatitis B virus (HBV) effects of *Boehmeria nivea* (*B. nivea*) root extract (BNE) by using the HepG2 2.2.15 cell model system.

METHODS: Hepatitis B surface antigen (HBsAg), hepatitis B virus e antigen (HBeAg), and HBV DNA were measured by using ELISA and real-time PCR, respectively. Viral DNA replication and RNA expression were determined by using Southern and Northern blot, respectively.

RESULTS: In HepG2 2.2.15 cells, HBeAg (60%, $P < 0.01$) and particle-associated HBV DNA (> 99%, $P < 0.01$) secretion into supernatant were significantly inhibited by BNE at a dose of 100 mg/L, whereas the HBsAg was not inhibited. With different doses of BNE, the reduced HBeAg was correlated with the inhibition of HBV DNA. The anti-HBV effect of BNE was not caused by its cytotoxicity to cells or inhibition of viral DNA replication and RNA expression.

CONCLUSION: BNE could effectively reduce the HBV production and its anti-HBV machinery might differ from the nucleoside analogues.

INTRODUCTION

Hepatitis B virus (HBV) has infected more than 4 million people worldwide. About 20% of patients infected with HBV may lead to chronic hepatitis, liver cirrhosis, and hepatocarcinoma. HBV, belonging to the *Hepadnaviridae* family, is a non-cytopathic DNA virus with an icosahedral capsid that replicates *via* reverse transcription of an RNA intermediate^[1]. Although the molecular biology aspects of the HBV genome have been described in detail, the mechanisms of viral packaging and transport remain to be elucidated^[2]. Nevertheless, HBV-DNA-transfected cells and virus infection animal models have aided the efforts to reveal the mechanism behind the HBV replication cycle. These results led to the identification of the first antiviral agents targeting the reverse transcription process^[3].

Chronic hepatitis type-B patients are clinically treated with interferon alpha (INF- α) and nucleoside analogue lamivudine (3TC), adefovir or entecavir^[4,5], which are analogues of reverse-transcriptase inhibitors^[6,7]. INF- α inhibits viral replication and acts as an immuno-modulator. However, its disadvantages include limited effectiveness (40% response rate)^[8], low efficacy with respect to cost, and serious side effects. For 3TC, its inhibition is reversible, and continuous treatment often leads to the development of drug-resistant HBV variants (70% of patients after 4 years of treatment)^[9]. Both adefovir and entecavir are used against 3TC-resistant viruses; however, resistances to these two drugs have been reported in lamivudine-resistant patients^[10-12]. The use of combination therapy, such as INF- α plus 3TC, 3TC plus adefovir and 3TC plus entecavir, may yield additive or synergistic effects or reduce the emergence of resistance, though serious side effects and unsatisfactory efficacy still present problems. Undeniably, there is a demand for new and improved therapies.

The large repertoire of herbal compounds may show potential in developing new ways to combat previously considered "incurable" diseases, provided that these compounds (or often, mixtures of compounds) could satisfy current government regulations. At present, alternative or traditional medical resources are used by more than 80% of the population in developing countries and by an increasing number of people in other parts of

the globe^[13,14]. Complementary and alternative therapies for chronic hepatitis are also intensively explored and the results appear promising^[15]. Patients with chronic liver diseases are treated with some medicinal herbs exhibiting strong antiviral activities^[16], including daphnoretin from *Wikstroemia indica*^[17], costunolide and dehydrocostus lactone from *Saussurea lappa* Clarks^[18], osthole from *Angelica pubescens*^[19], and the extracts of genus *Phyllanthus* of the *Euphobiaceae* family^[20]. Furthermore, genus *Phyllanthus* exhibited a positive effect on the clearance of serum HBsAg in clinical trials conducted on chronic HBV infections, and a synergistic effect when administered with IFN- α ^[20]. *B. nivea* has been distributed and used therapeutically in China and Taiwan for diuretic, antipyretic, and hepatoprotective purposes. Recently, it has been reported that root extracts of *B. nivea* exhibited hepatoprotective activities against CCl₄-induced liver injuries, and anti-oxidant effects on FeCl₂-ascorbate-induced lipid peroxidation in rat liver homogenate^[21].

To investigate the anti-viral mechanism of *B. nivea* extract (BNE), HBV-producing hepatoma HepG2 2.2.15 cells, which secrete HBsAg, HBeAg and complete Dane particles^[22], were chosen for the evaluation of the anti-HBV effect of BNE. Here, we assess anti-HBV activities of BNE by measuring HBsAg, HBeAg, HBV DNA in supernatant, and replication intermediate HBV DNA and HBV RNA within the cells.

MATERIALS AND METHODS

Preparation of BNE

To prepare the *B. nivea* plant extract utilized in our experiments, the roots of the plants were collected and dried. One hundred gram of the dried roots was cut into pieces approximately 0.5 cm in length before boiling them in 1 L of 200 mL/L ethanol (1:10 ratio) under reflux for 3 h. The decoction was filtered through a 0.22- μ m filter and lyophilized. The lyophilized powder was dissolved in normal PBS and adjusted to stock concentration (100 g/L) prior to application to the cells.

Cell lines and culture

The HepG2 2.2.15 cell line was kindly provided by Dr. Ho MS (Academia Sinica, Taipei, Taiwan, China), and Human hepatoma HepG2 cells were obtained from American Type Culture Collection (ATCC). These cells were maintained in MEM (Eagle) plus 100 mL/L fetal bovine serum (FBS) supplement with 1.5 g/L sodium bicarbonate, 0.1 mmol/L non-essential amino acids, 1.0 mmol/L sodium pyruvate, and 100 units/mL penicillin G and 100 mg/L streptomycin. A final concentration of 200 mg/L G418 was contained in the medium for the maintenance of HepG2 2.2.15 cells. Before the experiment, the cell count was adjusted to 1×10^6 /mL, and cell viability to higher than 85% by trypan blue exclusion test.

Drug treatment protocols

For drug treatment, 1×10^5 cells of HepG2 2.2.15 were seeded in a 12-well plate and allowed to grow for 3 d before treatment with different concentrations of BNE. Cells were refed with drug-containing fresh medium every 3 d for up to 12 d in time-dependent experiment. In Southern and

Northern blot assay, the culture condition was the same as described above (10 mg/L 3TC were also added), and in which time of drug treatments were only for 1 d.

Analysis of cytotoxicity

HepG2 2.2.15 cells were used for determining cytotoxicity of BNE. Cells were inoculated onto a 96-well plate at a density of 1×10^4 cells per 100 μ L prior to drug treatment. BNE was added at concentrations of 0.1, 1, 10, and 100 mg/L and the cells were refed with drug-containing fresh medium every 3 d for up to 12 d. After drug treatment, the cytotoxicity was measured based on the reduction of MTT (Sigma, St. Louis, USA) in mitochondria^[23].

Determination of HBsAg and HBeAg levels by ELISA

Conditioned medium was collected and the HBsAg and HBeAg levels were determined semi-quantitatively using ELISA assay [SURASE B-96 (TMB), General Biologicals corp., Taiwan, China] according to the manufacturer's instructions.

Supernatant HBV DNA extraction and analysis by quantitative real-time PCR

The supernatant HBV DNA was extracted from conditioned medium as previously described^[24] and stored in -20°C prior to real-time PCR analysis. The quantity of HBV DNA in culture medium was quantified with the ABI 7500 Sequence Detection System by using HBV RealQuant PCR kit (General Biologicals Corp., Taiwan, China) according to the manufacturer's instructions. Briefly, the PCR programming was performed with an initial denaturing steps at 50°C for 2 min and 95°C for 10 min, followed by 45 amplification cycles at 95°C for 15 s and annealing/extending at 58°C for 1 min.

The 50% effective concentration (EC₅₀), defined as the drug concentration that reduces the level of HBV DNA in the culture medium by 50%, was calculated by four parameter logistic curve equation.

Southern and Northern blot detection of HBV DNA and mRNA in HepG2.2.15 cell

HepG2 2.2.15 cells were cultured in MEM medium and treated with 0.1, 1, and 10 mg/L BNE for 1 d. Cells were lysed with 0.8 mL of 0.01 mol/L Tris-HCl (pH 8.0), 0.05 mol/L NaCl, 5 mL/L NP-40, 1 mmol/L EDTA at room temperature for 10 min as previously described^[25]. For the Southern hybridizations, 20 μ g of total DNA was digested with *Hind*III, electrophoresed on a 14 g/L agarose gel, and then transferred to nylon membrane. The probe for hybridization was synthesized from PCR amplification of a plasmid containing the full-length HBV genome (kindly provided by Dr. Ho MS, Academia Sinica, Taipei, Taiwan, China), and then the probe was labeled with digoxigenin-dUTP (DIG) by the DIG-high Prime DNA labeling and Detection Starter kit II according to the manufacturer's protocol (Roche, Basel, Switzerland). The membrane was hybridized with HBV probe at 50°C overnight. For Northern blot analysis, total RNA was isolated from BNE-treated and untreated HepG2 2.2.15 cells by using the TRIZOL kit (Invitrogen, CA, USA). A total of 20 μ g of RNA was resolved in 12 g/L denatured gel and then

transferred onto the nylon membrane and the membrane was hybridized with DIG-labeled HBV DNA fragment described above. For hybridization of glyceraldehyde-3-phosphate dehydrogenase (G3PDH), the full-length HBV DNA probe was removed from the membrane by washing twice at 37°C in 0.2 mol/L NaOH containing 1 mL/L sodium dodecyl sulfate (SDS) solution for 15 min and then re-hybridized with DIG-labeled probe for G3PDH.

Statistical analysis

Data were expressed as mean \pm SE of three independent experiments. Statistical analysis was performed using Student's *t*-test. A *P* value less than 0.05 was considered statistically significant.

RESULTS

Effects of BNE on secreted HBsAg, HBeAg and HBV DNA from HepG2 2.2.15 cultures

Anti-HBV activity of BNE was investigated by using HepG2 2.2.15 cells, which can secrete HBV particles. When HepG2 2.2.15 cells were treated with various concentrations of BNE, secretion of HBeAg, but not HBsAg, was significantly suppressed compared to vehicle controls (Figure 1A and B). The suppression of HBeAg was dose-dependent and approximately 20% of inhibition was observed in cells treated with 10 mg/L BNE. Moreover, a significant suppression of HBeAg secretion (approximately 60%) was observed in cells treated with 100 mg/L BNE (Figure 1B).

We also measured the amount of viral DNA secreted in the medium (supernatant HBV DNA) by using real-time PCR. As shown in Figure 1C, supernatant HBV DNA was dramatically decreased compared to vehicle control, since the first day of treatment, in 10 and 100 mg/L BNE-treated culture medium. Although the amounts of supernatant HBV DNA increased while cells continued to grow during the experiment, approximately 95% inhibition of DNA secretion was observed in the 12-d culture treated with BNE (10 mg/L) (Figure 1C). Notably, these results showed that the production of HBsAg and HBeAg was only slightly suppressed by 10 mg/L BNE, but supernatant HBV DNA levels were dramatically suppressed by BNE at the same dose.

Cytotoxic effects of BNE on HepG2 2.2.15 cells

Suppression of HBV production by BNE might be a result of its cytotoxicity, and this possibility was examined in HepG2 2.2.15 cells by using MTT assay. No apparent cytotoxicity was detected in HepG2 2.2.15 cells up to 12 d after exposure to BNE at different concentrations (0.1, 1, 10 and 100 mg/L) (Figure 2), suggesting that the suppression of supernatant viral DNA levels by BNE was not caused by its cytotoxicity.

Determination of the effective concentration of BNE anti-HBV activity

The effective concentration of BNE to suppress 50% of secreted HBV DNA (EC_{50}) was determined with various concentrations of BNE on d 1. The suppression of secreted HBV DNA was shown in a dose-dependent

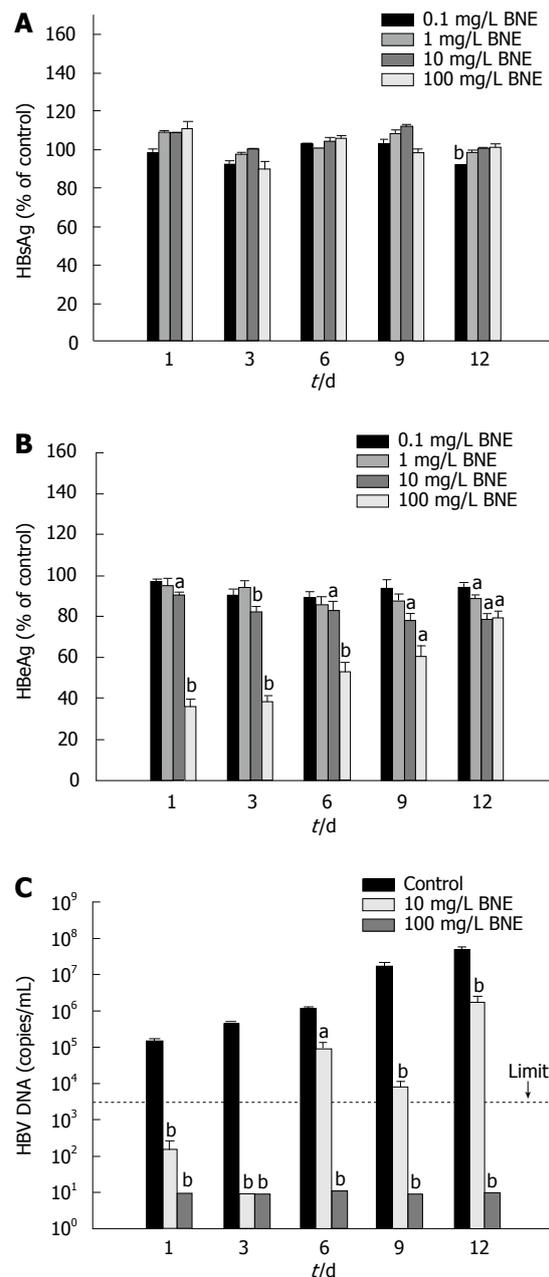

Figure 1 Effects of BNE on secreted HBsAg, HBeAg and HBV DNA from HepG2 2.2.15 cell cultures. **A:** HBsAg level; **B:** HBeAg level; **C:** Viral DNA. The dotted line presents the limitation of this kit (3000 copies/mL). manner with BNE treatment (70% at 0.1 mg/L and 100% at \geq 10 mg/L) (Figure 3); accordingly, the EC_{50} was 0.0462 mg/L. Here, the concentration of BNE (10 mg/L) used for the study of anti-HBV activity was about 200-fold of EC_{50} .

Effects of BNE on intracellular HBV DNA replication and transcription in HepG2 2.2.15 cells

To address the mechanism of inhibition by BNE in HepG2 2.2.15 cells, we analyzed the viral mRNA after 24 h exposure to BNE by Northern blot using full-length HBV genome as a probe (Figure 4A) and intracellular relaxed circular (RC) and single-stranded (SS) forms of HBV DNA by Southern blot in parallel (Figure 4B). The levels

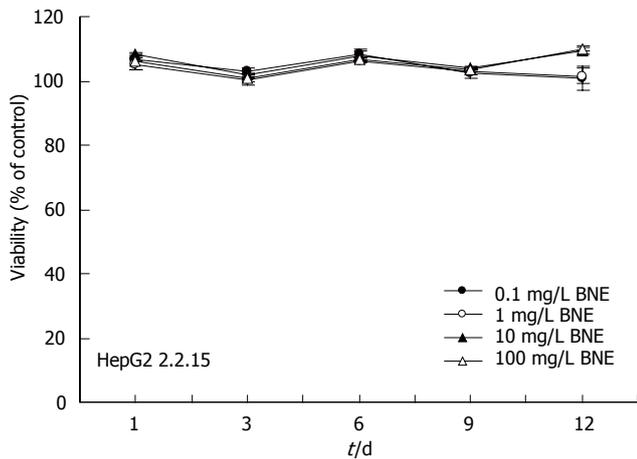

Figure 2 Cytotoxic effects of BNE on HepG2 2.2.15 cells. Data are expressed as mean ± SE of three independent experiments (MTT assay).

of viral mRNA were not affected in either BNE-treated or 3TC-treated cells (Figure 4A). Moreover, Southern blot results indicated that BNE did not suppress intracellular RC and SS forms of HBV DNA. In contrast, an apparent inhibition of intracellular RC and SS forms of HBV DNA was observed in 3TC-treated cells, which was significantly different from the BNE group (Figure 4B). These results suggested that BNE did not apparently decrease viral DNA replication and viral mRNA expression in HepG2 2.2.15 cells, and that the anti-HBV mechanism of BNE seemed to be different from that of 3TC.

DISCUSSION

In this study, we first demonstrated that BNE had anti-HBV activity of inhibiting the supernatant HBV DNA levels in a dose-dependent manner in HepG2 2.2.15 cells without blocking HBsAg secretion. This inhibition was caused neither by the toxicity of BNE to HepG2 2.2.15 cells, nor by blocking HBV gene expression and replication. The significant inhibition of supernatant HBV DNA levels was observed at a concentration greater than 10 mg/L of BNE in HepG2 2.2.15 cells. In addition, BNE could also dose-dependently inhibit the secretion of HBeAg. Although BNE had higher inhibitory ability on HBeAg secretion at 100 mg/L than that at 10 mg/L, it still could efficiently inhibit secreted HBV DNA at the latter concentration. This result might be due to the fact that BNE comprise multiple compounds, and the effective concentration of those compounds to inhibit secreted HBV DNA was lower than that of the compounds required for inhibition of HBeAg.

Currently, 3TC and other nucleoside analogues have been shown to inhibit HBV replication both *in vitro* and *in vivo*^[24,26,27]. A previous study had reported that 3TC, a viral polymerase inhibitor, reduced episomal DNA (RC and SS form), whereas HBV-specific RNAs were not affected in HepG2 2.2.15 cells^[24]. In this study, we could not find any apparent reduction of HBV-specific RNAs or intracellular SS and RC DNA in response to BNE, and that these data revealed that the anti-HBV mechanism of BNE might be different from 3TC that targeted the viral

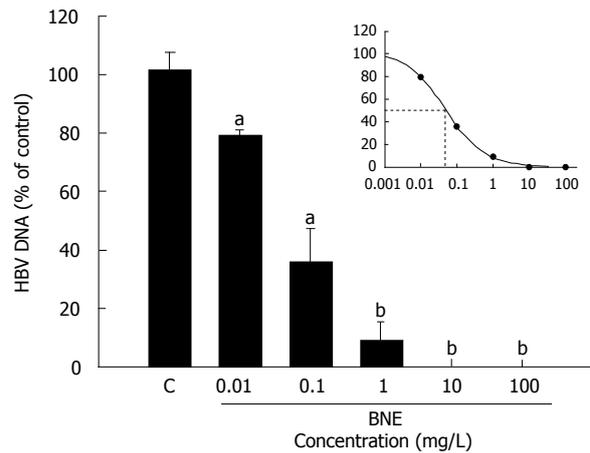

Figure 3 Determination of the effective concentration of BNE anti-HBV activity. Cells were treated for 24 h. Data are expressed as mean ± SE of three independent experiments. ^a*P* < 0.05, ^b*P* < 0.01 vs the corresponding controls (Student's *t*-test).

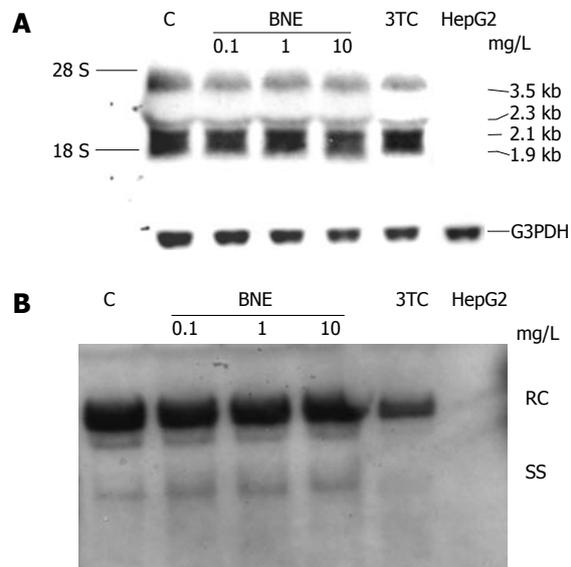

Figure 4 Effects of BNE on intracellular HBV DNA replication and transcription in HepG2 2.2.15 cells. Cells were treated for 1 d. **A:** Northern analysis; **B:** Southern analysis.

polymerase. Since the HBV mRNAs were transcribed from the integrated DNA, it was not unexpected that HBV-specific transcripts were not affected by BNE treatment. The finding that supernatant HBV DNA rather than HBsAg and HBeAg was dramatically inhibited by 10 mg/L BNE after 24-h treatment might come from the possibility that exported virions have outer protein coats or HBsAg without packaging DNA. Though the mechanism of anti-viral effects by BNE remains unclear, we deduced that BNE might block coating and secretion of HBV containing nucleocapsids or destabilize HBV DNA containing nucleocapsids.

Whether the HBV-inhibiting effects of BNE could be contributed to a single component, or multiple components, is currently unknown. In order to explore the active compound for anti-HBV activity, we have attempted to analyze the chemical composition of BNE by HPLC. Very

little, if any, nucleotide analogues were detected (data not shown). Fractionation experiments of BNE are currently being executed in our laboratory. Recently, Herteroaryldihy dropyrimidines (HAP)^[28], Bis-ANS^[29], and alkylated imino sugars^[30,31] have been found to block the viral production by interference with either nucleocapsid assembly or nucleocapsid maturation, and these compounds might have the potential to be developed as non-viral polymerase targeting antiviral drugs.

In conclusion, the BNE, together with other medicinal herbs that exploit different action modes to inhibit HBV, could be administered in combination with other polymerase inhibitors or cytokines, providing possibly a novel HBV treatment strategy to the current therapies.

ACKNOWLEDGMENTS

We gratefully thank to Dr. Ho MS for providing the materials, HepG2 2.2.15 cells and full-length HBV plasmid, and also thank the Dr. Ho MS and Dr. Yuan TT for giving comments on this manuscript.

INTRODUCTION

The prognosis of pancreatic body and tail cancer is dismal^[1-10]. Its curative resection is rarely performed, only a few reports are available^[4-10]. The outcome of 8 Chinese patients with non-cystic adenocarcinoma in pancreatic body and tail (NCAPBT) after resection is reported and the clinical-pathological characteristics and surgical strategy of NCAPBT are discussed in this paper.

MATERIALS AND METHODS

Resection of NCAPBT was performed in eight Chinese patients with complete clinical-pathological data from January 2000 to September 2004 in our hospital. The outcome of all the patients is summarized in Tables 1 and 2. The average age of the patients was 67 years (range, 53-79 years) and the ratio of male to female was 1:1. Abdominal pain was found in 87.5%, weight loss in 75% and back pain in 62.5% patients, respectively. No patient had jaundice. The mean tumor size was 5.04 cm (range, 2.3-8 cm). Curative distal pancreatectomy and splenectomy were performed in 3 patients, palliative distal pancreatectomy and splenectomy in 4 patients, palliative segmental pancreatectomy in 1 patient. Curative resection was defined as resection with all gross tumor tissues removed and negative microscopic margins. Resection with gross residual tumor and/or distal metastasis was considered palliative resection. All the 8 patients had histology-verified NCAPBT. Seven of 8 NCAPBTs were ductal adenocarcinoma. No.4 NCAPBT was mucinous non-cystic adenocarcinoma (Tables 1 and 2). No cystic adenocarcinoma and other rare adenocarcinomas such as adenosquamous carcinoma, undifferentiated adenocarcinoma and primary cancer were found. All the 8 patients were followed up. The log-rank test was used for comparison of differences in survival. Chi-square test or Fisher's exact test was used to evaluate the correlation between categorical data. $P < 0.05$ was considered statistically significant.

RESULTS

The outcome of the 8 patients is summarized in Tables 1 and 2. Intra-abdominal abscess was found in 1 patient and no major postoperative complications were found in

Abstract

AIM: To report the outcome of Chinese patents with non-cystic adenocarcinoma in pancreatic body and tail (NCAPBT) after resection and to discuss its surgical strategy.

METHODS: Resection of NCAPBT was performed in eight Chinese patients with complete clinical-pathological data in our hospital from January 2000 to May 2004. The surgical strategy was explored by analyzing the results of these patients.

RESULTS: The resection rate of NCAPBT in patients without back pain was higher than that in patients with back pain (66.67% vs 20%, 2/3 vs 1/5). The prognosis in the group receiving palliative resection was poorer than that in the group receiving curative resection. The median survival time was 12 mo in the curative resection group and 6 mo in the palliative resection group, respectively.

CONCLUSION: The overall survival time of the Chinese patients with NCAPBT is dismal. The Chinese patients after curative resection of NCAPBT have a longer survival time. The Chinese NCAPBT patients with back pain trend to have a lower curative resection rate, but back pain should not be considered a contraindication for curative resection.

the other 7 patients. Major complications were defined as those threatening the life potentially. Neither re-operation was performed nor death of patients occurred during operation. None of the 8 patients was treated in ICU. The curative resection rate of the patients without back pain was higher than that of those with back pain (66.67% *vs* 20%, 2/3 *vs* 1/5). The median survival time was 6 in the palliative resection group and 12 mo in the curative resection group, respectively. The latter group had a longer survival time than the former group, while the former group had a higher 1-year survival rate than the latter group (66.7% *vs* 0%).

DISCUSSION

The prognosis of pancreatic body and tail cancer is poor even after surgical resection^[1-10]. Due to the absence of painless obstructive jaundice and earlier symptoms, most patients with pancreatic body and tail cancer are found in an advanced stage, which results in a low resection rate^[1-10]. The 5-year survival rate of pancreatic body and tail cancer patients after surgical resection ranges from 0% to 25%, and the median survival time is 10 to 15.9 mo^[4-10]. In our study, no NCAPBT patient survived longer than 5 years, the median survival time of the patients after curative resection was comparable with that of other reports^[5-10], but the median survival time of the patients after palliative resection was much shorter than that of those after curative resection (Table 2). The portal vein and/or superior mesenteric vein resection combined

with pancreatectomy can be successfully performed^[9,10], preoperative CT scan or other image analysis should be emphasized on the relationship between the tumor and its major adjacent vessels, such as superior mesenteric artery, abdominal aorta and celiac trunk, because they help surgeons to more precisely judge the resectability of the tumor before operation.

Bathe *et al*^[11] reported that old NCAPBT patients have a higher ratio of major postoperative complications and a significantly shorter survival time, and need to receive radical resection. An interesting finding in our study is that three old patients (≥ 70 years of age) had no major postoperative complications, however, 1 of 5 patients (< 70 years of age) had major postoperative complications. No patient received re-operation. Furthermore, 2 patients in the older patient group (≥ 70 years of age) after curative resection had a longer survival time than those after palliative resection, suggesting that surgical resection of NCAPBT in old patients might not result in more major postoperative complications than in younger patients.

Pancreatic cancer patients with back pain have a low resection rate and poor prognosis^[12]. In our study, the patients without back pain tended to have more chances of curative resection, however, the longest survivors were those with back pain, indicating that back pain should not be considered a contraindication, though the patients with back pain had less chance of curative resection.

Metastasis occurs in most patients with adenocarcinoma of the body and tail of the pancreas^[3,10,13,14]. In our study, one patient with liver metastasis had a comparable

survival time with the other 4 after palliative resection, suggesting that the prognosis of patients with liver metastasis after palliative resection of NCAPBT is not poorer than that of patients without distal metastasis.

Sboup *et al*^[10] reported that the survival rate is correlated with histological differentiation. An interesting finding in our study is that three patients with poorly- or moderately-differentiated tumor in the curative resection group had a longer survival time than the other three patients with well-differentiated tumor in the palliative resection group, indicating that though histological differentiation is related with survival, curative resection of NCAPBT is a more important prognostic factor.

Segmental pancreatectomy is mainly performed for benign or low malignant tumor in the pancreatic body and leads to more postoperative complications than distal pancreatectomy^[15]. In our study, one patient after palliative segmental pancreatectomy had no major complications and was discharged ten days after the operation. The survival time was a little longer than that of the other 4 patients after palliative resection, suggesting that segmental pancreatectomy is a feasible surgery and can preserve more pancreatic tissues.

Sboup *et al*^[10] reported that if extended resection is considered necessary for curative resection of the tumor, the resection is justified in patients with NCAPBT. Fabre *et al*^[4] found that only patients with tumor not more than 4 cm in diameter, but without lymph involvement and metastasis have a significant longer survival time after resection. In our study, the patients in the curative resection group had a longer survival time than those in the palliative resection group. The median survival time of the latter group was only half of the former group. No patients survived more than 1 year in the palliative resection group. The data showed that curative resections of NCAPBT should be recommended. Furthermore, in the curative resection group, one patient with a tumor over 4 cm in diameter and lymph involvement, survived only 8 mo which was a little longer than the median survival time of those in the palliative resection group, while survival time of the two patients with tumor not more than 4 cm in diameter but without lymph involvement and metastasis was not less than 1 year, indicating that the theory of Fabre *et al*^[4] seems to fit for the Chinese patients.

In conclusion, the overall survival of Chinese NCAPBT patients is dismal. Chinese NCAPBT patients after curative resection may have a longer survival time. Chinese NCAPBT patients with back pain, tend to have a lower curative resection rate, but back pain should not

be considered a contraindication for curative NCAPBT resection.

Abstract

Hepatocellular carcinoma (HCC) recurs with a reported frequency of 12%-18% after liver transplantation. Recurrence is associated with a mortality rate exceeding 75%. Approximately one-third of recurrences develop in the transplanted liver and are therefore amenable to local therapy. A variety of treatment modalities have been reported including resection, transarterial chemoembolization (TACE), radiofrequency ablation (RFA), ethanol ablation, cryoablation, and external beam irradiation. Goals of treatment are tumor control and the minimization of toxic effect to functional parenchyma. Efficacy of treatment is mitigated by the need for ongoing immunosuppression. Yttrium-90 microspheres have been used as a treatment modality both for primary HCC and for pre-transplant management of HCC with promising results.

Twenty-two months after liver transplantation for hepatitis C cirrhosis complicated by HCC, a 42-year old man developed recurrence of HCC in his transplant allograft. Treatment of multiple right lobe lesions with anatomic resection and adjuvant chemotherapy was unsuccessful. Multifocal recurrence in the remaining liver allograft was treated with hepatic intra-arterial infusion of yttrium-90 microspheres (SIR-Spheres, Sirtex Medical Inc., Lake Forest, IL, USA). Efficacy was demonstrated by tumor necrosis on imaging and a decrease in alpha-fetoprotein (AFP) level. There were no adverse consequences of initial treatment.

INTRODUCTION

Strict criteria developed to select patients with hepatocellular carcinoma (HCC) for liver transplantation have increased the survival and decreased the recurrence of tumor after transplantation^[1]. However, tumor recurrence and subsequent mortality continue to be observed. Tumor recurrence is reported to occur with a frequency of 12%-18%^[2-4]. Seventy percent of recurrences are observed within the first year after transplantation^[3]. Unfortunately, recurrence-related mortality is high and exceeds 75%^[2]. Extra-hepatic recurrence is encountered most commonly, with an estimated incidence of 67%^[2]. Recurrence isolated to the transplant liver is relatively infrequent, yet, it represents an opportunity for targeted treatment. Local therapies include resection, trans-arterial chemoembolization (TACE), radiofrequency ablation (RFA), ethanol ablation, cryoablation, and external beam irradiation. Treatment efficacy varies according to tumor characteristics such as location, size, and number. Efficacy also varies with the degree of underlying hepatic dysfunction. Hepatic arterial infusion of microspheres impregnated with the beta-radiation emitter yttrium-90 has been successfully employed in the palliative treatment of unresectable HCC and most recently to down-stage HCC to allow liver transplantation^[5]. Results for the treatment of primary HCC reveal a 38%-65% partial response rate, and a median survival of 23 mo which is 2.6-4.7 times the length of median survival seen in historic controls^[6].

The following case report describes a 42-year old man who underwent liver transplantation for hepatitis C

cirrhosis with stage II HCC and 22 mo later developed recurrent HCC isolated to the liver allograft. When conventional treatment modalities failed, hepatic arterial infusion of yttrium-90 beads (SIR-Spheres, Sirtex Medical Inc., Lake Forest, IL, USA) was safely employed to treat the HCC recurrence in the liver allograft.

CASE REPORT

This hispanic man was diagnosed at 38 years of age with end-stage liver dysfunction secondary to hepatitis C infection (genotype 1a) and listed with UNOS for transplantation in 2001 (UNOS status 3, MELD score 12). Nine months after being listed, serial CT examination of the liver suggested a new 1.5 cm lesion in segment IV. Follow-up imaging five months later showed the lesion to have grown in size to 3 cm consistent with HCC (stage II, T2NxMx). AFP level at this time was 38.7 $\mu\text{g/L}$. He underwent percutaneous RFA of the lesion while awaiting transplantation with a slight decrease in the AFP level to 32.9 $\mu\text{g/L}$ and no residual tumor on CT after treatment. He received the standard MELD exception score at the time of 29 for his stage II HCC. A deceased donor liver transplant became available 5 mo after receiving his exception score (3.5 mo after RFA and 23 mo after being originally listed for transplant). The donor was a 52-year old CMV-positive man. Standard caval interposition technique without veno-venous bypass was used and the total graft ischemic time was 7 h and 40 min. Induction immunotherapy consisted of 20 mg of basiliximab, 300 mg of azathioprine and 1 g of methylprednisolone. Contrary to the post-RFA CT scan from 10 wk earlier, pathologic evaluation of the hepatic explant was notable for the presence of three foci of HCC in the right lobe of the liver. The lesions measured 2.8 cm, 2.7 cm and 1.5 cm each, in maximum dimension. The largest was 60% necrotic as a result of RFA treatment. Each tumor was moderately or well differentiated and demonstrated no angiolymphatic invasion.

Following transplantation, steroid doses were tapered to 15 mg/d by postoperative day seven. Azathioprine was discontinued on postoperative day seven and maintenance immunosuppression with tacrolimus was begun. His first allograft biopsy three weeks after transplant revealed only mild ischemia-reperfusion changes and no evidence of rejection or recurrent HCV infection. The tacrolimus dose was adjusted to achieve a trough of 10-15 $\mu\text{g/L}$ for the first three months after transplant. After three months, transaminases were elevated and a liver biopsy done at this time revealed recurrent HCV with grade 1 (0-4) inflammation and steatosis without fibrosis (stage 0, 0-4). Prednisone dose was tapered and subsequently discontinued. Tacrolimus doses were further decreased to achieve a target trough level of 6-10 $\mu\text{g/L}$. A one-year liver biopsy, however, demonstrated progression to fibrosis (stage 2, 0-4). Transaminases remained mildly elevated and new hyperbilirubinemia (total bilirubin 29.1 $\mu\text{mol/L}$) was also noted. Quantitative HCV RNA testing revealed high-level viremia with viral tiers of 5.8 GU/L. HCV treatment with pegylated interferon and ribavirin was begun. After a 15 wk course of interferon-based anti-viral therapy, he had

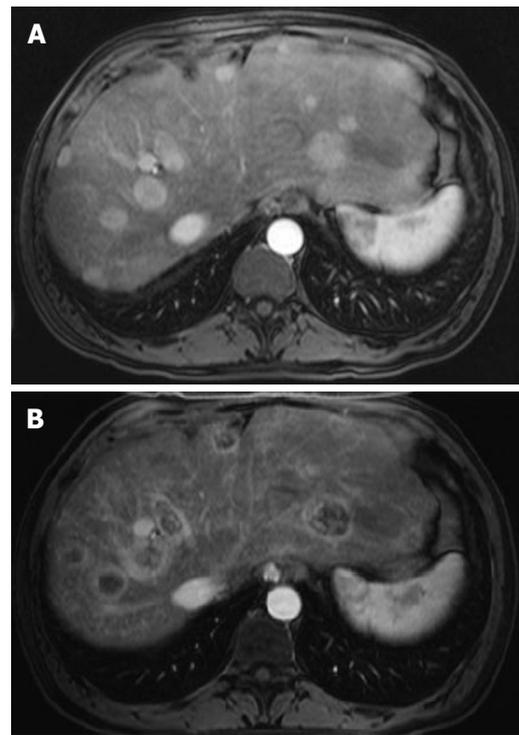

Figure 1 Pre-treatment magnetic resonance imaging of the liver demonstrating multifocal recurrent tumor within liver allograft (A) and paired post-treatment image showing central necrosis of lesions after treatment with yttrium-90 microspheres (B).

only a transient decrease in transaminases and bilirubin with persistently high HCV RNA levels. HCV treatment was discontinued.

HCC surveillance with serial imaging and AFP levels remained negative for the first 18 mo following transplantation. An elevated AFP level of 16 $\mu\text{g/L}$ was noted at 22 mo post transplant. A CT scan of the liver revealed a 3 cm nodule in segment VI not seen on the imaging five months earlier. Recurrent HCC was confirmed by needle biopsy, bone scan and chest CT were negative for distant metastatic disease. The patient was offered a segmental resection of the tumor and underwent laparotomy. No extra-hepatic tumor was identified. Intraoperative ultrasound revealed two additional 1 cm lesions in segments III and IV. These and the initial segment VI lesion were segmentally resected. The patient's post-operative course was uncomplicated. Post-operative AFP level decreased to 7 $\mu\text{g/L}$. One month after surgery, maintenance immunotherapy was switched from tacrolimus monotherapy to sirolimus monotherapy with target trough levels of 5-8 $\mu\text{g/L}$ and adjuvant chemotherapy with systemic doxorubicin (200 mg/m² over 20 wk) was begun. Chemotherapy was complicated by the development of diabetes mellitus and anemia. AFP level increased to 820 $\mu\text{g/L}$ despite chemotherapy. A CT scan done 3 mo into his course of doxorubicin showed vague hyper-enhancement in segment VIII and magnetic resonance imaging (MRI) scan of the liver obtained at the completion of treatment revealed uniformly enhancing, multifocal nodules consistent with HCC in the remaining liver allograft with the largest nodule measuring 3.8 cm (Figure 1A).

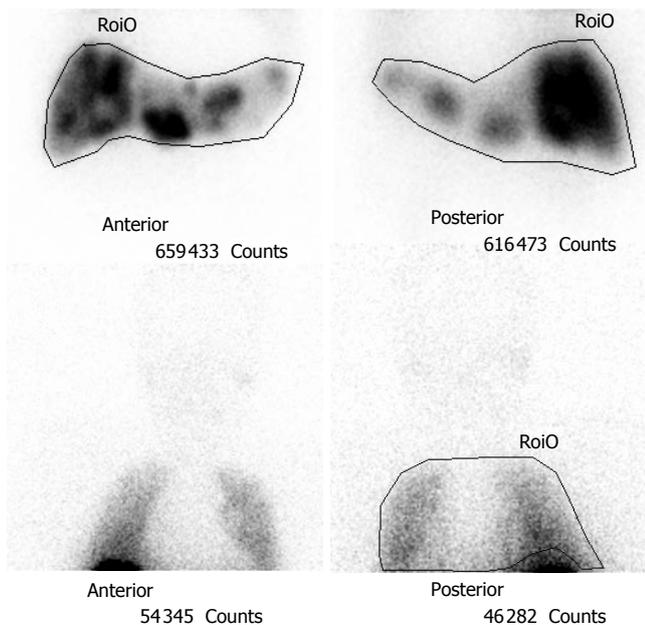

Figure 2 Pre-treatment screening by injection of macroaggregated albumin to determine shunt fraction to lungs.

After presentation at a multidisciplinary tumor board it was decided to proceed with a trial of hepatic intra-arterial radiotherapy with yttrium-90 microspheres (SIR-Spheres). Pre-procedure evaluation with hepatic arteriography was notable for the absence of collateral vessels to the allograft, given that the liver was supplied by the donor vessels and the native gastroduodenal artery was ligated at the time of transplantation. Injection of macroaggregated albumin to determine the degree of hepato-pulmonary shunting revealed a radioactive shunt fraction of 7.3% (Figure 2). CT volumetry of the affected liver allowed calculation of a targeted tumor volume of 120.6 cm³. He underwent yttrium-90 intra-hepatic arterial injection 32 mo after liver transplantation. The patient received a dose of 1.5 GBq of isotope. The procedure was uncomplicated and he was discharged to home six hours after the procedure was completed. The patient experienced only minimal symptoms related to the treatment, including mild right upper quadrant abdominal pain and intermittent nausea. Follow-up MRI of the liver was done two months post-treatment. Pre- and post treatment MRI images (Figure 1A and B) demonstrated loss of uniform arterial enhancement and development of peripheral enhancement consistent with tumor necrosis and treatment response. The number of lesions remained stable. Post-procedure AFP levels decreased to 20 µg/L at 2 mo following the procedure. Liver function, both clinical and biochemical, was unaffected by the treatment.

DISCUSSION

Following liver transplantation, recurrence of HCC that is isolated to the liver occurs with a frequency of around 3%-5% with the current liver transplant candidate selection criteria^[2-4]. Most recurrences occur within the first two years of transplantation and the two-year mortality after recurrence is high, approaching 75%^[4]. Recurrent

HCC may be heralded by impairment in graft function and elevation of AFP levels. Treatment measures usually include reduction of immunosuppression and local tumor therapy. Hepatic recurrence is multifocal in 60% of cases and tumor grade is T3 or greater in up to 90% of cases^[3]. As a result, impaired hepatic function along with multifocal disease often limits the potential for surgical resection. Local ablative techniques such as RFA, cryoablation or percutaneous ethanol ablation require repeated administrations and also have limited efficacy when there is extensive or diffuse tumor burden. TACE has evolved as a useful tool for treatment of HCC recurrence because it can be utilized for treatment of bilateral, multifocal lesions with efficacy and limited repeated administration^[6]. However, treatment requires infusion of chemotherapy and embolization of the selected hepatic artery. Systemic and local toxicity as a result of chemotherapy and hepatic ischemia is not rare^[6].

This is the first known report of hepatic intra-arterial brachytherapy with yttrium 90 microsphere (SIR-Spheres) for the treatment of HCC in a liver transplant recipient. Intrahepatic yttrium 90 microsphere (SIR-Spheres) has been used for the treatment of unresectable HCC and metastatic hepatic tumors^[7,8]. Yttrium-90 isotopes incorporated into a resin sphere slightly larger than the size of the capillary in the liver arterial system are delivered intra-arterially. Yttrium 90 emits beta-radiation and the permanently implanted spheres deliver a therapeutic dose radiation with an effective mean range of about 2.5 mm. The half-life of the isotope is 64 h with 95% of the dose given in the first 11 d. Higher doses of radiation are able to be delivered selectively than with external beam radiation therapy (EBRT). In addition, large segments of liver are not rendered ischemic because embolization is not a feature of the therapy. Therefore, there is less toxicity to functioning parenchyma than seen with EBRT or TACE.

Therapy is typically administered in one cycle, with a range of one-to-three cycles. Suitable candidates for treatment include patients with unilobar or bilobar disease and preserved liver function with bilirubin < 34.2 µmol/L^[7]. Contrast enhanced CT imaging of the liver serves to determine tumor volume and allow calculation of radiation dose requirement. In order to minimize treatment-related toxicity, hepatic arteriography is necessary to determine arterial anatomy and administer 99 mTc-macro-aggregated albumin to calculate the shunt fraction delivered to the lungs. In most patients, arteries that arise from the hepatic arteries and supply the stomach or intestines must be embolized to prevent radiation necrosis. If the hepatic arterial supply cannot be isolated, then the patient is generally considered not to be a candidate for therapy. Because of the isolated arterial supply of the liver allograft in our patient, this was not an issue. Pulmonary shunt fraction greater than 15% on 99 mTc-macro-aggregated albumin scan predisposes to radiation pneumonitis and precludes safe treatment with yttrium 90.

The median radiation dose for a treatment is 134 Gy which is delivered in a range of 50-150 Gy^[7]. The dose of yttrium 90 equates to 5-10 GBq or 2-4 million microspheres. Treatment is typically provided on an outpatient basis and does not require patient isolation

because yttrium 90 is a beta emitter. Local response to treatment is demonstrated by decrease in size and tumor vascularity. Thirty-eight percent of patients experience partial response demonstrated by a decrease in tumor size^[7]. In 65% of patients, response is demonstrated by substantial decrease in tumor vascularity^[7]. Monitoring of tumor markers such as AFP may also be of benefit in determining response to therapy^[8]. Impact on survival varies according to the severity of underlying hepatic disease but the median survival time after yttrium 90 microsphere (Theraspheres, MDS Nordion, Ottawa, Canada) treatment was 23 mo in one study of 65 patients with unresectable HCC^[7]. This represents an increase in survival of 2.6-4.7 times that of historic control. One multicenter review of treated patients reported that death resulting from therapy-induced liver failure is responsible for half of the treatment-related deaths and occurs in 5% of all patients^[9]. All of these liver failure deaths attributed to the yttrium 90 therapy are occurred in patients felt to be at high risk for the procedure. When compared to TACE, quality of life measures is higher at 12 mo^[10]. Toxicities of yttrium-90 include worsening ascites, lower extremity edema, nausea, vomiting, fever, abdominal pain, hyperbilirubinemia and lymphopenia^[7,8]. Mild adverse effects include nausea, vomiting fatigue, abdominal pain, fever^[7,8]. Serious adverse effects include tumor lysis syndrome, transient elevations in liver enzymes, gastritis, gastric or duodenal perforation, cholecystitis, and radiation induced pneumonitis^[7,8].

A recent multicenter review of low risk patients treated with yttrium 90 microspheres reported that liver toxicities including elevation of bilirubin and serum transaminase levels and ascites occur after treatment in 42% of patients, fifty percent of these adverse events are thought to be related to treatment, and toxicities are resolved in 78% of patients on short term follow-up^[11]. Development of toxicity is associated with pretreatment bilirubin > 17.2 $\mu\text{mol/L}$ and radiation dose > 137 Gy. There are no occurrences of radiation-induced liver disease or death related to treatment^[11]. Another multicenter review on the use of intrahepatic yttrium 90 microspheres has reported a three-month post-treatment mortality of 18%. Ten percent of deaths are thought to be related to treatment and occur in association with at least one or more of the following risk factors: presence of infiltrative tumor, tumor bulk > 50%, albumin < 30 g/L, bilirubin \geq 34.2 $\mu\text{mol/L}$, AST or ALT > five times the upper limit of normal, and a lung radiation dose of > 30 Gy^[9]. The results of these and other reports suggest that treatment in carefully selected patients is safe and efficacious.

Hepatic intra-arterial yttrium-90 microsphere treatment was safely and effectively used in this patient with

recurrent multifocal HCC after liver transplantation. Clearly, further prospective investigation is needed to determine whether this therapy can be applied with similar safety and efficacy to other patients with recurrent HCC after liver transplantation. The availability of this treatment modality in the post-transplant setting may help to prolong patient and graft survival in those recipients unfortunate enough to develop recurrent HCC who are not amenable to other treatment options.

Abstract

A 41-year old alcoholic male with a history of chronic pancreatitis was admitted for nausea, vomiting and weight loss. Angiogram was performed and demonstrated an aneurysmal sac with a narrow neck originating from the inferior aspect of the distal portion of the proper hepatic artery. The origin of the pseudoaneurysm was covered with a 5 mm × 2.5 cm Viabahn cover stent (Gore). A repeat angiogram showed some leak and a second stent (6 mm × 2.3 cm) was deployed and overlapped with the first stent by 3 mm. Contrast was injected and a repeat angiogram demonstrated complete exclusion of the aneurysm. A repeat computerized axial tomography (CAT) scan of the abdomen after 24 h showed successful stenting. The patient had an uneventful post-operative course.

INTRODUCTION

Hepatic artery pseudoaneurysm (HAP) is a serious complication of acute or chronic surgical injury to the hepatic artery. It is also seen following blunt and penetrating abdominal injury as well as in patients with chronic pancreatitis and after orthotopic liver transplantation^[1]. Transcatheter embolization has been considered the treatment of choice but we report a case of HAP successfully treated by stenting of the pseudoaneurysm.

CASE REPORT

A 41-year old male with a history of chronic alcohol consumption and chronic recurrent pancreatitis presented to the emergency department with abdominal pain, nausea and weight loss. Physical examination revealed remarkable ascites. No bruit was present. Serum upper gastrointestinal (GI) endoscopy revealed grade 1 esophageal varices. Abdominal ultrasonography (USG) demonstrated dilated pancreatic ducts. Abdominal MRI/MRA showed a lesion in the porta hepatis measuring 5 cm × 5 cm. Contrast-enhanced CAT scan of the abdomen showed a 6 cm × 6 cm pseudoaneurysm of the proper hepatic artery (Figure 1). Stenting of the pseudoaneurysm was done. The technique could selectively catheterize the proper hepatic artery by using a 5 French RC-1 catheter (Angiodynamic-Queensbury-NY). Angiogram was performed and demonstrated an aneurysmal sac with a narrow neck originating from the inferior aspect of the distal portion of the proper hepatic artery (Figure 2). The origin of the pseudoaneurysm was covered with a 5 mm × 2.5 cm Viabahn cover stent (Gore). A repeat angiogram showed some leak and a second stent (6 mm × 2.3 cm) was deployed and overlapped with the first stent by 3 mm. Contrast was injected and a repeat angiogram demonstrated complete exclusion of the aneurysm (Figure 3). A repeat computerized axial tomography (CAT) scan of the abdomen after 24 h showed successful stenting (Figure 4). The patient had an uneventful post-operative course.

DISCUSSION

Hepatic artery pseudoaneurysms are rare. However, rupture is common and occurs in 76% of patients. The mortality of patients requiring operative intervention is 75%^[1]. Pseudoaneurysm formation in pancreatitis is thought to occur because of autodigestion of pancreatic enzymes, especially elastase, liberated due to pancreatitis. Although angiography remains the gold standard for detection of pancreatitis, USG and CAT scan are often diagnostic and may provide an early mechanism for identifying patients with pseudoaneurysms occurring consequently to pancreatitis^[2]. Otherwise diagnosis is usually made late in the course of disease when severe or even fatal hemorrhage has occurred. Transcatheter embolization is the standard of care.

Literature search revealed one case report of a 60-year old female with HAP as a complication of surgical treatment of Klatskin tumor treated with a

Figure 1 Contrast-enhanced CAT of the abdomen showing a 6 cm × 6 cm pseudoaneurysm of the proper hepatic artery.

Figure 3 Repeat angiogram demonstrating complete exclusion of the aneurysm.

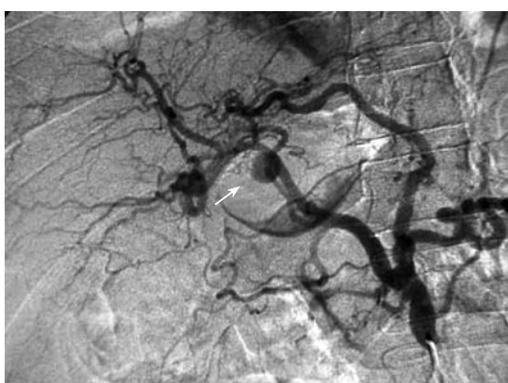

Figure 2 Angiogram showing an aneurysmal sac with a narrow neck originating from the inferior aspect of the distal portion of the proper hepatic artery.

Figure 4 A repeat CAT scan of the abdomen after 24 h showing successful stenting.

coronary stent-graft via transfemoral approach^[3]. Two other cases have been reported, one being stenting of HAP secondary to liver transplantation following unsuccessful coil embolization^[4] and the other being stenting of HAP secondary to therapeutic management of a choledochol cholangiocarcinoma, following failed arterial embolization^[5]. In our case HAP developed as a complication of chronic alcoholic pancreatitis with symptoms of abdominal pain. Early diagnosis with CAT scan followed by stenting resulted in complete occlusion of the pseudoaneurysm.

The long-term data regarding the use of this or other stent-grafts in the visceral vessels are extremely limited, and consequently we cannot recommend stent-grafts as the primary treatment option for visceral artery pseudoaneurysms. However, we expect that, with continued follow-up of cases such as these, further refinements in stent-graft design, greater availability, and increased operator experience, these devices will become an increasingly valuable therapeutic option. Early diagnosis and intervention with stenting, which is a reasonable

alternative to embolization, can result in excellent long-term outcome.

INTRODUCTION

Hepatobiliary cystadenomas (HBC) are rare neoplasms of the liver or extrahepatic bile ducts, accounting for less than 5% of all the cystadenomas found in the liver. These lesions are mainly seen in middle-aged females^[1,2] and can show malignant degeneration to hepatobiliary cystadenocarcinoma. Most of these patients are asymptomatic, because these lesions usually are incidental findings on abdominal diagnostic imaging for evaluation of other complaints. If there are presenting symptoms, these are right upper quadrant pain or discomfort. Obstructive jaundice only rarely occurs as a presenting symptom^[3]. We describe here the diagnostic evaluation, surgical management and pathological characteristics of four patients with HBC and one patient with hepatobiliary cystadenocarcinoma who presented with obstructive jaundice.

CASE REPORT

Case 1

A 50-year old woman underwent laparoscopic cholecystectomy because of symptomatic cholelithiasis 3 years prior to presentation. She was admitted for intermittent colicky pain and recurrent biliary obstruction. Physical examination showed no abnormalities. Routine liver function tests revealed elevated plasma levels of alkaline phosphatase (AP) of 118 U/L (normal range, 40-120 U/L) and gamma-glutamyltransferase (GGT) of 260 U/L (normal, < 40 U/L). Serum bilirubin level was normal. Endoscopic retrograde cholangiopancreatography (ERCP) demonstrated a polypoid lesion inside the left hepatic duct. Helical computed tomography (CT) of the liver revealed a cystic lesion measuring 10 cm in diameter located in the left lobe of the liver with protrusion into the left hepatic duct. Calcifications were present in the wall of the lesion and septations were visible inside the cyst (Figure 1A). ERCP showed the image of an extrinsic mass proximal to the polypoid lesion, creating a compression on the intrahepatic ducts of the left biliary system (Figure 1B). These findings suggested that the episodes of colicky pain and cholestasis were caused by a cystic lesion with a polypoid protrusion into the left bile duct, giving rise to intermittent obstruction. Distinction between hepatobiliary cystadenoma and cystadenocarcinoma could not be made on the basis of imaging studies. The patient underwent left hemihepatectomy and

Abstract

Hepatobiliary cystadenomas (HBC) and cystadenocarcinomas are rare cystic lesions. Most patients with these lesions are asymptomatic, but presentation with obstructive jaundice may occur. The first patient presented with intermittent colicky pain and recurrent obstructive jaundice. Imaging studies revealed a polypoid lesion in the left hepatic duct. The second patient had recurrent jaundice and cholangitis. Endoscopic retrograde cholangiopancreatography (ERCP) showed a cystic lesion at the confluence of the hepatic duct. In the third patient with intermittent jaundice and cholangitis, cholangioscopy revealed a papillomatous structure protruding into the left bile duct system. In the fourth patient with obstructive jaundice, CT-scan showed slight dilatation of the intrahepatic bile ducts and dilatation of the common bile duct of 3 cm. ERCP showed filling of a cystic lesion. All patients underwent partial liver resection, revealing HBC in the specimen. In the fifth patient presenting with obstructive jaundice, ultrasound examination showed a hyperechoic cystic lesion centrally in the liver. The resection specimen revealed a hepatobiliary cystadenocarcinoma. HBC and cystadenocarcinoma may give rise to obstructive jaundice. Evaluation with cross-sectional imaging techniques is useful. ERCP is a useful tool to differentiate extraductal from intraductal obstruction.

Erdogan D, Busch ORC, Rauws EAJ, van Delden OM, Gouma DJ, van Gulik TM. Obstructive jaundice due to hepatobiliary cystadenoma or cystadenocarcinoma. *World J Gastroenterol* 2006; 12(35): 5735-5738

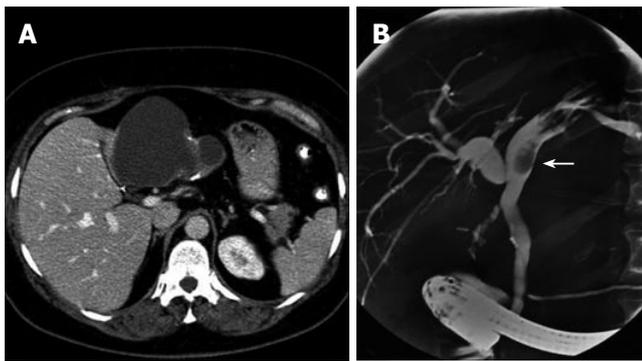

Figure 1 Abdominal CT-scan showing a large cystic mass in the left liver lobe with internal septations and calcifications in the cyst wall (A) and ERCP showing a polypoid lesion in the left hepatic duct (arrow) in case 1 (B).

the histopathological diagnosis of hepatobiliary mucinous cystadenoma was made. The postoperative course was uneventful and the complaints resolved after operation. The patient died 56 mo after operation because of other reasons not related to the initial disease.

Case 2

A 46-year old woman underwent cholecystectomy with common bile duct exploration because of gallstones 6 years prior to presentation. During cholecystectomy, fenestration of a presumed simple intraluminal cyst at the confluence of the hepatic duct was performed. Microscopic examination of the cyst wall showed biliary epithelium without mesenchymal stroma. She had recurrent jaundice and cholangitis. Initial investigations revealed elevated levels of serum bilirubin level of 79 $\mu\text{mol/L}$ (normal, < 17 $\mu\text{mol/L}$), AP of 311 U/L (normal range, 40-120 U/L), GGT of 448 U/L (normal, < 40 U/L), AST of 96 U/L and ALT of 142 U/L (normal, < 45 U/L). ERCP showed filling of a cystic lesion at the confluence of the hepatic duct. Brush cytology revealed no malignancy. A plastic stent was placed for decompression of the biliary system. Abdominal ultrasonography (US) and CT-scan revealed multiple cystic lesions involving segment 4 of the liver with dilatation of the left central and peripheral intrahepatic bile ducts and the right central intrahepatic bile ducts. At laparotomy, multiple cysts in segment 4 of the liver were found with a dominant cystic lesion of 2.5 cm located in the area of hepatic hilum. Hilar resection in combination with left hemihepatectomy was performed. Microscopically, the cyst wall was composed of cylindrical epithelium. The features of the subepithelial stroma were typical for the diagnosis hepatobiliary mucinous cystadenoma. The complaints resolved after operation. The patient was still alive 103 mo after operation.

Case 3

A 40-year old woman underwent laparoscopic cholecystectomy for symptomatic cholelithiasis 4 mo ago. She had intermittent complaints of jaundice and cholangitis. Liver function tests showed slightly elevated AP levels of 103 U/L and GGT level of 44 U/L. The serum bilirubin and alanine transaminase levels were normal. ERCP revealed a filling defect in the left hepatic duct (Figure 2A).

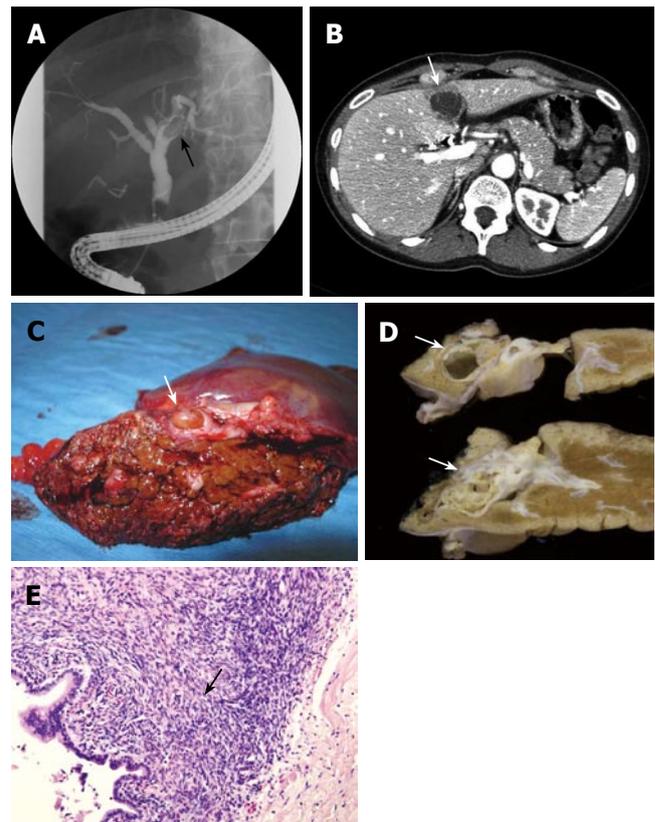

Figure 2 ERCP showing a filling defect due to an intraluminal lesion (arrow) in the left hepatic duct (A), CT-scan showing a cystic lesion with internal septations measuring 3.6 cm located in segment 4 (arrow) (B), specimen after left hemihepatectomy showing macroscopic features of a large lesion (arrow) inside the left bile duct filling up the entire lumen (C), macroscopical cut sections of a multicystic lesion (arrows) encapsulated by a thick fibrous capsule arising from the left hepatic duct (D), microscopical features showing columnar mucinous epithelium with underlying dense-cellular stroma resembling ovarian stroma (arrow) (HE X 200) (E) in case 3.

A stent was placed for decompression of the biliary system. The second ERCP at our hospital suggested that the filling defect was caused by an intraductal tissue mass. Subsequent cholangioscopy showed a papillomatous structure protruding into the left bile duct system from the bile duct wall. CT scan showed a cystic lesion with septations located in segment 4 of the liver. It was unclear if there was a connection between the lesion and the left hepatic duct. The lesion was 3.6 cm in diameter (Figure 2B). The patient underwent a left hemihepatectomy. Macroscopically, a tumour with smooth surface was seen protruding inside the bile duct and filling up the entire lumen (Figure 2C). Cut sections revealed a multicystic lesion encapsulated by a thick fibrous capsule arising from the left hepatic duct (Figure 2D). The cystic lesion was surrounded by stroma containing spindle-shaped cells, resembling ovarian stroma (Figure 2E). The diagnosis of hepatobiliary mucinous cystadenoma was made. No signs of malignancy were seen. The patient remained alive 19 mo after operation.

Case 4

A 43-year old woman with an unremarkable previous medical history presented with progressive obstructive jaundice three weeks ago. Abdominal US showed dilatation of in-

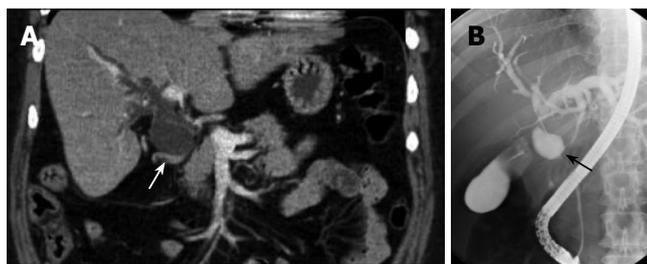

Figure 3 Abdominal coronal CT-scan showing dilated intrahepatic bile ducts and common bile duct (arrow) (A), ERCP showing filling of a cystic lesion (arrow) connected to the common bile duct, initially diagnosed as a duplicate gallbladder or choledochal cyst (B) in case 4.

tra- and extra-hepatic bile ducts and a collapsed gallbladder without a clear cause. ERCP showed a normal pancreatic duct but the common bile duct could not be visualized. CT showed slight dilatation of the intrahepatic bile ducts and dilatation of part of the common bile duct with a diameter of 3 cm (Figure 3A). Subsequent MRCP showed the same images as obtained with CT. ERCP showed filling of a cystic lesion connected to the common bile duct (Figure 3B). A diagnosis of a duplicate gallbladder or choledochal cyst at the level of the common hepatic duct was considered. A cystic lesion was detected during laparotomy and a decision was made to resect the common bile duct and the gallbladder. Continuity of the bile duct was restored using a hepaticojejunostomy. Histopathological examination of the resection specimen revealed a multilocular hepatobiliary cystadenoma with necrotizing inflammation. The patient was still alive 46 mo after operation.

Case 5

A 39-year old woman presented with obstructive jaundice, nausea and weight loss which began three months before presentation. Liver function tests showed elevated bilirubin levels of 128 $\mu\text{mol/L}$, AP of 1053 U/L, GGT of 500 U/L, AST of 172 U/L and ALT of 142 U/L. The alpha-fetoprotein level was normal. Because of failure of ERCP, percutaneous transhepatic drainage (PTD) was performed for biliary decompression via the right intrahepatic bile ducts (Figure 4A). Complete obstruction at the level of the proximal bile duct was seen. US showed a well defined hyperechogenic cystic lesion of 4.4 cm, centrally in the liver. A solid calcification of 1 cm was situated inside the lesion. CT showed a cystic lesion with irregularly thickened wall, in conjunction with dilated intrahepatic bile ducts (Figure 4B). Preoperative differential diagnosis of hepatobiliary cystadenoma, cystadenocarcinoma or choledochal cyst was made. The patient underwent hilar resection combined with extended right hemihepatectomy and biliary reconstruction using a hepaticojejunostomy. The diagnosis of hepatobiliary cystadenocarcinoma was made microscopically. The lesion was completely resected with microscopically free margins. The patient was still alive 59 mo after operation. Follow-up imaging showed no signs of local or distant tumor recurrence.

DISCUSSION

HBC are rare cystic neoplasms that may occur in the liver

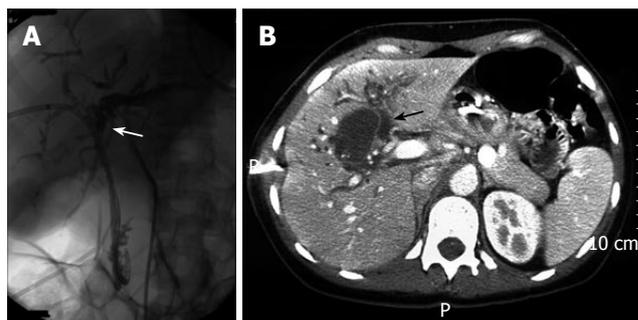

Figure 4 Percutaneous transhepatic drainage (PTD) showing complete obstruction at level of the proximal bile duct (A), abdominal CT showing a cystic lesion with irregularly thickened wall in conjunction with dilated intrahepatic bile ducts (arrow) (B) in case 5.

or in the extrahepatic biliary system. It is estimated that these cystic liver neoplasms comprise 5% of all cystic liver lesions^[1]. Only a minority of patients with HBC develop symptoms, the most commonly reported symptoms are right abdominal pain, abdominal swelling, anorexia or nausea. Rarely, patients present with colicky pain or jaundice caused by obstruction of the biliary system. The differential diagnosis of HBC without symptoms includes simple cysts, choledochal cysts, hepatobiliary cystadenocarcinoma, hydatid cysts, abscess or haematoma. Obstructive jaundice is usually a presenting symptom of choledocholithiasis or malignant cholangiocarcinoma.

In the past 14 years, 13 patients have been diagnosed with HBC or cystadenocarcinoma in our institution. Five of these patients (38.5%) presented with biliary obstruction, which is usually caused by external biliary compression or by internal obstruction due to a mass inside the bile duct. Mucus hypersecretion in case of HBC or cystadenocarcinoma communicating with the bile ducts may also give rise to obstruction symptoms^[4]. Three patients in this series presented with intermittent obstruction jaundice and two patients had continuous jaundice. In contrast, continuous biliary obstruction usually is the presenting symptom of patients with hilar cholangiocarcinoma.

Typically elevated cholestatic parameters in the blood are secondary to obstruction or compression of the biliary system. Some authors have suggested that serum CA-19-9 levels can be used for diagnosis or as a parameter of tumor activity during follow-up after resection^[5,6]. CA-19-9, a serum marker normally synthesized by normal pancreatic and biliary ductal epithelium, is elevated both in benign biliary lesions and in malignant pancreatic carcinomas^[7]. These serum markers, however, may be elevated in the presence of cholestasis and are therefore less reliable in the diagnosis of bile duct lesions. On imaging studies, distinction between HBC and simple cysts can be made by the presence of septations and irregularly thickened cyst walls with or without calcifications^[8]. The most accurate imaging methods for detecting cystadenomas are abdominal ultrasound and CT-scan^[9].

ERCP is useful, apart from establishing the diagnosis, in stenting the bile duct and decompressing the biliary system as was done in our patients. It can also help to differentiate between extraductal and intraductal obstructions.

However, it still remains difficult to differentiate between cystadenoma and cystadenocarcinoma by imaging methods^[10]. In patients with cystic lesion at the hepatic hilum, diagnosis of choledochal cyst should be considered as well^[11,12]. Liver hydatid disease, caused by *Echinococcus* granulosis, is usually asymptomatic and should also be considered as rupture of a hydatid cyst into the biliary tract, a well know complication, which also may give rise to colicky pain, cholangitis and obstructive jaundice. In these patients, ERCP is useful in detecting communication between the cystic lesion and the biliary system^[13].

The use of percutaneous biopsy for preoperative diagnosis has no additional value considering the fact that it rarely produces a definitive diagnosis. There is also the additional risk of peritoneal dissemination in case of malignancy. Histopathological examination is required for definitive diagnosis. Microscopically, the linings of HBC are composed of a biliary type, mucus-secreting cuboidal or columnar epithelium. The underlying stroma shows presence of ovarian stroma in 85%-90% of HBC^[14]. Distinction with simple liver cysts is made among other features, on the basis of the presence of subepithelial ovarian stroma in HBC. Simple liver cysts are composed of an outer layer of fibrous tissue and an inner lining of single columnar or cuboidal epithelium.

In the past, different treatment strategies such as partial resection, percutaneous aspiration or application of sclerosant agents inside the lesions have been applied to HBC. Patients treated with these techniques have shown high recurrence rates when compared to those who have undergone radical partial liver resection^[15]. Another reason for resection is the possibility of malignant degeneration, although the precise risk remains unknown. In our series, cystadenocarcinoma was only seen in 2 of the 13 patients (15.4%) with HBC, which is comparable with the incidence in literature ranging from 5% to 25%^[3,16]. The mean age of patients with cystadenocarcinomas has been reported to be approximately 17 years which is older than that of those without malignant degeneration^[14]. The risk of malignant degeneration is also supported by the presence of benign epithelium in the wall of most cystadenocarcinomas^[11]. Therefore, the treatment of choice should be radical surgical resection. The 5-year survival rate for cystadenocarcinomas after surgical resection ranges from 25% to 100%^[17,18]. We observed no recurrence of cystadenocarcinomas during a mean follow-up of 56 mo (range 19-103 mo) by abdominal ultrasound or CT.

In conclusion, hepatobiliary cystadenoma or cystadenocarcinoma should be considered in patients with obstructive jaundice in the presence of a cystic liver lesion. ERCP and cross-sectional imaging techniques have a great value for establishing the diagnosis.

Abstract

Benign multicystic peritoneal mesothelioma (BMPM) is a rare tumor that occurs mainly in women in their reproductive age. The pathogenesis of BMPM is unclear and a controversy regarding its neoplastic and reactive nature exists.

The biological behavior of BMPM is characterized by its slowly progressive process and high rate of recurrence after surgical resection. In addition this lesion does not present a strong tendency to transform into malignancy. Today approximately 130 cases have been reported.

We here report a 62-year-old woman who had diffuse abdominal pain, nausea and vomiting. Physical examination revealed a painful mass in her upper abdomen. She reported a mild dehydration, but the vital signs were normal. Peristaltic rushes, gurgles and high-pitched tinkles were audible. Upright plain abdominal film revealed small bowel loops with air-fluid levels. She was diagnosed having an incarcerated incisional hernia that resulted in intestinal obstruction. The patient underwent surgery during which a cystic mass of the right ovary measuring 6 cm x 5 cm x 4 cm, four small cysts of the small bowel (1 cm in diameter) and a cyst at the retroperitoneum measuring 11 cm x 10 cm x 3 cm were found. Complete resection of the lesion was performed. The patient had an uneventful recovery and had no recurrence two years after surgery.

Safioleas MC, Constantinos K, Michael S, Konstantinos G, Constantinos S, Alkiviadis K. Benign multicystic peritoneal mesothelioma: A case report and review of the literature.

INTRODUCTION

Benign multicystic peritoneal mesothelioma (BMPM), also known as multilocular peritoneal inclusion cysts, is an uncommon lesion arising from the peritoneal mesothelium that covers the serous cavity. This lesion occurs most frequently in women during their reproductive years^[1-3] and is associated with a history of previous abdominal surgery^[4], endometriosis^[5,6] or pelvic inflammatory disease^[4]. However, there are reports concerning men^[7-9] or children^[10-11], as well as rare extra-abdominal cases^[12-14]. To date, approximately 130 cases have been reported^[1,6,8,15-18]. While the origin of the disease is known, the pathogenesis and pathological differential diagnosis remain unclear and controversial. We here report a case of BMPM admitted to our department with a review of the literature.

CASE REPORT

A 62-year-old woman was referred to the Surgical Outpatient Department due to diffuse abdominal pain, nausea and vomiting for 24 h. On physical examination a painful mass in the upper part of a median subumbilical incision was palpated. She reported a history of hysterectomy five years earlier. A mild dehydration was noted, but the vital signs were normal. Peristaltic rushes, gurgles and high-pitched tinkles were audible. An upright plain abdominal film revealed small bowel loops with air-fluid levels. She was diagnosed having an incarcerated incisional hernia that resulted in intestinal obstruction. The patient underwent an emergency surgery during which a cystic mass of the right ovary measuring 6 cm × 5 cm × 4 cm, four small cysts of the small bowel (1 cm in diameter) and a cyst at the retroperitoneum measuring 11 cm × 10 cm × 3 cm were revealed. Complete resection of the lesion was performed. The pathology report was benign multicystic mesothelioma of the ovary, bowel and peritoneum (Figure 1). The patient had an uneventful recovery and was closely followed-up by US and CT. She remained free of symptoms and had no recurrence two years after surgery.

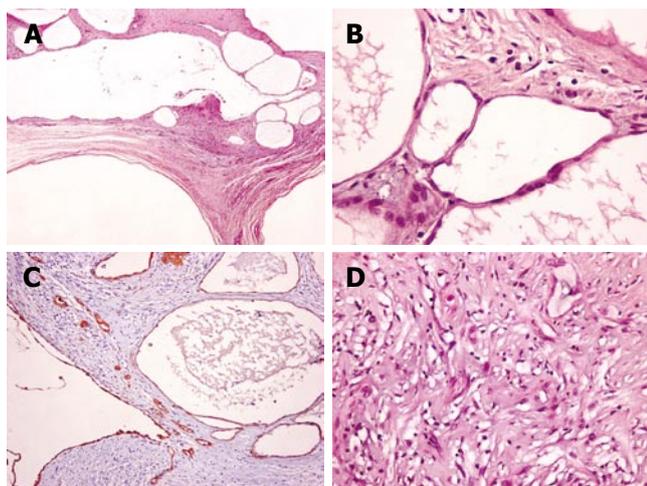

Figure 1 Histological and immunohistochemical findings in benign multicystic mesothelioma (A-C) and in ovary adenomatoid tumor (D) within collagenous stroma (A: HE x 20; B: HE x 400; C: AE1/AE3 x 100; D: HE x 400).

DISCUSSION

BMPM was first described in 1979 by Menemeyer and Smith^[19]. Since then approximately 130 cases have been reported^[20] and the information regarding BMPM is derived from a small number of patients from one institution or from isolated case reports. There are larger series reported from pathologist consultation files with patients from different institutions with incomplete clinical information and lack of long-time follow-up data^[1,17]. Therefore, this disease is classified as an exceedingly rare medical entity, which challenges its origin, pathogenesis, diagnosis and therapy.

Origin

BMPM, a localized tumor arising from the epithelial and mesenchymal elements of the mesothelial cells, does not metastasize. It has a strong predilection for the surface of the pelvic viscera. When the tumor is found in the peritoneal cavity, lesions are found intimately attached to serosal surfaces of the intestine and omentum or in the retroperitoneal space, spleen and liver^[21].

Pathogenesis

The pathogenesis of BMPM is a controversial entity. Some authors believe that the lesion is neoplastic, while others favor a reactive process^[1,15-17,22]. The close relationship with inflammation, a history of prior surgery, endometriosis or uterine leiomyoma suggests that BMPM is probably a peculiar peritoneal reaction to chronic irritation stimuli, with mesothelial cell entrapment, reactive proliferation and cystic formation. Microscopic examination of the lesion reveals an inflammatory component in many cases. The close association of BMPM with familial Mediterranean fever characterized by periodic fever and peritonitis reinforces this assumption^[23].

Other authors have proposed a neoplastic origin based on a slow but progressive growth of the untreated lesions, a marked tendency to recur after surgical resection, a low

incidence of previous abdominal infection and a high disease-related mortality^[1,15]. Malignant transformation of BMPM, an unusual occurrence, indicating a neoplastic nature underscoring the necessity of long-term follow-up has also been reported^[20].

BMPM is rarely associated with adenomatoid tumor, another benign mesothelial lesion with its neoplastic and hyperplastic pathogenesis still argued^[24]. Tumors with mixed histological features of multicystic mesothelioma and adenomatoid tumor have also been reported^[24,25]. These facts indicate that a histogenetic relationship has led some authors to suggest that BMPM represents possibly a borderline lesion between an adenomatoid tumor and a malignant mesothelioma.

Pathological differential diagnosis

Pathological differential diagnosis includes a number of benign and malignant lesions that present as cystic or multicystic abdominal masses. Benign lesions include cystic lymphangioma (cystic hygroma)^[8,15], cystic forms of endosalpingiosis^[26,27], endometriosis^[28], mullerian cysts involving the retroperitoneum^[29], cystic adenomatoid tumors^[30] and cystic mesonephric duct remnants^[1]. Malignant lesions include malignant mesothelioma^[17] and serous tumors involving the peritoneum^[17]. Among the benign lesions, the most important differential diagnosis is BMPM from cystic lymphangioma and adenomatoid tumor. Cystic lymphangioma is restricted to the mesentery, omentum, mesocolon and retroperitoneum but rarely reported in the ovary. On gross examination the cystic component is often chylous and microscopic examination reveals bounds of smooth muscle and aggregates of lymphoid tissue. The cystic spaces are lined by a single layer of flattened endothelial cells which are immunoreactive to vascular markers (CD31, CD34, factor VIII, and VEGFR3). Cystic adenomatoid tumors are easily confused with BMPM on macroscopic and histological examination. However, the cystic component is usually accompanied with a recognizable solid component. Occasionally short papillae lined by mesothelial cells are seen. There are cases of tumors with mixed features of both adenomatoid tumor and BMPM^[24,25], indicating that the two lesions are probably pathogenetically related. Cystic forms of endosalpingiosis differ from BMPM by the presence of a tubal type epithelium that may include peg cells, ciliated cells and/or secretory type cells. Blunt papillae and psammoma bodies may also present. The so-called "florid cystic endosalpingiosis" with multicystic involvement of either uterine or extrauterine sites appears to represent the extreme examples of this process^[26,27]. Endometrioid cysts typically containing dark chocolate-brown materials are composed histologically of endometrial stroma lined by endometrial-type epithelium. Commonly there is evidence of old or recent hemorrhage. Mullerian cyst is another benign condition that may be confused with BMPM. Nevertheless, as its name implies, it is composed of mullerian-type serous or mucinous epithelium containing smooth muscle fibers in the wall. The malignant conditions that mimic BMPM can be easily differentiated on the basis of malignant features including

cellular atypia, increased mitotic count, abnormal mitoses and destructive infiltration of the underlying stroma.

Diagnosis

In most cases, BMPM remains silent in abdominal cavity and may invade several underlying organs, and more rarely the retroperitoneum^[31]. Sometimes BMPM is manifested as acute abdomen. In the case described here the first sign of the lesion was revealed only during surgery, which was performed on an emergency basis. In fact, most patients are diagnosed incidentally during examination or laparotomies for other reasons. The available modern imaging techniques, such as ultrasonography, computerized tomography and magnetic resonance imaging, can demonstrate the lesion. However a differential diagnosis is difficult to be made from other cystic neoplastic or inflammatory lesions arising from these anatomical areas^[32-34]. From a clinical point of view, the differential diagnosis of BMPM from cystic tumors of ovaries is most important, since BMPM may be treated by local excision with preservation of the ovaries. Preoperative fine-needle aspiration biopsy of cystic lesions may help the differential diagnosis^[35-37]. The diagnosis can be confirmed by electron microscopy and immunohistochemistry^[38]. Benign cystic neoplasm with which BMPM is most likely confused is cystic lymphangioma, which occurs more commonly in males and may develop in children as well^[17], but rarely recurs^[8].

Therapy

Surgery is the only effective treatment for BMPM. Complete removal of the cystic lesion if possible, remains the mainstay of treatment and the only hope to avoid local recurrence. Aggressive surgical approaches including cytoreductive surgery with peritonectomy are recommended^[39]. However, some investigators who support more conservative methods particularly claim that treatment options and timing of surgery should be made individually based on the benign morphologic pattern of the lesion^[40]. The laparoscopic approach has also been attempted^[41,42]. Recurrences occur more frequently in women and can be shown by CT guided cystic aspiration^[43], and treated by hormonal therapy with anti-oestrogens^[44] and gonadotrophin-releasing analogues^[45], hyperthermic intraperitoneal chemotherapy^[46,47], and sclerotherapy with tetracycline^[48]. In any case the degree of success following these procedures varies. Adjuvant chemotherapy and radiotherapy are not indicated because these tumors have a prevailing benign character.

In conclusion, BMPM is a rare benign cystic tumor. Although its recurrence is high after surgical resection, it does not present a tendency to transform into malignancy. Two cases of malignant transformation^[20,49] out of the approximately reported 130 cases cannot establish the incidence of this change, even if its neoplastic nature is supported. Finally, a prolonged systematic follow-up of these patients, perhaps for life, is required since the lesion usually reappears and further resection or other therapy may be indicated. Moreover, this strategy may lead the investigators to have a definite aspect concerning the biological behavior of the disease.

TO THE EDITOR

Hepatocellular carcinoma (HCC) is thought to develop through a multistep process^[1]. A long history of viral

hepatitis or prolonged exposure to environmental toxins predisposes liver cells to mutations of the genes critical in the control of hepatocyte growth. In fact, both activation of cellular oncogenes and inactivation of tumor-suppressor genes are involved in the development of HCC. Activation of oncogenes by hepatitis virus integration has been shown in the woodchuck animal model^[2], although the significance of this finding in human hepatocarcinogenesis is still under investigation. Tyrosine kinases, though a minor class of cellular protein, represent a major class of oncogenes. These tyrosine kinases are classified into two major groups^[3,4]. The first is receptor-type protein tyrosine kinases, the second is non-receptor type tyrosine kinases. The main representatives of the latter group are non-receptor-linked and membrane-associated Src family tyrosine kinases. At least nine Src-related tyrosine kinases have been identified thus far, including c-Yes, c-Src, c-Lck, c-Fyn, c-Hck, c-Lyn, c-Blk, c-Fgr and c-Yrk protooncogene products. The cellular oncogene c-Yes, a member of the Src family, encodes a 62-kilodalton, cytoplasmic and membrane-associated protein-tyrosine kinase^[5]. c-Yes expression and its kinase activity have been shown to be increased in colorectal cancer^[6,7], melanoma^[8] and metastatic liver cancer^[9]. However, the activation of c-Yes in human HCC has not yet been investigated at all. In the present study, we determined the activity of c-Yes both in the normal liver (NL) tissues and in chronic hepatitis (CH), tumorous (T) and adjacent nontumorous (N) cirrhotic liver tissues. This is the first report on the activity of c-Yes in various liver diseases including HCC.

Tissue samples, including the tumorous and surrounding nontumorous cirrhotic tissues, were obtained during surgery from 9 patients with HCC (7 males and 2 females; mean age, 68.2 ± 4.4 years; range, 59-73 years). All the patients were positive for hepatitis C virus (HCV), as determined by the reverse-transcriptase polymerase chain reaction method (Amplicor, Roche Diagnostics Ltd). The number of patients with well-, moderately- and poorly-differentiated HCC was 2, 5 and 2, respectively. The fibrosis stage of the surrounding liver tissues was assessed as cirrhosis in all the HCC cases. Liver tissue samples from three patients with HCV-induced CH were obtained by liver biopsy. During surgery, two normal liver tissue samples were also obtained from patients with liver metastases of colon cancer. The serum samples of these patients with NL were negative for HCV and hepatitis B virus (HBV).

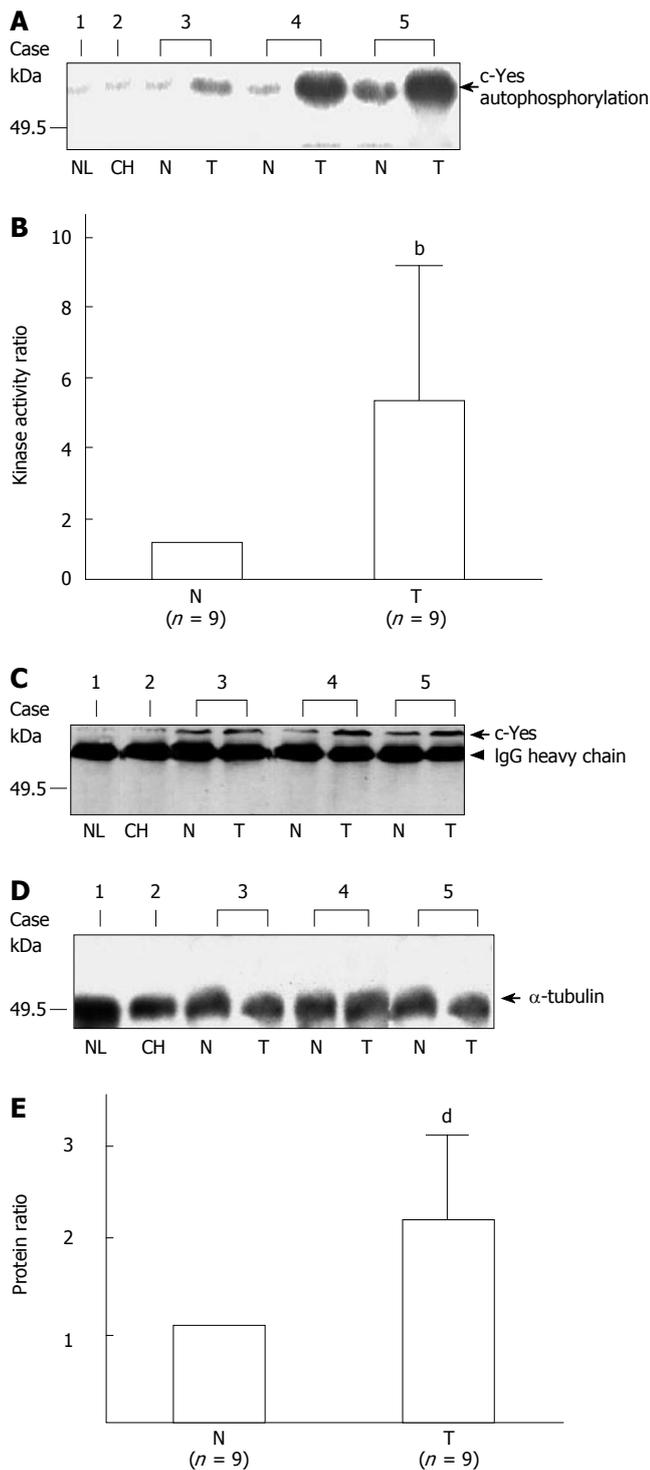

Figure 1 Activities and levels of c-Yes kinase in different liver tissues. **A:** Activity of c-Yes in normal liver (NL), chronic hepatitis (CH), nontumorous cirrhotic (N) and tumorous (T) tissues. The arrow indicates the band corresponding to c-Yes autophosphorylation; **B:** Relative levels of total c-Yes activity (mean \pm SE, Student's *t*-test, $^bP < 0.001$); **C:** Levels of c-Yes in the NL, CH, N, and T portions of HCC. The arrow and arrowhead indicate the bands corresponding to c-Yes protein and the heavy-chain of the c-Yes antibody, respectively; **D:** Level of α -tubulin in lysate containing 100 μ g of cellular protein used in the immunoprecipitation (arrow); **E:** Relative levels of c-Yes protein in T and N tissues (mean \pm SE, Student's *t*-test, $^dP < 0.01$).

To determine the protein kinase activity of c-Yes in the NL, CH, N and T portions of HCC, we prepared lysates containing 100 μ g of cellular protein of tissue samples, precipitated the protein with a monoclonal antibody specif-

ic for c-Yes [MAb (3H9), Wako Pure Chemical Co, Tokyo], and measured the autophosphorylation of c-Yes using an *in vitro* protein kinase assay described previously^[6,8]. Activities of c-Yes in the representative results of NL (patient 1), CH (patient 2), N and T tissues (patients 3-5), respectively, are shown in Figure 1A. When the kinase level of N tissues was used as a reference level ($n = 1$), c-Yes activity ratio in the T tissues ($n = 9$) was 5.0 ± 3.7 times higher than that in the N tissues, as measured by autophosphorylation (Student's *t*-test, $P < 0.001$) (Figure 1B). Patients 3-5 were classified as well-differentiated, moderately-differentiated and poorly-differentiated HCC, respectively. In addition, the c-Yes activity in all NL and CH tissues used in this study was very low as measured by autophosphorylation of c-Yes. Thus, c-Yes activity was notably high in human liver tissues with malignancy. In addition, our results showed that although the kinase activity of c-Yes was very low in NL and CH, it was already activated in liver cirrhosis (nontumorous cirrhotic tissues). Because the kinase activity of c-Yes was already activated at the preneoplastic stage (cirrhosis), *i.e.*, before the development of HCC, these data suggest that HCV-induced liver cirrhosis is a precancerous condition.

Protein levels of c-Yes were determined by Western blot analysis. Immunoprecipitates used for the protein kinase assays were also applied to sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) before transfer to nitrocellulose membranes. As shown in Figure 1C, two proteins were detected in each lane. The upper protein was c-Yes, and the lower one was the heavy chain of the c-Yes monoclonal antibody. Although the level of c-Yes was very low in NL and CH, it was elevated in N and T tissues of HCC (Figure 1C). As an internal control, the amount of α -tubulin in lysate containing 100 μ g of cellular protein used in the immunoprecipitation was almost the same in each lane (Figure 1D). When the protein level of N tissues was used as a reference level ($n = 1$), the level of c-Yes protein in T tissues ($n = 9$) was 2.1 ± 0.84 times higher than that in the surrounding N tissues from the same patients (Student's *t*-test, $^dP < 0.01$) (Figure 1E). The ratio (T tissue *vs* surrounding N tissue) of the protein level of c-Yes was smaller than that of the kinase activity. These data suggest that the high c-Yes kinase activity in the HCC is probably caused not only by an increase of c-Yes protein but also by an increase of the enzyme activity.

In conclusion, activation of the protooncogene product c-Yes may play a significant role in the malignant transformation of hepatocytes. The suppression of c-Yes kinase activity may offer a novel strategy for overcoming the development and invasion of HCC. Further studies are necessary to investigate such processes.

<http://www.wjgnet.com/1007-9327/12/5746.asp>

TO THE EDITOR

A 61 year old man with cirrhosis and hepatocellular carcinoma developed on the background of chronic hepatitis B was admitted because of acute and gradually intensified right thigh pain and swelling, which, within a few hours, was expanded to his right foot. The patient, due to ascites refractory to diuretics, was almost weekly subjected to large volume paracentesis of ascitic fluid for the last six months; meanwhile he has developed a left inguinal, a right femoral and an umbilical hernia. It should be noted that 48 h before admission, the patient was referred to the emergency room because of dyspnoea and 5 L of ascitic fluid were removed.

Physical examination was notable of tense ascites and his right lower extremity was profoundly more edematous (thigh, calf and foot) compared to his left leg (Figure 1), without signs of inflammation. Inguinal lymph nodes were not enlarged, Homan's sign was absent, and peripheral arteries were palpable. There was also a left inguinal hernia and an umbilical hernia containing fluid in the sac, while

there was no edema in the scrotum.

The patient was initially subjected to duplex ultrasonography of his right leg, which turned negative for deep venous thrombosis. Subsequently, a CT scan of the right thigh and abdomen was performed, revealing an enormous fluid collection within the peritoneal cavity (Figure 2A) and a notable fluid collection within the lateral aspect of the right thigh (Figure 2C). The fluid in the right thigh exhibited approximately the same density with ascitic fluid (Figure 2A and C). No masses were detected in the pelvis.

Figure 1 Significant edema of the right leg without signs of inflammation in our cirrhotic patient with tense ascites.

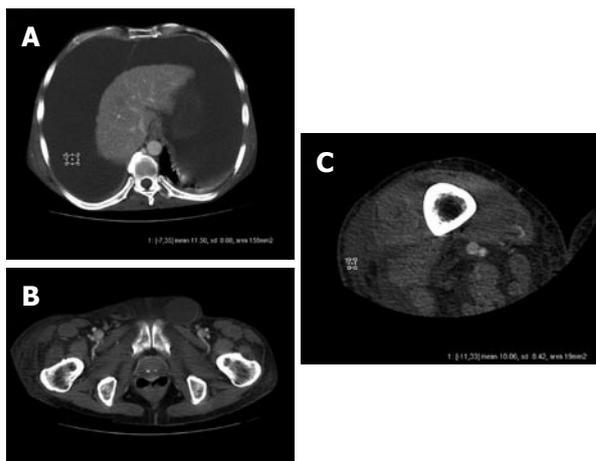

Figure 2 A: Enormous fluid collection within the peritoneal cavity. The fluid density was measured to be 11.5 Hounsfield Units; B: No masses were detected in the pelvis, whereas there was fluid collection into the left inguinal canal and no evidence of fluid collection into the right inguinal canal; C: Fluid collection within the lateral aspect of the right thigh with a density of 10.06 Hounsfield Units.

In addition, fluid was also seen in the left inguinal canal, but not in the scrotum, while no hernia was seen in the right femoral ring (Figure 2B). What could be the etiology

of the patient's right lower extremity edema?

According to the diagnostic evaluation performed, the possibility of deep venous thrombosis of the right leg was practically excluded based on negative duplex, increased international normalized ratio (INR) (2.2) and low platelet count (70000/mm³) that our patient exhibited in the text of his cirrhosis. Also any mechanical reasons that could induce unilateral venous or lymphatic stasis were ruled out. However, according to the CT scan findings, it seemed that the patient's lower extremity edema was caused by accumulation of ascitic fluid, which somehow passed from the peritoneal cavity to the right thigh. Interestingly, the known right femoral hernia was detected neither by physical examination, nor by CT scan, tempting us to speculate that drainage of fluid contained within the femoral hernial sac to the thigh might have occurred.

Asking in more detail the patient's history we were informed that in his prior admission to the emergency room (48 h ago), he was subjected to right femoral vein puncture for blood sampling. A potential mechanism of ascitic fluid accumulation in the right thigh could be the injury of the right femoral hernial sac during femoral vein

puncture. The femoral hernial sac and its content pass through the femoral ring and are generally localized between the external femoral vein and Gimbernat's lacunar ligament medially. These hernias, having penetrated Scarpa's triangle, through stretching of the cribrate lamina, are visible subcutaneously in the thigh. Reasonably, perforation of the femoral hernial sac would permit the drainage of ascitic fluid to the subcutaneous tissue of the right thigh, forced by the high intraabdominal pressure, whereas the scrotum would remain unaffected (unlike the case of an inguinal hernia perforation). The patient was subjected to repeated large volume paracentesis and along with ascites improvement his right leg edema was significantly decreased.

This case presents a rare complication of femoral vein puncture in a patient with tense ascites, which raised diagnostic dilemmas and led to expensive diagnostic evaluation. Clinicians handling cirrhotic patients should be aware of this potential complication and perform femoral vein or artery puncture with caution or ideally under scan control in case of coexistence of ascites and femoral or inguinal hernias.

TO THE EDITOR

I have read with great interest the very recent article titled "Intestinal Behçet's disease with pyoderma gangrenosum: A case report" of Nakamura T *et al* that was published in your journal. The authors stated that they presented a very rare case of intestinal Behçet's disease with pyoderma gangrenosum in a 16-year old patient. However, I would like to make some important contributions and suggestions to the presented case and have a few questions to ask the authors.

First, the exact diagnosis of Behçet disease in a single case depends first on the recognition of a characteristic set of sufficient symptoms and/or signs to allow the physician to diagnose with various levels of certainty from "complete or definitive" Behçet disease to "suspected or possible" Behçet disease^[1] based on the clinical sign constellation in Japanese Behçet Disease Research Committee Criteria, the preferred diagnostic criteria before 1989^[2]. According to the criteria, such a "complete" or "definitive" diagnosis of Behçet disease needs either at least three major criteria or two major criteria (one of which is ocular disease) or two major criteria associated with 2 minor criteria. This means that the correct diagnosis of Behçet disease can be established only on

the basis of aforementioned strict rules that need the complete fulfillment of the criteria with careful differential diagnosis from other etiologies. Therefore, the authors' statement that "she was diagnosed with intestinal Behçet's disease by the presence of cutaneous pathergy together with two major criteria (oral and genital aphthoses) and one minor criterion (gastrointestinal manifestations) in 1984" cannot be accepted as the presented case does not fulfill the requirements of "Japanese Behçet Disease Research Committee Criteria", the preferred diagnostic criteria in that period, in which cutaneous pathergy is not included in the major or minor criteria. Although oral aphthous and genital ulcerations with a positive pathergy test of the presented case meet the diagnostic criteria of International Study Group^[3], published in 1990, however, diagnosis and surgical intervention of the presented case with "incomplete diagnosis" were made in 1989. In other words, the case can be accepted as "suspected" Behçet disease according to the Japanese criteria, provided that other etiologies for these manifestations have been strictly ruled out including inflammatory bowel disease (IBD). Therefore, the authors should first clarify this diagnostic confusion.

Second, the presented case was stated to have colitis involving the entire colon demonstrated by colonoscopy. However, typical intestinal involvement in Behçet disease is characterized mainly by changes in the small intestine or ulcerative lesions at the terminal ileum or cecum, resulting in various digestive symptoms^[4]. I think the differential diagnosis was not performed strictly enough in this single case as the aforementioned symptoms are seen in IBD, namely Crohn's disease and ulcerative colitis that need careful evaluation. Although the resected specimen demonstrated severe inflammation with neutrophil accumulation, this is a general finding in inflammatory diseases and intestinal Behçet disease is often indistinguishable from IBD by histological evaluation. Therefore, such a general finding cannot be used as the histological hallmark of intestinal Behçet disease as its diagnosis is based on the presence of deep colonic ulcerations frequently situated in healthy mucosa along with the presence of an adjacent non-specific inflammatory infiltrate affecting the entire colonic wall that is characterized by leukocytoclastic vasculitis and perivasculitis of the arteries and veins with signs of fibrinoid necrosis. Moreover, there is not any knowledge in the presented article about the presence or absence of granulomatous or non-granulomatous changes or caseation with or without confluent (diffuse) or skipping

(segmental) lesions (*i.e.*, mural thickening) that strongly need strict differential diagnosis of intestinal Behçet disease from IBD. Indeed, ulcerative colon, for instance, is restricted to the colon, and exhibits proximal extension over time with full thickness involvement in case of toxic megacolon^[5]. Therefore, nothing in the article can exclude these questions in that single case that seems to need clarification.

Third, the authors stated that the patient received 20 mg oral prednisolone treatment for a month, though cutaneous and intestinal lesions of the girl were poorly controlled. However, to our knowledge, corticosteroids (CSs) alone are not used for the treatment^[1] and management^[6] of Behçet disease at least in the used dose, and no study has found that CSs alone are effective on any symptom or sign as well as on any etiological factors including cutaneous and intestinal lesions that are accused for the pathogenesis of Behçet disease^[7-13]. Moreover, CSs are of little value for the maintenance of remission. Indeed, the results of Mat C *et al*^[14] are important and demonstrate that CSs alone for about a six-month duration are not effective even on oromucocutaneous symptoms despite the well-known underlying vasculitic pathology of the condition. Because most of the treatments have been shown to work in Behçet disease or in IBD, the used dose of CSs seems not sufficient for such a severe intestinal involvement in the present case and therefore, the patient should have been treated first with a higher dose of CSs (1-2 mg/kg prednisolone per day) for a short time with some other immunomodulating/immunosuppressive agents or their combinations with cyclophosphamide, chlorambucil, colchicine, dapsone, cyclosporine and especially azathioprine that could be used in that period for the management and treatment of complete or incomplete Behçet disease patients with or without intestinal findings, to induce rapid and durable remission of intestinal attacks before the decision of an invasive surgery (total colectomy) is made^[15-21]. In other words, whether the patient is supposed to suffer from Behçet disease or IBD, the indication for surgical treatment can be made upon failure of sufficient and appropriate medical treatment or based on the severe complications such as abscess, fistula formation and iatrogenic perforation. Although systemic CSs may be useful in the early stages of severe inflammatory attacks, they are of limited value for long-term management of serious involvements whereas sustained remission can be accomplished only by the immunomodulatory agents. For instance, azathioprine or chlorambucil associated with high dose CSs should have been tried initially for the girl to obtain possible remission with long-term steroid-sparing effects. Similarly, cyclophosphamide- and cyclosporine-CS combinations have also been used between 1971 and 1989 for various symptoms of Behçet disease, even in cases resistant to conventional therapy^[22-28]. Furthermore, Sanderson^[29] has evaluated chronic IBD in children including Crohn's disease, ulcerative colitis, indeterminate colitis and Behçet's colitis in the review in that period and stated that treatment with drugs (sulphasalazine, steroids, azathioprine) and elemental diet are helpful and concluded that the prognosis of chronic IBD in childhood is good. More importantly,

sulphasalazine with or without cyclosporine and CSs has successfully been used for the treatment of both intestinal Behçet disease and IBD^[30-32].

Fourth, the authors further stated that intractable ulceration of the left foot surprisingly disappeared postoperatively after total colectomy within two weeks with no relapse of pyoderma gangrenosum for 10 years afterwards, suggesting a close relationship between pyoderma gangrenosum and intestinal Behçet disease. I do not agree with the authors on this regard and I believe that if the patient had really had Behçet disease, pyoderma gangrenosum or any other kind of cutaneous manifestations might have developed in its due course as the disease is known to be most active during the second and third decades of life. Indeed, the authors further stated in their paper that pyoderma gangrenosum might respond to surgical resection of the associated diseases, such as ulcerative colitis and Crohn's disease (see discussion section, second paragraph), and then stated in the following sentences that pyoderma gangrenosum in the present case rapidly improved after total colectomy. I agree on this regard and fortunately, total colectomy results in cure of IBD with reasonable long-term benefit in many cases. Therefore, both the authors' statements in their paper and the literature again indicate that the girl had an IBD with or without Behçet disease.

Although aphthous punched-out ulcerations may be found in about one-tenth of Behçet disease patients, they occur most frequently in the terminal ileum and cecum^[33] and this finding alone is still not sufficient for the diagnosis of Behçet disease as the case should strictly fulfill the whole systemic diagnostic criteria as stated above and aphthae in the colon may be seen not only in Behçet disease, but also, for instance, in Crohn's disease^[34]. Moreover, a very recent study has demonstrated that none of the clinical parameters of a total of 162 consecutive adult patients with diagnosis of IBD consisting of Crohn's disease and ulcerative colitis fulfill the Behçet disease diagnostic criteria^[35]. In other words, Behçet disease was diagnosed in none of the patients even though they had various symptoms such as intestinal involvement, pyoderma gangrenosum, articular disease, skin lesions, and oral ulcer with or without HLA-B51 positivity. Furthermore, such case reports with identical and perplexing clinical presentations as compared to those of Nakamura *et al*, are still present in the literature, describing association of both diseases^[32,36,37].

In conclusion, although I agree that the gastrointestinal and systemic features of Behçet disease and IBD overlap to a considerable extent that need addressing both in terms of increasing our understanding of pathogenesis and improving therapy, they are generally viewed as two distinct diseases, and oral aphthous ulcerations, genital ulcerations, papulopustular lesions or pyoderma gangrenosum on the leg with or without pathergy test positivity are all encountered findings during the course of IBD. In addition, constellation of findings for the diagnosis of Behçet disease is applicable only in the absence of other clinical explanations such as IBD. Therefore, the absence of sufficient symptoms to diagnose this young girl as "complete" or "definitive" Behçet disease

along with the presence of active colitis and ulcerations involving the entire alimentary tract, mainly colon in that case, reaching up to the terminal ileum associated with a rapid disappearance of intractable foot ulceration after surgery with the lack of demonstrated thrombotic or leukocytoclastic vasculitis (typical hallmark of Behçet disease) on colonic histopathological examination in the presented case, strongly indicates a diagnosis of pyoderma gangrenosum associated with IBD characterized by Behçet disease-like clinical presentation^[38-40]. Consequently, I suggest that the authors of the present case perform HLA analysis in their patient. If it reveals HLA-B51 positivity, then the very unusual diagnosis of classified or unclassified IBD associated with Behçet disease can be made in that case. If it reveals HLA-B27 positivity, then the patient can be classified in that case as HLAB-27 positive IBD. Even if the patient is still to be accepted as having intestinal Behçet disease, it seems that the rules for the treatment of such an involvement have not been followed before the surgery.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents[®]/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch[®]) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology

Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China

E-mail: wjg@wjgnet.com

<http://www.wjgnet.com>

Telephone: +86-10-85381901

Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5

line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

Key words

Please list 6-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P*<0.05, ^b*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, ^c*P*<0.05 and ^d*P*<0.01 are used. Third series of *P* values can be expressed as ^e*P*<0.05 and ^f*P*<0.01. Other notes in tables or under

illustrations should be expressed as 1F , 2F , 3F ; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (<http://www.wjgnet.com/cgi-bin/index.pl>), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

- 16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂ not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please download CAF from <http://www.wjgnet.com/wjg/help/9.doc>.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to *WJG* all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The *WJG* requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1) direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3) supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The *WJG* does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to *WJG* if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Final check list for authors

The format is at: <http://www.wjgnet.com/wjg/help/13.doc>

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: <http://www.wjgnet.com/wjg/help/10.doc>

Abstract

H pylori is now accepted as the cause of gastritis and gastritis-associated diseases, such as duodenal ulcer, gastric ulcer, gastric carcinoma, and gastric MALT lymphoma. The natural history of *H pylori* gastritis includes inflammation progressing from the antrum into the adjacent corpus resulting in an atrophic front of advancing injury leading to a reduction in acid secretion and eventual loss of parietal cells and development of atrophy. Sub-typing intestinal metaplasia has no clinical value to the patient, the pathologist, or the endoscopist. The pattern, extent, and severity of atrophy, with or without intestinal metaplasia, is a far more important predictor than is intestinal metaplasia subtype. The challenge remains to identify a reliable marker that relates to pre-malignant potential.

GASTRITIS DUE TO *H PYLORI* INFECTION

H pylori is now accepted as the cause of gastritis and gastritis-associated diseases, such as duodenal ulcer, gastric ulcer, gastric carcinoma, and gastric MALT lymphoma. Overall, two rules are clear: (1) the pattern of gastritis is the major determinant of disease outcome^[1,2], and (2) countries with a high prevalence of gastric cancer and gastric ulcer, such as Japan or Peru, have a low incidence of duodenal ulcer^[3]. Duodenal ulcer is typically associated with antral predominant gastritis, little or no atrophy and normal or increased acid secretion^[4-7]. Gastric ulcer and intestinal gastric cancer are typically associated with extensive gastritis, widespread intestinal metaplasia and

hypo- or achlorhydria^[3,4,8,9]. However, both rules can be broken^[9,10]: (1) wide spread intestinal cancer has been documented in the corpus of Korean duodenal ulcer patients, and (2) both diseases (duodenal ulcer and gastric cancer) are frequent diagnoses in dyspeptic Korean patients^[9,10]. One of the keys to this apparent paradox is a person's natural acid secretory status.

DUODENAL ULCER AND GASTRIC ULCER REPRESENT TWO ENDS OF ONE DISEASE "*H PYLORI* INFECTION"

Although *H pylori* are found throughout the stomach, in the early stages of disease, *H pylori*-associated inflammation is often mild, superficial, or even absent in the gastric corpus^[10,11]. The natural history of *H pylori* gastritis is for the inflammation to progress from the antrum into the adjacent corpus resulting in an atrophic front of advancing injury, leading to a reduction in acid secretion and eventually loss of parietal cells and development of atrophy^[10,12,13]. This progression is not inevitable. In the general population it progresses at a rate of 1%-2% per year^[12]. The rate of progression of gastritis differs among different countries, different regions of the same country and among different *H pylori*-related diseases^[14,15]. Overall, the incidence of gastric cancer is highest in countries and regions with a high incidence of early development of atrophic corpus gastritis^[12,16-19] (Figure 1). In contrast, in duodenal ulcer patients, gastritis tends to stay largely confined to the antrum and either does not advance, or spreads very slowly, to involve the gastric corpus^[12,20,21]. Atrophic pangastritis with hypochlorhydria is rare or develops sufficiently late in life that the risk of gastric cancer for the population of patients with duodenal ulcer remains low.

The rate of progression of *H pylori* gastritis progression depends on the acid milieu. Thus, *H pylori* corpus gastritis is accelerated in clinical scenarios associated with low acid secretion, such as chronic therapy with proton pump inhibitors, which are widely used in gastro-esophageal reflux disease^[8,22-37]. Omeprazole therapy is associated with a reduction in bacterial load, both in the antrum and in the corpus, and a tendency for antral histology to improve and corpus gastritis to either not change or worsen. With omeprazole therapy, not only does the corpus mucosa fail to show histologic improvement, but there is a significant progression of the inflammatory reaction deeper within the pit involving the proliferative zone^[38].

A person's natural acid secretory status thus appears to determine whether they will develop duodenal or gastric

ulcer disease^[39,40] with the acid secretory status appearing to affect both the distribution and severity of *H pylori*-related gastritis. There is some evidence that some cases of duodenal ulcer disease may “burn out” and this has been postulated to be due to the extension of gastritis into the corpus, thus reducing acid secretion to the point where it is no longer possible to sustain an active duodenal ulcer^[41]. One possibility is that with continued inflammation, antral atrophy may lead to a sufficient destruction of gastrin producing cells^[42] to produce a fall in acid secretion^[43,44], which would allow the development of corpus gastritis. In most duodenal ulcer cases, gastritis extends slowly or not at all giving the impression of localization to the antrum^[45]. Thus, antral predominant gastritis may in some instances represent an earlier stage of atrophic pangastritis such that these patterns actually represent two ends of the spectrum of “*H pylori* infection” rather than mutually exclusive diseases^[10,46,47] (Figure 1).

The rate of progression from gastritis to atrophy varies in different geographic regions related to other environmental factors. While diet is probably the most important factor that reduces acid secretion, other factors such as childhood infections may be very important^[10,14,48,49]. The rate of development and the proportion of the population with atrophic gastritis is a critical determinant for the risk of gastric cancer in that population^[14,15]. The apparent higher prevalence of concomitant duodenal ulcer and gastric cancer in Korea^[46] and the presence of atrophic gastritis with intestinal metaplasia in the corpus of Korean duodenal ulcer patients^[10] suggest that in Korea the rate of expansion of the atrophic front is more rapid than in patients in other geographic areas.

DIAGNOSING AND STAGING GASTRIC ATROPHY

This review only covers the histopathological diagnosis and staging of gastric atrophy; serologic measures are not addressed. The natural history of *H pylori* gastritis is to go through a cascade of events that involves non-atrophic gastritis, atrophic gastritis, and finally dysplasia^[50-52]. Atrophy begins at the fundic- or B-boundary line (defined as a margin between the corpus, with complete fundic gland mucosa, and the antrum)^[18,53,54] as a sheet of pseudo-pyloric metaplasia with islands of intestinal metaplasia^[10,13,55] and shifts proximally such that the antrum appears to expand replacing fundic gland mucosa with advancing atrophic gastritis^[18,20,53,56]. Corpus atrophy progresses proximally to variably sized regions of the adjacent greater curve, proximal half of the lesser curve, and neighboring anterior and posterior walls of the corpus^[15,18,53,57]. We will address intestinal metaplasia and pseudo-pyloric metaplasia separately.

INTESTINAL METAPLASIA

Because the development of gastric carcinoma is a slow and unpredictable process, and intestinal metaplasia is an easily recognizable marker for atrophy, investigators have suggested that sub-typing intestinal metaplasia using high-

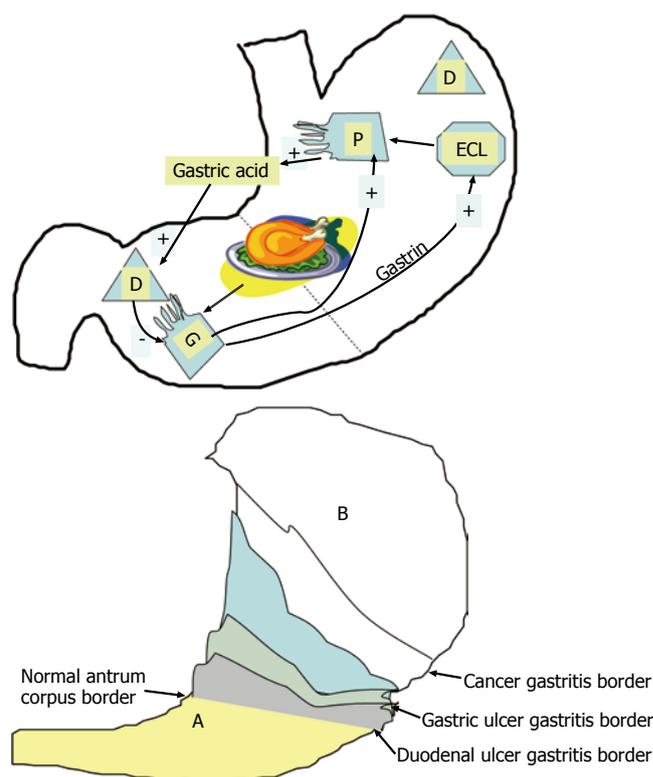

Figure 1 Duodenal ulcer and gastric ulcer represent two ends of one disease “*H pylori* infection”. Unlike gastric ulcer patients, duodenal ulcer patients have a long lag period before developing gastric atrophy. Disease progression is dependent on *H pylori* infection (cured/uncured) and other environmental factors such that in some countries DU would be considered protective against the development of gastric carcinoma.

iron diamine staining might identify subgroups of patients with different risk potential. Intestinal metaplasia sub-typed as III is often considered as a precursor lesion for the intestinal form of gastric cancer^[58-61]. In practice, areas of intestinal metaplasia (or a certain sub-type) are generally small and can easily be missed at follow-up^[62]. Sampling error is likely the critical factor responsible for the fact that an approximately equal number of studies have suggested that intestinal metaplasia regresses or does not regress after treatment of *H pylori* infection^[62-70]. Prior studies suggesting an association of type III intestinal metaplasia with the development of gastric cancer^[59-61,71] did not take into account the higher prevalence of incomplete intestinal metaplasia (type III) in the gastric antrum^[15,72,73]. In addition, while type III intestinal metaplasia is present in all specimens with intestinal type gastric carcinoma, it can easily be missed in biopsy as it can be present in very small areas^[13].

A small percentage of cancer patients can show complete replacement of the antrum mucosa with intestinal metaplasia and have normal appearing oxyntic mucosa^[13]. It is unknown if these individuals had normal or reduced acid secretion. Continued inflammation with antral atrophy could possibly lead to sufficient destruction of gastrin producing cells^[45], which can result in a fall in acid secretion^[74,75]. Alternatively, contiguous sheets of intestinal metaplasia may be unstable epithelium especially upon exposure to carcinogens.

Pepsinogen I (PG I) normal corpus vs metaplasia (pseudopyloric metaplasia)

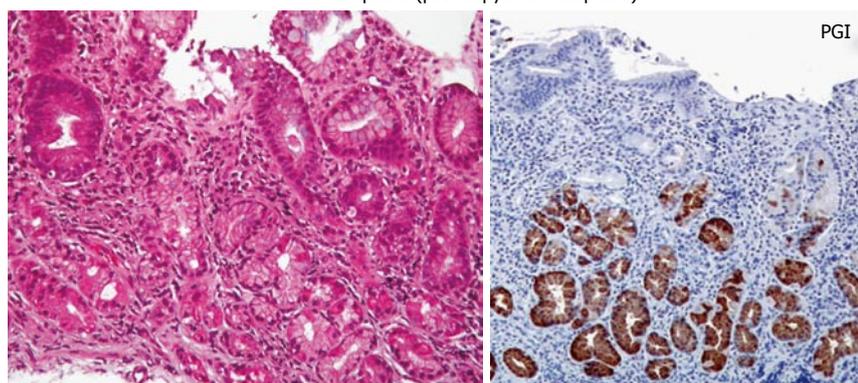

Figure 2 The diagnosis of pseudopyloric metaplasia can be facilitated by using pepsinogen I immunostain. Pepsinogen I (PG I) is localized in chief cells, mucous-neck cells and transitional mucous-neck/chief cells of the human fundic mucosa^[78] and is negative in antral gland cells.

Table 1 The diagnosis of pseudopyloric metaplasia can be facilitated by using pepsinogen I immunostain

	Pepsinogen I (PG I)	Pepsinogen II (PG II)
Chief cells	Positive	Positive
Mucous neck cells	Positive	Positive
Antral gland cells	Negative	Positive

Pepsinogen I (PG I) is localized in chief cells, mucous-neck cells and transitional mucous-neck/chief cells of the human fundic mucosa^[78]; it is not localized in antral gland cells. Pepsinogen II, on the other hand is localized in chief cells, mucous neck cells, and antral gland cells.

Overall, it is apparent that it is not currently possible to make recommendations or prognoses based on either a single or multiple biopsies showing sulphomucin in areas with intestinal metaplasia^[62,72,76,77]. All data suggest that the extent of mucosal atrophy within a region of the stomach may have a more important relation with the intestinal type of gastric cancer than the presence or type of intestinal metaplasia. While intestinal metaplasia is a form of atrophy that is easy for pathologists to recognize, it is also important to determine whether intestinal metaplasia is present as an isolated patch within non-atrophic mucosa or amidst an atrophic lawn^[10,13].

PSEUDO-PYLORIC METAPLASIA

The normal oxyntic mucosa has straight glands composed of tightly packed chief cells, parietal cells, endocrine cells, and mucus cells with a higher ratio of glands to foveola than the antrum. With continuous inflammation, and progressive atrophy, there is a progressive loss of parietal cells. Eventually, the oxyntic mucosa glandular compartment can resemble antral/pyloric glands on H&E exam (pseudopyloric metaplasia). The diagnosis of pseudopyloric metaplasia can be facilitated by using pepsinogen I immunostain (e.g. anti-pepsinogen I from Biogenesis Kingston, NH). Pepsinogen I (PG I) is localized in chief cells, mucous-neck cells and transitional mucous-neck/chief cells of the human fundic mucosa^[78]; it is not localized in antral gland cells (Figure 2). Pepsinogen II, on the other hand is localized in chief cells, mucous neck cells, and antral gland cells (Table 1). Pseudo-pyloric metaplasia is identified by the presence of mucosa that

is phenotypically antrum, stains positive for pepsinogen I, and is anatomically in a region where corpus would be expected^[113,55].

Pseudopyloric metaplasia has been described as early as 1959^[79] in benign gastric ulcers proximal to the normal border zone (antrum-corporum junction). In fact, prior to the rediscovery of *H pylori*, a proximally advancing atrophic front with pseudopyloric metaplasia was considered part of the normal aging process^[18,56]. Following the rediscovery of *H pylori*, a positive association has been demonstrated between the presence of mucous glands in corpus biopsies (pseudo-pyloric or mucous metaplasia) and the age of *H pylori* infected patients. This association was more prevalent in Korea where gastric carcinoma is common^[10]. The pattern of atrophy in the form of pseudo-pyloric metaplasia is considered regenerative in nature^[80,81] and has been observed in experimental models^[82], as well as in gastric remnants following distal gastrectomy with gastroenteric anastomosis^[83]. In fact, routine screening for gastric cancer in asymptomatic patients with gastric remnants often reveals pseudo-pyloric metaplasia in oxyntic type mucosa.

STAGING ATROPHY

In staging corpus atrophy, it is important to remember four rules: (1) atrophy begins at the border line (antrum-corporum border); (2) atrophy replaces fundic gland mucosa with both pseudopyloric metaplasia and/or intestinal metaplasia^[115,53,84]; (3) the atrophic border extends proximally more rapidly up the lesser curve than the greater curvature such that locations high on the greater curvature are among the last to manifest atrophy^[113,53,79,84]; and (4) the presence of a higher density of mucosa mononuclear cells that infiltrate deep into the lamina propria is a predictor for the presence of gastric atrophy^[38,85].

In early stages of atrophic gastritis, observed in children^[55], the location of the antral-corporum border would be expected to be nearer to the normal anatomic border^[10]. As such, the identification of atrophy requires biopsies be taken close to the normal antrum corpus junction^[55]. In contrast, the atrophic front (atrophic border) is expected to be more proximal in patients in developing countries, in countries with a high incidence of gastric carcinoma (Figure 1), and within particular groups in developed

countries that have a higher incidence of gastric carcinoma, including the socially and economically disadvantaged^[86], with the atrophic border advancing more proximally with age^[10]. To note, the cardia is not only a high yield zone for *H pylori*^[11], but also both intestinal metaplasia and pseudo pyloric metaplasia have been identified in the cardia of children with early atrophic gastritis^[55].

The Sydney system and Updated Sydney system^[87] were primarily designed to provide standardization for reports of gastric biopsies. The Sydney system^[88] recommended a minimum of two biopsies from the respective gastric compartments to be taken from the anterior and posterior wall. In 1994, the Sydney system for the classification and grading of gastritis was updated. The recommendation was unchanged regarding the need for a minimum of two biopsies from the respective gastric compartments but the location was changed from the anterior and posterior walls to the greater and lesser curves of the stomach^[87]. In both instances the sites were chosen arbitrarily. Though the Sydney biopsy sites have proven to provide reliable identification of *H pylori* infection^[44,89,90], the sites recommended by the Sydney system can only identify corpus atrophy when it is extensive^[10,62,90,91]. The recommended biopsy sites for research studies designed to identify the presence, pattern, or changes in atrophic gastritis over time or following a therapeutic intervention must be carefully selected to ensure that they encompass the advancing atrophic border. The number and sites chosen will therefore depend on the average degree and severity of atrophic gastritis expected in the population^[13,55]. Use of a standardized reporting system, such as the updated Sydney system, is useful for biopsy specimens particularly as it promotes the use of a visual analog scale to score mucosal findings. For research we suggest the use of a 6 point scale^[92] as it provides finer gradation than the 4 point scale used for reporting clinical specimens^[87].

In summary, to increase our likelihood of identifying corpus atrophy, when present, special emphasis should be placed on: (1) targeting biopsy sites to encompass the likely sites of the advancing atrophic border and the cardia^[55], (2) consistently including intestinal metaplasia and pseudopyloric metaplasia in our evaluation of corpus biopsies for atrophy^[13,87], and lastly, (3) raising our suspicion for corpus atrophy in biopsies with a higher density of mucosa mononuclear cells that infiltrate deep into the lamina propria^[38,85].

Abstract

Esophageal achalasia is an infrequent motility disorder characterized by a progressive stasis and dilation of the oesophagus; with subsequent risk of aspiration, weight loss, and malnutrition. Although the treatment of achalasia has been traditionally based on a surgical approach, especially with the introduction of laparoscopic techniques, there is still some space for a medical approach. The present article reviews the non-surgical therapeutic options for achalasia.

INTRODUCTION

Esophageal achalasia is a rare neuromuscular disorder characterized by degenerative changes of myenteric plexus leading to a selective loss of inhibitory nerve endings. The consequences of this damage are the irreversible loss of peristaltic contractions and the impaired relaxation of the lower esophageal sphincter (LES)^[1]. The ultimate cause of ganglion cell degeneration is unknown, but an association with class II HLA antigens^[2,3] and some virus infections^[4,5] has been described. An autoimmune pathogenesis in achalasia has been hypothesized due to the description of

antimyenteric neuron antibodies in a subset of patients^[6], although a genetic predisposition cannot be excluded^[7,8].

If untreated, in due course the disorder causes a progressive stasis and dilation of the oesophagus; with subsequent risk of aspiration, weight loss, and malnutrition. Because the etiology of achalasia remains obscure, the treatment is strictly palliative and is aimed at reducing the basal and residual LES pressure. Thus, esophageal emptying is allowed by gravity. The treatment of achalasia has traditionally relied on a surgical approach; the advent of minimally invasive surgery with a shorter hospital stay, reduced morbidity, and quicker return to daily activity, makes this option even more attractive^[9,10]. However, the high cost of this approach, the access to reference centers, the surgeon's learning curve, and some methodological debates, are still an issue.

In contrast, there is presently recent evidence that some medical strategies may be of benefit in many patients with this disorder^[11-13]. This review summarizes the current knowledge of non-surgical management of achalasia.

PHARMACOLOGIC TREATMENT

A number of pharmacological agents have been used to decrease the LES pressure. However, most acute and chronic studies were uncontrolled ones, and usually included only a small number of patients. Very few single- or double-blind, placebo-controlled trials are available. Overall, the clinical efficacy is often poorly described, even though several studies have shown that some compounds may be temporarily useful, while waiting for a more definitive therapeutic option. Table 1, Table 2, and Table 3, report the results of the most acute, chronic, and controlled studies, respectively.

The nitrates are claimed to be effective in achalasia; however, the relatively high frequency of side effects and the lack of controlled studies limits their clinical use^[14]. Therefore, the calcium channel blockers have been more frequently used. In particular, nifedipine has the wider published clinical and experimental evidence of efficacy. The therapeutic schedule suggests a sublingual administration of 10-20 mg, 15-30 min before meals. Its efficacy varies largely (between 50% and 90% in clinical trials), with side effects complained by up to 30% of patients. These include peripheral edema, headache and hypotension, and may wane over time. To date, however, nitrates and nifedipine could be recommended only in patients with an early stage disease, as a temporary measure before a more definitive option is selected.

Table 1 Acute drug studies in esophageal achalasia

Author	Drug	n	% of LES decrease
Wright (1961)	Butylschopolamine	3	Decreased
Von Weiser (1977)	Nifedipine	6	30
Becker (1981)	Verapamil	3	Unchanged
Cargill (1982)	Nifedipine	6	Decreased
Hongo (1982)	Nifedipine	8	45
Di Marino (1982)	Carbutoerol	10	55
Nashrallah (1983)	Nifedipine	7	55
Becker (1983)	Verapamil	7	31
Traube (1984)	Nifedipine	20	30
Wong (1987)	Terbutaline	15	Decreased
	Aminophyllin		
Bassotti (1988)	Nitroglycerin	9	70
Guelrud (1992)	VIP	6	51
Marzio (1994)	Cimetropium	20	Decreased
Penagini (1994)	Loperamide	9	Decreased
Bortolotti (1994)	Isosorbide	9	49
	Nifedipine	7	65
Bortolotti (2000)	Sildenafil	7	50

Table 2 Chronic drug studies in esophageal achalasia

Author	Drug	n	% efficacy	Follow-up (mo)
Yon (1975)	Anticholinergics	7	14	12
Gelfond (1981)	Isosorbide	24	79	2-19
Silverstein (1982)	Diltiazem	8	50	6
Gelfond (1982)	Nifedipine	15	53	8-14
Traube (1983)	Nifedipine	14	65-80	6
Maksimak (1986)	Nifedipine	4	LES decrease	3-6
Garia (1987)	Nifedipine	20	LES decrease	4
Coccia (1992)	Nifedipine	14	77	21

BOTULINUM TOXIN TREATMENT

Botulinum neurotoxins (represented by seven serotypes, abbreviated BoTx A to G) cause a sustained inhibition of neurotransmitter release at cholinergic terminals. These toxins specifically bind the presynaptic membrane, and enter the cytosol of the nerve terminal where they cleave different proteins involved in neuroexocytosis. The botulinum toxin A, which is currently used for the treatment of various dystonic skeletal muscle disorders, cleaves the SNAP-25 molecule at the presynaptic membrane, thus blocking the acetylcholine release and causing a denervation atrophy. Its beneficial effects are currently being extended to a variety of diseases with increased cholinergic function^[15-17].

The above considerations prompted Pasricha and colleagues to evaluate, for the first time, the usefulness of intrasphincteric injection of BoTx in esophageal achalasia^[18,19]. The rationale was that the selective loss of the inhibitory nerves in achalasia upsets the excitatory (cholinergic) influences on LES. Thus, by blocking the release of acetylcholine, locally injected BoTx might reduce the LES pressure and improve the "passive" esophageal emptying. These authors developed a protocol

Table 3 Controlled drug studies in esophageal achalasia (NA = not available)

that has become, with slight modification mostly due to the different toxin dosages, the standard one currently used in almost all centers. The toxin is injected through a standard sclerotherapy needle during an upper endoscopy performed under conscious sedation, and 80 to 100 Units of BoTx A are injected in each quadrant of the LES at 4 to 8 sites in 1 or 0.5 mL aliquots. Following the first observation, several investigators have found a success rate of 70% to 100% in relieving symptoms in the short-term with a parallel decrease of LES pressure and improvement of esophageal emptying, although probably to a lesser extent than that obtained after pneumatic dilation.

Table 4 summarizes most of the largest studies published on BoTx in achalasia; after a single injection of toxin, almost 80% of patients report good to excellent relief of symptoms. More than half are still in remission at six months and one third at one year. This waning of efficacy was expected on the basis of neurological experience^[20]. The presynaptic nerve endings of skeletal muscles start to sprout new branches after 2-3 mo thus re-innervating the neuromuscular junction; for this reason, in a neurological setting, the injection of toxin is repeated every 3-4 mo. The effect of toxin on gastrointestinal smooth muscle and myenteric plexus has yet to be elucidated; nevertheless, the mean duration of a single injection of toxin in esophageal achalasia is 10-12 mo, with a wide variability ranging from three months up to three years. The reason for such variability is unknown,

but is probably related to another drawback of the toxin: the development of an autoimmune response with the production of antibodies that may in turn decrease its efficacy in some patients. This problem, however, could be solved with the use of different serotypes (i.e. BoTx C) which bind to different presynaptic receptors^[21].

In the attempt to optimize the dose and time of administration of toxin, two multicenter studies, coordinated by our centers, have been recently performed. The first trial^[22] demonstrated the relative similarity in the efficacy of 100 Units of Botox[®] (Allergan) with 250 Units of Dysport[®] (Ipsen, U.K.), the other commercially available toxin A in our country. Another study found the advantage of early repetition of the toxin with a second injection of 100 Units after one month^[23]. This schedule allowed a remission rate of 75% at one year compared with a 35% rate obtained with the same amount (200 Units) in a single injection. Interestingly, this schedule has been proven to be effective in older (or aging) (more than 75 years) achalasic patients in inducing symptom remission^[24].

Only a few studies are available on the long-term efficacy of BoTx. Pasricha *et al.*^[25] reported a 30% efficacy rate after a mean follow-up of more than two years, despite repeated injections. In our experience, however, 72% of patients were still in remission after a mean follow-up of 18 mo, provided that the toxin was repeated when symptoms relapsed^[26]. More recently, after a mean follow-up of 49 mo (range 6-100 mo), we found a 70% rate of good or excellent control of symptoms in a series of 149 patients (Annese V, *et al.*, unpublished data).

Overall, the endoscopic injection of toxin has been remarkably safe, and this is a common experience with this approach^[27]. In less than 10% of patients, a mild chest pain develops shortly after the procedure, but this usually does not require specific treatment. More importantly, in case of failure, the injection of toxin does not influence the functional results of subsequent surgical myotomy or dilatation. However, a number of surgeons have reported, similarly to the situation found after repeated dilations, a more difficult myotomy because of an increased adhesion of muscular layers to mucosal plan with an increased danger of mucosal perforation during the procedure. However, no need of conversion to open approach has been reported in these patients.

PNEUMATIC DILATATION

Historically, the dilation was the first attempt of therapy in esophageal achalasia, described in 1674 by Sir Thomas Willis^[28]. In that case (and in subsequent ones) a whale bone with a sponge tip was successfully used, at least in the short-term. Later, mercury-filled bougies and metal devices were used. More modern dilators consisted of expanding bags or balloons that dilated forcefully the LES, rupturing muscular fibers, like the Syppy pneumatic dilator. The dilators more commonly used today are the polyethylene Microvasive Rigiflex dilator (Boston Scientific Co.), passed over a guided wire, and the Witzel dilator (American Endoscopy) consisting of a polyurethane balloon, mounted over the endoscope.

Forceful dilation of the LES is considered to date to

be the most effective non-surgical treatment for achalasia, although details of the procedure vary in different institutions. The main variables are the type of dilator used, fluoroscopic or endoscopic positioning, and the degree and duration of inflation. We prefer to carry out the procedure under fluoroscopic control in a supine position, as previously described^[29]. Nothing is allowed by mouth for at least 8 h before the procedure. Intravenous midazolam is used for conscious sedation. The dilator is passed over a guidewire, placed endoscopically in the stomach, and positioned across the diaphragmatic hiatus using radiopaque markers as guides. The correct location is assessed by moving the balloon until the waist at inflation of 2-3 psi is observed fluoroscopically in the midportion of the balloon. We start with a 30-mm diameter balloon in the first session; the balloon is inflated to 5 psi during 1 min and subsequently (depending on patient tolerance) to 10-12 psi, and pressure is maintained for another minute. If the procedure is well tolerated, a second session is performed in the consecutive day with a 35-mm balloon, once again in two steps at 5 and 10-12 psi, until the obliteration of the waist occurs. If no symptoms develop during the following 6 h, patients are allowed to eat. If symptoms (fever, chest pain, or cough) or abnormality at chest auscultation occur, a gastrografin swallow is performed. When mucosal tears are observed at the predilation endoscopy, the dilation is postponed for a month.

Overall, a literature analysis of more than 3000 patients showed that the efficacy of pneumatic dilation is 85% in relieving symptoms, with a range of 65%-90%. The average decrease in LES pressure is 54% (range 40%-65%) (V. Annese and G. Bassotti, unpublished data). The results obtained with Rigiflex dilators closely approach those obtained with myotomy, with a perforation rate of about 2%. This is probably the main drawback of pneumatic dilation, which often may require a surgical repair. Risk factors are the use of a large size balloon, and previous dilations. Another drawback of pneumatic dilation is a possible relapse of symptoms, which require additional dilations. This figure is still puzzling, due to large variability between studies and the scanty long-term reports; however, 20%-50% of patients may require additional dilations.

CONCLUSIONS

Achalasia is still an intriguing "mystery", and although different "solutions" are available the definitive "cure" is missing. The variety of therapeutic options may confound patients and doctors; therefore, controlled trials are welcome. These studies, besides the relief of symptoms, should also give information on esophageal emptying, long-term efficacy, patients' satisfaction, cost of procedure, availability of access to referral centers. Unfortunately, it has been estimated that to reach an adequate statistical power a large size trial should be realized, with more than 400 patients enrolled. Waiting for this information, the patients should be informed about all the therapeutic options and institutional experience.

In young patients (under 40 years) or in the presence of a large diameter (> 5-6 cm) oesophagus, a laparoscopic

myotomy is probably the better choice. In the group of patients between 40 and 65 years of age, the graded pneumatic dilation using the Rigiflex balloon should be advised. In elderly patients, poor candidates for surgery, and probably in patients with vigorous achalasia, the initial treatment with botulinum toxin should be the preferred approach. The toxin is also helpful when the pneumatic dilation or myotomy failed^[30] or as a temporary measure.

The usefulness of nifedipine and nitrates is scarce, and these drugs should be used only on a temporary basis, waiting for more effective therapeutic options. In contrast, this pharmacologic approach may be useful on demand in case of severe chest pain.

Abstract

During the last decade, inflammation (carditis) and intestinal metaplasia localized to immediately below the human gastro-oesophageal junction have received much attention in relation to the rising incidence of cancer at this site. Since these histological findings are frequently observed even among those who are *H pylori*-negative, the causative factors for such histologic events at the human gastro-oesophageal junction remain obscure. A series of recent studies have demonstrated that a high level of salivary nitrite is sustained over several hours after the ingestion of a high nitrate meal, and that the nitrite in swallowed saliva is rapidly converted to nitric oxide by an acid catalyzed chemical reaction at the gastro-oesophageal junction. Eventually, a substantial amount of nitric oxide diffuses from the lumen into the adjacent tissue. Therefore, the human gastro-oesophageal junction is likely to be a region of high nitrosative stress. Considering the life-time exposure of the gastro-oesophageal junction to cytotoxic levels of nitric oxide, this may account for the high prevalence of inflammation, intestinal metaplasia, and subsequent development of neoplasia at this site. Although gastric acid, pepsin, and bile acid have been intensively investigated as a cause of adenocarcinoma at the gastro-oesophageal junction and the distal esophagus, nitric oxide and the related nitrosative stress should also be examined.

CARDITIS AND INTESTINAL METAPLASIA AT THE GASTRO-ESOPHAGEAL JUNCTION

The incidence of adenocarcinoma of the cardia of the stomach and adjacent gastro-oesophageal (GO) junction has been rising over the past 25 years, especially in Western countries^[1]. In recent years, a similar trend has been reported in Japan, although GO junction adenocarcinoma is still rare^[2]. We recently reported that this type of cancer occurs in subjects with preserved gastric acid secretion and is not associated with *H pylori* infection^[3]. Although gastric acid, pepsin, and bile have a deleterious effect on the epithelium at that site, the carcinogen for this type of cancer remains unknown. A sequence of histological events in which chronic inflammation progresses to metaplasia, dysplasia and, finally, carcinoma has been documented in distal gastric cancer, and is associated with *H pylori* infection in most cases. The sequence is also well defined for esophageal adenocarcinoma through the formation of intestinal metaplasia (IM) in the distal esophagus (Barrett's esophagus). Although such a process has not been established in the cardia, a similar sequence of events would occur at that site as IM at the squamo-columnar junction which was shown to have a malignant potential similar to that of Barrett's esophagus^[4,5].

During the last decade, inflammation (carditis) and IM localized to the immediate vicinity of the squamo-columnar junction have received much attention in relation to the rising incidence of cancer at this site. These histological findings are reported to be highly prevalent (38%-79% for carditis^[6-10], 10%-36% for IM^[7,11-15]) even among healthy subjects. Of these two histological parameters, the junctional IM is usually associated with carditis^[7,15], and hence the IM could be assumed to be a consequence of chronic inflammation at the cardia as in more distal areas of the stomach^[18]. There are two distinct patterns of carditis^[6,7,9,10]. One is associated with *H pylori* infection and is characterized by inflammation in other sites of the stomach. The other, which is unassociated with *H pylori* infection, comprises inflammation confined to the cardiac mucosa and is seen in patients with otherwise healthy stomachs. There are also differences in the grade and activity of the inflammatory infiltrate involving the columnar mucosa at the squamo-columnar junction, that is, patients with *H pylori*-associated carditis have more severe inflammation than patients with healthy stomachs and neutrophil infiltration is uncommon in the latter group^[6,7,10,17]. Although carditis in *H pylori*-negative subjects is sometimes accompanied by the presence of

gastro-oesophageal reflux disease^[6-10,16,17], its cause remains obscure and it may well represent the histological response to many different types of insult. Considering the milder inflammation usually seen in the absence of neutrophil infiltration, chemical insult can be a probable candidate as a cause of the carditis.

LUMINAL NITRIC OXIDE GENERATION AT THE GASTRO-OESOPHAGEAL JUNCTION

Recently, the hypothesis that a high concentration of luminal nitric oxide (NO) at the human GO junction after nitrate ingestion may be relevant to various diseases at that site was made by a group of researchers in Glasgow^[19,20]. Since then, that group and the present authors have been doing further research on this issue^[21-24].

NO is an important radical that mediates a wide range of physiologic and pathologic events. It is generated at low concentrations by the enzyme constitutive nitric oxide synthase (cNOS) to modulate neuromuscular and vascular functions. Higher concentrations are generated by the inducible form of the enzyme as a part of the immune and inflammatory response. Sustained generation of NO by inducible NO synthase (iNOS) has been implicated in the aetiology of the mutagenesis and neoplasia related to chronic inflammation.

The highest concentrations of NO occurring in the body are not the result of enzymatic synthesis but rather by chemical reactions within the lumen of the stomach, especially in the most proximal area. A previous study reported that high, potentially mutagenic concentrations of NO are generated luminally at the GO junction through the entero-salivary re-circulation of dietary nitrate in humans^[19]. This is explained as follows. Ingested nitrate as an ingredient of food is absorbed from the small intestine, and 25% of this is re-secreted into the mouth by the salivary glands. Bacteria on the dorsum of the tongue then reduce about 30% of this nitrate to nitrite. When salivary nitrite enters the stomach, the combination of the acidity and the ascorbic acid content of the gastric juice converts the nitrite to NO. Since this reaction between nitrite and ascorbic acid at an acidic pH is very rapid^[21], the intraluminal concentration of NO generated by the reaction is maximal at the GO junction and cardia, where the nitrite in saliva first encounters gastric acid. Indeed, this was confirmed by the afore-mentioned study in healthy volunteers which reported that substantial amounts of NO are generated following nitrate ingestion at these anatomical locations, in some case in excess of 50 $\mu\text{mol/L}$ ^[19].

The entero-salivary re-circulation of dietary nitrate is sustained for several hours, during which period the adjacent epithelium of the GO junction is exposed to abundant amounts of NO generated in the lumen. Membranes in the tissues are not barriers to the diffusion of NO because of its gaseous and lipophilic properties. Since NO is known to have dual effects within the tissue, i. e. cytoprotective and cytotoxic depending on the gas level, determination of the NO level is required to evaluate its function in the tissue. We recently developed a rat animal model in which nitrite and acidified ascorbic acid were

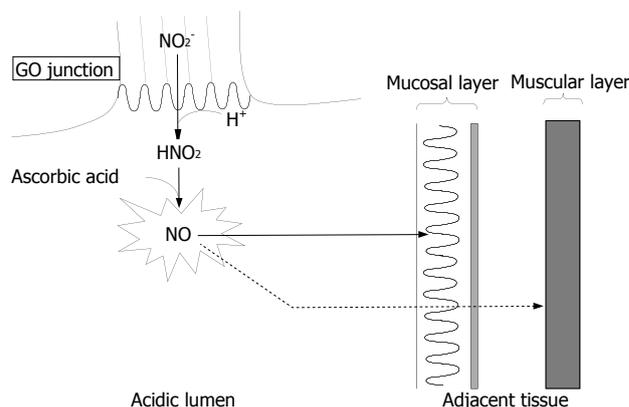

Figure 1 Nitric oxide chemistry at human gastro-oesophageal junction. Nitrite (NO_2^-) in swallowed saliva is converted to nitric oxide (NO) promptly at the gastro-oesophageal (GO) junction where encountering gastric acid containing ascorbic acid. NO thus formed diffuses into the adjacent tissue of the GO junction because of its gaseous and lipophilic properties. The majority of the NO arising from the lumen will be exhausted within the superficial mucosal layer by reacting with surrounding molecules while a small portion of the NO can reach the inner muscular layer. The luminal generation of NO is sustained for several hours after nitrate ingestion, during which period the GO junction is exposed to abundant amounts of NO.

administered separately so that the generation of NO from nitrite would be maximal at the GO junction where the reactants first meet^[24]. In that model, we demonstrated by means of electron paramagnetic resonance spectroscopy with an exogenously supplied NO trapping agent that the NO generated luminally diffused into adjacent tissues to a substantial degree and at a level comparable to that of iNOS derived-NO production and altered the integrity of the surrounding epithelium. As we applied a concentration of nitrite that has been observed in human saliva after the ingestion of a high nitrate meal, this finding may be applicable to the GO junction in humans^[24] (Figure 1).

Briefly, a high level of salivary nitrite is sustained over several hours after the ingestion of a high nitrate meal and the nitrite in swallowed saliva is rapidly converted to NO at the GO junction. Then, a substantial amount of NO eventually diffuses from the lumen into the adjacent tissue. Therefore, the human GO junction is likely to be a region of high nitrosative stress. Considering the lifetime exposure of the GO junction to a high level of NO, this may account for the high prevalence of inflammation and IM at that site. Assuming the metaplasia-dysplasia-adenocarcinoma sequence at the GO junction, NO may eventually lead to the development of carcinoma at that site. In addition to being mediated through such a sequence, a high concentration of NO can directly exert a mutagenic and carcinogenic effect through the formation of higher oxides of nitrogen such as N_2O_3 , which can damage DNA directly via deamination of bases and indirectly by forming N-nitrosocompounds. N_2O_3 is also known to inactivate DNA repair enzymes such as O⁶-alkylguanine DNA alkyltransferase^[25-27].

POSSIBLE IMPLICATIONS OF NITRIC OXIDE AT THE GASTRO-OESOPHAGEAL JUNCTION

In this chemical reaction occurring at the GO junction,

the presence of sufficient gastric acid is essential, and this condition is ensured only at the GO junction and the cardia after eating, where the acidic gastric juice largely escapes the buffering effect of food, which decreases the acidity of the gastric juice in the rest of the stomach^[28]. The necessity of gastric acid for luminal NO generation is consistent with our recent clinical study which found that the preservation of gastric acid is necessary for the development of cancer at the GO junction^[3]. In addition, a recent study has demonstrated that the site of NO generation shifted orally to the distal esophagus in cases with gastro-oesophageal reflux^[23]. Hence, the NO thus generated in the distal esophagus may also be relevant to the formation of Barrett's oesophagus and oesophageal adenocarcinoma.

Interestingly, although the majority of NO arising from the lumen would become exhausted within the superficial epithelial layer in our rat model, a small but significant amount of NO was detected even in the inner muscular layer of the GO junction, especially when a high concentration of nitrite was administered^[24]. This suggests that a part of the nitric oxide arising from the lumen could escape from autoxidation occurring within the superficial layer and reach the inner tissue. It is well known that NO endogenously derived from cNOS localized to non-adrenergic, non-cholinergic nerves mediates the relaxation of the smooth muscle cells, including those of the lower esophageal sphincter^[29]. An *in vitro* study using muscle strips from opossum lower esophageal sphincter demonstrated that a tiny amount of NO (in the range of nmol/L) was sufficient to induce relaxation of the muscle^[30]. Therefore, the amount of NO formed in the lumen at the human GO junction may be sufficient to penetrate the epithelium and then affect the inner smooth muscle cell of the lower esophageal sphincter, leading to relaxation of the muscle and reflux of the acidic gastric content into the oesophagus. Actually, a recent report demonstrated in humans that NO generated luminally at the GO junction did affect the lower esophageal sphincter, leading to a significant increase in the transient relaxation of the lower esophageal sphincter^[31]. Further studies are required to clarify to what extent this phenomenon is responsible for the pathogenesis of ordinary gastro-oesophageal reflux disease in humans. However, it may be related at least to the symptoms of heartburn that are known to be invoked after the ingestion of certain foods^[32,33] (Figure 1).

Needless to say, NO is known to have some beneficial effects on the stomach as well. It has been shown that intragastric topical application or parental administration of nitric oxide-releasing substances protects the gastric mucosa from damage induced by injurious agents, suggesting that NO plays an important role in the protection of the gastric mucosa^[34-36]. However, this protective effect is dose-sensitive; as some studies have reported that high doses of exogenous NO can exacerbate gastric mucosal injury^[37,38]. Thus, a high concentration of local NO at the gastric cardia may be involved in the pathology of mucosal injury at that site as a potential cytotoxic mediator. On the other hand, a relatively low

concentration of nitric oxide as seen in the distal stomach may function as a protective mediator to maintain the gastric mucosal integrity. Similarly, ascorbic acid, which is secreted in the healthy human stomach, could show even an undesirable effect on the GO junction by the rapid conversion of salivary nitrite to NO at that site^[21,22], although the vitamin is well known to have beneficial effects as an antioxidant in the remaining stomach.

FUTURE STUDIES ON THE RELEVANCE OF NITRIC OXIDE TO THE VARIOUS DISEASES AT THE GASTRO-OESOPHAGEAL JUNCTION

Further studies to investigate the effect of the diffused NO on the cell biology in the tissue are required to clarify the pathologic relevance of NO to the various histological events occurring at the human GO junction. Accordingly, the characteristic features of NO, for example, the gas is generated abundantly by the unique chemical reaction in the acidic lumen, need to be considered with reference to other examples of pathological circumstances involving NO such as models of inflammation in humans. First, in inflammation, not only NO but other radicals such as superoxides are also generated from inflammatory cells and then the reaction products with NO (for example, peroxynitrite), not NO itself, may be exerting deleterious effects on the tissue^[39]. In contrast, the effect of the diffused NO on the tissue at the GO junction should be mainly an NO-mediated process, at least at the early stage, although once the inflammatory process is initiated by the diffused NO other radicals are also formed. Second, since once the NO is diffused from the acidic lumen into the tissue at neutral pH it will be irreversibly metabolized to nitrite and nitrate, it is the very surface of the epithelium that is exposed to the highest concentration of NO, in contrast with examples of inflammation in which the immediate vicinity of inflammatory cells expressing iNOS would be exposed to the highest levels of endogenous NO^[39]. Hence, the tight junction of the surface epithelium at the GO junction is likely to be the principal target of the NO arising from the lumen^[40,41]. Third, as opposed to the inflammation that occurs only under specific circumstances, the exposure of the human GO junction to localized luminal NO occurs as long as the stomach is healthy and has sufficient acid secretion. In fact, it has been demonstrated that, after the ingestion of nitrate, the luminal NO concentration was maximal at the GO junction in 73% of subjects, although the gas level varied among individuals^[19]. Thus, it appears reasonable that the locally generated NO is the cause of inflammation and IM at the cardia, both of which are frequently observed even in healthy subjects as previously mentioned. However, since neoplasia develops only in a small number of people, individual susceptibility to NO toxicity such as from mutations in cancer-related genes (for example p53) may be important in determining its ultimate contribution to carcinogenesis at the GO junction^[42].

In conclusion, a cytotoxic concentration of NO is generated luminally at the human GO junction and the

gas diffuses into the adjacent tissue. Although gastric acid, pepsin, and bile acid have been intensively investigated as a cause of adenocarcinoma at the GO junction and the distal esophagus, NO and the related nitrosative stress should also be examined.

were not eldest among his/her siblings had an increased risk of GCs in the distal and middle thirds, and their ORs were 1.7 (95% CI 1.0-2.8) and 1.9 (95% CI 0.8-4.3), respectively. The corresponding OR in the upper third stomach was 0.3 (95% CI 0.1-0.9). The differences of those three ORs were statistically significant ($P = 0.010$).

CONCLUSION: The present study shows that birth order, salt intake, consumption of fruits and vegetables, the type of cooking, and cigarette smoking are related to GC risk. In histology and tumor-location specific analyses, non-eldest person among their siblings is related to an increased GC risk in the distal and middle thirds of the stomach, and is related to a decreased GC risk in the cardia.

Abstract

AIM: To examine histology- and tumor-location specific risk factors of gastric cancer (GC).

METHODS: This was a case-control study. The study subjects were 216 GC patients newly diagnosed during the period 2000-2002 and 431 controls selected from non-cancer patients matching in age, gender, and hospital. We obtained information on lifestyles, dietary habits, and others by a questionnaire.

RESULTS: The subjects who were not eldest among his/her siblings were at a slightly elevated GC risk (OR 1.3; 95% CI 0.8-2.0). Salting meals before tasting was related to an increased GC risk (OR 3.5; 95% CI 1.6-7.3). Frequent consumptions of fruits (OR 0.3; 95% CI 0.1-1.0) and vegetables (OR 0.3; 95% CI 0.1-1.0) were related to decreased GC risks. On the other hand, frying foods (OR 1.9; 95% CI 1.0-3.6) and cooking with coal (OR 1.8; 95% CI 1.3-2.6) were related to increased GC risks. Neither Lauren's histological classification (intestinal and diffuse types) nor tumor location significantly affected those associations except birth order. The subjects who

INTRODUCTION

Gastric cancer (GC) is still one of the most common cancers worldwide^[1,2] although its mortality has been decreasing over the years in many countries, including Colombia^[3], due to the changing dietary habits and lifestyles^[1]. Lauren classified GCs into two histological types, i.e., intestinal and diffuse types^[4], and pointed out that intestinal-type GC is more frequent in populations with a high GC incidence while the diffuse-type GC is more frequent in populations with a low incidence^[5]. Lauren suggested the importance of environmental, dietary and socioeconomic factors in development of intestinal-type GCs while he suspected the involvement of genetic factors in diffuse-type GCs.

Correa postulated a multifactorial model for gastric carcinogenesis, in which *H pylori* infection is considered to play important roles in development of preneoplastic and precursor conditions^[6-8]. Relationships between *H pylori*

and those gastric lesions have been documented in many countries^[9-12]. Early childhood infection with *H pylori* is considered an important risk factor for GC^[10,13]. A larger sibling size and higher birth order is related to earlier *H pylori* infection in childhood, a condition that is considered an important risk factor for GC^[10,13]. In Colombia, 50% of rural populations are reported to have *H pylori* infection by age 2, and nearly 90% are infected by age 9^[9].

Some studies reported that *H pylori* infection is related to both intestinal- and diffuse-type GCs^[14-16]. Interestingly, microscopic studies suggest that *H pylori* infection seems to be more strongly related to intestinal-type rather than diffuse-type GCs whereas serological studies do not^[16].

Regarding other risk factors, a case-control study in the US, has shown that a high intake of dietary calories increases only intestinal-type GCs^[17]. A population-based prospective study in Japan, reported that the frequent intake of vegetables and fruits, even in low amounts, is associated with reduction of GC risk, and it was observed only in differentiated (intestinal) type^[18]. Another study in Mexico showed that intake of dietary fiber and vitamin E tends to reduce risk of both intestinal- and diffuse-type GCs^[19]. They also reported that the association between high saturated fat consumption and the increase of GC risk is statistically significant among the intestinal type but not in the diffuse type; on the other hand, polyunsaturated fatty acids reduce the GC risk in both intestinal and diffuse types^[19]. The associations of tobacco smoking with different histological types of GCs have been examined by three studies, two conducted in Japan^[20,21] and one in Sweden^[22], to our knowledge. However, none of them showed any evident difference between intestinal and diffuse types with respect to GC risk associated with smoking.

Proximally-located GCs are known to have etiological backgrounds and clinico-pathological features different from more distally located stomach carcinomas^[1]. However, only a small number of studies have examined risk factors of GC by tumor locations. Inoue *et al*^[23] reported that habitual smoking was more strongly associated with the risk of GCs in the upper third of the stomach than that in more-distal parts. However, subsequent studies showed that GCs in the cardia and non-cardia have no evident differences in their associations with smoking^[21,22].

In the present study, we selected factors known, or strongly suspected, to be related to GC risk, and examined whether their associations were affected by Lauren's histological types and tumor location, or not.

MATERIALS AND METHODS

Patients and controls

Cases were GC patients newly diagnosed during the period between Sep 2000 and Aug 2002, in the following three major reference hospitals in Cali, Colombia: Instituto de los Seguros Sociales "Rafael Uribe Uribe", Hospital Universitario del Valle, and Hospital San Juan de Dios. These are reference hospitals not only for cancer but also for non-cancer diseases, including cardiovascular diseases (CVD), metabolic syndromes, trauma, *etc.*

We reviewed medical records, pathological reports and hospital registration records of those hospitals and affiliated medical institutions, including endoscopy clinics and oncology outpatient clinics to obtain information on clinical and pathological diagnosis, disease history, socioeconomic status, and contact address of the GC patients.

We identified 395 GC patients during the study period, and the following 81 cases were excluded: 16 recurrent cases of GCs; 65 patients who lived in Valle del Cauca less than five years. There were 91 patients we could not contact, and 7 patients refused to participate in the study. Among 216 patients in the present study, 30 had died before interview but their relatives accepted to answer the questionnaire and provide the necessary information.

Information on tumor location was obtained from pathological reports and clinical records. The location of a tumor, defined as the predominant location of the tumor, was divided into the following three categories: the upper-third, middle-third and lower-third parts according to the guidelines of the Japanese Research Society for Gastric Cancer^[24]. We could not obtain information on tumor location for 23 cases, and those cases were excluded from the tumor location specific analysis.

We could retrieve formalin-fixed paraffin-embedded blocks of 173 GCs, mainly surgically resected tumors. We examined those specimens, and histological diagnosis was made based on the Japanese classification^[25].

Controls were selected from hospitalized patients diagnosed as neither malignant diseases nor gastric illnesses. Two controls were selected from non-cancer patients for each case, matching in gender, age (5-year category), and hospitals. Controls were selected after their case was interviewed. The mean period of time between the interviews of a case and its controls was 25 wk (range 1-109). Among 528 patients as potential controls, 67 patients were excluded because they had lived in Valle del Cauca less than 5 years. Twenty-nine patients refused to participate in the study, including 19 patients in severe clinical conditions. After all procedures for selection and matching, one patient turned out to be inappropriate as a control because he had been diagnosed as GC 15 years before. Thus, the total number of controls was 431. Four major causes of hospitalization of control patients were cardiovascular diseases ($n = 208$), trauma ($n = 117$), infectious diseases ($n = 38$), and urological disorders ($n = 21$). The Institutional Review Board of the Faculty of Health, Universidad del Valle, Cali, Colombia, approved this study and all subjects gave informed consent.

Interview procedures

The interview was conducted during the period from Sept 2000 to Dec 2002. All subjects were interviewed during hospitalization, except 30 deceased patients. The interviewer visited at houses of those patients' relatives for interview. We used a validated questionnaire to obtain the personal and family information of all subjects as well as lifestyles, dietary intakes, culinary uses, and occupational exposure.

Answers to the questions of fruit and vegetable intakes, the way of cooking and so on were dichotomized

Table 1 Gender specific distribution of age and hospitals *n* (%)

as follows: "yes" (more than 3 d/wk) and "no" (equal to or less than 3 d/wk). Salt intake was assessed by asking the habit of seasoning a dish with salt before tasting, and the answers were coded as "yes" (usually or some times) and "no" (never). To the question about salting, 4.2% of the cases and 0.9% of the controls answered "sometimes". The simplified dietary habit questionnaire used in the present study was developed on the basis of the validated semi-quantitative food-frequency questionnaire (FFQ) used in a Colombian study in 1998^[26]. The FFQ has been originally developed as Colombian version of the FFQ used in the Nurses Health Study by Willet *et al*^[27]. The validity of our simplified dietary habit questionnaire was confirmed in a study reported by Garcia *et al*^[28].

Statistical analysis

The association between GC risk and each factor was analyzed using conditional logistic regression models. Maximum likelihood estimates of odds ratios (ORs) and corresponding 95% confidence intervals (95% CIs) were calculated. All *P* values presented are two-sided. *P* < 0.05 was taken as significant.

RESULTS

We successfully interviewed 216 GC cases and 431 control patients (Table 1). Table 2 summarizes the gender specific distributions of tumor location and histological classification of GCs. We observed no difference in the distribution of tumor location between male and female cases. Male GCs were more frequently found to be intestinal-type tumors when compared to female cases. Among males, the mean age of cases was highest in the GCs located in the upper-third stomach among the three tumor locations. On the other hand, female cases with tumors in the lower-third stomach showed a relatively higher mean age than those with tumors in other locations. Regarding histological type, female cases with intestinal-type tumors showed a higher mean age than other

¹Histological patterns were classified on the basis of Japanese classification as follows: well differentiated tubular adenocarcinoma (tub1), moderately differentiated tubular adenocarcinoma (tub2), solid poorly differentiated adenocarcinoma (por1), non-solid poorly differentiated adenocarcinoma (por2), signet ring cell carcinoma (sig), and mucinous carcinoma (muc). Intestinal type consists of tub1, tub2, and muc, and diffuse type consists of por1, por2, and sig.

subgroups including males.

We examined the association of GC risk with well-known or strongly suspected factors related to GC risk (Table 3). GC risk was related to the habit of seasoning a dish with salt before tasting (*P* = 0.001), the lower frequency of eating fruits (*P* = 0.046) and vegetables (*P* = 0.041), and the higher frequency of frying food consumption (*P* = 0.039), and cooking with coal (*P* < 0.001). The associations were not significantly changed after excluding patients with cardiovascular diseases or trauma from the control series. All those variables that were found to be significantly related to GC risk were independently associated with GC risk in the multivariate analysis involving all those factors (data not shown). The associations of GC risk with occupations and occupational exposures were examined as well. None of them was significantly related to GC risk (data not shown).

We estimated histology specific ORs of GC risk (Table 4). Among those who were not eldest among their siblings, diffuse-type GCs showed a significantly increased risk whereas intestinal-type GCs did not. The observations that non-eldest person among their siblings was related to diffuse-type GC risk but not to intestinal-type GC risk do not necessarily mean that those two histological types have significantly different associations with birth orders. A statistical test addressing this question gave a *P* value larger than 0.05, indicating that observed difference of ORs between intestinal and diffuse types was not statistically significant. When examining potential GC risk factors as shown in Table 3, we found that their ORs did not show any significant differences between the two histological types. On the other hand, smoking was found to be related to diffuse-type GC risk but not to intestinal-type. Here again, however, the difference in the ORs between two

¹Information on birth order was missing in 2 cases and 3 controls; ²P for trend.

histological types was not statistically significant.

Table 5 summarizes the results of tumor-location specific analyses. The ORs of GCs in the lower and middle third parts of the stomach were increased among those who were not eldest among their siblings. The ORs were 1.7 and 1.9, respectively. On the other hand, the corresponding OR for GCs in the upper-third stomach was lower than the unity (OR = 0.3). The differences of

ORs among those three tumor locations were statistically significant ($P = 0.010$). When cases with tumors in the lower and middle thirds of the stomach were combined, the OR of non-eldest person was 1.7 (95% CI = 1.1- 2.7, $P = 0.017$). When this OR was compared with that in the upper third of the stomach (OR = 0.3), P value for the difference became smaller and was 0.003. When examining the habit of seasoning a dish with salt before tasting, the low frequency of fruit and vegetable intakes, the frequent consumption of frying foods, and the use of coal for cooking, we found that their ORs were not significantly affected by tumor location.

Smoking was related to the risk of GCs in the upper third of the stomach but not in other locations. A statistical test examining the difference of the ORs in three tumor locations gave a P value larger than 0.05, indicating that the difference was not statistically significant.

DISCUSSION

In the present study, subjects who were not eldest among their siblings were at an elevated risk of GCs in the distal and the middle thirds, indicating a possibility that birth order may be related to age at first *H pylori* infection as suggested by Blaser *et al*¹⁰. On the other hand, a decreased OR of GC in the proximal third of the stomach was observed among those who were not eldest among their siblings. Those findings are of interest since *H pylori* infection is suspected to be associated with a decreased risk of GCs in the cardia or proximally located GCs, and with an increased risk of GCs in the non-cardia or distally located GCs¹⁶. Studies in the US and Europe showed an inverse relationship between seroprevalence of *H pylori* and GC risk in the cardia^{29,30}, suggesting that proximal and distal parts of the stomach may have differences in the interaction between *H pylori* and the host defense system.

We had information about *H pylori* infection for 96 patients. *H pylori* was reported positive in 24% of GCs in the lower third of the stomach ($n = 71$) and 36% of GCs located in the middle part ($n = 17$) whereas none in the tumors located in the upper third of the stomach ($n = 8$). Those findings, albeit small in number, support the notion that *H pylori* is not related to GC risk in the proximally located GCs.

High salt intake produces atrophic gastritis and decreases the acidity of the stomach, creating a condition favoring *H pylori* infection. It is also suspected that *H pylori* infection and high salt intake may act synergistically to promote GC development^{11,12}. If that is the case, it may be expected that salt intake is strongly related to non-cardia cancer but not to the cancer of the cardia (since *H pylori* infection is suspected to increase non-cardia GC risk but decrease cardia GC risk). In the present study, however, the habit of seasoning a dish with salt before tasting was related to an elevated GC risk regardless of histological type or tumor location. It may be because the upper third of the stomach includes not only the cardia but also the non-cardia part of the stomach. We did not have information to identify the cases occurring in the cardia. It is of note that Mayne *et al* examined the effect of sodium intake on tumor-location-specific GC risk and

¹Information on birth order was missing in a patient with diffuse-type GC and in 3 controls.

showed that the OR of GCs was 1.31 (95% CI = 0.86-2.00) in the cardia and was 1.46 (95% CI = 1.00-2.15) in the non-cardia^[31].

The tumor-location specific analyses showed that smoking appeared to be more strongly related to tumors in the upper third of the stomach. However, the difference

in the magnitude of associations was not statistically significant as was the case with histological type. A recent Japanese study showed that the association of smoking with GC in the upper third of the stomach was only slightly weaker than that with GC in the middle and lower thirds of the stomach^[21]. A Swedish study by Ye *et*

¹Information on birth order was missing in a patient with tumor in the lower third of the stomach and in 3 controls.

al^[22] also reported that smoking was related not only to cancer of the cardia but also to cancer of the non-cardia. Both studies mentioned above also showed no evident difference of smoking-related GC risk between the two histological types.

Frequent intakes of fruits and vegetables were related to a decreased GC risk in the present study. No significant difference in magnitude of their associations with respect to histological type and tumor location was

observed, confirming what was reported by other previous studies^[17,32,33]. Although the mechanisms involved in the protective effects of frequent fruit and vegetable intakes on GC risk are yet to be elucidated, Yuasa *et al*^[34] showed the intake of some specific vegetables may prevent hypermethylation of the CDX2 gene, which upregulates the expression of MUC2, an important mucin protein related to the intestinal phenotype of GCs.

We observed a significant association between GC risk

and frying foods. In Cali, Colombia, residents tend to fry starch-rich foods, including potatoes, green banana, corn, and mandioca. De Stefani *et al*^[35] reported a relationship between starchy rich foods and the GC risk, suggesting mechanical damages to the gastric mucosa and promotion of nitrosation by low-protein diets. Mayne *et al*^[31] suggested that this association may be related with micronutrient deficiencies.

We also observed an association between cooking with coal and the GC risk. It is known that barbecued foods contain high concentrations of N-benzil pyrene and nitrites, which are related to an increased GC risk^[11,21]. Although some studies suggest that cooking meats at a very high temperature produces nitrosamines and mutagen substances^[36,37], further studies are required to confirm this association.

Taken together, well-known and strongly-suspected risk factors of GCs did not show any statistically significant predisposition to particular histological types or tumor location. An exception was the finding that the non-eldest person was related to an increased risk of GCs in the distal and middle third of the stomach, and was associated with a decreased cancer risk in the proximal third of the stomach.

One of the explanations for the absence of difference in other risk factors was a lack of statistical power. It may be particularly so with respect to tumor location; the number of cancer cases in the upper third of the stomach in the present study may be too small to find any differences. That may also be true for the lack of difference in the risk factors for two histological-type GCs. However, another explanation may also be possible; those findings in the present study, together with the observations that *H pylori* infection is related to both intestinal- and diffuse-type GCs, may be casting a doubt on the hypothesis that intestinal- and diffuse-type GCs are distinctly different in their etiological backgrounds.

Intestinal and diffuse types of Lauren's classification correspond, in principle, to well-differentiated and poorly differentiated ones of Sugano and Nakamura^[38,39], respectively. It is of note, here however, that Lauren's classification is created by studying advanced tumors while the classification of Nakamura and Sugano is obtained from analysis of early carcinomas. Nakamura^[39] reported that 85% of micro carcinomas of the stomach (< 5 mm) were of well-differentiated type, and, conversely, the proportion of undifferentiated type was higher in larger tumors; thus such a proportion increased according to tumor size. On the basis of mucin phenotype expression of GCs, Tatematsu *et al*^[40] have postulated that GC starts as gastric-phenotype carcinomas, expressing mucin that is only expressed in gastric membranes, and during development into large carcinomas, some tumors express mucins whose expressions are specific for intestinal membranes. They pointed out a possibility of intestinal metaplasia accompanying GCs, particularly intestinal-type GCs, unrelated to GC development.

In conclusion, the present study showed that birth order, salt intake, consumptions of fruits and vegetables, the type of cooking, and cigarette smoking are related to GC risk. In histology and tumor-location specific

analyses, non-eldest person among their siblings is related to an increased GC risk in the distal and middle thirds of the stomach, and is related to a decreased GC risk in the cardia. Those findings may help understand the mechanisms of the GC development in different locations of the stomach. Further studies seem warranted.

ACKNOWLEDGMENTS

We appreciate the support for the case and control recruitment from the medical and administrative staffs of the institutions. We are indebted to Drs. Carlos A. Pelaez (Statistic Department, Hospital Universitario del Valle, Cali), Luis E. Bravo (Cancer Registry, Cali), Tito Collazos (Cancer Registry, Cali) and Jesus A. Hoyos (Internal Medicine-Endoscopy, Hospital Universitario del Valle, Cali).

Abstract

AIM: To investigate the inhibitory effect of As₂O₃ on angiogenesis of tumor and expression of vascular endothelial growth factor (VEGF) in tumor cells *in vivo* and *in vitro*.

METHODS: The solid tumor model was formed in nude mice with the gastric cancer cell line SGC-7901. The animals were randomly divided into three groups. As₂O₃ was injected into the arsenic-treated groups (2.5 mg/kg and 5 mg/kg) and the same volume of saline solution was injected into the control group. Microvessel density (MVD) and expression of VEGF were detected with immunofluorescence laser confocal technology. Further expression of VEGF protein and VEGF mRNA was measured with Western blotting and fluorescence quantitative RT-PCR in SGC-7901 cells treated with As₂O₃.

RESULTS: In nude mice, after treatment with 5 mg/kg and 2.5 mg/kg As₂O₃ respectively, about 50% and 30% tumor growth inhibition were observed correspondingly ($P < 0.05$, $P < 0.05$). Decrease in MVD appeared in As₂O₃-treated tumors compared with control group ($P < 0.001$, $P < 0.001$). MVD in tumors was significantly lower in 5 mg/kg group than in 2.5 mg/kg group ($P < 0.01$). The fluorescence intensity levels of VEGF in tumor cells were significantly lowered in the arsenic-treated groups ($P < 0.01$, $P < 0.01$). The fluorescence intensity level of VEGF in 5 mg/kg group was lower than that in 2.5 mg/kg group ($P < 0.01$). *In vitro*, the expression of VEGF

protein decreased in dose- and time-dependent manner after the treatment with As₂O₃, but in VEGF mRNA no significant difference was found between the control group and the treated groups.

CONCLUSION: As₂O₃ can inhibit solid tumor growth by inhibiting the formation of new blood vessels. One of the mechanisms is that As₂O₃ can inhibit VEGF protein expression.

INTRODUCTION

Arsenic has been used since ancient times as a therapeutic agent. However, until recently its use in modern medicine has been restricted to the treatment of a limited number of parasitic infections. Since the early 1990s, arsenic trioxide (As₂O₃) has been used successfully in the treatment of patients with relapsed and refractory acute promyelocytic leukemia (APL)^[1,2]. As₂O₃ has been shown to cause degradation of PML-RAR alpha, promoting differentiation^[3,4]. However, degradation of PML-RAR alpha may not be wholly responsible for the great sensitivity of APL cells to As₂O₃. Other investigations subsequently found that As₂O₃ can induce apoptosis of APL cells, other malignant myeloid, lymphoid, and megakaryocytic cells.

The mechanism by which arsenic exerts effect of inhibiting tumor still remains uncertain. Investigations of arsenic have found that its efficacy is dependent upon a number of mechanisms. Arsenic may affect numerous intracellular signal transduction pathways and causes many alterations in cellular function^[5-8]. Recently, it has been reported that As₂O₃ can decrease microvessel density and inhibit angiogenesis in solid tumors^[9-11], but its pathway is

not clear.

Angiogenesis is an important factor in the progression and enlargement of solid neoplasms and is in close relation to invasion and metastases^[12-14]. Angiogenesis can be divided into a series of temporally regulated responses, including protease induction, endothelial cell migration, proliferation and differentiation^[15]. This process begins with the production and release of angiogenic factors by endothelial cells, tumor cells and matrix cells. Vascular endothelial growth factor (VEGF) produced by tumor cells is a potent angiogenic factor, and it binds to endothelial cell surface receptors and activates various functions of the cells^[16-19]. Therefore, angiogenesis can be reflected by the expression of VEGF.

In the present report, we investigated the inhibitory effect of As₂O₃ on angiogenesis of tumor and expression of VEGF in tumor cells *in vivo* and *in vitro*. The solid tumor model was formed in nude mice with the gastric cancer cell line SGC-7901. Microvessel density (MVD) and expression of VEGF were detected by immunofluorescence laser confocal technology. *In vitro* we measured further expression of VEGF protein and VEGF mRNA with Western blots and real-time fluorescence quantitative RT-PCR.

MATERIALS AND METHODS

Animals and cells

Thirty 5-wk-old male BALB/C-nu/nu mice weighing 19-21 g were purchased from Shanghai Institute for Biological Sciences, Chinese Academy of Sciences, Shanghai, China. Mice were acclimatized at the Animal Laboratory Centre of the Fourth Military University for 1 wk before receiving injections of cancer cells. The mice were kept in a laminar-filtered airflow cabinet under pathogen-free conditions with a constant temperature of $22 \pm 2^\circ\text{C}$, relative humidity of $55\% \pm 5\%$ and 12-h dark/light cycles. All experiments were carried out according to the guidelines of the Laboratory Protocol of Animal Handling of the Fourth Military Medical University. Human gastric cancer cell line, SGC-7901, was purchased from the Animal Laboratory Centre of the Fourth Military Medical University. SGC-7901 cells were cultured in RPMI 1640 medium supplemented with 100 mL/L fetal bovine serum (FBS) at 37°C in a 50 mL/L CO₂ incubator.

Drug and instruments

Arsenious acid [$\text{H}_3\text{As}_2\text{O}_3$ ($\text{As}_2\text{O}_3 + 3\text{H}_2\text{O} \rightleftharpoons \text{H}_3\text{As}_2\text{O}_3$)] was supplied by Yida Pharmaceutical Co, Harbin, China. VEGF expression in tumor xenografts was examined by a TCS SP2 laser confocal microscope made by LEICA Cc, Germany. VEGF mRNA was examined by real time system ABI7000 (Applied Biosystems, Foster City, CA, USA).

Xenografts in nude mice and treatment

Thirty mice received sc injection into the right flanks with a 200 μL cell suspension containing 2×10^7 SGC-7901 cells. After 10 d, when established tumors of 0.2-0.3 cm³ diameter were detected, drug administration was started. The animals were randomly divided into three groups consisting of 10 animals in each. Arsenious acid diluted with 9 g/L saline solution was injected into the peritoneal cavity

every day to the two treatment groups (2.5 mg As₂O₃/kg and 5 mg As₂O₃/kg in 0.2 mL) and the same volume of 9 g/L saline solution was injected to the control group. After 10 d of treatment, the three groups of mice were sacrificed and the tumor masses were removed. After the weights of tumor mass were measured, the tumor mass was fixed in 40 g/L paraformaldehyde and frozen sections prepared with a cryostat (HM505E Cryomicrom, Germany) for immunofluorescence analysis. The liver and kidneys were prepared for paraffin sections routinely for pathological examination.

Inhibition of tumor growth

Tumor growth inhibition (TGI) was used to assess the therapeutic efficacy against xenografts. The tumor weight was to calculate TGI, that is, $\text{TGI} (\%) = (1 - W_t/W_c) \times 100\%$, where W_t is the mean tumor weight of the arsenic-treated group, W_c is the mean tumor weight of the control group. Tumor growth inhibition was expressed by tumor volumes that were measured before treatment and 6 and 11 d after treatment respectively. Tumor volume expressed as cm³ is calculated using the formula: tumor volume = $1/2ab$, where a is the long axis, b is the short axis. $\text{TGI} (\%) = (1 - V_t/V_c) \times 100\%$, where V_t is the mean tumor volume of the arsenic-treated group, V_c is the mean tumor volume of the control group.

Immunofluorescence examination

CD31 antigen was used as an immunofluorescence marker of vessel endothelial cells. For the immunofluorescent staining of CD31 and VEGF, the frozen sections were kept at room temperature for 30 min, incubated in distilled water for 5 min and in PBS for 5 min, permeabilized in 1 g/L Triton-X-100 for 10 min, washed with PBS (5 min \times 3), blocked with 100 mL/L sheep serum (Sgima) at 37°C for 20 min, incubated in the primary antibody, rat anti-mouse CD31 (Biologend, USA) or rabbit anti-human VEGF polyclonal antibody (Labvision, USA) at 4°C overnight, washed with PBS (5 min \times 3), incubated in the secondary antibody (goat anti-rat IgG conjugated TRITC or sheep anti-rabbit IgG conjugated FITC, Sigma) for 1h at 37°C , washed with PBS (10 min \times 3) and then examined under a TCS SP2 laser confocal microscope.

For each group, several field images of VEGF in each tumor tissue section were captured under confocal microscope, fluorescence intensity of each section in the confocal fluorescence images was measured using the Leica Confocal analysis system. The mean fluorescence intensity in each section was then calculated.

Assessment of microvessel density

Microvessel density (MVD) was determined under a confocal microscope in the area of tumor tissue sections. The microvessels were carefully counted on 20 fields ($\times 400$). The mean and SE were expressed as the number of microvessels identified within the area.

Cell culture and administration of As₂O₃ in vitro

SGC-7901 cells were routinely grown in plastic tissue culture flasks in RPMI 1640 medium with 100 mL/L FBS, 100 KU/L penicillin and 100 mg/L streptomycin and

were cultured at 37°C in a 50 mL/L CO₂ humidified atmosphere. SGC-7901 cells in logarithmic growth phase were inoculated in culture medium, without adding (control group) and adding As₂O₃ according to different concentrations of below 0.5, 1, 2 and 3 μmol/L. The tumor cells were collected respectively at 24 h, 48 h and 72 h for Western blot of VEGF. The fluorescent quantitative RT-PCR of VEGF was analyzed in the tumor cells collected at 48 h.

Western blotting for VEGF

After treatment with As₂O₃, SGC-7901 cells were washed with ice-cold PBS and dissolved with lysis buffer (1 mmol/L Na₃VO₄, 0.017 g/L aprotonin, 2 mmol/L PMSF, 25 μmol/L P-N-P, 0.1 g/L leupeptin, 10 g/L NP-40, 0.15 mol/L NaCl, 0.02 mol/L Tris HCl, 0.1 g/L NAN₃). The protein lysates were centrifuged at 12000 r/min for 10 min at 4°C. The protein lysates were mixed with 5 × sample buffer, boiled for 10 min, and analyzed by 120 g/L sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). After SDS-PAGE, the gel was transferred to a 0.45-μm pure nitrocellulose membrane. The membrane was blocked with 5 mL/L skim milk in TBS-Tween 20 for 1 h at room temperature, and reacted with mouse anti-human VEGF monoclonal antibody (Santa Cruz) at 4°C overnight. The membrane was then incubated with the secondary antibody (rabbit anti-mouse IgG). The protein content was visualized using HRP-conjugated secondary antibodies, followed by enhanced chemiluminescence (ECL).

Fluorescence quantitative RT-PCR for VEGF

RT-PCR for VEGF, total RNA was extracted from tumor cells using Trizol reagent according to the manufacturer's protocol (Promega, Madison, WI, USA). RNA was reversely transcribed to cDNA by the kit (Promega, Madison, WI, USA). Prime and probe were designed with the assistance of Primer Express 2.0. MGB-TaqMan probe of VEGF (VEGF-FAM): 5'-ACCATGCAGATTATG-3'. For VEGF, the following primers were used: 5'-GCCCACTGAGGAGTCCAACA-3', 5'TGGCCTTG-GTGAGGTTTGGAT-3'. MGB-TaqMan probe of β-actin (HBA-TAMRA-FAM): 5'CCAGGGCCGTGATGGTGG-GCAT 3'. For β-actin the following primers were used: HBA-TAMRA-FP 5'CCGTCTTCCCCTCCATCG 3' HBA-TAMRA-RP 5'GTCCCAGTTGGTGACGATGC 3'. The primers and probes were synthesized by Shanghai GeneCore BioTechnologies Co., Ltd. All PCR reactions were performed on a real time system ABI7000 (Applied Biosystems, Foster City, CA, USA). The thermal cycle conditions comprised 2 min at 50°C, 10 min at 95°C, 30 s at 95°C and 30 s at 60°C. Each PCR run included five points of calibration curve (5 samples were obtained by tenfold serially dilutions of standard product, and the standard curve was established from the 5 samples for the determination of the relative quantity of genes), a non-template control, and the respective sample cDNA.

Statistical analysis

The data were represented as mean ± SD. The data was analyzed with statistical software of SPSS10.0. Multiple statistical comparisons were performed using ANOVA in

Table 1 Tumor growth inhibition (TGI) of tumors treated with arsenic (*n* = 10, mean ± SD)

Group	Tumor volume (V) mm ³			Mass (mg)	TGI (%)	
	D 0	D6	D11		D6	D11
Control	67 ± 45	343 ± 160	999 ± 338	784 ± 185		
2.5 mg/kg	63 ± 36	307 ± 80	696 ± 125 ^a	556 ± 211 ^a	11.7%	30.3% (29.1%)
5 mg/kg	66 ± 48	240 ± 203	491 ± 116 ^{a,c}	375 ± 167 ^{a,c}	30.0%	50.9% (52.2%)

^a*P* < 0.05 vs control; ^c*P* < 0.05 vs 2.5 mg/kg; TGI calculated using tumor volume was given in parenthesis.

a multivariate linear model. Student's *t* test was used to assess differences between the treatment group and control group. *P* < 0.05 was considered statistically significant.

RESULTS

Inhibition of tumor growth by arsenic trioxide

All nude mice developed tumor after 10 d in implantation of SGC-7901 cells. When drug administration was started, there was no significant difference in the tumor volume of the three groups (*P* > 0.05). The increase in tumor volume and weight in the three groups from d 0 to 11 after treatment is shown in Table 1. Tumor volume growth of 2.5 mg/kg or 5 mg/kg of the arsenic-treated group was reduced by 30.3% or 50.9% after 10 d administration of arsenic trioxide. Tumor weight growth was inhibited by 29.1% and 52.2% respectively in the 2.5 mg/kg and 5 mg/kg arsenic-treated group. There were statistical differences in the tumor volumes and weights in the arsenic-treated group (2.5 mg/kg group and 5 mg/kg group) and control (*P* < 0.05). On the other hand, the tumor volumes and weights in the 5 mg/kg group were significantly less than that in 2.5 mg/kg group (*P* < 0.05). No obvious toxic effects attributable to As₂O₃ therapy were noted. The body weight of the mice was not affected. All of the 30 studied mice were alive at the end of treatment. HE staining of the nude mice's liver and kidney did not reveal pathological changes.

Inhibition of tumor angiogenesis by arsenic trioxide

Sections of tumors from the mice in all three treatment groups were stained for CD31 immunofluorescence to detect the number of endothelial cells (ECs) as a measure of tumor angiogenesis. A single microvessel was defined as any immunofluorescence stained endothelial cell distinguished from adjacent tumor cells and other connective tissue elements. Microvessel density as a parameter of angiogenic activity was decreased in tumors of experimental groups treated with 2.5 mg/kg (Figure 1B) and 5 mg/kg arsenic trioxide (Figure 1C). Microvessel density of arsenic-treated groups was significantly lower than that of the control group (Figure 1A). Significantly lower microvessel density was present in the 5 mg/kg group than that in the 2.5 mg/kg group. These studies demonstrated the decreased capillary density of the tumor with treatment of As₂O₃ (Table 2).

Effect of arsenic trioxide on expression of VEGF in vivo

Expression of VEGF was confirmed by the presence

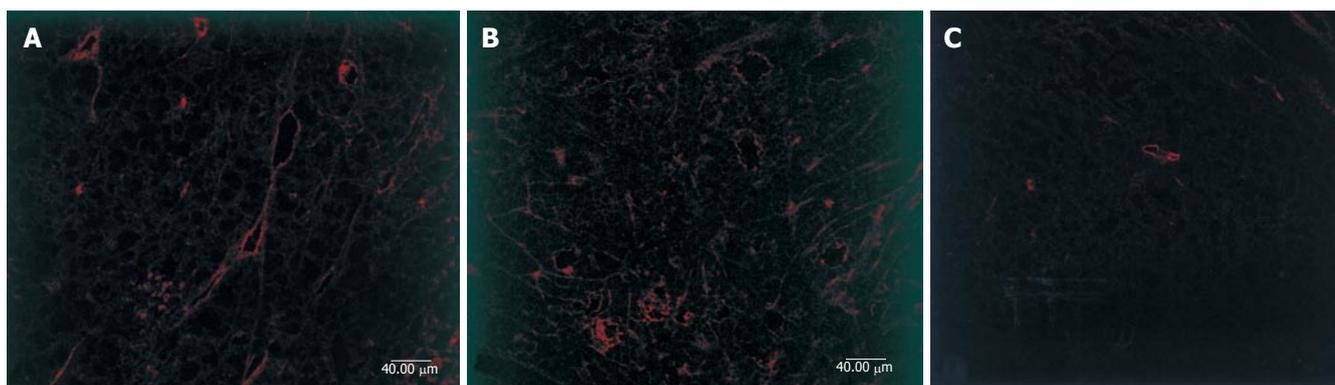

Figure 1 Immunofluorescence staining for microvessel (CD31) in xenograft tumor. Microvessel or endothelial cells were identified by fluorescence staining. Original magnification $\times 400$. A: Control group; B: 2.5 mg/kg group; C: 5 mg/kg group.

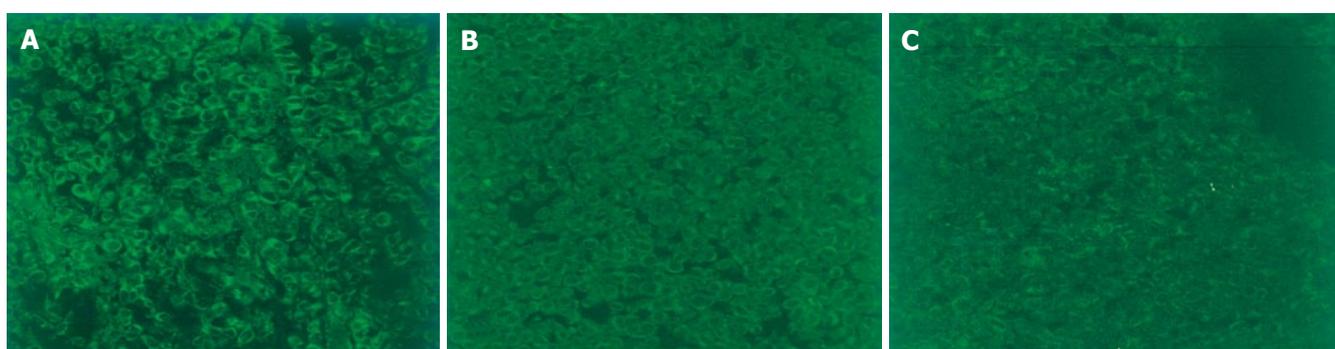

Figure 2 VEGF expression in xenograft tumor. Original magnification $\times 400$. A: Control group; B: 2.5 mg/kg group; C: 5 mg/kg group. The fluorescence expression of VEGF in tumor cells were decreased in the arsenic-treated groups.

Table 2 Effect of As_2O_3 on microvessel density and VEGF expression in tumor xenografts ($n = 10$, mean \pm SD)

Group	MVD	VEGF
Control	9.32 \pm 0.33	49.23 \pm 2.12
2.5 mg/kg	5.36 \pm 0.32 ^b	20.07 \pm 1.19 ^b
5 mg/kg	3.05 \pm 0.24 ^{b,d}	11.93 \pm 1.07 ^{b,d}
F	111.841	163.461
P	< 0.001	< 0.001

^b $P < 0.01$ vs Control; ^d $P < 0.01$: vs 2.5 mg/kg.

of fluorescence-stained cytoplasm in the tumor cells. It is shown in Figure 2, strong immunoreactivity to VEGF was found in all the SGC-7901 tumor xenografts of the control group (Figure 2A). The weaker fluorescence intensity expression was observed in SGC-7901 tumor of the groups treated with 2.5 and 5 mg/kg arsenic trioxide (Figure 2B and C). The fluorescence intensity levels of VEGF in tumor cells were significantly lower in the arsenic-treated groups than in control group ($P < 0.01$). The fluorescence intensity level of VEGF in 5mg/kg group was lower than that in 2.5 mg/kg ($P < 0.01$, Table 2).

Effect of arsenic trioxide on expression of VEGF mRNA and protein in SGC-7901 cell line *in vitro*

To further analyze the effect of arsenic trioxide on VEGF expression in tumor, we assessed VEGF expressions of

Table 3 Effect of As_2O_3 on VEGF mRNA in SGC-7901 cell by real time RT-PCR

As_2O_3 (μ mol/L)	VEGF mRNA	β -actin mRNA	VEGF mRNA/ β -actin mRNA
0	1.28 $\times 10^6$	3.72 $\times 10^7$	3.44 $\times 10^{-2}$
0.5	2.34 $\times 10^4$	7.92 $\times 10^5$	2.95 $\times 10^{-2}$
1.0	4.74 $\times 10^2$	9.96 $\times 10^3$	4.76 $\times 10^{-2}$
2.0	2.16 $\times 10^6$	7.24 $\times 10^7$	2.89 $\times 10^{-2}$
3.0	3.21 $\times 10^3$	8.2 $\times 10^4$	3.91 $\times 10^{-2}$

SGC-7901 cells *in vitro* using Western blotting and fluorescent quantitative RT-PCR. Western blot analysis revealed that the expression of VEGF protein decreased in a dose- and time-dependent manner after treatment with As_2O_3 (Figure 3). But VEGF mRNA expression was not in agreement with the VEGF protein expression results, VEGF mRNA data did not reveal a significant difference between the control group and the treatment groups (Table 3, Figures 4 and 5).

DISCUSSION

The development of a growing tumor requires an abundant blood supply. Angiogenesis is an important factor in the progression and enlargement of solid neoplasms and close relation to invasion and metastases^[12-14]. Vascularisa-

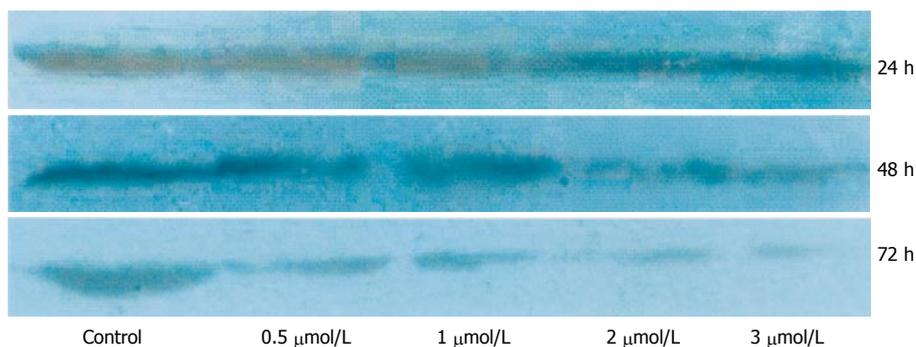

Figure 3 Effect of As_2O_3 on expression of VEGF in SGC-7901 cells by Western blots Analysis.

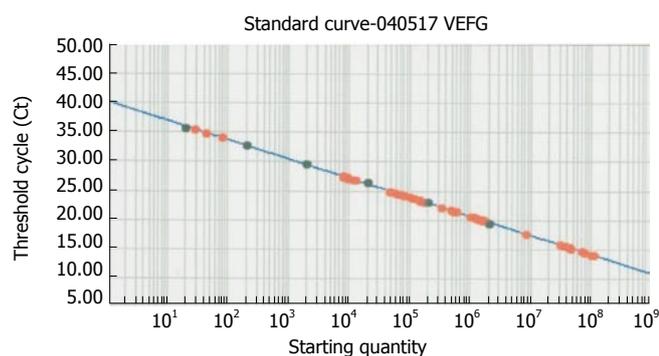

Figure 4 Standard Curve of VEGF.

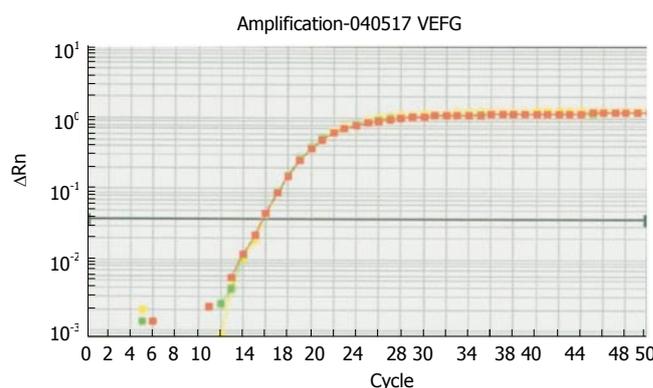

Figure 5 Amplification Curve of VEGF mRNA in SGC-7901.

tion within the primary tumor has a direct relation with the tumor growth rate. Inhibition of angiogenesis may lead to control of tumor growth and metastasis, therefore, antiangiogenesis is a promising therapeutic approach for treatment of cancer^[20-22]. The results presented here indicated that the As_2O_3 is active against angiogenesis *in vivo* and *in vitro*. We examined the effect of As_2O_3 on angiogenesis in a human tumor model in nude mice. The result showed that subcutaneous injection of SGC-7901 cells yielded a 100% tumor uptake rate. About 50% and 30% SGC-7901 tumor growth inhibition was following treatment of As_2O_3 with 5 mg/kg and 2.5 mg/kg separately.

We measured the MVD in tumor tissues by labeled CD31, which marked endothelial cells of microvessels. Decrease of the MVD in tumor tissue was related to treatment of As_2O_3 . A high degree of tumor angiogenesis was observed in mice without treatment of As_2O_3 , but MVD was low in As_2O_3 -treated tumors. There was a significant difference in MVD between the control group and treatment groups. MVD was significantly lower in the high dosage group with 5 mg/kg As_2O_3 than in the low dosage group with 2.5 mg/kg. Our observation was in agreement with the results of Shen^[9]. This study demonstrated that As_2O_3 induced a dose-dependent decrease of MVD, accompanied by inhibition of tumor growth. These suggest that induction of angiogenesis is an important step in carcinogenesis and As_2O_3 inhibits tumor growth by, at least in part, decreasing intratumor MVD.

It has been reported that neovascularization is regulated by accelerators, such as vascular endothelial growth

factor (VEGF), basic fibroblast growth factor (FGF), hepatocyte growth factor (HGF), thymidine phosphorylase, endothelin, IL-4, and IL-8, and by inhibitors such as thrombospondin, endostatin, angiostatin, transforming growth factor β 1 (TGF- β 1), tumor necrotic factor (TNF) and IL-6^[23]. Of these factors, VEGF is involved very much in the proliferation and metastasis of various cancers. There is evidence that the degree of several surrogate angiogenic markers such as microvessel density or (VEGF) expression levels in primary tumor tissue can reflect the biological aggressiveness of tumors and provide prognostic information^[18,23-25].

The VEGF gene family currently includes six members: VEGF-A (prototype VEGF), VEGF-B, VEGF-C, VEGF-D, VEGF-E and placenta growth factor. Of them, vascular VEGF, also known as vascular permeability factor, is a potent angiogenic cytokine that induces mitosis and also regulates permeability of endothelial cells. In addition, VEGF prolongs the survival of new blood vessels by inducing the expression of Bcl-2 protein. VEGF plays a crucial role in vasculogenesis and angiogenesis, and is closely related to invasion and metastases of tumors^[26,27].

Several studies reported that the degree of VEGF expression in tumors correlated positively with the level of MVD, the degree of malignancy, stage of tumor, presence/absence of peritoneal dissemination and metastases, and correlated negatively with prognosis^[12,23,28]. In the present study, high expression VEGF existed in tumor tissues without treatment of As_2O_3 which also showed an increase of MVD, suggesting that VEGF is

most closely associated with induction and maintenance of the neovasculature in human gastric cancer. Since human gastric cancer SGC-7901 cells secrete high amounts of VEGF and develop in nude mice tumors whose growth is highly VEGF-dependent, they provide a good model to test the availability of molecules that inhibit VEGF bioactivity.

In recent years, it has been widely shown that VEGF activity is a key feature during tumor growth and angiogenesis, and that blocking of this signal transduction pathway may inhibit tumor progression. *In vivo*, VEGF acts as a potent mitogenic factor for endothelial cells and as blood vessel permeabilising agents^[29]. Our *in vivo* study indicated that expression of VEGF was significantly reduced after As₂O₃ treatment, which demonstrated that As₂O₃ can inhibit VEGF expression. The formation of new blood vessels is inhibited due to suppression of tumor cell secretion of VEGF by As₂O₃.

We further explored the mechanism of the inhibitory action of As₂O₃ on VEGF in tumor cells *in vitro*. We measured expression of VEGF protein and VEGF mRNA in the SGC-7901 cell line with Western blots and real time RT-PCR separately. The results showed that As₂O₃ induced a dose- and time-dependent down-regulation of VEGF protein expression in the SGC-7901 cell line, but did not affect VEGF mRNA expression. The results reveal the effect of As₂O₃ on VEGF expression on the protein level rather than the mRNA level.

These studies have demonstrated that As₂O₃ can inhibit solid tumor growth *in vivo*, possibly by inhibiting the formation of new blood vessels. One of the mechanisms is that As₂O₃ can inhibit VEGF protein expression. These results may be useful in devising better strategies for cancer treatment.

Abstract

AIM: To evaluate the prevalence of autoantibodies in chronic hepatitis C virus (HCV)-infected children focusing on thyroid autoimmunity.

METHODS: We investigated the prevalence of autoantibodies in 123 chronic HCV-infected children before, during and after monotherapy with interferon-alpha (IFN- α) or combined treatment with interferon- α or peginterferon- α and ribavirin. Besides antibodies against smooth muscle (SMA), nuclei (ANA), and liver/kidney microsomes (LKM), the incidence of anti-thyroid peroxidase antibodies as well as thyroid function parameters (TSH, FT3 and FT4) were determined.

RESULTS: We found that 8% of children had autoantibodies before treatment. During treatment, 18% of children were found positive for at least one autoantibody; 15.5% of children developed pathologic thyroid values during IFN- α treatment compared to only one child before therapy. Six children had to be substituted while developing laboratory signs of hypothyroidism.

CONCLUSION: Our data indicate a strong correlation between interferon- α treatment and autoimmune phenomena, notably the emergence of thyroid antibodies. The fact that some children required hormone replacement underlines the need of close monitoring in particularly those who respond to therapy and have to be treated for more than 6 mo.

INTRODUCTION

Since the discovery of the hepatitis C virus (HCV) in 1989^[1], an increasing number of studies report an association of chronic HCV infection with autoimmune phenomena. In studies among adult patients, the prevalence of autoantibodies in chronic HCV-infected patients varies from 25% to 66%^[2-5]. The most commonly detected autoantibodies are anti-smooth muscle antibodies (SMA), followed by anti-nuclear antibodies (ANA), and anti-liver/kidney microsomal antibodies (LKM). The latter have been associated with ALT flares during interferon-alpha (IFN- α) administration, leading to discontinuation of treatment^[6]. The non-organ-specific autoantibodies (NOSA) ANA, SMA and LKM detected during chronic HCV infection are also found in patients with autoimmune hepatitis (AIH). A discrimination of HCV-related appearance of autoantibodies and AIH is usually possible based on the detection of viral RNA, the subtype of the examined autoantibodies, histology and response to treatment^[4,7]. In rare occasions, an overlapping clinical and histological pattern of chronic HCV and AIH is found. In these cases, a careful assessment of either an immunosuppressive or anti-viral therapeutic approach is necessary^[8].

Various studies in adult patients addressed the question of whether the presence of NOSA in chronic HCV infection influences the response to IFN- α treatment. NOSA detection correlates with significantly higher ALT levels and higher histological activity^[3,4]. The majority of studies did not observe any effects of NOSA on the final outcome of treatment^[4-6]. The limitation of most of these

studies is that they only deal with IFN- α monotherapy. A very recent study investigating the effects of NOSA in patients receiving combined treatment not only detected a significantly higher viral load and higher ALT levels, but also observed a poorer response to treatment^[2]. Besides the detection of autoantibodies, the natural course of HCV infection is accompanied by an increased prevalence of autoimmune diseases^[9,10].

One of the most common phenomena in chronic HCV infection is the appearance of autoantibodies against the thyroid^[11-15]. A significant percentage of patients with anti-thyroid antibodies develop signs of thyroid dysfunction, predominantly hypothyroidism^[12]. Several studies observed that IFN- α treatment increased the risk of thyroid dysfunction^[13-15], whereas in most cases, thyroid dysfunction is reversed after discontinuation of IFN- α treatment. A recent study by Carella *et al*^[16] observed the development of long-term thyroiditis following IFN- α therapy. It is important to note that IFN- α treatment itself is associated with autoimmune manifestations^[17]. These are not only observed in the context of HCV treatment, but also when IFN- α is used as a therapeutic agent in various oncologic diseases^[18].

The prevalences of autoantibodies and risk to develop autoimmune diseases in children and adolescents with chronic HCV have only been investigated in three pediatric cohorts^[7,19-21]. These studies have in common that they: (1) analyzed intensively the overall prevalence of autoantibodies in HCV-infected children; (2) correlated autoantibody appearance with IFN- α monotherapy; and (3) investigated the response of LKM-positive children to IFN- α treatment. However, they did not elucidate the emergence of NOSA and thyroid autoantibodies under combination treatment.

Based on our experience with children requiring thyroid hormone replacement during treatment for chronic HCV, a systematic surveillance is needed in order to avoid harmful clinical side effects.

We therefore aimed to investigate the prevalence and dynamics of the appearance of autoantibodies in our cohort of HCV-positive children that underwent IFN- α treatment with and without ribavirin, to analyze the risk of chronically HCV-infected children to develop clinical or laboratory signs of thyroid dysfunction, and to obtain follow-up data after ceasing therapy.

MATERIALS AND METHODS

Patients

We evaluated a total of 123 children with chronic HCV infection who underwent IFN- α treatment. The diagnosis of chronic hepatitis C was based on: (1) presence of abnormal alanine aminotransferase (ALT) levels; (2) detection of anti-HCV antibodies; (3) detection of HCV-RNA over a period of at least 6 mo; and (4) histological evidence of hepatitis in patients with available liver biopsy. None of the patients had serological evidence of co-infection with hepatitis B, delta hepatitis, HIV, or clinical signs of an autoimmune disease prior to treatment with IFN- α . After interferon first became available for treatment of children, 21 children were treated with

Table 1 Epidemiological, clinical, and biochemical baseline data for HCV-infected patients who underwent either IFN- α monotherapy or combined therapy with IFN- α or peginterferon- α plus ribavirin

	IFN- α (<i>n</i> = 21)	IFN- α + ribavirin (<i>n</i> = 40)	Peginterferon- α + ribavirin (<i>n</i> = 62)
Male/female (<i>n</i>)	12/9	19/21	29/33
Median age, yr (range)	9.5 (2-17)	8.1 (2-16)	10.6 (2-17)
Route of infection, <i>n</i> (%)			
Parenteral	12 (57%)	14 (35%)	28 (45.1%)
Vertical	9 (43%)	21 (52.5%)	25 (40.3%)
Unknown	-	5 (12.5%)	9 (14.6%)
Median time between diagnosis and treatment, yr (range)	2.8 (1-9)	2.5 (1-5)	Not determined
Response to treatment, <i>n</i> (%)			
Sustained	6 (29%)	24 (60%)	36 (59%)
Transient	3 (14%)	1 (2.5%)	7 (11%)
No response	12 (57%)	15 (37.5%)	19 (30%)
Median ALT level (U/L) (range)			
Before treatment	39 (13-386)	35.5 (7-90)	41.6 (11-293)
After treatment (24 mo)	35 (9-137)	22.1 (6-104)	23.1 (7-71)

IFN- α alone. Additionally, 102 chronically HCV-infected children received combined treatment of IFN- α or peginterferon- α and ribavirin^[22,23]. Forty nine percent of the children were male. The predominant route of infection for the interferon-monotherapy treatment group was parenteral (57%), whereas, for the combined treatment group, parenteral and vertical infections were almost the same (41% *vs* 45%). The age ranged between 2-17 years at the beginning of treatment with a median age of approximately 9 years. The average time between diagnosis and start of treatment was 2.5 years (Table 1).

Treatment

In addition to those mentioned above, inclusion criteria for treatment of chronic HCV infection were normal values for hemoglobin, platelets, white blood cells, bilirubin, glucose, and serum creatinine. Criteria for exclusion were underlying systemic disease, metabolic liver disorders, prior immune suppressive therapy, and severe neurologic impairment. The parents of each patient gave written consent and the University Ethics Committee approved the studies.

Children treated with IFN- α received recombinant 5 mU IFN- α -2b/m² of body surface inoculated subcutaneously (sc) 3 times weekly over a period of 12 mo. Children treated with IFN- α combined with ribavirin received the same dose of IFN- α or 1.5 μ g/kg peginterferon- α -2b once a week and 15 mg/kg ribavirin twice daily orally over 12 mo. Patients who remained HCV-RNA seropositive 6 mo after the beginning of treatment discontinued therapy. Complete sustained virologic response was defined as normalization of serum aminotransferase levels and undetectable HCV RNA during the course of treatment and persisting during the entire post-therapy follow-up.

Screening for auto-antibodies and thyroid markers

Serum samples were taken at the time of primary

Table 2 Positive¹ autoantibodies in the two treatment groups before, during and 12 mo after treatment

Group	n	Before treatment			During treatment			After treatment

¹Antibody titer was considered positive at values $\geq 1:40$; ²Liver kidney microsomal antibody; ³Anti-smooth muscle antibody; ⁴Antinuclear antibody.

diagnosis, before, during and after treatment. During treatment, samples were taken at 3 mo intervals. Antinuclear antibodies (ANA), anti-smooth-muscle antibodies (SMA), and antibodies against liver/kidney microsomes (LKM) were assessed by indirect immunofluorescence (IFL) on cryostat sections of rat liver and kidney specimens. ANA-positive samples were subsequently tested by IFL on Hep-2 cells. Antibody titers $\geq 1:40$ were considered positive. Along with testing auto-antibodies, thyroid function was evaluated by measuring the serum levels of free triiodothyronine (FT3; normal values: 1.8-4.6 ng/L), free thyroxine (FT4; normal values: 0.9-1.7 ng/dL) and thyroid-stimulating hormone (TSH; normal values: 0.3-4.2 mU/L). The sera were analyzed on site using commercially available kits. Furthermore, we determined anti-thyroglobulin antibody (TGA; normal values < 50 U/L) and anti-thyroid peroxidase antibodies (TPO; normal values: < 35 IU/mL) in the samples.

Statistical analysis

Results were analyzed using the SigmaStat 3.0 statistics program (Jandel Scientific, San Raael, CA). When comparing more than two groups, a one-way ANOVA was performed, followed by a Dunn's test to determine which groups differed significantly. $P < 0.05$ was considered statistically significant.

RESULTS

Duration of treatment

Of the 21 children treated with IFN- α -2b monotherapy, 12 (57%) remained HCV-RNA-positive and therefore discontinued after 6 mo, 3 patients showed a transient response with reappearance of viral RNA, and 6 (29%) children had a sustained response. Thus, 9 individuals were treated for 12 mo (Table 1). Forty children were enrolled in the second study that consisted of a combination treatment with IFN- α and ribavirin^[22]. Fifty seven percent of the treated children and adolescents displayed a transient or sustained virologic response and were treated for 12 mo. With introduction of peginterferon- α into the combined treatment group, the percentage of children with sustained response remained at a similar level. A total of 39 (63%) individuals were treated for 12 mo^[23].

Prevalence of non-organ specific autoantibodies

A total of 39 children had a complete record of their autoantibody status (Table 2). Before treatment, 3 of the 39 (8%) were positive for autoantibodies. One child was

positive for LKM and two children were positive for SMA. All measured antibody titers were in a low range between 1:40 and 1:80. None of the children had any apparent signs of autoimmune disease. The child found positive for LKM antibodies had slightly elevated ALT levels (56 U/L) and was closely monitored.

Autoantibodies and interferon treatment

During interferon treatment, there was a significantly higher number of autoantibody-positive children. Altogether, 7 of 39 (18%) children were positive for either LKM, SMA, or ANA. In all cases, the patients were positive for only one of the autoantibodies tested. The antibody titers were higher than that measured before treatment (maximum = 1:320). None of the children had any clinical signs of autoimmune disease, which would cause interferon treatment to be discontinued. Both children, who were LKM-positive, displayed stable ALT levels during treatment. When correlating ALT levels and autoantibody prevalence, we found slightly higher ALT values in autoantibody-positive children (average ALT level 54.5 U/L *vs* 40.9 U/L). Autoantibody prevalence did not correlate with treatment outcome.

Influence of interferon on thyroid function

None of the children with chronic HCV prior to treatment had clinical signs of thyroid dysfunction. Except for two children, all had normal values for TGA, TPO, TSH, FT3, and FT4 (Table 3). In the case of one child, TSH was slightly elevated (5.45 mU/L) without any apparent clinical sign or laboratory value of thyroid dysfunction. The other child had borderline thyroid antibody levels, with an otherwise normal laboratory and clinical evaluation. During treatment, 19 (15.5%) children had at least one pathologic thyroid parameter. When these children were further analyzed, significant increases in serum TPO and TSH levels were observed (Table 4). Of the 14 children that became positive for TPO antibodies, 12 also displayed increased serum TSH values. The increase in TSH was accompanied by a 50% decrease in serum FT3 and a slight decrease in FT4. Because of pathologic thyroid values, 6 children received a weight-adjusted dose of L-thyroxin until completion of treatment. The substitution could be discontinued in 4 cases during the follow-up period. Two children required hormone supplementation 12 mo after the cessation of the ribavirin/IFN- α treatment. Despite significant increases in pathologic thyroid values, the interferon-treated children did not reveal any clinical signs of hypo- or hyperthyroidism upon physical examination.

Table 4 Overview of the thyroid function and auto-antibody titers of the 12 children who developed pathologic values during the course of IFN- α treatment Median (range)

Treatment	TGA ¹	TPOAb ²	TSH ³	FT3 ⁴	FT4 ⁵
Before	29.0 (9.4-53.0)	3.2 (0-41.0)	2.7 (1.0-5.5)	3.15 (2.1-5.3)	1.2 (1.1-1.3)
During	100.0 (8.0-141.0)	82.5 ^a (4-3 909)	7.3 ^a (1.7-76.0)	2.12 (1.1-4.3)	1 (0.4-1.3)
After	40.0 (13-163.0)	4.5 (0-289.0)	2.2 (0.9-4.2)	4.0 (2.0-5.3)	1.1 (1.0-1.3)

^a $P < 0.05$ vs before and after treatment. ¹Thyroglobulin antibody (normal range < 50 U/L); ²Thyroid peroxidase antibody (normal range < 35 IU/mL); ³Thyroid-stimulating hormone (normal range 0.3-4.2 mU/L); ⁴Free triiodothyronine (normal range 1.8-4.6 ng/L); ⁵Free thyroxine (normal range 7-19 ng/L).

Comparing the two treatment groups, there were more patients with TPO antibodies in the interferon monotherapy group (23%) than in the combined treatment group (9%). This difference was also apparent, but not as prominent, with regards to pathologic TSH values, which were 14% in the monotherapy group *versus* 10% in the group that underwent combined treatment. Notably, the prevalence of thyroid antibodies increased over the treatment period, particularly in the second half. While only 4.9% of children were positive after 3 mo, 12.8% were positive after 9 mo of medication.

DISCUSSION

In this study, we investigated the prevalence of autoimmune phenomena in chronic HCV-infected children treated in Germany. As we reported recently, over 50% of children and adolescents treated with IFN- α plus ribavirin displayed a sustained virologic response^[22,23]. In the present study, we also incorporated HCV-positive children treated solely with IFN- α before the implementation of combination therapy. Concordant with other reports, these children had a sustained response in 29% of all cases^[24]. Of the 39 children with complete autoantibody evaluation, 3 (2 ANA/1 LKM) were positive for autoantibodies before treatment. The overall prevalence of non-organ-specific autoantibodies (8%) was significantly lower than that found in the three published pediatric cohorts (32.5%-65%)^[7,19,21]. Surprisingly, none of our children was SMA-positive before IFN- α treatment, compared to 17%-67% of the children in the aforementioned studies^[7,19,21]. The number of autoantibody-positive children increased to 23% during treatment, which is still significantly lower than previously reported, then dropped to an approximate 10% after treatment completion. In contrast to the other pediatric cohorts, the two patients that were LKM-positive did not

develop any significant ALT flare during IFN- α treatment.

Two possible factors might explain the differences observed in autoantibody prevalence: (1) the methodology used and cut-off for positive results, and (2) geographic differences and, therefore, differences in genetic predisposition. Interestingly, all the published pediatric cohorts came from various regions in Italy; the majority of the patients in our cohort were from Germany or Eastern Europe. It is well known that autoimmune diseases are influenced by genetic background and HLA type^[25-27]. We compared liver enzyme levels in the sera of autoantibody-positive and -negative children. Average ALT levels were higher in the autoantibody-positive group, though the difference was not statistically significant. This finding correlates with similar observations in pediatric and adult cohorts^[4,7]. As in the majority of adult studies, we could not detect any connection between autoantibody appearance and treatment outcome^[4-6]. A very recent study in adults observed a better response in autoantibody-negative patients treated with IFN- α plus ribavirin^[2]. We did not observe a similar tendency in children that received combined treatment.

To the best of our knowledge, this is the first pediatric study that investigates the correlation between chronic HCV infection and thyroid dysfunction. Before initiation of treatment, all children were euthyroid and only one child had low levels of TPO antibodies. This finding differs significantly from most adult studies, which report 4.8%-21% TPO autoantibody prevalence in their patient cohorts and up to 13% of patients with thyroid dysfunction^[11,12,15]. A very recent publication by Mandac *et al*^[28] emphasizes again the clinical significance of thyroiditis in patients receiving interferon therapy and suggests the classification as autoimmune type and non-autoimmune type. During the course of IFN- α treatment, 11% of the children became positive for antibody

specific for TPO. The prevalence of TPO antibody was accompanied by a significant increase in TSH levels and a decrease in FT3 values. Six children became hypothyroid and had to be treated. The risk of developing signs of thyroid dysfunction became particularly prominent during the 2nd half of the treatment period. Overall, the number of HCV-infected children with thyroid dysfunction was significantly lower and strongly associated to IFN- α treatment, which is in contrast to adult studies that reported a high prevalence of thyroid dysfunctions even before IFN- α treatment.

In summary, we found a lower prevalence of non-organ-specific, as well as thyroid-specific autoantibodies than reported in related pediatric and adult cohorts. The prevalence of NOSA and thyroid antibodies strongly correlated with IFN- α treatment; six children developed signs of hypothyroidism. Since serum thyroid antibodies and TSH levels increased significantly in the second 6-mo treatment period, some individuals may require thyroid hormone substitution. It must be emphasized that close monitoring of thyroid function is mandatory, especially in children who respond to therapy and have to be treated for more than 6 mo.

Abstract

AIM: To examine human β -defensin-3 (hBD-3) expression in inflamed gastric mucosal tissues or MKN45 gastric cancer cells with or without *H pylori* infection for better understanding the innate immune response to *H pylori*.

METHODS: We used reverse transcription-polymerase chain reactions and immunohistochemistry to examine hBD-3 expression in inflamed gastric mucosal tissues or MKN45 gastric cancer cells with or without *H pylori*. Effects of hBD-3 against *H pylori* were also evaluated.

RESULTS: The mean mRNA expression of hBD-3 in *H pylori*-positive specimens was significantly higher than that in *H pylori*-negative specimens ($P = 0.0002$, Mann-Whitney). In addition, unlike uninfected samples, 8 of 15 (53.33%) infected mucosal samples expressed hBD-3 protein. *H pylori* dose-dependently induced mRNA expression of hBD-3 in MKN45 cells, an effect inhibited by adding anti-toll-like receptor (TLR)-4 antibody. hBD-3 protein completely inhibited *H pylori* growth.

CONCLUSION: Our results suggest that like hBD-2, hBD-3 may be involved in the pathophysiology of *H pylori*-induced gastritis.

INTRODUCTION

Defensins are antimicrobial peptide components of the innate immune system. Three subfamilies, α -defensins, β -defensins, and θ -defensins, distinguished according to structural features at the gene and protein levels, have been identified in vertebrates^[1-3]. Four human β -defensins (hBD) have recently been characterized in various human epithelial cells. hBD-1 mRNA is expressed constitutively in various epithelial tissues^[1-2]. hBD-2 mRNA expression has been detected in epithelial cells of skin, lung, trachea, and urogenital tract; expression can be induced by treatment with tumor necrosis factor (TNF)- α or interleukin (IL)-1, or by exposure to microorganisms^[1-9]. Both hBD-1 and hBD-2 show antimicrobial activity, predominantly against Gram-negative bacteria. In skin, tonsil, and trachea, hBD-3 mRNA expression can be induced in epithelial cells by treatment with TNF- α or contact with *Pseudomonas aeruginosa*^[9]. hBD-3 protein shows antimicrobial activity against both Gram-negative and Gram-positive bacteria^[9]. Intense hBD-4 mRNA expression has been found in testis and gastric antrum, with lower, presumably constitutive, expression observed in uterus, thyroid gland, lung, kidney, and neutrophils^[10]. hBD-4 mRNA expression can be induced by treatment with phorbol 12-myristate 13-acetate (PMA) or contact with *P. aeruginosa* or *Streptococcus pneumoniae* in SAEC 6043 small airway epithelial cells, but not by IL-1, IL-6, interferon (IFN)- γ , or TNF- α . hBD-4 shows antimicrobial activity against both Gram-negative and Gram-positive bacteria^[10]. However, isolation of natural hBD-4 has not yet been reported.

Recently, induction of hBD-2 mRNA expression by *H pylori* has been shown in human gastric cancer cell lines (MKN 45 and AGS)^[4-8]. Gastric colonization by *H pylori*, which is Gram negative, is pathogenetically important in gastritis, peptic ulcer, gastric cancer, and gastric mucosa-associated lymphoid tissue lymphoma. However, hBD-3 mRNA expression in gastric mucosal tissues has not been fully characterized^[1].

To better understand the innate immune response to *H pylori*, we determined hBD-3 expression in various gastric mucosal tissues with or without *H pylori* infection using a semiquantitative TaqMan reverse transcription-

polymerase chain reaction (RT-PCR) assay as well as immunohistochemistry. Additionally, the antimicrobial effect of hBD-3 against *H pylori* was evaluated.

MATERIALS AND METHODS

Bacterial strain and antibodies

H pylori (ATCC49504) was used for hBD-2 mRNA and hBD-3 mRNA induction. Anti-toll-like receptor (TLR)-4 antibody (Clone: HTA125) and non-immune subclass-matched antibody (IgG_{2a}) were purchased from BD Biosciences Pharmingen. Polyclonal goat antibodies against hBD-2 and hBD-3 were purchased from Santa Cruz Biotechnology.

HBD-2 mRNA and hBD-3 mRNA induction in MKN45 gastric cancer cells

MKN-45 gastric cancer cells were cultured in RPMI 1640 medium (Bio Whittaker) supplemented with heat-inactivated fetal bovine serum (FBS) (JRH BIOSCIENCES) at 37°C in an humidified atmosphere containing 50 mL/L CO₂. Induction of hBD-2 mRNA and hBD-3 mRNA was carried out as described previously^[7,8]. Briefly, 10⁶ MKN45 cells were seeded into dishes 60 mm in diameter and incubated for 12 h. Culture medium was replaced with 2 mL of fresh RPMI 1640 medium without FBS. Bacterial suspensions (100 µL; 0 to 10⁹ CFU/mL in RPMI 1640 medium) were added to the dishes, and incubation was continued for various time periods.

Tissue samples

Samples of non-cancerous mucosa with or without chronic gastritis were obtained from 25 patients with previously untreated gastric cancer following surgery at Sapporo Medical University Hospital. Informed consent was obtained from all patients. After tissue removal, all samples were immediately frozen and fixed in 100 mL/L formalin.

Determination of *H pylori* infection

Sections were Giemsa-stained, and the rapid urease test (CLO test, Tri-Med Specialties Inc) was performed with fresh samples taken from the prepyloric antrum, greater curvature of the corpus, and fundus^[12]. *H pylori* infection was defined as positive when *H pylori* was detected and/or the CLO test was positive.

Quantitative RT-PCR assays for hBD-2 mRNA and hBD-3 mRNA

ISOGEN (Nippon Gene) was used to extract total RNA from cells or tissues, and this extract was assayed for RNA with the GeneQuant DNA/RNA calculator (Amersham Pharmacia Biotech). For quantitative RT-PCR, fluorescent hybridization probes, TaqMan PCR Core Reagents kit with AmpliTaq Gold (Perkin-Elmer Applied Biosystems) were used with the ABI Prism 7700 Sequence Detection System (Perkin-Elmer Applied Biosystems). Expression of hBD mRNA was quantified as previously described^[8,13]. Primers and TaqMan probe for hBD-2 mRNA were

as follows: 5'-TGGTGGTATAGGCGATCCTGTT-3' (forward) and 5'-GGAGACCACAGGTGCCAATTT-3' (reverse); 5'-CCATATGTCATCCAGTTCTT-3' (TaqMan probe). Primers and TaqMan probe for hBD-3 mRNA were as follows. 5'-AGTGACCAAGCACACCTTTTCA-3' (forward) and 5'-CCAAAAACAGGAAGAGCAAAGC-3' (reverse); 5'-TATGAGGATCCATTATCTTCTGTT-3' (TaqMan probe). Aliquots of 25 ng of total RNA from samples was used for one-step RT-PCR. Conditions of one-step RT-PCR were as follows: 30 min at 48°C (stage 1, reverse transcription), 10 min at 95°C (stage 2, RT inactivation and AmpliTaq Gold activation), and then 40 cycles of amplification for 15 s at 95°C and 1 min at 60°C (stage 3, PCR). Data were normalized as the ratio of hBD-2 optical densities relative to glyceraldehyde-3-phosphate dehydrogenase (GAPDH) and were represented as arbitrary units.

Immunostaining

Formalin-fixed, paraffin-embedded tissue sections were stained with polyclonal goat antibodies against hBD-2, hBD-3 or non-immune goat serum using an indirect immunoperoxidase technique.

Antimicrobial assay

To evaluate the antimicrobial effects of hBD-2 and hBD-3 on *H pylori*, 25 µL of 4 × 10⁶ CFU/mL *H pylori* strain (ATCC49504) was cultured on HP agar (Eikenkagaku) after a 1-h pre-incubation at 37°C in the presence or absence of hBD-2 protein and hBD-3 protein (Peptide Institute). To determine the CFU number, the pre-incubation mixture was immediately diluted 100-fold with culture medium, and samples were cultured in triplicate. Viable cells (CFU/mL) were counted after 3 d in culture at 37°C.

RESULTS

Induction of hBD-2 mRNA and hBD-3 mRNA expression in MKN45 cells and various gastric mucosal tissue specimens

To clarify the effects of *H pylori* on hBD-2 mRNA and hBD-3 mRNA expression, according to TaqMan RT-PCR, MKN45 cells first were incubated for 0 to 72 h with *H pylori*. hBD-2 mRNA and hBD-3 mRNA expression was detected in MKN45 cells 12 h after initiating incubation with *H pylori*, and then increased gradually (Figure 1).

To determine a suitable number of *H pylori* bacteria for induction of hBD-2 mRNA and hBD-3 mRNA expression, 100 µL of 0 to 10⁹ CFU/mL *H pylori* was incubated with MKN45 cells for 48 h, representing multiple inoculum sizes. hBD-2 mRNA and hBD-3 mRNA expression was up-regulated in a manner dependent on bacterial number (Figure 2), an effect first detectable at 10⁷ CFU/mL.

To evaluate the effect of *H pylori* colonization in gastric tissues on hBD-2 and hBD-3 expression, mucosal samples showing gastritis from 15 *H pylori*-positive and 10 *H pylori*-negative patients were assessed by TaqMan RT-PCR

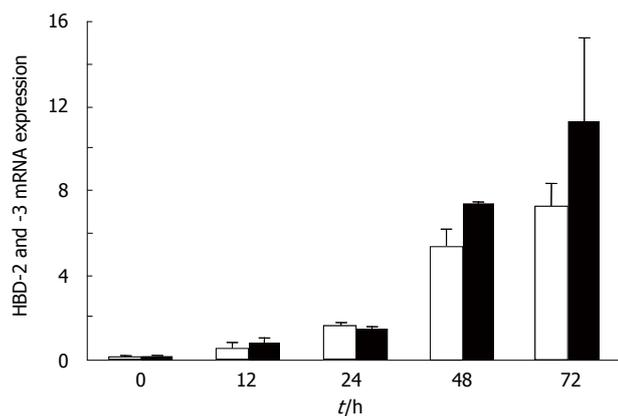

Figure 1 Time course of human β -defensin mRNA expression induced by *H pylori* in a gastric cancer cell line MKN45. MKN45 cells (10^5) were seeded into dishes 60 mm in diameter and incubated for 12 h. Culture medium was replaced with 2 mL of fresh RPMI 1640 medium without FBS. The cells were incubated for 0 to 72 h with 100 μ L of 10^3 CFU/mL *H pylori*. Human β -defensin mRNA expression was measured using TaqMan RT-PCR assay. hBD-2 (\square), hBD-3 (\blacksquare).

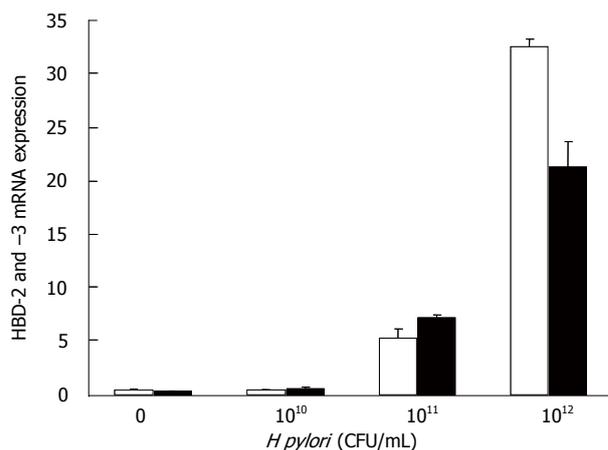

Figure 2 Induction of human β -defensin mRNA expression by various numbers of *H pylori*. MKN45 cells (10^5) were seeded into dishes 60 mm in diameter and incubated for 12 h. Culture medium was replaced with 2 mL of fresh RPMI 1640 medium without FBS. Bacterial suspensions (100 μ L; 0 to 10^9 CFU/mL in RPMI 1640 medium) were added to the dishes, and incubation was continued for 48 h. Human β -defensin mRNA expression was measured using TaqMan RT-PCR assay. hBD-2 (\square), hBD-3 (\blacksquare).

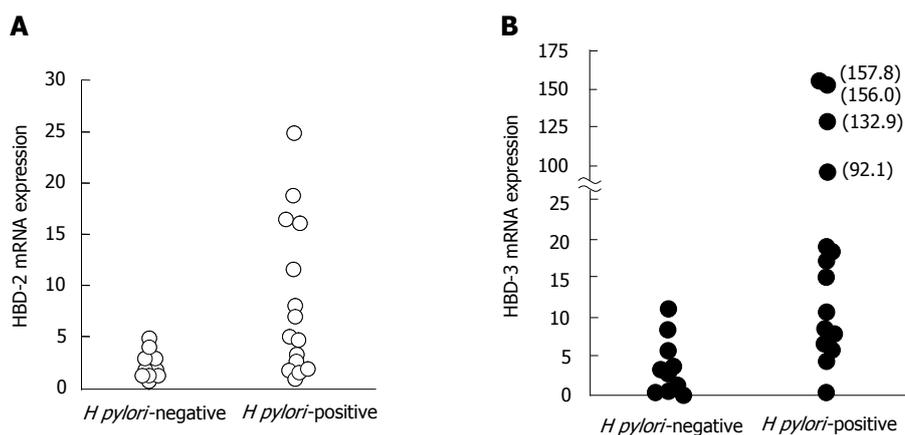

Figure 3 Human β -defensin mRNA expressions in gastric mucosal tissues from 15 *H pylori*-positive patients (\circ) and 10 *H pylori*-negative patients (\bullet). Human β -defensin mRNA expression was measured using TaqMan RT-PCR assay. A: hBD-2; B: hBD-3.

analysis and immunostaining. Mean mRNA expression of hBD-2 (8.5) and hBD-3 (45.0) in *H pylori*-positive specimens was significantly higher than that in hBD-2 (1.6) and hBD-3 (3.9) in *H pylori*-negative specimens, respectively (Figure 3A and B; $P = 0.002$, Mann-Whitney). However, levels of hBD-3 mRNA expression did not correlate with those of hBD-2 mRNA expression in *H pylori*-positive specimens. In addition, 7 and 8 of 15 *H pylori*-positive patients with gastritis showed hBD-2 and hBD-3 protein expression in their mucosa, respectively, while none of the *H pylori*-negative patients showed hBD-2 and hBD-3 protein expression (Figure 4A-D).

Inhibition of induction of hBD-2 mRNA and hBD-3 mRNA expression in MKN45 cells by treatment with anti-TLR-4 antibody

To determine whether hBD-2 and hBD-3 mRNA expression in MKN45 cells was induced via TLR-4, MKN45 cells were incubated for 40 h with 100 μ L of 10^9 CFU/mL of *H pylori* in the presence or absence of anti-TLR-4 antibody (100 μ g/mL) and control antibody

(100 μ g/mL). Expression of hBD-2 and hBD-3 mRNA in *H pylori*-exposed MKN45 cells treated with anti-TLR-4 antibody was reduced to 55.7% and 64.1% of the expression in untreated MKN45 cells, respectively.

Antimicrobial effects of hBD-2 and hBD-3 against H pylori

To evaluate the antimicrobial effects of hBD-2 and hBD-3 on *H pylori*, *H pylori* was cultured on HP agar for 4 d after a 1-h pre-incubation in the presence or absence of chemically synthesized hBD-2 and hBD-3. At concentrations of 50 μ g/mL or more, hBD-2 and hBD-3 inhibited growth of *H pylori* (Figure 5A and B).

DISCUSSION

Using TaqMan RT-PCR for hBD-3 mRNA and immunostaining for hBD-3 protein, we demonstrated, probably for the first time, that like hBD-2, hBD-3 is frequently expressed in gastric mucosa with *H pylori* infection showing gastritis, but not in inflamed mucosa without *H pylori* infection. The amount of hBD-3 mRNA

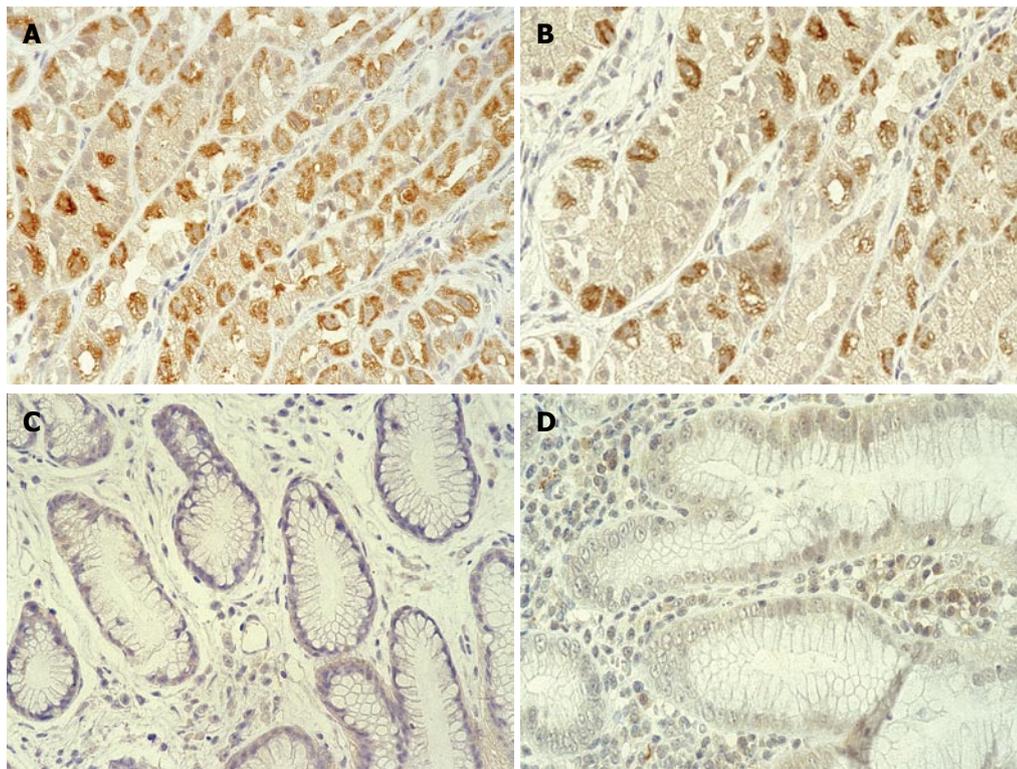

Figure 4 Human β -defensin protein expressions in gastric mucosal tissues with or without *H. pylori* infection. Tissues were stained with anti-hBD-2 antibody (A and C) or hBD-3 antibody (B and D). Case 1: A and B, gastric mucosa with *H. pylori*-associated gastritis. Immunostaining was observed in gastric cancer cells in A and gastric epithelial cells in B. Case 2: C and D, gastric mucosa with gastritis but without *H. pylori* infection. No staining was observed in C and D.

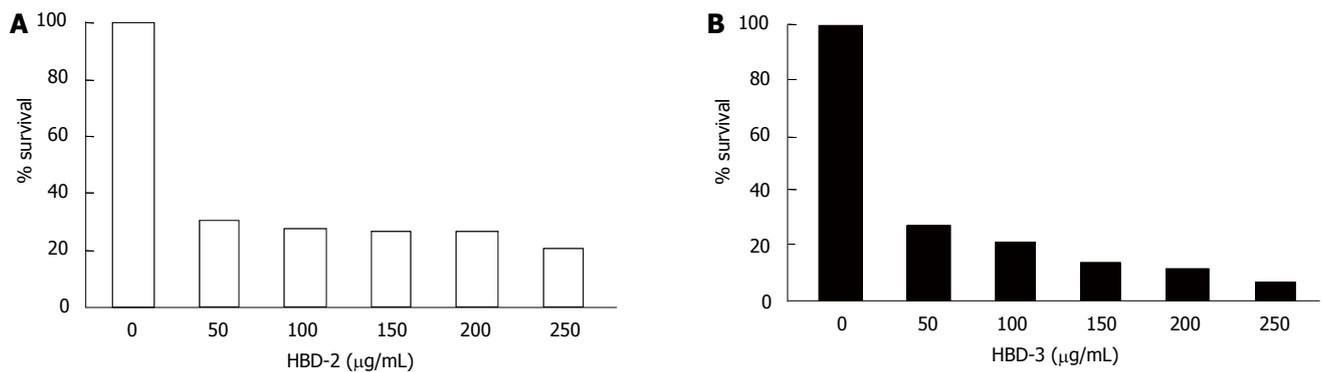

Figure 5 Antimicrobial effects of human β -defensin protein on *H. pylori* (ATCC49504). *H. pylori* were cultured on HP agar for 4 d after a 1-h pre-incubation in the presence or absence of hBD-2 (A) and hBD-3 (B).

expression in *H. pylori*-positive specimens was 11.5 times higher than in *H. pylori*-negative specimens. In addition, hBD-3 was induced by contact of MKN45 cells with *H. pylori*. Recent reports indicated that hBD-3 mRNA expression was induced in primary cultures of tracheal epithelial cells by pro-inflammatory cytokines, such as TNF- α , and in the MKN7 gastric cancer cell line by contact with *H. pylori*. Considered together with recent reports, our results implied that contact of gastric epithelial cells with *H. pylori* as well as amounts of pro-inflammatory cytokines are important for induction of hBD-3 mRNA expression.

At 10^{-5} mol/L, chemically synthesized hBD-2 (30 μ g/mL) was reported to completely inhibit growth of *H. pylori*, while recombinant hBD-3 began to inhibit growth of *H. pylori* at a concentration of 10^{-7} mol/L^[5,11]. In the present study, we demonstrated that synthesized hBD-3 as well as hBD-2 inhibited *H. pylori* growth at concentrations of 50

μ g/mL or more.

Isomoto *et al*^[14] detected activated nuclear factor (NF)- κ B in epithelial cells in gastric mucosa from patients with *H. pylori*-associated gastritis. Diamond *et al*^[15] reported that expression of hBD-3 was regulated by NF- κ B-independent mechanisms, that remain to be characterized. Su *et al*^[16] reported that *H. pylori* up-regulated TLR-4 expression in two gastric cancer cell lines (AGS and MKN45). These reports suggest that *H. pylori* may induce hBD-3 mRNA expression via direct or indirect activation of NF- κ B or other mechanisms. Pathogen-associated molecular patterns in *H. pylori* and pattern recognition receptors in gastric epithelial cells will require further study. In the present investigation, anti-TLR-4 antibody inhibited, but not completely, the expression of hBD-3 mRNA in MKN45 cells induced by contact with *H. pylori*. This suggests that not only *H. pylori* binding to TLR-4, but also other mechanisms may exist for the induction

of hBD-3 mRNA in gastric epithelial cells by *H pylori* infection. In addition, in the present study, levels of hBD-3 mRNA expression did not correlate with those of hBD-2 mRNA expression in *H pylori*-positive specimens. This also suggests that the expression of hBD-3 and hBD-2 mRNA in gastric epithelial cells is likely to be regulated differently.

In conclusion, expression of hBD-3 increases in response to *H pylori* infection with a bacterial effect. Further study is needed to detect the role and regulating mechanism of hBD-3.

Abstract

AIM: To study the effect of bromophenacyl bromide (BPB), a phospholipase A₂ inhibitor on gastric secretion and to protect chemically induced gastric and duodenal ulcers in rats.

METHODS: Acid secretion studies were undertaken in pylorus-ligated rats with BPB treatment (0, 5, 15 and 45 mg/kg). Gastric and duodenal lesions in the rats were induced by ethanol and cysteamine respectively. The levels of gastric wall mucus, nonprotein sulfhydryls (NP-SH) and myeloperoxidase (MPO) were also measured in the glandular stomach of rats following ethanol induced gastric lesions.

RESULTS: BPB produced a dose-dependent inhibition of gastric acid secretion and acidity in rats. Pretreatment with BPB significantly attenuated the formation of ethanol induced gastric lesion. BPB also protected intestinal mucosa against cysteamine-induced duodenal ulcers. The antiulcer activity of BPB was associated with significant inhibition of ethanol-induced depletion of gastric wall mucus, NP-SH and MPO. These findings pointed towards the mediation of sulfhydryls in BPB induced gastrointestinal cytoprotection.

CONCLUSION: BPB possesses significant antiulcer and cytoprotective activity against experimentally induced gastroduodenal lesions.

INTRODUCTION

Phospholipids play an important role in the preservation of gastrointestinal homeostasis^[1]. The gastric mucosa has a hydrophobic lining which is assumed to have protective functions against luminal acid as well as intrinsic and extrinsic corrosive agents^[2,3]. The hydrophobicity of the mucosal lining is attributed to a surfactant like phospholipid monolayer adsorbed to the mucosal surface which acts as a mucosal barrier and impedes back-diffusion of luminal H⁺ into the mucosal tissue and defends gastric mucosa against damage induced by strong acids^[4] and other barrier breaking agents^[5,6]. Altered phospholipids profile of gastric mucosa has been noticed in clinical gastropathies including *H. pylori* induced gastritis and peptic ulcers^[7,8]. Injury of the intestinal surface layer leads to an inflammatory reaction that is characterized by a variety of inflammatory mediators, activation of complement cascade system and of lipid mediator synthesis^[9]. In addition, damage of the gastrointestinal surface protection system and the breakdown of complex membrane lipids activate phospholipase A₂ (PLA₂), a key enzyme in the production of inflammatory lipid mediators^[7]. High concentrations of PLA₂ have been reported in gastric mucosa^[10,11]. PLA₂ mediated hydrolysis of membrane lipids results in membrane perturbation, cell degranulation and stripping of cell surface receptors^[10,12]. Intracellular PLA₂ plays an important role in inflammation by acting upon the cell membrane to release arachidonic acid from membrane phospholipids for the synthesis of eicosanoids, lypophospholipids and platelet activating factor^[13,14]. Arachidonic acid serves as a primary substrate for eicosanoid production yielding prostaglandins, leukotrienes and lipoxins; all of them have multiple vasoactive and cellular regulatory functions^[11,12]. There is abundant evidence suggesting the role of mucosal microcirculatory disturbances in experimental gastrointestinal damage^[15-17].

Exposure of gastric mucosa to necrotizing agents results in edema, vacuolization and necrosis of the luminal epithelial cells; these lesions morphologically resemble those caused by ischemic-reperfusion injury in the intestine^[18]. The ischemia is known to deplete tissue adenosine triphosphate (ATP) and significantly increase its metabolic product hypoxanthine, which in the presence of xanthine oxidase results in the production of xanthine and highly reactive superoxide radicals^[19]. Ischemic insult to intestinal mucosa causes excessive production of oxygen derived free radicals (ODFR) that may initiate a chain of reactions in membrane-bound lipids leading to lipid peroxidation and PLA₂ activation^[20,21]. Inhibition of this cascade by scavenging ODFR and/or inhibiting PLA₂ could be an effective tool to protect gastrointestinal mucosa against chemically induced lesions. Earlier studies have shown the protective effects of quinacrine, a PLA₂ inhibitor, against ischemia and injury of various organs including heart^[22], stomach^[23], intestine^[20] and lungs^[24]. Bromophenacyl bromide (BPB) is a PLA₂ inhibitor which is structurally different from quinacrine and inhibits PLA₂ by covalently binding to its active site rather than affecting the enzyme-substrate interface (mode of quinacrine-induced PLA₂ inhibition). The present investigation was aimed to study the effect of BPB on chemically induced gastroduodenal ulcers in rats.

MATERIALS AND METHODS

Animals and dosing

Albino Wistar rats of either sex, approximately of the same age, weighing 150 to 200 g and fed on standard chow diet were used. They were randomly divided into experimental groups of 6 rats each. The aqueous solutions of ulcerogens and BPB were freshly prepared before administration. BPB at doses of 5, 15 and 45 mg/kg was given intraperitoneally for gastric secretion studies and by gavage for antiulcer studies. The rats were sacrificed, and the stomachs removed and opened along the greater curvature. After washing with saline the gastric lesions were quantified by a person unaware of the treatments. The protocol of animal studies was approved by the Research and Ethics Committee of Armed Forces Hospital, Riyadh, Saudi Arabia.

Pylorus ligated rats

The rats were fasted for 36 h with access to water *ad libitum* before the pylorus was ligated under ether anesthesia, care being taken not to cause bleeding or to occlude blood vessels^[25]. BPB was administered immediately after pylorus ligation (Shay) by ip route. The rats were sacrificed at 6 h after the pylorus ligation. The stomachs were removed; the contents were collected, volumes measured, centrifuged and analyzed for titratable acidity against 0.01 mol/L NaOH to pH 7 and the total acid output was calculated.

Cysteamine-induced duodenal ulcers

Duodenal ulcers were induced by two doses of cysteamine hydrochloride (400 mg/kg ig in 10% aqueous solution) at an interval of 4 h according to the method described by

Szabo^[26]. BPB was administered 30 min before each dose of cysteamine. All the rats were sacrificed 24 h after the first dose of cysteamine and the duodenum was excised carefully and opened along the antimesenteric side. The duodenal ulcers were scored using a scale of 0 to 3, where 0 = no ulcer, 1 = superficial mucosal erosion, 2 = deep ulcer or transmural necrosis, and 3 = perforated or penetrated ulcer (into the pancreas or liver). The sum of the intensity of each lesion was used as the ulcer index.

Ethanol-induced gastric ulcers

The rats were administered (ig) with 1 mL of absolute ethanol^[27]. BPB was given 30 min before the administration of ethanol. One hour after the administration of ethanol the rats were sacrificed and examined for lesions in the stomach. The scoring of lesions, assays of gastric wall mucus and sulfhydryls in the stomach were done as follows: The patchal lesions of stomach induced by ethanol were scored according to the method described by Schiantarelli *et al.*^[28] using the following scale: 0 = normal mucosa; 1 = hyperemic mucosa or up to 3 small patches; 2 = from 4 to 10 small patches; 3 = more than 10 small or up to 3 medium-sized patches; 4 = from 4 to 6 medium-sized patches; 5 = more than 6 medium-sized or up to 3 large patches; 6 = from 4 to 6 large patches; 7 = from 7 to 10 large patches; 8 = more than 10 large patches or extensive necrotic zones. "Small" was defined as up to 2 mm across (max. diameter), "medium-sized" as between 2 and 4 mm across and "large" as more than 4 mm across.

Determination of gastric wall mucus

Gastric wall mucus was determined according to the modified procedure of Corne *et al.*^[29]. The glandular segment of the stomach was separated from the lumen of the stomach, weighed, and transferred immediately to 10 mL of 0.1% w/v Alcian blue solution (in 0.16 mmol/L sucrose solution buffered with 0.05 mL sodium acetate at pH 5). Tissue was stained for 2 h in Alcian blue, and excess dye was removed by two successive rinses with 10 mL of 0.25 mmol/L sucrose, first for 15 min and then for 45 min. Dye complexed with the gastric wall mucus was extracted with 10 mL of 0.5 mmol/L magnesium chloride which was intermittently shaken for 1 min at 30 min intervals for 2 h. Four milliliters of blue extract were then vigorously shaken with an equal volume of diethyl ether. The resulting emulsion was centrifuged at 4000 r/min for 10 min and the absorbance of aqueous layer was recorded at 580 nm. The quantity of Alcian blue extracted per gram of wet glandular tissue was then calculated.

Estimation of nonprotein sulfhydryls

Gastric mucosal nonprotein sulfhydryls (NP-SH) was measured according to the method of Sedlak and Lindsay^[30]. The glandular part of the stomach was homogenized in ice-cold 0.02 mmol/L EDTA. Aliquots of 5 mL of the homogenates were mixed in 15 mL test tubes with 4 mL of distilled water and 1 mL of 50% trichloroacetic acid. The tubes were shaken intermittently for 10 min and centrifuged at 3000 g. Two milliliters of supernatant were mixed with 4 mL of 0.4 mol/L Tris buffer at pH 8.9; 0.1

mL of DTNB [5, 5'-dithio-bis-(2-nitrobenzoic acid)] was added and the sample was shaken. The absorbance was measured within 5 min of addition of DTNB at 412 nm against a reagent blank.

Determination of myeloperoxidase activity

Myeloperoxidase (MPO) activity in the gastric mucosa was measured according to the methods described earlier^[31]. Pre-weighed tissue was homogenized (1:10 wt/vol) in 0.5% hexadecyltrimethyl ammonium bromide in 50 mmol potassium phosphate buffer (pH 6.0) before sonication in an ice bath for 20 s. Three freeze/thaw cycles were performed followed by sonication (20 s in ice bath). The samples were centrifuged at 17000 *g* (5 min, 4°C) and MPO in the supernatant was assayed by mixing of 0.1 mL of supernatant with 2.9 mL of 50 mmol/L potassium phosphate buffer (pH 6.0) containing 0.167 g/L *o*-dianasidine dihydrochloride and 0.0005% hydrogen peroxide. The change in absorbance at 460 nm was measured for 4 min using an UV-visible spectrophotometer (UV-160A, Shimadzu, Japan).

Statistical analysis

Data were analyzed by one-way analysis of variance (ANOVA) followed by Dunnett's multiple comparison test. Differences with $P < 0.05$ were considered as statistically significant.

RESULTS

Effect of BPB on gastric secretions in 6 h pylorus-ligated rats

In control rats, pylorus ligation for 6 h resulted in the accumulation of 9.8 ± 0.55 mL of gastric secretions and a total acid output of 663 ± 48.7 mEq (Table 1). The volume of gastric secretion in the rats treated with 5, 15 and 45 mg/kg of BPB significantly reduced to 7.4 ± 0.42 mL, 6.6 ± 0.59 mL and 4.5 ± 0.47 mL respectively (ANOVA, $F = 17.25$, $P < 0.001$). A significant decrease in total acid output was observed in the rats treated with 15 mg/kg (193 ± 51.5 mEq) and 45 mg/kg (162 ± 34.8 mEq) of BPB (ANOVA, $F = 26.71$, $P < 0.001$). The rats treated with 5 mg/kg of BPB failed to show any significant change (576 ± 66.9 mEq) in total acid output as compared to control group (Table 1).

Effect of BPB on cysteamine-induced duodenal ulcers

Administration of cysteamine produced elongated lesions extending longitudinally down the duodenum. The lesion area of the rats in control group was 33.3 ± 0.21 mm². Treatment of rats with BPB reduced the area of lesions in all the groups. A significant reduction in lesion area was observed in the rats treated with 15 mg/kg (1.0 ± 0.26 mm²) and 45 mg/kg (1.5 ± 0.22 mm²) of BPB (ANOVA, $F = 17.45$, $P < 0.001$). The decrease in lesion area of the rats treated with 5 mg/kg (3.0 ± 0.36 mm²) was not statistically significant (Figure 1).

Effect of BPB on ethanol-induced gastric lesions

The treatment of rats with absolute ethanol produced extensive gastric lesions in the glandular mucosa of the

stomach in all the control rats. The ulcer index was 8.0 ± 0.31 in control rats 1 h after ethanol administration. Pretreatment of rats with BPB at the doses of 5 mg/kg (ulcer index = 3.0 ± 0.63), 15 mg/kg (0.6 ± 0.24) and 45 mg/kg (0.0 ± 0.0) significantly inhibited the formation of gastric lesions (ANOVA, $F = 72.07$, $P < 0.001$) (Figure 2). Ethanol-induced lesions were characterized by multiple

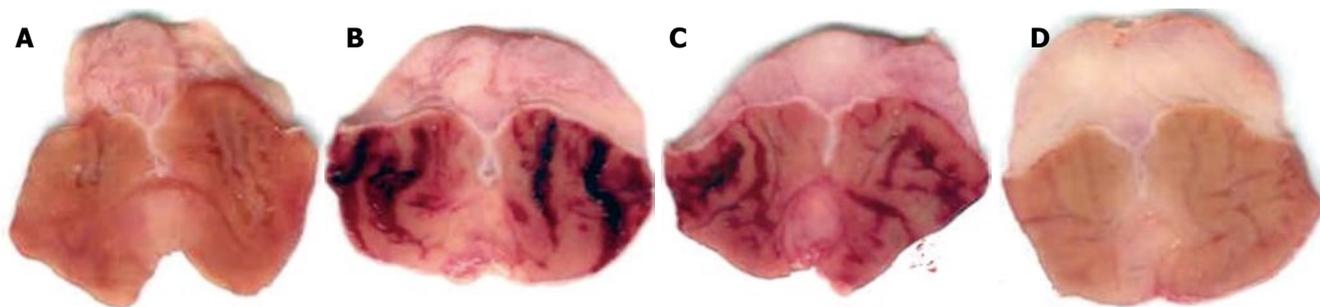

Figure 3 Morphological appearance of ethanol-induced band like hemorrhagic lesions in the stomach of rats. **A:** Normal mucosa; **B:** Ethanol produced lesion; **C:** Pretreatment of rats with BPB 15 mg/kg; **D:** Pretreatment of rats with BPB 45 mg/kg.

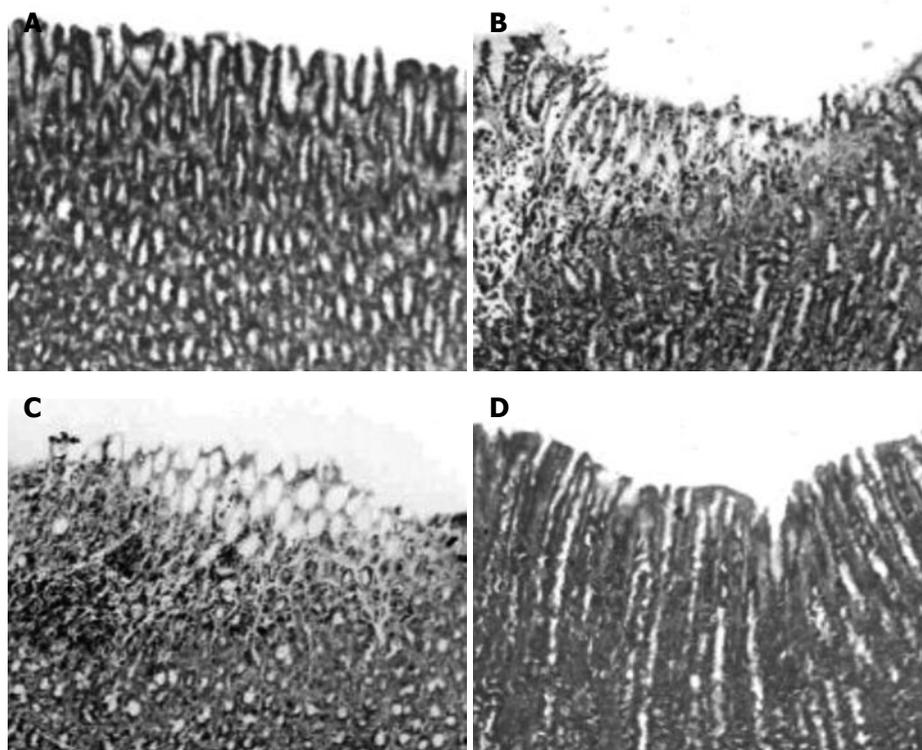

Figure 4 Light micrographs showing the effect of BPB on ethanol-induced gastric lesions of rats. **A:** Normal mucosa; **B:** Ethanol produced lesion; **C:** Pretreatment of rats with BPB 15 mg/kg; **D:** Pretreatment of rats with BPB 45 mg/kg.

hemorrhagic red bands (patches) of different size along the axis of the glandular stomach (Figure 3). Histological examination of gastric mucosa showed the appearance of these lesions in the form of gastric pits with detachment of the surface epithelium; epithelial cells appeared to be vacuolated and microvessels elongated (Figure 4). Pretreatment with BPB dose-dependently prevented ethanol-induced mucosal damage.

Effect of BPB on ethanol-induced changes in gastric wall mucus

The treatment of rats with ethanol significantly decreased the Alcian blue binding capacity of gastric wall mucus ($688 \pm 25.2 \mu\text{g}$ Alcian blue/g of tissue) as compared to control rats ($935 \pm 60.5 \mu\text{g/g}$). Pretreatment of rats with BPB at the doses of 5 mg/kg ($847 \pm 75.8 \mu\text{g/g}$), 15 mg/kg ($820 \pm 70.6 \mu\text{g/g}$) and 45 mg/kg ($927 \pm 34.2 \mu\text{g/g}$) significantly enhanced Alcian blue binding capacity of gastric mucosa (ANOVA $F = 3.09$, $P < 0.05$, Table 2).

Effect of BPB on ethanol-induced depletion of gastric mucosal NP-SH

The level of NP-SH in the gastric mucosa of control rats was $4.26 \pm 0.11 \mu\text{mol/g}$ of tissue, which was significantly decreased to $2.96 \pm 0.22 \mu\text{mol/g}$ following the administration of ethanol. Pretreatment of rats with BPB at all the three doses significantly inhibited ethanol-induced depletion of NP-SH (ANOVA $F = 13.76$, $P < 0.001$, Table 2).

Effect of BPB on ethanol-induced changes in gastric MPO activity

Changes in gastric accumulation of leukocytes following ethanol-induced lesions were evaluated by measurement of gastric MPO activity, which was significantly increased as compared to control mucosa (Table 2). Pretreatment with BPB significantly attenuated ethanol-induced increase in gastric MPO activity in rats (ANOVA, $F = 8.16$, $P < 0.001$).

Table 2 Effect of BPB on ethanol induced changes in Alcian blue binding capacity, NP-SH levels and MPO activity in gastric mucosa of rats (mean \pm SE)

Treatment	Alcian blue binding (mg/g tissue)	Non-protein sulfhydryl (mmol/g tissue)	Myeloperoxidase activity (Δ A/g tissue)
Normal	935 \pm 60.5	4.26 \pm 0.11	0.081 \pm 0.019
Ethanol (EtOH) alone	688 \pm 25.2 ^a	2.96 \pm 0.22 ^b	0.974 \pm 0.067 ^b

DISCUSSION

Pretreatment with BPB produced a dose dependent decrease in the volume and acid output of gastric secretions in Shay rats (Table 1). The increase in gastric acidity is considered as an important contributing factor in the pathogenesis of gastric and duodenal ulcers and is often termed as the 'aggressive factor'^[32]. The regulation of gastric acid secretion is complex and maintained by endogenous gastrin, histamine, somatostatin and cholinergic mechanisms^[33]. For acid secretion the expulsion of H⁺ across the apical membrane is coupled with the movement of K⁺ into the cell^[33]. Phospholipase A₂ inhibitors are known to modulate proton conductance across cell membranes^[34,35]. BPB has been shown to inhibit PLA₂ mediated histamine release from parietal cells in rats^[36]. A significant protective effect of BPB was observed against cysteamine-induced duodenal ulcers (Figure 1). The pathogenesis of cysteamine-induced duodenal lesions is far from clear. Cysteamine ulcers are considered to be associated with the hypersecretion of gastrin and hydrochloric acid and decreased mucosal resistance^[37]. The antiulcer activity of BPB may to some extent be attributed to its ability to inhibit gastric acid secretions (Table 1) and to preserve mucosal integrity (Table 2). Our results revealed that BPB significantly protected gastric mucosa against the depletion of gastric wall mucus (Table 2). The mucus gel adhering to the gastric mucosal surface protects the underlying epithelium against acid^[38,39], pepsin^[38] and necrotizing agents such as ethanol and indomethacin^[40]. It plays a more important role in the defense of the gastric mucosa against chemical or mechanical aggressions than the soluble mucus found in the lumen of the stomach^[41]. The gastric mucus coat is thought to be important in facilitating the repair of the damaged gastric epithelium^[42]. It seemed likely that the cytoprotective activity of this BPB could result, at least in part, from its interaction with the adhering gastric mucus layer.

Our results revealed that pretreatment of rats with BPB protected them against ethanol-induced gastric lesions (Figures 2-4). Numerous studies have indicated a substantial role for ODFR and PLA₂ in mediating ethanol-induced intestinal mucosal injury^[43,44]. The enhanced PLA₂ activity results in breakdown of membrane phospholipids

and activation of arachidonic acid cascade generating leukotrienes, prostaglandins and lipoxins^[45]. Prostacyclin is the major vasodilator and inhibitor of platelet aggregation, whereas thromboxan A₂ has the opposite effects^[46]. The ability of BPB to inhibit this proinflammatory cascade^[47-49] might be responsible for protecting gastric mucosa against chemically-induced lesions. The cytoprotective effect of BPB was accompanied by attenuation of ethanol-induced increase in MPO, a marker of neutrophil activity (Table 2). Neutrophils are the major inflammatory cell type infiltrating the injured mucosa following exposure to ethanol^[50]. Strategies to counteract neutrophil infiltration/activation have been shown to protect animals against gastric ulcers^[51,52].

A significant decrease in gastric NP-SH following ethanol administration indicated massive generation of ODFR (Table 2). Our findings are in agreement with earlier reports showing depletion of sulfhydryls in ethanol-induced gastric lesions^[53,54]. Within an inflammatory process, ODFRs are generated and initiate a chain reaction within membrane-bound lipids leading to lipid peroxidation. Treatment of rats with glutathione depletors has been shown to significantly potentiate ulcerogen-induced gastric mucosal injury^[55], whereas increase in mucosal NP-SH exerts gastroprotective effect^[56,57]. Sulfhydryl compounds play an important role in the formation of gastrointestinal mucus, which protects underlying gastric mucosa against necrotizing agents^[58,59]. Moreover, sulfhydryls have the ability to scavenge ODFR produced in tissues following exposure to cytotoxic compounds^[60]. These observations clearly point towards the mediation of sulfhydryls in BPB induced gastroprotection.

In conclusion, our findings show that BPB possesses both antisecretory and antiulcer effects. Further studies are required to determine the role of BPB in the prophylaxis and/or the treatment of gastrointestinal ulcer diseases.

Abstract

AIM: To study the effect of blocking intestinal lymphatic circulation in two-hit rats and explore the significance of intestinal lymphatic circulation in two-hit.

METHODS: Wistar rats were divided equally into three groups: mesenteric lymph duct ligation group, non-ligation group and sham group. Mesenteric lymph was diverted by ligation of mesenteric lymph duct, and the two-hit model was established by hemorrhage and lipopolysaccharide (LPS) methods. All rats were sampled for serum pre-experiment and 24 h post-experiment. The organs including kidney, liver, lung and heart were collected for pathomorphologic observation and biochemical investigation. The nitric oxide (NO), malondialdehyde (MDA) and superoxide dismutase (SOD) were determined in serum and tissue homogenate.

RESULTS: Pathomorphology study showed that the structures of kidney, lung, liver and heart tissues were normal in sham group; congestion, degeneration and necrosis in non-ligation group; but only mild lesions in ligation group. After two-hits, the contents of AST, ALT, BUN, Cr and LDH-1 in the serum of non-ligation group and ligation group were obviously higher than that in pre-experiment group and sham group, but obviously lower than that in non-ligation group. The contents of NO₂⁻/NO₃⁻, NOS, iNOS and MDA in the serum of non-ligation group were significantly increased, compared with pre-experiment and sham group, but SOD was significantly lower. These parameters were significantly different in ligation group compared with that in sham group, but NO₂⁻/NO₃⁻, iNOS and MDA in ligation group were significantly lower than that in non-ligation group.

INTRODUCTION

Multiple organ dysfunction syndrome (MODS) is a common but poorly understood complication in a variety of critical illnesses^[1-3]. In recent years, much attention has been paid to the study of MODS, and encouraging progress has been achieved. It has been accepted that the lymph system has an independent function and significance, which is different from the traditional concept that it is an assistant system of organic fluid circumfluence. In various pathogenesis of MODS, the complicated net of inflammatory mediators and cytokines is increasingly noticed. It has always been believed that their transport and transmit are *via* blood^[4-6]. However, whether the lymphatic pathway is meaningful to pathogenesis of MODS is yet to be clarified. We previously showed that lymph microcirculation is closely related to the occurrence and development of shock^[7,8]. Deitch *et al*^[9-12] reported that mesenteric lymph could activate neutrophils *in vivo* and *ex vivo*, promote the development of acute lung injury after resuscitation of hemorrhagic shock; when mesenteric lymph duct was ligated in advance, lung injury could be avoided. In the present study, in order to disclose the pathogenic importance of mesenteric lymph in MODS, the two-hit model was duplicated by two-hits of hemorrhage/resuscitation and lipopolysaccharide (LPS); the protective effect of intestinal lymphatic circulation block on organs in two-hit rats was investigated, and the influence of mesenteric lymph duct ligation on nitric oxide (NO) and free radicals in two-hit rats was explored.

MATERIALS AND METHODS

Animals

Forty-five male Wistar rats weighing 280 to 350 g (supplied by the Experimental Animal Center of Hebei Medical University), were divided equally into three groups: mesenteric lymph duct ligation group, non-ligation group and sham group.

Duplication of two-hit model

Rats were generally anesthetized with pentobarbital sodium (50 mg/kg) by intramuscular injection. A median incision was made in nuchae. The right common carotid arteries and left jugular veins were dissected, and cannulated to facilitate the blood withdrawal and infusion resuscitation. The two-hit model was duplicated by modified Spain's method^[13]. Blood (one sixth of body blood volume and one thirteenth of avoirdupois) was drawn by the automatic withdrawal-infusion machine (type of ZCZ-50) until the mean arterial pressure fell to a low level (less than 50 mmHg). The rate in the beginning was 0.4 mL/min for 5 min, then uniform velocity maintained at 0.1 mL/min. The process of blood withdrawal lasted more than 20 min and the blood was stored for serum tests. After being hypotensive for 40 min, the rats of both the ligation group and non-ligation group were resuscitated by Ringer's solution for as much as 3 times the lost blood volume for more than 30 min, then ligated through the right common carotid arteries and left jugular veins, and the incisions were then sutured. All the rats of the three groups received an abdominal operation with a vertical incision of 4 cm in length. The end of the mesentery was exposed. The mesenteric lymphatic ducts, which ran along the superior mesenteric artery, were separated. The rats of the ligation groups were additionally ligated at the mesenteric lymph duct, whereas sham and non-ligation groups were not, these were only threaded with cotton below the mesenteric lymph duct and then the abdomen was closed. After 6 h, LPS (O111:B4, Sigma) was injected intraperitoneally at a dose of 4 mg/kg, and 5% glucose saline at 20 mL/kg every 2 h until after 22 h for supportive therapy. After 24 h, all rats were anesthetized again with sodium pentobarbital (25 mg/kg), and their left common carotid arteries were cannulated to sample blood for serum tests by centrifugation. Then all rats were sacrificed and the organs were taken out, including the kidney, liver, lung and heart. Microscopic sections were made. The sera and tissue homogenate were stored at -26°C for later use.

Biochemical indexes and pathomorphology

The biochemical indexes of hepatic and renal function and myocardial enzymes including the aspartate aminotransferase (AST), alanine aminotransferase (ALT), blood urea nitrogen (BUN), creatinine (Cr), lactic acid dehydrogenase-1 (LDH-1) were determined before and after experimentation by an automatic biochemical analyzer type of Aeroset. The kidney, liver, lung and heart tissues were fixed by formaldehyde, embedded in paraffin, sliced and stained by HE. The pathological changes of the tissues were observed.

Determination of NO₂/NO₃⁻, NOS, SOD and MDA in serum and tissue homogenate

The concentrations of NO₂⁻/NO₃⁻, nitric oxide synthase (NOS), inducible nitric oxide synthase (iNOS), superoxide dismutase (SOD) and malondialdehyde (MDA) in serum and tissue homogenate were determined by nitrate reductase method, chemical chromogenic reaction, modified TBA microdetermination, xanthinoxidase method (Naijing Jiancheng, China).

Statistical analysis

All data were expressed as mean ± SD. SPSS software (Version 11.0 for Windows 98) was employed, one-way analysis of variance was used between groups, paired *t* test within group, and χ^2 test for survival analysis. *P* < 0.05 was considered statistically significant.

RESULTS

Survival rate of two-hit rats

In the process of the two-hit for 24 h, the survival rates of rats in the sham group, non-ligation group and ligation group were 100% (15/15), 53.3% (8/15), 73.3% (11/15) respectively, with a significant difference between the three groups ($\chi^2 = 8.904$, *P* < 0.05).

Effect of mesenteric lymph duct ligation on biochemical indexes in two-hit rats

There was no obvious difference between the three groups in the serum biochemical indexes of liver, kidney and cardiac muscle function before experimentation, as well as before and after experimentation in the sham group. The levels of AST, ALT, BUN, Cr and LDH-1 in the ligation group and non-ligation group were obviously higher than that in the sham group after experimentation, as well as before experimentation (*P* < 0.01, *P* < 0.05). The levels of ALT, BUN and Cr in the ligation group were obviously lower than that in non-ligation group (*P* < 0.01, Table 1).

Pathomorphologic changes of the vital organs

Kidney: The structure of the glomerulus and renal tubule, proximal and distal convoluted tubes were seen clearly in the sham group (Figure 1A). Fibrinoid necrosis of capillary vessels of the glomerulus, plasma protein precipitation in the glomerular capsule, and necrosis in some renal tubules could be observed in the non-ligation group (Figure 1B). There was fibrinoid necrosis on the capillary wall of the glomerulus in the ligation group, but only a few protein casts in the renal tubule (Figure 1C).

Lung: In the sham group, the structure of the alveolus was normal. The alveolar wall was thin. There were alveolar epithelial cells on the surface. Capillary vessels of the alveolar wall were not dilated or congested. There was no exudate in the alveolar cavity (Figure 2A). In the non-ligation group, severe monopyrenous cell hyperplasia and hemorrhage in the alveolar gap could be seen, leading to atelectasis and some alveolar emphysematous change (Figure 2B). In the ligation group, there were hyperplasia of monopyrenous cells and hemorrhage in the alveolar

gap, resulting in widening of the alveolar gap and atrophy of alveoli. The surrounding alveoli were compensatorily emphysematous and the alveolar walls were thinner and broken. The local blood vessels were dilated and hematose (Figure 2C).

Liver: In the sham group, the central vein of the liver lobule was dilated slightly. The liver cells were arranged slightly disordered, but all were of the same size.

Their nucleoli were round and centrally located. Their karyotheca was clear (Figure 3A). In the non-ligation group, the liver cells were necrotic, with karyopycnosis, karyorrhexis, karyolysis and focal hemorrhage (Figure 3B). In the ligation group, the central vein of the liver lobule and the surrounding liver sinuses were obviously dilated and hematose. Liver cells arranged disorderly, but their conformations were normal (Nucleoli were of the same

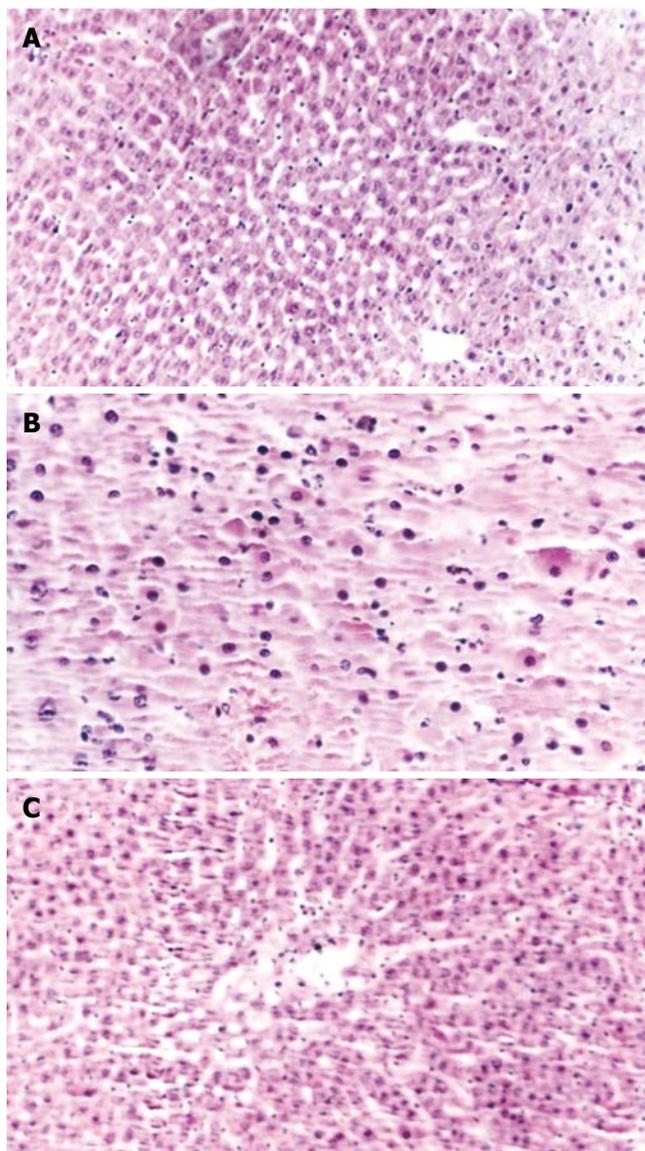

Figure 3 Effect of mesenteric lymph duct ligation on pathomorphology of liver in MODS rats (HE \times 100). A: Sham; B: Non-ligation; C: Ligation.

size, round and centered. The karyotheca was clear). Only some liver cells were necrotic, such as karyopycnosis, karyorrhexis and karyolysis (Figure 3C).

Cardiac muscle: In the sham group, the structure of the cardiac muscle fiber was normal. Cell nucleolus was centered, karyotheca was clear, and cardiac muscle cells were of the same size (Figure 4A). In the non-ligation group, there were coagulation necroses in the cardiac muscle fiber. Only the nucleolus of the myocardial mesenchyme was left, with focal sarcoplasm lysis and necrosis. A few structures of mesenchyme were seen (Figure 4B). In the ligation group, there were focal sarcoplasm coagulations in the cardiac muscle fiber. The nucleolus disappeared and the myocardial mesenchyme had focal infiltration of inflammatory cells (Figure 4C).

Effects of mesenteric lymph duct ligation on NO content and NOS activity in two-hit rats

Effects on NO content and NOS activity in serum: The contents of $\text{NO}_2^-/\text{NO}_3^-$, NOS and iNOS in serum

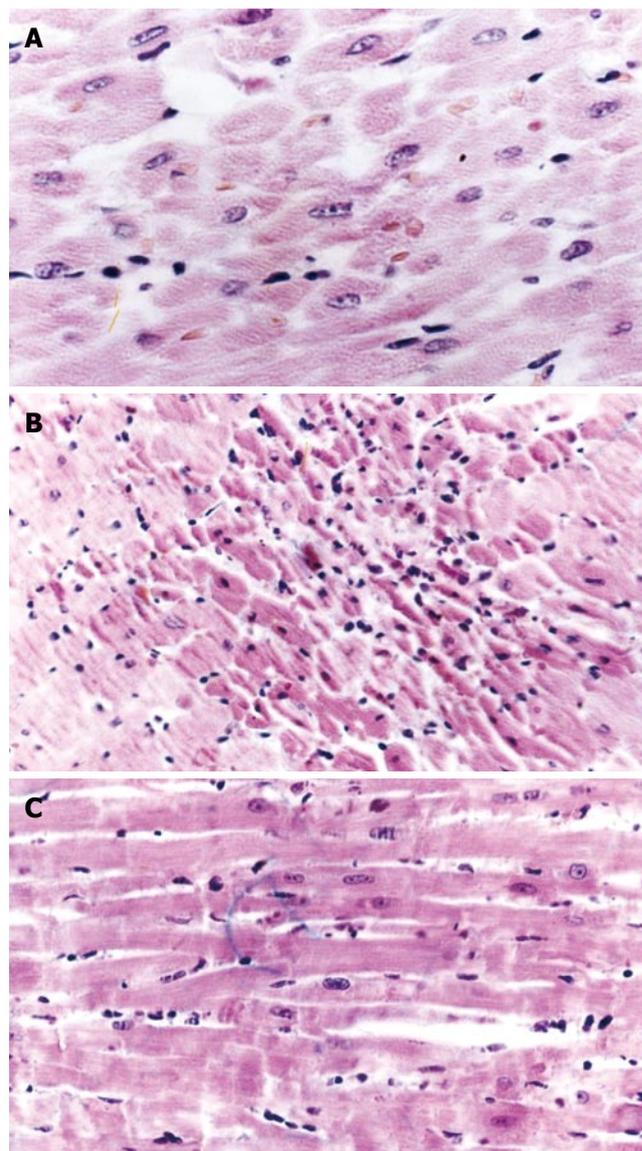

Figure 4 Effect of mesenteric lymph duct ligation on pathomorphology of heart in MODS rats (HE \times 200). A: Sham; B: Non-ligation; C: Ligation.

had no significant difference between the three groups before experimentation and in the sham group between pre- and post-experimentation. After two-hit, the contents of $\text{NO}_2^-/\text{NO}_3^-$, NOS and iNOS in the serum of the non-ligation group were significantly higher than that before experimentation and in the sham group ($P < 0.01$). The contents of $\text{NO}_2^-/\text{NO}_3^-$ and NOS of the ligation group were significantly higher than that in the sham group ($P < 0.05$), but were significantly lower than in the non-ligation group ($P < 0.01$, Table 2).

Effects on NO content and NOS activity in tissue homogenate: Compared with the sham group, the contents of $\text{NO}_2^-/\text{NO}_3^-$ in intestine, kidney, liver, lung and heart homogenates in the non-ligation group were significantly increased ($P < 0.01$), as well as in kidney, lung and heart homogenate in the ligation group, but no significant difference existed in intestine and liver ($P > 0.05$). The contents of $\text{NO}_2^-/\text{NO}_3^-$ in intestine, kidney and liver homogenate of the ligation group were significantly lower than that of the non-ligation group ($P < 0.01$), but

^a $P < 0.05$ vs sham; ^c $P < 0.05$ vs non-ligation.

ligation group and of kidney and liver homogenate in the ligation group were higher than that in the sham group ($P < 0.05$). The MDA content of lung and heart homogenate in non-ligation and of intestine, lung, heart homogenate in the ligation group had no significant difference from those of the sham group ($P > 0.05$), and no significant difference existed between the non-ligation group and the ligation group, either ($P > 0.05$, Table 5).

DISCUSSION

The occurrence of MODS is related to the pathogenic causes such as trauma, shock, ischemia-reperfusion injury and endotoxemia, *etc*^[14]. The various inflammatory cells are continuously stimulated and activated by pathogenic factors, producing and releasing mass cytokines and inflammatory mediators. There are complex chain reactions and cytokine networks between cytokines, cytokine and inflammatory mediators^[12,15]. In the process of production and release, they stimulate each other, act synergistically, or inhibit and counteract with each other, producing a cytokine cascade effect, and gradually an amplified effect on every organ and system, leading to the non-specific injury of tissues, damage of organs, and finally the occurrence of systemic inflammatory response syndrome (SIRS)^[11,16-19]. This is also the important pathophysiologic mechanism causing MODS. The MODS model can be made by one-hit and two-hit methods^[13]. In our study, the MODS rat model was successfully established by a two-hit method of hemorrhage/resuscitation and LPS, and the two-hit model showed different degrees of damage and dysfunction of liver, kidney and myocardium from pathomorphology and biochemical indexes of hepatic, renal function and myocardial enzyme at pre- and post-experimentation. Through this model, the effect of blocking intestinal lymphatic circulation in two-hit rats was studied.

In pathogenesis of diphasic type MODS, damage of the intestinal barrier function would induce intestinal endotoxemia and bacterial translocation from intestine^[14,21]. The circumfluence of intestinal and celiac contents has both blood and lymph routes^[22]. We investigated the importance of intestinal mesenteric lymph circumfluence in MODS pathogenesis in two-hit rats by ligating mesenteric lymphatic duct. The biochemical indexes of liver, kidney, and heart function before and after two-hit in three groups showed that after two-hit, the contents of AST, ALT, BUN, Cr and LDH-1 in the serum of the non-

ligation group and ligation group were obviously higher than that before experimentation and in the sham group. The contents of ALT, BUN and Cr in the ligation group were obviously lower than in the non-ligation group. All these suggest that the ligation of mesenteric lymph duct had a protective effect on the function of liver, kidney and heart because the ligation led to a decrease of the entry of intestinal bacteria and endotoxins into blood. A pathomorphologic study showed that the cellular structures of the kidney, lung, liver and heart tissues in the sham group were normal, while congestion, degeneration and necrosis were found in organs of the non-ligation group, and only mild lesions could be found in the ligation group. It suggests that the ligation of mesenteric lymph duct had a protective effect on the liver, kidney, lung, and heart in two-hit rats. In addition, ligating mesenteric lymph duct could help resuscitation from two hits of hemorrhage and LPS, improve the survival rate; meanwhile it also confirmed the protective effects of mesenteric lymph diversion.

After LPS was injected into the abdominal cavity of the wounded rats, the histology of lymphatic tissue showed that there existed a lymphatic micronet at the visceral and parietal peritoneum; the largest surface area was those covering the digestive tube. These lymphatic capillary nets formed the lymphatic plexus, which sent out collecting lymphatic vessels to regional nodes. Mesenteric lymph duct is a chief excurrent passage. When the function of intestinal barrier was damaged, the toxic substance also could be translocated through mesenteric lymph duct^[23]. By ligation of mesenteric lymph duct, the blockage of the lymph stream from intestines and peritoneum would make LPS (MW = 30 kD) and other intestinal poisonous substances difficult to get into mesenteric lymph duct, thus relieving the morphologic damage and functional disorder of many organs.

Intestinal barrier dysfunction and intestinal inflammation caused by bacteria/endotoxin translocation (BET) are the main reason for pyotoxemia and MODS in severe inflammatory patients with unclear origin^[24-27]. In recent years^[28,29], some scholars also put forward that the intestines are the "center" organ for MODS and the chief cell origin for TNF α . Thus the intestines are not only the target organs of damage, but also the main links in MODS. In our experiment, probably *via* blocking the linkage function of the intestines as center organs, ligation of mesenteric lymph duct exerted the protective effect on several organs. From the contents of NO, NOS, iNOS

and MDA in serum and tissue homogenate, it indicates that the cytokine cascade reaction was induced by two-hits of hemorrhage and LPS. It also suggests that ligation could reduce iNOS, NOS, NO and free radicals produced and released by the intestines into the systemic circulation through lymph ducts, thus alleviating their damage to the organs.

LPS is a main component of the outer cell wall structure of Gram-negative bacteria. Although micro-lymph ducts have the function of absorbing macromolecular substances actively, in this experiment, LPS was injected into the abdominal cavity, but not the digestive cavity directly. Therefore, the majority of LPS not only could be absorbed *via* the visceral peritoneum of the digestive tube which has the largest area, but also could be absorbed *via* micro-lymph ducts of other visceral peritoneum, then through lymphatic plexus which send out collecting lymphatic vessels to regional nodes, or through microvessels into blood. This might be the reason for high MDA content in liver and kidney homogenate of the ligation group, which was significantly higher than that of the sham group, but not significantly different from the non-ligation group.

In conclusion, ligation of mesenteric lymph duct has a protective effect in two-hit rats. It could reduce the production of iNOS, synthesis of NO, release of free radicals, and consumption of SOD, thus improving the disturbance of organic function and pathomorphological changes, and relieving the damage of two-hits on kidney, liver, lung, heart and intestine. It indicates that mesenteric lymph plays an important role in cytokine production and transportation of inflammatory response mediators in two-hit rats. Blockade of mesenteric lymph might be a new approach in prevention and treatment of two-hits.

Abstract

AIM: To assess the effectiveness of the current UK clinical practice in reducing hepatic fat (IHCL).

METHODS: Whole body MRI and ¹H MRS were obtained, before and after 6 mo nutritional counselling, from liver, soleus and tibialis muscles in 10 subjects with non-alcoholic fatty liver disease (NAFLD).

RESULTS: A 500 Kcal-restricted diet resulted in an average weight loss of 4% (-3.4 kg,) accompanied by significant reductions in most adipose tissue (AT) depots, including subcutaneous (-9.9%), abdominal subcutaneous (-10.2%) and intra-abdominal-AT (-11.4%). Intramyocellular lipids (IMCL) were significantly reduced in the tibialis muscle (-28.2%). Decreases in both IHCL (-39.9%) and soleus IMCL (-12.2%) content were also observed, although these were not significant. Several individuals showed dramatic decreases in IHCL, while others paradoxically showed increases in IHCL content. Changes in body composition were accompanied by improvements in certain liver function tests: serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT). Significant correlations were found between decreases in IHCL and reductions in both intra-abdominal and abdominal

subcutaneous AT. Improvements in liver function tests were associated with reductions in intra-abdominal AT, but not with changes in IHCL.

CONCLUSION: This study shows that even a very modest reduction in body weight achieved through lifestyle modification can result in changes in body fat depots and improvements in LFTs.

INTRODUCTION

The incidence of non-alcoholic fatty liver disease (NAFLD) has increased rapidly over the last few years and is now one of the commonest causes of abnormal liver function test (LFT) results in patients presenting to hepatology clinics in both Europe and the USA^[1]. Hepatic steatosis may be prevalent in more than 30% of the population^[2,3]. NAFLD encompasses a wide spectrum of liver diseases, from mild fatty infiltration, through to steatohepatitis, cirrhosis and fibrosis^[4]. One of the major factors thought to be responsible for fat accumulation in the liver is obesity^[5], with NAFLD being a key feature of insulin resistance and the metabolic syndrome^[5]. Treatment is currently limited, although lifestyle modification including dietary change and increased exercise to promote weight loss are thought beneficial^[6].

The nature and rapidity of weight loss has been shown to be important^[7]. Previous studies have used gastric banding^[8,9], or very low calorie diets^[7,10] to promote significant, or rapid weight loss, resulting in reduced

intrahepatocellular lipid (IHCL) content. However, rapid reduction in weight may worsen underlying inflammation and fibrosis in patients with non-alcoholic steatohepatitis (NASH)^[7,9]. Several studies have shown that liver fat content in NAFLD can be reduced through more moderate weight loss, achieved by dietary restriction, either alone^[11,12], in combination with exercise^[13-17], or using pharmacological intervention^[18-26]. To date, no study has looked at the effects of first line treatment in clinical management algorithms offered to most people attending outpatient clinics with NAFLD. The aim of this study was therefore to assess the impact of current United Kingdom nutritional clinical practice to reduce body adiposity and its impact on liver fat content and measures of hepatic function.

MATERIALS AND METHODS

Written informed consent was obtained from all volunteers. Permission for this study was obtained from the Ethics Committee of Hammersmith Hospital, Imperial College London, (Rec. 93/4047; 93/3995). The study protocol conformed to the ethical guidelines of the 1975 Declaration of Helsinki.

Subjects

Ten patients, referred to the Hepatology Outpatient Clinics at the Hammersmith and St Mary's Hospitals in London, were recruited (ST-R). All had unexplained abnormal liver function tests (LFTs) as a reason for referral with raised serum aspartate transaminase (AST) and/or gamma-glutamyl transpeptidase levels (γ GT). All were clinically obese with a mean body mass index of $31.6 \pm 4.6 \text{ kg/m}^2$. Three subjects had type II diabetes diagnosed within the last 3 years, two were treated with diet only, and one subject took metformin. Five had a history of dyslipidaemia. No patient drank alcohol in excess of 20 g/d and none had a history of excess alcohol consumption. No co-existing reason for the LFT abnormalities was found on screening for viral hepatitis or autoimmune liver disease. Serum copper, caeruloplasmin and iron studies were normal in each patient. All had increased echogenicity on hepatic ultrasound examination, compatible with hepatic steatosis. This was confirmed on subsequent liver biopsy in four of the subjects (RDG). The characteristics of the study group at baseline are shown in Table 1.

Dietary Intervention

All patients were referred to the Hammersmith Hospital 'Lifestyle Clinic'. The aim of the treatment was a gradual weight loss of 5%-10% of initial body weight within 6 mo. Subjects attended seven appointments with a registered dietician (AEB) over 6 mo, with fortnightly phone calls between appointments. Reported energy intakes using 3 d diaries were $2464 \pm 66 \text{ kcal}$, (of which 46% \pm 4% carbohydrate, 35% \pm 3% fat, 18% \pm 1% protein), in line with typical British diets. All subjects were sedentary at baseline scoring 7.1 ± 0.4 using Baecke activity questionnaires. Subjects were given advice on modifying their diets, which centred on behaviour change around

Table 1 Anthropometry results before and after dietary intervention mean \pm SD

	Pre-diet (n = 10)	Post-diet (n = 10)	P
Weight (kg)	96.3 (87.9-105.6)	93.0 (83.9-103.0)	0.006
BMI (kg/m ²)	31.3 (28.3-34.9)	30.2 (27.2-33.9)	0.006
Waist circumference (cm)	114.6 (107.8-121.4)	107.9 (101.6-114.3)	0.001
Systolic BP (mmHg)	133.4 (117.0-149.8)	129.8 (121.3-138.2)	0.62
Diastolic BP (mmHg)	79.4 (76.5-82.3)	77.6 (71.9-83.8)	0.50
Pulse (bpm)	67.3 (60.6-75.2)	66.3 (55.3-79.9)	0.60

Significance taken as $P < 0.05$. BMI: Body mass index; BP: Blood pressure; bpm: Beats per minute.

dietary intake in accordance with Hammersmith Hospitals Dietetic Department policy^[27]. The aim was to induce a 500 kcal energy deficit in the diet. Activity was encouraged in the form of walking using the "10 000 steps a day" campaign and pedometers were advised to aid compliance.

Biochemistry

Fasting blood samples were obtained for measurement of glucose, insulin, cholesterol, triglycerides and glycosylated haemoglobin (HbA_{1c}). AST, ALT, and γ GT were determined as recommended by the European Committee for clinical laboratory standards.

Anthropometry

Body weight was measured to the nearest 100 g. Height was measured using a stadiometer to the nearest centimetre. Waist circumference was measured mid-way between the lowest rib and the iliac crest^[28].

Total body adipose tissue content

Rapid T₁-weighted MR images (TR 36 ms, TE 14 ms) were acquired as previously described^[29]. Subjects lay in a prone position with arms straight above the head, and were scanned from fingertips to toes, acquiring 10 mm-thick transverse images with 30 mm gaps between slices in the arms and legs, and 10 mm gaps between slices in the trunk. Images were analysed using SliceOmatic (Tomovision, Montreal, Quebec, Canada). Total and regional adipose tissue (AT) volumes were measured^[29].

MRS of the liver

¹H MR spectra were acquired on a 1.5T Eclipse multi-nuclear system (Phillips Medical Systems, Cleveland, Ohio) using a flexible body coil. Spectra were obtained from the right lobe of the liver using a PRESS sequence (TR 1500 ms, TE 135 ms) without water saturation and with 128 signal averages. Intrahepatocellular lipids (IHCL) were measured relative to liver water content as previously described^[30].

MRS of muscle

Intramyocellular lipids (IMCL) were measured in the soleus (S-IMCL) and tibialis (T-IMCL) muscles by ¹H MRS (TR 1500 ms, TE 135 ms, 256 averages). IMCL

Non-abdominal internal	5.7 (4.7 to 6.9)	5.4 (4.4 to 6.6)	-5.4 (-14.4 to 4.5)	0.24

t -tests were performed on log-transformed data, significance taken as $P < 0.05$. AT = adipose tissue; Sc = subcutaneous.

were measured relative to total muscle creatine signal, as previously described^[51].

Statistical analysis

Statistical advice was provided by Dr Caroline Doré, MRC Clinical Trials Unit, London UK. The distribution of the data was tested for using the Shapiro-Wilk normality test. Normally distributed data are expressed as mean and 95% confidence interval (CI). Log₁₀ transformation was used to correct variables that were not normally distributed. Results for log-transformed variables are presented as geometric mean and 95% CI. Comparison before and after lifestyle intervention were tested using a paired t -test. Associations between variables were assessed using Pearson's correlation coefficients. The level of significance was set at 5%. Stepwise multiple regression analysis was performed to predict changes in AST, ALT and IHCL. Given the small number of patients, only forward variable selection was used. Data were analysed using Unistat version 5.5 (Unistat Ltd, London, UK) and Stata (StataCorp 2001 Stata Statistical Software, Release 7.0; Stata Corporation, College Station, Texas, USA).

RESULTS

All patients who participated in this study lost weight, with a mean loss of -3.5 kg (range -0.6 to -10.0 kg, $P = 0.006$). Total AT content was also reduced, with a mean reduction of -3.5 litres (range -0.75 to -10.43 litres, $P = 0.003$). There was also a significant reduction in waist circumference -6.6

cm (range -2.5 to -13.0 cm, $P = 0.001$) (Table 1). There were significant decreases in most AT depots following this life style intervention (Table 2). The largest decrease was found in intra-abdominal AT (-11.4%) (Figure 1), with slightly smaller quantities of subcutaneous AT lost from abdominal (-10.2%) and peripheral areas (-9.7%). There was a strong relationship between the amount of abdominal AT lost subcutaneously and internally ($r = 0.81$, $P < 0.01$).

A reduction in AST and ALT was observed, although the latter did not reach significance (Table 3). There was no significant change in γ GT. HbA_{1c} was also significantly reduced following the lifestyle intervention, suggesting an improvement in glycemic control. This may also be inferred by an improvement in insulin sensitivity observed in some individuals (HOMA %S), although as a group the increase did not reach significance.

The ¹H MRS findings are shown in Table 4. Although, seven of the 10 subjects showed marked reductions in IHCL (-57.2%), three subjects showed increases (33.2%), despite no significant difference between the groups in terms of weight loss (Figure 2). Thus, as a group the decrease in IHCL did not reach significance (-39.9%, $P = 0.12$). Interestingly, there was a significant correlation between changes in IHCL, weight loss ($r = 0.74$, $P < 0.01$) and intra-abdominal AT changes ($r = 0.83$, $P < 0.01$). This relationship was also significant for changes in IHCL and abdominal subcutaneous depot ($r = 0.76$, $P < 0.01$). There was a significant decrease in T-IMCL levels, but not for S-IMCL. Changes in T-IMCL were related to decreased

Table 3 Serum biochemistry results before and after dietary manipulation ($n = 10$)

Biochemistry	Pre-diet	Post-diet	P
Glucose (mmol/L)	5.7 (5.2-6.2)	5.5 (4.8-6.1)	0.55

HOMA: Homeostatic model assessment, %S estimates insulin sensitivity; %B estimates β -cell function; Chol: Cholesterol; HDL: High density lipoprotein; TG: Triglyceride; AST: Serum aspartate aminotransferase; ALT: Alanine aminotransferase; γ GT: Gamma-glutamyl transpeptidase.

intra-abdominal AT ($r = 0.73$, $P < 0.02$), whereas changes in S-IMCL were related to decreased subcutaneous AT in both abdominal ($r = 0.81$, $P < 0.01$) and peripheral regions ($r = 0.69$, $P < 0.05$).

Changes in LFTs showed significant association with alterations in body composition, (Table 5). A significant correlation was found between reduction in intra-abdominal AT and changes in both ALT ($r = 0.83$, $P < 0.01$) and AST ($r = 0.71$, $P < 0.05$). A weaker correlation was found between changes in ALT and IHCL ($r = 0.62$, $P = 0.05$). Stepwise multiple regression analyses were performed to predict changes in AST, ALT and IHCL. Variables considered for inclusion in this model were changes in abdominal and peripheral subcutaneous AT, intra-abdominal and non-abdominal internal AT, weight and IMCL in the soleus and tibialis muscles. Only changes in intra-abdominal AT were able to predict changes in AST, ALT and IHCL. Changes in AST and ALT were unable to predict changes in IHCL.

DISCUSSION

In this study we have shown that modest weight loss, obtained through routinely available hospital dietetic clinical care, can have worthwhile effects on whole body adiposity, hepatic and muscle fat content and LFTs in NAFLD patients. These findings indicate that current UK clinical practice is effective in promoting a lifestyle change that has a positive effect on reducing adiposity. Huang *et al* used a similar nutritional method to that employed in the current study to promote weight loss and looked at changes in liver histology on biopsy. They found histological improvement in patients with a weight loss of 7%, but not in those who lost only 2%^[12]. Similar findings were reported by Tikkainen *et al* in patients with an 8% weight loss^[11]. Tamura *et al* using diet with or without exercise in a strictly controlled study, reported decreases in body fat of 9.6% and 8.2%, with a 25%-30% reduction in IHCL. IMCL also decreased, but only with exercise^[13]. Hickman, reported an improvement in steatosis and liver

Table 4 Hepatic and Muscle fat before and after dietary modification ($n = 10$, geometric mean, t -test)

	Pre-diet	Post-diet	Change (%)	P
¹ IHCL	13.3 (5.8-30.9)	8.0 (2.4-26.4)	-39.9 (-69.5-18.4)	0.12
¹ IMCL soleus	19.6 (10.3-37.2)	17.2 (10.8-27.3)	-12.2 (-53.0-64.2)	0.65

histology following 12 wk of diet and exercise, with a weight loss of 6.6%^[14,15]. In our study, subjects lost on average 4% of their body weight, with variable effects on IHCL and IMCL levels. It is possible that a greater weight loss than this is necessary to have a significant effect on IHCL, or it may be that the nature/stage of the disease is important for overall reduction in steatosis. For example, in the present study, while several individuals had dramatic decreases in IHCL, others paradoxically showed increases in IHCL. The reasons for this are not immediately apparent. Recent studies have suggested that IHCL content may be altered by a single meal^[32], however we scanned our subjects following overnight fast, to minimise any potential effects. There were no obvious phenotypic or clinical differences between those subjects who responded to the weight loss with reductions in IHCL and the non-responders, who lost similar levels of body weight, but increased their IHCL content. However, where biopsy data were available (4/10 subjects), responders showed mild steatohepatitis, whereas non-responders additionally showed signs of more severe inflammation and fibrosis. Thus, IHCL reduction, as a result of dietary intervention, may be hampered in individuals whose fatty infiltration has already begun to progress to fibrosis, compared to those who solely have steatosis. Larger scale studies are clearly required to elucidate this further.

Very-low calorie formula diets or gastric banding has been used to promote more significant or rapid weight

loss to reduce hepatic fat content^[7-10]. Andersen *et al* placed morbidly obese subjects on a very low calorie liquid diet (388 kcal/d), resulting in a weight loss of 34 kg, and significant reduction in hepatic fat^[7]. Similarly, type-2 diabetic patients on very low fat (3%) liquid diets for 3-12 wk, lost 8 kg of body weight, with an 81% decrease in hepatic fat. Others have shown significant improvements in liver histology following large weight losses of over 30 kg^[8,9]. However, morbidly obese patients undergoing rapid weight reduction, may develop portal inflammation, fibrosis and hepatitis in addition to the decrease in hepatic fat content^[7,9]. Drug interventions have also been used to reduce hepatic fat and improve liver histology^[18-26]. Orlistat and metformin in combination with diet, can reduce in both weight and hepatic fat^[18,19], while metformin alone reduces body fat content (specifically subcutaneous AT), but has no effect on hepatic fat^[20]. Reductions in hepatic fat have been observed following treatment with pioglitazone^[21,22], rosiglitazone^[20,23-25] and pantethine^[26], despite the increases in body weight associated with glitazone therapy.

Only a few studies have compared changes in hepatic fat with changes in regional AT depots. Tiikkainen *et al* using diet restriction to reduce hepatic fat found that AT was lost from both subcutaneous and IAAT^[11]. However, unlike the present study they found no correlation between changes in liver fat and the changes in subcutaneous and IAAT. Carey *et al*, using rosiglitazone found an increase in subcutaneous AT, with no change in IAAT^[24]. Osono *et al* found decreased liver fat with pantethine, accompanied by a decrease in IAAT and an increase in subcutaneous AT^[26]. It is clear from the differences between these studies that diet and drug interventions may result in quite different mechanisms for the clearance of fat from the liver and reduction in AT volume. We found significant correlations between improvements in hepatic fat and reductions in both subcutaneous abdominal and IAAT. There were also strong correlations between decreased IAAT and decreased AST and ALT. However, regression analyses suggested that only reduction in IAAT could predict improvements in liver function and hepatic fat. Weight loss from other depots may well have other benefits, but not directly on hepatic function. A correlation was found between reduction in subcutaneous abdominal AT and S-IMCL, which may have implications for improving insulin sensitivity, since insulin resistant individuals have elevated IMCL^[33-35].

Several studies have looked at the effect of dietary restriction on AT content and distribution. A review of intervention strategies to reduce AT, suggests that most dietary interventions report a preferential loss of IAAT^[36]. Most papers included used a greater degree of calorie restriction than the present study and generally used females^[36]. In a study comparable to our own, Ross *et al* placed male subjects on a 700 kcal/d calorie restriction for 12 wk^[37]. They reported reductions of 0.7 kg and 0.8 kg from the abdominal subcutaneous and IAAT depots respectively^[37]. In our study, we found that similar proportions of AT were lost from both IAAT and subcutaneous abdominal depots, suggesting modest weight loss, achieved gradually, results in a non-selective loss of

AT from both IAAT and subcutaneous abdominal depots. A significant reduction in T-IMCL, but not in S-IMCL, was observed. Previous studies have shown decreases in S-IMCL in response to large weight loss (24%)^[38], but not to smaller reductions (8%-9%)^[10,11,38]. The tibialis may be more sensitive to weight change than the soleus. Indeed, T-IMCL may be more sensitive to catabolic lipid metabolism than the soleus^[39], which may explain its more significant response to intervention in this and previous studies^[40-43].

Both serum AST and ALT were reduced following weight loss, though only AST reached significance. Most studies looking at the relationship between liver enzymes and adiposity have focused on ALT, since elevated ALT is associated with obesity and insulin resistance^[44]. The lack of significance in the reduction in ALT observed in the present study could be explained by the suggested insensitivity of ALT to detect low levels of hepatic fat^[45]. Alternatively, although patients were referred to the study with elevated LFTs, the levels had improved somewhat by the time of inclusion in the study. Therefore despite ultrasound and subsequently MRS showing elevated liver fat, baseline LFT values in several subjects, although elevated, were not significantly outside the normal range. A significant decrease in LFTs within a 'normal' range may be difficult to achieve, this also indicates that normal LFTs are not necessarily a good indicator of liver fat content. Huang *et al* found no change in either AST or ALT following a similar study of nutritional counselling, despite improvements in liver histology^[12]. Interestingly, when their subjects were subdivided into responders and non-responders, the former showed a significant reduction in both ALT and AST^[12]. We observed similar effects, subjects showing reduced IHCL also showed a significant reduction in ALT. However, regression analyses suggest that changes in AST and ALT are only associated with modulation of IAAT during weight loss. Clearly, any relationship between hepatic steatosis and LFTs must include potential effects of other fat depots, especially IAAT. Several of the results in this study approached significance or were not significant, despite many suggesting a trend of 'improvement'. This is likely due to the small number of subjects ($n = 10$) included in this study, therefore type-2 statistical errors must be considered as confounding factors.

In summary, we have shown that modest weight loss achieved through UK clinically-implemented nutritional counselling regimens can result in worthwhile changes in regional adiposity, improvements in liver function, and reductions in both hepatic and tibialis muscle fat content. This study used clinically available, standard nutritional regimens as such, and our results are representative of clinical practice for NAFLD patients within the UK. Although there were some individual decreases in hepatic fat content, a more significant weight loss may be required to ensure consistent changes.

ACKNOWLEDGMENTS

We would like to thank Dr Adrian Lim, Consultant Radiologist, for his help with this project and Alexei

Jaccard-Siegler *por inspiratio*. ELT and AEB contributed to the design of the study, collection and analysis of data, and writing of the manuscript. GH, NP, AS and RDG contributed to the collection and analysis of the data and reviewed and approved the final manuscript. GF, JDB and STR contributed to the design of the study and provided advice and consultation on the writing of the manuscript as well as final review and approval. None of the authors had a personal or financial conflict of interest.

CONCLUSION: Pretransplant ERC is safe and superior over standard MRC for detection of biliary variations that occur with a high frequency. However, precise knowledge of biliary variants did not reduce the incidence of postoperative biliary complications.

Abstract

AIM: To compare the value of endoscopic retrograde cholangiography (ERC) and standard T2-weighted magnetic resonance cholangiography (MRC) in the evaluation process as adult-to-adult right lobe living donor liver transplantation (LDLTx) demands a successful outcome, and exact knowledge of the biliary tree is implicated to avoid biliary complications, postoperatively.

METHODS: After starting the LDLTx program, 18 liver transplant candidates were selected for LDLTx by a stepwise evaluation process. ERC and standard T2-weighted MRC were performed to evaluate the biliary system of the donor liver. The anatomical findings of ERC and MRC mapping were compared using the Ohkubo classification.

RESULTS: ERC allowed mapping of the whole biliary system in 15/15 (100%) cases, including 14/15 (93.3%) with biliary variants while routine MRC was only accurate in 2/13 (15.4%) cases. MRC was limited in depicting the biliary system proximal of the hepatic bifurcation. Postoperative biliary complications occurred in 2 donors and 8 recipients. Biliary complications were associated with Ohkubo type C, E or G in 6/8 recipients, and 2/3 recipients with biliary leak received a graft with multiple (≥ 2) bile ducts.

INTRODUCTION

Over the past decade, a critical shortage of cadaveric organs for adults in need of liver transplants has developed. The current mortality for patients awaiting liver transplantation (LTx) ranges from 20% to 30%. During this time, the waiting period for LTx and the mortality among patients on waiting lists have increased by a factor of more than 10 while the donor pool has expanded only marginally^[1]. The use of adult-to-adult right lobe living donor liver transplantation (LDLTx) provides an alternative technique to reduce the waiting list mortality^[2-4]. Hereby, a transplant candidate gains survival time and quality of life while a proven healthy individual undergoes liver resection for living donation of right or left lobe. The greatest risk in LDLTx is the death of the donor which is estimated to range between 0.1% to 0.5%^[5-7]. Furthermore, a potentially uneventful outcome of the recipient is a psychological threat for the donor. Thus, healthy donors might undergo an extended invasive diagnostic during evaluation. Also, complications are relatively common in living liver donors^[8]. Therefore, donor safety has the highest priority when LDLTx is performed^[9], and selection

criteria and management of living donors requires continuous refinement^[10]. Finally, potential advantages in recipients must be faced against any potential risk of morbidity and mortality in the living donor.

Bile duct leaks and stenosis impact morbidity and mortality in the early and late phase after LTx^[11]. After LDLTx, only few studies focused on anatomical variations of the biliary tree, which is the rule rather than the exception in liver surgery^[12]. The reported incidences of absent hepatic duct are 26% for the right and 2% for the left side^[12]. In LDLTx, anatomic variations of intrahepatic bile ducts can complicate both, the donor and the recipient operation^[13]. Full hepatic lobectomy is required for adult-to-adult LDLTx, and the postoperative risk is greater after right lobe resection^[14]. Preoperative delineation of the biliary system appears important to achieve a successful outcome^[13].

Management of bile duct variations in LDLTx is technically demanding and lacking awareness of biliary variation increases the risk of postoperative complications^[15,16]. The biliary anatomy is mainly evaluated by endoscopic retrograde cholangiography (ERC), magnetic resonance cholangiography (MRC) or intraoperative cholangiography. The last might cause technical complications or results in oversight of biliary anomalies with consecutive biliary complications^[17]. Hitherto, about half of the LDLTx programs perform ERC for the evaluation of donor bile-duct anatomy, and about one third of the programs use MRC^[8]. Therefore, we compared the value of ERC and standard MRC in living donors prior to LTx.

MATERIALS AND METHODS

Subjects

Between March 1st, 2000 and October 5, 2005, 18 liver transplant candidates were selected for LDLTx by a stepwise evaluation process including identification of potential candidacy, assessment of clinical status and risk factors, assessment of liver function and anatomy, and final measures^[18].

Mean age of 18 donors (11 female, 7 male) was 50.4 ± 9.7 years, and 47 ± 9.2 years in 18 recipients (12 male, 6 female). Seven donors had genetic and 11 emotional relation to their recipient. Indications for LTx were hepatitis B or hepatitis C related cirrhosis ($n = 6$), postalcoholic cirrhosis ($n = 4$), hepatic metastasis of neuroendocrine tumor ($n = 2$), primary biliary cirrhosis ($n = 1$), primary sclerosing cholangitis ($n = 1$), cryptogenic cirrhosis ($n = 1$), bile duct cysts ($n = 1$), hepatic metastasis of gastrointestinal stroma tumor ($n = 1$), and echinococcus multilocularis hydatitis with postalcoholic cirrhosis ($n = 1$). Patients with cirrhosis were staged Child A ($n = 3$), B ($n = 6$), and C ($n = 5$) according to the Child-Pugh-Turcotte classification.

Evaluation of biliary anatomy

Biliary anatomy was evaluated by standard MRC and ERC. Standard MRC technique was provided by a radiologist in daily routine with Half-Fourier Spin-Echo in single shot technique and by Turbo-Spin-Echo with multiplanar

reconstruction in T2-weighted images. Standard ERC was performed by one experienced hepato-gastroenterologist. Patients received midazolam, propofol, and butylscopolaminiumbromide immediately before ERC. Serum amylase and lipase were controlled before and after ERC. Additionally, biliary anatomy was assessed by graft preparation and intraoperative cholangiography.

The biliary anatomy of MRC and ERC films were classified retrospectively according to Ohkubo^[12] by the specialists in radiology, hepato-gastroenterology, and transplantation surgery at our institution (Table 1).

RESULTS

Evaluation of donor biliary anatomy

ERC did not cause procedure-related complications. ERC (MRC) images were completely available in 15 (13) donors for retrospective analysis (Table 1). ERC allowed mapping of the whole biliary system in 15/15 cases (100%), while routine MRC was only accurate in 2/13 cases (15.4%). MRC was limited to depict the biliary anatomy only up to the first hepatic branches (Figure 1, Figure 2, Figure 3). Interestingly, 14/15 (93.3%) donors had biliary variants detected by ERC. Biliary anatomical variants classified according to Ohkubo *et al*^[12] are depicted in Table 1. Donor livers were classified type A ($n = 2$), B ($n = 2$), C ($n = 4$), E ($n = 5$), G ($n = 1$), and K ($n = 1$). Right hepatic duct (RHD) was present in 2 (13.3%) and absent in 12 (80.0%) donor livers. Left hepatic duct (LHD) was absent in one donor liver.

The biliary anatomy determined by preoperative ERC was identical to the intraoperative findings (Table 1). Seven of 18 (38.9%) grafts had one, 7/18 (38.9%) two, and 4/18 (22.2%) three bile ducts. In total, 11/18 (61.1%) right lobe grafts presented with two or more bile ducts.

Biliary complications

Postoperatively, 2/18 donors developed biliary complications (11.1%) including one biliary leak (Ohkubo type E, 2 bile ducts) and one bile duct stenosis (Ohkubo type C, one bile duct). Both complications occurred in livers with absent RHD. The biliary leak was located at the cutting surface and resolved without intervention, but the T-drain was kept for a longer period. Bile duct stenosis was successfully treated by endoscopic stenting. Eight of 18 (44.4%) recipients developed biliary complications (Table 1) including 3 biliary leakages, one bilioma, one bile duct necrosis, and 3 bile duct stenoses. Biliary leakages were associated with Ohkubo type G ($n = 1$) or not classified ($n = 2$). One leakage was related to stent dislocation. This graft had 3 bile ducts reconstructed by hepaticojejunostomy (HJS) with insertion of transhepatic stents. Two leakages were located at the cutting surface. A segment 6 necrosis occurred in one recipient who received an Ohkubo type C graft with one bile duct that was reconstructed by HJS and placement of a transhepatic stent. This patient also developed intrahepatic bilioma. Segmental necrosis might be related to transection of the arterial supply. One recipient developed bile duct necrosis located at the T-tube insertion side. Bile duct stenosis occurred in 3 recipients. One of these patients had received an Ohkubo type E graft including two bile

successfully treated by a Yamakawa prosthesis.

In summary, preoperative ERC detected biliary variants in 93.3% of donors. MRC confirmed ERC findings in only 15.4%, and was restricted in depicting the biliary anatomy above the hepatic bifurcation. Biliary complications occurred in 2 donors and 8 recipients. Ohkubo type C, E or G grafts were associated with biliary complications in 6/8 (75%) recipients. Two of 3 recipients with biliary leakage received a graft with multiple (≥ 2) bile ducts.

DISCUSSION

Determination of biliary anatomy in LDLTx can be performed preoperatively by ERC, MRC, contrast-enhanced CT-cholangiography, and intraoperative cholangiography. MRC is less invasive than ERC that can cause pancreatitis as a known complication. In a meta-analysis of 15 prospective trials using endoscopic retrograde cholangio-pancreaticography (ERCP), 14 risk factors of ERCP-associated pancreatitis have been identified involving nine related to the endoscopic technique (e.g. precut sphincterotomy) with a relative risk of 2.2 to 4.09^[19]. In our series, we used ERC only diagnostically without intervention or pancreatic injection. ERC was well tolerated and none of the patients developed pancreatitis or other procedure related complications. In contrast to standard routine MRC, ERC allowed complete mapping of the biliary system. Preoperative ERC detected variations of biliary anatomy in 93.3% of donors that were confirmed by our intraoperative findings.

The inaccuracy of standard routine MRC in our series might be explained by the imaging slice thickness and artifacts. Recently, new modified MRC techniques such as volumetric mangafodipir trisodium enhanced MRC, heavily T2-weighted thin section MRCP, and gadobenate

dimeglumine enhanced MRC have been developed^[20-24]. Sensitivity of heavily T2-weighted axial/coronal thin section MRCP for normal biliary anatomy was 89.5% and 71.4% for variants in LDLTx. The accuracy in depicting biliary anatomy was 84.6%^[22]. In another series, the sensitivity, specificity, positive predictive, and negative predictive value of preoperative heavily T2-weighted radial slab MRC was 92%, 100%, 100%, and 94%^[24]. Mangafodipir trisodium enhanced 3D MRC in combination with conventional T2-weighted MRC depicted the intrahepatic biliary anatomy correctly in 94% of living liver donors. Especially right duct variants were more accurately depicted with mangafodipir trisodium enhanced 3D MRC compared to conventional T2-weighted MRC^[21]. Another new technique of mapping the biliary anatomy is multidetector computed topography cholangiography (MDCT-CA) with 1 mm collimation^[16]. This method depicted anatomical biliary variations up to the fourth level of intrahepatic branches. Superiority of MDCT-CA over conventional MRC is explained by better spatial resolution using 1 mm instead of 4 mm slice thickness. Also, conventional MRC is susceptible for artifacts in T2-weighted images. Therefore, the use T1-weighted images is recommended in combination with Gd-EOB-DTPA or Gd-BOPTA, both biliary excreted contrast-agents^[25,26]. Also, Gd-BOPTA-MRC can be combined with CE-MRA without injection of a second contrast agent^[16,26]. Gd-BOPTA-enhanced MRC is superior over T2-weighted MRC sequences in mapping the biliary tree, but spatial resolution remains moderate^[25,26]. In principal, both imaging modalities can be performed as an all-in-one-protocol for evaluation of liver parenchyma, arterial, venous, and biliary anatomy. However, MDCT-CA harbors potential risks like X-ray exposure and allergic reaction to contrast medium. Both risk factors can be

avoided with Gd-BOPTA T1-weighted MRC^[26]. However, the role of the above-mentioned procedures needs to be defined for evaluation of biliary anatomy in living liver donors in the near future. At present these new techniques have not been compared to preoperative ERC yet.

In our series, biliary complications occurred in 2/18 (11.1%) donors. In larger series, incidence of biliary complications ranged from 4% to 13%^[27-31]. Incidence of biliary leaks at the cutting surface is approximately 5% in living donors^[32-36] and was 5.6% (1/18 donors) in our series. Notable, donors with absent RHD (Ohkubo type C and G) grafts are at risk to develop biliary leakage or obstruction^[12]. Both biliary complications in our donors occurred in livers with absent RHD (Ohkubo type C and E). In recipients, biliary complications are the Achilles' heel of all segmental LTx^[9]. Incidence of biliary complications in LDLTx recipients is 15%-40%^[8,9,15]. In our series, 8/16 (44.4%) recipients had complications despite exact preoperative determination of biliary variants by ERC. Nevertheless, anatomic variations of the biliary tract are common but may not contraindicate donation^[13,37]. The risks of biliary complications increase with the number of bile duct openings in the graft^[38]. Rogiers *et al*^[9] focused on two complex biliary variations: (1) Ramus posteriomediales (RPM) drains into the common hepatic duct (CHD), ramus lateralis (RL) merges with segment (S) II, and drain together into the left hepatic duct (LHD), and (2) RPM drains into CHD; S I, S II, S III, and S IV drain separately or together into RL. These two biliary variations cease splitting of the liver in selected cases. Recently, a case was published in which an anatomic biliary variation was seen as a contraindication for right lobe LDLTx^[38].

In conclusion, biliary anatomy in living liver donors is highly variable, but does not exclude from donation. ERC is superior to the standard MRC technique for detailed preoperative mapping of intra- and extrahepatic bile ducts, but does not reduce the incidence of postoperative biliary complications.

Abstract

AIM: To evaluate carotid intima-media thickening (IMT) and plaques, gallstone disease (GD) and fatty liver (FL) as a function of age.

METHODS: In 449 subjects, FL and carotid disease were assessed ultrasonographically. In a subgroup of 65/449 patients with non-alcoholic fatty liver disease (NAFLD), carotid disease, GD and associated factors were determined.

RESULTS: FL of unspecified etiology was more common in younger and GD in older individuals. FL subjects had an increased prevalence of IMT and a decreased prevalence of plaques and manifested carotid disease earlier. Plaques were more common in subjects with GD. Age was an independent predictor of carotid disease outcome and FL was a protective factor for plaques. In NAFLD, there was an inverse correlation between body weight and age and the latter independently predicted carotid findings.

CONCLUSION: Cardiovascular risk in patients with FL and NAFLD needs to be assessed as a function of age and body weight.

INTRODUCTION

Atherothrombosis (AT), fatty liver (FL) and gallstone disease (GD) represent a clinically heterogeneous group of disorders which commonly occur in the general population and impose a heavy economic burden for direct and indirect health expenditures^[1-4]. Given that insulin resistance is an acknowledged risk factor for their development^[5-7], it is expected that AT, non-alcoholic fatty liver disease (NAFLD), one of the most common etiologies of fatty liver, and GD might often affect the same individuals. Several studies have suggested a link between NAFLD and endothelial dysfunction, carotid intima-media thickening (IMT) and carotid plaques^[8-10]. However, the development of AT is a complex process involving endothelial dysfunction and IMT as early lesions. IMT, in particular, does not represent definite AT disease but rather it is a marker for its development^[10]. In addition, some previous studies may not be representative of NAFLD due to enrollment of only male patients in a narrow range of body mass index (BMI) and age^[9,11]; therefore, the occurrence of increased cardiovascular risk in NAFLD remains a controversial issue^[12,13].

NAFLD patients might theoretically be prone to GD *via* impaired gallbladder motility and increased bile lithogenicity. Both physiopathologic mechanisms occur in type 2 diabetes mellitus (T2DM) and obesity, which are often associated with NAFLD^[7]. However, the NAFLD-GD association remains uncertain given that it has been reported in some studies but rejected in others^[14-17]. Furthermore, the association between AT and GD has been reported^[18-20], but some authors argue this association might be spurious and influenced by confounders^[21]. Although they share a common pathogenetic mechanism, AT, GD and NAFLD occur to a different extent in various age groups. For instance, increasing age is a risk factor for the development of AT and GD^[1,4] but a protective factor for NAFLD^[22]. Given that no previous studies have evaluated simultaneously the occurrence of AT, GD and FL, we evaluated the patterns of age distribution of FL of

unspecified etiology and its association with carotid disease and GD in either gender across a wide range of age-groups. In addition, we also assessed the independent predictors of carotid disease in a subgroup of patients with definite NAFLD.

MATERIALS AND METHODS

Patients

The electronic database of ultrasound reports for in- and out-patients examined at Modena City Hospital (Operating Unit Internal Medicine and Gastroenterology, to whom one of the authors belonged at the time when data were collected) was searched. Criteria for inclusion in the study were to have undergone both liver and carotid ultrasonographic assessment in the same day or, in any case, not later than 12 mo apart. Focal liver lesions, ascites or other ultrasonographic stigmata of portal hypertension (such as ascites, splenomegaly, presence of patent umbilical vein, varices in the hepato-gastric ligament or spontaneous spleno-renal shunts) were criteria for exclusion. Approximately 1200 liver ultrasound examinations per year were recorded in the 1993-2005 period of time; out of them, all 449 subjects fulfilling the enrollment criteria were selected.

In 384 of 449 cases, information on gender, age, presence/absence of FL and evaluation of carotid morphology was available. No information on being in- or out-patient, final diagnosis, etiology of FL or anthropometric and biochemical data was included in the software of the electronic database. Sixty-five of 449 subjects were part of the series recruited into the POLISTENA study and thus their bright livers were due to NAFLD. In this sub-group, in addition to the previous parameters including liver and carotid US evaluation, a complete history, anthropometric parameters and metabolic data were also available as a part of the protocol of the POLISTENA study^[23,24].

In the entire population of 449 subjects, we evaluated the prevalence of FL of unspecified etiology and its relationship with the US carotid findings and GD. In the subgroup of 65 NAFLD patients, the prevalences of carotid alterations, GD and the associated factors were determined.

Parameters evaluated in the whole population

Fatty liver of unspecified etiology: The presence of FL was evaluated through ultrasound scanning with a 3.5 MHz commercially available transducer and defined by the main criterion of "bright" liver as described elsewhere^[25]. Additional diagnostic criteria considered were vessel blurring and posterior attenuation of the ultrasound beam. Ultrasound was performed by trained physicians who were unaware of the results of the carotid evaluation. The evaluation of presence/absence of FL among the various operators was evaluated using Chi-square test and no significant difference was found.

Gallstone disease: GD was defined by the presence of one or more echogenic, distal acoustic shadowing, possibly moveable structures in the gallbladder or empty gallbladder fossa in a subjects with a history of cholecystectomy^[7].

Carotid intima-media thickening and plaque: Carotid ultrasound evaluation was performed by a single trained operator who was blind to the clinical features of patients.

Repeated measurements on the same subject gave coefficients of variation within 5%. The imaging unit was a commercially available machine (AU 600, Hitachi Medical Co., Tokyo, Japan) equipped with a 5-MHz linear array commercially available transducer. The pulsed Doppler frequency was 4.0 MHz. The imaging protocol^[26] involved scanning along the entire course of the cervical carotid artery from the supraclavicular notch cephalad to the angle of the mandible. Examination of the right and left common and internal carotid arteries was also performed. The maximum wall thickness observed for either side was taken into consideration. Findings were classified as: (1) normal (intima < 1 mm); (2) intimal thickening (intima-media measuring ≥ 1 mm and < 1.3 mm); and (3) plaque (focal widening of the vessel wall relative to adjacent segments ≥ 1.3 mm) or complicated plaque (any plaque narrowing > 70% of the lumen).

Parameters evaluated in the subset of patients with NAFLD

Diagnosis of NAFLD: The diagnosis of NAFLD in the subgroup of 65 patients enrolled in the POLISTENA study was based on: (1) absent-to-low alcohol consumption (≤ 30 g alcohol daily for men and ≤ 20 g for women); (2) evidence of FL at ultrasound scanning as detailed above; and (3) absence of alternative etiologies of chronic liver disease, notably viral, autoimmune, thyroid, drug-induced, hemodynamic and genetic-metabolic (alpha1-antitrypsin, hemochromatosis, Wilson disease). In addition to abdominal ultrasonography and ultrasound carotid scanning, all patients underwent a questionnaire, physical examination and blood sampling for biochemical analysis. In 23 of 65 subjects, liver biopsy was clinically indicated on the grounds of hepatomegaly and/or particularly altered liver function tests and was performed under ultrasound guidance.

Questionnaire: The questionnaire investigated family and personal history, including concurrent diseases, previous surgery, past and current use of medications, possible contacts with toxic agents. Alcohol intake, smoking habits and physical activity were also recorded. Alcohol consumption was assessed through separate interviews with the patient, the referring physician, and family members. Subjects were classified as never smokers (never smoked currently or in the past 5 years) or current smokers. The latter group comprised those smokers of as much as one cigarette a day and also included those ex-smokers who had quit tobacco since less than 5 years. Physical activity was defined as any exercise, such as jogging, swimming, attending a gymnastics course, cycling, playing tennis, dancing or heavy gardening. Based on their leisure time physical activity, subjects were classified as sedentary (those exercising less than 1 h per week) or non-sedentary (all the others).

General physical examination: It was performed by one of the senior authors. Anthropometric parameters and blood pressure measurements were performed by a trained nurse. Waist girth was measured at the smallest circumference between the ribs and the iliac crest and hip at the maximum circumference between the iliac crest and the crotch. Waist-hip ratio (WHR) was calculated as waist circumference/hip circumference.

Laboratory tests: Laboratory evaluation included renal and liver function tests, blood cell count, total and fractionated proteins, parameters of iron metabolism (serum iron, transferrin and ferritin), lipid profile (total cholesterol, HDL-cholesterol, LDL-cholesterol, triglycerides, apo-A, apo-B), fasting glucose, fasting insulin, and uric acid. Serum concentrations of copper, ceruloplasmin and alpha1-antitrypsin were performed to exclude Wilson disease and alpha1-antitrypsin deficiency. Non-organ-specific autoantibodies were also evaluated. In all patients, the presence of viral serologic markers for B and C infection was assessed by standard methods. Insulin resistance was calculated according to the Homeostasis Model Assessment of Insulin Resistance (HOMA-IR) index computed through the formula: fasting serum insulin ($\mu\text{U}/\text{mL}$) \times fasting serum glucose (mmol/L)/22.5^[27]. The diagnosis of impaired glucose tolerance and diabetes was based on the American Diabetes Association criteria^[28]. Subjects with impaired glucose tolerance included individuals with fasting glucose levels ≥ 6.1 mmol/L but < 7 mmol/L and with a 2-h post-load glucose ≥ 140 mg/dL (7.8 mmol/L) and < 200 mg/dL (11.1 mmol/L). Diabetes prevalence was based on the number of individuals with fasting plasma glucose ≥ 126 mg/dL (7 mmol/L) checked twice or having a past history of diabetes^[28]. Body mass index (BMI) was calculated with the formula: mass (kg)/height (m)² and obesity was defined by BMI ≥ 30 kg/m². Normal limits for blood lipids were defined accordingly to the third report of the National Cholesterol Education Program (NCEP). Hypercholesterolemia was defined as serum cholesterol ≥ 5.10 mmol/L, hypertriglyceridemia as serum triglycerides ≥ 1.65 mmol/L^[29]. Hypertension was diagnosed if patients had a past history of hypertension, were taking antihypertensive drugs or had a blood pressure $\geq 140/90$ mmHg.

Liver biopsy: Sections were stained with H&E; silver stain for reticulin, Sirius red for collagen, periodic acid Schiff for glycogen, periodic Schiff-diastase for glycoproteins, and Perl's for iron. Liver biopsy specimens were considered to be adequate if 6 or more portal tracts were included. Evaluation of steatosis and fibrosis was performed following the criteria developed by Brunt *et al*^[30]. A diagnosis of NASH required the following features: steatosis, parenchymal inflammation and ballooning degeneration of hepatocytes with or without fibrosis and Mallory bodies^[31]. Informed written consent was obtained from all participating individuals before taking blood samples and prior to liver biopsy. The study was performed in agreement with the Declaration of Helsinki.

Statistical analysis

Data were expressed as mean \pm SE for variables normally distributed and as median (25th-75th percentile) for those not normally distributed. Normalization of age was achieved through square transformation. The following tests were used as appropriate: Chi-square, Mann-Whitney, Oneway Scheffe's test, ANOVA, linear regression, binary logistic regression. Given that vascular carotid disease may manifest three different features (normal findings, IMT and plaques), we chose to adopt multinomial logistic regression which enables us to keep this distinction in

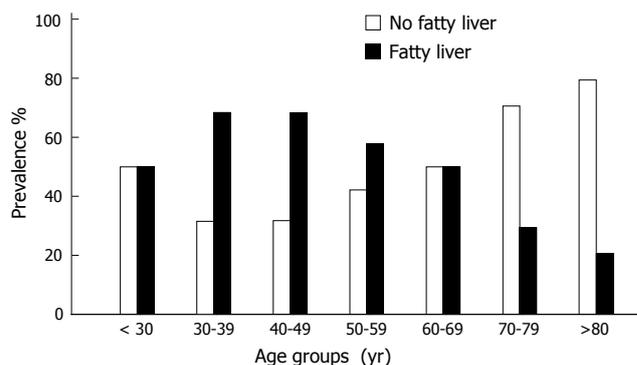

Figure 1 Distribution of ultrasonographically diagnosed fatty liver of unspecified etiology in the various age-groups of adulthood. The number of patients enrolled in each age-group is as follows: < 30: 8 cases; 30-39: 19 cases; 40-49: 44 cases; 50-59: 64 cases; 60-69: 98 cases; 70-79: 119 cases; and >80: 97 cases.

carotid ultrasonographic findings. The software used was SPSS Inc. Chicago, Illinois USA, release 14.0.

RESULTS

Data analysis in the whole population

Of the 449 subjects fulfilling enrollment criteria, 203 (45.2%) were men and 246 (54.8%) women; the median of the age was 69 years (56.5-78 years). Men were younger [median: 66 years (53-76 years)] than women [median: 72 years (59-81.25)] (Mann-Whitney test, $Z = -3.419$, $P = 0.001$).

Fatty liver of unspecified etiology

FL was present in 42.1% (189/449) of subjects, and the majority (102/189, 54.0%) were males ($\chi^2 = 10.104$, $P = 0.0014$). The distribution of FL per age-group is shown in Figure 1. The median age of the subjects with FL was 62 years (49-72 years) *versus* 75 years (65-81.75) in those without FL (Mann-Whitney test, $Z = -7.479$, $P = 7.52 \times 10^{-14}$). Logistic regression analysis using FL as the dependent variable and age and sex as predictors disclosed OR = -0.956, 95% CI = 0.943-0.969 ($P = 2.12 \times 10^{-10}$) for age and OR = -0.631, 95% CI = 0.422-0.942 ($P = 0.024$) for sex, demonstrating that FL is more common in younger male individuals.

Gallstone disease

The overall prevalence of GD was 32.5% (146/449), not significantly different in patients with FL *versus* those without FL (28.6% *vs* 35.2%; $\chi^2 = 2.315$, $P = 0.128$). Patients with GD were older than those without GD [73 years (61-82 years) *vs* 68 years (53-77 years); Mann-Whitney test, $Z = -3.497$, $P = 0.00047$] and GD was present more often in women than in men (38.6% *vs* 25.1%; $\chi^2 = 9.230$, $P = 0.002$). Logistic regression analysis using GD as the dependent variable confirmed that advanced age and female gender rather than steatosis predict the presence of GD (OR for age: 1.024, 95% CI: 1.009-1.039, $P = 0.002$; OR for female gender: 1.698, 95% CI = 1.118-2.578, $P = 0.013$). Fifty-four subjects had concurrent FL and GD. Compared with subjects with FL alone, these patients had more advanced median age [64 years (53-73 years) *vs* 60

Table 1 Ultrasonographic carotid findings in subjects with or without fatty liver of unspecified etiology

Carotid findings	Fatty liver		P
	Absent n (%)	Present n (%)	
Normal	19 (7.3)	39 (20.6)	P = 4.65 × 10 ⁻¹⁰
IMT	27 (10.4)	45 (23.8)

χ² test.

years(48-71 years); Mann-Whitney test, Z = -2.121, P = 0.034], but there was no female gender prevalence (females 55.6% *vs* males 44.0%; χ² = 2.76, P = 0.097).

Carotid ultrasonographic-Doppler evaluation

Fifty-eight of 449 subjects (12.9%) had normal carotid ultrasonographic findings. IMT was found in 16.0% (72/449) of subjects; the prevalence of atherosclerotic plaques was 71% (319/449). The distribution of carotid lesions per age-group is shown in Figure 2. All 8 subjects aged < 30 years had normal carotid findings (Figure 2). Carotid ultrasonographic-Doppler evaluation showed that median age was 45 years (33.75-55.25) for normal, 58 years (48.25-65) for IMT, 75 years (65-81) for plaques (Scheffe’s Oneway on squared age F = 134.118; P = 2.48 × 10⁻⁴⁶).

Relationship between FL of unspecified etiology, GD and carotid ultrasonographic-doppler findings

Table 1 summarises carotid findings as a function of presence/absence of FL. The frequency of subjects with IMT was more than two-fold in those with FL than in those without FL (23.8% *vs* 10.4 %). In contrast, the prevalence of plaques was decreased in those with FL of unspecified etiology than in those without it (55.6% *vs* 82.3%; χ² = 38.373, P = 4.65 × 10⁻¹⁰).

Table 2 shows median age and 25th-75th percentile in subjects with/without FL as a function of carotid findings.

Table 4 Independent predictors of intima-media thickening (IMT) or plaques in fatty liver of unspecified etiology

Carotid findings		B	Standard error	P	Exp (B) (95% CI)
IMT	Intercept	-3.736	0.916	0.000	
	Male	-0.019	0.405	0.962	0.981 (0.443-2.169)
	Age	0.079	0.016	0.0000014	1.082 (1.048-1.117)
Fatty liver		0.093	0.426	0.827	0.911 (0.395-2.101)
	Intercept	-7.879	1.050	0.000	
	Male	0.042	0.403	0.1719	1.719 (0.781-3.786)
Age		0.166	0.018	2.27 × 10 ⁻²⁰	1.181 (1.040-1.223)
	Fatty liver	0.873	0.416	0.036	0.418 (0.185-0.945)

Multivariate multinomial logistic regression. Dependent variable: carotid findings (IMT or plaques). Reference category: normal carotid findings. Age, sex (forced entry terms), fatty liver and GD (forward entry term) were entered as covariates.

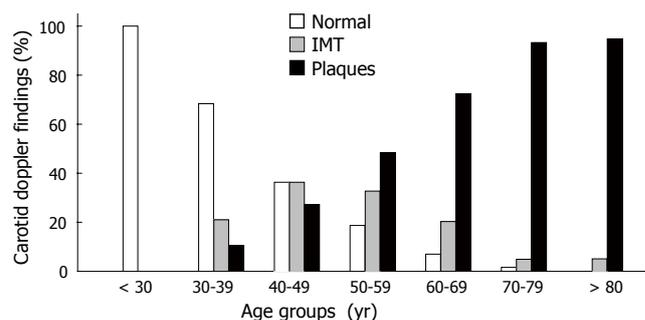

Figure 2 Distribution of carotid ultrasound findings in the various age-groups of adulthood. The number of patients enrolled in each age-group is the same as reported in Figure 1.

Following normalization obtained through square elevation, age was compared through ANOVA. Carotid findings (F = 114.457, P = 8.47 × 10⁻⁴¹) and FL (F = 6.311, P = 0.012) rather than gender (data not shown, F = 1.529, P = 0.217) were statistically different. Subjects with GD had a higher prevalence of plaques than those without plaques (78.8% *vs* 67.3%; χ² = 8.351, P = 0.015) (Table 3). In order to determine those variables that were predictive of plaques or IMT, multinomial logistic regression was used. Carotid findings were the dependent variable (normal as the reference value) and age and gender as fixed covariates; factors were FL and GD (forward). As shown in Table 4, age turned out to be an independent predictor of ultrasonographic carotid outcome, OR for IMT being 1.082 (95% CI: 1.048-1.117, P = 1.40 × 10⁻⁶) and for plaques 1.181 (95% CI: 1.140-1.228, P = 2.27 × 10⁻²⁰). The presence of FL was a protective factor for plaques (OR = 0.418, 95% CI: 0.185-0.945, P = 0.036) rather than for IMT (OR = 0.911, 95% CI: 0.443-2.169, P = 0.827).

Data analysis of the subset of patients with NAFLD

¹23 of 65 NAFLD patients underwent liver biopsy; 7 had normal findings, 10 IMT, and 6 carotid plaques. ²Kruskall-Wallis test; ³One way analysis of variance.

**Figure 3** Inverse correlation between body weight and age in NAFLD patients.

obesity 36.9% (24/65); hypertriglyceridemia 33.85% (22/65); IGT 27.7% (18/65); and T2DM 21.5% (14/65). Out of 65 patients, 10 (15.4%) had GD. These GD patients were older than those without GD (59.00 \pm 1.65 years *vs* 52.40 \pm 1.56; $t = -2.91$, $P = 0.007$), with a similar proportion of males and females (9.68% *vs* 20.59%; Fisher's exact test, $P = 0.309$).

Patients with normal carotid findings were younger than those with IMT and with plaques (Oneway Scheffe's test, $F = 7.652$, $P = 0.001$). Individuals with plaques had lower body weight (Oneway Scheffe's test, $F = 3.878$, $P = 0.026$) and transferrin serum levels (Oneway Scheffe's test, $F = 4.491$, $P = 0.015$) than those with normal carotid findings (Table 5), indicating a significant inverse relationship ($r^2 = 0.116$; $P = 0.006$) between age and body weight (Figure 3). We also found a direct relationship between HOMA and BMI ($r^2 = 0.26$, $P = 0.000017$) rather than between HOMA and age. No relationship was found between histological variables and carotid ultrasonographic findings in the limited number of cases available (Table 6).

The distribution of carotid ultrasonographic findings in the various age-groups of adulthood is shown in Figure

Table 7 Independent predictors of intima-media thickening (IMT) or plaques in NAFLD subjects

Carotid findings		B	Standard error	P ¹	Exp (B) (95% CI)
IMT	Intercept	-0.955	2.648	0.718	
	Age	0.087	0.034	0.010	1.091 (1.021-1.165)
	BMI	-0.102	0.071	0.150	0.903 (0.785-1.038)
Plaques	Intercept	-0.913	3.628	0.801	
	Age	0.119	0.042	0.005	1.126 (1.037-1.223)
	BMI	-0.189	0.097	0.052	0.828 (0.684-1.002)

¹Multivariate multinomial logistic regression. Dependent variable: carotid findings (IMT or plaques). Reference category: normal carotid findings. Age, body mass (forced entry terms) and HOMA (forward entry term) were entered as covariates.

4. Variables associated with IMT and plaques (the reference being normal findings) were evaluated using univariate logistic multinomial regression, where age, BMI and HOMA were found to be significant independent predictors (data not shown). In the multivariate logistic multinomial regression (Table 7), only age turned out to be the significant independent predictor of carotid IMT (OR: 1.091, 95% CI: 1.021-1.165, *P* = 0.010) and plaques (OR: 1.126, 95% CI: 1.037-1.223, *P* = 0.005).

DISCUSSION

To the best of our knowledge, this is the first study which explores the prevalence and determinants of carotid disease, FL and gallstones. A major finding of this study was that distribution of FL per age-classes (Figure 1) peaked in the 30-49 years age-group and declined in the younger and more advanced age groups. This “inverted U” pattern resembles that reported for FL distribution in the general population in Japan^[14] and closely mirrors the curve of altered transaminase levels in USA^[32,33] and in Israel^[34]. Taken collectively, these data further support the theory that FL, most likely NAFLD, accounts for the vast majority of altered liver function tests (LFTs) in the Western world. We have no explanation as to why the prevalence of FL of unspecified etiology declined after the age of 49 years. Several hypotheses can be put forward. The phenomenon may reflect a simple decrease in risk factor for NAFLD, notably including obesity, as supported by the finding in the present study that body weight declines with age (Figure 3). An alternative explanation is that mortality might be selectively increased among those with FL of unspecified etiology. A recent study has shown that the presence of NAFLD is associated with an increased mortality as compared with the general population^[35]. A unifying explanation could be that only those NAFLD subjects who lose weight will survive till more advanced age. This hypothesis, though, remains speculative and needs support from prospective studies.

Relevant findings of this study are that subjects with FL of unspecified etiology had an increased prevalence of IMT and a decreased prevalence of plaques; in contrast, GD was associated with increased prevalence of plaques. Of interest, carotid disease was found to occur in

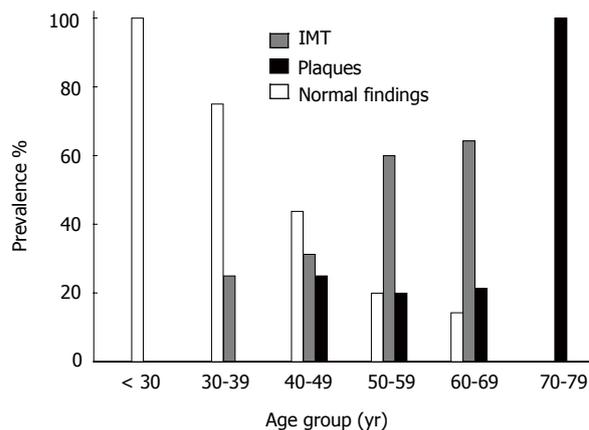

Figure 4 Distribution of carotid ultrasound findings in the various age-groups of adulthood with NAFLD. The number of patients enrolled in each age-group is as follows: < 30: 2 cases; 30-39: 4 cases; 40-49: 16 cases; 50-59: 25 cases; 60-69: 14 cases; and 70-79: 4 cases.

FL patients approximately 8 to 9 years earlier than those observed in subjects without FL. In FL of unspecified etiology, age was found to be an independent predictor of IMT and plaques, and steatosis had a protective effect in plaques only. Age was also recognized as the only independent predictor of carotid findings in NAFLD.

Although the prevalence of IMT among subjects with FL of unspecified etiology was increased, FL of unspecified etiology was not shown an independent predictor of IMT and was a negative predictor of plaques at logistic regression multinomial analysis; in contrast, GD and carotid plaques were shown to be associated. These findings can all be accounted for by the influence of age on the diseases in study. IMT and FL of unspecified etiology had the same distribution per age-classes, namely decreased in individuals aged > 40 years, whereas carotid atherosclerosis and GD increased in such over-40-year-old subjects (Figure 1). An increased prevalence of IMT among subjects with FL has also been reported in previous studies^[9,36]. However, while these authors reported the absolute value of IMT expressed in mm, we used a > 1-1.3 mm cut-off value, namely the threshold level predicting the occurrence of cardiovascular events^[37]. These methodological differences imply that we might have underestimated the true prevalence of IMT among subjects with FL of unspecified etiology to the advantage of predicting clinically relevant events. A recent study^[38] showed that after adjustment for confounders, NAFLD was significantly associated with an increased risk of cardiovascular diseases. However, additional adjustment for the metabolic syndrome appreciably attenuated this association without abolishing it. The finding that FL of unspecified etiology is an independent negative predictor of carotid plaques is probably linked to the inverse relationship linking age and body weight (Figure 3). Therefore, we emphasize that these data do not support a true “protective” effect of FL of unspecified etiology on the development of carotid plaques but probably represent the effect of selective mortality in those with FL and advanced AT, as suggested by the finding in this study that those with FL and IMT or plaques were 8 to 9 years younger than those with the same carotid findings without

FL.

Our data confirm the association between GD and carotid plaques^[19,20] but, in agreement with a previous study^[16], challenge that between GD and NAFLD. Both these findings are accounted for by the fact that carotid disease and GD both increase, whereas FL of unspecified etiology decreases, with age.

The importance of distribution per age-groups of subjects with various carotid findings, FL, NAFLD and GD also links the first (FL of unspecified etiology) and the second part (NAFLD) of our study. Individuals with NAFLD were significantly younger than those included in the first part of the study and thus they were less prone to the development of carotid plaques and GD. We highlight that in this subset of patients where all data were available, no other anthropometric, biological or histological parameters except for age, is an independent predictor of IMT and carotid plaques as found in the whole series. This finding fits with a previous study indicating that age is a powerful determinant of maximum IMT in both diabetic and healthy subjects^[39].

Some studies suggest that NAFLD patients have an increased incidence of carotid atherosclerosis^[9,40,41]. However, there is not enough hard data coming from natural history to support or rule out an association between NAFLD and cardiovascular disease. Indeed, some follow-up studies indicate that excess mortality in NAFLD is due to liver-related causes rather than to cardiovascular events^[12,13,35,42]. Enrollment criteria and referral pattern of patients might affect the vascular risk in NAFLD patients. NAFLD individuals included in our series were young and had a low prevalence of arterial hypertension and reduced HDL cholesterol that are strong determinants of AT^[43-45]. Furthermore, factors that are associated with the onset of carotid plaques might be different from those that cause clinical events of (complicated) AT.

Some specific features of our study need to be emphasized. First, the large series of subjects who were recruited. These individuals were distributed across all age-groups of adulthood, so providing an exhaustive cross-sectional picture of the relationship between the variables. Furthermore, our study enabled to evaluate those risk factors that add to the background dysmetabolic milieu linked to NAFLD *per se*. Indeed, our "control" group consisted of NAFLD patients with normal carotid findings rather than of subjects with a normal liver (i.e. without FL). Finally, we used the statistical procedure of multinomial logistic regression analysis which is particularly suitable in the analysis of unrelated multiple events, such as the varying outcomes of carotid ultrasonographic findings. We acknowledge, however, that ours is not a prospective study and that absence of anthropometric and biochemical data in the population with FL of unspecified etiology together with the limited number of NAFLD subjects may preclude exhaustive analysis of the etiological link between evaluated variables. Furthermore, the indications for prescribing ultrasound scanning of the liver or carotid depend on the clinical picture displayed by patients rather than by a standardized protocol. This may have reduced the number of subjects included in some age-groups (e.g. those aged 30 to 39 years) because these younger individuals seldom

present indications to undergo ultrasound scanning of carotid. This might somewhat bias our findings, that need to be duplicated by future studies.

In conclusion, our data show that in a large population comprising all ages of adulthood, age is an independent predictor of carotid IMT and plaques. FL of unspecified etiology is a negative predictor of carotid plaques, probably indicating selective death of those with FL or disappearance of liver fat with ageing. While we confirm an increased prevalence of IMT among patients with FL of unspecified etiology, and an association of GD with carotid atherosclerosis, we were unable to find any independent relationship between any conventional parameters, such as anthropometric, metabolic, hemodynamic, and histological liver features and carotid disease in NAFLD. In this specific subset of individuals, again, age is the only independent predictor of ultrasonographic carotid findings. Studies of natural history are needed to evaluate the real entity of cardiovascular risk in patients with FL of unspecified etiology and NAFLD as a function of age.

Abstract

AIM: To investigate and compare the hepatogenic transdifferentiation of adipose tissue-derived stem cells (ADSC) and bone marrow-derived mesenchymal stem cells (BMSC) *in vitro*. Transdifferentiation of BMSC into hepatic cells *in vivo* has been described. Adipose tissue represents an accessible source of ADSC, with similar characteristics to BMSC.

METHODS: BMSCs were obtained from patients undergoing total hip arthroplasty and ADSC from human adipose tissue obtained from lipectomy. Cells were grown in medium containing 15% human serum. Cultures were serum deprived for 2 d before cultivating under similar pro-hepatogenic conditions to those of liver development using a 2-step protocol with sequential addition of growth factors, cytokines and hormones. Hepatic differentiation was RT-PCR-assessed and liver-marker genes were immunohistochemically analysed.

RESULTS: BMSC and ADSC exhibited a fibroblastic morphology that changed to a polygonal shape when cells differentiated. Expression of stem cell marker Thy1 decreased in differentiated ADSC and BMSC. However, the expression of the hepatic markers, albumin and CYPs increased to a similar extent in differentiated BMSC and ADSC. Hepatic gene activation could be attributed to increased liver-enriched transcription factors (C/EBP β and HNF4 α), as demonstrated by adenoviral expression vectors.

CONCLUSION: Mesenchymal stem cells can be induced to hepatogenic transdifferentiation *in vitro*. ADSCs have a similar hepatogenic differentiation potential to BMSC, but a longer culture period and higher proliferation capacity. Therefore, adipose tissue may be an ideal source of large amounts of autologous stem cells, and may become an alternative for hepatocyte regeneration, liver cell transplantation or preclinical drug testing.

INTRODUCTION

Most liver diseases lead to hepatocyte dysfunction with the possibility of eventual organ failure. The replacement of diseased hepatocytes and the stimulation of endogenous or exogenous regeneration by stem cells are the main aims of liver-directed cell therapy. There is growing evidence to suggest that reservoirs of stem cells may reside in several types of adult tissue^[1,2]. These cells may retain the potential to transdifferentiate from one phenotype to another, presenting exciting possibilities for cellular therapies. One of

the important findings is that liver stem cells might be derived from bone marrow. Petersen *et al.*^[3] first identified this phenomenon in a rat model of liver injury. Subsequently, many researchers have reported similar *in vivo* and *in vitro* findings^[4-8]. Bone marrow cells have been hypothesized as the third recruitment source in liver regeneration besides hepatocytes and endogenous liver stem cells^[9].

Human bone marrow, derived from the embryonic mesoderm, is a complex tissue formed by a population of hematopoietic stem cells (HSC), supported by a mesenchymal stroma. The bone marrow stroma is heterogeneous in composition and is a reservoir of several stem cell populations, such as mesenchymal stem cells (MSC), and multi-potent adult progenitor stem cells (MAPC)^[10]. It has been reported that MSC contributes to the regeneration of a variety of mesenchymal tissues. Furthermore, it retains the ability to differentiate into cells of the mesoderm lineage, such as osteoblasts, chondrocytes, adipocytes, myoblasts and cardiomyocytes, and into various types of tissue cells derived from other embryonic layers, including neural and liver cells^[11-16]. The transdifferentiation of BMSC into hepatic cells *in vivo* was described in rats^[3,17], mice^[7] and humans^[8,18]. This has brought new hope to cell therapy using autologous bone marrow cells as these present few ethical problems and could be applied to severe liver disease. MSC can easily be obtained following a simple bone marrow aspiration procedure, and may be subsequently cultured and expanded *in vitro* without losing their stem cell potential, making them an attractive target for cell therapy. In addition to long-term self-renewal capability, MSC possess versatile differentiation potential ranging from mesenchyme-related multipotency to neuroectodermal and endodermal competency. However, traditional bone marrow procurement procedures may be distressful for the patient and may yield low numbers of MSCs upon processing, which has recently led to investigate alternative MSC sources outside the bone marrow microenvironment.

Although bone marrow was the first source reported to contain MSC, it has been reported that MSC can also be isolated from human umbilical cord blood, synovium, placenta, periosteum, skeletal muscle, and adipose tissue^[1,19-24]. Adult adipose tissue, like bone marrow, is derived from the embryonic mesenchyme, and a putative stem cell population within the adipose stromal compartment has been identified. Adipose tissue represents a rich source of mesenchymal stem cells, and provides an abundant and accessible source of adult stem cells with minimal patient discomfort. These cells have been termed adipose tissue-derived stem cells (ADSC). The characterization of these ADSC has defined a population similar to bone marrow-derived and skeletal muscle-derived stem cells. This cell population can be isolated from human lipoaspirates, and can be differentiated toward the osteogenic, adipogenic, neurogenic, myogenic and chondrogenic lineages^[25-29] like bone marrow BMSC. In fact, some works have shown that human ADSC have similar characteristics to BMSC *in vitro* and *in vivo*^[22,23,30,31]. In addition, ADSC compared with MSC from other sources possessed the longest culture period and the highest proliferation capacity^[23]. Thus, adipose tissue may

be an ideal source of large amounts of autologous stem cells attainable by a less invasive method than BMSC.

The success seen in differentiating ADSC into various mesenchymal lineages generates great interest in the use of ADSC for hepatic differentiation. To our knowledge, however, only a very recent report has shown the hepatogenic differentiation potential of ADSC^[32] by using a differentiation protocol showing significant differences to the one used in this study. In addition, a comparative study of the hepatogenic differentiation potential *in vitro* of both types of MSC has not yet been performed.

Based on these previous findings, the aim of this study was to investigate and compare the hepatic differentiation of human MSC from bone marrow (BMSC) and adipose tissue (ADSC) obtained from healthy donors. To this end, these cells were isolated and cultured under similar pro-hepatogenic conditions to those of liver development to define the different capacities of hepatic differentiation of the two subsets *in vitro*. Briefly, BMSC and ADSC cultures were serum deprived for 2 d and pre-cultured with EGF and bFGF (conditioning step). Then a 2-step differentiation protocol followed with a sequential addition of growth factors, cytokines and hormones (step-1 differentiation: HGF and bFGF for 7 d and step-2 differentiation: OMS, dexamethasone, and ITS + up to d 21). Moreover, the response to inductive extracellular signals and the role of key liver-enriched transcription factors (LEFTs) in the differentiation process *in vitro* have been revealed.

MATERIALS AND METHODS

Materials and reagents

Medium Dulbecco's Modified Eagle's medium (DMEM-low glucose), Ham's F-12 and Leibovitz L-15 were purchased from Gibco (Paisley, UK), gentamicine from Normon (Madrid, Spain), phosphate-buffered saline (PBS) and dexamethasone from Merck Pharma (Mollet del Vallés, Spain) and trypsin-EDTA and newborn calf serum were obtained from Biochrom AG (Berlin, Germany), ITS + premix from BD Biosciencias (Madrid, Spain). Basic fibroblast growth factor (bFGF) was purchased from Invitrogen (Barcelona, Spain), epidermal growth factor (EGF) and nicotinamide were from Sigma-Aldrich (Madrid, Spain). Oncostatin M (OMS) was purchased from PeproTech EC (London, UK). Hepatocyte growth factor (HGF) was a kind gift from Dr. T. Nakamura (Tokohu University, Sendai, Japan). Trizol and DNase I Amplification Grade were purchased from Invitrogen, Life Technologies (Barcelona, Spain), 3,3'-diaminobenzidine from Sigma-Aldrich (Madrid, Spain) and toluidine blue from BDH chemicals (Poole, UK). Monoclonal antibodies against human antigens CD13-PE, CD34-APC, CD45-FITC, CD90-APC, were purchased from Becton Dickinson (Mountain View, CA); CD105-PE from Serotec (Oxford, UK) and 7-Amino-actinomycin D (7-AAD) from Sigma-Aldrich (Madrid, Spain). Mouse monoclonal anti-human alphafetoprotein was purchased from Santa Cruz Biotechnology (Madrid, Spain) and polyclonal rabbit anti-human albumin, alphafetoprotein, polyclonal goat anti-mouse HRP and polyclonal goat anti-rabbit HRP were from DakoCytomation (Barcelona, Spain).

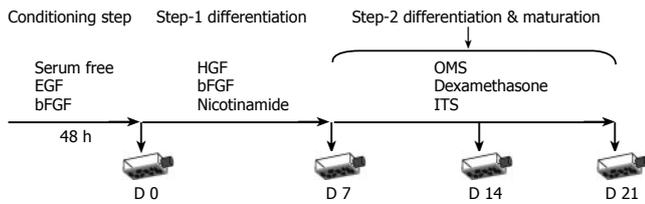

Figure 1 Hepatic differentiation protocol by sequential addition of exogenous factors according to embryogenesis. Passage 2 cultures at 85% of confluency were used for differentiation assays. Cells were pre-cultured in serum-free medium supplemented with EGF and bFGF for 2 d (Conditioning step). Then cells were cultured in medium supplemented with HGF, bFGF and nicotinamide, for 7 d (Step-1 differentiation). Finally cells were cultured in maturation medium supplemented with OMS, dexamethasone, and ITS + premix (insulin, transferrin, selenious acid, BSA and linoleic acid) up to 21 d (Step-2 differentiation; maturation). Media were changed twice a week and hepatic differentiation was assessed at different time points.

Cell cultures

Cancellous bone was obtained from the femoral heads of five patients (aged between 60 and 69 yr) undergoing total hip arthroplasty. Human adipose tissue was obtained by suction-assisted lipectomy (i.e. liposuction) as discarded tissue from surgical interventions from six patients (aged between 38 and 49 years). These protocols were approved by the institutional review board. Tissues were obtained in conformity with the rules of the Hospital's Ethics Committee and after obtaining an informed consent from patients.

Both bone and fat were dissected into small pieces. Trabecular bone fragments were digested with collagenase II (3 mg/mL) in Hank's balanced salt solution (HBSS) at 37°C for two hours with intermittent shaking. Adipose tissue fragments were digested with collagenase I (1 mg/mL) in HBSS at 37°C for 60 min with intermittent shaking. Thereafter, the resulting suspensions (bone and fat) were filtered using two layers of cotton gauze to remove debris and then centrifuged at 400 *g* for 10 min. Supernatants were discarded and pellets were resuspended in 160 mmol/L NH₄Cl at room temperature for 10 min to lyse the remaining red blood cells. Cells were collected by centrifugation, as detailed above, resuspended in culture medium (DMEM-low glucose supplemented with 15% AB human serum stock (pooled from 10 donors) from our regional transfusion centre and 50 µg/mL of gentamicin). These primary cells were plated in tissue culture flasks in a humidified atmosphere at 37°C with 50 mL/L CO₂ for 48 h. Thereafter, the cultures were washed to remove non-adherent cells. Media were changed twice a week, maintaining cells at subconfluent levels. The cells were subcultured with 0.4% trypsin/0.2% EDTA solution, seeded at a density of 5-10 × 10³ cells/cm² and cultured in the same conditions used for the primary culture (passage 1). Five to seven days later, subconfluent monolayers were subcultured (passage 2) and cells were seeded at the same density as for passage 1 to be used for differentiation assays.

Cell lines

HepG2 cells were plated in Ham's F-12/Leibovitz L-15 (1:1 v/v) supplemented with 7% newborn calf serum, 50 U penicillin/mL and 50 µg streptomycin/mL. Cells were subcultured with 0.25% trypsin/0.02% EDTA at 37°C.

Hepatic differentiation protocol

Passage 2 BMSC and ADSC cultures at 85% confluency were used for differentiation assays. Cells were serum deprived for 2 d and pre-cultured in DMEM supplemented with 20 ng/mL EGF and 10 ng/mL bFGF (conditioning step) to stop cell proliferation, prior to induction of differentiation toward a hepatic phenotype. Then a 2-step differentiation protocol was performed, followed by a sequential addition of growth factors, cytokines and hormones (Figure 1). Step-1 differentiation medium, consisting of DMEM supplemented with 20 ng/mL HGF, 10 ng/mL bFGF and nicotinamide 4.9 mmol/L, for 7 d, followed by step-2 differentiation medium, consisting of DMEM supplemented with 20 ng/mL OMS, 1 µmol/L dexamethasone, and 10 µL/mL ITS + premix (final concentration: 100 µmol/L insulin, 6.25 µg/mL transferrin, 3.6 µmol/L selenious acid, 1.25 mg/mL BSA and 190 µmol/L linoleic acid) to achieve cell maturation up to D21. Media were changed twice weekly and hepatic differentiation was assessed at different time points by RT-PCR for liver-associated genes, as listed in Table 1. The protocol was applied to BMSC and ADSC from five and six different donors, respectively, and identical results were obtained.

Flow cytometry analysis

Flow cytometric analysis was performed with a FACScalibur flow cytometer (Becton Dickinson, Mountain View, CA) after labelling 1 × 10⁶ cells with respective directly conjugated antibodies, using isotype-matched controls. 7-Aminoactinomycin D was used in order to exclude non-viable cells from the analysis, and nonspecific staining was performed as previously described^[53]. This analysis was carried out after the initial sample was obtained and later in the following culture stage.

Immunohistochemistry

MSC in monolayer were washed twice with phosphate buffered saline (PBS), fixed with ethanol 70% for 10 min, and with ethanol 100% for 10 min thereafter. Plates were washed three times with PBS. Then, plates were incubated for 30 min at room temperature with a solution of methanol with 1.7% H₂O₂, and washed again with PBS. Plates were then incubated for 30 min at 37°C with sheep serum diluted 1/10 in PBS, and washed with PBS tween (0.05%) four times. Subsequently, the plates were incubated for 2 h at 37°C with the primary antibody diluted in PBS tween 0.05%: anti-human alphafetoprotein (1/50) and anti-human albumin (1/2000). After incubation, plates were washed with PBS tween (0.05%) four times and incubated for 1 hour at 37°C with peroxidase labelled goat anti-mouse IgG diluted 1/100 in PBS tween 0.05% for alphafetoprotein, and with peroxidase labelled goat anti-rabbit IgG diluted 1/1000 in PBS tween 0.05% for albumin. After repeated washes, plates were incubated with the substrate (3,3'-diaminobenzidine diluted in PBS with 0.1% H₂O₂). H₂O was used to stop the reaction, and toluidine blue was employed as contrast staining. Finally, plates were examined under the microscope.

RNA extraction and real-time quantitative PCR

Total RNA was extracted from undifferentiated (used as control), differentiating and differentiated cells using Trizol reagent, following the manufacturer's recommendations; contaminating genomic DNA was removed by incubation with DNase I Amplification Grade. The amount of purified RNA was estimated by ribogreen fluorescence (Molecular Probes), and its purity was assessed by the absorbance ratio 260/280 nm. RNA integrity was examined by agarose gel electrophoresis. RNA (1 µg) was reverse transcribed as described^[34,35]. Diluted cDNA (3 µL) was amplified with a rapid thermal cycler (LightCycler Instrument, Roche Diagnostics) in 15 µL of LightCycler DNA Master SYBR Green I (Roche Molecular Biochemicals), 5 mmol/L MgCl₂ and 0.3 µmol/L of each oligonucleotide. Optimal MgCl₂ concentration was empirically determined for each set of primers. Gene-specific primers were designed using OLIGO software. The sequence of both the forward and reverse primers and the expected sizes of the PCR-amplified DNA are listed in Table 1. In parallel, we analyzed the mRNA concentration of the human housekeeping porphobilinogen deaminase (PBGD, hydroxymethylbilane synthase) as an internal control for normalization. A no-template negative control (H₂O) was also run for every cDNA-specific primer set. Each sample cDNA was measured in duplicate. PCR amplicons were confirmed to be specific by size and melting curve analysis. After denaturing for 30 s at 95°C, amplification was performed with 40 cycles of 1 s at 94°C, 5 s at 62°C and 20 s at 72°C. The real-time monitoring of the PCR reaction, the precise quantification of the products in the exponential phase of the amplification and the melting curve analysis were performed with the LightCycler quantification software, as recommended by the manufacturer.

Transduction with adenoviral vectors encoding C/EBP α and β

CCAAT/enhancer-binding proteins (C/EBP) are a family of liver-enriched transcription factors, which play an important role in regulating the transcription of multiple hepatic genes, including CYPs. Recombinant adenoviruses encoding the C/EBP α and C/EBP β full-length proteins were prepared as described elsewhere^[36,37]. Briefly, recombinant shuttle pAC/CMVpLpA plasmids containing full-length C/EBP α and C/EBP β cDNAs were cotransfected into 293 cells with pJM17 (AdE1A-transformed human embryonic kidney cells) by calcium phosphate/DNA coprecipitation. The expression cassette of pAC/CMVpLpA is located between the sequences representing 0-1.3 mu and 9.2-16 mu of adenovirus type 5, whereas pJM17 encodes a full length adenovirus-5 genome (dl309) interrupted by the insertion of the bacterial plasmid pBRX at position 3.7 mu, thereby exceeding the packaging limit for the adenovirus. A homologous recombination between adenovirus sequences in the shuttle vector and in the pJM17 plasmid results in the substitution of the pBRX sequences in pJM17 by the chimeric gene. This generates a genome of a packageable size in which most of the adenovirus early region 1 is lacking, thus rendering the recombinant virus replication defective. The resulting viruses (called Ad-C/EBP α , Ad-C/EBP β) were plaque-purified, expanded into a high-concentration stock and titrated by plaque assay, as previously described^[38]. ADSCs and BMSCs were infected with recombinant adenoviruses for 120 min at a MOI (multiplicity of infection) ranging from 3 to 15 PFUs (plaque forming units) per cell (MOI). Thereafter, cells were washed with PBS and fresh medium was added. Forty-eight hours post-transduction cells were analyzed or harvested for analysis and frozen in liquid N₂. MSCs were also transduced with a control adenoviral vector expressing GFP to confirm a highly efficient transduction of adenovirus exposed human cells and to demonstrate that adenoviral transduction *per se* does not cause unspecific alterations in differentiation marker genes.

Statistical analysis

Data were expressed as mean \pm SE. Results were analysed by the Student's *t* test. *P* < 0.05 was considered statistically significant.

RESULTS

Differentiation of human BMSC and ADSC to hepatic phenotype

Analysis by flow cytometry of cell surface markers of BMSC and ASDSC after isolation was performed.

Homogeneity and reproducibility of the isolation procedure of BMSC and ADSC were demonstrated by flow cytometry. Two analytical regions were established combining R1 region, which selects viable cells, and R2 in forward and side characteristics of both MSC types (Figures 2A, B and 3A, B). The surface antigen markers of human mesenchymal stem cells CD13, CD45, CD90 and CD105 expression on BMSC and ADSC were analysed after isolation

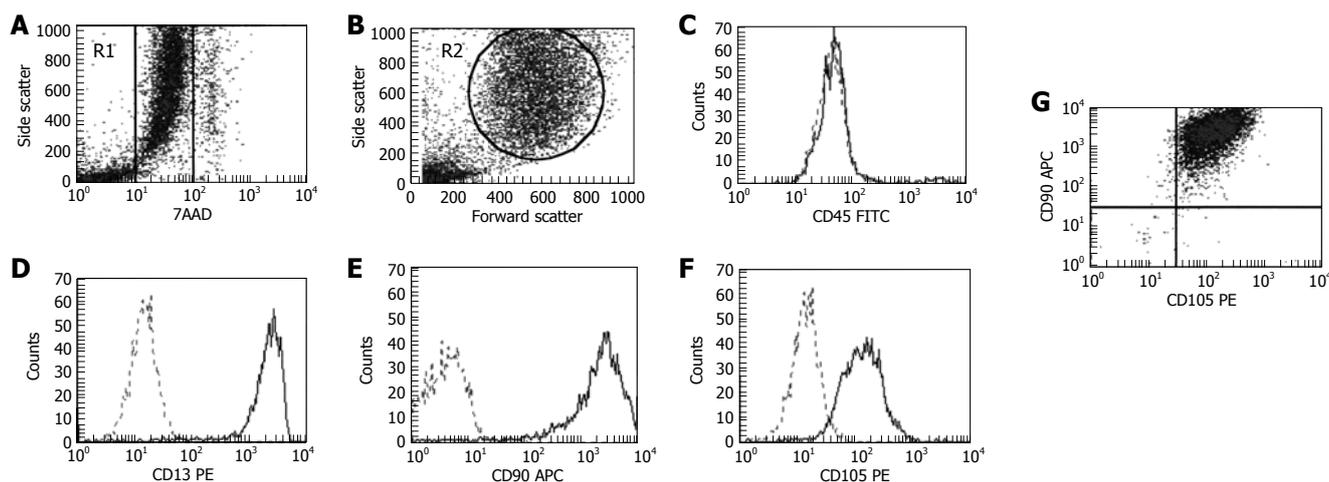

Figure 2 Flow cytometry analysis of surface protein markers of BMSC. Two analytical regions were established combining R1 region (A), which selects viable cells, and R2 (B) in forward and side characteristics of BMSC. Surface antigen markers were positive vis-à-vis isotypic controls for CD13 (D), CD90 (E) and CD105 (F) and negative for CD45 (C). Co-expression of CD90-CD105 is shown in dot-plots (G). 7ADD: 7-Aminoactinomycin D.

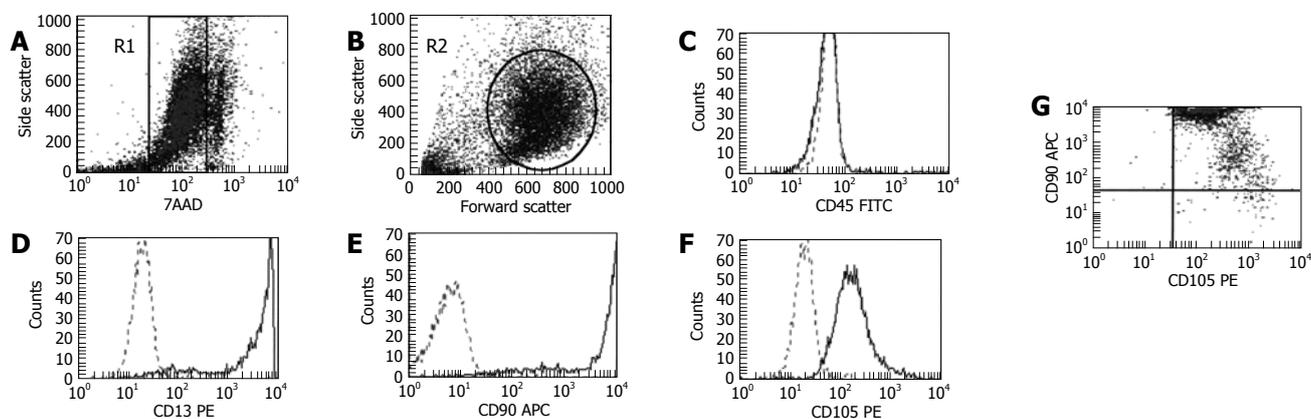

Figure 3 Flow cytometry analysis of surface protein markers of ADSC. Two analytical regions were established combining R1 region (A), which selects viable cells, and R2 (B) in forward and side characteristics of ADSC. Surface antigen markers were positive vis-à-vis isotypic controls for CD13 (D), CD90 (E) and CD105 (F) and negative for CD45 (C). Co-expression of CD90-CD105 is shown in dot-plots (G). 7ADD: 7-Aminoactinomycin D.

and at different steps of the culture. Representative histograms for BMSC and ADSC are shown in Figures 2 and 3 respectively. Both types of undifferentiated MSC were positive for the mesenchymal markers CD13 (Figures 2D and 3D), CD90 (Thy1) (Figures 2E and 3E) and CD105 (Figures 2F and 3F), but did not express the hematopoietic marker CD45 (Figures 2C and 3C). As shown in Figures 2G and 3G, the coexpression of both antigens CD90 (Thy1) and CD105 is found in ADSC and BMSC. ADSC showed an identical pattern of surface protein expression as BMSC, and no significant variation of surface marker expression was observed among cells from different donors. Table 2 shows that the percentage of positive cells after the primary culture of BMSC and ADSC is similar. Data for the mean fluorescence intensity for the markers CD90 and CD105 show differences between individual donors with a mean fluorescence greater for both markers in ADSC than BMSC. Nevertheless these last data may take into account the variations in the photomultiplier settings of the cytometer for the timing of the different cultures.

Morphologic changes in cultured ADSC and BMSC

We analysed the morphological changes of BMSC and ADSC at the various differentiation protocol stages in order to evaluate the effect of growth factors, hormones and cytokines. Both MSC obtained from human adipose tissue and human bone marrow expanded easily *in vitro*. However, ADSC showed a higher proliferation rate and longer survival in culture than BMSC. When cells were pre-cultured for 2 d in serum-free medium supplemented with EGF and bFGF, cell proliferation stopped. Cells before differentiation (D0) exhibited a fibroblast-like morphology (Figure 4A and B). Cell morphology of both BMSC (Figure 4C) and ADSC (Figure 4D) did not change significantly during differentiation step-1, when cultures were treated with HGF, although the fibroblastic morphology was lost and cells developed a broadened flattened shape. However, a polygonal shape developed during differentiation step-2 when cells were exposed to media containing OMS and hormones (Figure 4E and F). The protocol used includes the sequential addition of exogenous factors that have

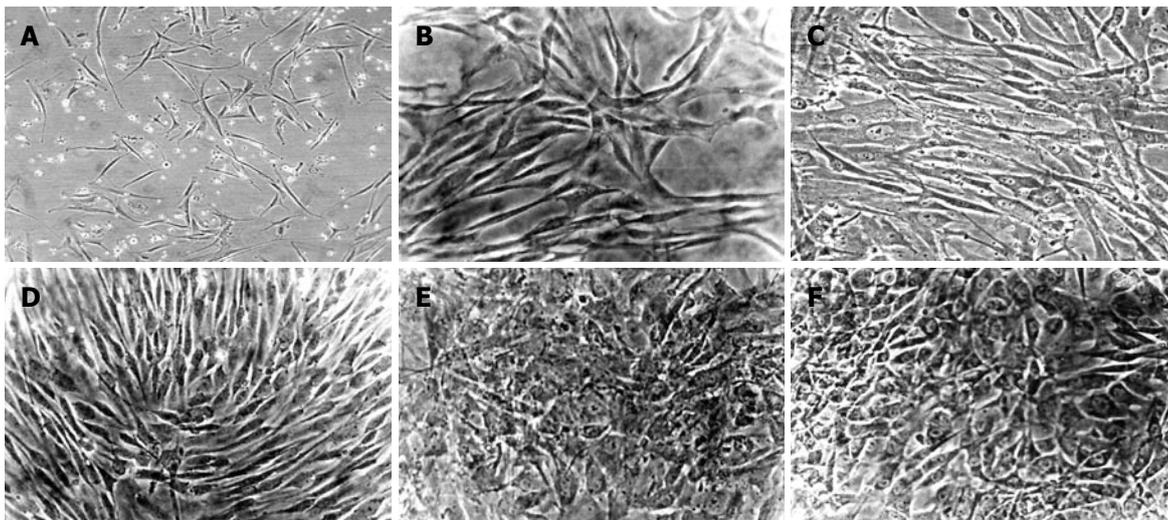

Figure 4 Morphology of human mesenchymal stem cells from bone marrow and adipose tissue during the differentiation protocol. Cells were induced to differentiate by using a sequential addition of growth factors, cytokines and hormones. Morphology of passage 2 BMSC (A) and ADSC (B) cells. No significant morphological changes were observed in BMSC (C) nor in ADSC (D) cells during the step-1 differentiation. However, both BMSC (E) and ADSC (F) cells significantly changed the morphology, and developed a polygonal shape during step-2 differentiation (magnification 20 x for all pictures).

Table 2 Expression of CD90 and CD105 in ADSC and BMSC after the initial culture

Donor	ADSC				BMSC			
	CD90 ⁺		CD105 ⁺		CD90 ⁺		CD105 ⁺	
	Cell population %	Mean channel fluorescence	Cell population %	Mean channel fluorescence	Cell population %	Mean channel fluorescence	Cell population %	Mean channel fluorescence

been reported to be implicated in liver development and proved to be effective to induce the hepatic differentiation of human MSC from human bone marrow and umbilical cord blood^[39].

RT-PCR analysis of hepatic gene expression of BMSC and ADSC differentiated cells

To determine whether differentiated cells show the characteristic expression of hepatic phenotype markers, total RNA from BMSC and ADSC was isolated at D7, 14 and 21 of the differentiation protocol and the mRNA levels of several hepatic genes were examined by RT-PCR. Undifferentiated cells were used as controls (D0 of the differentiation protocol). The CK-18 and CK-19 expression did not significantly change by induction of differentiation (data not shown). Expression of HNF4 α , C/EBP β (liver-enriched transcription factors that play important roles in regulating the expression of hepatic genes) and albumin were significantly increased with the

differentiation time in both cell types, BMSC and ADSC. However, the expression of hepatocyte specific markers in ADSC occurs predominantly in the first differentiation step, whereas the second differentiation step is required in BMSC. It is unclear whether this fact could imply functional differences between both cell populations, and further research is needed to clarify this point. The time-course induction of C/EBP β correlated well with albumin upregulation (Figure 5A-C), while HNF4 α induction showed a different profile (Figure 5D). The increase in key liver-enriched transcription factors suggests that our differentiation protocol was effective in driving MSC toward a hepatic phenotype.

Then, we went on to compare the levels of the Thy1 (CD90) and alphafetoprotein (AFP) expressions in ADSC and BMSC with that of adult human liver tissue from a liver bank (pooled liver from 10 donors). To this aim, we performed quantitative RT-PCR relative to housekeeping hPBGD at the initial and final times of the differentiation

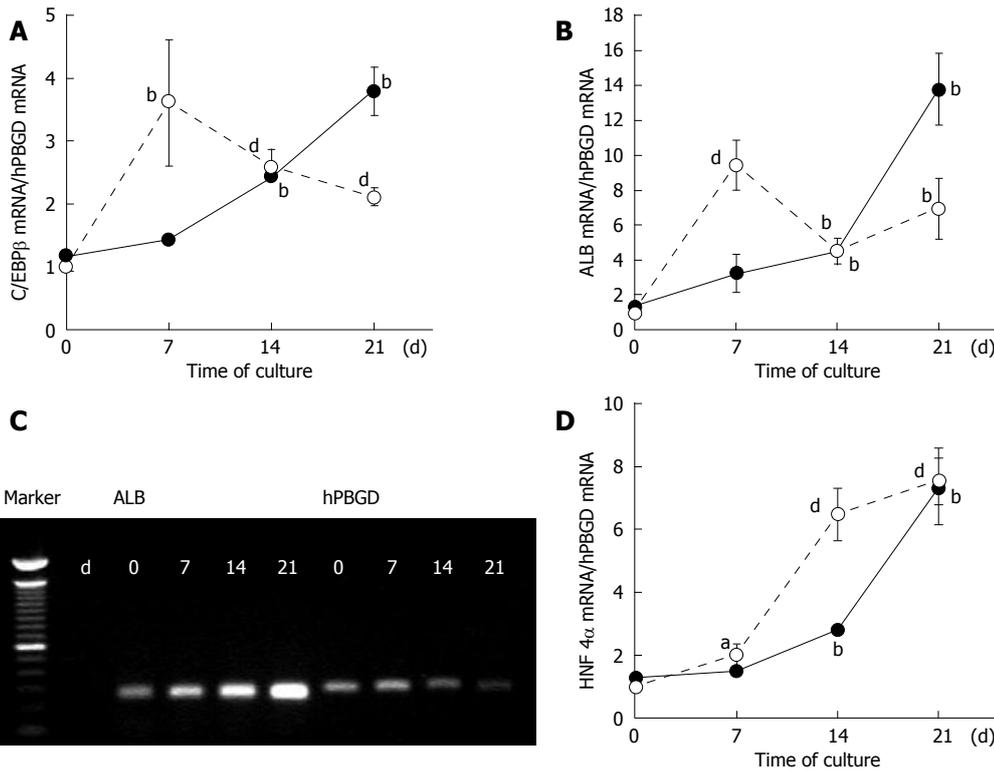

Figure 5 Real-time PCR analysis of the expression of mRNA for liver markers determined at established times in the transdifferentiation protocol of BMSC and ADSC. Expression of C/EBPβ (A) (liver-enriched transcription factor, that plays important roles in regulating the expression of hepatic genes), albumin (B and C) and HNF4α (D), were analysed in BMSC (bold symbols) and ADSC (clear symbols) at different time points of the differentiation protocol. Data are shown as the fold increase in the mRNA level compared to the undifferentiated cells (d 0 of the differentiation protocol), and were normalized by hPBGD. The agarose gel shows the ALB expression of BMSC (C). HNF4α: hepatocyte nuclear factor 4 alpha; C/EBPβ: CCAAT / enhancer binding protein beta; ALB: albumin. Data are the mean ± SE of 5 and 6 different cultures of BMSC and ADSC respectively. ^a*P* < 0.05; ^b*P* < 0.01; ^c*P* < 0.001.

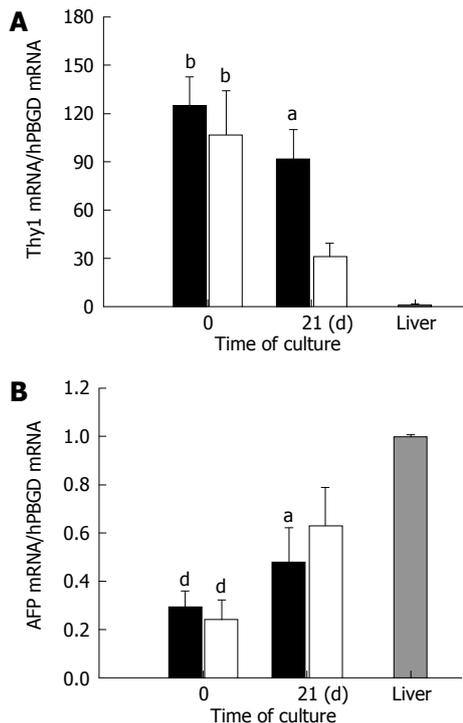

Figure 6 Real-time PCR analysis of the expressions of mRNA for Thy1 and alphafetoprotein in BMSC and ADSC. The levels of Thy1 (CD90) (A) and the alphafetoprotein (B) expression in differentiated BMSC (black bars) and ADSC (clear bars) were quantified by RT-PCR at the initial and final times of the differentiation protocol, and compared with that of human pooled liver tissue from a liver bank. Data are shown as a fold increase in the mRNA level compared to the liver tissue and normalized by hPBGD. AFP, alphafetoprotein. Data are the mean ± SE of 4 different cultures of BMSC and ADSC. ^a*P* < 0.05; ^b*P* < 0.01; ^c*P* < 0.001.

protocol. The relative mRNA levels of the mesenchymal marker Thy1 in undifferentiated ADSC and BMSC was significantly higher (*P* < 0.01), than in human liver, as expected (Figure 6A). However, after 21 d of the

differentiation protocol ADSC significantly reduced the Thy1 expression level, while a more modest decrease was observed in BMSC (*P* < 0.05). AFP is considered a characteristic fetal hepatic marker. AFP expression levels in fetal mouse liver steadily increases 1000-fold from day 9.5 to 15.5 of gestation and drops dramatically in adult liver. At low levels however, AFP is still reproducibly detected in multiple adult liver samples by real-time RT-PCR. Regarding AFP, a similar level of expression was observed in undifferentiated ADSC and BMSC, where it was significantly lower than that in liver (*P* < 0.001). However, differences with liver tissue were reduced in ADSC (NS) and BMSC (*P* < 0.05) after the step-2 protocol (Figure 6B). In the less differentiated human hepatoma HepG2 cells, AFP expression was much higher than in differentiated MSCs or liver tissue (data not shown).

We also determined the expression of CYPs (CYP2E1 and CYP3A4) as well as the differentiated markers of adult hepatic phenotype in ADSC and BMSC. We compared expression levels by RT-PCR at the initial and final times of the differentiation procedure (Figure 7). Levels of CYP2E1 in the undifferentiated MSC were not significantly different from that of the human hepatoma HepG2, a cell line showing characteristics of fetal hepatocytes. However, a significant increase of CYP2E1 expression was observed at the final differentiation time in both ADSC (*P* < 0.01) and BMSC (*P* < 0.001) (Figure 7A). Levels of CYP3A4 at the initial time were significantly lower in MSC when compared with HepG2 (*P* < 0.001), but these levels increased in the differentiated cells: BMSC showed a similar mRNA level while ADSC reached a higher expression level than the HepG2 cells (*P* < 0.001) (Figure 7B and C). The expression level of CYP2E1 and CYP3A4 in differentiated MSCs was still lower than in human hepatocytes (data not shown), which suggests that

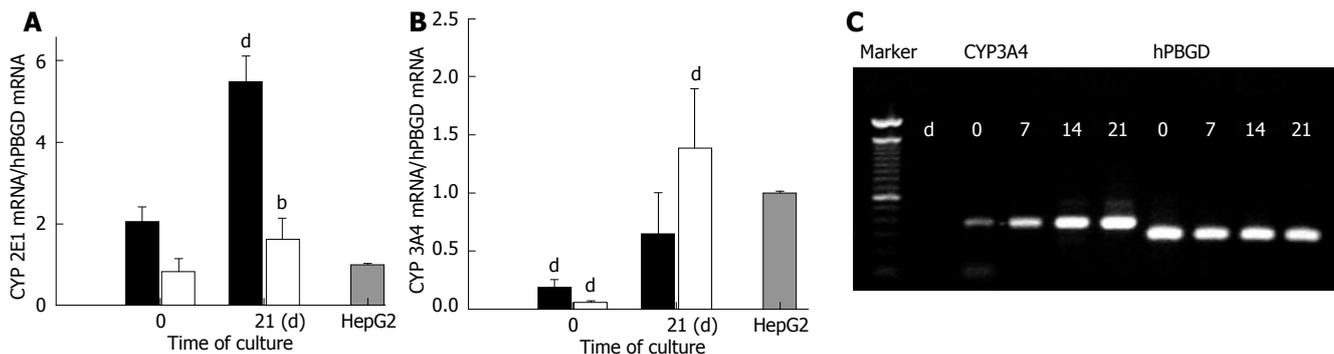

Figure 7 Real-time PCR analysis of the expression of mRNA for CYP2E1 and CYP3A4 in BMSC and ADSC. The expression of two major drug metabolising enzymes, CYP2E1 (A) and CYP3A4 (B), in BMSC (black bars) and ADSC (clear bars) were quantified by RT-PCR at the initial and final times of the differentiation protocol, and compared with that of the human hepatoma cells HepG2. The agarose gel shows the CYP3A4 expression of ADSC (C). Data are shown as a fold increase in the mRNA level compared to HepG2, and were normalized by hPBGD. Data are the mean \pm SE of 3 different cultures of BMSC and ADSC. ³*P* < 0.01; ⁴*P* < 0.001.

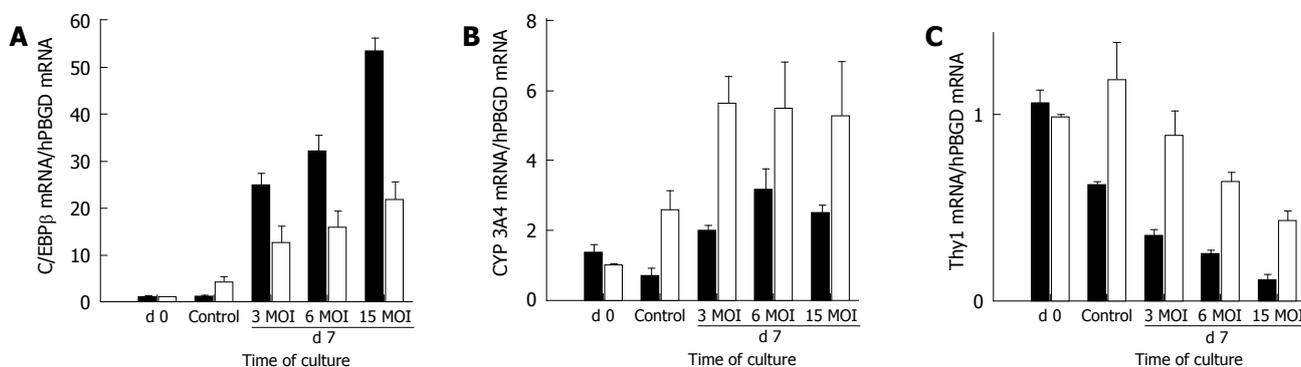

Figure 8 Evaluation of the role of C/EBP transcription factors in the differentiation of BMSC and ADSC cells. Adenoviral transduction caused a dose-dependent increase in the level of C/EBPβ mRNA, as assessed by real-time PCR analysis (A). Concomitantly, an up-regulation of CYP3A4 was observed which was more significant in ADSCs (B), and was paralleled by a significant down-regulation of the mesenchymal cells marker Thy1 in both BMSC and ADSC (C). Controls were not transduced. Data are shown as a fold increase in the mRNA level compared to the control and normalized by hPBGD. Data are the mean \pm SE of 3 different cultures of BMSC and ADSC.

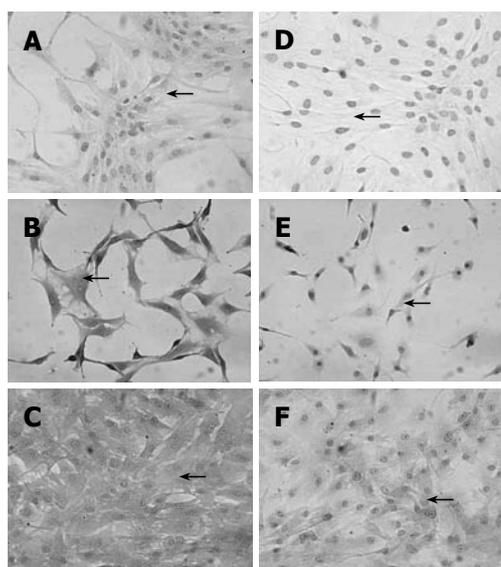

Figure 9 Immunohistochemical analysis of albumin and AFP in ADSC cells. Homogeneous expression of albumin (A-C) and AFP (D-F) in ADSC cells was further confirmed by immunocytochemistry. Staining for both albumin and AFP was negative in undifferentiated cells (A,D). ADSC cells homogeneously increase their protein expression levels in response to the differentiation protocol. Positive staining was shown after 14 d (B, E) and 21 d (C, F) of the 2-step differentiation protocol. AFP; alphafetoprotein.

additional stimuli may be needed to reach adult physiologic expression levels of CYP genes. By taking these results together it is difficult to clarify whether ADSC and BMSC are in fact equally potent hepatic progenitor cells, and further functional studies are required.

Role of C/EBP transcription factors in mesenchymal to hepatic transition

We observed a significant increase in the expression of key liver transcription factors during the transdifferentiation of MSC into the hepatic phenotype. To investigate the relevance of this finding, we transduced undifferentiated cells with adenoviral vectors encoding full-length C/EBP proteins and analyzed their effects by driving MSC towards the hepatic phenotype. The most important results were found with C/EBPβ, while C/EBPα appeared to play a minor role.

Cells were transduced after seven d of culture with increasing doses of adenoviruses, ranging from 3-15 MOI. Infection of MSC with a control adenovirus expressing the GFP demonstrated an 85%-95% transduction efficiency. Moreover, transduction of MSC with Ad-GFP or Ad-PAC (insertless adenoviral vector) up to 15 MOI neither modified the morphology nor the expression of

differentiation marker genes, demonstrating that all the effects observed in Ad-C/EBP transduced cells can be attributed to the increased expression of the adenoviral transgene (data not shown). As expected, adenoviral transduction caused a dose-dependent increase in the level of C/EBP β mRNA (Figure 8A). Concomitantly, we observed an up-regulation of CYP3A4, which was more significant in ADSCs (Figure 8B), and expression levels above those found in well-differentiated hepatoma cells were reached. In parallel, we observed a significant down-regulation of the mesenchymal marker Thy1 (Figure 8C), suggesting that the C/EBP β up-regulation is an important event in triggering the mesenchymal to hepatogenic transition.

Immunohistochemistry

To further confirm the homogeneous expression of albumin and AFP in our cell populations, we examined differentiated ADSC by immunocytochemistry. This analysis showed that undifferentiated cells stain negative for albumin and AFP (Figure 9A and D). Positive staining was detected at the end of step-1 differentiation when cells had been exposed to HGF (Figure 9B and E), and a more intense positive staining was found at d 21 at the end of step-2 differentiation, when cells were cultured with OSM and hormones (Figure 9C and F). Our results demonstrate that the levels of hepatic protein markers increased homogeneously in most of the ADSC cells in response to the differentiation protocol, correlating well with mRNA expression analysis.

DISCUSSION

Over recent years, stem cells have generated great interest given their potential therapeutic use. Bone marrow has been the best characterized tissue, and has been considered as the major source of multipotent adult MSC since it is able to differentiate into mesodermal and ectodermal lineages^[11-16]. Several studies have indeed shown the potential of BMSC to differentiate into hepatocyte-like cells^[3,7,8,17,18]. However, the presence of uncommitted MSC has been found in many other tissues, such as adipose tissue, thus representing an alternative source of multipotent stromal cells^[1,19-22]. In fact, human ADSC have similar characteristics to BMSC^[22,23,30,31]. In addition, Zuk *et al*^[22] reported that ADSC are capable of differentiating *in vitro* into several cell lineages. Moreover, it has been recently shown for the first time that human ADSC can differentiate towards hepatic lineage *in vitro* under appropriate culture conditions^[22]. Therefore, adipose tissue may be readily accessible and a good candidate as a source of stem cells with a therapeutic potential for hepatic cell therapy and tissue engineering. Although this is a controversial area, some studies clearly show that transplanted bone-marrow-derived hepatocytes can colonise a wide variety of tissues in the body of a host due to cell fusion^[40,41], while others do not report cell fusion^[42].

Although the stem cell differentiation mechanism remains unclear to date, transdifferentiation might either be induced by stimulating with suitable media/substrates/factors, or by genetic reprogramming *in vitro*^[43-45]. Liver

development is known to proceed *via* several distinct steps in which growth factors and cytokines are involved. Among the factors implied in the embryonic liver development, fibroblast growth factors (FGFs), produced by cardiac mesodermal cells, are involved at an initial stage of endodermal patterning to induce hepatic fate^[46,47]; OSM, a member of the interleukin-6 cytokine family produced by hematopoietic cells, is required from the mid-fetal to the neonatal stages^[48] and apparently coordinates liver development and hematopoiesis in the fetus^[49]; finally, several extracellular signals including EGF, HGF, OSM, FGFs, glucocorticoids and insulin are involved in the late maturation stage leading to an increase in liver-specific gene expressions, and their effects on differentiation vary as a function of gestation age^[50]. Corticosteroids, HGF and EGF play important roles in hepatic biology^[51]. HGF is a more potent proliferating factor for human hepatocytes in culture than EGF^[52,53], and plays an important role in liver development and regeneration in humans^[54,55]. The differentiation of BMSCs into hepatocyte-like phenotypes *in vitro* by induction with HGF has been reported^[55,56]. Other reports showed differentiation of bone marrow-derived MAPC toward hepatocyte-like cells induced by FGF-4, however the degree of differentiation was higher when cells were also treated with HGF^[6]. This is consistent with the fact that FGF-4 may play a role in endoderm specification^[47], and that HGF induces differentiation of hepatocytes that are not actively proliferating^[55]. Bone marrow cells cultured with HGF and EGF showed morphologic and phenotypic characteristics of mature hepatocytes^[54]. OSM has been shown to have a specific differentiation-inducing effect on primary fetal hepatic cells towards mature hepatocytes, and the presence of glucocorticoids is required for OSM effects^[49,58].

In this study we have investigated the induction to the hepatogenic differentiation of human ADSC in comparison with BMSC. Seo *et al*^[32] first showed that ADSC can be differentiated into hepatocyte-like cells by treatment with cytokine mixtures (HGF and OSM) and DMSO in serum-free medium. However, we have used a 2-step differentiation protocol with a sequential addition of growth factors (bFGF), cytokines (OSM and HGF), hormones (dexamethasone and insulin) and nicotinamide, which have been reported to be involved in the development and differentiation of hepatocytes^[57,59]. The choice of exogenous factors and the time course to induce hepatogenic transdifferentiation are based on previous reports on BMSC differentiation^[6,39]. As previously mentioned, HGF plays an essential role in the development and regeneration of the liver^[57]; bFGF is required to induce a hepatic fate in the foregut endoderm^[6]; OSM increases hepatocyte size and enhances hepatic differentiation^[57], whereas nicotinamide significantly enhances the *in vitro* maturation of fetal liver cells^[59].

The morphologic and phenotypic features and gene expression changes in both types of cells have been compared. Finally, the role of key hepatic transcription factors in the regulation of the transdifferentiation process has been investigated using adenoviral vectors. The results show that MSCs are capable of giving rise to a hepatogenic transdifferentiation in response to a sequential addition of

growth factors, assessed by an examination of morphology and hepatocyte-specific markers.

It should be highlighted that we have established the culture conditions of both human BMSC and ADSC, as well as the differentiation protocol under adequate conditions for a suitable supply of hepatocyte-like resources for the potential use of human cell transplantation therapy. To achieve this purpose, we have used only a human serum controlled stock from our blood bank instead of fetal calf serum for cell cultures. Cells were serum deprived for 2 d prior to inducing hepatic transdifferentiation, and were then cultured in serum-free conditions (Figure 1). Furthermore, we always used passage 2 cultures for differentiation assays, as it is convenient to differentiate cells for clinical use in low passages to avoid spontaneous differentiation.

Similar morphological changes were observed in BMSC and ADSC, as shown in Figure 4. During Step-1, cells developed a fibroblastic-like flattened shape, but changed to a polygonal morphology during Step-2 in the presence of OMS and hormones. These morphological changes, in parallel with the differentiation process, are coincident with those shown in previous reports either in BMSC^[6,39] or ADSC^[30,32]. BMSC and ADSC cells showed similar expression pattern surface protein markers, and no significant variations of surface marker expression were noted among different samples (Figures 2 and 3). We also found that both undifferentiated MSC cell types were positive for stem cell markers, such as Thy1, CD105 and CD13, but they did not express the hematopoietic marker CD45 in agreement with previous reports^[30,32,58]. The relative amount of Thy1 in undifferentiated ADSC and BMSC cells was significantly higher than in liver cells, but a significant decrease was observed in the differentiated cells, particularly in ADSC. A similar pattern was observed in the amount of AFP in undifferentiated ADSC and BMSC, and it was lower than that in liver. The differentiation potential of BMSCs and ADSC toward the hepatic phenotype was supported by the expression of albumin and CYP isozymes (CYP2E1 and CYP3A4). Albumin expression increased similarly in differentiated BMSCs and ADSC. Homogeneous albumin expression in differentiated ADSC was further confirmed by immunocytochemical analysis, as also shown in BMSC by other authors^[6,32,60]. Concerning the biotransformation capability of differentiated ADSC and BMSC assessed by the expression of CYP2E1 and CYP3A4, a significant increase in CYP2E1 levels was found in differentiated MSCs when compared with the HepG2 cells. The widely used human hepatoma cell line HepG2 expresses gene products that are characteristic of fetal hepatocytes, including serum albumin^[61]. However, hepatoma cells of the fetal phenotype are deficient in the use of certain hepatic transcription factors and show low levels of well-characterized adult liver genes, such as CYP2E1 and CYP3A4. Differentiated ADSC showed higher CYP mRNA levels than HepG2 cells, although the gene expression was still lower than that in the adult liver. Thus, our results suggest that hepatogenic differentiation in ADSC cells was successful, although the hepatocyte adult phenotype was not reached and may require further differentiation steps.

CYP3A4 levels were significantly increased in both differentiated MSCs, although the increase of CYP3A4 levels in differentiated ADSC was consistently higher compared with both the initial time and with HepG2 cells levels. Biotransformation capability, assessed by PROD activity, has been reported in human and rat MAPC derived from bone marrow^[6]. However, studies on ADSC differentiation into hepatic lineage are very scarce^[30,32] and there are no previous results showing CYP expression in differentiated ADSC. The expression pattern and related activity profiles of CYP isoenzymes in the differentiated cells suggest that these cultures might be useful to study many aspects of drug metabolism and drug-related toxicity pathways^[62].

The molecular mechanism, by which our 2-step protocol induces the transdifferentiation of ADSC and BMSC into hepatic lineage cells, seems to be dependent on the induction of several liver-enriched transcription factors, such as C/EBP β and HNF4 α . We opted to investigate these two transcription factors for several reasons. C/EBP β is a key component that distinguishes the liver program of differentiation. The relevance of C/EBP β has been emphasized in recent studies which reveal that pancreatic cells can be transdifferentiated into hepatocytes. In these studies, transdifferentiation was associated with both an elevation of expression of the transcription factor C/EBP β and a reduction of the transcription factor Pdx-1 (pancreatic duodenal homeobox-1). Moreover, transfection of C/EBP β into the cells can provoke transdifferentiation; while a dominant-negative form of C/EBP β can inhibit the process^[63,64]. Similarly, HNF4 α seems to be a very important factor to establish hepatic lineage as HNF4 α was shown to be responsible for the final commitment of oval cells to differentiate into hepatocytes, which regenerate the liver parenchyma^[65]. Moreover, HNF4 α is essential for the morphological and functional differentiation of hepatocytes and the generation of a hepatic epithelium. It has been shown that HNF4 α is a dominant regulator of the epithelial phenotype because its ectopic expression in fibroblasts induces a mesenchymal-to-epithelial transition.

Other liver-enriched transcription factors have also been shown to be associated with the hepatic transdifferentiation of BMSC^[60]. The expressions of HNF1 α , HNF3 α , HNF3 β , HNF4 α , GATA4 and GATA6 were increased during the transdifferentiation of BMSCs, suggesting that hepatic nuclear factors and the GATA family of proteins could also be major components to induce this transdifferentiation^[60]. In this study however, C/EBP α and C/EBP β did not change. Our results demonstrate the induction of C/EBP β during the hepatic transdifferentiation of ADSC and BMSC. This discrepancy in the role of C/EBP β could result from a divergent differentiation protocol. In the study by Saji *et al.*^[60], bFGF was used to induce BMSC transdifferentiation and bFGF may not induce C/EBP β . However, HGF could well be a potent inducer of this transcription factor. It has been shown that HGF induced an early transition of albumin ALB-negative stem cells to ALB-positive hepatic precursors resembling hepatoblasts, and then OMS promoted their differentiation to mature

hepatocytes^[66]. In the first step of stem cell differentiation induced by HGF, the expression of C/EBP β was induced dramatically; when the C/EBP function was inhibited in stem cells, these no longer differentiated to hepatocyte-lineage cells^[66].

In conclusion, the autologous nature of mesenchymal stem cells, together with their putative multipotentiality, may make these cells an excellent choice for many future tissue engineering strategies and cell-based therapies. Previous results indicating the great similarity of the gene expression between BMSC and ADSC by gene array analysis have been reported^[30], supporting the hypothesis that both types of MSC cells originated from a common precursor. They both have a proliferation potential and similar expression pattern of surface markers.

The present study indicates that under certain defined inducing conditions, MSC, isolated from bone marrow and adipose tissue, can differentiate toward a hepatic phenotype *in vitro*. In addition to hepatic biochemical functions, as shown in a previous report^[32], our results demonstrate for the first time that differentiated ADSC also express key drug metabolising enzymes. ADSC have a similar differentiation potential towards the hepatic lineage just as BMSC have, but their abundance and accessibility, their longer culture period and higher proliferation capacity differ from BMSC (as suggested by the present study and previous reports)^[23,30,32]. Therefore, adipose tissue seems to be an ideal source of high large amounts of autologous multilineage mesodermal stem cells for tissue repair and cell therapy of hepatic tissues as well as for preclinical drug testing.

and smokers.

CONCLUSION: Our present method was proved to be a simple and accurate tool for measuring plasma 8-isoprostane. However, the clinical utility of plasma 8-isoprostane for drinking and smoking habits was limited since elevated 8-isoprostane levels were observed in female heavy drinkers, and no association was found between smokers and nonsmokers.

Abstract

AIM: To develop a simple and accurate method for quantifying 8-isoprostane in plasma by employing a combination of two-step solid-phase extraction of samples and a commercially available ELISA kit, and by this method to examine the effects of drinking and smoking habits against the levels of plasma 8-isoprostane in healthy Japanese volunteers.

METHODS: Plasma 8-isoprostane was extracted with ODS gel suspension followed by NH₂ Sep-Pak column. The 8-isoprostane fractions were assayed using a commercially available ELISA kit. We measured plasma 8-isoprostane levels in 157 healthy Japanese volunteers divided into three groups (64 non-habitual drinkers, 56 moderate drinkers and 37 habitual drinkers) according to their alcohol consumption per week. Genotypes of aldehyde dehydrogenase 2 (ALDH2) were also determined to investigate the plasma 8-isoprostane levels with reference to drinking habits. In addition, the plasma 8-isoprostane levels of 96 non-smokers and 61 smokers from the same subjects were compared.

RESULTS: Our method fulfilled all the requirements for use in routine clinical assays with respect to sensitivity, intra- and inter-assay reproducibility, accuracy and dynamic assay range. Significant increases of plasma 8-isoprostane levels were observed in female habitual drinkers when compared with those of non-habitual drinkers ($t = 5.494$, $P < 0.0001$) as well as moderate drinkers ($t = 3.542$, $P < 0.005$), and 8-isoprostane levels were also significantly different between *ALDH2*2/1* and *ALDH2*1/1* in the female habitual drinkers ($t = 6.930$, $P < 0.0001$), suggesting that excessive drinking of alcohol may increase oxidization stress, especially in females. On the contrary, no significant difference of the plasma 8-isoprostane levels was observed between non-smokers

INTRODUCTION

A number of studies have revealed that oxidative stress plays important roles in the pathogenesis of various diseases, such as cancer, diabetes and atherosclerosis^[1,2]. The 8-isoprostane present in biological fluids is produced from arachidonic acid by a non-enzymatic, free radical-catalyzed reaction, and has been proposed as a reliable marker for lipid peroxidation and oxidative stress *in vivo*^[3]. 8-Isoprostane is chemically stable, in contrast to other conventional markers of oxidative stress, and its levels in either plasma or urine are elevated in subjects who smoke^[4-8] and ingest alcohol^[9,10], as well as in patients with diabetes mellitus^[11], heart disease^[12-15], hypertension^[16], preeclampsia^[17] and asthma^[18]. Urinary 8-isoprostane levels increase during the progression of alcohol-induced liver disease^[9] and are decreased by abstinence^[10]. However, accurate measurement of 8-isoprostane is not easy and requires special instruments, such as GC/MS or LC/MS, since various types of analogues and metabolites are present in biological fluids. For instance, the plasma and urinary 8-isoprostane levels determined by a recently developed immunoassay were much higher than those obtained by GC/MS or LC/MS assays^[19,20]. This could be attributed to cross-reaction of the 8-isoprostane analogues and metabolites in the samples with the 8-isoprostane antibody used in the immunoassay.

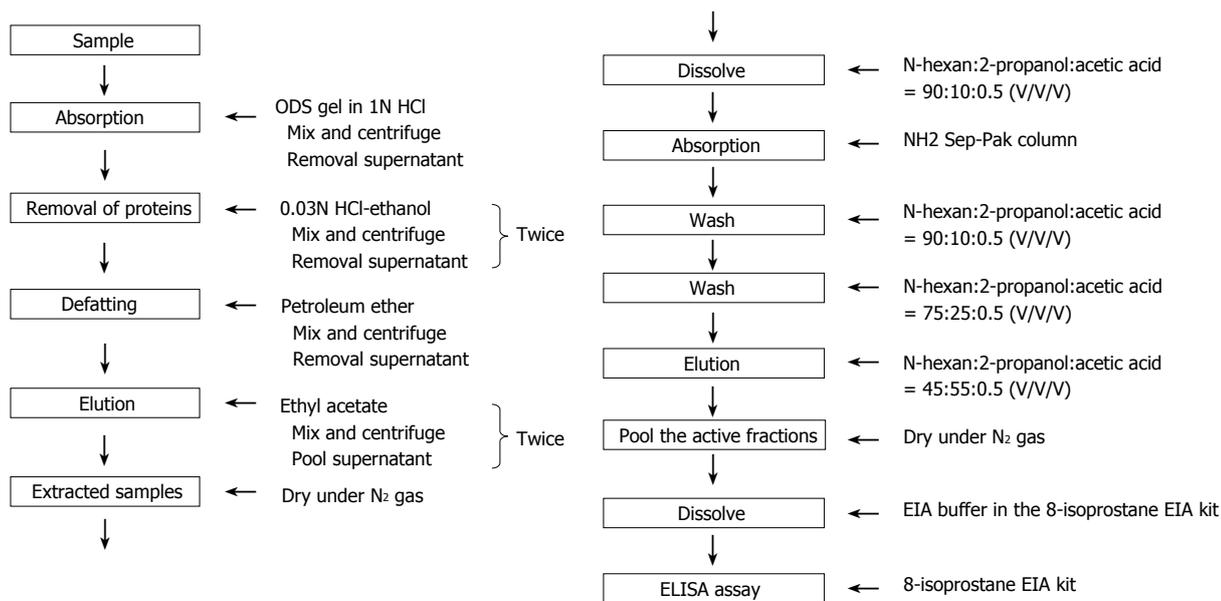

Figure 1 Flow chart of the improved ELISA for plasma 8-isoprostane.

In this study, we developed a new method for pretreatment before analyzing by the commercially available ELISA kit, and performed various examinations for accurate assay of 8-isoprostane. Using this method, we examined the effects of drinking and smoking habits against the levels of plasma 8-isoprostane in healthy Japanese volunteers.

MATERIALS AND METHODS

Samples

After informed consent was obtained, 157 healthy volunteers (83 males and 74 females; age 36.2 ± 8.4 years) were enrolled in this study. The information on drinking and smoking habits was collected by questionnaire. Volunteers were asked the frequency of drinking (nondrinker, rare drinking, 1-2 times/wk, 3-5 times/wk, almost every day), and smoker or nonsmoker. Various lipid parameters (TC, TG, LDL-C, HDL-C, ApoA-I, apoB, apoE and Lp (a)) were measured by EDTA·2Na, and hepatic functions (AST, ALT and γ -GTP) were measured by serum. Blood samples for plasma 8-isoprostane assay were collected in the specific tubes containing 10 mmol/L EDTA·3Na, 20 kU/L Trasylol and 0.1 mmol/L indomethacin, and were separated within 4 h in an ice cooling both. Among the 157 subjects, plasma (heparin) samples were also collected from 3 healthy volunteers to test whether these samples could be used interchangeably for the 8-isoprostane assay. Furthermore, another 3 healthy volunteers as control subjects (2 males, 1 female; age 36.2 ± 8.4 years) were given alcohol (0.5-1.3 g/kg), and their plasma 8-isoprostane, serum AST, ALT, and γ -GTP were measured on D1 (ca. 12 h) and 2 (ca. 36 h) after drinking to investigate the influence of alcohol on these levels. All plasma and serum samples were stored at -80°C until analysis.

Extraction of 8-isoprostane from plasma samples

A two-step solid-phase extraction procedure that was pre-

viously used for quantifying plasma TXA₂^[21] was modified for the purification of plasma 8-isoprostane. In principle, the first step of the extraction was performed to remove proteins and lipids using ODS gel (ODS-Q3; Fuji Gel, Tokyo, Japan) and the second step was used to separate 8-isoprostane from its analogues and related compounds using an NH₂ Sep-Pac column (Sep-Pak Vac NH₂; Waters, MA, USA). To optimize the extraction conditions, ³H-labeled 8-isoprostane and other related compounds including PGF₂ α , TXB₂, 6-keto-PGF₁, PGE₂ and PGD₂ (Cayman Chemical, MI, USA) were used as spiked tracers.

Extraction and measurement of 8-isoprostane

The detailed procedure for plasma 8-isoprostane extraction is shown in Figure 1. One milliliter of ODS gel suspension (80 mg silica gel ODS-Q3 in 0.1 mol/L HCl containing 40 mL/L ethanol) was mixed with 0.5 mL of plasma and allowed to stand at room temperature for 5 min. The gel was collected by centrifugation and washed twice with 1 mL of 0.03 mol/L HCl containing 150 mL/L ethanol and once with 1 mL of petroleum ether to remove proteins and lipids. 8-isoprostane was eluted from the gel twice using 1 mL of ethyl acetate for each elution. The eluates were combined, transferred to another test tube and dried under N₂ gas. The residue containing 8-isoprostane was dissolved in 1 mL of solution A (hexane: 2-propanol: acetic acid = 90:10:0.5, V/V/V), and applied to an NH₂ Sep-Pac column pre-equilibrated with solution A. The column was washed once with 5 mL of solution A, followed by another wash with 5 mL of solution B (hexane: 2-propanol: acetic acid = 75:25:0.5, V/V/V). Finally, 8-isoprostane was eluted from the column with solution C (hexane: 2-propanol: acetic acid = 45:55:0.5, V/V/V) and dried under N₂ gas. The residue was dissolved in 1 mL of the assay buffer included in the 8-isoprostane ELISA kit (Cayman Chemical). The ELISA was performed according to the manufacturer's instructions without further

purification of the samples, and the absorbance was measured with a plate reader (V-Max; Molecular Dynamics, NJ, USA). The 8-isoprostane standards included in the ELISA kit were extracted in the same way as the samples to obtain a calibration curve, which was used to estimate the 8-isoprostane levels in the samples.

Effect of interfering substances on the assay

Interference with the 8-isoprostane assay was tested before and after the addition of free and conjugated-bilirubin (up to 342 $\mu\text{mol/L}$), hemoglobin (up to 5 g/L) and triacylglycerol (up to 55 mmol/L) to each plasma sample. A concentrated reagent set of the interfering substances was purchased from International Reagents Co. Ltd. (Hyogo, Japan).

Storage stability of plasma 8-isoprostane under various conditions

Plasma samples were collected from the 3 control subjects using special tubes as described above. Aliquots of the samples were separately stored at -80°C , 4°C and 25°C . The 8-isoprostane levels were tested within 4 h after the blood collection and on d 1, 3, 7, 14, 21, 28 and 120 using fresh aliquots of the samples at each time point.

Determination of other lipid profiles and hepatic functions in blood samples

The concentration of TC, TG, LDL-C and HDL-C were determined by an enzymatic method (Kyowa Medics Co. Ltd, Tokyo, Japan). ApoA-I, apoB, apoE and Lp (a) were measured by using immunoturbidimetric assay kits (Daiichi Pure Chemicals Co. Ltd., Tokyo, Japan). AST and ALT were determined using UV method^[22] and γ -GTP were determined by L- γ -glutamyl-3-carboxy-4-nitroanilid substrate method^[23].

Genotyping of ALDH2

DNA was extracted from blood samples collected with EDTA \cdot 2Na using a commercially available kit (Sanko Pure Chemicals Co. Ltd., Tokyo, Japan). Mismatched PCR primers for determining the ALDH2 genotypes were designed with reference to the ALDH2 gene sequence (GenBank Accession No. AH002599). The wild-type allele (*ALDH2*1*) of ALDH2 was amplified using the forward and reverse primers CAAATTACAGGGTCAACTGCTATG and CCACACTCACAGTTTTCACTTC, respectively. The mutant type (*ALDH2*2*) of ALDH2 was amplified using the forward and reverse primers CAAATTACAGGGTCAACTGCTATG and CCACACTCACAGTTTTCACTTT, respectively. Amplification was performed in 25 μL of $1 \times$ Qiagen PCR buffer containing 0.2 $\mu\text{mol/L}$ of each ALDH2 primer, 200 $\mu\text{mol/L}$ of each dNTP, and 2 U of HotStartTaq DNA polymerase (Qiagen, Hilden, Germany). The PCR conditions were denaturation at 95°C for 10 min, followed by 35 cycles of amplification (30 s at 94°C , 30 s at 58°C and 30 s at 72°C). After electrophoresis in a 25 g/L agarose gel, the 135-bp PCR products were stained with ethidium bromide and visualized under UV light.

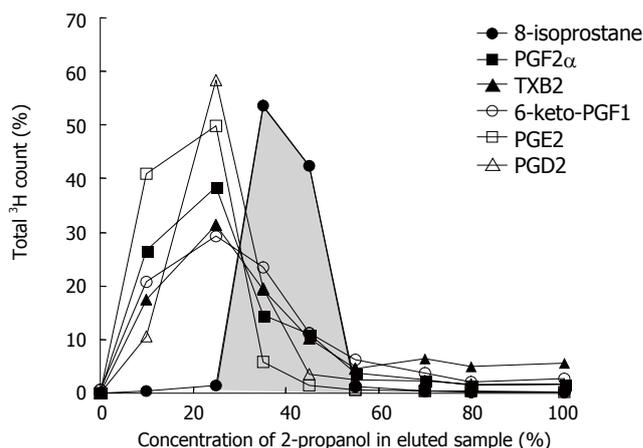

Figure 2 Results of the second extraction step using an NH_2 Sep-Pac column to isolate the plasma 8-isoprostane. Spiked plasma samples containing ^3H -labeled 8-isoprostane, $\text{PGF}2\alpha$, TXB2, 6-keto-PGF1, PGE2 or PGD2 were used. Samples extracted with ODS gel were used to assess the absorption by, washing and elution from the NH_2 Sep-Pac column.

Statistical analysis

Statistical analyses of the data were performed by the paired *t*-test using the In Stat computer software (version 3.06; GraphPad Software Inc.). The correlation between two variables was calculated by the non-parametric Spearman rank coefficient test. A corrected value of $P < 0.05$ was considered statistically significant.

RESULTS

Extraction of plasma 8-isoprostane

Using ^3H -labeled 8-isoprostane and its related compounds as spiked tracers, optimal conditions for the two-step solid-phase extraction of plasma 8-isoprostane were carefully determined. The method was based on a procedure used in a radioimmunoassay for serum TXA2^[21]. First, the plasma samples were treated with reverse-phase ODS gel to remove proteins and lipids. The 8-isoprostane bound to the gel was then eluted and separated from its related compounds on a Sep-Pac NH_2 column by stepwise elution with increasing concentrations of 2-propanol in the eluent. As shown in Figure 2, most of the 8-isoprostane eluted from the column at 55% 2-propanol, whereas the other compounds eluted at 10%-25% 2-propanol. The average yield of plasma 8-isoprostane in the overall extraction was estimated to be 67.1% by counting the ^3H -labeled 8-isoprostane in 5 spiked plasma samples.

Quantification of extracted 8-isoprostane by ELISA

Since it has been shown that plasma 8-isoprostane can be accurately measured using a commercially available ELISA kit after the two-step extraction, we next evaluated the analytical performance and accuracy of the overall ELISA for plasma 8-isoprostane. The detection limit of the ELISA kit was 2.2 ng/L, and this was defined as the concentration corresponding to the optical density of the zero calibrator plus 2SD. The reproducibility of this method estimated using the plasma samples from 3 control subjects was

Table 1 Plasma 8-isoprostane in three groups with different drinking habits (means \pm SD)

CI: 95% Confidence Interval.

4.2%-6.3% for the within-run (8 repeats) and 0.8%-8.1% for the between-run (5 repeats), respectively. To assess the linearity of the assay, the above mentioned plasma samples were diluted serially, extracted and measured for their 8-isoprostane levels. A good dilution linearity was obtained for the assay, as shown in Figure 3. Analytical recovery studies were carried out using 3 plasma samples containing 3 different concentrations of 8-isoprostane, revealing that the recovery rate ranged from 95.9%-97.8%. There were no significant differences between the 8-isoprostane levels in serum and those of the plasma collected with heparin, EDTA or EDTA + trasirol + indomethacin. All of the samples were freshly prepared and subjected to assay. No interference in the assay was observed for hemoglobin (up to 5 g/L), free bilirubin (up to 342 μ mol/L), conjugated bilirubin (up to 342 μ mol/L) or triacylglycerol (up to 55 mmol/L).

Storage stability of plasma 8-isoprostane

The 8-isoprostane in the plasma samples was stable for at least 120 d at -80°C , as long as freezing and thawing were avoided. However, 2 cycles of freezing at -80°C and thawing at room temperature decreased the apparent 8-isoprostane levels by 30%. It was previously reported that plasma 8-isoprostane was stable for 6 mo at -80°C , and increased approximately 1.4-fold after 3 cycles of freeze and thawing^[4]. Although the reason for this disagreement is not clear, it may be attributed to the method of blood collection, since we used blood collection tubes containing 10 mmol/L EDTA \cdot 3Na, 20 kU/L trasyolol and 0.1 mmol/L indomethacin, while they used common evacuated tubes containing EDTA \cdot 2Na (2.5 mmol/L). The EDTA and indomethacin could function to prevent the induction of new synthesis of 8-isoprostane in plasma samples during storage. When the plasma samples were stored at 4°C , 8-isoprostane levels increased rapidly after 1 wk and were 3-4-fold higher after 28 d. When the samples were stored at 25°C , 8-isoprostane levels reached 15-50-fold the original values after 28 d.

Association of plasma 8-isoprostane levels with drinking habits

The mean level of the plasma 8-isoprostane in 157 healthy subjects using our method was 20.9 ± 9.3 ng/L and no age

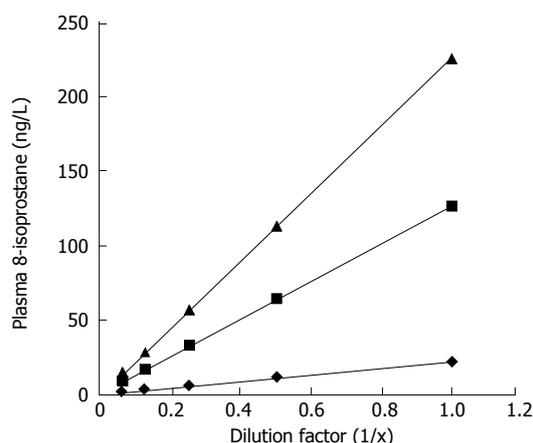

Figure 3 Dilution curves of plasma 8-isoprostane in 3 different plasma samples (\blacktriangle $y = 227.6x - 2.34$, $r = 0.999$; \blacksquare $y = 126.3x + 0.06$, $r = 1.000$; \blacklozenge $y = 21.8x - 0.04$, $r = 0.999$).

or gender differences were observed. For the drinking habits obtained by questionnaire, the subjects of each gender were divided into three groups according to their alcohol consumption, namely non-habitual drinkers (nondrinker, rare drinking, Group I, $n = 64$), moderate drinkers (1-2 times drinking/wk Group II, $n = 56$), and habitual drinkers (3-5 times drinking /wk, Group III, $n = 37$), and the plasma 8-isoprostane levels were compared among these groups. In females, the plasma 8-isoprostane levels were significantly higher in Group III (30.0 ± 10.3 ng/L) than in Group I (18.1 ± 5.0 ng/L, $P < 0.0001$) and II (20.8 ± 6.6 ng/L, $P < 0.005$), but not males (Table 1). The serum γ -GTP levels in Group III were elevated in both genders (males: 488 ± 335 nkat/L at 37°C ; females: 298 ± 185 nkat/L at 37°C) compared with those in Group I (males: 343 ± 253 nkat/L at 37°C ; females: 220 ± 70 nkat/L at 37°C ; $P < 0.05$ each). No significant differences in AST and ALT were observed among the three groups. The plasma 8-isoprostane levels showed no correlations with AST, ALT, γ -GTP and various lipid parameters (TC, TG, LDL-C, HDL-C, ApoA-I, apoB and Lp(a)) in the subjects (Table 2).

Next, the subjects in each group were further divided into 3 groups according to their ALDH2 genotypes, and the plasma 8-isoprostane levels were compared along with those of AST, ALT and γ -GTP. For both the *ALDH2*1/1* and *ALDH2*2/1* genotypes, the plasma 8-isoprostane level was significantly higher in Group III than that in Groups I and II (Table 3) in both genders. This tendency was more prominent in females with the *ALDH2*2/1* genotype. Especially, the 8-isoprostane level was significantly higher in female habitual drinkers with the *ALDH2*2/1* than those with the *ALDH2*1/1* genotype (41.2 ± 12.3 vs 26.9 ± 7.7 ng/L, $P < 0.0001$). The mean level of AST in subjects with the *ALDH2*1/2* genotype was significantly higher in Group III than in Group II (22.3 ± 9.2 vs 17.1 ± 2.5 nkat/L at 37°C , $P < 0.05$). The γ -GTP level was significantly higher in subjects with the *ALDH2*1/1* genotype than those with the *ALDH2*1/2* genotype (478 ± 396 vs 303 ± 198 nkat/L at 37°C , $P < 0.005$). Three healthy subjects (2 males, 1 female) were given alcohol (0.5-1.3 g/kg), and the changes in plasma

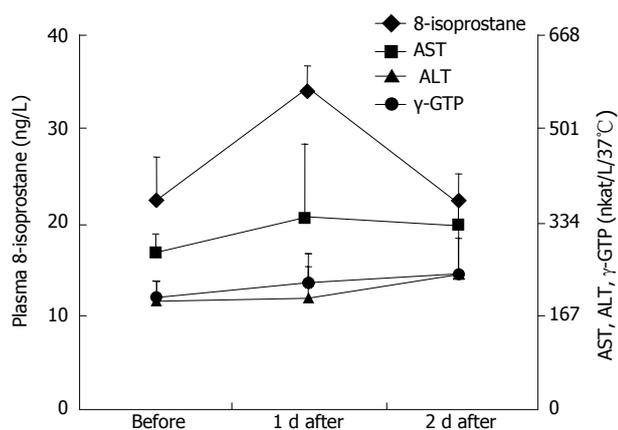

Figure 4 Changes in AST, ALT, γ -GTP and plasma 8-isoprostane after alcohol intake. The levels of plasma 8-isoprostane in the 3 individuals increase significantly on d 1 after drinking, but return to their original levels on d 2. No significant changes are observed in AST, ALT and γ -GTP.

8-isoprostane were assayed together with the serum AST, ALT and γ -GTP. Plasma 8-isoprostane significantly increased on d 1, and returned to its original level on d 2 (Figure 4).

Association of plasma 8-isoprostane with smoking habits

The same population of 157 healthy subjects were divided into two groups: non-smokers ($n = 96$; age 36.7 ± 8.2 years) and smokers ($n = 61$; age 35.3 ± 8.7 years), and their plasma 8-isoprostane levels were compared. As shown in Figure 5, no significant difference of plasma 8-isoprostane level was observed between these two groups (21.5 ± 7.3 vs 22.8 ± 7.4 pg/mg).

DISCUSSION

We have developed a simple and accurate method for quantifying plasma 8-isoprostane by employing a combination of two-step solid-phase extraction of samples and a commercially available ELISA kit.

When the plasma 8-isoprostane level was measured by using our method, the mean value of 157 healthy volunteers was 20.9 ± 9.3 ng/L, which is almost equal to the reported values using GC/MS or LC/MS^[5,24,25]. The level of plasma 8-isoprostane in 4 healthy subjects among these samples measured directly by ELISA without

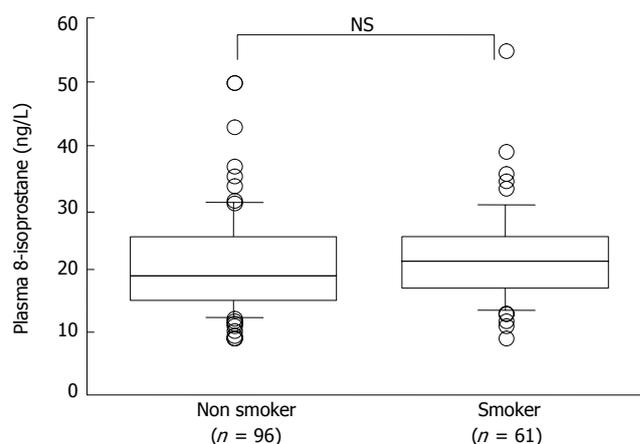

Figure 5 Effect of smoking habit on plasma 8-isoprostane levels. The levels of plasma 8-isoprostane were not significantly different between non smokers and smokers (21.5 ± 7.3 vs 22.8 ± 7.4 ng/L).

extraction was more than 20-fold higher than those obtained by the combination of the two-step extraction and ELISA (651.5 ± 149.2 vs 24.4 ± 4.1 ng/L). According to 8-Isoprostane EIA kit booklet, although the cross-reactivity of the anti 8-isoprostane antibody employed in the ELISA kit is reported to be low, the extraction of plasma 8-isoprostane from plasma prior to the assay is indispensable. In fact, it has been reported that various 8-isoprostane analogues and related compounds are present at dozens to hundreds of times than the concentration of 8-isoprostane in biological fluids^[26].

In an association study of plasma 8-isoprostane with drinking habits, heavy drinkers were higher than non-habitual drinkers and moderate drinkers. However, the plasma 8-isoprostane level was not significantly different when compared among the 3 male groups. Also, the plasma 8-isoprostane levels were significantly higher in heavy drinkers than in non-habitual and moderate drinkers. This tendency was more prominent in females, and with the *ALDH2*21/1* genotype. In other words, the 8-isoprostane level was significantly higher in female habitual drinkers with the *ALDH2*2/1* than with the *ALDH2*1/1* genotype. These results suggest that excessive drinking may increase oxidative stress, especially in females with the *ALDH2*2/1* genotype. When the same amount of alcohol is ingested, females tend to show

Table 3 Plasma 8-isoprostane analyzed by ALDH2 genotype in three groups with different drinking habits (means ± SD)

		Plasma 8-isoprostane (ng/L)			Group III vs	Group III vs

a higher concentration of blood alcohol than males due to their lower body weight and higher ratio of adipose tissue into which alcohol shows poor penetration. In addition, female hormones, such as estradiol, inhibit the activity of ADH, contributing to the increased concentration of blood alcohol^[27].

Changes in plasma 8-isoprostane levels after alcohol (0.5-1.3 g/kg) intake for 3 d, showed 8-isoprostane significantly increased on d 1, and returned to its original level on d 2. It was previously reported that alcohol consumption induced lipid peroxidation in healthy volunteers, and urinary 8-isoprostane increased in a dose- and time-dependent manner reaching its peak at 0-6 h after ingestion^[9], and through induction of the CYP450 2E1 isozyme, alcohol intake may increase the generation of reactive oxygen intermediates that have the potential to peroxidize lipids^[28,29]. Similarly, our results may suggest that alcohol ingestion induced oxidative stress in a relatively short time after drinking.

It has been reported that smoking induces oxidative stress and increases urinary 8-isoprostane^[30]. Therefore, we compared plasma 8-isoprostane levels in non-smokers and smokers. In contrast to urinary 8-isoprostane, no difference in plasma 8-isoprostane was observed between these 2 groups. This is consistent with a previous report measured by LC/MS^[5]. The plasma 8-isoprostane may be rapidly metabolized since 75% of plasma 8-isoprostane is excreted in the urine within 4.5 h^[31].

In conclusion, we have developed a simple and accurate method for quantifying plasma 8-isoprostane by employing a combination of two-step solid-phase extraction of samples and a commercially available ELISA kit. Our method fulfilled all the requirements for use in routine clinical assays with respect to sensitivity, intra- and inter-assay reproducibility, accuracy and dynamic assay range. However, the clinical utility of plasma 8-isoprostane for drinking and smoking habits was limited. Further studies

using a large population is required for a final conclusion for an association of plasma 8-isoprostane with drinking and smoking habits.

Abstract

AIM: To elucidate the significance of Doppler measurements of hepatic vein in cirrhotic patients and to correlate with liver dysfunction and hepatic hemodynamics.

METHODS: One hundred patients with liver cirrhosis and 60 non-cirrhotic controls were studied. Doppler waveforms were obtained from right hepatic vein and flow velocity measured during quiet respiration. Doppler measurements were also obtained from portal trunk, right portal vein and proper hepatic artery.

RESULTS: Hepatic vein waveforms were classified into three classical patterns. Flat waveform was uncommon. Mean hepatic vein velocity was significantly higher in cirrhotic patients (12.7 ± 6.4 vs 5.1 ± 2.1 and 6.2 ± 3.2 cm/s; $P < 0.0001$). The poorer the grade of cirrhosis, the higher was the mean velocity. Maximum forward velocity was never greater than 40 cm/s in controls. Degree of ascites was found to be highly correlated with mean velocity. "Very high" group (≥ 20 cm/s) presented clinically with moderate to massive ascites. Correlations between right portal flow and mean velocity was significant ($P < 0.0001$, $r = 0.687$).

CONCLUSION: Doppler waveforms of hepatic vein, which is independent of liver dysfunction, should be obtained during normal respiration. Mean hepatic vein velocity reflects the change in hepatic circulation associated with progression of liver cirrhosis. It can be used as a new parameter in the assessment of liver cirrhosis.

Key words: Hepatic vein; Hepatic vein velocity; Doppler ultrasound

INTRODUCTION

There are many studies on inflow to the liver in liver cirrhosis (LC) in relation to hepatic dysfunction and portal hypertension. In LC, there are changes in liver parenchyma as well as alteration of hepatic vasculature, including morphological changes of the hepatic vein. Furthermore, it is accepted that abnormal circulation caused by hyperdynamic circulation and intrahepatic shunt persists in cirrhotic liver. Therefore, we assumed that an alteration in hepatic venous hemodynamics is present in cirrhotic liver. It is of interest to find out the clinical significance of hepatic venous hemodynamic changes in liver cirrhosis, and to explore which factor, singly or in combination, produces such changes if there is any. Due to the fact that hemodynamic studies of the hepatic vein is still limited, we aimed to study the hepatic venous hemodynamics using non-invasive Doppler ultrasonography.

Doppler waveform of the hepatic vein (HV) in healthy humans is a triphasic waveform, consisting of two negative waves and one positive wave^[1]. As for abnormal hemodynamics of the hepatic vein in cirrhotic liver, there are reports of Doppler studies suggesting that the waveform becomes flat when hepatocellular function is impaired, and some studies even proposed that flattening of the hepatic waveform could be used as a diagnostic tool for chronic parenchymal liver disease^[2-6]. However, there are equivocal results regarding change in waveforms of the HV in parenchymal liver diseases. The large degree of overlap in the waveforms between various types of parenchymal liver diseases makes the interpretation of waveform difficult. In this study, we aimed to reevaluate the use of Doppler waveform of the right hepatic vein in LC without respiratory maneuver, as there have been conflicting reports on use of it as a diagnostic tool in the chronic parenchymal liver disease. Furthermore, we studied a quantitative analysis of hepatic venous blood flow, which, to the best of our knowledge, has not been reported previously.

MATERIALS AND METHODS

Subjects

One hundred and sixteen consecutive patients with LC, subjected to Doppler examination from July 2002 to September 2003, were enrolled in this prospectively designed study. Patients with enlarged inferior right hepatic vein ($n = 2$), portal thrombosis ($n = 5$), hepatofugal portal blood flow ($n = 2$), tricuspid regurgitation ($n = 2$), insufficient visualization of hepatic artery ($n = 2$), right portal vein ($n = 1$), and right hepatic vein ($n = 2$) were excluded from the study. Remaining 100 patients (57 women and 43 men; mean age 63 ± 7 years) were studied. The diagnosis of LC was based on histopathology and/or imaging diagnosis along with clinical and biochemistry parameters. The etiology of LC was viral in 77 (HCV: 69; HBV: 7; HCV + HBV: 1), alcohol in 14 and primary biliary cirrhosis in 9 patients. The severity of liver dysfunction, as assessed by Child-Pugh scoring system^[7], was A in 46, B in 29 and C in 25 patients. In addition, study was carried out in randomly selected 60 non-cirrhotic patients as controls. Among them were 30 patients with histopathological diagnosis of chronic hepatitis (14 women and 16 men; mean age 57 ± 7 years) without any evidence of LC and same number of volunteers (17 women and 13 men; mean age 57 ± 6 years) without any clinical, laboratory or imaging evidence of liver disease. Causes of chronic hepatitis were hepatitis C virus in 24, hepatitis B virus in 6 patients. The control group did not differ significantly from the study population with respect to age, sex, height and weight. Cardiac disease and respiratory disease that may cause change in the Doppler waveform of the hepatic vein were ruled out in all patients and controls.

Instrument

The instrument used in this study was a pulsed Doppler flowmeter (PowerVision 8000) with a 3.75-MHz convex and sector probe. The system is equipped with software to compute the time-averaged velocity from the velocity spectral display after placement of the calipers. Doppler sample volume was positioned in the center of the vessel or at the point when it was defined. The sample width was selected to cover almost entire vessel diameter. Pulse repetition frequency was adjusted so as not to exceed the limit of the displayed maximum velocity. Care was taken to ensure that the angle of insonation was always smaller than 60. Internal diameter of the vessels was measured manually after optimizing B mode images.

Doppler measurements

Each subject was examined after overnight fasting in supine position after a rest of 15 min so as to avoid any influence of food, posture and exercise. Overall assessment of the hepatobiliary system by B mode was made before Doppler examination. Size of the right lobe in cirrhotic patients was assessed by the method described by Matsutani *et al*^[8]. Visual grading of ascites as appeared during ultrasonography was done. Right hepatic vein was approached from right intercostal space. The reason behind choosing the right hepatic vein over other is that the middle and left hepatic vein often join each other before draining to the inferior venacava. Doppler study

of the hepatic vein was performed by positioning the sample volume between 2-3 cm from the opening into the inferior venacava. Patients were asked to breath normally during tracing of the waveforms. Hepatic Doppler waveforms were divided into three types. The waveforms were considered triphasic when one of the waves showed reversed flow, that is, any wave above the baseline. Flat waveforms were those without any phasic oscillation. Those without reversed flow but showing phasic oscillations were regarded as biphasic waveform. Mean flow velocity was calculated automatically by the instrument after tracing of the spectral display (of one cardiac cycle), whereas maximum and minimum velocity were calculated manually. For flat waveforms, ECG was simultaneously recorded to determine one complete cardiac cycle.

The portal vein was evaluated at about middle of the portal trunk by approaching from the epigastrium with the probe placed slightly obliquely. The right portal vein was approached from the right intercostal spaces. Mean velocity and flow (of portal trunk and right portal vein) were calculated by instrument after obtaining Doppler waveforms. The hepatic artery was examined similarly to the portal trunk as it runs almost parallel with the portal vein before entering into the hepatic hilum. At this position gastroduodenal arteries are expected to have branched from the common hepatic artery. Peak systolic velocity was calculated manually, whereas mean velocity was calculated by the instrument after manual tracing of the maximum point of the spectral display. Doppler examinations were performed by two authors (SKC and SM) without prior knowledge of clinical and biochemical status of the study population. Three readings were taken for each vessel and the mean of three was noted as the final reading. Written informed consent was obtained from all the patients and controls. The study protocol conforms to the ethical guidelines of the 1975 Helsinki Declaration, and approved by Senior Staff Committee.

Statistical analysis

The statistical analyses were carried out using SPSS ver. 10.0 (SPSS Inc., Chicago, IL, USA). All the measurements were expressed as mean \pm SD. To compare means, Student's *t* test was performed. For multiple values, ANOVA (analysis of variance) with LSD (least square design) was used. $P < 0.05$ and $r > 0.6$ were considered statistically significant.

RESULTS

Hepatic vein waveforms

All non-cirrhotic controls showed triphasic waveforms of HV. In cirrhotic patients triphasic pattern was observed in 49 (49%) patients, biphasic in 48 (48%) patients and flat in 3 (3%) patients. Types of the waveforms according to the grade of liver function are shown in Table 1. The result showed that the appearance of waveform was independent of the degree of severity of liver dysfunction as graded by Child-Pugh score. Flat waveform was very rare, appearing only on three occasions. Out of 3 patients, 2 were Child-Pugh A and were clinically stable. Hepatic encephalopathy and ascites were absent in all 3 patients.

Table 1 Hepatic vein waveforms in study population *n* (%)

	Non-cirrhotic controls		Liver cirrhosis patients		
	No liver pathology	Chronic hepatitis	A <i>n</i> = 46	B <i>n</i> = 29	C <i>n</i> = 25
Triphasic	30	30	26 (56.6%)	16 (55.2%)	7 (28%)
Biphasic	0	0	18 (39.1%)	13 (44.8%)	17 (68%)
Flat	0	0	2 (4.3%)	0	1 (4%)

There was no correlation between waveforms and liver dysfunction.

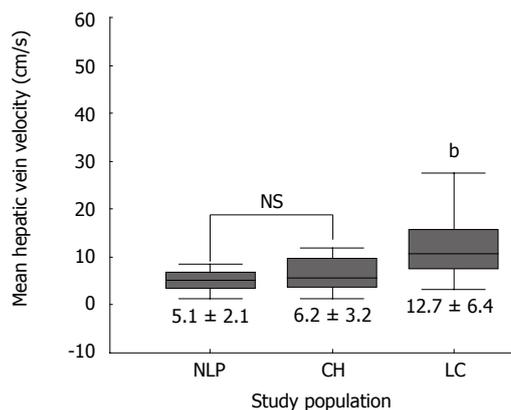

Figure 1 Mean hepatic vein velocity in study populations. It was significantly higher in cirrhotic patients than non-cirrhotic controls. (mean \pm SD; $^bP < 0.0001$ vs NLP and CH).

Correlation of hepatic vein velocity with liver dysfunction

Table 2 summarizes the results of hemodynamic data in the study population. Mean hepatic vein velocity was significantly higher in cirrhotics than non-cirrhotic controls (12.7 ± 6.4 vs 5.1 ± 2.1 and 6.2 ± 3.2 cm/s; $P < 0.001$) (Figure 1). There was no statistical significance of mean among three etiological subsets of cirrhotic patients (data not shown). The poorer the grade of cirrhosis by Child-Pugh grade, the higher was the velocity (Figure 2). Rise in MHVV was independent of hepatic vein diameter. We defined the “very high” group as those patients who had MHVV 20 cm/s or more. We took watershed of 20 cm/s as it was more than mean plus SD values and provided best separation between two groups. There were 15 patients who had MHVV more than 20 cm/s. Similarly, maximum forward velocity was higher in LC patients than controls (Figure 3). It was never more than 40 cm/s in controls. There was no correlation of MHVV with serum bilirubin ($P < 0.11$, $r = 0.279$), serum albumin ($P < 0.12$, $r = -0.276$) and prothrombin time ($P < 0.002$, $r = -0.377$) (Figure 4 A-C). On the other hand, there was strong correlation of MHVV with grades of ascites. We divided the patients into three groups: nil ($n = 62$), minimal ($n = 16$) and moderate to massive ($n = 22$), depending upon the accumulation of ascitic fluid. Cases associated with moderate to massive ascites had significantly higher MHVV than other groups (Figure 5). Correspondingly, “very high” group were always associated with moderate to massive ascites.

Correlation of hepatic vein velocity with hepatic hemodynamics

There was no correlation of MHVV with portal flow,

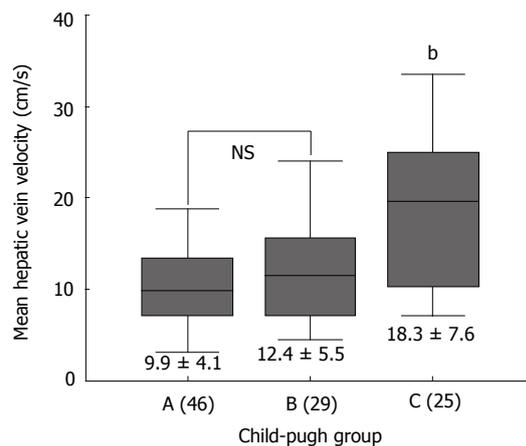

Figure 2 Mean hepatic vein velocity in study population. Hepatic vein velocity in cirrhotic patients according to Child-Pugh group (mean \pm SD; $^bP < 0.0001$ vs A and B).

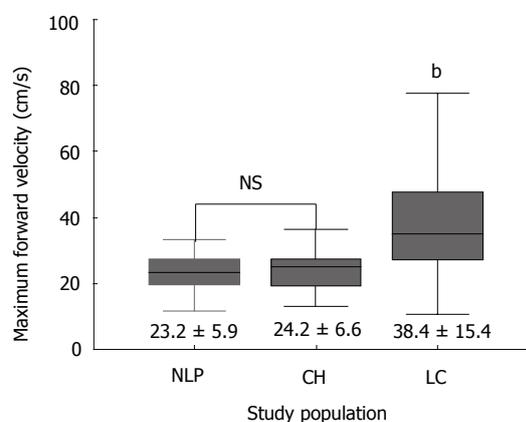

Figure 3 Maximum forward velocity of hepatic vein in study populations. (mean \pm SD; $^bP < 0.0001$ vs NLP and CH).

portal velocity and hepatic artery velocity ($r = -0.105$, 0.391 and 0.297 , respectively). However, we found a significant correlation of MHVV with right portal flow in LC patients ($P < 0.0001$, $r = 0.687$) (Figure 6A). No such correlation was seen in non-cirrhotic controls ($P < 0.767$, $r = -0.042$) (Figure 6B). Right portal flow was significantly higher in the “very high” group (331 ± 120 mL/min vs 526 ± 133 mL/min) (Figure 7). Those cases, which were not associated with increased right portal flow, had increased peak systolic velocity of the hepatic artery in the “very high” group.

The intra-observer variability was 5% in the hepatic vein, 7% in the portal trunk and right portal vein and 10% in the hepatic artery measurements. Regarding tracing of waveform of right hepatic vein, it was nil.

DISCUSSION

This study argues against the appearance of flat waveform of the hepatic vein in cirrhotic patients with impaired liver function. This is based on the finding that the waveform of the hepatic vein in this study was independent of liver function and Child-Pugh score. Only 3 patients showed flat waveform and only 1 of them was C by Child-Pugh grading. However, change of waveform to biphasic from

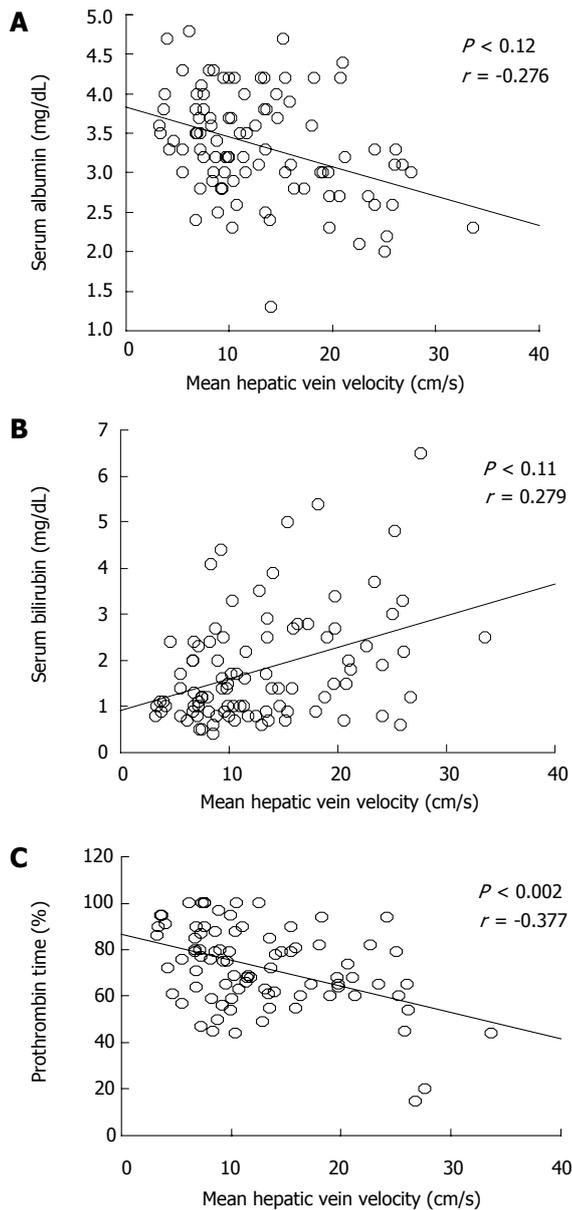

Figure 4 Relation between mean hepatic vein velocity and liver function test in cirrhotic patients. **A:** serum albumin; **B:** serum bilirubin; **C:** prothrombin time.

triphasic seems suggestive of some changes in the liver parenchyma as only cirrhotic patients showed change from triphasic to biphasic or flat waveform. Although the phasicity is cardiac in origin, predominantly the change in right atrial pressure changes, respiratory motion can alter the HV waveforms and its components^[9]. We noticed that the negative oscillation disappears with respiratory maneuvers in some patients and this may be the reason for discrepancy in findings regarding the negative waves in many studies. However, this change in waveforms with different respiratory maneuvers was an equivocal finding and the reason is not well understood why it occurs in some patients only. In the same line, flat waveform in 9.33% (7/75) subjects without liver and cardiac disease can be explained^[10]. Bolondi *et al*^[2] have reported that the underlying mechanism of the change in the hepatic vein waveform may be related to liver fibrosis, which progressively reduces phasic oscillation in hepatic veins. However, in our patients, triphasic waveform was seen

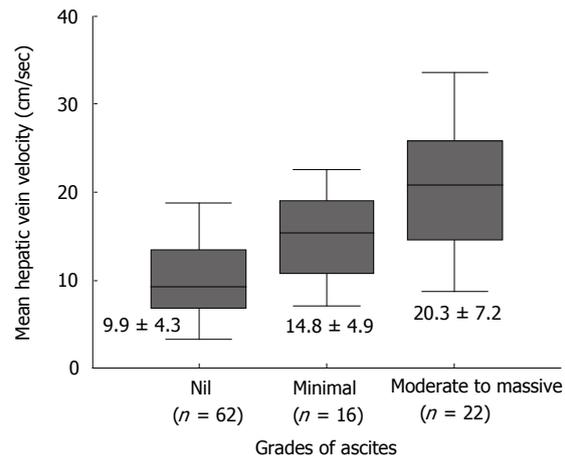

Figure 5 Mean hepatic vein velocity in patients depending upon the accumulation of ascites. (mean \pm SD; ^b $P < 0.01$ vs nil and moderate to massive).

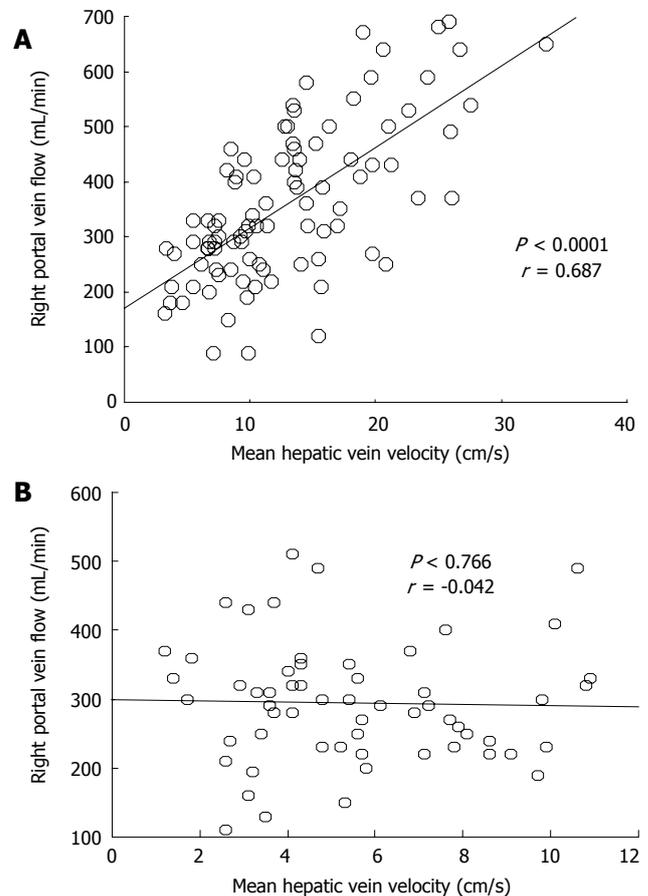

Figure 6 Correlation between mean hepatic vein velocity and right portal vein flow in cirrhotic patients (**A**) and controls (**B**).

even in significantly atrophied liver with marked nodule formation on histopathological specimens. Our experience showed that inadvertent measurement of Doppler waveform from inferior right hepatic vein or enlarged marginal vein sometimes might give flat waveform. In two of the cases that were excluded in this study, flat waveforms were obtained from the inferior right hepatic vein, while right hepatic vein showed triphasic waveforms.

To our knowledge, this is the first time MHVV has

been measured by Doppler in cirrhotic patients. It was significantly higher in cirrhotic than non-cirrhotic patients and there was significant difference of mean between cirrhotic and non-cirrhotic controls. Furthermore, the poorer the liver function, the higher was the MHVV. No increase in MHVV in chronic hepatitis patients indicates that no measurable hemodynamic changes occur before the onset of LC. On line with other studies^[4], maximum forward velocity was also significantly elevated in LC patients. In non-cirrhotic patients, the maximum velocity was never higher than 40 cm/s. Thus, we propose that coupled with maximum forward velocity, it can be used as a supplementary diagnostic tool in liver cirrhosis. As there was no correlation between serum albumin, serum bilirubin, prothrombin time, role of liver cell dysfunction was ruled out. However, ascites showed significant correlation with MHVV which was significantly higher in the patients presenting clinically with moderate to massive ascites. Thus, we hypothesize that the MHVV is subjected to change with hepatic hemodynamics not directly related to liver cell function.

A positive correlation of hepatic vein velocity with grades of ascites was found. Although authentic volumetric data was not obtained in study cases, those cases with very high velocity had atrophied right lobe of the liver on ultrasonography (data not included). Our finding is also supported by Torres *et al*^[11], who have reported that in LC, the right lobe frequently atrophies, while the left lateral lobe becomes hypertrophic. High inflow of the atrophied right lobe of the liver may be one of the plausible explanations of relation with ascites. In an *in vitro* liver perfusion system, lymph could be seen oozing from the surface of the liver when portal perfusion pressure was acutely increased^[12]. However, further study is considered necessary to establish the exact role of hepatic microcirculation, which appears to be instrumental in modifying MHVV, with ascites formation, as it is still

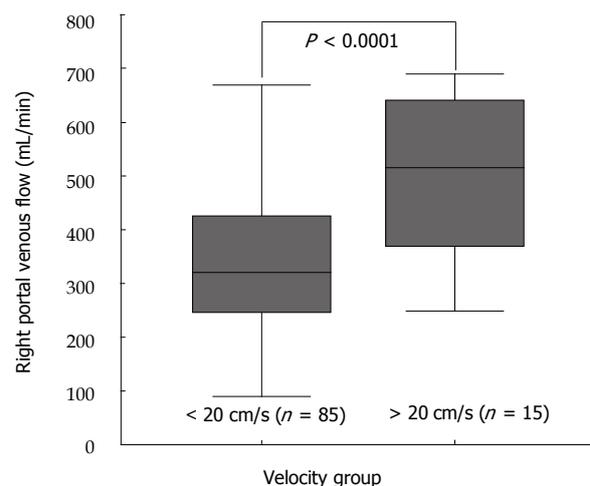

Figure 7 Right portal flow in cirrhotic patients. "Very high" group, which we defined as those having velocity \geq 20 cm/s had increased perfusion of right lobe of the liver.

imprecisely known. If the mechanism is uncovered, measurement of MHVV can be used to evaluate the efficacy of different treatment modalities in the treatment of ascites related to LC.

In this study, cirrhotic patients showed correlation of MHVV with right portal flow, while non-cirrhotic controls demonstrated no correlation between them. In normal subjects, blood flows from the portal venules into the hepatic vein system traversing through hepatic sinusoids. An autoregulation of flow at the level of sinusoids is present in normal liver, which is supposed to control the blood flowing to the hepatic vein. However, in the cirrhotic liver, there are various changes. It is reported that a direct communication occurs between two venous systems^[13]. Moreover, it has been hypothesized that functionally inactive pre-existing arterio-venous shunts are opened in a response to intense vasodilatation^[14]. Hiraki *et al*^[15] showed

that maximum peak velocity of right portal vein decreased substantially with temporary occlusion of the right hepatic vein. Change in hepatic arterial hemodynamics was seen with the same maneuver. Therefore, the alteration in hemodynamics of the portal vein and hepatic artery can have an influence on hepatic vein, its flow and waveform. Our study also proves this fact as those cases associated with high velocity of the right hepatic vein were found to have increased perfusion of the right lobe of the liver by right portal vein. It can be explained by the fact that there is increased porto-venous shunt in cirrhotic liver and the flow may have bypassed to the hepatic vein, thereby increasing its flow velocity. In cases not associated with increased right portal flow, hepatic artery velocity was increased. Arterial flow is expected to increase in LC due to arterIALIZATION of the cirrhotic liver that contributes to increased inflow to the liver^[16]. Furthermore, there is arterio-venous shunt formation in cirrhotic liver that usually can not be detected, even by standard imaging diagnostic procedures. In recent years, transit-time analysis of contrast agent in cirrhotic patients has been proposed for non-invasive diagnosis of LC^[17]. The findings have shown that there is early arrival time of the contrast agent and early peak enhancement in HV of cirrhotic patients compared to non-cirrhotic patients. Similar study carried out recently concluded that intrahepatic hemodynamic changes are responsible for this^[18]. This supports the result of our findings. However, there is deranged autoregulation of sinusoidal flow present in cirrhotic liver along with intrahepatic shunt formation; it is difficult to arbitrate which factor is more predominant to determine the correlation.

In vitro study has shown that Doppler flowmetry is relatively accurate and reproducible. Thus, this technique is increasingly being used in clinical practice to study hepatic hemodynamics. We have applied it to study the right hepatic vein and an attempt has been made to correlate the hemodynamic findings with severity of liver dysfunction in cirrhotic patients. We observed that the cirrhotic patients had increased velocity of the hepatic vein and those cases with very high velocity were having poorer liver function as graded by Child-Pugh classification. Correlation of MHVV with ascites, but not albumin, bilirubin or prothrombin time substantiates its association with hepatic microcirculation. Simple measurement of hepatic vein velocity can give information on deranged hepatic microcirculation. Hence, we advocate that Doppler measurement of hepatic vein velocity, which is non-invasive, can be used as a new parameter in the investigation of chronic parenchymal liver disease.

weighted images were, respectively, 85% for pancreatic fascial plane, 77% for left renal fascial plane, 55% for peripancreatic fat stranding, 42% for right renal fascial plane, 45% for perivascular fluid, 40% for thickened pancreatic lobular septum and 25% for peripancreatic fluid, which were markedly higher than those on in-phase or SSFSE T2-weighted images ($P < 0.001$).

CONCLUSION: IEP primarily manifests on non-enhanced MR images as thickened pancreatic fascial plane, left renal fascial plane, peripancreatic fat stranding, and peripancreatic fluid. R-T T2-weighted imaging is more sensitive than in-phase and SSFSE T2-weighted imaging for depicting IEP.

Abstract

AIM: To study the appearances of acute interstitial edematous pancreatitis (IEP) on non-enhanced MR imaging.

METHODS: A total of 53 patients with IEP diagnosed by clinical features and laboratory findings were underwent MR imaging. MR imaging sequences included fast spoiled gradient echo (FSPGR) fat saturation axial T1-weighted imaging, gradient echo T1-weighted (in phase), single shot fast spin echo (SSFSE) T2-weighted, respiratory triggered (R-T) T2-weighted with fat saturation, and MR cholangiopancreatography. Using the MR severity score index, pancreatitis was graded as mild (0-2 points), moderate (3-6 points) and severe (7-10 points).

RESULTS: Among the 53 patients, IEP was graded as mild in 37 patients and as moderate in 16 patients. Forty-seven of 53 (89%) patients had at least one abnormality on MR images. Pancreas was hypointense relative to liver on FSPGR T1-weighted images in 18.9% of patients, and hyperintense in 25% and 30% on SSFSE T2-weighted and R-T T2-weighted images, respectively. The prevalences of the findings of IEP on R-T T2-

INTRODUCTION

Acute pancreatitis (AP) is a protean disease of wide clinical variation ranging from mild discomfort to severe multiorgan failure and death. Acute interstitial edematous pancreatitis (IEP), found in approximately 75% of patients presenting with AP, consists of edema and inflammation of the pancreas and is typically a self-limiting process with a mild clinical course^[1,2]. Necrotizing pancreatitis (NP) is a far more severe form of pancreatitis, which is characterized by extensive fat necrosis, hemorrhage, and necrotic liquefaction of the pancreas. Dynamic CT is well established for differentiating IEP from NP^[3]. However, CT is not necessary in depicting IEP or mild acute pancreatitis^[2,4,5]. Patients with AP are often young and require multiple follow-up CT examinations; substitution of MRI for CT in some patients would reduce their collective radiation dose considerably. In addition, experimental study^[6] and clinical retrospective analysis^[7]

of pancreatitis suggested that iodinated contrast medium might worsen or prolong attacks of acute pancreatitis.

Recent advances in abdominal MRI improve the spatial resolution of images and allow optimal imaging of the pancreas. MRI can have an important role in staging the severity of acute pancreatitis and may be superior to other imaging techniques for the characterization of peripancreatic collections^[8-10]. Amano *et al*^[11] reported 12 patients with mild AP who had CT and MRI examinations, and found non-enhanced MR imaging was superior to CT for depiction and confirmation of mild AP. However, there was a variety of intermediary forms from mild to severe pancreatitis which occurred in clinical practice^[3]. We hypothesized that IEP may include mild AP and some intermediary forms based on clinical classification of AP, and that non-enhanced MR imaging could depict these abnormalities of IEP.

MATERIALS AND METHODS

Patients

All patients in this study were diagnosed as IEP based on clinical features and laboratory findings in our institute from January 2002 to March 2005. The recruitment criteria of patients were: (1) acute history; (2) pancreatitis at first onset; (3) elevated amylase or lipase, excluding other abnormalities with an elevated enzymes; (4) MRI examination; (5) maximum three-days interval between the MRI examination and the IEP onset; (6) minimal organ dysfunction or an uneventful recovery; and (7) no clinical or imaging appearance of pancreatic necrosis, pseudocyst, or abscess.

In this retrospective study, 53 patients (26 men and 27 women; average age: 47 ± 16 years, range: 10-73 years) with IEP were enrolled according to the aforementioned criteria. Medical records of the 53 patients were reviewed to investigate the recovery and the length of hospital stay. Review of images and medical records was conducted according to our Institutional Review Board's guidelines, including approval for our department to conduct these reviews.

MR Imaging

All examinations were conducted on a 1.5-T MR scanner with 38 mT/M gradients and 120 mT/M per second slope (Signa Excite; GE Medical Systems, Milwaukee, Wis), using phased-array torso-pelvis coil. The sequences included axial fast spoiled gradient echo (FSPGR) T1-weighted imaging with fat suppression, gradient-echo (GRE) T1-weighted in-phase and out-of-phase MR imaging, respiratory-triggered (R-T) axial fast recovery fast spin-echo (FRFSE) T2-weighted MR imaging with fat suppression, coronal and axial single shot fast spin-echo (SSFSE) T2-weighted MR imaging, and three-dimension (3D) FSPGR dynamic enhanced MR imaging.

FSPGR T1-weighted imaging with fat suppression was obtained in 1 or 2 breathholds, with the following parameters: TR ms/TE ms = 150-170/1.6; flip angle = 80°; matrix = 512 × 160-192; field of view = 26-32 cm; section thickness = 5 mm (gap ≤ 0.5 mm); number of signals acquired (NSA) = 1; and the sampling bandwidth

= 20.8 kHz.

GRE in-phase and out-of-phase MR imaging were acquired in breath hold, with the following parameters: TR ms/TE ms = 150/4.4, 2.2; flip angle = 90°; matrix = 256 × 192-224; field of view = 26-32 cm; section thickness = 5 mm (gap ≤ 0.5 mm); number of signals acquired (NSA) = 1; and the sampling bandwidth = 31 or 62 kHz.

R-T FRFSE T2-weighted sequence were obtained with the following parameters: repetition time [TR] ms/echo time [TE] ms = 10 000-12 000/90-100, TR determined by the frequency of respiration; section thickness = 5 mm; intersection gap = 0.5 mm; matrix = 256 × 192; number of signals acquired (NSA) = 3; and field of view = 34 cm × 34 cm. It took about 3-4 min to complete the acquisition.

Coronal and axial SSFSE T2-weighted images were obtained in breathhold, with the following parameters: TE = 90-100 ms; 2 s between slice acquisitions; section thickness = 5 mm; intersection gap = 0.5 mm; matrix = 384 × 224; one-half signal acquired; and field of view = 33 cm × 33 cm.

Radial oblique slab SSFSE images were obtained for MRCP with the following parameters: TE = 1300 ms; 6 s between image acquisitions; section thickness = 40 mm; matrix = 384 × 224; one-half signal acquired; and field of view = 30 cm × 30 cm.

Dynamic enhanced imaging was performed with axial fat saturated 3D FSPGR sequence. Gadolinium chelate was administered (0.2 mmol/L per kilogram of body weight) intravenously at approximately 3.5 mL/s by projector (Spectris MR Injection System, Medrad Inc., USA) injection, followed by a 20-mL saline solution flush. An additional delayed phase was acquired using 2D FSPGR fat suppression axial T1-weighted imaging.

Image interpretation

The original MR imaging data was loaded onto a workstation (GE, AW4.1, Sun Microsystems, Palo Alto, CA) to be reviewed. Two observers (with 4 and 6 years' experience in interpreting abdominal MRI examinations), who were blinded to the laboratory data and clinical outcome, reviewed MR images. Any discrepancy between the two readers was settled by consensus.

The enlarged pancreas was defined as anterior-posterior diameter ≥ 3 cm on axial images^[12]. Decreased signal intensity of pancreas on FSPGR T1-weighted imaging was defined as not higher than that of liver^[13,14]. The signal intensity of normal pancreas was defined as slightly higher than that of liver on T2-weighted images^[13]. Pancreatic lobular septum thickening (PLST) with increased signal intensity was defined as a thickness of the septum surrounding pancreatic lobules ≥ 2 mm and its signal intensity significantly higher than that of liver. The pancreatic fascial plane (PFP) was defined as linear signal intensity along the surface of the pancreas which was hypointense on in-phase images or hyperintense on T2-weighted images.

Peripancreatic fat stranding (PPFS) referred to the stranding with hypointensity on in-phase images or hyperintensity on T2 weighted images. Peripancreatic fluid (PPF) collections referred to poorly defined fluid

collection in the anterior pararenal space around the gland and in the lesser peritoneal sac, with diameter larger than 2 cm. The renal fascial plane (RFP) was defined as renal fascia thickness over 3 mm^[15], which was hypointense on in-phase and hyperintense on T2-weighted images. Perivascular fluid referred to fluid surrounding portal vein, superior mesentery vein (SMV) or artery (SMA), which was hyperintense on T2-weighted images.

The diameter of the pancreatic main duct was measured at the level of the head or body of the pancreas on MRCP images. Pancreatic necrosis was also noted on gadolinium chelate 3D FSPGR dynamic enhanced images.

The grade of the pancreatitis was scored with the MR severity score index (MRSI) (Table 1), which was derived from the CT severity score index developed by Balthazar and others^[4,15-17]. The severity of pancreatitis was expressed as mild (score = 0-2 points), moderate (score = 3-6 points), and severe (score = 7-10 points).

Statistical analysis

Results were expressed as mean \pm SD for continuous data. Two-tailed student's *t* test was used to calculate differences between two observers. The Chi-square test was used to evaluate the difference for MR findings among IEP patients on in-phase, SSFSE T2- and R-T T2- weighted imaging, as well as to compare the prevalence of MR findings for IEP on R-T T2- weighted images. Relationship of length of hospitalization variables to the severity of IEP was tested using *t* tests, and to the continuous variables with Pearson product-moment correlations. *P* < 0.05 was considered statistically significant.

RESULTS

Sample characteristics

In this study, 49% (26/53) of patients had cholecystopathy or cholelithiasis confirmed by surgery or laparoscopy. One patient had congenital choledochoceles and cholecystitis, confirmed at laparotomy. Of them, 17% (9/53) patients had alcohol abuse, and 34% (18/53) were idiopathic.

MRI findings

The anterior-posterior diameter of the pancreas on FSPGR T1-weighted imaging was, respectively, 2.3 \pm 0.4 cm and 2.4 \pm 0.4 cm (*P* = 0.1) for observer 1 and observer 2. Only one patient had a diameter of the pancreas larger than 3 cm.

Of the 53 patients with IEP, 89% (47/53) had at least one abnormality on MR images, whereas 11% (6/53) showed normal pancreas. We found that 19% (10/53) of patients showed decreased pancreatic signal intensity on FSPGR T1-weighted images, while 81% (43/53) of patients showed normal pancreatic signal intensity. In addition, 25% (13/53) and 30% (16/53) of patients showed increased signal intensity on SSFSE T2-weighted and R-T T2-weighted images (Figure 1), respectively ($\chi^2 = 0.5-1.8$, *P* > 0.05). As shown in Figures 1 and 2, 21% (11/53) and 40% (21/53) of patients had PLST with increased signal intensity on SSFSE T2-weighted and R-T T2-weighted images, respectively ($\chi^2 = 4.5$, *P* < 0.05).

The other MR findings of IEP are shown in Table 2,

Table 1 MR severity score index

Prognostic indications	Characteristic	Points
Pancreatic	Normal pancreas	0
Inflammation	Focal or diffuse enlargement of the pancreas	1
	Intrinsic pancreatic abnormalities with inflammatory changes in pancreatic fat	2
	Single, poorly defined fluid collection or phlegmon	3
	Two or more poorly defined collection or presence of gas in or adjacent to the pancreas	4
Pancreatic necrosis	No necrosis	0
	30%	2
	30%-50%	4
	> 50%	6

and illustrated in Figure 1, Figure 2, Figure 3, Figure 4. The prevalence of most findings of IEP on R-T T2-weighted imaging was higher than that on in-phase or SSFSE T2-weighted imaging (Table 2). The commonest finding of IEP on R-T T2-weighted imaging was PFP (85%), left RFP (77%) and PPFS (55%), whose prevalence was significantly higher than those for PPF, right RFP, perivascular fluid and free ascites, respectively (Table 2) ($\chi^2 = 78.5$, *P* < 0.001).

All of the 29 (54.71%) patients with PPFS and 13 (24.52%) patients with PPF had PFP. All these 13 patients had lesser peritoneal sac fluid collections, including 5 with collections in the left anterior pararenal space fluid collections, 1 with a right anterior pararenal space fluid collection, and 2 with both right and left anterior pararenal space fluid collections.

Of 53 patients, 43 (81%) showed RFP, including 22 (42%) with both left and right RFP, 1 (2%) with only right RFP and 20 (38%) with only left RFP. The number of patients with left RFP was significantly higher than those with right RFP (42 *vs* 23 cases; $\chi^2 = 14.4$, *P* < 0.001).

On MRCP images, the main pancreatic duct was smooth, and its diameter was 2.2 \pm 0.7 mm and 2.1 \pm 0.6 mm (*P* = 0.7) for observer 1 and observer 2, respectively. No pancreatic necrosis was seen on gadolinium chelate 3D FSPGR dynamic MR imaging or other sequences.

Length of hospitalization and MRSI

The average length of hospitalization of the 53 patients was 14 \pm 7 d (range: 4-33 d). The MRSI ranged from 0 points to 4 points with the average of 2.1 \pm 1.2 points. The IEP was graded as mild in 37 (70%) patients, as moderate in 16 (30%) patients and as severe in 0 patients. The severity of pancreatitis was not related to the length of hospitalization (*r* = 0.1, *P* > 0.05).

DISCUSSION

In our study, we found 89% of patients with IEP had at least one abnormality on non-enhanced MR imaging, depicted primarily on T2-weighted images. These abnormalities mainly included pancreatic fascial plane (85%), left renal fascial plane (77%), peripancreatic fat

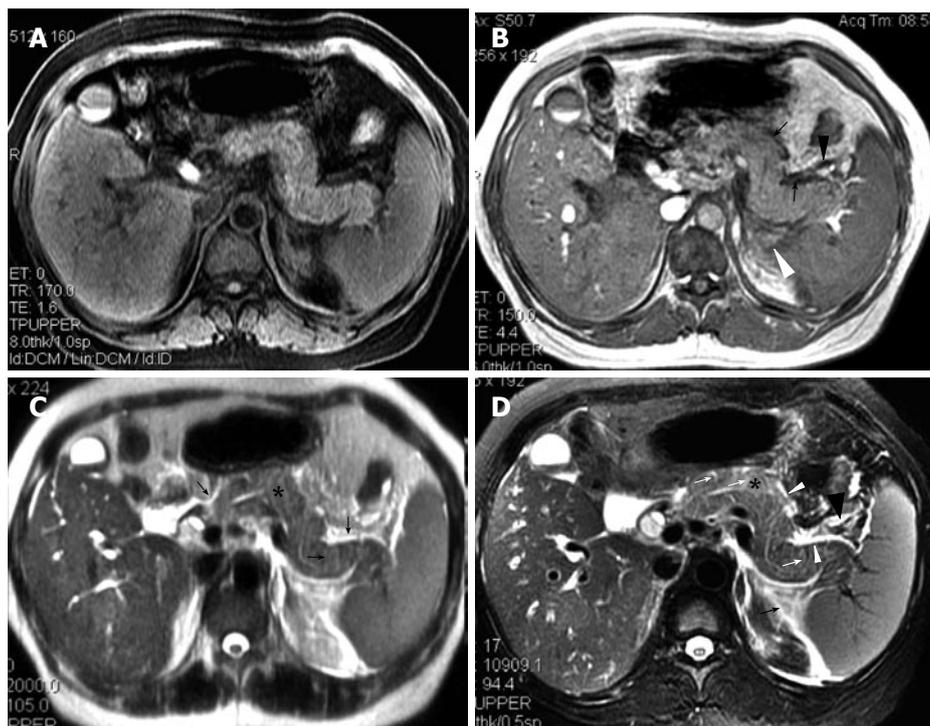

Figure 1 A 42-year-old woman with interstitial edematous pancreatitis. **A:** SPGR fat-suppressed T1-weighted (TR/TE = 170/1.6 ms) image shows pancreatic signal intensity comparable to that of liver; **B:** GRE in-phase (TR/TE = 150/4.4 ms) image shows pancreatic fascial plane (arrows) and peripancreatic fat stranding (arrow heads); **C:** SSFSE T2-weighted (TE = 90 ms) image shows increased pancreatic signal intensity (asterisk). Stranding in the pancreatic fascial plane (large arrow) and peripancreatic fat and thickened pancreatic lobular septum (small arrow) can also be seen; **D:** R-T T2-weighted (TR/TE = 11 800/93 ms) image shows above findings much better (Asterisk indicates pancreatic parenchyma, white arrows indicate thickened pancreatic lobular septum, white arrow head indicates pancreatic fascial plane, and black arrow and arrow head indicate fat stranding).

stranding (55%), peripancreatic fluid (55%), perivascular fluid (45%), right renal fascial plane (42%), and pancreatic lobular septum thickening (40%). R-T T2-weighted imaging was much more sensitive than in-phase and SSFSE T2-weighted imaging in the depiction of the aforementioned abnormalities.

The pathology of IEP included pancreatic edema and mild cellular infiltration, sometimes with a few small scattered foci of necrosis and saponification in the peripancreatic fatty tissue^[3]. The histological changes noted in experimental pancreatitis are progressive interstitial edema, and mononuclear-cell infiltration, without hemorrhage or necrosis, with regeneration of the pancreas in 6 d^[18]. In our study, 19% of patients showed decreased pancreatic signal intensity on FSPGR T1-weighted images, while 25%-30% of patients showed increased pancreatic signal intensity on SSFSE T2-weighted and R-T T2-weighted images. The abnormal signal intensity of pancreatic parenchyma may partly reflect the inflammation of the pancreas in IEP. However, our results indicate that the signal intensity of the pancreatic parenchyma on both T1-weighted and T2-weighted imaging is not sensitive for depicting IEP. In the 12 patients with mild acute pancreatitis reported by Amano *et al*^[11], 75% (9/12)

of patients showed a prolonged T1 and T2 lesions of the pancreas. However, the patients selected in our study differ from those in theirs. IEP is not the same as mild acute pancreatitis, including a variety of intermediary forms from mild to severe pancreatitis which occur in clinical practice^[3].

The pancreas does not have a well-developed fibrous capsule, but is surrounded by thin loose connective tissue, which is called the “fusion fascia of Treita” in the head and the “fusion fascia of Toldt” in the body and tail of the pancreas^[19]. In our study, we found the commonest sign was PFP on T2-weighted images (85%). In the 29 patients with PPFS and 13 patients with PPF, all had PFP. We speculate that the pancreatic fascia may be first involved in acute pancreatitis. When the inflammation penetrated through the Toldt fusion fascia of the pancreas, peripancreas fat infiltration or fluid accumulation may develop. The peripancreatic vessels run in the fusion fascia^[19]. It is possible that peripancreatic perivascular fluid in IEP resulted from inflammation of intra-fusion fascia of the pancreas.

In AP, the earliest changes appear to be in the acinar cells^[20]. An increase in pancreatic ductal pressure has been described as the initial mechanism of acinar cell injury. The

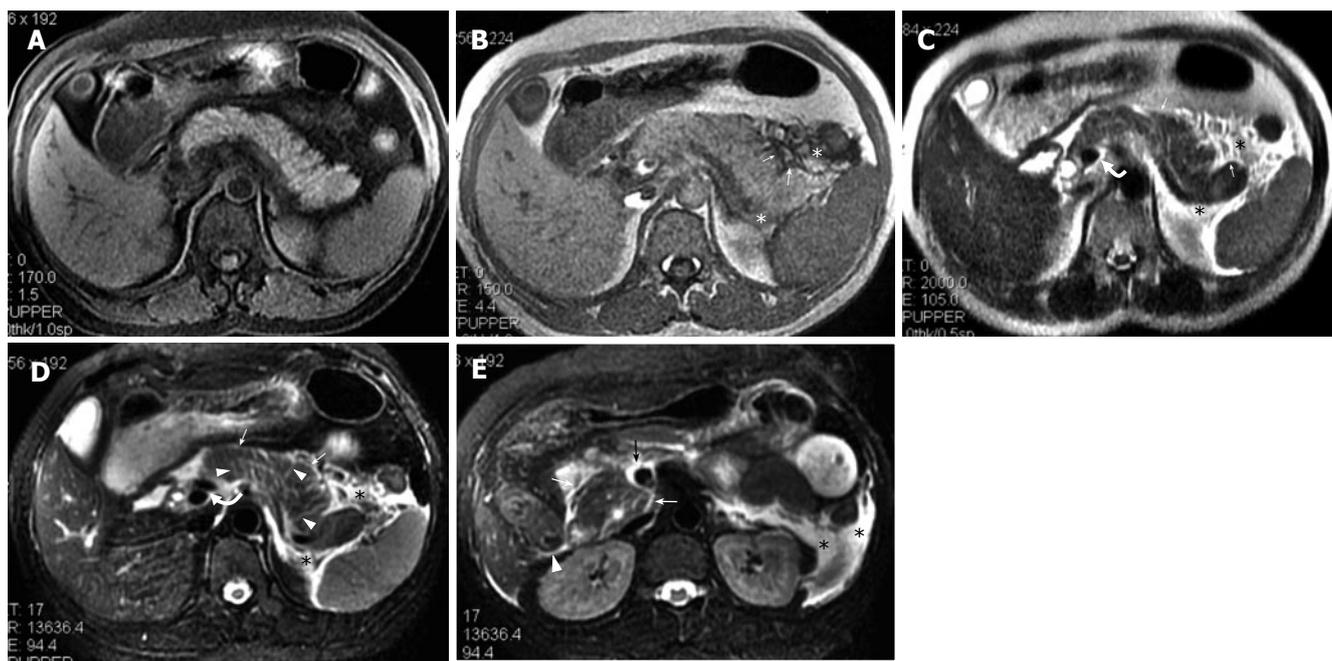

Figure 2 A 28-year-old man with IEP. **A:** SPGR fat-suppressed T1-weighted (TR/TE = 170/1.6 ms) image shows normal pancreatic signal intensity; **B:** pancreatic fascial (arrows) and peripancreatic fat (asterisk) stranding can be seen on GRE in-phase (TR/TE, 150/4.4 ms) image; **C:** SSFSE T2-weighted (TE = 90 ms) image; **D:** R-T T2-weighted (TR/TE = 12300/98 ms) image. Perivascular fluid (curve arrow) can be seen on latter two sequences. Thickened pancreatic lobular septum (arrow heads) can only be seen on R-T T2-weighted image (**D**); **E:** At the level of the head of the pancreas, R-T T2-weighted image (**E**) shows pancreatic fascial plane (white arrow), right renal fascia plane (white arrow head), fluid surrounding SMV (black arrow), and left anterior pararenal space and lateroconal plane fluid collections (asterisk).

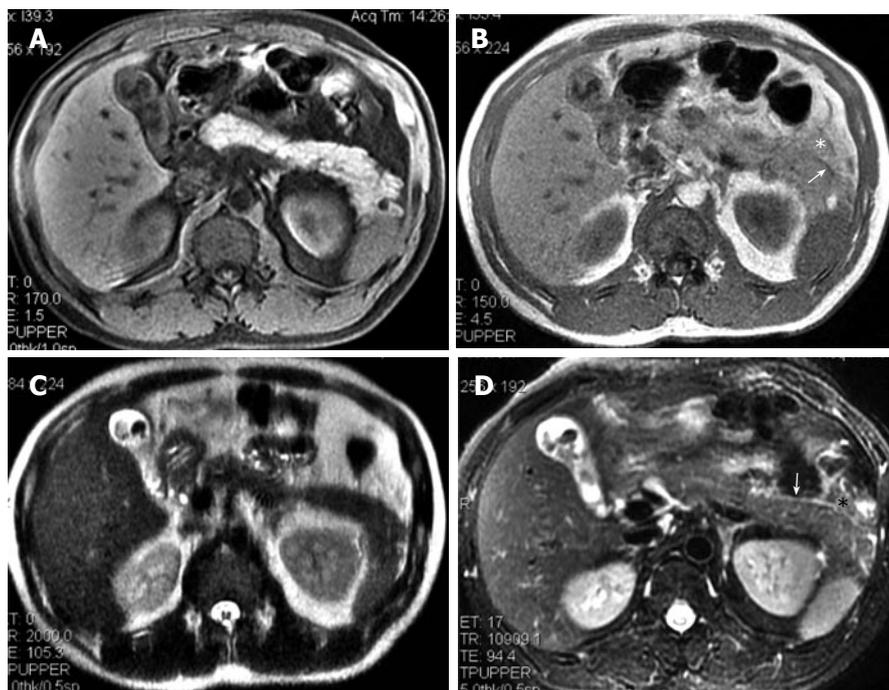

Figure 3 A 45-year-old woman with IEP and cholelithiasis. **(A)** SPGR fat-suppressed T1-weighted (TR/TE = 170/1.6 ms) image shows normal pancreatic signal intensity. GRE in-phase (TR/TE = 150/4.4 ms) **(B)** and SSFSE T2 weighted (TE = 90 ms) **(C)** images show the pancreatic fascia plane (arrows) and the peripancreatic fat stranding (asterisk), which appear more extensive on R-T T2-weighted (TR/TE = 12 300/98 ms) image **(D)**.

subsequent cellular events are not well understood, but the result appears to be activation of pancreatic digestive enzymes within the acinar cell^[21]. Ultrastructural studies by Kloppel *et al*^[22] indicate that an early event, irrespective of etiology, is the release of activated enzymes by acini at the periphery of lobules into the interstitium, resulting in perilobular fat necrosis. Experimentally, tracer material introduced by retrograde injection into the main pancreatic duct (MPD) is localized to the periacinar space^[23] and

human AP may show a similar pattern, irrespective of etiology^[24]. Early microcirculatory changes in patients with AP include an increase in vascular permeability and the accumulation of extravagated fluid in the perilobular space. A decrease in flow velocity was noted 2 h after the onset of severe pancreatitis^[25]. We found that 21%-40% of patients had PLST with increased signal intensity on T2-weighted images. We speculate that this resulted primarily from the accumulation of extravagated fluid in the

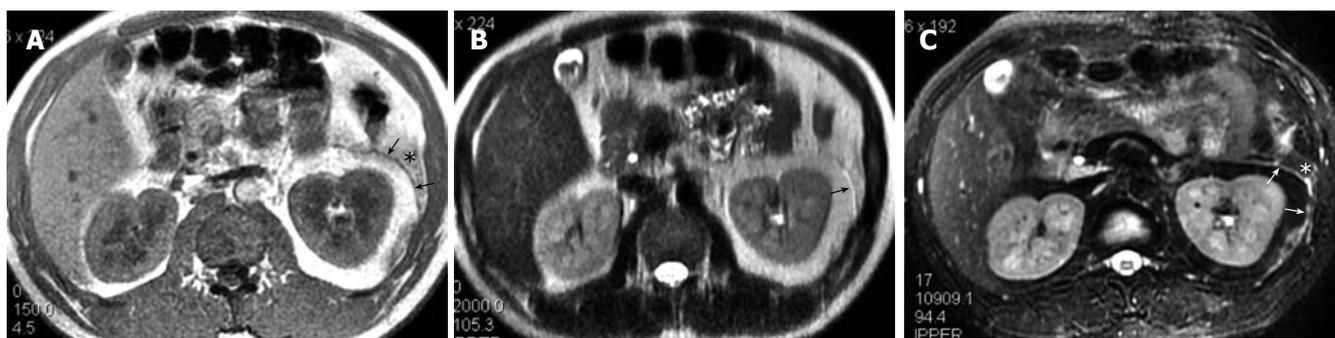

Figure 4 The same patient as in Figure 3. At the level of the head of the pancreas, left renal fascial plane (arrow) and anterior pararenal space fat stranding (asterisk) present on GRE in-phase (A), SSFSE T2-weighted (B) and R-T T2-weighted (C) images, but they are most prominent on R-T T2-weighted image.

perilobular space and perilobular fat necrosis.

CT has been helpful in revealing inflammatory thickening of the retroperitoneal fascial membranes and edema or lipolysis of the retroperitoneal fat resulting from acute pancreatitis. Nicholson *et al*^[15] reported that 46% of patients with pancreatitis demonstrated renal fascial thickening and 27% of patients had increased fat density. Chintapalli *et al*^[16] reported that renal fascial thickening was seen in 62% of patients with pancreatitis, involving left and right renal fascia in 59% (42/71) and 30% (21/71), respectively. The patients in the above two reports had various forms of pancreatitis. In our study, 81% of patients with IEP showed RFP, including 77% with left RFP and 42% with right RFP. The prevalence of left RFP was significantly higher than that of right RFP ($P < 0.05$), although the prevalence of RFP in MRI was higher than that reported in CT^[15,16]. It is possible that MR imaging is more sensitive than CT for detecting renal fascia inflammatory thickening. The predominance of left RFP is consistent with earlier studies by CT, attributed to the proximity of the body and tail of the pancreas^[16].

Mortele *et al*^[26] reported that the pancreas appeared abnormal on MRI and MRCP in 57% (31/54) patients with asymptomatic mild serum hyperamylasemia and hyperlipasemia, while 43% of patients had normal pancreas. In our study, 11% (6/53) of patients showed normal pancreas on MR imaging. Each of these 6 patients had 3 times or more elevations of serum amylase and lipase at hospital admission, and serum amylase and lipase levels decreased within a few days. It is possible that the pancreatitis in these 6 patients was too mild to be seen with current non-enhanced MR imaging.

In our study, we did not find any correlation between the length of hospitalization and MRSI ($r = 0.1$, $P > 0.05$), which was in agreement with the findings by Lecesne *et al*^[8]. Most of the patients with IEP were graded as mild (70%), and none were graded as severe in our study. Also, 49% of patients had cholecystopathy or cholelithiasis. We agree with Lecesne *et al*^[8] that the length of hospitalization may not accurately represent morbidity, since social factors or selective surgery may prolong the length of stay, which was not included in the design of our study.

We also did not analyze the correlation of the level of serum amylase and lipase to the MR findings or to the length of hospitalization. Reports in the early literature

indicated that the severity of acute pancreatitis was independent of the elevation in serum amylase/lipase level (≤ 3 or > 3 times of higher limit of normal range) on admission. Patients with only a slight increase can also have or develop severe acute pancreatitis^[27]. In diabetic ketoacidosis, non-specific elevations of amylase and lipase occurred in 16%-25% of cases. Diagnosis of acute pancreatitis based solely on elevated amylase or lipase, even > 3 times normal, is not justifiable^[28]. Mortele *et al*^[26] reported that 43% of patients with asymptomatic serum hyperamylasemia and hyperlipasemia had normal pancreas on MRCP. The above reports indicate that the level of serum amylase and lipase was not relative to the findings on MR imaging and the severity of acute pancreatitis.

In our study only 3 patients had repeated MR imaging, so we were not able to document serial changes in the development of pancreatic inflammation. However, the short-term clinic status of all patients improved. Munoz-Bongrand *et al*^[29] reported that serial computed tomography is rarely necessary in patients with acute pancreatitis, and repeated MR examinations may similarly be unnecessary in patients with IEP.

In conclusion, interstitial edematous pancreatitis primarily manifests on unenhanced MR images as the pancreatic fascial plane, left renal fascial plane and peripancreatic fat stranding, as well as peripancreatic fluid. Non-enhanced MR imaging, especially R-T T2-weighted imaging with fat suppression, is effective for depicting interstitial edematous pancreatitis.

Abstract

AIM: To discover the causes of markedly raised ferritin levels in patients seen at a teaching hospital in Newcastle Upon Tyne, United Kingdom.

METHODS: Demographic and medical data were collected for all patients over 18 years who had a serum ferritin levels recorded as $\geq 1500 \mu\text{g/L}$ during the period January to September 2002. The cause or causes for their hyperferritinaemia were identified from their medical notes. Patients from a defined local population were identified.

RESULTS: A total of 19 583 measurements were provided of which 406 from 199 patients were $\geq 1500 \mu\text{g/L}$. An annual incidence for the local population was determined to be 0.44/1000. 150/199 medical notes were scrutinised and 81 patients were identified as having a single cause for their raised ferritin level. The most common single cause was alcoholic liver disease in the local population and renal failure was the most common single cause in the overall population. Confirmed hereditary haemochromatosis was the 10th most common cause. Liver disease contributed to hyperferritinaemia in 44% of the patients. Weight loss may have contributed to hyperferritinaemia in up to 11%.

CONCLUSION: Alcohol related liver disease, haematological disease, renal failure and neoplasia are much more common causes of marked hyperferritinaemia than haemochromatosis. The role of weight loss in hyperferritinaemia may warrant further investigation.

Key words: Ferritin; Epidemiology; Haemochromatosis

INTRODUCTION

Ferritin is a protein with a molecular mass of 450 kilo Daltons (kD) and is composed of 24 subunits^[1]. These subunits form a hollow sphere, which can contain up to 4000 atoms of iron stored as ferric oxyhydroxide phosphate; haemosiderin is a condensate of ferritin. Ferritin acts as an intracellular store of iron whilst the protein coat protects the cell from potentially toxic ionised iron. In normal and iron overload states, serum ferritin levels correlate with mobilisable, stored iron. Iron overload may result from disease; e.g. haemochromatosis, administered iron or iatrogenically from recurrent blood.

Raised ferritin levels that are not due to iron overload are seen in many other conditions. Parenchymal liver damage, infection, inflammation (e.g. rheumatoid arthritis) and malignant disease may all be associated with raised serum ferritin. It has also been postulated that weight loss per se may be associated with elevated levels of ferritin^[2].

Clinicians may request a serum ferritin test to exclude iron deficiency in an anaemic patient or when considering a condition that is associated with elevated levels of ferritin. However, clinicians may not be aware of all the reasons for markedly elevated levels of ferritin and the relative frequencies of these different causes, and therefore may miss a potentially important diagnosis.

We conducted a study to look at the frequency of various diseases in a patient group with markedly raised ferritin levels who lived within a defined area. The patient group was made up of those seen at a teaching hospital that had various specialist units. We also looked at weight loss as a contributing factor in hyperferritinaemia.

MATERIALS AND METHODS

Patients

The Newcastle Hospital's NHS Trust serves a local population of around 270 000 and is a tertiary referral centre for up to 4 million people. Among other services it provides the regional renal transplant, liver and haematology service.

All patients aged over 18 years who had serum ferritin

Table 1 Conditions associated with raised ferritin and diagnostic criteria used

Condition	Requirements for diagnosis
Hereditary haemochromatosis	Genotyped and / or biopsy proven
Renal failure	Dialysis dependent
Alcoholic liver disease (ALD)	Liver biopsy or Liver Function Test (LFT) abnormality compatible with ALD in patients with history of alcohol excess (> 30 u/wk) in whom other causes have been excluded
Inflammatory disease	Raised C-Reactive Protein (CRP) and/or Erythrocyte Sedimentation Rate (ESR) on more than one consecutive test and recognised active inflammatory disease
Repeated blood transfusion	More than 4 unit packed cell transfusion in preceding 6 mo
Autoimmune disease	Recognised autoimmune disease with positive auto-antibody test
Other liver disease	All other recognised causes of parenchymal liver damage with abnormal LFTs, excluding ALD and HHC
Haematological disease	Bone marrow or blood film proven primary haematological disorder
Neoplasia	Histologically proven neoplastic disease
Weight loss	More than 10% body mass (kg) lost in preceding six months
Human immuno-deficiency virus (HIV)	Positive HIV test

Table 2 Causes of ferritin ≥ 1500 $\mu\text{g/L}$ in local and general population

Condition	All patients, $n = 150$ (% total)	Local patients, $n = 71$ (% total)	Number with condition as single cause for raised ferritin (%)
HHC	13 (8.6)	8 (11.3)	5/13 (38.5)
Alcoholic liver disease	33 (22)	22 (31.0)	24/33 (72.7)
Other liver disease	20 (13.3)	10 (14.1)	8/20 (40.0)
Inflammatory Disease	28 (18.6)	9 (12.6)	7/28 (25.0)
Neoplasia	29 (19.3)	11 (15.4)	6/29 (20.7)
Repeated blood transfusion	26 (17.3)	9 (12.6)	1/26 (3.8)
Autoimmune disease	21 (14.0)	8 (11.3)	2/21 (9.5)
Haematological disease	38 (25.3)	11 (15.4)	6/38 (15.7)
Renal failure	42 (28.0)	15 (21.1)	20/42 (47.6)
Weight loss	17 (11.3)	6 (8.4)	2/17 (11.7)
HIV	1 (0.7)	1 (1.4)	0/1 (0)
Unexplained	3 (2.0)	3 (4.2)	3/3 (100)

assayed between January 2002 and September 2002 were identified. All those with a ferritin level of ≥ 1500 micrograms/litre ($\mu\text{g/L}$) (normal range 12-200 $\mu\text{g/L}$) were included in the study. Demographic data, medical histories (including blood transfusion history and documented weight loss), biochemical markers and histopathological data were collected for each patient. The medical notes of patients with specific diagnoses, such as Hereditary Haemochromatosis (HHC), were scrutinised to ensure diagnostic criteria had been met before the patients were classified^[3] (Table 1).

RESULTS

19 583 ferritin level results were obtained for a nine month period (equivalent to 80 tests per day). 199 patients had serum ferritin results of ≥ 1500 $\mu\text{g/L}$ (from 406 samples among them). Hyperferritinaemia was thereby identified with an annual incidence of 0.44/1000 in the local population.

150/199 (75%) case notes were retrieved for 97 male

Table 3 The most common causes of hyperferritinaemia

All patients (%)	Local Patients (%)
Renal failure (28.0)	Alcoholic liver disease (31.0)
Haematological disease (25.3)	Renal failure (21.1)
Alcoholic liver disease (22)	Neoplasia (15.4)
Neoplasia (19.3)	Haematological disease (15.4)
Inflammatory disease (18.6)	Other liver disease (14.1)
Repeated blood transfusion (17.3)	Repeated blood transfusion (12.6)
Autoimmune disease (14.0)	Inflammatory disease (12.6)
Other liver disease (13.3)	HHC (11.4)
Weight loss (11.3)	Autoimmune disease (11.4)
HHC (8.6)	Weight loss (8.4)
Unexplained (2.0)	Unexplained (4.2)
HIV (0.7)	HIV (1.4)

patients and 53 female patients (ratio 1.8:1). The median age (taken at 1/1/02) was 54 years. 71 (47.3%) were "local" from Newcastle upon Tyne (postcode NE1 - NE12) (Table 2). Of the notes we were unable to obtain, 27/49 were local patients (55%) and 30/49 were male (ratio 1.6:1). The median age of this group was 54 years.

Causes of raised ferritin in general and local populations

Of the 150 patients evaluated in detail, 81 had one single identifiable cause for their hyperferritinaemia, with only 3 patients having none of the listed potential causes (Table 1) recorded in their medical records as well as no significant weight loss. Table 2 gives details of the frequency of conditions associated with a markedly elevated serum ferritin level. Table 3 lists the 10 most common causes for hyperferritinaemia in all patients studied as well as for patients who lived locally.

Renal failure was the most common cause for hyperferritinaemia in the overall patient population of the hospital trust that provides significant tertiary care, however, alcoholic liver disease was the most common cause of a raised ferritin level in the local population. 51% of patients in our study had only one cause identified for their hyperferritinaemia, with alcoholic liver disease being the most common single cause for a raised ferritin

level. Hereditary haemochromatosis accounted for only 9% of cases, ranking as the 10th commonest cause of hyperferritinaemia. Liver disease (alone) accounted for 25% of cases, but contributed to raised ferritin levels in 44%.

Degree of hyperferritinaemia

The median ferritin level was 2613 µg/L. Those with liver diseases had the highest ferritin levels (Table 4). Patients with haematological disease (or repeated blood transfusion) as the single cause of a ferritin level \geq 1500 µg/L also had very high median ferritin level results. Patients with renal failure had relatively lower median ferritin level results.

DISCUSSION

Tests to determine serum ferritin levels are frequently requested, and causes of a markedly raised ferritin level are multiple. This study concentrated on the conditions found in patients known to have hyperferritinaemia, and did not look at the initial indication for checking the serum ferritin level. Clinicians may not routinely check serum ferritin in all patients with, for example, normal liver function tests or normal haemoglobin, and thus our list of associated conditions may not accurately reflect all the causes of hyperferritinaemia.

We chose 1500 µg/L (more than seven times the upper limit of normal) as our cut-off for defining hyperferritinaemia. This gave us a large enough study cohort to provide meaningful data, whilst producing a manageable number from which to accurately retrieve patient information.

Hereditary Haemochromatosis

Dying red blood cells in macrophages are broken down to release iron to serum transferrin, which is then taken up by transferrin receptors on parenchymal tissues and in the bone marrow. In HHC, it is thought the binding of transferrin receptor 1 is inhibited in crypt and reticuloendothelial cells via the protein hepcidin^[4]. This leads to raised ferritin, high transferrin saturation and high liver iron concentration.

HHC is a relatively rare cause of markedly raised ferritin ranking as the 8th most common cause in the local population. Local guidelines for the diagnosis of HHC suggest that unless the transferrin saturation is $>$ 45% genotyping is not indicated^[3]. A serum ferritin greater than 300 µg/L (for men and post-menopausal women) is regarded as requiring further investigation for HHC. Our cut-off of 1500 µg/L is likely to have missed a large proportion of patients with HHC, which would include both those with a mild degree of iron overload and patients with HHC undergoing successful venesection treatment. HHC has a prevalence of 1/300 (which should be 900 patients locally). Clearly, if stable patients are having their ferritin levels checked twice yearly as recommended, our study would have missed a large proportion of these patients, suggesting that local venesection therapy is working.

It is well-known now that patients who are ho-

Table 4 Median ferritin levels in each condition

Condition (n)	Median ferritin µg/L	Number with condition as single identifiable cause for ferritin \geq 1500 µg/L	Median ferritin in those with = cause for ferritin \geq 1500 µg/L
HHC (13)	5031	5	7432
Other liver disease (19)	2889	8	3055
Unexplained (3)	2606	n/a	n/a
Weight loss (16)	2508	2	2160
ALD (31)	2484	24	2121
Autoimmune disease (21)	2203	2	2017
Haematological disease (31)	2075	5	3974

Repeated blood transfusion (29)	1977	1	6315
Renal failure (40)	1975	20	1954
Neoplasia (26)	1767	3	2409
HIV (1)	1711	0	n/a

mozygous for HHC and who drink more than 60 g alcohol per day are approximately 9 times more likely to develop cirrhosis than those who drink less. This is associated with a massive rise in iron concentrations on biopsy^[5]. All eight patients with HHC who had more than one identifiable risk factor for hyperferritinaemia were heavy drinkers.

Other Liver Diseases

The liver diseases (particularly HHC) produce the most markedly raised ferritin levels, especially in those with no other contributing factors (Table 4). There is evidence now of an association between iron excess on liver biopsy with other metabolic disorders^[6]. A study in 2001 confirmed that an increased ferritin level with normal transferrin saturation is frequently found in patients with hepatic steatosis^[7] but reflects iron overload only in those in whom it persists despite an appropriate diet. We did not include non-alcoholic steatohepatitis or fatty liver disease as separate diagnoses, nor did we look at associated metabolic disease, other than HHC, but it seems likely given the above evidence, that some of the patients in the “other liver disease” category had these conditions.

Investigating patients who were referred with abnormal liver function tests who were found to have a raised serum ferritin level is potentially time-consuming and costly. Time and resources could be reduced if cut-off levels for serum ferritin, above which specific diagnoses could be included or excluded from the differential diagnosis, were available. To do this most effectively, we would need to look at median ferritin levels at diagnosis for all patients with each of the liver diseases (e.g., ALD, HHC, fatty liver, autoimmune hepatitis) and not just at those patients identified with marked hyperferritinaemia. This may then enable greater targeting in subsequent investigations. From our limited study, it seems likely that patients with massively raised ferritin levels (e.g. $>$ 5000 µg/L) are more likely to have HHC than any of the other chronic liver diseases or conditions commonly associated with hyperferritinaemia.

Weight Loss

More patients had weight loss as an identifiable potential cause of their hyperferritinaemia than had haemochromatosis. The weight loss in the majority of these patients was associated with neoplasia or chronic inflammatory disease. It is not possible to determine whether this was a significant factor in the development of hyperferritinaemia. Only two patients seemed to have weight loss alone as a cause for their hyperferritinaemia.

Patients with anorexia nervosa may be found to have increased ferritin and abnormal liver biopsies with high iron content. A study looking at malnourished children demonstrated abundant iron stores in the liver despite evidence of iron deficiency [personal communication, Professor Alan Jackson, University of Southampton]. The causes for this are unclear but it is postulated that the demand for oxygen carriage is reduced in the face of a diminished lean body mass, and hence red cell mass is lower due to the release of iron to be stored. It is also thought that bone marrow activity may be directly or indirectly suppressed due to ongoing stress or infection-related challenge, thus reducing demand on stored iron. Limited nutrient availability may also suppress marrow activity^[8]. These possible explanations are not mutually exclusive.

Renal Failure

Usual tests to diagnose iron deficient anaemia and measure iron stores are suspect in those with chronic renal failure, who are plagued by poor nutrition, multiple medications and acute and chronic inflammatory processes^[9]. Iron replacement therapy in chronic renal failure is common and these patients frequently undergo ferritin checks as a measure of their iron stores. There may be therefore a disproportionately high number of patients with chronic renal failure included in our study. The median ferritin level in patients with renal failure was 1959 µg/L (1954 µg/L in those with RF as a single cause). 52% (22/42) of patients

with renal failure had a ferritin level < 2000 µg/L making up 38% of all those with ferritin levels < 2000 µg/L in this study.

CONCLUSIONS

Serum ferritin level tests are frequently requested by clinicians. Clinicians should remember that alcohol related liver disease, haematological disease, renal failure and neoplasia are much more common causes of marked hyperferritinaemia than haemochromatosis. Further investigations into the role of weight loss as a contributing factor to raised ferritin levels are needed.

Abstract

AIM: To investigate the expression of nucleoporin 88 (Nup88) in hepatitis B virus (HBV) and C virus (HCV)-related liver diseases.

METHODS: We generated a new monoclonal Nup88 antibody to investigate the Nup88 protein expression by immunohistochemistry (IHC) in 294 paraffin-embedded liver specimens comprising all stages of hepatocellular carcinogenesis. In addition, in cell culture experiments HBV-positive (HepG2.2.15 and HB611) and HBV-negative (HepG2) hepatoma cell lines were tested for the Nup88 expression by Western-immunoblotting to test data obtained by IHC.

RESULTS: Specific Nup88 expression was found in chronic HCV hepatitis and unspecific chronic hepatitis, whereas no or very weak Nup88 expression was detected in normal liver. The Nup88 expression was markedly reduced or missing in mild chronic HBV infection and inversely correlated with HBcAg expression. Irrespective of the HBV- or HCV-status, increasing Nup88 expression was observed in cirrhosis and dysplastic nodules, and Nup88 was highly expressed in hepatocellular carcinomas. The intensity of Nup88 expression significantly increased during carcinogenesis ($P < 0.0001$) and correlated with dedifferentiation ($P < 0.0001$). Interestingly, Nup88 protein expression was significantly

downregulated in HBV-positive HepG2.2.15 ($P < 0.002$) and HB611 ($P < 0.001$) cell lines as compared to HBV-negative HepG2 cells.

CONCLUSION: Based on our immunohistochemical data, HBV and HCV are unlikely to influence the expression of Nup88 in cirrhotic and neoplastic liver tissue, but point to an interaction of HBV with the nuclear pore in chronic hepatitis. The expression of Nup88 in nonneoplastic liver tissue might reflect enhanced metabolic activity of the liver tissue. Our data strongly indicate a dichotomous role for Nup88 in non-neoplastic and neoplastic conditions of the liver.

INTRODUCTION

Hepatocellular carcinoma (HCC) ranks fifth of the most common cancers worldwide and its incidence is rising in the Western world^[1]. Due to the high mortality associated with HCC it is the third leading cause of cancer death worldwide^[1]. The majority of HCCs develop due to chronic hepatitis B virus (HBV) or hepatitis C virus (HCV) infection. However, the precise molecular etiology of HBV- and HCV- related HCC development remains poorly understood.

Bidirectional nuclear-cytoplasmic transport activity of oncogenes and tumorsuppressors through the nuclear pore is profoundly disturbed in cancer cells^[2]. It is assumed that transport through the nuclear pore is necessarily a crucial event in the development and maintenance of the tumor phenotype^[3]. Nucleoporin 88 (Nup88) is a protein located at the nuclear membrane and is involved in the bidirectional nuclear-cytoplasmic transport of proteins by forming nuclear pore complexes (NPC)

with other nucleoporins^[4,5]. Nup88 is associated in a dynamic subcomplex with CAN/Nup214, which has been implicated in nuclear protein import, nuclear mRNA export, and cell cycle regulation^[6]. Recently, overexpression of Nup88 has been demonstrated in a wide range of premalignant lesions and malignant tumors by using a polyclonal antibody^[7-9]. Thus, Nup88 has been suggested as a putative marker of malignant transformation. In addition, it has been shown that overexpression of Nup88 is involved in the tumorigenesis and aggressiveness of colorectal cancers^[10]. Overexpression of Nup88 is also linked to the enhanced metastatic potential of melanoma cells and it has been shown that Nup88 expression is up-regulated in primary foreskin melanocytes upon UV-A irradiation^[11,12]. In the present study we generated a new monoclonal Nup88 antibody and analyzed the expression of Nup88 in HBV- and HCV- related diseases of hepatocellular carcinogenesis in a large patient cohort and correlated major findings to cell culture experiments.

MATERIALS AND METHODS

Tissue samples

A total of 294 tissues were investigated for Nup88 expression by immunohistochemistry (IHC). One hundred and forty-one specimens were assessed on a liver tissue microarray (TMA) consisting of premalignant dysplastic nodules (DNs: $n = 33$) and hepatocellular carcinomas (HCCs: $n = 108$). Twenty-eight DN and 43 HCCs were infected with HCV, 16 DN and 17 HCCs were infected with HBV, and 11 DN and 8 HCCs were coinfecting with HBV and HCV. In addition, liver biopsies ($n = 153$) collected at the Institute of Pathology at Cologne were tested for Nup88 expression. These included cases of chronic HBV hepatitis ($n = 24$) and chronic HCV hepatitis ($n = 38$) with mild inflammatory activity, 53 cases of liver cirrhosis (HBV-positive, $n = 24$; HCV-positive, $n = 24$; alcohol induced, $n = 5$) and 18 cases of normal liver biopsies and 20 cases of mild unspecific chronic hepatitis (UCH), i.e. patients who underwent liver biopsies in the context of clinically elevated transaminases in the absence of HBV/HCV or any other known liver diseases.

Antibody production

Mouse monoclonal antibodies (mAbs) to protein Nup88 were obtained by immunization with the peptide representing the amino acid sequence (aa 1-263) deduced from the human cDNA sequence of Nup88 (NCBI, accession number: NP002523). As an immunogen the peptide was used to conjugate to keyhole limpet hemocyanin (KLH). For screening the carrier protein conjugated to the peptide was bovine serum albumin (BSA). Screening was performed using ELISA and Western immunoblotting following standard protocols. The mAbs were raised according to the method of Köhler and Milstein^[13].

Immunohistochemistry

Nup88 IHC was established on paraffin-embedded and formalin-fixed tissues. Colon adenomas and carcinomas ($n = 3$), breast carcinomas ($n = 2$) and lymph nodes with

Hodgkin's disease ($n = 3$) were used as positive controls^[18,9]. After deparaffinization and dehydration endogenous peroxidase was blocked by 1% H₂O₂ in methanol for 30 min. Without further pretreatment the slides were incubated with the mAb (clone 7, 1:750) in diluent buffer (Zymed Laboratories Inc., San Francisco, USA) at 4°C overnight. The Envision System HRP mouse (DakoCytomation, Carpinteria, USA) was applied to signal amplification for 30 min. For signal detection 3,3'-diaminobenzidine (DAB; Sigma Chemical Co., St. Louis, USA) was used. Slides were weakly counterstained with hematoxylin. Staining intensity and nuclear accumulation of Nup88 were evaluated by four independent observers and scored as: 0 = no signal; 1 = weak, pale nuclear staining; 2 = moderate staining; and 3 = strong staining. The HBV- and HCV-status was assessed by serology. Biopsies without serological information were tested for HBcAg and surface antigen (HBsAg) by IHC (see below) or by HCV-specific RT-PCR^[14]. Immunohistochemical double staining for HBcAg and Nup88 was performed on tissue specimens from mild chronic HBV hepatitis patients. In brief, the specimens were first treated with anti-HbcAg rabbit serum (DAKO, Hamburg, Germany) at a dilution of 1:400 for one hour at 37°C. After treatment with the secondary antibody for 30 min at room temperature, fast red alkaline phosphatase (Dako) was used as a chromogen. The Nup88 IHC was carried out as a second step according to the above protocol.

Cell culture experiments and Western immunoblotting

To analyze Nup88 expression in relation to HBV in cell culture, Nup88 and HbcAg expressions were tested in a hepatoma cell line. The HBV-negative HepG2 hepatoma cell line and its HBV-positive counterpart HepG2.2.15 were used^[15]. The latter contains the full length HBV genome and has been shown to produce infectious virions^[15]. Western immunoblots were performed as previously described using 75 g/L polyacrylamid gel^[17]. The monoclonal Nup88 antibody (clone 7, 1:2000 dilution) detected the 88 kDa Nup88 protein, the monoclonal HBcAg antibody (1:1000 dilution) and the 23 kDa HBcAg protein. Equal amounts of protein were loaded on the gel as tested by Bradford assay, Ponceau staining and GAPDH-Western blotting (Sigma, Germany; 1:1000) (Figure 3B).

Statistical analysis

For statistical analysis of the immunohistochemistry data of the TMA, chi-square test was applied. Densitometric evaluation of Western blot results from 6 independent experiments using *EASY plus Rev 4.16* were expressed as mean \pm SE. Results were compared using Student's *t*-test. $P < 0.05$ was considered statistically significant.

RESULTS

Nup88 expression in chronic HBV- and HCV-related hepatitis

In order to determine the Nup88 expression in viral hepatocellular carcinogenesis by IHC we first evaluated the efficacy of the new mAb Nup88 using different positive controls, i.e. colon carcinomas, breast carcinomas and

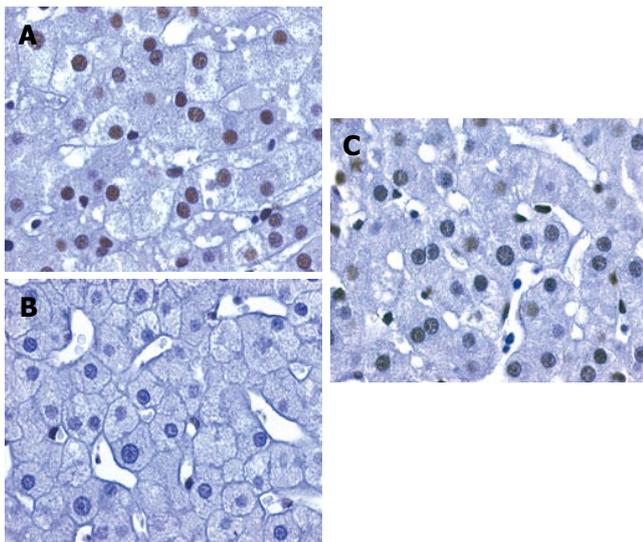

Figure 1 Nuclear Nup88 expression (brown nuclei) in non-neoplastic hepatocytes of a liver biopsy with mild unspecific chronic hepatitis (A), weak nuclear expression of Nup88 in chronic HBV-related hepatitis with mild inflammatory changes (B), and moderate nuclear expression of Nup88 in chronic HCV-related hepatitis with mild inflammatory changes (C).

lymph nodes with Hodgkin's disease^[8,9]. All positive controls demonstrated specific nuclear staining for Nup88 in the tumor cells whereas adjacent non-neoplastic tissue revealed no Nup88 expression. Of interest, no or only very weak Nup88 expression was detected in the 18 cases of normal liver biopsies, but in all 20 cases with mild reactive changes (mean staining score 2.4) (Figure 1A). In these cases Nup88 expression was found in most hepatocytes and occasionally in sinusoidal non-parenchymal liver cells. In contrast, in mild chronic HBV infection Nup88 expression was patchy, remarkably weaker or missing ($n = 24$, mean staining score 1.25) as compared to normal liver biopsies (Figure 1B). Stage-matched mild chronic HCV-infected liver samples ($n = 38$) revealed a moderate nuclear Nup88 expression (mean staining score 1.94; Figure 1C). No difference was observed in Nup88 expression between HBV- and HCV-related cirrhosis (mean staining score HBV-cirrhosis 1.91; HCV-cirrhosis: 2.04).

Double staining of Nup88 and HBcAg in mild chronic HBV-related hepatitis

In chronic HBV-related hepatitis with mild inflammatory activity HBcAg expression was patchy and restricted to single clusters of hepatocytes. To determine whether Nup88 was co-expressed with HBcAg in mild chronic HBV-related hepatitis we analyzed the relation between Nup88 and HBcAg expressions in mild chronic HBV-related hepatitis ($n = 5$) by IHC on serial sections and by IHC double staining. IHC staining for Nup88 and HBcAg on serial sections revealed a mutually exclusive staining of Nup88 or HBcAg. This inverse correlation between Nup88 and HBcAg expression patterns was confirmed by IHC double staining in which hepatocytes expressing HBcAg showed negative Nup88 expression and vice versa (data not shown).

Nup88 expression in hepatoma cell lines

To evaluate the impact of the presence of HBV on Nup88

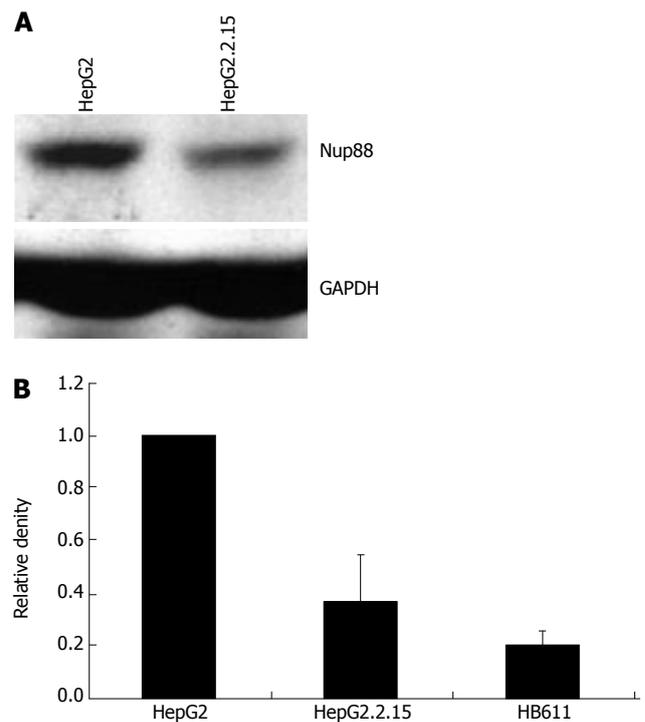

Figure 2 Western blot analysis showing reduced expression of Nup88 in HBV-positive HepG2.2.15 cells (A) and increased Nup88 expression in HBV-negative HepG2 and HBV-positive HepG2.2.15 ($P < 0.002$) and HB611 ($P < 0.001$) cells (B).

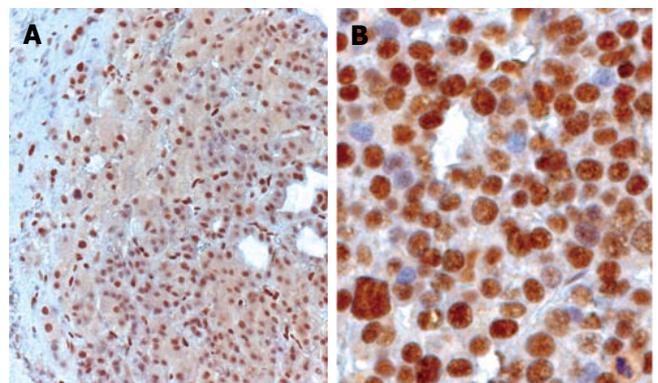

Figure 3 Nuclear Nup88-expression in a DN (A) and in dark brown nuclei of an undifferentiated HCC (B).

expression in cell culture the expression of Nup88 was assessed in hepatoma cell lines, i.e. the HBV-negative HepG2 and HBV-positive HepG2.2.15 and HB611 cell lines, by Western blot analysis. As expected, in HBV-negative HepG2 cells (Figure 2A) Nup88 expression could be clearly demonstrated. In contrast, Nup88 expression was significantly reduced in the HBV-positive HepG2.2.15 ($P < 0.002$) and HB611 ($P < 0.001$) hepatoma cell lines compared to HBV-negative HepG2 cells (Figure 2A and B).

Nup88 expression in dysplastic nodules and hepatocellular carcinomas

Nup88 was highly expressed in neoplastic hepatocytes of DN (Figure 3A) and HCC, but no significant differences were observed by IHC in Nup88 expression between

HBV- or HCV- associated HCCs and DN. Most if not all HCCs revealed a strong nuclear expression of Nup88. The strongest staining intensity was observed in undifferentiated HCC (Figure 3B). The high overexpression of Nup88 correlated with the degree of tumor cell dedifferentiation ($P < 0.0001$). In contrast, a weaker Nup88 expression was observed in DN. By comparing Nup88 expression intensity between DN and different grades of HCC, a significant increase was observed ($P < 0.0001$).

DISCUSSION

HCC is a major global health problem^[17]. The most common cause of HCC worldwide is chronic infection with HBV and HCV^[18]. Although the link of virus-related hepatocellular carcinogenesis has been well established, the underlying molecular pathogenesis is still poorly understood. In the present study we investigated the Nup88 expression in chronic viral hepatitis and virus-associated hepatocellular carcinogenesis. Nup88 is one of the known components of nucleoporins forming the nuclear pore complex (NPC) which is involved in nuclear transport. By using a polyclonal antiserum it has recently been shown that Nup88 is highly expressed in premalignant and malignant conditions^[7-11]. Here, we introduce a new monoclonal anti-Nup88 antibody which specifically detects Nup88 in Western-immunoblotting. In addition, this is the first monoclonal antibody to specifically detect Nup88 in paraffin-embedded and formalin-fixed tissues by IHC. In line with recently published data, our Nup88 antibody can also specifically detect neoplastic colorectal, mammary and lymphoma cells^[8,9]. Nup88 expression has recently been suggested as a marker for premalignant or malignant transformation. Therefore, the expression of Nup88 in non-neoplastic hepatocytes is remarkable. According to our results the expression of Nup88 in non-neoplastic liver tissue might reflect an elevated metabolic activity of cells that ensures the nuclear import and export of transcription factors^[2]. This hypothesis is supported by the finding of nuclear Nup88 expression in viral hepatitis as well as in HCC. In both cases hepatocytes exhibit an increased metabolic activity due to inflammation or malignant transformation. Until today Nup88 expression has only been described in the context of malignant transformation or tumor progression. Thus, our data might indicate additional functions of Nup88 expression in non-neoplastic liver tissue.

Reduced Nup88 expression in mild chronic HBV hepatitis compared to normal liver tissue and liver samples with mild uncharacteristic changes may contribute new insights to the understanding of HBV and NPC interaction. Recently, it has been shown that the HBV core protein binds to the NPC^[20,21]. However, the target domain of the anti-NPC antibody used in this study has not been exactly defined within the NPC, which consists of many different nucleoporins^[4,5]. We tempt to speculate that the low Nup88 detection in mild chronic HBV-associated hepatitis is due to an interaction of HBV with Nup88. The mechanism of this interference is not clear. However, it could occur directly by protein-protein interaction and therefore masking the Nup88 epitope or HBV may be

able to downregulate Nup88 at the transcriptional or protein level. Another hypothesis is that HBV, most likely the core antigen, might compete for NPC-components like CAN/Nup214. This is supported by the mutual exclusiveness of Nup88 and HBcAg expression in mild chronic HBV-associated hepatitis. In line with these data we have demonstrated in cell culture experiments that Nup88 expression is significantly reduced in HBV-positive HepG2.2.15 and HB611 cells compared to HBV-negative HepG2 cells. Moreover, recent work has identified the NPC-filament protein CAN/Nup214 as a docking site for incoming adenovirus type 2 (Ad2) capsid proteins^[22]. Therefore we hypothesize that NPC components like CAN/Nup214 and/or Nup88 might serve as docking sites for different viruses, e.g. HBV. Currently we are investigating not only this hypothesis in our laboratories by generating monoclonal Nup214 antibodies but also the possible transcriptional regulation of Nup88 by HBV. It is of interest that this phenomenon seems to be restricted to mild chronic HBV hepatitis and is not observed in later stages of hepatocellular carcinogenesis. Both increased nuclear Nup88 expression and elevated intensity correlate with the dedifferentiation of HCC and might be of interest in histopathological diagnostics. Although Nup88 expression in tumor cells is a marker for malignant transformation, it is highly overexpressed especially in undifferentiated HCC. Increased Nup88 expression has also been found in the colorectal adenoma/carcinoma sequence and overexpression of Nup88 mRNA has been shown to be associated with high aggressiveness of breast cancer^[3,9,10]. In contrast to Emlerling and coworkers^[10] we were not able to determine in our patient cohort whether the expression of Nup88 is of relevance with the survival of HCC patients, although undifferentiated HCCs tend to have a worse clinical outcome.

In summary, Nup88 is expressed in non-neoplastic and malignant hepatocytes, indicating that Nup88 plays a dichotomous role in non-neoplastic and neoplastic conditions of the liver. In addition, Nup88 is significantly overexpressed in poorly differentiated HCCs. The markedly reduced Nup88 expression in mild chronic HBV hepatitis and significantly less Nup88 expression in HBV-positive HepG2.2.15 and HB611 cells strongly point to an interference of HBV with the nuclear pore.

Abstract

AIM: To investigate plasma levels of N-terminal pro-brain natriuretic peptide (NT-proBNP), an established marker of cardiac function, in patients with chronic hepatitis C during interferon-based antiviral therapy.

METHODS: Using a sandwich immunoassay, plasma levels of NT-proBNP were determined in 48 patients with chronic hepatitis C at baseline, wk 24 and 48 during antiviral therapy and at wk 72 during follow-up.

RESULTS: Plasma NT-proBNP concentrations were significantly increased ($P < 0.05$) at wk 24, 48 and 72 compared to the baseline values. NT-proBNP concentrations at baseline and wk 24 were closely correlated ($r = 0.8$; $P < 0.001$). At wk 24, 7 (14.6%) patients had NT-proBNP concentrations above 200 ng/L compared to 1 (2%) patient at baseline ($P = 0.059$). Six of these 7 patients had been treated with high-dose IFN- α induction therapy. In multiple regression analysis, NT-proBNP was not related to other clinical parameters, biochemical parameters of liver disease or virus load and response to therapy.

CONCLUSION: Elevated levels of NT-proBNP during and after interferon-based antiviral therapy of chronic hepatitis C may indicate the presence of cardiac dysfunction, which may contribute to the clinical symptoms observed in patients during therapy. Plasma levels of NT-proBNP may be used as a diagnostic tool and for guiding therapy in patients during interferon-based antiviral therapy.

Key words: Hepatitis C; N-terminal pro-brain natriuretic peptide; Interferon; Cardiomyopathy; Treatment side effects

INTRODUCTION

The current standard of care for patients with chronic hepatitis C is the combination treatment with (pegylated) interferon plus ribavirin^[1,2]. Almost all patients experience side effects like fatigue, dyspnea and reduced physical activity. However, in many patients, these symptoms are not proportional to the decline of hemoglobin and resemble symptoms of heart failure.

Cardiotoxicity is assumed to be a rare complication of interferon therapy with few significant life-threatening cardiovascular effects reported^[3,4]. A small number of cases of suspected interferon-induced cardiomyopathy have been documented and in most of the patients, cardiac toxicity was reversible following the cessation of the drug therapy^[5].

Several studies have shown that plasma levels of brain natriuretic peptide (BNP) and N-terminal proBNP (NT-proBNP) are reliable diagnostic and prognostic markers for cardiac disease^[6,7] that correlate with symptoms of heart failure and the severity of systolic and diastolic dysfunction^[8]. In addition, BNP also predicts death, first major cardiovascular events, heart failure and stroke^[9].

In the present study, we assessed concentrations of circulating NT-proBNP in chronic hepatitis C patients before and during interferon-based antiviral therapy. Levels of this cardiac peptide were related to clinical, biochemical and virologic parameters in these patients.

MATERIALS AND METHODS

Subjects

The study population comprised of 48 patients (15 females and 33 males; mean age: 51 years, range: 33-76 years) with chronic hepatitis C virus infection. None of the patients had signs of heart failure, organic renal disease, thyroid disease, diabetes, cancer, or any other major diseases. All patients had normal cardiac physical examination and normal blood pressure. Thirty one patients were infected

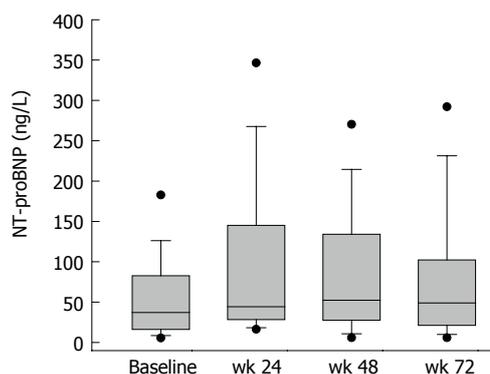

Figure 1 Plasma NT-proBNP concentrations before treatment, at wk 24 and 48 of therapy with interferon and ribavirin and at wk 72 of follow-up in patients with chronic hepatitis C virus infection (median with 5th/95th percentile; mean as a dotted line; Friedman repeated measures ANOVA, Student-Newman-Keuls method).

with hepatitis C virus genotype 1, 6 with genotype 2, 10 with genotype 3 and 1 with genotype 4. All patients received interferon-based antiviral therapy for 48 wk. Sixteen patients received 3 Mio IU IFN-2b three times a week plus ribavirin 1000/1200 mg per day; 14 patients received 9 Mio IU IFN-2a per day for 2 wk, 6 Mio IU per day for 4 wk, 3 Mio IU per day for 6 wk and then 3x3 Mio IU per week plus ribavirin 1000/1200 mg per day; 11 patients received 10 Mio IU IFN-2b daily for 2 wk, then 5 Mio IU for 6 wk, 3 Mio IU for 16 wk and finally 3 Mio IU three times a week plus ribavirin 1000/1200 mg per day; 3 patients received 1.5 µg/kg PEG-IFN-2b for 4 wk, then 0.5 µg/kg plus 1000-1200 mg ribavirin; 2 patients received PEG 2a 180 µg plus 1000/1200 mg ribavirin; and 2 patients received PEG 2b 1.5 µg/kg plus ribavirin 800 mg daily.

Assays

All blood samples were drawn in the morning after an overnight fast. Blood samples for analysis of plasma NT-proBNP were collected, centrifuged and plasma was stored at -80°C until analysis. Plasma concentrations of NT-proBNP were measured by a sandwich immunoassay on an Elecsys 2010 (Roche Diagnostics, Mannheim, Germany). Blood samples were taken at baseline, at wk 24 and 48 during antiviral therapy, and at wk 72, i.e. 24 wk after the end of therapy.

Statistical analysis

Comparison of plasma NT-proBNP concentrations at baseline and during antiviral therapy and follow-up was performed with a Friedman repeated measures analysis of variance (ANOVA) on Ranks with an all pairwise multiple comparison procedure using the Student-Newman-Keuls method. Correlations were performed by the Spearman rank order correlation test. Fisher exact test was used to compare categorical variables. A multiple regression model was used to evaluate the relation between plasma NT-proBNP concentrations at baseline, during antiviral therapy and follow-up on the one hand and clinical, biochemical and virologic parameters on the other hand. Values were expressed as Mean ± SE. A *P* value less than 0.05 was considered statistically significant.

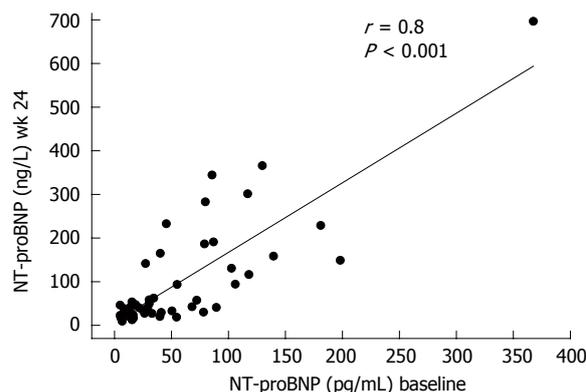

Figure 2 Correlation between plasma NT-proBNP concentrations before treatment and at wk 24 of therapy with interferon and ribavirin in patients with chronic hepatitis C virus infection (Spearman rank order correlation test).

RESULTS

Plasma NT-proBNP concentrations were significantly higher at wk 24 of therapy (mean 102 ± 18.4 ng/L; median 44.3 ng/L, range 9.2-696.4; *P* < 0.05), wk 48 of therapy (mean 89 ± 12.4 ng/L; median 52.4 ng/L, range 5.0-376.4; *P* < 0.05) and remained elevated in the follow-up period (mean 83 ± 14.1 ng/L; median 49.0 ng/L, range 5.0-433.3; *P* < 0.05) compared to baseline values before treatment (mean 59 ± 9.4 ng/L; median 37.1 ng/L, range 5.0-367.60; Figure 1). NT-proBNP concentrations at baseline and wk 24 were closely correlated (*r* = 0.8; *P* < 0.001; Figure 2). At wk 24, 7 (14.6%) patients had NT-proBNP concentrations above 200 ng/L compared with 1 (2%) patient at baseline (*P* = 0.059). Six of these 7 patients had received high-dose of interferon at the beginning of the treatment as an induction therapy, whereas 1 had received standard regimen with pegylated IFN once a week (*P* = 0.21).

In multiple regression analysis, plasma NT-proBNP concentrations before therapy were not related to other clinical or biochemical parameters of liver disease or virologic parameters and response to therapy (Table 1). However, elevated plasma NT-proBNP concentrations at wk 24 of therapy were predicted by plasma NT-proBNP concentrations before therapy (*P* < 0.01; Table 1).

DISCUSSION

The present study showed that circulating NT-proBNP concentrations increased significantly in patients with chronic hepatitis C virus infection during interferon-based antiviral therapy with a trend to affect patients more often that had received high-dose of interferon at the beginning of the therapy. This effect persisted during follow-up up to 24 wk after the end of therapy.

The findings of the present study may have important implications for patients with chronic hepatitis C virus infection during interferon-based antiviral therapy. Most patients complain about fatigue, dyspnea and reduced physical capacity during antiviral therapy which is frequently discontinued for these reasons. The pathogenesis of these symptoms is not well understood and sometimes attributed to the development of anemia. However, it seems possible that these patients experience

Table 1 Baseline characteristics of clinical, biochemical and virologic variables and their relations to baseline NT-proBNP concentrations in multiple regression analysis (mean \pm SE)

Variables	Value (mean \pm SE)	Regression coefficient	Standard error	P
Age (yr)	51 \pm 1.6	-0.03	0.8	0.96

cardiac impairment causing or at least contributing to these symptoms. Testing of NT-proBNP may serve as a screening marker for cardiac insufficiency in the differential diagnosis of fatigue and dyspnea and may alleviate the decision for further diagnostic testing of cardiac function as it has been described for other groups of patients^[10-13]. Besides diagnostic consequences, evaluation of NT-proBNP may have therapeutic consequences for patients with chronic hepatitis C virus infection during antiviral therapy with interferons as well. In patients with known congestive heart failure, elevated plasma BNP concentrations could be reduced by treatment with ACE inhibitors^[14], angiotensin II receptor antagonists^[15] as well as treatment with diuretics and vasodilators^[16]. As a consequence, plasma NT-proBNP concentrations may guide the intensity of pharmacotherapy as some interventional studies have suggested^[17,18].

In conclusion, this is probably the first study reporting elevated levels of NT-proBNP during and after interferon-based antiviral therapy in patients with chronic hepatitis C. This may indicate the presence of cardiac dysfunction and explain the clinical symptoms of patients during therapy and the discrepancy between these symptoms and the severity of anemia. Further prospective studies quantifying symptoms and correlating these with echocardiographic parameters are needed to confirm this association. In addition, interventional studies are required whether therapy of cardiac insufficiency can improve the side effect profile of interferon-based therapy in patients treated for chronic hepatitis C.

Abstract

AIM: To study the presence of sustained low diffusing capacity (DL_{CO}) after liver transplantation (LT) in patients with hepatopulmonary syndrome (HPS).

METHODS: Six patients with mild-to-severe HPS and 24 without HPS who underwent LT were prospectively followed before and after LT at mid-term (median, 15 mo). HPS patients were also assessed at long-term (median, 86 mo).

RESULTS: Before LT, HPS patients showed lower PaO₂ (71 ± 8 mmHg), higher AaPO₂ (43 ± 10 mmHg) and lower DL_{CO} (54% ± 9% predicted), due to a combination of moderate-to-severe ventilation-perfusion (V_A/Q) imbalance, mild shunt and diffusion limitation, than non-HPS patients (94 ± 4 mmHg and 19 ± 3 mmHg, and 85% ± 3% predicted, respectively) (*P* < 0.05 each). Seven non-HPS patients had also reduced DL_{CO} (70% ± 4% predicted).

At mid- and long-term after LT, compared to pre-LT, HPS patients normalized PaO₂ (91 ± 3 mmHg and 87 ± 5 mmHg), AaPO₂ (14 ± 3 mmHg and 23 ± 5 mmHg) and all V_A/Q descriptors (*P* < 0.05 each) without changes in DL_{CO} (53% ± 8% and 56% ± 7% predicted, respectively). Post-LT DL_{CO} in non-HPS patients with pre-LT low DL_{CO} was unchanged (75% ± 6% predicted).

CONCLUSION: While complete V_A/Q resolution in HPS indicates a reversible functional disturbance, sustained low DL_{CO} after LT also present in some non-HPS patients, points to persistence of sub-clinical liver-induced pulmonary vascular changes.

INTRODUCTION

Single-breath diffusing capacity (DL_{CO}) for carbon monoxide (transfer factor) impairment is the single most commonly abnormal lung function test in patients with end-stage hepatic disease^[1]. Although the mechanism of this isolated abnormality in advanced hepatic patients without chronic respiratory co-morbidities remains largely unknown, its high prevalence suggests sub-clinical liver-induced changes in the pulmonary vascular bed. Pathophysiologically, alveolar ventilation to pulmonary blood flow (V_A/Q) imbalance secondary to narrowing and early closure of airways to dependent lung zones as a consequence of interstitial edema and/or ascites in the context of fluid retention has been suggested as the most plausible mechanism^[1,2].

Alternatively, in patients with hepatopulmonary syndrome (HPS), an arterial oxygenation defect caused by intrapulmonary vascular dilatations (IPVD) in patients with liver disease^[3,4], V_A/Q mismatching along with intrapulmonary shunt (i.e., zero V_A/Q units) and diffusion limitation for oxygen essentially reflecting a diffusion-perfusion defect^[5] encompass the frequent finding of low DL_{CO}^[4]. It is highly likely that in HPS DL_{CO} is reduced because the distance between the alveoli and the red cells in the central stream of the dilated pulmonary microvessels is too great for complete equilibration of CO with hemoglobin^[4]. Diffusion limitation for oxygen may be aggravated in part by a high cardiac output (Q_T) resulting in a shorter transit time of the red blood cell, hence contributing to the development of the diffusion-perfusion abnormality^[4].

We have shown that, in patients with HPS, several gas exchange markers, namely PaO₂, alveolar-to-arterial PO₂

difference (AaPO₂), intrapulmonary shunt and increased low V_A/Q regions, correlate with DL_{CO}^[6]. Similarly, greater predicted (calculated according to the multiple inert gas elimination technique [MIGET]^[7]) than measured PaO₂, an indirect estimate of diffusion limitation for oxygen, correlates with DL_{CO} in hypoxemic HPS patients^[6]. Low transfer factor is also a reliable predictor for the diagnosis of HPS^[6].

Liver transplantation (LT) is the only therapeutic approach leading conclusively to complete resolution of advanced hepatic disease, including gas exchange abnormalities in HPS^[4,8-10]. Although sustained low DL_{CO} in hepatic patients with and without HPS has been reported after LT^[8,9,11,12], this finding remains controversial. Persistence of low DL_{CO} after LT would point to an underlying pulmonary vascular derangement.

We therefore decided to investigate comprehensively gas exchange status before and after LT in hepatic patients with and without HPS, to shed further light into the pathophysiology of low DL_{CO} in advanced hepatic disease states.

MATERIALS AND METHODS

Subjects

From our original cohort of 80 candidates for LT (14 patients with and 66 without HPS)^[6], a subset of 42 recipients of LT (53%) (9 with and 33 without HPS) between 1995 and 1997 was prospectively followed. An additional patient with HPS transplanted in 2000 was also included. From these 43 patients, 4 HPS (3 died before follow-up, 1 declined consent) and 9 non-HPS patients (6 died before follow-up, 3 refused to participate) were lost, the final population including 30 patients (6 with and 24 without HPS) (Table 1). Initial immunosuppressive therapy consisted of systemic corticosteroids, azathioprine and cyclosporine. Azathioprine was administered only during the first postoperative month. The dosage of corticosteroids was progressively tapered until discontinuation at the 18-24th mo. Cyclosporine was maintained through the period. The doses of these immunosuppressive drugs were also appropriately modified according to development of serious adverse effects or organ rejection. The study was approved by the Ethics Committee of our centre and all patients gave their written informed consent.

The diagnosis of HPS was based on the presence of an oxygenation defect [namely, increased AaPO₂ ≥ 15 mmHg while breathing air in upright position, irrespective of the presence of hypoxemia (PaO₂ < 80 mmHg)] and indicative evidence of IPVD [using contrast-enhanced echocardiography (CEE)] in a patient with underlying chronic hepatic disease, according to the European Respiratory Society (ERS) recommendations^[4].

Study design

Lung function tests were assessed in all patients before LT (median, 4 mo; range, 2 wk-18 mo; HPS patients, 2 wk-12 mo) and between 12 and 18 mo (median, 15 mo; mid-term ≤ 1.5 yr) following LT. Patients with HPS were also evaluated at long-term (≥ 3 yr after LT) (median, 86 mo;

range, 45-117 mo) (one patient refused arterial puncture at this time point only). CEE measured as previously described^[6], was performed before LT in all patients and also after LT in HPS patients (at mid-term only). In the latter individuals, V_A/Q distributions were also estimated before and at mid-term after LT.

Measurements

Forced spirometry, static lung volumes, DL_{CO} after correction for anemia^[13], minute ventilation (V_E), arterial respiratory blood gases (PaO₂, PaCO₂, AaPO₂) and pH, and oxygen consumption (VO₂) were measured or calculated as previously described^[6]. In the 6 patients with HPS, V_A/Q distributions were calculated using MIGET as previously described^[6]. A pulmonary artery catheter was inserted (Swan-Ganz catheter, Baxter Healthcare, Irvine, CA, USA) in 4 patients and MIGET was computed using mixed venous respiratory and inert gases and cardiac output (Q_T) determined by thermodilution. In the remaining 2 HPS patients, Q_T was measured by dye dilution (DC-410; Waters Instruments, Rochester, MN, USA) such that mixed venous inert gases and PO₂ were estimated by mass balance in the customary manner^[7]. The agreement between these two MIGET approaches has been previously validated in our laboratory^[14]. The dispersion of the distributions of pulmonary blood flow (Log SDQ) and alveolar ventilation (Log SDV) on a logarithmic scale (upper normal limit, 0.60 and 0.65, respectively)^[15], key descriptors of the amount of low and high V_A/Q units respectively, and the difference among measured retentions and excretions of the inert gases corrected for the

elimination of acetone (DISP R-E*) (normal values < 3.0), an overall (mathematical) index of V_A/Q heterogeneity^[16], all dimensionless, were the most accurately used indices of V_A/Q imbalance. Intrapulmonary shunt and low V_A/Q regions were defined as the fraction of blood flow diverted to lung units with low V_A/Q ratios < 0.005 and between 0.005 and 0.1, respectively. Dead space was defined as the fraction of alveolar ventilation diverted to lung units with V_A/Q ratios > 100 .

Statistical analysis

Descriptive data are expressed as mean \pm SE. Paired and unpaired Student's *t* tests were used to compare data before and after LT and Pearson's correlations test was used when appropriate. $P \leq 0.05$ was considered statistically significant at all effects.

RESULTS

Before LT

Lung function tests before and after LT in patients with and without HPS are set out in Table 2. Respiratory symptoms and signs were more prevalent in HPS patients. Although mean spirometric and static lung volumes were within normal limits without differences between the two subgroups, individually one non-smoker with HPS (No.3)

had a mild restrictive pattern (due to pleural thickening) and 3 other HPS patients (No.4-6) (one smoker and two ex-smokers) had mild to moderate airflow limitation (Table 3). Compared to patients without HPS (Table 2), DLco and DLco/alveolar volume (Kco) were mildly to severely decreased ($< 80\%$ predicted) in each HPS patient ($P < 0.05$ each). In patients without HPS, DLco was mildly to moderately reduced ($70\% \pm 4\%$ predicted; range, 54%-79% predicted) in 7 (Figure 1), all but 2 (PaO₂, 58 and 74 mmHg each) normoxemic (PaO₂, 92 ± 8 mmHg; FEV₁, $93\% \pm 5\%$; FEV₁/FVC ratio, $78\% \pm 2\%$). In contrast, DLco was normal ($91\% \pm 3\%$ predicted; range, 80%-131% predicted; PaO₂, 95 ± 5 mmHg) in the 17 remainders without other differences between these two subgroups. Both V_E and VO₂ in all patients and Q_T, measured in HPS patients only, were increased. Chest high-resolution CT scans in HPS patients excluded the coexistence of emphysematous and/or diffuse interstitial changes.

Three HPS patients (No.1, No.3 and No.4) had severe disease (PaO₂ $< 60 - \geq 50$ mmHg), one (No.2) moderate (PaO₂ $< 80 - \geq 60$ mmHg) and the two remainders (No.5 and No.6) a mild stage (PaO₂ ≥ 80 mmHg; AaPO₂, 26 and 17 mmHg each)^[4] (Figure 1). Patients with HPS had lower PaO₂ and higher AaPO₂ than non-HPS patients ($P < 0.05$ each), while PaCO₂ was equally decreased in the two groups. Distributions of V_A/Q ratios were

¹Percentage of blood flow to unventilated units (V_A/Q < 0.005) (normal, 0% of Q_T); ²Cardiac output; ³Perfusion to units with V_A/Q ratios between 0.005 and 0.1 (normal, 0% of Q_T); ⁴Mean V_A/Q of the perfusion distribution; ⁵Dispersion of blood flow distribution (normal < 0.60); ⁶Mean V_A/Q of the ventilation distribution; ⁷Dispersion of ventilation distribution (normal < 0.65); ⁸The difference among measured retentions and excretions of the inert gases corrected for the excretion of acetone (normal < 3.0); ⁹Predicted PaO₂ (by MIGET)-actual PaO₂ (measured). ^aP < 0.05 vs pre-LT.

abnormal in each HPS patient, as shown by mild to severe increases in Log SDQ and DISP R-E*, mild to moderate increases in intrapulmonary shunt and mildly increased low V_A/Q regions (Table 4). The mean distribution of pulmonary blood flow (mean Q) was mildly reduced (normal, ~1.0). By contrast, Log SDV was normal and the mean distribution of alveolar ventilation (mean V) was moderately increased. Dead space was severely reduced. In 3 hypoxemic HPS patients, predicted (according to MIGET) PaO₂ (68 \pm 2 mmHg) was greater than actual measured PaO₂ (55 \pm 2 mmHg). There was a negative correlation between the latter PO₂ difference and low DL_{CO} in all HPS patients ($r = -0.85$; $P < 0.05$), suggesting a close relationship between diffusion impairment for oxygen and DL_{CO}.

After LT

Liver function tests were within normal limits in all patients and diseases such as *de novo* autoimmune hepatitis, non-alcoholic steato-hepatitis, chronic rejection, and severe hepatitis C recurrence were excluded. At mid-term, all patients improved clinically while mean FEV₁ and lung volumes remained unchanged.

In patients with HPS, CEE-evidence for IPVD normalized, while both breathlessness and exercise tolerance substantially ameliorated or disappeared. Three HPS patients showed progressive resolution of finger clubbing. As opposed to the absence of any improvement in both DL_{CO} and K_{CO}, the three arterial blood gas markers substantially ameliorated reaching normal limits ($P < 0.05$ each) close to those of non-HPS patients before LT. This was essentially due to resolution of all V_A/Q descriptors, namely intrapulmonary shunt, regions of low V_A/Q units, Log SDQ and DISP R-E* ($P < 0.05$ each) (Table 4). Dead space and mean V remained unchanged. Predicted (98 \pm 2 mmHg) and actual (91 \pm 3 mmHg) PaO₂ in pre-LT hypoxemic HPS normalized and there was no correlation between the latter PO₂ difference and low DL_{CO}.

In patients without HPS, mean PaO₂, AaPO₂ and

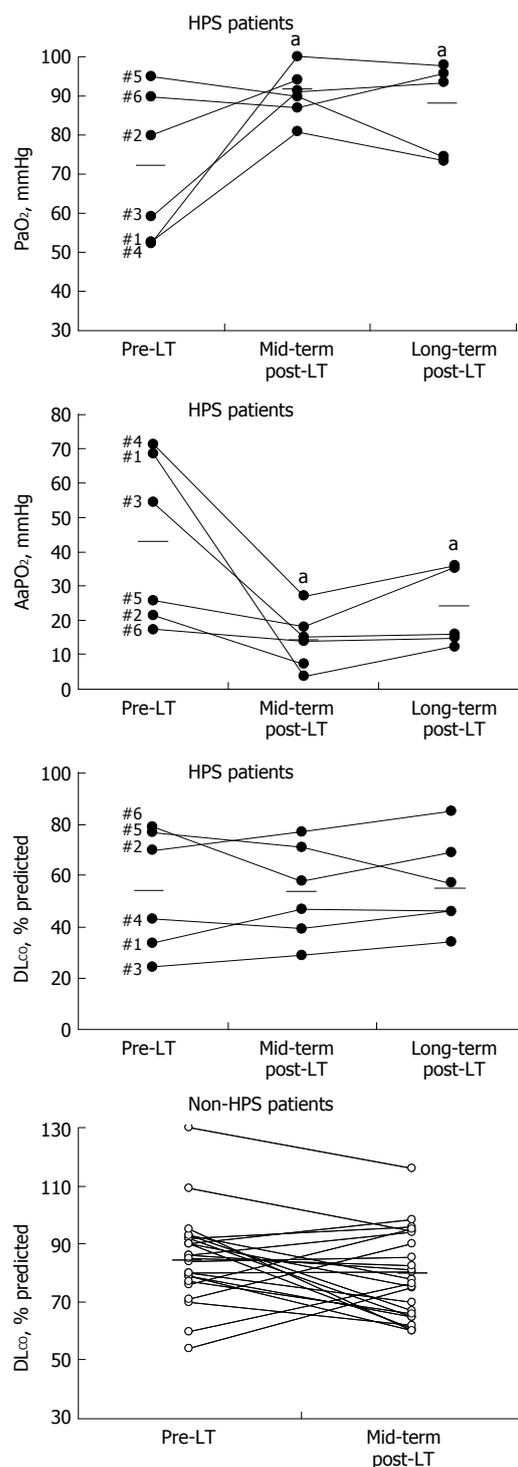

Figure 1 Individual values of arterial PO₂, AaPO₂ and DL_{CO} in patients with and without HPS before and after LT. Bold bars denote mean values. ^aP < 0.05 between pre- and post-LT measurements.

DL_{CO} remained unvaried (Table 2) including the DL_{CO} values of the 7 patients with pre-LT low DL_{CO} (75% \pm 6% predicted; range, 60%-95% predicted; PaO₂, 91 \pm 3 mmHg), in whom 2 had normalized DL_{CO}. Mean DL_{CO} in the remaining 17 non-HPS patients slightly decreased (to 81% \pm 4% predicted; range, 65%-116% predicted; PaO₂, 94 \pm 2 mmHg) ($P < 0.05$), whose physiological significance remained uncertain.

Mean PaCO₂ increased ($P < 0.05$ in HPS patients only) and arterial pH decreased ($P < 0.05$) in both HPS and non-

HPS patients, to reach normal limits without differences between the two populations. Increased PaCO₂ kept pace with decreased V_E, although only significantly in HPS patients ($P < 0.05$).

Pulmonary vascular resistance (PVR) increased (from 92 ± 69 dyn.s.cm⁻⁵ to 123 ± 78 dyn.s.cm⁻⁵), Q_T decreased (from 10.6 ± 4 to 6.6 ± 2 L/min) ($P < 0.05$ each) and pulmonary artery pressure was unchanged (from 18 ± 8 mmHg to 17 ± 6 mmHg) in the 4 patients with HPS in whom hemodynamics were carried out. Mean VO₂ decreased in HPS patients only ($P < 0.05$).

At long-term, 3 HPS patients had abnormal spirometry (Table 3): patient No.3 had a similar moderate restrictive pattern shown before LT, patient No.4 (ex-smoker) asymptomatic moderate airflow limitation possibly due to coexisting chronic obstructive pulmonary disease (COPD), and patient No.5 (smoker) mild-to-moderate undefined ventilatory pattern. Patient No.6 had normal spirometry. Unlike the persisting normalcy of arterial blood gases, mean DL_{CO} and K_{CO} in HPS remained unchanged at the same pre-LT levels (Figure 1).

DISCUSSION

The most salient finding of the present study is that all patients with HPS and a small subset of patients without HPS showed sustained reduced DL_{CO} as the most remarkable abnormal lung function test following successful LT. More importantly, in HPS patients these findings were observed in conjunction with normalization of all respiratory (PaO₂, PaCO₂ and AaPO₂) and inert gas exchange indices, namely regions with low V_A/Q units, increased dispersion of pulmonary blood flow (Log SDQ) and increased overall index of V_A/Q heterogeneity (DISP R-E*), intrapulmonary shunt and diffusion-perfusion defect (as shown by a greater predicted MIGET than actual measured PaO₂). Furthermore, most of the clinical, functional and hemodynamic abnormalities in HPS patients ablated or decreased and CEE-based IPVD disappeared. The absence of noticeable DL_{CO} changes after LT in non-HPS patients who received the same immunosuppressive therapy compared with patients with HPS, rules out at first glance any complementary iatrogenic interstitial lung effect. All in all, our findings point to persistence of sub-clinical structural changes at the pulmonary vascular bed.

Our results complement and extend a few prospective, although inconclusive and contentious, studies on the outcome of gas exchange disturbances after LT in patients with advanced hepatic disease^[8,9,11,12]. Eriksson *et al*^[8] observed in 6 patients with end-stage liver disease, but without proven-diagnosis of HPS, complete resolution of respiratory and inert gas exchange after LT, but they have not reported post-DL_{CO}. Krowka *et al*^[9] found that PaCO₂ and steady-state diffusing capacity are improved after LT without any reference to HPS. In contrast, Laberge *et al*^[11] reported that HPS is resolved in two children with HPS who normalized DL_{CO} and do particularly well after LT. It is postulated that, in juvenile HPS, the response of the pulmonary vasculature to LT appears to be more favorable than in adults^[17]. Finally, Battaglia *et al*^[12] have demonstrated

sustained low DL_{CO} after LT although improvement or resolution of hypoxemia and/or widened AaPO₂ is related to pulmonary capillary thickening^[18]. Notwithstanding, both the poor resolution of the gas exchange tools used and the lack of a solid definition of HPS in these studies have limited partially more evidence-based conclusions.

We are confronted therefore with the pathological basis of this intriguing sustained reduced DL_{CO} after LT in patients with and without HPS. We hypothesize that the persistence of low DL_{CO} after LT in patients with HPS may be consistent with structural pulmonary vascular changes already present before LT, such as increased thickness of the walls of small veins originally shown in a post-mortem case of liver cirrhosis complicated by cyanosis strongly suggestive of HPS^[19]. Ultrastructurally, this thickening is essentially due to a layer of collagen fibers interspersed with fine filamentous material whilst the basement membrane and many capillary walls are thickened with collagen, which provokes an approximately two-fold increase in the minimum blood-gas distance and contributes to the reduction in DL_{CO}^[19]. This structural vascular abnormality in HPS can be sub-clinical and still consistent with post-LT V_A/Q normalization and disappearance of intrapulmonary shunt and diffusion-perfusion defect. Persisting low DL_{CO} after LT in most of the subset of patients without HPS may be due either to a similar, albeit plausibly less severe, derangement than the one alluded to^[19] or alternatively to a different unknown abnormality of the pulmonary vascular bed as yet. Very recently, we have shown that pulmonary exchange defects in HPS patients remain unchanged after administration of N^G-nitro-L-arginine methyl ester (L-NAME), an inhibitor of nitric oxide (NO) synthase, hence suggesting that HPS-induced gas exchange disturbances may be related to pulmonary vascular remodeling rather than to an ongoing vasodilator effect of enhanced NO production^[20].

Decline of DL_{CO} occurs after heart transplantation (HT) and persists for up to three years^[21], a finding that appears to contribute to exercise limitation in HT recipients^[22]. Post-HT DL_{CO} decline has been related to increased intra-capillary resistance to CO transfer secondary to a combination of anemia and reduced pulmonary capillary blood volume (Vc)^[23]. Post-HT normalization of pulmonary hemodynamics along with persisting structural pulmonary vascular changes due to pre-HT severe chronic heart failure may lie behind reduced Vc after HT^[23]. Notwithstanding severe pulmonary arterial hypertension in HT candidates is never present in patients with HPS. Accordingly, it may be unlikely that pulmonary hemodynamic changes after LT in our study might play a major role in post-LT persisting low DL_{CO}. Moreover, although three out of six HPS patients had an active (1) or past smoking (2) history, only one (patient No.4) had associated asymptomatic moderate airflow limitation that could explain, at least in part, persisting low DL_{CO} after LT. We have shown, however, that HPS-induced gas exchange disturbances and hemodynamic findings predominate in the face of coexisting chronic respiratory disorders, such as COPD^[24]. We did not assess the components of DL_{CO} because our primary aim was to ascertain in HPS patients whether or not pre-LT could reduce DL_{CO} persisted

within the context of gas exchange status following LT as compared to patients without HPS.

There are two strengths in our study, namely its prospective nature and lengthy design using clear-cut diagnostic criteria for patients with^[4] and without HPS, and the combined use of routine lung function tests along with one of the most robust tools to unravel the intrapulmonary determinants of arterial deoxygenation in HPS. We acknowledge, however, three limitations. The number of HPS patients studied is relatively small; the absence of pathological basis represents a weakness; and diffusion impairment cannot be estimated with MIGET when arterial hypoxemia is not present.

Persisting low DL_{CO} after LT in end-stage hepatic patients with and without coexisting HPS has not been previously reported in such a comprehensive manner. Whatever the ultimate mechanism for this unique and intriguing post-LT DL_{CO} impairment is, our findings point to the presence of pulmonary vascular involvement in advanced liver disease.

Abstract

AIM: To investigate the possible role of polysaccharide-K (PSK) -related markers in predicting distant metastasis and in the clinical outcome of colorectal cancer (CRC).

METHODS: Firstly, we used protein microarrays to analyze the *in vitro* expression profiles of potential PSK-related markers in the human colorectal adenocarcinoma cell line SW480, which carries a mutant *p53* gene. Then, we investigated the clinical implications of these markers in the prognosis of CRC patients.

RESULTS: ECA39, a direct target of c-Myc, was identified as a candidate protein affected by the anti-metastatic effects of PSK. Immunohistochemistry revealed that ECA39 was expressed at significantly higher levels in tumor tissues with distant metastases compared to those without ($P < 0.00001$). Positive ECA39 expression was shown to be highly reliable for the prediction of distant metastases (sensitivity: 86.7%, specificity: 90%, positive predictive value: 86.7%, negative predictive value: 90%). A significantly higher cumulative 5-yr disease free survival rate was observed in the ECA39-negative patient group (77.3%) compared with the ECA39-positive patient group (25.8%) ($P < 0.05$).

INTRODUCTION

Colorectal cancer (CRC) is one of the three most frequent malignancies in Western countries. CRC patient survival rates are delineated by local recurrence and lymphatic and hematogenous dissemination^[1,2] and, once metastatic disease is diagnosed, the 5-year survival rate is less than 5%. In the majority of cases, chemotherapy is the recommended treatment for patients with advanced metastatic disease. Recently, we have achieved good clinical results in the treatment of CRC using 'Pharmacokinetic Modulating Chemotherapy (PMC)', which was designed as a hybrid of lower metronomic and higher shorter plasma 5-FU concentration. The cumulative 5-year survival rate of Dukes' C CRC patients was 95% in the group treated with PMC, compared with 67% in the non-PMC group ($P = 0.003$)^[3,4]. Our PMC regimen also significantly decreased liver metastasis, resulting in a median liver metastasis-free time after hepatectomy of 34.2 mo in the PMC group compared with 18.4 mo in the non-PMC group ($P = 0.00002$)^[5]. PMC offers the advantages of reduced toxicity and lower costs through outpatient treatment. However, the prognosis of some patients remains poor despite vigorous anti-cancer therapy. Extrahepatic recurrence, mostly in the lung, cannot always be reduced by PMC alone, although PMC turned out well for the risk reduction of liver metastasis. Indeed, intensive chemotherapy has been shown to

cause a comparatively higher risk of extrahepatic distant metastases such as the lung, bone, brain and peritoneum, with an overall recurrence rate in CRC patients receiving PMC of 13.1%^[6]. While chemotherapy with hepatic arterial infusion or second-look liver resection can control the prognosis of liver metastasis to some extent, extrahepatic recurrence is refractory to any known treatment. The management of extrahepatic recurrence is a major problem as the prognosis of patients suffering extrahepatic recurrence is significantly worse (mean survival of 2 mo from diagnosis) compared with those with liver metastasis alone (mean survival of 26 mo from diagnosis) ($P < 0.05$)^[6].

The integration of immunopotentiating agents with the extant treatment regimens of surgery, chemotherapy, and radiation therapy has gained popularity as an adjuvant therapy for cancer during the last three decades. The use of complementary and alternative medicine (CAM) is a growing field in health care, particularly among cancer patients in the advanced stages of disease. However, recent reports have shown that while expenditure on CAM is high, 44.6%-66.7% of cancer patients receiving palliative care use CAM without sufficient information^[7,8].

Polysaccharide-K (PSK), or Krestin, is a protein-bound polysaccharide biological response modifier prepared from the mushroom *Coriolus versicolor*, that has been used in traditional Chinese medicine for centuries. PSK is widely used in adjuvant therapy after surgery or radiotherapy in Japan and other Asian countries, and the Japanese National Health Insurance scheme covers the use of PSK for gastric, colorectal, and lung cancers. Randomized, controlled clinical studies have revealed that the use of PSK in adjuvant therapy for gastric, colorectal, esophageal, and lung cancers significantly extends the 5-year survival rates of patients by 10% to 20%^[9-12]. Compared with CRC patients who did not receive PSK, PSK-treated patients showed a higher 5-year survival rate (73.0% in PSK group *vs* 58.8% in non-PSK group in stage II or III, and 60.0% *vs* 32.1% in stage III only) and lower rates of local recurrence (OR 0.74) and systemic recurrence (OR 0.52); lung metastases (OR 0.27), lymph node recurrence (OR 0.16), and peritoneal dissemination (OR 0.86)^[10]. Based on the findings of these studies, we have been administering PSK to patients with advanced CRC since 2001. Compatible with the findings of Ohwada *et al*^[10], we have observed that extrahepatic recurrences are significantly decreased when PSK therapy is used in combination with the standard PMC regimen (manuscript in preparation).

PSK produces very few adverse side effects, and its characteristics allow long-term oral administration. *In vitro* studies have confirmed that PSK induces the expression of several cytokine genes including *TNF- α* , *IL-1*, *IL-1R*, *IL-2*, *IL-4*, *IL-6*, *IL-7*, and *IL-8*^[12-15]. Anti-neoplastic effects of PSK have also been reported in animal models, and involve the radical trapping and modulation of cytokine production and effector cell functions^[16,17]. Recently, we have shown that PSK may have an additional anti-tumor effect on the cancer cells *per se* without disturbing cell-cycle progression^[18]. PSK might also alter the local characteristics of tissue-specific factors as well as their host-mediated

activities^[18].

We hypothesized that some PSK-related markers could be influential in predicting the occurrence of distant metastasis in CRC patients. In order to identify those molecular markers associated with the transition from primary CRC to distant metastases, we used a protein array containing 500 human antibodies in the human colorectal adenocarcinoma cell line SW480 to screen for alterations in protein expression that are potentially required for the direct action of PSK. SW480 carries a mutant *p53* gene; such mutations have been found in approximately half of all colorectal cancers and are associated with lymphatic dissemination and poor prognosis^[19,20]. We examined the expressions of candidate marker proteins in cancerous tissue obtained from CRC patients and accordingly assessed their usefulness as prognostic markers for distant metastasis.

MATERIALS AND METHODS

Cell culture and PSK treatment

The colorectal adenocarcinoma cell line, SW480, carrying a mutant *p53* gene was obtained from the Human Science Research Resource Bank (Tokyo, Japan). Cells were grown in RPMI 1640 medium (Gibco, Grand Island, NY, USA) supplemented with 100 mL/L fetal bovine serum (FBS; HyClone, Logan, UT, USA), 2 mmol/L glutamine, 100 000 U/L penicillin, 100 mg/L streptomycin, and 40 mg/L gentamycin at 37°C in a humidified atmosphere of 50 mL/L CO₂. For the cell growth study, 10⁶ cells were plated per 60-mm dish and treated with various concentrations of PSK (Kureha Chemical Co., Tokyo, Japan). Cells were counted using a hemocytometer on the days indicated. Then they were prepared for protein extraction and Ab arrays (Clontech, Palo Alto, CA, USA).

Identification of protein expression profiles by antibody microarray

Extraction of whole cellular protein, microarray hybridization, scanning, grid-assisted spot identification, and analysis were performed according to the manufacturer's instructions (Clontech). Briefly, 25 μ g whole cellular protein was extracted, labelled with the same volume of Cy3 and Cy5, hybridized with Antibody (Ab) Microarray, and the level of radioactivity was measured by scintillation counting. Sample and control-labelled probes were mixed together and hybridized to Ab Microarray slides containing 500 human antibodies in the Ab Microarray (No. 3080600). The names of these proteins are available at <http://www.clontech.com/clontech/products/families/abarray/nanoscale.shtml>. Hybridized slides were scanned and the scanner output images were analyzed using AtlasImageTM software, following localization by the overlaying of a grid on the fluorescent images. Fluorescent signal intensities were normalized by the Ab Microarray Analysis Workbook. Both final reported intensities were filtered, and those spots with intensities less than 0.75 or more than 1.32 were eliminated. The results were obtained from two independent experiments.

Patients

Sixty-three patients (31 women and 32 men) with a mean age of 60 years (range 37-83 years) and with surgically excised Dukes' C lower rectal carcinomas beneath the peritoneal reflexion were studied in the Hyogo College of Medicine between April 1986 and March 1995. Thirty-five of these patients (12 women and 23 men) with a mean age of 62.9 years (range 41-83 years) were enrolled in this study. The histological grades of carcinomas are as follows: 6 were well differentiated, 27 were moderately differentiated, and 2 were poorly differentiated or mucinous carcinomas. Follow-up information was obtained from office charts and hospital records. All patients were followed up for 60 mo after the initial operation. Local recurrence was defined as any tumor recurrence within the pelvis or anal canal. Distant recurrence was defined as any tumor recurrence outside the pelvis and included metastasis to the liver, lung, bone or the abdominal cavity. No recurrence was observed in 22 patients, distant recurrence was observed in 13 (3 cases of recurrence in the lymph nodes, 3 in the liver and 7 in the lungs), and local recurrence in 2 patients. The Ethics Committee of the Institution approved the study protocol.

Immunohistochemistry

CRC tissue specimens were processed using conventional procedures for paraffin embedding, cut into 4- μ m sections, and mounted onto poly-l-lysine-coated slides. Sections were dewaxed in xylene, rehydrated in a descending alcohol series, heated twice in a microwave oven for 5 min for antigen retrieval, blocked for endogenous peroxidase activity with 30 mL/L H₂O₂ in methanol, and then blocked for non-specific antibody binding with normal rabbit serum. They were incubated overnight at 4°C with a mouse monoclonal Ab against human ECA39 (BD Biosciences Pharmingen, San Jose, CA, USA) followed by treatment with a standard avidin-biotin-peroxidase complex. The slides were developed with 3, 3'-diaminobenzidine tetrahydrochloride solution containing 1 mL/L H₂O₂ and were lightly counterstained with hematoxylin. Normal mouse IgG was substituted for the primary antibody as a negative control. The sections were examined microscopically by three of the authors (Y.F., R.Y., and T.H.-T.) without knowledge of their clinicopathologic features. ECA39 expression was categorized according to staining intensity compared with interstitial infiltrates as follows: score 3 (strong), staining intensity more than interstitial infiltrates; score 2 (moderate), staining intensity equal to interstitial infiltrates; score 1 (mild), staining intensity less than interstitial infiltrates; and score 0 (negative), no staining. We then categorized ECA39 expression according to ECA39 expression scores: score 1 to 3, ECA39 positive; score 0, ECA39 negative.

Statistical analysis

Disease-free survival (DFS) and overall survival (OS) curves were generated by the Kaplan-Meier method, and the Cox-Mantel test was used to compare the curves. Death without recurrence was excluded from the analysis. Values of $P < 0.05$ were considered statistically significant. Statistical analyses were carried out using STATISTICA

Table 1 Differential protein expression in SW480 cell line following exposure to PSK, defined by a 1.32-fold or greater change

No.	Antidody/antigen name	Normalized average INR

statistical software, version 06J (STATISTICA, Tulsa, OK, USA).

RESULTS

Suppression of cell growth by PSK

The effects of various concentrations of PSK (0 to 1000 mg/L) on the growth of SW480 cells was examined 96 h after treatment, and exposure to 10, 100, 500 and 1000 mg/L PSK was shown to suppress growth by 92.1%, 83.6%, 69.5% and 60.8%, respectively. Each figure represents the mean of more than three independent experiments.

Analysis of expression profiles

Protein expression in SW480 cells was analyzed following 24 h treatment with 500 mg/L PSK using an Ab Microarray (No. 3080600). Under basic selection conditions, a total of 10 proteins were selected from the 500 human proteins available on the array slide. These proteins were identified on the basis of their altered expression following exposure to PSK, with 1.32-fold or higher ratios, and included 5 up-regulated and 5 downregulated proteins (Table 1). Proteins showing upregulated expression, in the order of decreasing ratio, are HDJ-2, TNIK, TRAX, C-NAP1, and Moesin. Proteins showing downregulation, in the order of increasing ratio, are ECA39, Caspase-9/ICE-LAP6/Apaf-3, Synaptotagmin, ERK2 (MAPK2), and PMCA2.

Correlation of ECA39 expression with CRC patient prognosis

ECA39 was selected from these 10 candidate proteins as a distant metastasis-related marker in CRC after immunohistochemical analysis of CRC tissue specimens (Figure 1). ECA39 was expressed at significantly higher levels in tumor tissues with distant metastases (13 of 15 expressed positive ECA39) compared to those without metastases (2 of 20 expressed positive ECA39, $P < 0.00001$). Positive ECA39 expression was also shown to be highly reliable in predicting distant metastases (sensitivity: 86.7%, specificity: 90%, positive predictive value: 86.7%, and negative predictive value: 90%). Kaplan-Meier analysis revealed a significant

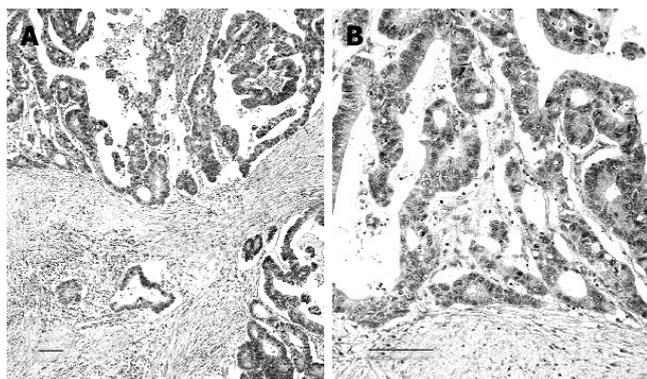

Figure 1 Immunohistochemical detection of ECA39 in rectal cancers (A: $\times 40$; B: $\times 100$. Bars indicate 100 μm).

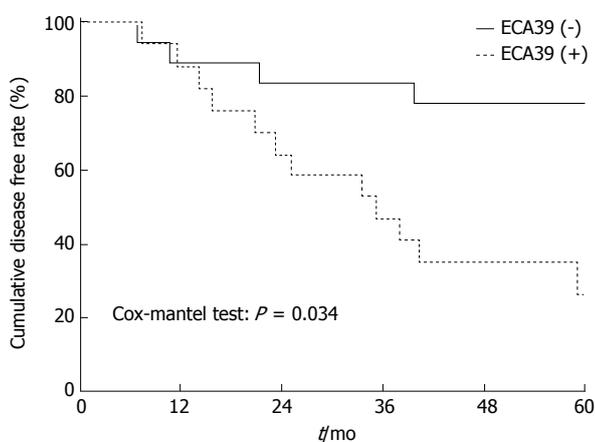

Figure 2 Five-year disease-free survival curves for eligible patients with pathologic stage III cancer in the ECA39-negative group and ECA39-positive group.

decrease in DFS of patients with positive ECA39 expression (25.8%) compared with patients with negative ECA39 expression (77.3%) ($P = 0.034$; Figure 2). The 5-year OS rate of ECA39-positive patients was 53.0%, compared with 83.3% for ECA39-negative patients, although this difference was not statistically significant ($P = 0.055$; Figure 3).

DISCUSSION

Normal cells undergo certain changes during their transformation into invasive malignant clones with metastatic potential. Molecular determinants occurring during the development of sporadic CRC include mutations in certain tumor suppressor genes (*APC*, *DCC*, *Smad-2*, *Smad-4*, *p53*) and oncogenes (*K-ras*) that have been summarized in the adenoma-carcinoma sequence initially proposed by Fearon and Vogelstein^[21]. However, because only 8% of CRC harbor concomitant mutations of *APC*, *K-ras*, and *p53*, it seems likely that additional pathogenic alterations are instrumental in the mediation of the progression and metastasis of CRC^[22]. Cellular transformation provokes tissue remodeling inside neoplastic lesions and in the periphery of the tumor. Disorders in the local characteristics of tissue-specific factors play an essential role in cancer

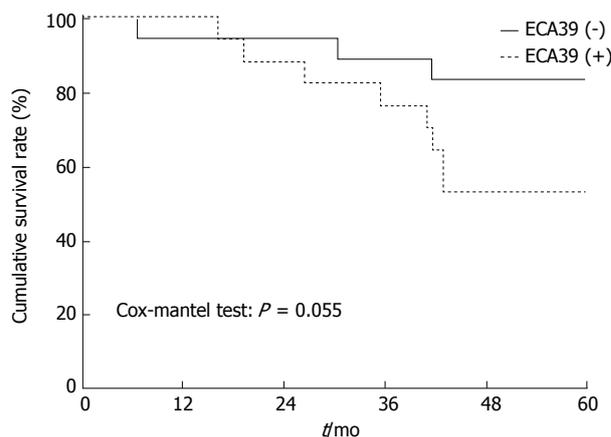

Figure 3 Five-year overall survival curves for eligible patients with pathologic stage III cancer in the ECA39-negative group and ECA39-positive group.

progression. In the present study, we have demonstrated that the ECA39 expression, which can be suppressed by PSK, has the potential to predict distant metastasis.

The ECA39 protein was originally identified by the overexpression of its mRNA in an undifferentiated mouse teratocarcinoma cell line^[23]. The *ECA39* gene harbors a functional *c-Myc* binding sequence located 3' of its transcription initiation site, and has been shown to be a direct target for c-Myc activity in both mice and humans^[24,25]. The functional implications of individual *c-Myc* target genes including ornithine decarboxylase^[26,27], *p53*^[28], and *cdc25A*^[29], are now complemented by large surveys of the c-Myc network as a therapeutic target in cancer^[30]. The *c-myc* oncogene is essential for cell proliferation but, paradoxically, also promotes cell death. The biological rationale for this dual signal is that c-Myc intrinsically regulates malignant transformation. ECA39 shares significant homology with the prokaryotic protein branched-chain amino acid aminotransferase (BCAT), and is highly expressed during the log phase and is down-regulated during the stationary phase of growth^[31]. Thus, ECA39 might be involved in the regulation of the cell cycle. Disruption of the *ECA39* gene results in an increased growth rate in comparison to wild type^[25]. As shown in the present study, ECA39 is a highly reliable marker in the prediction of distant metastasis and, in combination with other biomarkers, might produce an even higher predictability of poor prognosis. Despite significant progress in the identification of markers predicting CRC patient prognosis, there remains a need for clinical predictors of distant metastasis in order to strengthen patient surveillance. This would allow the tailoring of treatment to individual patients and the application of evidence-oriented integrated medicine, thus maximizing the probability of optimal response to the therapy.

Previous reports have demonstrated that c-Myc acts as a biomarker in the prediction of patient response to treatment with 5-FU and camptothecin^[32,33]. Evidence of ECA39-based administration of PSK could also favor some CRC patients by sensitizing their response to chemotherapy, protecting normal cells during treatment as well as having an anti-metastatic effect. Such possibilities need to be confirmed in larger clinical studies, which are war-

ranted both in Japan and world-wide. We believe that the acquisition of knowledge of integrated medicine by physicians, especially oncologists, is essential and should not be underestimated. Moreover, oncologists should discuss the role of integrated medicine with their patients and encourage patients to participate in well-organized research on integrated approaches to therapy.

Here, we identified ECA39 as a biomarker that predicts distant metastasis in CRC patients. ECA39 is thought to play a role in metastasis, and could represent a potential diagnostic, prognostic, or even therapeutic target. Furthermore, the metastasis-tumor associated ECA39 profile could be of use in the selection process of tumors that are likely to develop metastases, thus optimizing the application of immunotherapy by PSK and improving clinical outcome.

Abstract

AIM: To determine the causative agents of spontaneous bacterial peritonitis (SBP) in children with liver disease and ascites in our center.

METHODS: During a 2.5 year period, from September 2003 to March 2006, 12 patients with 13 episodes of SBP were studied. In all cases at the time of admission serum albumin and glucose, urinalysis and urine culture was performed. Analysis [white blood cell (WBC) count with differential, albumin, glucose], gram stain, culture by BACTEC method and antibiogram was done on ascitic fluids. Abdominal paracentesis was repeated after 48 h of antibiotic therapy for bacteriologic assay. The patients were followed for at least three months in a gastroenterology clinic.

RESULTS: There were 7 girls (58%) and 5 boys (42%) with a median age of 5.2 years (range, 6 mo to 16 years). All cases had positive ascitic fluid culture. Gram stain was positive in 5 (38.5%) of them. The isolated organisms were *S. pneumoniae* in 5 (38.5%), *E. coli* in 2 (15.3%), *S. viridans* in 2 (15.3%), and *K. pneumoniae*, *H. influenza*, *Enterococci*, and nontypable *Streptococcus* each in one (7.7%). All of them except *Enterococci* were sensitive to ciprofloxacin and ceftriaxone. All ascitic fluid cultures were negative after 48 h of antibiotic therapy.

CONCLUSION: *S. pneumoniae* is the most common cause of SBP in the pediatric age group and we recommend a third generation cephalosporine (e.g., Ceftriaxone or Cefotaxime) for empirical therapy in children with SBP.

Key words: Spontaneous bacterial peritonitis; Children;

INTRODUCTION

Spontaneous bacterial peritonitis (SBP) is defined as an ascitic fluid infection without a demonstrable intra-abdominal cause^[1]. It is a well known complication of cirrhosis in adults, occurring in 8% to 13% of patients^[2-5]. The diagnosis is established by a positive ascitic fluid bacterial culture and an elevated ascitic fluid absolute polymorphonuclear leukocyte (PMN) count ($\geq 2.5 \times 10^5/L$). In adults, the organisms of SBP are usually gram-negative bacteria^[2-4,6], but they may differ in children^[5,7]. The aim of the present study was to determine the causative agents of SBP in children with liver disease and ascites in our center.

MATERIALS AND METHODS

During a period of 2.5 years, from September 2003 to March 2006, 63 children with liver disease and ascites were prospectively studied in the Department of Pediatric Gastroenterology in Nemazee Hospital affiliated with Shiraz University of Medical Sciences, the major referral center in Southern Iran. Written consent was obtained from all parents after informing them about this study which was approved by the Ethics Committee of the University.

Of the children involved in this study 12 had met the criteria for SBP (polymorphonuclear leukocyte count greater than $2.5 \times 10^5/L$ and positive ascitic fluid culture). In total 13 episodes of SBP were documented, of which two occurred with one patient, 4 mo apart. The patients and their parents answered a structured questionnaire, which included name, age, sex, clinical history, underlying liver diseases, history of antibiotic and diuretic use, history of previous variceal bleeding and episodes of SBP. All children had undergone a thorough physical examination.

Serum albumin and glucose, urinalysis and urine culture were done in all patients. Paracentesis was performed

Table 1 Results of ascitic fluid cultures in 12 patients with SBP

Organism	n	%
<i>S. pneumoniae</i>	5	38.5
<i>E. coli</i>	2	15.3
<i>S. viridans</i>	2	15.3
<i>K. pneumoniae</i>	1	7.7
<i>H. influenza</i>	1	7.7
Enterococci	1	7.7
Nontypable streptococcus	1	7.7

on all patients under sterile conditions and analysis of fluid (Albumin, glucose, WBC count and differential) and gram stain was done. Ten milliliter of ascitic fluid was inoculated at the bedside in a blood culture bottle (BACTEC, PEDS PLUS/F medium, Becton, Dickinson Co. USA) using the BACTEC 9240 system (Becton, Dickinson Co. USA). Antibiogram was performed with the disk diffusion method (Kirby-Bauer method) for ciprofloxacin (5), cefotaxime (30), ceftriaxone (30), gentamicin (10) and cotrimoxazole (1.25-23.15) (MAST Co. UK). Intravenous ceftriaxone (100 mg per kilogram body weight) was started empirically for all patients after paracentesis, as recommended in adult series^[8,9]. After 48 h of antibiotic therapy ascites were resolved in 4 patients. We could not obtain ascitic fluid despite sonographic guidance. One patient expired. Abdominal paracentesis was repeated in 8 cases for analysis and culture. The patients were followed for at least three months in our gastroenterology clinic.

RESULTS

Of the patients involved in this study, 27 had normal ascitic fluid analysis and negative cultures. In 22 patients fluid analysis showed greater than 2.5×10^5 per liter, but fluid cultures were negative. These patients were treated as culture negative neutrocytic ascites and were excluded from this study. Two patients had normal ascitic fluid analysis, but ascitic fluid cultures were positive for staphylococcus coagulase positive and negative, which were considered as non-neutrocytic Bacterascites. These were excluded from this study.

Of the SBP patients, there were 7 girls (58.3%) and 5 boys (41.6%) with a mean age of 5.2 years (range, 6 mo to 16 years). The most common clinical manifestations were as follows: fever in 12 (92.3%), abdominal pain in 12 (92.3%), abdominal tenderness in 12 (92.3%), change in level of consciousness in 5 (38.5%) and decreased bowel sounds in 3 (23%). Urinalyses were normal and urine cultures were negative in all patients. Serum-ascitic fluid albumin gradient was greater than 11 g/L in all (100%) patients. Total protein concentration of ascitic fluid was less than 10 g/L in 11 (85%) patients. Ascitic fluid glucose was greater than 0.5 g/L in all but one. Gram stains of ascitic fluid were positive in five patients (38.5%), including four gram positive cocci and one gram negative bacilli. Results of BACTEC cultures are shown in Table 1. The most common organism of SBP in this study was *Streptococcus*

Table 2 Ascitic fluid analysis on admission and after 48 h of antibiotic therapy in SBP patients

Patient No.	WBC ¹ count on admission	WBC ¹ count after 48 h	Rate of WBC ¹ decline (%)	PMN ² count On admission	PMN ² count after 48 h	Rate of PMN ² decline (%)
1	6600	3000	0.45	5940	1200	0.44
2	1400	500	0.36	910	200	0.61
3	600	550	0.92	480	165	0.37
4	950	140	0.15	684	56	0.55
7	4000	3200	0.80	3000	704	0.29
10	3680	85	0.02	3496	70	0.86
12	840	100	0.12	689	53	0.65
13	1000	78	0.08	800	37	0.60

¹White blood cell; ²Polymorphonuclear leukocyte.

pneumoniae (38.5%). All organisms except *Enterococci* and one case of *E. coli* were sensitive to cefotaxime, and all of them except *Enterococci* were sensitive to ceftriaxone and ciprofloxacin. All patients became asymptomatic after 72 h of antibiotic therapy, except one infant with diagnosis of neonatal hepatitis and cirrhosis, who expired after 48 h due to encephalopathy. Abdominal paracentesis repeated in 8 cases after 48 h of antibiotic therapy. The results are shown in Table 2. Total WBC declined to 30% of primary counts, and PMN count halved after 48 h. All ascitic fluid cultures were negative after 48 h of antibiotic therapy.

DISCUSSION

Since the first descriptions of SBP by Kerr *et al* in 1963^[10] and Conn and Fessel in 1964^[11], the clinical presentation, treatment and prognosis of this disease have been well established. However, other aspects are still subject to investigation such as its pathogenesis^[12], diagnosis^[13] and prevention^[14].

Although most episodes of SBP occur in patients with advanced cirrhosis with ascites, occasionally it has been observed in non-cirrhotic patients such as fulminant hepatic failure^[15], nephrotic syndrome^[16] and congestive heart failure^[17]. SBP is a serious infection in patients with ascites, and it is the largest abscess in humans^[18]. To date, most studies of SBP have been done in adults with cirrhosis. The lack of reports focusing on pediatric patients is remarkable^[19]. The prevalence of SBP in our patients was 20.6%, which is relatively similar to Vieira *et al* study (19.5%)^[19]. The mean age of our cases was 5.2 years (6 mo to 16 years), which is relatively similar to the Larcher *et al* series (5.5 years)^[7]. Fever and abdominal pain were the most common clinical presentations in our cases, which is also similar to previous reports^[2-4,7]. In all cases in our study, urinalysis was normal and urine cultures were negative, so we conclude that there is no association between SBP and urinary tract infections. This result differs from the Hoefs *et al* study^[20] which concluded that the urinary tract can be a source of infection in SBP patients. The high incidence of pneumococcal infection (38.5%) in our study, which was lower than that reported by Larcher *et al* (75%)^[7],

distinguishes our series from most adult series^[2-4,6,21]. In our series there were 9 cases (69%) of gram positive and 4 cases (31%) of gram negative organisms, which is different from the adult series^[2-4,6]. In this study all organisms except one *Enterococci* were sensitive to ceftriaxone and ciprofloxacin.

In summary, Gram positive organisms are a more common cause of SBP than gram negative organisms in cirrhotic children in our area and a third generation of cephalosporin such as ceftriaxone or cefotaxime can be a suitable antibiotic for empirical therapy of children with SBP. We suggest that pneumococcal vaccination may play a role in the prevention of SBP in children, but its efficacy can only be established by further studies.

Abstract

AIM: To evaluate different methods in differentiating idiopathic neonatal hepatitis from biliary atresia.

METHODS: Sixty-five infants with cholestatic jaundice and final diagnosis of idiopathic neonatal hepatitis and biliary atresia were studied prospectively from September 2003 to March 2006. A thorough history and physical examination were undertaken and the liver enzymes were examined. All cases underwent abdominal ultrasonography, hepatobiliary scintigraphy, and percutaneous liver biopsy. The accuracy, sensitivity, specificity and predictive values of these various methods were compared.

RESULTS: There were 34 girls and 31 boys, among them 46 subjects had idiopathic neonatal hepatitis (age, 61 ± 17 d) and 19 had biliary atresia (age, 64 ± 18 d). The mean age at onset of jaundice was significantly lower in cases of biliary atresia when compared to idiopathic neonatal hepatitis cases (9 ± 13 d vs 20 ± 21 d; $P = 0.032$). The diagnostic accuracy of different methods was as follows: liver biopsy, 96.9%; clinical evaluation, 70.8%; ultrasonography, 69.2%; hepatobiliary scintigraphy, 58.5%; and liver enzymes, 50.8%.

CONCLUSION: Our results indicate that clinical evaluation by an experienced pediatric hepatologist and a biopsy of the liver are considered as the most reliable methods to differentiate idiopathic neonatal hepatitis and biliary atresia.

INTRODUCTION

Cholestatic jaundice in early infancy is an important clinical condition that results from diminished bile flow and/or excretion, and can be caused by a number of disorders. Idiopathic neonatal hepatitis (INH) and biliary atresia (BA) are two main causes^[1,2].

It is important to distinguish INH from BA in an infant presented with jaundice, as the former purely needs a medical management and the later requires surgical intervention as soon as possible. Therefore, rapid and accurate differentiation is crucial for early surgery in patients with BA^[3]. In this study, we evaluated and compared the different diagnostic methods for this differentiation.

MATERIALS AND METHODS

In a prospective study from September 2003 to March 2006, the differential diagnosis and etiologic work-up of cholestasis in infancy were carried out. A written consent was provided from all parents after informing them about this study which was also approved by the Ethic Committee of the University. Sixty-five consecutive cholestatic infants (34 girls, 31 boys) with a final diagnosis of INH or BA were entered in our study. These patients were all referred to the Department of Pediatric Gastroenterology in Nemazee Hospital affiliated with Shiraz University of Medical Sciences, which is the major referral center in Southern Iran.

A thorough history and physical examinations were provided, including age at onset of jaundice, birth weight, stool color, and any signs of systemic diseases. Ophthalmologic, cardiac and rectal examination, presence of any organomegaly, and assessment of growth state were performed.

For all patients, a complete blood count, urinalysis, urine reducing substances, thyroid function tests, bacterial culture of both urine and blood, serum alpha-1-antitrypsin and screening for cystic fibrosis (sweat chloride test) were performed. Acid-base status was determined as

¹Accurately diagnosed cases/performed cases.

an initial step to evaluate the metabolic disorders.

For all patients, serum alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase (ALP) were checked and all underwent ultrasonography of the abdomen, hepatobiliary scintigraphy and percutaneous liver biopsy.

Cases with etiologies other than INH and BA were excluded from the study. Cases suspicious for BA underwent laparotomy and intraoperative cholangiography.

Later onset of jaundice, lower birth weight, poor growth, deep yellow or greenish stools, presence of signs of systemic diseases and consanguinity were considered as clinical criteria for diagnosis of INH. ALT and AST 10 times more than normal mean and ALP 5 times less than normal mean are considered as criteria for INH. ALT and AST 5 times less than normal mean and ALP 5 times more than normal mean are considered as criteria for BA. Ultrasonographic evidences of dilatation or absence of the main bile duct near the hilum, absence of the gall bladder and presence of triangular cord sign were considered as criteria for BA.

Finally, the accuracy of the five diagnostic methods (clinical evaluation, liver enzymes, abdominal ultrasonography, hepatobiliary scintigraphy, and liver biopsy) was evaluated for differential diagnosis of INH and BA. The sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) of each method were also calculated.

RESULTS

There were 65 cholestatic infants, including 34 (52.3%) girls and 31 (47.7%) boys with a mean age of 62 ± 17 d (30-91 d). There were 46 (70.8%) cases (22 girls, 24 boys) of INH, and 19 (29.2%) cases (12 girls, 7 boys) of BA. The mean age of INH patients was 61 ± 17 d (33-90 d), and BA patients was 64 ± 18 d (30-91 d) and the difference was not statistically significant.

Mean birth weight of patients with INH was 2893 ± 629 g (1150-3900 g) and with BA was 2951 ± 556 g (1900-4150 g), and the difference was not significant.

Age at onset of jaundice in INH was 20 ± 21 d (1-65 d) and in BA was 9 ± 13 d (1-45 d), and the difference was significant ($P = 0.032$).

Forty-four (67.7%) cases had clay-colored stools, among them, 26 cases had INH and 18 cases had BA; and 21 (32.3%) cases had normal-colored stools, among them, 20 cases had INH and one had BA ($P = 0.003$).

The difference in mean ALT, AST and ALP values between INH and BA patients was not significant.

Table 1 shows comparison of the various methods in diagnosing of 65 infants with cholestasis. Table 2 shows the diagnostic accuracy of each method in the order of accuracy. Liver biopsy had 100% diagnostic accuracy for BA and 95.2% for INH, and clinical evaluation had diagnostic accuracy of 84.2% and 65.2% for BA and INH, respectively. Table 3 shows the sensitivity and specificity and Table 4 demonstrates the positive and negative predictive values of each method in differentiating BA and INH. Liver biopsy had the highest sensitivity and specificity for differentiating BA and INH.

DISCUSSION

The North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) guideline for the evaluation of cholestatic jaundice in infants recommends that any infant noted to be jaundiced at the two-week well child visit should be evaluated for cholestasis^[1]. Evaluation of breast-fed infants may be delayed until three weeks of age if they have a normal

Table 3 Sensitivity and specificity of various diagnostic methods for BA and INH

Diagnostic method	Sensitivity for BA		Specificity for BA	
	%	<i>n</i>	%	<i>n</i>
Clinical evaluation	84.2	16/19	65.2	30/46
Liver enzymes	68.4	13/19	43.5	20/46
Ultrasonography	52.6	10/19	76.1	35/46
Hepatobiliary scintigraphy	84.2	16/19	47.8	22/46
Liver biopsy	100	19/19	95.7	44/46

Sensitivity for BA was equivalent to specificity for INH, and specificity for BA was identical to sensitivity for INH.

physical examination, no history of dark urine or light stools, and can be reliably monitored^[1,4,5]. Neonatal hepatitis and BA, which typically occur in term infants, account for 70%-80% of cases^[6].

Evaluation should be undertaken in a staged approach^[7]. The initial step is rapid diagnosis and early initiation of therapy of treatable disorders. Conditions, such as sepsis, hypothyroidism, panhypopituitarism, and inborn errors of metabolism (e.g., galactosemia), must be recognized and treated promptly to avoid significant progression of the illness. Extrahepatic biliary atresia must be differentiated from neonatal hepatitis because early surgical intervention (i.e., before two months of age) results in a better outcome.

In our study, clinical evaluation had good accuracy for diagnosing BA (84.2%) and moderate accuracy for INH (65.2%). Prevalences of acholic stools in our study were 94.7% for BA and 56.5% for INH that are comparable to the study by Mowat *et al.*^[2] (i.e., 83% and 52%, respectively). The mean values of ALT, AST and ALP in BA were 161 ± 107, 261 ± 141, and 2150 ± 830, respectively, and in INH were 212 ± 198, 324 ± 258, and 1791 ± 852, respectively, and the difference was not statistically significant. Therefore, considering the level of liver enzymes would not be an accurate method to differentiate BA and INH (diagnostic accuracy of 50.8%).

Abdominal ultrasonography is more helpful in the diagnosis of choledochal cysts but can also suggest the diagnosis of BA. Findings suggestive for the latter are non-visualized gall bladder and the presence of the triangular cord sign^[8-10]. The sensitivity and specificity of a small or absent gall bladder in detecting obstruction range from 73% to 100% and 67% to 100%, respectively, when correlated with pathologic, surgical, and subsequent clinical examinations^[1].

In our study, abdominal ultrasonography had sensitivity and specificity of 52.6% and 76.1% for BA, respectively. Accuracy of ultrasonography for differentiation between BA and INH in our series was 69.2%, that was lower than that reported by Lin *et al.*^[11] (sensitivity, specificity and accuracy were 86.7%, 77.1%, and 79.4%, respectively) and Park *et al.*^[12] (85%, 100%, and 95%, respectively). This lower accuracy may be due to lower experience of our sonographer for detection of triangular cord sign.

Hepatobiliary scintigraphy with technetium-labeled iminodiacetic acid analogs can be helpful for distinguishing

Table 4 Positive and negative predictive values of various diagnostic methods in BA and INH

Diagnostic method	Positive PV for BA and negative PV for INH		Negative PV for BA and positive PV for INH	
	%	<i>n</i>	%	<i>n</i>
Clinical evaluation	50	16/32	90.9	30/33
Liver enzymes	33.3	13/39	76.9	20/26
Ultrasonography	47.6	10/21	79.5	35/44
Hepatobiliary scintigraphy	40	16/40	88	22/25
Liver biopsy	90.5	19/21	100	44/44

PV: Predictive value.

biliary atresia from neonatal hepatitis and other causes of cholestasis. The sensitivity and specificity of scintigraphy in detecting of obstruction range from 83% to 100% and 33% to 100%, respectively^[1]. In the present study, scintigraphy had sensitivity and specificity of 84.2% and 47.8% for detecting BA, respectively. Scintigraphy adds little to the routine evaluation of the cholestatic infant, but may be of value in determining patency of the biliary tract, thereby excluding BA^[1].

Hepatobiliary scintigraphy had an accuracy of 58.5% in this study that is comparable to the data reported by Park *et al.*^[12], and Gupta *et al.*^[3], but lower than that by Lin *et al.*^[11] and Nadal *et al.*^[13].

Percutaneous liver biopsy is generally employed in the evaluation of neonatal cholestasis, particularly when biliary tract obstruction is high on the differential diagnosis^[14]. The NASPGHAN guideline recommends that a percutaneous liver biopsy to be performed in most infants with undiagnosed cholestasis^[1]. The biopsy should be interpreted by a pathologist with expertise in pediatric liver disease. Biopsy is recommended before performing a surgical procedure to diagnose biliary atresia. If the results are equivocal and biopsy was performed when the infant was < 6 wk of age, a repeated biopsy may be necessary.

Liver needle biopsy is the most invasive method among the various tests, but it is also the most accurate one. Our study found that liver needle biopsy was the most reliable method with the highest accuracy rate of 96.9%, which is similar to those in previous reports^[2,12,15].

In conclusion, clinical evaluation by an experienced pediatric hepatologist and liver needle biopsy might be the most reliable methods to differentiate idiopathic neonatal hepatitis and biliary atresia.

Abstract

AIM: To explore the mechanism of the exciting effects of electro-acupuncture (EA) at Sibai on the gastric myoelectric activities.

METHODS: A total of 32 rats were randomly divided into four groups. Through intraperitoneal injection with atropine (the anti-cholinergic agent by blockade of muscarinic receptors), hexamethonium (automatic nerve ganglion-blocking agent) and reserpine (anti-adrenergic agent by depleting the adrenergic nerve terminal of its norepinephrine store), effects of EA at Sibai on the gastric myoelectric activities of the denervated rats were observed.

RESULTS: After intraperitoneal injection of atropine and hexamethonium, the average amplitude and ratio of period to time in the phase of high activity of gastric myoelectric slow wave, and the average numbers of the peaks of gastric myoelectric fast wave were significantly decreased ($P < 0.01$, $P < 0.05$, $P < 0.01$), while after intraperitoneal injection of reserpine, the aforementioned three parameters were increased ($P < 0.01$, $P < 0.05$, $P < 0.01$). EA at Sibai point partially relieved the inhibitory effect of atropine and hexamethonium on the gastric myoelectric activities in the rats ($P < 0.05$ or $P > 0.05$).

CONCLUSION: Cholinergic and adrenergic nervous systems and autonomic nerve ganglion participate in the peripheral passage of the controlling effects of EA at Foot Yangming Channel on gastrointestinal tract.

INTRODUCTION

Electroacupuncture (EA) at certain points always exhibits marked effects (inhibitory or stimulatory) on organ activities. Our previous studies indicated that EA at the Sibai point exhibited exciting effects on gastric myoelectric activities. These stimulant actions appeared on average amplitude of high activities of slow waves, the ratio between the time-course of high activities of slow waves and cycle of slow waves, average frequency of fast waves. No apparent stimulation was observed at the control point after EA. These results suggest that there are inherent specific correlations between Channels and zang and fu organs. The aim of this study was to investigate the mechanism underlying the exciting effects of EA at Sibai on gastric myoelectric activities. To this purpose, atropine (the anti-cholinergic agent by blockade of muscarinic receptors), hexamethonium (automatic nerve ganglion- blocking agent) and reserpine (anti-adrenergic agent by depleting the adrenergic nerve terminal of its norepinephrine store) were used before EA at Sibai. Gastric myoelectric activities of the rats with nerve blockade were observed^[2-4].

MATERIALS AND METHODS

Animals and experimental design

Healthy adult rats ($n = 32$, female or male, body mass: 200-300 g) were randomly divided into four groups ($n = 8$ per group): (1) EA at Sibai plus saline group: EA at Sibai for 30 min and simultaneously recorded gastric myoelectric activities for 60 min as baseline (control); EA repetition and recording after intraperitoneal injection (ip) with 2 mL saline. (2) EA at Sibai plus atropine (ip) group: EA and recording gastric myoelectric activities same as the first group. (3) EA at Sibai plus hexamethonium (15 mg/kg, ip) group: EA and recording gastric myoelectric activities same as the first group. (4) EA at Sibai plus reserpine (0.5 mg/kg, ip 24 h and 48 h prior to EA) group: EA and

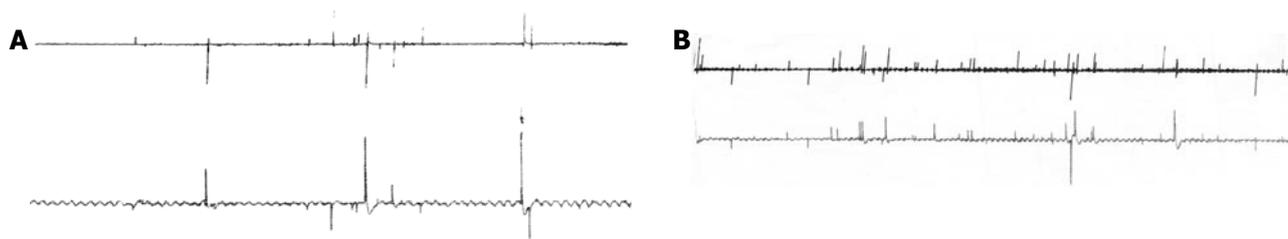

Figure 1 Slow and fast wave of the rats' gastric myoelectric activities before and after EA at Sibai. **A:** Before EA; **B:** After EA.

recording gastric myoelectric activities same as the first group.

Acupuncture points location and parameters for EA stimulation

The acupuncture points were chosen and located according to Lin's "Experimental Acupuncture" - "diagram of acupuncture points for experimental animals"^[1]. Comparative anatomic methods were also used as reference to locate the acupuncture points on rat. Parameters for EA stimulation, namely slow and fast waves (slow wave: 4 Hz; fast wave: 50 Hz), impulse width 0.5 ms, output voltage 2-4 V, output electricity 4-6 mA, 0-60 peak altitude (1 K Ω loaded), slight shake of the needle, were determined as threshold intensity. Stimulation time 30 min and output stimulation intensity were adjusted every 10 min interval to maintain proper intensity.

Placement of gastric electrode

Rats were deprived of food but not water 24 h prior to experiments. Rats were weighed and anesthetized with 10% urathe 0.5 mL (100 mg, ip), tightened and faced up. Abdomen was opened along the middle line. One platinode (diameter 2 mm) was placed under the gastric sinus portion and approximately 0.5 cm to the pyloric sphincter. The other platinode was placed on the body of the stomach and close to the first platinode, 1 cm. The cables were leaded to the skin and tightened with a plastic tube around the neck. Penicillin was injected to prevent infection. The experiments were processed after 7 d.

Recording of gastric myoelectric activities

Rats were deprived of food but not water 24 h prior to experiments. Rats were weighed and anesthetized with 10% urathe 0.5 mL (100 mg ip). Two cables were connected with the front amplifier of the two channels of the physiological recorder. Fast wave and slow wave were recorded simultaneously. Recording parameters for fast wave were: time constant 0.02 s, high frequency filter 30 Hz, and sensitivity 1 mV/cm. Recording parameters for the slow wave were: time constant 2 s, filtration 10 Hz, sensitivity 5 mV/cm. Paper speed was 10 mm/min.

Measurement of fast wave and slow waves of gastric myoelectric activities

Three minutes of wave shape, regularity, and a maximum of wave width of the slow wave were defined as one section; four such sections were accumulated and calculated the average amplitude of one section. Cycle

of slow wave was chosen in at least 3 sections. The cycle period and time courses of the high activity phase were measured, and the ratio of these two measurements were calculated. Consecutive 10 min of all fast waves were defined as one section; three such sections were accumulated and calculated the average frequency (time/min) of one section. The difference between these two measurements which treated before and after was also calculated.

Statistical analysis

Data were expressed as mean \pm SD. Paired *t* test was used to compare the difference before and after treatment within the same group. The difference among groups was analyzed by one-way ANOVA or *q*' test. All the data were processed with SPSS11.5 software.

RESULTS

Effect of EA on average amplitude of high activity phase of slow wave in anesthetized rats

There was no significant difference in average amplitude of high activity phase of slow wave among groups after EA. Both atropine and hexamethonium attenuated the average amplitude of high activity phase of slow wave ($P < 0.01$ vs before blocking agent; $P < 0.01$ vs Sibai plus saline group) (Figure 1). EA markedly abolished the inhibition induced by both atropine and hexamethonium and restrained the activity ($P < 0.05$ vs blocking agents alone). Reserpine obviously increased the average amplitude of high activity phase of slow wave ($P < 0.01$ vs before blocking agent; $P < 0.01$ vs Sibai plus saline group). EA at Sibai still enhanced the average amplitude even after pretreatment with reserpine ($P < 0.05$ vs (1) after EA) (Table 1, Figure 1).

Effect of EA on the ratio between time courses of high activity of slow wave and slow wave cycle in anesthetized rats

As shown in Table 2, there was no marked difference in the ratio between time courses of high activity of slow wave and slow wave cycles in anesthetized rats. Both atropine and hexamethonium decreased the ratio ($P < 0.05$ vs (1) after EA). EA restrained the inhibition and recovered the ratio to the prior value before using blocking agent ($P > 0.05$). Reserpine slightly increased the ratio without significant difference compared to the value before using blocking agent. EA at Sibai after reserpine application markedly enhanced the ratio ($P < 0.05$) (Table 2).

^a $P < 0.05$, ^b $P < 0.01$ vs (1) after EA; ^c $P < 0.05$ vs Sibai plus saline group.

Effect of EA on average frequency of fast wave in anesthetized rats

No significant change in the average frequency of fast wave was observed among groups after EA practice. Atropine and hexamethonium significantly reduced the average frequency of fast wave ($P < 0.01$ vs (1) after EA). The decreased average frequency induced by atropine or hexamethonium also appeared different with the saline group ($P < 0.05$). EA at Sibai slightly increased average frequency of fast wave, but did not reach the significance. Rats pretreated with reserpine exhibited increased average frequency ($P < 0.05$ vs (1) after EA) (Table 3).

DISCUSSION

“Twelve channels connect with arms and body surface outwardly and associate with zang and fu organs inwardly”. This theory has been widely recognized in channel theory and zang/xiang quotation of acupuncture, one of the branches of traditional Chinese medicine. The points on the body surface deeply correlate with zang and fu organs. “Following channels to select points” - this theory has been adapted in clinical practices. Experiments and clinical practices indicate that electroacupuncture at some points exhibits significant effects on certain organs. The subsequent challenge is how to clarify the mechanism underlying the correlation between points and organ activities. Nerve system and endocrine system dominate

most of the organ function and activities. The role of the nerve system in gastric myoelectric activities induced by electroacupuncture at Sibai is the main topic in this study.

Atropine is a typical anti-cholinergic agent, which acts through blockade of muscarinic receptors. Hexamethonium is a ganglion-blocking agent. Reserpine has been used to address the role of adrenergic nerve in physiological study; and it exhibits anti-adrenergic effect by depleting norepinephrine storage in the terminals. For this study, atropine, hexamethonium, and reserpine were administered by intraperitoneal injection to rats. Our results showed that both atropine and hexamethonium abolished the increased gastric activities induced by EA. The gastric activities were inhibited after both atropine and hexamethonium pretreatment. Average amplitude of high activity phase of slow wave, the ratio between time-courses of high activity phase of slow wave and slow wave cycle, and average wave frequency of fast wave were significantly reduced. These results suggest that cholinergic and sympathetic nerves are involved in the regulation induced by EA at point of Foot Yangming Channel. EA at Sibai exhibited strong exciting effects and antagonized the inhibition induced by both atropine and hexamethonium. These effects included enhanced average amplitude of high activity phase of slow wave, the ratio between time-courses of high activity phase of slow wave and slow wave cycle, and average wave frequency of fast wave. Thus, we can draw an important conclusion that both postganglionic

cholinergic nerve and preganglionic sympathetic nerve are involved in the gastric exciting effects induced by EA at Sibai. Meanwhile, both atropine and hexamethonium only partially inhibited the gastric activities. These experiments suggested that a third “no cholinergic, no adrenergic” nerve fiber may participate to control gastric myoelectric activities. Peptide nerve may mediate the gastric myoelectric activities. EA at Sibai may encourage some peptide transmitters release and regulate gastric activities. It has been reported that peptides are related to gastrointestinal mobility^[5,6,8]. EA at Zusanli, Tiansu, and Liangmeng of Foot Yangming Channel increased the complex mobility of gastric sinus portion, small intestine and closed empty intestine. Motilin, gastrin and substance P concentrations were increased. Acupuncture can incompletely abolish the inhibitory action on gastric motility induced by atropine^[7,9,10]. EA at Zusanli point of Foot Yangming Channel exhibits exciting effects on gastric myoelectric activities (amplitude, time-course, and frequency of wave) in anesthetized rats. Intravenous injection with atropine inhibits these effects^[11-14]. Contrast with this result, EA at Zusanli exhibits opposing effects on gastric myoelectric activities in awaken rabbits: inhibition of gastric mobility, gastric myoelectric frequency, and wave amplitude^[15,16]. Some authors suggest that the inhibition induced by EA at Zusanli on gastric activities is not inhibitory. The baseline control of gastric myoelectric activities plays an important role in the regulation of EA^[14,17,18]. EA leads to exciting effects for low gastric activities and inhibitory effects for high gastric activities. This phenomenon has been recognized as “Body-Organ” reflection^[19-21]. Most experiments proved that nerve-body fluid factors are involved in the effects of EA at points of Foot Yangming on gastric mobility function. Related experiments indicate that the inhibition of gastric mobility can be restrained by acupuncture at different points (head, body, and lower limb) of Foot Yangming Channel. Substance P, motilin, gastrin, and growth-inhibitory factors in gastric sinus section and medulla oblongata vary correspondingly. Acupuncture at Foot Yangming Channel regulates gastric mobility possibly through activating and releasing brain intestinal peptide (BIP) from central and local areas^[22-24]. Atropine reduces gastric myoelectric activities and BIP release. Acupuncture at Zusanli partially relieves the inhibitory effect and BIP content. These results indicated that peptide nerve may be involved in the efferent portion of acupuncture. Motilin, gastrin and substance P *etc.* released from peptide nerve participated in the process in which EA restored the inhibited gastric myoelectric activities to normal properties^[25-27], which is consistent with our present study.

Reserpine is an adrenergic nerve-blocking agent, which acts by depleting the adrenergic nerve terminal of its norepinephrine and 5-HT transmitters store^[28,29]. The gastric mobility was enhanced after the intraperitoneal injection of reserpine, suggesting that adrenergic nerve is involved in the gastric myoelectric activities regulation. Catecholamine participates in this process^[30]. Effects of acupuncture on gastric activities are related to domination of the vagus nerve and other exciting nerves on the basis of denervation of adrenergic action.

In conclusion, cholinergic and adrenergic nervous systems and autonomic nerve ganglion participate in the peripheral passage of the controlling effects of EA at the Foot Yangming Channel on gastrointestinal tract.

Abstract

A 55-year old man presented with acute sigmoid volvulus. The distal level of obstruction was above the level which could be reached by the rigid sigmoidoscope to allow decompression, and so a flatus tube was "lassoed" onto the side of a flexible endoscope which allowed accurate placement under direct vision. This technique allows accurate placement of catheters, feeding tubes and other devices endoscopically, which cannot be placed through the instrument channel of the endoscope.

INTRODUCTION

Acute sigmoid volvulus is frequently encountered in clinical practice. The distal level of obstruction can be reached by the rigid sigmoidoscope to allow decompression. A flatus tube (Figure 1) can be "lassoed" onto the side of a flexible endoscope which allows accurate placement under direct vision. This technique allows accurate placement of catheters, feeding tubes and other devices endoscopically, which cannot be placed through the instrument channel of the endoscope.

CASE REPORT

A 55-years old male presented acutely to the surgical on-

Figure 1 Flatus tube used in our study.

call team at our institution with a 2-d history of absolute constipation and abdominal distension followed by vomiting. He had a previous history of laryngotomy for carcinoma and hypertension.

Clinical examination revealed abdominal distension, obstructive bowel sounds and an empty rectum. Plain abdominal radiology demonstrated features of distal large bowel obstruction and computed tomography revealed colonic distension to the level of the sigmoid colon, indicating a sigmoid volvulus and decompression was planned.

Under intravenous sedation with propofol, the colonoscope was passed into the sigmoid colon and the proximal colon was decompressed, but on removal of the endoscope, the sigmoid colon re-volved above the proximal extent of the rigid sigmoidoscope.

We employed a novel method for placement of the flatus tube under direct vision by 'lassoing' an endoscopic snare wire (passed through the colonoscope) onto the end of the flatus tube. The free end of the flatus tube was clamped to prevent escape of insufflated air during placement. The colonoscope (with 'lassoed' flatus tube) was renegotiated into the sigmoid colon and once satisfactory positioning was achieved under direct vision, the snare was loosened and slipped over the distal end of the flatus tube, which was left in place after the scope was withdrawn. The flatus tube was unclamped and left *in-situ* with a drainage bag attached for 48 h. The patient was allowed full diet after the procedure and discharged on the third day.

DISCUSSION

Acute sigmoid volvulus is frequently encountered in clinical practice. However, no previous report has described

use of an endoscopic snare to guide the placement of either a hollow tube (to allow drainage or installation of substances) or a measuring catheter under direct vision. We employed a novel method for placement of the flatus tube under direct vision by 'lassoing' an endoscopic snare wire (passed through the colonoscope) onto the end of

the flatus tube. The patient was allowed full diet after the procedure and discharged on the third day. It is suggested that this technique can achieve rather good results in the treatment of acute sigmoid volvulus. This technique can also be employed for upper alimentary procedures such as the accurate placement of feeding tubes or pH catheters.

Abstract

Pancreatic cystic lesions comprise various entities with different histopathological characteristics and their differential diagnosis is often a challenge for clinicians. Autoimmune pancreatitis (AIP) is usually not considered in the differential diagnosis of cystic lesions, but often mimics the morphological aspects of pancreatic neoplasm. We report the case of a 64-year-old male patient with a cystic pancreatic head lesion (diameter 5 cm) and stenosis of the distal bile duct requiring repeated stenting. Because of the clinical presentation together with moderate elevation of serum CA19-9 and massive elevation of cyst fluid CA19-9 (122.695 U/L; normal range: < 37.0 U/L), the patient underwent explorative laparotomy and pylorus preserving partial pancreaticoduodenectomy. Histology revealed surprisingly AIP with an inflammatory pseudocyst. In conclusion, cyst fluid analysis of tumor markers and cyst fluid cytology lack high accuracy to clearly differentiate cystic pancreatic lesions. Although AIP is rarely associated with pseudocysts, the disease has to be considered in the differential diagnosis of cystic pancreatic lesions. Early examination of serum IgG, IgG₄ and auto-antibodies might save these patients from unnecessary endoscopic and surgical procedures.

INTRODUCTION

Autoimmune pancreatitis (AIP) is a benign disease that responds well to steroid treatment. Characteristics include radiological evidence of an irregular narrowing of the pancreatic main duct and a diffuse enlargement of the pancreas, together with increased levels of serum IgG and the IgG₄ subclass as well as antinuclear (ANA), antilactoferrin (ALF), anticarbonic anhydrase II antibodies (ACA-II) and rheumatoid factor^[1]. On histological examination, periductal lymphoplasmacytic infiltration, periductal fibrosis and venulitis are most frequently observed^[2]. Although there is no international consensus on the diagnostic criteria for AIP, histology should be considered the gold standard in cases in which tissue diagnosis is possible. AIP predominantly affects male patients and is often associated with other autoimmune diseases such as Sjögren's syndrome, primary sclerosing cholangitis or diabetes mellitus which lead to the hypothesis that AIP might be part of a systemic autoimmune disorder with increased IgG₄ and immune complexes (secondary AIP)^[1]. Although AIP has become more and more accepted as a distinct disease entity during the last years^[3], the presentation of the disease can be unusual and misleading as depicted in the reported case. The correct diagnosis of AIP is of great clinical relevance since this pancreatic disorder, in contrast to most other pancreatic pathologies, can be treated successfully by non-invasive therapies.

CASE REPORT

A 64-year-old male patient was referred to our department with a cystic lesion of the pancreatic head and a history of multiple biliary stent placements during a course of two years due to distal bile duct stenosis. There was no history of alcohol abuse. Three years earlier, the patient had undergone an explorative laparotomy, cholecystectomy and lymph node biopsy at a different hospital because of a pancreatic tumor of unknown etiology. However, intraoperative assessment and histology did not reveal neoplastic tumor growth. On follow-up, the patient developed recurrent attacks of abdominal pain with mild to moderate pancreatic enzyme elevation, and a distal bile duct stenosis requiring repeated stenting and dilation (Figure 1A). Fine needle aspiration cytology of the pancreas was consistent with chronic pancreatitis. On further follow-up, a cyst of the pancreatic head (diameter 5 cm) was diagnosed (Figures

Figure 1 MRCP (A) depicting the dilated bile duct (13 mm) in close vicinity to the pancreatic cyst; CT scans (B, C) showing the cystic pancreatic lesion in the pancreatic head (arrows).

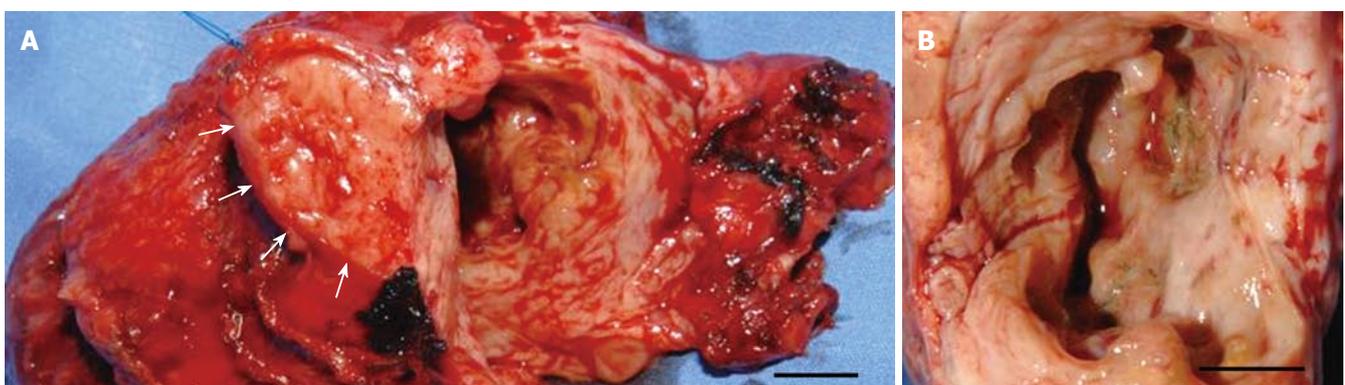

Figure 2 Intraoperative findings of the resected pancreatic specimen. A, B: Macroscopic appearance of the pancreaticoduodenectomy specimen (A) and the opened pseudocyst (B). Arrows indicate the pancreatic cut margin. Scale bar: 1 cm.

1B and C). Cyst fluid analysis showed a CEA of 55 ng/L (normal range: < 3.4 ng/L) and a CA19-9 of 122.695 U/L (normal range: < 37.0 U/L), without evidence of malignant cells. The patient was referred to our department for surgical therapy with the suspicion of a cystic neoplasm. Pertinent laboratory data on admission to our department were (in brackets: normal range): lipase 108 U/L (< 51 U/L), γ -glutamyl transferase 158 U/L (< 60 U/L), bilirubin 0.4 mg/dL (within normal range), calcium 2.32 mmol/L (within normal range), WBC 6.91/nL (within normal range), CA19-9 43.4 U/mL (< 37.0 U/mL), CEA 3.2 ng/mL (< 2.5 ng/mL).

The patient underwent a pylorus preserving partial pancreaticoduodenectomy. The postoperative course was uneventful and the patient was discharged after seven days. Grossly, the pancreatic head measured 7 cm \times 5 cm \times 3 cm and showed a whitish induration of the tissue with a cyst of 4 cm in diameter (Figure 2A and B). Histological examination revealed surprisingly autoimmune pancreatitis with an inflammatory pseudocyst without evidence for malignancy (Figure 3A and F).

DISCUSSION

Differentiating cystic pancreatic lesions remains a clinical challenge^[4]. Adding serological analysis (e.g. CEA, CA19-9) of aspirated cyst fluid to conventional imaging modalities

results in additional accuracy. Thus, of various markers including tumor markers and cytology, a CEA cutoff of 192 ng/mL (in the cyst fluid) demonstrated the highest accuracy in differentiating mucinous from non-mucinous cystic lesions^[5]. However, the sensitivity and specificity rates remain unsatisfactory. Therefore, resection of cystic lesions remains the treatment of choice if malignant or pre-malignant cystic neoplasm cannot be ruled out^[6].

AIP, on the other hand, is rarely associated with pseudocysts^[7,8], but involvement of the pancreatic head can mimic pancreatic neoplasm^[3]. AIP responds well to steroid treatment and is often associated with elevated serum IgG/IgG₄ and the presence of different auto-antibodies (e.g. ANA, and others)^[3,9]. In addition, pseudocysts in patients with AIP might represent a highly active inflammatory process, and these lesions have been shown to be steroid responsive if associated with AIP^[7]. In the present case, histology demonstrated that the inflammatory process involved the distal common bile duct, which is most likely the reason for the patients' history of recurrent bile duct stenosis.

The pseudocyst formation was detected almost 2 years after onset of abdominal symptoms. Muraki *et al* observed pancreatic cysts 1-3 years after onset of abdominal symptoms or diagnosis of AIP^[7], indicating that pseudocyst development in AIP occurs after prolonged disease activity.

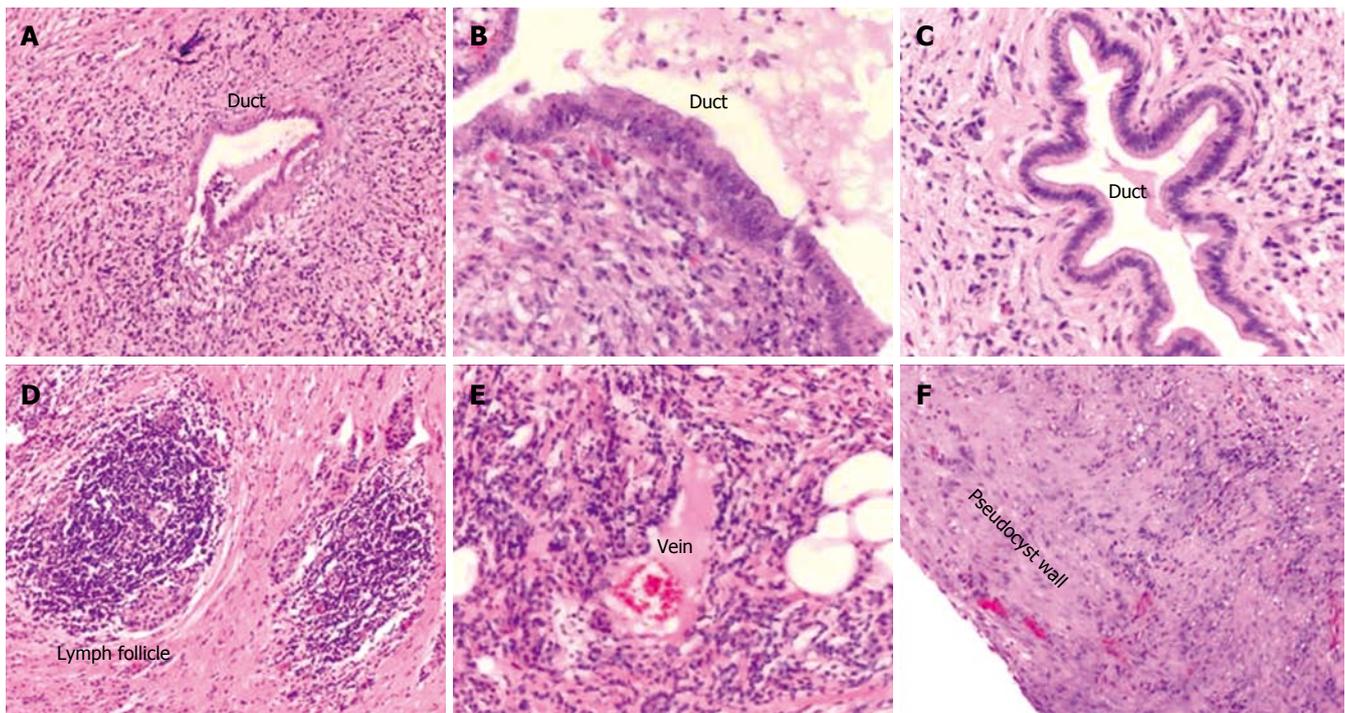

Figure 3 Histological findings of the resected pancreatic specimen. Histological examination displaying marked chronic periductal lymphoplasmacytic inflammation and fibrosis (A-C), intrapancreatic lymph follicle (D), and venulitis (E). F depicts the wall of the pseudocyst without evidence of epithelial lining.

In our case, the consideration of AIP before or after the first surgical exploration together with a trial of steroid therapy would likely have saved the patient a number of endoscopic and ultimately surgical therapies. This case highlights the clinical problem of differentiating cystic pancreatic lesions, and the importance of considering AIP as a differential diagnosis early in the course of the disease. Nonetheless, given the high cure rate of pancreatic cystic tumors with surgical resection, laparotomy should not be delayed in case of suspected malignancy.

Abstract

The standard adjuvant treatment of colon cancer is fluorouracil plus leucovorin. Oxaliplatin improves the efficacy of this combination in patients with stage III colon cancer and moreover its toxicity is well tolerable. We describe a rare clinical case of acute dyspnoea probably related to oxaliplatin at one month from the end of the adjuvant treatment. A 74-year-old man developed a locally advanced sigmoid carcinoma (pT3N1M0). A port a cath attached to an open-ended catheter was implanted in order to administer primary chemotherapy safely according to the FOLFOX4 schedule. One month following the end of the 6th cycle, the patient referred a persistent cough and moderate dyspnoea. Chest radiography displayed a change in the lung interstitium, chest CT scan confirmed this aspect of adult respiratory distress syndrome, spirometry reported a decreased carbon monoxide diffusion capacity. Antibiotic and corticosteroids were administered for 10 d, then a repeated chest X ray evidenced a progressive pulmonary infiltration. A transbronchial biopsy and cytology did not show an infective process, a CT scan reported radiological abnormalities including linear and nodular densities which were becoming confluent. Antimicrobial and antiviral drugs did not evidence any benefit. The antiviral therapy was stopped and high dose methylprednisolone was started. The patient died of pulmonary distress after 10 d.

Pasetto LM, Monfardini S. Is acute dyspnea related to oxaliplatin administration? *World J Gastroenterol* 2006; 12(36): 5907-5908

<http://www.wjgnet.com/1007-9327/12/5907.asp>

INTRODUCTION

For almost 15 years, adjuvant chemotherapy has been known to improve disease-free survival (DFS) and overall survival (OS) in colon cancer patients. The pivotal study of Moertel *et al* in 1990^[1], demonstrated that OS and DFS are improved after 12 mo of treatment with bolus 5-fluorouracil (5-FU) and levamisole, which has led to the First National Cancer Institute (NCI) consensus recommendation for stage III colon cancer^[2]. Subsequent studies conducted in the 1990s have established 6 to 8 mo of adjuvant therapy with bolus 5-FU plus leucovorin (LV) as standard of care. The positive results of the international multi-center study of oxaliplatin/5-fluorouracil/leucovorin in the adjuvant treatment of colon cancer (MOSAIC) trial^[3] enrolling both stage II and III patients, have led to US Food and Drug Administration approval of oxaliplatin plus 5-FU/LV (FOLFOX4) for patients with stage III colon cancer in November 2004^[4], which followed the European approval as adjuvant treatment of stage III (Dukes C) colon cancer after complete resection of the primary tumour in September 2004. The US Food and Drug Administration approval is based on the demonstration of the statistical superiority of FOLFOX4 to infusional plus bolus 5-FU/LV (LV5FU2 regimen) on 3- and 4-year DFS in the stage III subgroup of patients in the MOSAIC trial^[3-5]. Vomiting is observed in about 47% of cases, granulocytopenia in about 79% of cases and thrombocytopenia in 77% of cases, paresthesia in about 92% of cases and increased enzymes in about 57%, respectively. Other types of toxicities are of low grade.

CASE REPORT

We describe a rare clinical case of acute dyspnoea at one month from the end of adjuvant treatment.

A 74-year old man developed a locally advanced sigmoid carcinoma (pT3N1M0). A port a cath attached to an open-ended catheter, was implanted in order to administer primary chemotherapy safely according to the FOLFOX4 schedule (oxaliplatin 85 mg/m² d 1, 5-FU 400 mg/m² d 1, 2 administered as bolus, 5-FU 600 mg/m² d 1, 2 administered by 22 h continuous infusion and LV 100 mg/m² administered by 2 h infusion, every 2 wk). The 6-mo administration went without acute complications (except for a grade 1 thrombocytopenia and neutropenia). One month following the end of the 6th cycle, the patient

referred a persistent cough and moderate dyspnoea. Chest radiography documented a change in the lung interstitium, chest CT scan confirmed this aspect of adult respiratory distress syndrome, spirometry reported a decreased carbon monoxide diffusion capacity. Antibiotic and corticosteroids were administered for 10 d; a repeated chest X ray evidenced a progressive pulmonary infiltration. The patient was urgently admitted to our hospital for increasing fever and dyspnoea. Transbronchial biopsy and cytology did not show an infective process, CT scan reported radiological abnormalities including linear and nodular densities which were becoming confluent. Antimicrobial and antiviral drugs did not evidence any benefit. For a respiratory complication the patient was admitted to the Intensive Care Unit. The antiviral therapy was stopped and high dose methylprednisolone was started. The patient died of pulmonary distress after 10 d.

DISCUSSION

To our knowledge, this is one of the very few reports on such a phenomenon in patients with colorectal cancer (CRC) during FOLFOX4 chemotherapy. Rare cases of acute interstitial lung disease and of pulmonary fibrosis have been reported after oxaliplatin, including obliterated bronchiolitis with organized pneumopathy or interstitial pneumonia-like lung disease. The MOSAIC adjuvant trial has not reported such toxicity^[3].

In our clinical case, the interstitial aspect of lung fibrosis appeared to be rapidly evolutionary, showing no

improvement 7 d after steroid therapy.

Since the use of oxaliplatin chemotherapy has increased dramatically in the past 2 years in CRC patients, and because of the lack of clinical data in literature, we strongly recommend accurate basal pulmonary analysis with spirometry, especially in elderly patients, to evaluate the respiratory reserve and careful monitoring of any respiratory distress which may occur in patients during or at the end of oxaliplatin chemotherapy. Clinicians should be aware of the potential of lung toxicity caused by novel antineoplastic agents.

Abstract

Foreign bodies in the upper esophagus should be removed as soon as possible to avoid serious complications. However, removals of foreign bodies in the upper esophagus are very difficult, especially if they have sharp edges, such as press-through-packs (PTPs). We experienced four cases of the impacted PTPs in the upper esophagus which was successfully extracted endoscopically with the overtube. Because two edges of PTPs were so firmly impacted in the esophageal wall in all cases, the PTPs were not movable in the upper esophagus. However, after insertion of the overtube, PTPs became movable and were successfully extracted and no serious complications occurred after extraction of PTPs. In one case, insertion of the overtube rapidly expanded the upper esophagus and PTP progressed to the gastric cavity and it could be extracted with the endoscopic protector hood. The endoscopic removal with the overtube was a simple, safe and effective technique for the removal of the impacted PTPs in upper esophagus.

INTRODUCTION

Foreign bodies in the esophagus should be removed to

avoid serious complications, such as bleeding, mediastinitis, esophageal perforation and pulmonary aspiration^[1-5]. Esophageal impaction of a foreign body with sharp edges is considered a medical emergency because it is often associated with perforation or hemorrhage, the likelihood of which increases with the passage of time^[6-8]. Therefore, such objects should be removed as soon as possible after ingestion^[9]. However, the removal of foreign bodies with sharp edges that are located in the upper esophagus is difficult. Furthermore, complications, such as mediastinitis, pneumothorax and aorto-esophageal fistula, can develop during or after removal of a foreign body from the esophagus^[10-12]. The absence of a serosal layer in the esophageal wall increases the potential for serious complications^[13].

Press-through-packs (PTPs) are widely used in Korea for packaging drugs, and cases of impaction of PTPs in the esophagus have been reported^[14,15]. Because PTPs have three or four edges that may be razor-sharp, esophageal perforation or bleeding could develop during their removal. We experienced four cases of the impacted PTPs in the upper esophagus, which were successfully extracted endoscopically with the overtube.

CASE REPORT

Four patients who accidentally swallowed PTPs visited the Emergency Room of the Korea University Guro Hospital from October 2004 to December 2005 (Table 1). The median age of the four patients was 51 years (range, 34-76 years). All patients complained of severe dysphagia. They had upper respiratory tract infections and had taken several pills such as antibiotics, analgesics, etc., one of which was contained in a PTP. The patients had no history of dementia or psychological disease. One patient (case 4) had hypothyroidism, but the others had no comorbidities. Physical examinations revealed smooth breathing sounds, soft abdomens that were not tender, and active bowel sounds. Chest and neck radiograms were unrevealing.

After intravenous injection of 25 mg of pethidine for sedation, urgent endoscopic examinations were performed on each patient using a conventional Olympus video endoscope (Olympus Optical Co. Ltd., Tokyo, Japan), which revealed a PTP impacted in the upper esophagus (Figure 1). Attempts to extract the PTPs using forceps were unsuccessful because the edges of the PTPs were firmly impacted in the esophageal walls.

After the tip of the endoscope had been placed close

Table 1 Baseline characteristics of 4 cases with impacted press-through-packs in the upper esophagus

	Sex	Age	Duration from swallowing of PTP to endoscopy (h)	Distance of impacted PTP from incisor (cm)	Size of impacted PTP (length × width; mm)
Case 1	F	50	4	18	33 × 20
Case 2	F	35	1	19	25 × 17
Case 3	M	78	3	20	31 × 21
Case 4	F	52	8	19	23 × 21

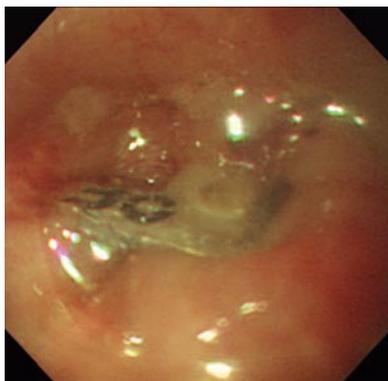

Figure 1 Endoscopic image showing a press-through-pack impacted in the upper esophageal wall.

to the PTP, a flexible overtube (length, 195 mm; inside diameter, 15 mm; outside diameter, 18 mm) was passed over the endoscope to a position just proximal to the edge of the PTP (Figure 2). Insertion of the overtube resulted in relaxation of the upper esophagus, which enabled the impacted PTP to be moved (Figure 3). We used endoscopic forceps to grasp the PTP and pull it into the overtube (Figure 4). After confirming that the edges of the PTP were within the overtube, the overtube and the PTP were removed simultaneously. In all four cases, insertion of the overtube enabled movement of the PTP and successful extraction without complications, such as mediastinitis, hemorrhage, perforation, or death. After removal, erosions were visible at the sites of impactions.

In one case (case 2), insertion of the overtube expanded the upper esophagus so rapidly that the PTP progressed to the gastric cavity before it could be grasped with the forceps. After locating the PTP in the middle of the stomach lumen, we removed the overtube and extracted the PTP using the endoscopic protector hood to prevent injury to the stomach and esophagus.

After extraction of the PTPs, the patients' dysphagia improved and no other symptoms developed. The results of chest radiographies after extraction of the PTPs were unrevealing. All patients were observed overnight and discharged. Prophylactic antibiotics were not prescribed. The patients were asymptomatic during follow-up consultations one week after the procedures.

DISCUSSION

Although esophageal foreign bodies in adults usually occur in prisoners and patients with underlying esophageal diseases, mental retardation, or psychiatric illnesses^[16], esophageal impactions of PTPs frequently occur in senile

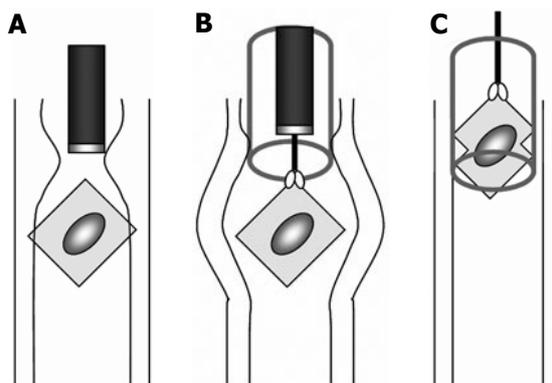

Figure 2 Method for removal of a press-through-pack impacted in the upper esophagus. A: The press-through-pack was located using a diagnostic endoscope; B: an overtube was inserted and resulted in relaxation of the upper esophagus, which enabled the impacted press-through-pack to be moved; C: forceful pulling of the press-through-pack using forceps caused the edges of the PTP to bend, enabling it to enter the overtube.

Figure 3 Endoscopic image showing distal relocation of a press-through-pack that was previously impacted and immovable. Erosions proximal to the press-through-pack indicate the site at which the press-through-pack was impacted until insertion of the overtube.

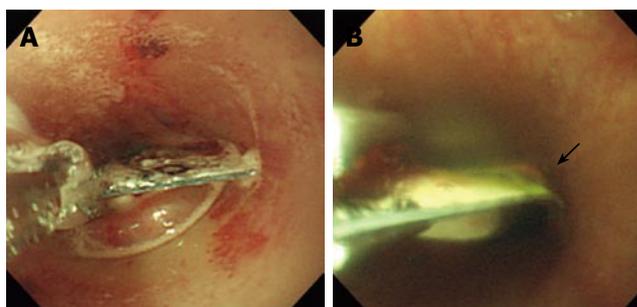

Figure 4 A: Endoscopic image showing forceful retraction of the press-through-pack by a forceps; B shows how the edges of the press-through-pack were bent (arrow) during entry into the overtube.

people who are not members of these high-risk groups^[17], and the incidence thereof is increasing rapidly and in proportion to the ageing of the population^[17].

Because PTPs usually have sharp edges, care is needed to prevent esophageal or posterior pharyngeal injuries during endoscopic removal of PTPs from the upper esophagus. The endoscopic protector hood reportedly permits easy and safe removal of sharp or pointed foreign bodies^[18]. However, the foreign body must be moved to the gastric cavity to flip the protector's hood back to its original shape for withdrawal through the lower esophageal sphincter^[18]. Such devices cannot be used when the foreign body is so

firmly impacted that it cannot be moved. In our patients, the PTPs could not be moved until the overtube was inserted. Tsutsui *et al*^[15] reported a case in which removal of a PTP from the esophagus was accomplished using two flexible endoscopes. However, this procedure requires two endoscopists and the insertion of additional equipment, which may cause more discomfort to the patient than an overtube. Recently, Jeon *et al*^[8] used an oral side-balloon that is generally used in esophageal variceal sclerotherapy; it was attached to the distal part of an endoscope to release impacted sharp foreign bodies, including PTPs, from the esophageal wall. However, in our patients, the impacted PTPs were so proximal that we would have been unable to progress the endoscope far enough down the esophagus to permit ballooning. In addition, this method does not prevent pharyngeal mucosal injury. A soft large cap (18 mm in tip diameter, D-206 series, Olympus) may be used for removal of esophageal foreign bodies^[8]. However, it might not be able to cover all length of the PTPs and this incomplete coverage may lead to pharyngeal and upper esophageal mucosal injury.

We used overtubes to remove the impacted PTPs. Although the overtubes were placed just above the proximal tips of the PTPs, they relaxed the esophageal lumens to the extent that the impacted PTPs were movable. This may have been caused by expansion of the proximal esophageal lumen or induction of esophageal peristalsis by the overtube. Swallowing movements induced by insertion of the overtube may initiate primary peristalsis, and the presence of the overtube in the esophagus after primary peristalsis may stimulate sensory receptors in the esophagus to initiate secondary peristalsis^[19].

The overtube technique cannot be used for the removal of foreign bodies that are wider than the internal diameter of the overtube. Although the PTPs in all four of our cases were wider than the internal diameter of the overtube, their flexibility enabled them to be pulled into the overtube using forceps. However, care should be taken not to cause mucosal injury by pinching the mucosa between the PTP and the overtube. Such injury can be avoided by changing the site at which the PTP is grasped.

The use of an overtube during removal of an impacted PTP has several merits. Firstly, it causes expansion of the upper esophagus, which releases the impacted PTP. Although esophageal relaxation resulted in progression of the PTP to the gastric cavity in one case, it was easily extracted using the endoscopic protector hood. Secondly, it prevents aspiration and esophageal or pharyngeal injury^[4,9,20,21].

However, the overtube must be used with caution, especially when the esophageal foreign body causes esophageal stricture. In such cases, an overtube could cause esophageal perforation^[22-24]. Berkelhammer *et al*^[23] reported that the use of an overtube for variceal ligation resulted in cricopharyngeal submucosal dissection with pneumomediastinum and proximal variceal bleeding. Therefore, endoscopic evaluation should be performed before passage of the overtube. In addition, because the impacted PTPs could lead serious complications, such as mediastinitis and aortic-esophageal fistula^[10,11],

careful evaluation should be performed to assess the relationship between PTPs and esophageal wall before endoscopic removal of PTPs. In our cases, chest and neck radiograms as well as physical examination did not show any sign of mediastinitis, and the location of PTPs were upper esophagus (18-20 cm from incisor), which were far from the aorta. Therefore, the possibility of serious complications was estimated to be very low and endoscopic removal for PTPs were performed.

In conclusion, the use of an overtube for endoscopic removal of impacted PTPs from the upper esophagus is simple, effective, and safe.

Abstract

We experienced a very rare case of ulcerative colitis (UC) accompanied with analogous lesions in the stomach, duodenum, and ileal J-pouch. Ileal J-pouch anal anastomosis was performed on a 29-year old woman in 1996. Six years later, she was admitted again to our hospital because of epigastralgia, nausea, watery diarrhea and low fever. Based on the results of endoscopic examination, we diagnosed it as pouchitis. Moreover, on hypotonic duodenography, expansion of the duodenal bulb and the descending portion were poor. Kerckring folds disappeared with typical lead-pipe appearance. The pathogenesis of the gastric and duodenal lesion in this patient was similar to that of the colonic lesions of UC. For the gastroduodenal lesions in this patient, symptomatic remission was obtained following administration of crushed mesalazine tablets (1500 mg/d) for 14 d with continuous administration of omeprazole. Firstly we used ciprofloxacin to treat pouchitis. On the fifth day, she got a fever because of catheter infection. In the catheter culture, methicillin-resistant *Staphylococcus aureus* (MRSA) was detected. Therefore we changed ciprofloxacin to vancomycin hydrochloride (Vancomycin®). Vancomycin was very effective, and the stool frequency dramatically improved in three days. Now she continues to take mesalazine, but her condition is stable and there has been no recurrence of pouchitis.

INTRODUCTION

Pouchitis after total colectomy with ileal pouch anal anastomosis can sometimes occur in patients with ulcerative colitis (UC). Despite intensive studies the cause of pouchitis remains unknown, but many contributing factors, such as faecal stasis, bacterial invasion, and faecal bile acids have been postulated. Data on the cumulative risk of pouchitis at 5 to 10 years after ileal J-pouch anal anastomosis (IPAA) in UC patients range from 30% to 50% in Western countries^[1]. On the other hand, the cumulative risk of pouchitis in Japanese UC patients is lower than that in Western countries^[2]. Gastroduodenal lesions in patients with UC are apparently rare, the stomach and duodenum are not generally considered as target organs in UC and there is no consensus regarding their significance or management. When we review the previous case reports, if anything, the number of reported cases of gastroduodenal lesions associated with UC is increasing in Japan. At this time, we experienced a very rare case of UC accompanied with analogous lesions in the stomach, duodenum, and ileal J-pouch. These findings suggest that UC is a generalized disease in which gastroduodenal changes can be regarded as one facet.

CASE REPORT

A 29-year old woman with a 3-year history of left-side colitis was referred to our hospital for 2 stage total proctocolectomy with mucosectomy, ileal J-pouch anal anastomosis in 1996. The diagnosis of UC was made on the basis of a barium enema and colonoscopic findings and confirmed by the typical histologic features of colorectal biopsies. No evidence of Crohn's disease (CD) was present at the time of surgery, and the gross and microscopic features of the colectomy specimen were those of UC. The postoperative course was uneventful, and oral prednisolone was gradually tapered off and completely stopped 2 mo after ileostomy closure. In

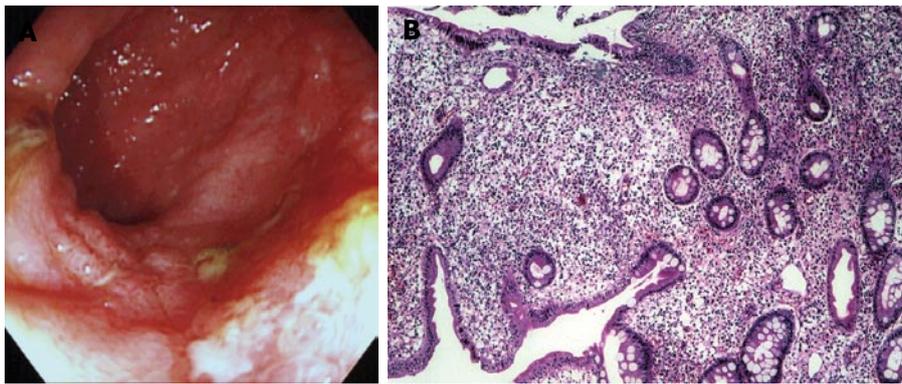

Figure 1 Endoscopy (A) and histological examination (B) showing pouchitis in the ileal J-pouch.

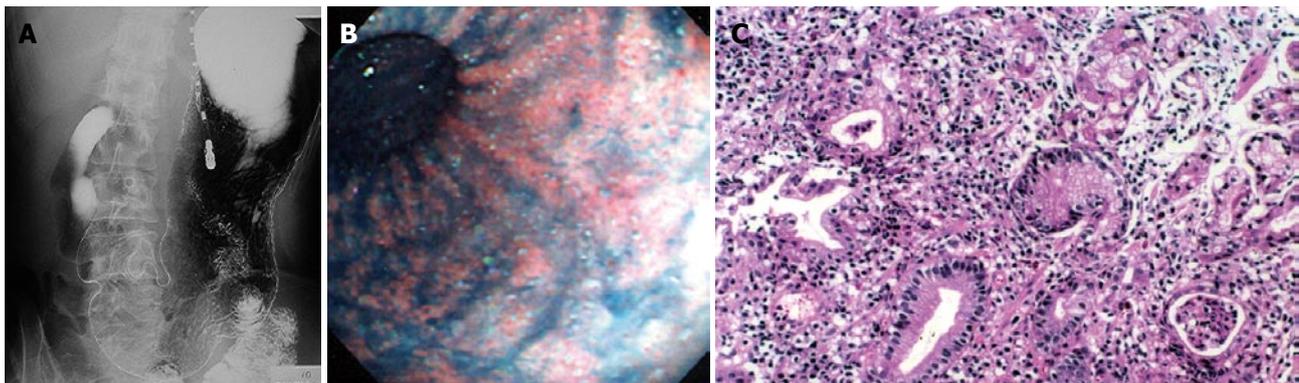

Figure 2 Upper gastrointestinal examination (A), endoscopy (B) and histological examination (C) showing lesions in the stomach.

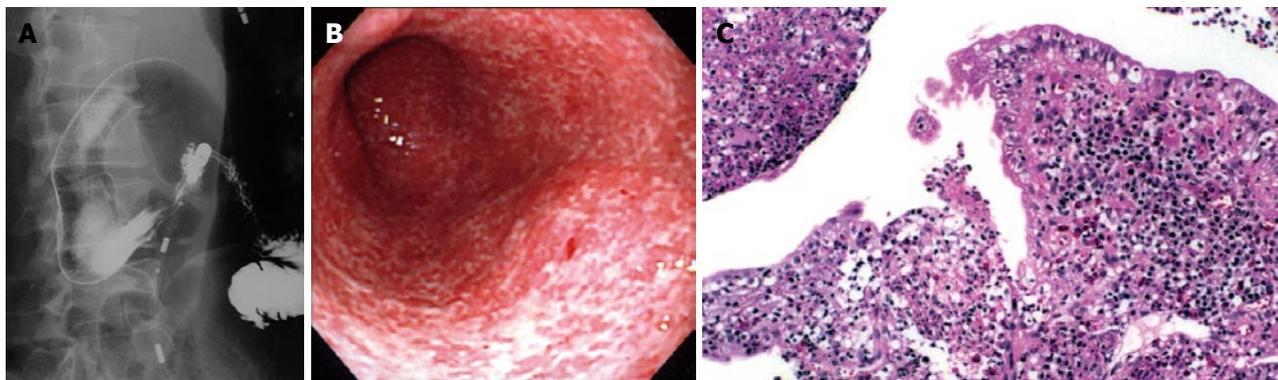

Figure 3 Hypotonic duodenography (A), endoscopy (B) and histological examination (C) showing lesions in the duodenum.

December 2002, this patient was admitted again to our hospital because of epigastralgia, nausea, watery diarrhea and low fever. On admission, the body temperature was 37.2°C and laboratory data were as follows: red blood cell count $467 \times 10^4/\mu\text{L}$, hemoglobin 12.3 g/dL, white blood cell count $6000/\mu\text{L}$. C-reactive protein (CRP) was slightly increased at 1.3 mg/dL.

At first we doubted it was pouchitis and performed endoscopy in the ileal J-pouch. The endoscopic features were edema, granularity, loss of vascular pattern, mucus exudates and ulcerations (Figure 1A). Histological examination of the ileal J-pouch biopsied in the active stage demonstrated severe infiltration of inflammatory cells in mucosa (Figure 1B). We used the pouchitis disease activity index (PDAI) as the diagnostic criteria. Her PDAI score was 12 points. We diagnosed her with pouchitis.

Endoscopy of the upper gastrointestinal tract disclosed multiple erosions and granular changes in the antral greater curvature of the stomach and similar features were noted in the duodenal bulb and the descending portion of the duodenum (Figures 2B and 3B). On hypotonic duodenography, expansion of the duodenal bulb and the descending portion were poor. Kerckring folds disappeared with a typical lead-pipe appearance (Figure 3A). The expansion of the gastric wall was kept but antral mucosa disclosed multiple granular changes (Figure 2A). Histological examination of the stomach biopsied in the active stage demonstrated severe infiltration of inflammatory cells in mucosa and crypt abscess in the mucous glandules (Figure 2C). Histology of the biopsy specimens revealed dense acute and chronic inflammatory infiltrates accompanied with cryptitis in the duodenum

(Figure 3C). Neither granuloma nor *H pylori* was detected in biopsied sections.

After admission, we performed intravenous hyperalimentation, because she exhibited dehydration due to severe watery diarrhea. The gastroduodenal lesions in this patient were not improved by oral omeprazole (20 mg/d) for 7 d, but symptomatic remission was obtained following administration of crushed mesalazine tablets (1 500 mg/d) for 14 d, with continuous administration of omeprazole. Firstly we used ciprofloxacin to treat pouchitis. On the fifth day, she got a fever because of catheter infection. Methicillin-resistant *Staphylococcus aureus* (MRSA) was detected in the catheter culture. Therefore we changed ciprofloxacin to vancomycin hydrochloride (Vancomycin®). Vancomycin was very effective, and the stool frequency dramatically improved in three days. The patient was discharged on the 44th hospital day. Now she continues to take mesalazine, but her condition is stable and there is no recurrence of pouchitis.

DISCUSSION

Pouchitis is an idiopathic inflammatory disease of the ileal reservoir in patients who have undergone ileal J-pouch anal anastomosis (IPAA), and is the most common long-term complication of IPAA in UC. The cumulative risk of developing pouchitis in Japanese UC patients is lower than that of western countries^[1,2]. On the other hand, reports of gastroduodenal lesions associated with UC are extremely rare in Western countries. In our search we found only 6 cases. Thompson and Borgen^[3] reported two cases in 1960 and Valdez *et al*^[4] reported four cases in 2000. In Japan, recently, the number of reports of gastroduodenal lesions associated with UC is increasing. In 2002, Warita *et al*^[5] reported 15 cases in Japan. The instance of both pouchitis and gastroduodenal lesion associated UC exists in only three cases. These cases were reported by Valdez *et al*^[4] in 2000. No patient with complicated pouchitis and gastroduodenal lesion has been reported in Japan.

Crohn's disease can affect the whole gastrointestinal tract. On the other hand, UC is a chronic inflammatory disease of the colon and includes various extracolonic manifestations. However, the stomach and duodenum are not generally considered target organs in UC. So in this patient, differential diagnosis from CD was important. In our patient, no evidence of CD was present at the time of surgery, and the gross and microscopic features of the colectomy specimen were those of ulcerative left-side colitis. Diffuse ulcerative duodenitis similar in appearance to the ulcerative colitis was found extending from the second to the third portion of the duodenum. Moreover, the pathogenesis of the gastric and duodenal lesions in this patient was similar to that of the colonic lesions of UC and these findings were not induced by *H pylori* infection. *H pylori* was negative in our patient, which is consistent with the finding of Warita *et al*^[5] reported who reported that five of 15 cases are negative for *H pylori* infection. Recent preliminary reports have described a reduced prevalence of *H pylori* infection in patients with inflammatory bowel disease compared with the general

population. Parente *et al*^[6] reported that previous exposure to sulphasalazine is associated with a significantly lower risk of infection, mainly in Crohn's disease but also in UC patients.

Medical treatment with mesalazine was very effective in our patient. Mitomi *et al*^[7] reported that the symptoms of their patient are resolved one month after treatment with sulfasalazopyrin (3.0 mg/d) and some antacids. Myojo *et al*^[8] reported that while the duodenitis does not respond to a proton-pump inhibitor, it improves obviously after treatment with mesalazine. Moreover, Sasaki *et al*^[9] reported that gastroduodenal lesions are not improved after oral omeprazole, but healing is obtained following intensive intravenous prednisolone therapy for 14 d with continuous administration of omeprazole. Although there is no consensus regarding these types of management, sulfasalazopyrin or mesalazine should be considered as fast-line therapies for gastroduodenal lesions. If these treatment modalities are ineffective, we should use steroids as the second-line therapy for gastroduodenal lesions.

Terashima *et al*^[10] reported that duodenal lesion accompanying UC may be a more common phenomenon, although it occurs infrequently during steroid therapy. In the future, patients with complicated gastroduodenal lesions in a postoperative steroid-free condition may increase. We have to recognize that UC is a generalized disease in which gastroduodenal changes can be regarded as one facet.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents[®]/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch[®]) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology

Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China

E-mail: wjg@wjgnet.com

<http://www.wjgnet.com>

Telephone: +86-10-85381901

Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5

line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

Key words

Please list 6-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P*<0.05, ^b*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, ^c*P*<0.05 and ^d*P*<0.01 are used. Third series of *P* values can be expressed as ^e*P*<0.05 and ^f*P*<0.01. Other notes in tables or under

illustrations should be expressed as 1F , 2F , 3F ; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (<http://www.wjgnet.com/cgi-bin/index.pl>), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂ not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please download CAF from <http://www.wjgnet.com/wjg/help/9.doc>.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to *WJG* all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The *WJG* requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1) direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3) supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The *WJG* does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to *WJG* if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Final check list for authors

The format is at: <http://www.wjgnet.com/wjg/help/13.doc>

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: <http://www.wjgnet.com/wjg/help/10.doc>

Abstract

Esophageal achalasia is the most commonly diagnosed primary esophageal motor disorder and the second most common functional esophageal disorder. Current therapy of achalasia is directed toward elimination of the outflow resistance caused by failure of the lower esophageal sphincter to relax completely upon swallowing. The advent of minimally invasive surgery has nearly replaced endoscopic pneumatic dilation as the first-line therapeutic approach. In this editorial, the rationale and the evidence supporting the use of laparoscopic Heller myotomy combined with fundoplication as a primary treatment of achalasia are reviewed.

Key words: Esophagus; Achalasia; Laparoscopy; Heller myotomy; Gastroesophageal reflux

Bonavina L. Minimally invasive surgery for esophageal achalasia. *World J Gastroenterol* 2006; 12(37): 5921-5925

<http://www.wjgnet.com/1007-9327/12/5921.asp>

INTRODUCTION

Idiopathic achalasia is a primary motor disorder characterized by incomplete relaxation of the lower esophageal sphincter and aperistalsis of the esophageal body secondary to loss of inhibitory ganglion cells in the myenteric plexus. It is unclear whether the primary event occurs in the brain or whether the neurologic changes are the result of a direct injury of the myenteric plexus. The etiology of the disease is unknown, with genetic, autoimmune, infectious, and environmental factors being implicated. Achalasia, usually diagnosed between 20 and 40 years or after 60 years of age, is the most common primary esophageal motor disorder; it is second only to gastroesophageal reflux disease as the most common

functional esophageal disorder to require surgical intervention. The first account of a successfully treated case of achalasia was described by Thomas Willis in 1674, in which a whale bone was used to forcibly dilate the cardia. The first surgical myotomy was performed by Ernst Heller in 1913.

PATHOPHYSIOLOGY AND ASSESSMENT OF ACHALASIA

Failure of the lower esophageal sphincter to completely relax upon swallowing results in a functional obstruction and pressurization of the esophageal body. Defective esophageal emptying progressively leads to dilatation and tortuosity of the esophagus with loss of the peristaltic waveform. Overall deterioration of esophageal function and structure with time, and the fact that peristalsis can return after surgical myotomy, suggest that the motor abnormalities secondary to esophageal outflow obstruction may be reversible and that early definitive treatment of achalasia is essential to preserve esophageal function^[1].

Achalasia has an insidious onset. Dysphagia and food regurgitation are the two major presenting symptoms of the disease. Nocturnal regurgitation often leads to recurrent episodes of aspiration pneumonia. In about 40% of patients the diagnosis of achalasia is delayed by the reported symptoms of chest pain and heartburn simulating gastroesophageal reflux disease. As the disease progresses, inability to swallow causes malnutrition and weight loss. Squamous-cell carcinoma of the esophagus appears to develop with greater frequency in patients with long-standing achalasia than in the normal population^[2].

The most sensitive tests for detecting achalasia are esophageal manometry and barium swallow videofluoroscopy. Aperistalsis and incomplete lower esophageal sphincter relaxation are the typical manometric features. Radiological abnormalities include aperistalsis, esophageal dilatation, and minimal lower esophageal sphincter opening with a bird-beak appearance. Endoscopic assessment is important to exclude the diagnosis of malignancy-induced secondary achalasia, often referred to as pseudoachalasia, before invasive therapies are implemented. Clinical features suggesting a tumor of the gastroesophageal junction are a short duration of dysphagia, a significant weight loss, and an elderly patient. Since adenocarcinoma of the cardia may present endoscopically as an infiltrating lesion with apparently normal mucosa, CT scan, endoscopic ultrasonography, and even exploratory laparoscopy should be used liberally in this subgroup of patients^[3].

MANAGEMENT OF ACHALASIA

Endoscopic dilation versus surgery

Treatment of achalasia is palliative and is directed toward elimination of the outflow resistance caused by the abnormal lower esophageal sphincter function without creating excessive gastroesophageal reflux. Sustained symptomatic relief of dysphagia can be achieved by endoscopic pneumatic dilation or by surgical myotomy. Retrospective studies have shown better results with myotomy performed by an experienced surgeon, and in the only prospective randomised trial myotomy gave better long-term results compared with pneumatic dilatation^[4]. A recent study of 217 patients who received a median of 4 pneumatic dilations over a 12-year period reported a long-term therapeutic success of only 50%^[5]. Over the past 15 years, the advent of minimally invasive technology has made surgery a more attractive option as a first-line therapy to both patients and referring physicians^[6]. It has been shown that pneumatic dilation is 72% effective versus 92% for the laparoscopic Heller myotomy. In addition, laparoscopic techniques have sharply reduced surgical morbidity^[7] (Table 1).

Principles of surgical therapy

The basic goal of surgery in the treatment of achalasia is the extramucosal division of both layers of the esophageal muscularis propria and of the oblique gastric fibers, the so-called Heller myotomy. For many years this operation has been performed through a laparotomy, often with the addition of a fundoplication, or through a left thoracotomy. The extent of the myotomy in the stomach, which in part depends on the type of surgical access, has long been a matter of controversy. Ellis, the pioneer of the transthoracic approach, advocated a limited (< 1 cm) gastric myotomy without an antireflux procedure. However, at a very late follow-up the level of symptomatic improvement markedly deteriorated over time with this approach, and the rate of excellent results (i.e., asymptomatic patients) progressively decreased from 54% at 10 years to 32% at 20 years^[8]. The majority of European surgeons have instead favored the transabdominal approach which includes a longer gastric myotomy (1 to 2 cm) and a fundoplication to protect the esophagus from iatrogenic gastroesophageal reflux. Another debated issue has been the direction of the myotomy over the stomach, which may be closer to the lesser curve or to the greater curve, and, as a consequence, can divide the semicircular (clasp) fibers and the oblique (sling) fibers in distinct proportions^[9].

A third major issue is the opportunity to add an antireflux repair to the myotomy. The rationale for considering a concomitant fundoplication is the assumption that a well performed surgical myotomy renders the lower esophageal sphincter incompetent. Furthermore, gastric contents propelled retrograde into an aperistaltic esophagus are not effectively cleared, thus magnifying the damage caused by postoperative reflux. The majority of surgeons worldwide presently favor a transabdominal approach and add to the myotomy a partial fundoplication, either a 180 degree anterior (Dor) or a 270 degree posterior fundoplication

Table 1 Pooled response rate of achalasia treatments^[7]

Therapy	n	Weighted response rate (%)	Weighted follow-up (yr)
Botulinum toxin	149	32	1.1
Pneumatic dilation	1276	72	4.9
Heller myotomy			
Thoracotomy	1221	84	5
Laparotomy	732	85	7.6
Laparoscopy	171	92	1.2

(Toupet). The partial fundoplication, as opposed to the 360 degree Nissen repair, does not cause significant resistance to esophageal emptying, therefore reducing the risk of postoperative dysphagia. The main advantage of an anterior Dor fundoplication is that this technique does not require mobilization of the distal esophagus and cardia, and provides a natural patch over the denuded esophageal mucosa. Overall, there has been a greater than 90% symptomatic relief and a less than 10% incidence of pH proven gastroesophageal reflux with this approach^[10]. This operation should be proposed as the first therapeutic option also in patients with sigmoid-shaped esophagus, although the chances of symptomatic relief are reduced in such circumstances and in some of these individuals an esophagectomy can eventually be required.

Minimally invasive surgery for achalasia

During the early times of the minimally invasive surgical approach, both laparoscopy and thoracoscopy have been used to perform a Heller myotomy. However, it soon became clear that laparoscopy offers several inherent advantages, including superior visualization of the gastroesophageal junction, a single lumen endotracheal intubation, the ability to add an antireflux procedure, and a shorter hospital stay. In addition, laparoscopy showed a better symptomatic outcome and a lesser incidence of postoperative gastroesophageal reflux^[11].

The first laparoscopic Heller procedures were performed in England and in Italy during the early 1990s^[12,13]. Compared to the open abdominal approach, a technical innovation introduced in the laparoscopic era has been the use of intraoperative endoscopy as a means of precisely identifying the gastroesophageal junction, checking for the completeness of the myotomy and testing for the presence of occult perforations. During the early phase of the learning curve, a Rigiflex balloon dilator was also used to distend the cardia in order to facilitate division of all residual muscle fibers^[14]. Subsequently, transillumination and air inflation provided by the endoscope were considered appropriate to assist the myotomy^[15]. Further demonstration of the effectiveness of intraoperative endoscopy came from a study showing that endoscopic and laparoscopic criteria were discordant in the identification of the esophagogastric junction in 58% of the cases, the cardia being in all these cases at a more distal site with endoscopic criteria. As a consequence, based on the laparoscopic appearance, the surgeon may err by underestimating the caudal extent of the myotomy and

can perform a too short myotomy on the gastric side^[16]. Although we are still convinced of the effectiveness of intraoperative endoscopy during the learning curve of this operation and during reoperative surgery, we have now discontinued this practice in our high-volume referral center where between 15 and 20 patients per year undergo Heller myotomy as a primary treatment for achalasia.

It should also be noted that a common reason for an incomplete myotomy on the gastric side is the fear of producing a mucosal injury, which typically occurs just at the esophagogastric junction. The mean reported rate of mucosal perforation is about 5%, but the frequency is largely dependent on surgeon's experience. There are no consequences if the mucosal injury is detected intraoperatively and repaired with interrupted stitches^[15].

The principle of limited surgical dissection of the cardia, already advocated by some surgeons in the open era^[10], has been successfully reproduced in many centers with the minimally invasive laparoscopic approach. Dissection is limited to the anterior and lateral attachments of the phrenoesophageal membrane as this allows enough space to perform the myotomy and helps to prevent the occurrence of postoperative gastroesophageal reflux. Only in patients with an associated hiatal hernia or epiphrenic diverticulum the distal esophagus is encircled and a posterior crural repair is performed. By grasping the cardia and pulling it in a caudal direction, the myotomy is started on the distal esophagus using a L-shaped electrocautery hook until the submucosal plane is identified. The myotomy is carried out for about 6 cm on the esophagus, toward the left of the anterior vagus nerve, and up to 2 cm on the gastric side to include the oblique fibers.

Despite the minimal surgical dissection herein described, an antireflux repair added to the Heller myotomy appears to be beneficial and is nowadays supported by the majority of esophageal surgeons. The anterior Dor fundoplication is a technically simple procedure, quick and safe to perform laparoscopically. It does not require mobilization of the cardia, and places a gastric fundic patch over the myotomy site to protect the mucosa and prevent re-healing of the myotomy. Reconstruction of the angle of His is first performed by suturing the medial wall of the fundus to the left edge of the myotomy and to the left crus of the diaphragm. The Dor fundoplication is fashioned by folding the anterior fundic wall over the myotomized surface and securing the stomach to the right crus of the diaphragm and to the right edge of the myotomy with interrupted stitches. It is important to pay attention to the geometry of the fundoplication in order to avoid undue tension and to provide a uniform patch over the myotomized esophagus, but usually there is no need to divide the short gastric vessels. The Heller-Dor operation is carried out in about one hour by an expert surgeon. A gastrographin swallow study is performed the following day to check esophageal transit and to rule out leaks. A soft diet is then permitted, and the patient is usually discharged home on postoperative d 2 or 3.

Studies including large number of patients have shown that an extramucosal myotomy of the esophagus and cardia combined with an anterior fundoplication can be

Table 2 Twenty-four h pH data of patients submitted to Heller myotomy and Heller myotomy plus Dor fundoplication in a randomized study^[24]

Parameter	Heller (n = 18)	Heller-Dor (n = 21)	P value
Time (%) pH < 4 upright	8.1 + 10.4	0.8 + 1.1	0.015
Time (%) pH < 4 supine	9.1 + 18.3	2.0 + 6.9	0.002
No. episodes pH < 4	113 + 128	25 + 6.9	0.001
No. episodes pH < 4 for ≤ 5 min	3.4 + 4.7	0.5 + 1.6	0.001

performed safely and effectively through laparoscopy, with clinical and functional results similar to that obtained with the open transabdominal approach and relief of dysphagia in more than 90% of patients^[17-22]. Although previous endoscopic treatments, such as balloon dilatation or intrasphincteric botulinum toxin injection, may cause submucosal scarring at the esophagogastric junction resulting in a more difficult surgical procedure and an increased operative morbidity, no statistically significant differences as far as concern the clinical outcome have been reported^[15].

Radiologic and manometric studies after the laparoscopic Heller-Dor operation have shown a significant decrease of the internal diameter of the thoracic esophagus and of the resting lower esophageal sphincter pressures^[19]. In a recent report, at a minimum follow-up of 6 years after the operation, about 82% of patients were satisfied with the treatment and were able to eat normally; more than a half of the symptomatic recurrences occurred during the first year of follow-up and were effectively treated with pneumatic dilations. Nine (12.7%) patients either had abnormal acid exposure on postoperative 24-h pH study or were on treatment with proton-pump inhibitors for reflux symptoms; however, in none of these individuals did endoscopy reveal more than grade A esophagitis^[23].

An important preoperative factor affecting the outcome of the laparoscopic operation is the magnitude of the resting pressure of the lower esophageal sphincter. On a multivariate analysis, only a high resting pressure prior to surgery was a predictor of resolution of dysphagia. Interestingly, all patients with a preoperative sphincter pressure greater than 36 mmHg had their dysphagia resolved after surgery^[24].

The issue of whether an antireflux procedure should be added to the Heller myotomy has long been controversial and supported only by personal feelings and retrospective studies. Recently, a randomised double-blind clinical trial comparing the outcome of myotomy plus Dor fundoplication versus myotomy alone has shown that the former operation is superior in terms of reflux control (Table 2). The addition of a Dor fundoplication reduces the risk of pathologic gastroesophageal reflux by 9-fold as tested by 24-hour esophageal pH monitoring. Even the median esophageal acid exposure was lower in the Heller-Dor group, indicating that the few unfortunate individuals in whom reflux might occur are easily managed with

medical therapy^[25].

The predominant mechanism of failure after the Heller operation is an incomplete distal myotomy. In such circumstances, pneumatic dilatation can represent a reasonable therapeutic option when dysphagia is mild. In patients with major symptoms, revisional laparoscopic surgery with repeat myotomy and fundoplication is feasible and effective with a low morbidity rate^[26]. Intraoperative endoscopy is helpful as a guide during dissection to identify the cleavage plans and to clearly recognize the gastroesophageal junction. When a properly performed myotomy has failed in a patient with sigmoid esophagus, and the redundant supradiaphragmatic esophageal loop still interferes with emptying, a transthoracic or a transhiatal esophagectomy is the treatment of choice^[27].

It has recently been suggested that a laparoscopic myotomy extended for 3 cm on the gastric side can result in better dysphagia scores and in fewer additional procedures to treat recurrent dysphagia, provided that a Toupet fundoplication is added to the procedure^[28]. However, this improved outcome should be balanced against the risk of severe gastroesophageal reflux disease induced by the longer gastric myotomy and the necessity to fully mobilize the cardia to perform a posterior fundoplication. Interestingly, a very long-term study of 67 patients who underwent an open Heller-Dor operation and were followed for more than 20 years has shown a progressive clinical deterioration of results and a 22.4% failure rate due to an increased esophageal acid exposure and development of Barrett's esophagus^[29], suggesting once again that surgical therapy for achalasia involves a very delicate balance between relief of outflow obstruction and destruction of the antireflux barrier.

Robot-assisted Heller operation has been performed with satisfactory outcomes and no mucosal perforation^[30]. Operative times were similar to those of standard laparoscopic operation after the first 30 cases in a multicenter study^[31]. No data from randomised clinical trials have been reported yet. At present time, despite the advantage of the three-dimensional view, elimination of tremor, and 360 degree of freedom of movement of the robotic arms, the role of this technology in the management of esophageal achalasia remains to be determined.

CONCLUSIONS

The management of achalasia has changed significantly over the past 15 years. Minimally invasive surgery has influenced the management of esophageal disease more than any other gastrointestinal disorder and in a manner similar as in the therapy of cholelithiasis. In several institutions around the world, the laparoscopic surgical myotomy has replaced pneumatic dilation as the initial therapy of choice for achalasia. Current evidence from the literature suggests that it is conceivable to extend the Heller myotomy on the gastric side for about 2 cm to encompass the oblique fibers without fear of inducing significant gastroesophageal reflux, provided that a minimal antero-lateral dissection of the phrenoesophageal membrane is performed and a Dor fundoplication is routinely added to the myotomy.

Abstract

Bleeding from gastric varices has been successfully treated by endoscopic modalities. Once the bleeding from the gastric varices is stabilized, endoscopic treatment and/or interventional radiology should be performed to eradicate varices completely. Partial splenic artery embolization is a supplemental treatment to prolong the obliteration of the veins feeding and/or draining the varices. The overall incidence of bleeding from gastric varices is lower than that from esophageal varices. No studies to date have definitively characterized the causal factors behind bleeding from gastric varices. The initial episodes of bleeding from esophageal varices or gastric varices without prior treatment may be at least partly triggered by a violation of the mucosal barrier overlying varices. This is especially likely in the case of varices of the fundus. In view of the high rate of hemostasis achieved among bleeding gastric varices, treatment should be administered in selective cases. Among untreated cases, steps to prevent gastric mucosal injury confer very important protection against gastric variceal bleeding.

INTRODUCTION

Bleeding from esophageal varices (EVs) or gastric varices (GVs) is a catastrophic complication of chronic liver disease. Bleeding from GV is generally thought to be more severe than bleeding from EVs^[1], but it occurs

less frequently^[2-4]. Though many recent developments have improved the outcome of treatments for GV, no consensus has been reached on the optimum treatment. In this paper we review the pathomorphology, hemodynamics, risk factors for bleeding, and treatments for GV. In the esophagogastric varices grading system of the Japan Society for Portal Hypertension^[5], the varices are evaluated based on color (white [Cw], and blue [Cb]), form (small and straight [F1], nodular [F2], and large or coiled [F3]), and the red color sign (RC0-3). GV are divided into cardiac varices (Lg-c), fundal varices (Lg-f), and varices involved both the cardia and fundus (Lg-cf). In this review, GV are divided into two categories and described accordingly: Lg-c (cardiac varices: CVs) and Lg-cf or Lg-f (fundal varices: FVs).

PATHOMORPHOLOGY OF GV

Arakawa *et al*^[6] reported that CVs are supplied by the left gastric vein (cardiac branch), a vessel which enters the stomach wall in the cardia at a point 2 to 3 cm from the esophagogastric junction and diverges into a profusion of branches running throughout the cardia. Some of these veins become markedly dilated, acquiring the features of varices. Most veins in the cardia diverge into parallel veins from the esophagogastric junction as the flow becomes hepatofugal. However, others will dilate, wind through the submucosa, and directly join EVs. Histologically, nearly the entire cross-section of the wall is the varix itself. The varices are covered by thinning layers of serosa and mucosa through which they can ultimately be seen.

The angio-architecture of a FV is quite different from that of a CV. Most FVs are supplied by the short gastric vein, though in some cases the blood is fed from the posterior or left gastric vein. Thus, the vascular anatomy of a FV is something like a splenorenal shunt running through the stomach wall. Bleeding from an EV most commonly occurs in the "critical area" 3 cm proximal to the esophagocardiac junction. Fine longitudinal veins in the lamina propria originate at the esophagocardiac junction and run in the lamina propria toward this critical area. EVs consist of multiple dilated veins. Those that rupture are usually located in the lamina propria^[7].

In the stomach, unlike its counterpart the esophagus a large winding vein runs through the submucosa without causing varicose veins to pile up. The ruptures in CVs occur in the submucosa, where they disrupt the muscularis mucosae and lamina propria mucosae. The mucosal layer covering a FV is somewhat thicker than that covering an EV. The difference between a CV and a FV lies in the

caliber of the varicose vein and the degree of vascular anastomosis. Most FVs are supplied *via* the short gastric vein, though some are fed by the posterior or left gastric vein. Anastomosis of FVs is generally uncommon. The varices within the wall penetrate the muscle layer and wind through the submucosal layer, where they displace and attenuate the muscularis mucosae and propria mucosae. The varicose veins protrude into the gastric lumen.

The lamina muscularis mucosa in the esophageal mucosa is loose, and the venous pressure in the submucosa is transmitted through communicating branches to the veins in the lamina propria. The lamina muscularis mucosa in the gastric mucosa, on the other hand, is tightly integrated with the lamina propria^[8].

The red color sign is an elevated red area which has proven to be important in portending variceal bleeding. The histological manifestation is a thinning of the epithelial layer. The North Italian Endoscopic Club for the Study and Treatment of Esophageal varices^[9] published a report establishing that the red color sign on EVs is predictive of bleeding. It remains unclear whether the endoscopic red color sign in the stomach has the same significance as the red color sign in the esophagus. In the latter case does it denote a thinning of the epithelial layer. The varix in the submucosa of the stomach is covered by the muscularis mucosae and propria mucosae. This generally confers an appearance different from that typical of the thinning epithelial layer of the esophagus^[6].

HEMODYNAMICS OF GVs

The portal hemodynamics of GVs should be evaluated in all patients with these varices to determine the most appropriate treatment. CVs are supplied by the left gastric vein (cardiac branch), a vessel which enters the stomach wall in the cardia at a point 2 to 3 cm from the esophagogastric junction and diverges into a profusion of branches running throughout the cardia. The main veins feeding the FVs are the left gastric vein (51%), posterior gastric vein (30%), and short gastric vein (69%). The principal drainage veins for the FVs are the gastro-renal shunt (87%) and gastric-inferior phrenic vein shunt (16%), though about 1% of FVs reported to communicate with neither^[10]. FVs are more frequently supplied by the short and posterior gastric veins than CVs. Concomitant collaterals such as EVs, para-esophageal veins, and para-umbilical veins are additionally observed in nearly 60% of FVs.

RISK FACTOR FOR BLEEDING FROM GVs

The incidence of variceal bleeding in patients who have never received treatment for EVs has been reported to range from 16 to 75.6%^[11,12]. The incidence of bleeding from GVs stands at 25%^[2], while cumulative bleeding rates from FVs at 1, 3, and 5 years have been estimated at 16%, 36%, and 44%, respectively^[13]. Thus, the overall incidence of bleeding from GVs is lower than that from EVs^[2]. In an earlier study on the natural course of GVs in 52 patients, our group treated bleeding from GVs in 4 patients over a mean follow-up period of 41 mo. Hemorrhage

was successfully halted in all 4 of these patients. The cumulative bleeding rates at 1, 3, and 5 years were 3.8%, 9.4%, and 9.4%, respectively. Three of the 4 patients were free of erosive gastritis and gastric ulcer at the time of entry into the study, though ulcers or erosions were found at the bleeding points of the GVs in all 4 when the varices ruptured. There were no significant differences in patient characteristics with ruptured *versus* non-ruptured GVs when the patients entered the study^[4].

The endoscopic risk factors for bleeding from EVs include the presence of raised red markings, cherry-red spots, blue color, and large size^[14]. The risk factors for bleeding from GVs have yet to be characterized. In another study, our group examined 70 cirrhotic patients with first-time bleeding from EVs or GVs without prior treatment^[15]. The red color sign was more common in EVs than in CVs or FVs ($P < 0.0001$). Mucosal erosion over the varices at the site of bleeding was more common in CVs ($P < 0.0005$) and FVs ($P < 0.0001$) than in EVs. An ulcer at the bleeding point was more common in CVs ($P < 0.01$) and FVs ($P < 0.0001$) than in EVs. Gastric ulcer was more common in CVs ($P < 0.05$) and FVs ($P < 0.001$) than in EVs. Erosive gastritis was more common in FVs ($P < 0.02$) than in EVs. The red color sign, a strong risk factor for the ruptures frequently encountered in EVs, was completely absent in the FVs. All of the CVs manifesting the red color sign communicated with EVs which manifested the red color sign themselves. This might have been due to the pronounced thickness of the mucosal layer overlying the FVs. FVs are usually two or three times larger than EVs and drain directly into an extremely dilated left gastric or posterior gastric vein^[16]. The volume of blood flow through a FV therefore usually exceeds that through an EV. Gastric ulcers that develop over GVs represent violation of the protective layer of gastric mucosa. Violation of the mucosal barrier overlying GVs place patients at risk of massive bleeding, especially when FVs are involved. Violations of this type could be an important precondition leading to variceal hemorrhage.

TREATMENT OF GVs

Treatment modalities for GVs include balloon tamponade, endoscopic treatment, embolization, and surgery.

Balloon tamponade

Balloon tamponade with the Sengstaken-Blakemore or the Linton-Nachlas tube is an emergent procedure for active hemorrhaging from GVs. The procedure is effective in the short term, but permanent hemostasis is obtained in fewer than 50% of cases^[17,18].

Endoscopic treatment

Two endoscopic treatment modalities are used for the treatment of esophagogastric varices: endoscopic injection sclerotherapy (EIS) and endoscopic variceal ligation (EVL)^[19-26]. EIS can be accomplished by either intravariceal EIS or extravariceal EIS^[21-23,26]. In the treatment of EVs, intravariceal EIS obliterates both the interconnecting perforating veins and the veins feeding the EVs. Most veins in the cardia become parallel veins from the

esophagogastric junction at the point at which the flow becomes hepatofugal. Nearby, however, a number of dilated winding cardiac veins run through the submucosa and directly join the EVs. This makes it possible to treat most CVs concomitantly with EVs when correcting the latter by intravariceal EIS.

EIS and EVL are both effective for the treatment of bleeding from EVs and CVs. EIS has been less successful in the treatment of bleeding from FVs, however. When used with 1% polidocanol, 5% ethanolamine oleate iopamidol (EOI), or thrombin for this purpose, EIS has a high rate of operative mortality^[27-29]. Fortunately, the rate of initial hemostasis has been significantly improved since the introduction of *N*-butyl-2-cyanoacrylate (Histoacryl) as the sclerosant in EIS^[30,31]. We should note, however, that bleeding from the GVs injection site and rebleeding from the rupture point have been reported in patients receiving EIS^[2,29].

While EVL is generally safe and effective for the treatment of CVs and FVs^[32], it sometimes causes deep or extensive ulcers and increases the risk of ensuing ulcer hemorrhage or secondary bleeding^[33]. FVs are usually twice or three times larger than EVs and are directly connected to an extremely dilated left gastric or posterior gastric vein^[16]. The volume of blood flow through an FV therefore usually exceeds that through an EV^[34]. A mucosal injury remains on the varices after endoscopic treatment. If the blood flow in the varices cannot be stopped completely, bleeding may recur at the site of this mucosal injury. This underlines the importance of ensuring the complete obliteration of the blood flow when treating FVs endoscopically. It may be dangerous to treat FVs by EVL alone.

GVs have also been treated by a combined endoscopic method using a detachable snare and simultaneous EIS and O-ring ligation^[35]. This technique is not yet in widespread use, however. Our group published a report on the treatment of ruptured GVs by EIS with Histoacryl followed by O-ring ligation (endoscopic scleroligation: EISL)^[24]. EISL was developed as a treatment modality for EVs to prevent bleeding from the injection site during needle removal^[21,36]. When treating GVs by EIS with Histoacryl, the immediate freezing of the Histoacryl around the needle hinders the removal of the needle after the injection. In some cases, bleeding from the GV injection site or rebleeding from the rupture point also occurs^[2,29]. Our group used the EISL procedure to treat ruptured GVs with punctures near the rupture points by simultaneous ligations of the injection sites and rupture points. EISL effectively stopped the bleeding from the GVs, enabled swift and easy needle removal, and successfully eliminated both bleeding from the injection site and rebleeding from the rupture point. An O-ring was placed at the point of the EISL injection with Histoacryl and left in position for a long time. As of this writing, EISL with Histoacryl is considered the most promising treatment for hemorrhaging GVs.

Interventional radiology (IVR)

The portal hemodynamics of GVs, the main feeding veins from the portal system, and the main drainage veins into

the vena cava should be determined in all patients with the GV. Angiography can determine the hemodynamics of the GV simultaneously during treatment by embolization.

Transportal obliteration: Two methods have been used to obliterate the feeding veins of GVs: percutaneous transhepatic obliteration and trans-ileocolic vein obliteration. The catheter is inserted directly into the portal vein, the portal circulation is visualized by portography, a balloon catheter is inserted selectively into the inflow site of the feeding veins for the varices, the balloon is inflated, and a test dose of a contrast medium is injected to determine the optimal volume of sclerosant fluid. Five percent EOI and/or 500 g/L glucose is injected to obliterate the feeding vein, then steel coils are used to complete the obliteration^[37]. The procedure is quite effective, though only transportal obliteration is sometimes incomplete, especially in FVs.

Balloon-occluded retrograde transvenous obliteration (BRTO): BRTO is a notable IVR procedure developed specially for the treatment of FVs. The technique is performed by inserting a balloon catheter into the outflow shunt (gastric-renal shunt or gastric-inferior phrenic vein shunt) *via* the femoral or internal jugular vein. Any existing collateral veins are treated with coils, absolute ethanol, or a small amount of 5% EOI. The balloon is inflated and a test dose of contrast medium is injected to determine the optimal volume of the sclerosant solution. Five percent EOI is slowly injected through the catheter until the shunt is filled with the sclerosant fluid. The catheter is removed after 24 h of balloon occlusion^[38-40]. A remarkably high rate of FV eradication or reduction in FV size can be expected if the BRTO procedure is technically successful. Indeed, long-term eradication of treated FVs without recurrence is achieved in most patients^[38,41]. Kanagawa *et al*^[38] confirmed eradication of FVs in 97% of 32 patients treated by this procedure, and no FVs recurred in any of those patients within an average follow-up period of 14 mo. In earlier reports, the eradication rate of FVs exceeded 89% and the recurrence rate was less than 7%. In light of the minimal invasiveness and high safety of the procedure, BRTO is applicable not only for elective cases, but also for emergency cases with FVs.

FV treatment by BRTO has two significant effects, namely, eradication of the FVs themselves and obliteration of the unified portal-systemic shunt. Thus, most of the benefits and adverse effects of BRTO are related to obliteration of the unified portal-systemic shunt. Benefits such as decreased blood ammonia levels and improved porto-systemic encephalopathy are sometimes observed. Possible adverse effects include transient ascites, increases of ascites, pleural effusion, and the appearance of EVs manifesting the red color sign. These adverse effects may be due to elevation of the portal pressure in reaction to the occlusion of the portal-systemic shunt.

Partial splenic artery embolization (PSE): The femoral artery approach is used for super-selective catheterization of the splenic artery. The catheter tip is placed as distally as possible in either the hilus of the spleen or in an intrasplenic artery. Embolization is achieved by injecting 2-mm cubes of gelatin sponge suspended in a saline solution containing antibiotics^[42,43]. PSE has been

performed to treat hypersplenism, EVs, GVs, portal hypertensive gastropathy, pancreatic carcinoma, and porto-systemic encephalopathy^[37,43-53]. Our group evaluated PSE in a long-term study of 26 patients with hepatic cirrhosis alongside 26 patients who did not undergo the PSE procedure^[42]. The red blood cell counts of the PSE (+) group increased significantly by 6 mo after the procedure and remained increased for up to 7.5 years. The platelet counts peaked only 2 wk after PSE and gradually fell thereafter. Even so, the platelet counts remained significantly higher than the pre-PSE level for up to 8 years. No significant changes were observed in the aspartate aminotransferase and alanine aminotransferase activities in serum during the follow-up. Cholinesterase activity was increased significantly by 6 mo after PSE and remained increased for more than 7 years. The serum albumin concentration increased significantly from 6 mo after PSE and the level remained significantly increased for 6 years. Survival did not differ between the PSE (+) and PSE (-) groups. PSE, a non-surgical treatment, can benefit patients with cirrhosis by improving the capacity of hepatic protein synthesis and conferring protection against hemorrhage due to thrombocytopenia.

Combination modalities with IVR: Our group also reported the long-term results of PSE as supplemental treatment for portal-systemic encephalopathy. We divided 25 patients with portal-systemic encephalopathy due to portal-systemic shunts into two groups, one treated by transportal obliteration and/or BRTO of portal-systemic shunt, followed by PSE (PSE (+) group; $n = 14$), the other treated by transportal obliteration and/or BRTO of the portal-systemic shunt without PSE (PSE (-) group; $n = 11$). The serum ammonia levels and grades of encephalopathy were lower in the PSE (+) group than in the PSE (-) group at 6, 9, 12, and 24 mo after treatment. Obliteration of the portal-systemic shunt raised the portal venous pressure in every case. As all of the patients had cirrhosis, the portal-systemic shunt drainage reduced portal hypertension and the obliteration of the portal-systemic shunt led to portal congestion and increased portal venous pressure. Our study thus confirmed the benefits of obliteration of the portal-systemic shunt by PSE in patients with portal-systemic encephalopathy^[43].

PSE is performed incrementally during the monitoring of the portal pressure in order to reduce the portal venous pressure to the level measured before obliteration of the veins feeding and/or draining the GVs^[22,42,43,49,54]. PSE is a supplemental modality to prolong the effect of obliteration of the veins feeding and/or draining the GVs.

Combination of endoscopic treatment and IVR

Treatment of GVs solely by endoscopic modalities or by IVR is occasionally incomplete. Our group previously reported that combined treatments with IVRs and endoscopic modalities had significant impacts on long-term rebleeding and retreatment rates in patients with EVs or GVs^[37,48,50,51]. In elective cases, complete GV treatment should be administered in order to prevent rebleeding with greater assurance.

Surgery

A number of surgical procedures have been developed to manage esophagogastric varices. These can be classified as shunting and nonshunting procedures. The goal of shunting is to reduce the incidence of variceal bleeding by lowering the pressure in the portal system using a portal-systemic shunt. While the standard portocaval shunt effectively reduces the incidence of variceal bleeding, impairment of the hepatic protein metabolism in patients undergoing the procedure frequently leads to the development of hepatic encephalopathy due to hyperammonemia^[55-57]. The distal splenorenal shunt (DSRS) was developed by Warren *et al.*^[58] in 1967 as a way to preserve portal blood flow through the liver while lowering variceal pressure. The hope, in developing this approach, was to prevent both bleeding and hyperammonemia. While DSRS effectively prevents rebleeding, patients who undergo DSRS still can develop hyperammonemia. Our group responded by designing a DSRS with a splenopancreatic disconnection and gastric transection, modifications to prevent the loss of shunt selectivity. This modified DSRS has been proved to reduce the incidence of postoperative hyperammonemia^[59].

As an alternative to shunting, Hassab^[60] and Sugiura *et al.*^[61] developed a method of gastro-esophageal decompression and splenectomy for the treatment of varices. The Hassab operation devascularizes the distal esophagus and proximal stomach. Splenectomy, selective vagotomy, and pyloroplasty can be performed concomitantly with the procedure. Sugiura *et al.*^[61] developed a method of esophageal transection for patients with GVs and EVs. Sugiura's method is performed concomitantly with the Hassab operation to divide and reanastomose the distal esophagus in order to disrupt the blood supply to the EVs. While both procedures may solve the problem of hepatic encephalopathy, varices are likely to recur earlier than they are in patients undergoing DSRS^[62].

Abstract

Microsatellite instability (MSI) is a prognostic factor and a marker of deficient mismatch repair (MMR) in colorectal adenocarcinomas (CRC). However, a proper application of this marker requires understanding the following: (1) The MSI concept: The PCR approach must amplify the correct locus and accurately identify the microsatellite pattern in the patient's normal tissue. MSI is demonstrated when the length of DNA sequences in a tumor differs from that of nontumor tissue. Any anomalous expansion or reduction of tandem repeats results in extra-bands normally located in the expected size range (100 bp, above or below the expected product), differ from the germline pattern by some multiple of the repeating unit, and must show appropriate stutter. (2) MSI mechanisms: MMR gene inactivation (by either mutation or protein down-regulation as frequently present in deep CRC compartments) leads to mutation accumulation in a cell with every cellular division, resulting in malignant transformation. These mechanisms can express tumor progression and result in a decreased prevalence of aneuploid cells and loss of the physiologic cell kinetic correlations in the deep CRC compartments. MSI molecular mechanisms are not necessarily independent from chromosomal instability and may coexist in a given CRC. (3) Because of intratumoural heterogeneity, at least two samples from each CRC should be screened, preferably from the superficial (tumor cells above the muscularis propria) and deep (tumor cells infiltrating the muscularis propria) CRC compartments to cover the topographic tumor heterogeneity. (4) Pathologists play a critical role in identifying microsatellite-unstable CRC, such as occur in young patients with synchronous or metachronous tumors or with tumors showing classic histologic features. In these cases, MSI testing and/or MMR immunohistochemistry are advisable, along with gene sequencing and genetic

INTRODUCTION

Colorectal carcinoma (CRC) is generally classified into three categories, based on increasing hereditary influence and cancer risk^[1,2]: sporadic CRC (approximately 60% of cases and comprises patients with no notable family history and, by definition, with no identifiable inherited gene mutation that accelerates cancer development), familial CRC (approximately 30% of cases and refers to patients who have at least one blood relative with CRC or an adenoma, but with no specific germline mutation or clear pattern of inheritance), and hereditary CRC syndromes (approximately 10% of cases, which result from inheritance of a single gene mutation in highly penetrant cancer susceptibility genes). Although the last group has the lowest frequency, it has elucidated molecular mechanisms of carcinogenesis applicable to sporadic CRC^[3].

The microsatellite profile of sporadic CRC is a prognostically useful marker^[4-7]. Microsatellites are repeating DNA sequences of unknown function that are found throughout the genome^[8]. Microsatellite instability (MSI) is demonstrated when the length of DNA sequences in tumor and nontumor tissues is different and MSI has been identified in a wide variety of human tumors, due to defects in one of the DNA mismatch repair (MMR) genes, especially *MLH1* or *MSH2*^[1,9]. However, MSI presence alone does not establish a diagnosis of hereditary non-polyposis colon cancer (HNPCC) because MSI has also been identified in 10%-30% of sporadic CRC. Certain histological features also correlate with the presence of

MSI CRC	Feature	MSS CRC
94%	Right side	34%
59%	Size > 6 cm	29%
53%	Poorly differentiated	7%
35%	Mucinous	7%
47%	Lymph infiltrates	10%

Figure 1 Microsatellite unstable CRCs are normally located proximal to the splenic flexure and reveal non-polypoid pattern. MSI can be demonstrated by fluorescence in-situ hybridization (FISH) or molecular techniques. Histopathologically, these tumors show solid growth, mucinous differentiation, prominent lymphocytic infiltrate, and no dirty necrosis^[10].

MSI in sporadic CRC (Figure 1)^[5,10-13], which can be key elements in the design of more effective therapeutic protocols^[12,13].

Both basic and clinical implications of MSI and MMR defects need to be considered in an appropriate context, which requires clarifying the definition of MSI, the biological consequences of tumor MSI, interference of intratumor heterogeneity on MSI detection, differences in clinical testing for MSI and for MMR defects, and MSI prognostic and therapeutic implications.

MSI DEFINITION AND CLINICAL TESTING FOR MSI

Any useful application of prognostic factors requires a reliable definition of the factor. Microsatellites belong to the family of highly polymorphic and repetitive non-coding DNA sequences that, although widely distributed in the human genome, are not uniformly spaced (underrepresented in subtelomeric chromosome regions). Microsatellites are useful molecular markers due to their

ubiquity, PCR typability (except for (dA)_n multimers, whose size polymorphisms are difficult to type), Mendelian co-dominant inheritance, and extreme polymorphism^[8], but their origin and function are not clear^[14]. They have been demonstrated to be very useful in cell lineage delineation, positional cloning, and several applications in forensic medicine^[15,16]. Microsatellite instability (MSI) is demonstrated when the lengths of DNA sequences in a tumor differ from those of nontumor tissue. MSI has been identified in a wide variety of human tumors.

Currently, tumor MSI analyses require molecular tests and the application of strict criteria. MSI can be defined as a change in any DNA sequence length due to either insertion or deletion of repeating units in a microsatellite within a tumor when compared to normal tissue^[17,18]. The tests must be run with appropriate controls (known positive and negative controls along with the patient's normal tissue)^[8,19], which are extremely important due to the non-exceptional presence of extra-bands. The PCR approach must amplify the correct locus and accurately identify the microsatellite pattern in the patient's normal tissue. Any anomalous expansion or reduction of tandem repeats due to MSI results in extra-bands. True extra-bands expressing tumor MSI are normally located in the expected size range (usually about 100 bp), are above or below the expected PCR product, differ from the germline pattern by some multiple of the repeating unit (e.g. delta 6 bases for dinucleotides), must show appropriate stutter (e.g. -2, -4 for dinucleotides), and are not present in the normal control. These tests should be carefully analyzed considering the following: (1) Sample homogeneity/heterogeneity can vary. Very small samples (even single cells) have been used in genetic analyses to avoid normal cell contamination. However, the lower the number of cells the higher the probability of technically-related abnormal results^[20], which can be partially resolved with appropriate methods. The high incidence of PCR artifacts using microdissected samples is related to the small concentration of target DNA, fixation induced changes of DNA, and conditions in the amplification of repetitive sequences (especially for those CG-rich sequences) favouring misannealing and hairpin formation. Appropriate modifications to avoid the above conditions will significantly improve the reproducibility of LOH and MSI tests in microdissected samples^[21]. (2) Appropriate controls are necessary for every step of the molecular tests to avoid false results. Sufficient levels of amplification with all markers should be obtained to detect low amounts of shifted microsatellites. (3) PCR bias against one allele (especially the larger one in a pair) can result in preferential amplification of the other allele (usually the smaller in a pair), which is the so-called artifactual allele dropout^[22,23]. An appropriate extraction method, providing DNA of quality^[24], and PCR designs including both long denaturation and extension in the first three cycles and 7-deazadGTP in the amplification mixture to improve the amplification of CG-rich DNA regions, will be reasonably helpful in avoiding that bias^[8,19,21,23,25]. (4) The number of polymorphic DNA regions agreed to at the NCI consensus conference includes a primary panel of at least 2 mononucleotide

Table 1 False negative in antigen positive neoplasms, comparative features of microsatellite unstable sporadic adenocarcinoma and hnpcc colon carcinomas

	MSI-H sporadic adenocarcinomas	HNPCC adenocarcinomas
Patient age	Older	Younger
Number of tumors	Single	Single/Multiple (synchronous/metachronic)
Colonic distribution	Right colon	Right colon
Histological clues	Poorly differentiated, medullary type Crohn-like inflammation	Poorly differentiated, medullary type Crohn-like inflammation
Mechanism of MMR deficiency	MLH1 promoter hypermethylation	Inactivating germline mutation of MMR proteins
Tumor prognosis	Better than MSI-L/ MSS sporadic adenoca	Better than MSI-L/ MSS sporadic adenoca

and 3 dinucleotide microsatellites, along with 19 alternate loci (both mono- and dinucleotides)^[26]. The choice of microsatellite markers is important in MSI testing, with the examination of mononucleotide repeats being sufficient for detection of MMR deficient tumors, whereas instability only in dinucleotides is characteristic of MSI-L/MMR-positive tumors^[27]. Depending on the number of abnormal loci from the total analyzed, the cases are classified into MSI-high ($\geq 30\%$ -40% of abnormal loci), MSI-low (< 30%-40% of abnormal loci), and MSS (no abnormal loci).

Which patients should be tested? The neoplasm histological features closely correlate with MSI and should be the key elements used to select sporadic CRC for MSI investigation^[5,10-13]. The sets of criteria for the clinical diagnosis of HNPCC appear under Clinical Testing for MMR defects. The implications of these analyses in sporadic and HNPCC carcinomas are compared in Table 1.

BIOLOGICAL CONSEQUENCES OF TUMOR MSI

Microsatellite-unstable CRC are biologically different and have a better survival rate than sporadic CRC when matched for cancer stage^[28-30]. The development of proximal and distal CRC involves partly different mechanisms associated with the MSI and the chromosomal instability (CIN) pathways^[31].

These two pathways are not always independent and some CRCs show a significant degree of overlap between these two mechanisms^[32]. In one study, 35% of CRC were microsatellite-unstable (21% MSI-low and 14% were MSI-high) and 51% of CRC had at least one LOH event, with the most frequent chromosomal losses observed on 18q (72.5%)^[32]. A significant degree of overlap between MSI and CIN pathways has been reported in that series: 6.5% of CRC with LOH were also MSI-high, and 23.3% of MSI-high CRC also had one or more LOH events. These data suggest that molecular mechanisms of genomic instability are not necessarily independent and may not

be fully defined by either the MSI or CIN pathways. In addition, a subgroup of CRCs showed no evidence of alterations in either of these two pathways of genomic instability (37.8% of microsatellite-stable CRCs had no LOH events identified)^[32], a situation similar to that reported in muscle-invasive transitional cell carcinomas of the bladder^[25].

MMR proteins normally identify and correct mismatched DNA sequences that can occur during DNA replication. An inactivating mutation in any of these genes leads to mutation accumulation in a cell with every cellular division, resulting in malignant transformation^[6,8,33-36]. Tumor progression in the deep compartments may be the result of MMR protein down-regulation, which would contribute to the following: (1) There is a decreased prevalence of aneuploid cell lines and K-RAS and B-RAF mutations detected in microsatellite-unstable CRC and in the deep compartments of sporadic CRC^[7,29,37,38]. Microsatellite-unstable CRCs tend to be diploid^[37,39], and to have lower DNA indices^[39]. Supporting these findings, the MMR protein down-regulation observed in the deep compartments of sporadic CRC has shown correlation with increased frequency of diploid DNA content^[40,41]. (2) Differential cell kinetics (proliferation and apoptosis) has been identified in superficial and deep compartments (above muscularis propria vs. muscularis propria) of sporadic CRC, which has demonstrated a close correlation with MMR protein expression (Figure 2)^[41,42]. Physiologic correlations between MMR protein expression and kinetic variables (mitotic figures, Ki-67 expression, ISEL index) were preserved in the superficial compartment only. In addition, G₂ + M phase fraction correlated with hMLH1 expression only in superficial compartments and hMSH2 expression only in deep compartments. Both the high cellular turnover and the maintained cell kinetic balance suggest that superficial compartments of sporadic CRC are expansile. In the deep compartments, the expression of MMR proteins is inefficient (not correlated with G₂ + M phase fraction) and is dissociated (only one gene product correlates with G₂ + M), which would eventually result in mutation accumulation and progression^[41].

INTRATUMOR HETEROGENEITY AND MICROSATELLITE ANALYSIS

Tumor cell heterogeneity is linked to genetic instability and biologic progression. This problem must be studied by including several tumor samples of sufficient size from each tumor.

The sample size is an important parameter. Microdissection techniques allow selectively picking up very small samples, which can show false cellular homogeneity, based on the loss of heterozygosity or allelic imbalance. If the tumor cell populations selected for molecular analysis are taken before they become a biologically prominent component (with kinetic or invasive advantages), the results might be confusing and clinically non-relevant. This would be a case of tumor microheterogeneity, which tends to give disparate results with meanings essentially unknown. Except for intraepithelial proliferation, all

microdissected cell samples provide target cell-rich samples with varying degrees of host cell contamination (including stromal, inflammatory, and endothelial cells). Therefore, multiple samples from the same case should always be studied and assays performed in duplicate before accepting the results as relevant.

The intratumor heterogeneity can result in discordant results for a given marker depending on the sample origin. The comparison of MMR protein expression and PCR-based MSI studies has revealed discordant results in 8% of right-sided sporadic CRC and complete concordance after performing further analyses on other tumor areas^[43]. Because of this intratumor heterogeneity, at least two samples from each CRC should be screened, although no systematic approach has been used to address this topic in sporadic CRC. Microsatellite analysis in muscle-invasive transitional cell carcinomas of the bladder have revealed topographic heterogeneity in 32% of cases, showing that the deep compartment had more microsatellite abnormalities (20%)^[25]. We have found significant differences between superficial (tumor cells above the muscularis propria) and the deep (tumor cells infiltrating the muscularis propria) compartments of sporadic CRC, the deep compartments showing MMR protein down-regulation and increased MSI^[41,44]. At least one-third of unstable tumors in deep compartments can be expected to be stable in superficial compartments. These differences can eventually result in the classification of a given tumor as MMS or MSI depending on the sample origin (superficial or deep).

CLINICAL TESTING FOR MMR DEFECTS

MSI results from the dysfunction of MMR proteins, which can be detected at genetic or protein levels. It is recommended that a CRC should be tested for MSI prior to gene testing, since this test is inexpensive and will help predict whether or not an individual has a germline MMR gene mutation^[45,46]. Since up to 5% of HNPCC tumors do not have MSI, negative MSI tests cannot completely rule out HNPCC. Conversely, a positive MSI test is not diagnostic of HNPCC because 15%-30% of unselected CRC have MSI (due to *MLH1* promoter methylation), whereas only 1%-6% of all CRC are associated with detectable HNPCC mutations. If the tumor is MSI-positive, further analyses for MMR defects are recommended.

Genetic testing for MMR defects

MMR defects are due to either inactivating point mutations spread throughout the genes, therefore needing full-length sequencing, or promoter hypermethylation (especially *MLH1* in sporadic CRC). HNPCC is an autosomal dominant disorder caused by germline MMR gene mutations, in particular in *MLH1*, *MSH2*, *MSH6*, and *PMS2*. No strong genotype-phenotype correlations have been observed to date, but *MSH2* mutations do appear to be associated with more extracolonic manifestations than *MLH1* mutations. *MSH6* mutations are more common in endometrial tumors and *PMS2* mutations are especially

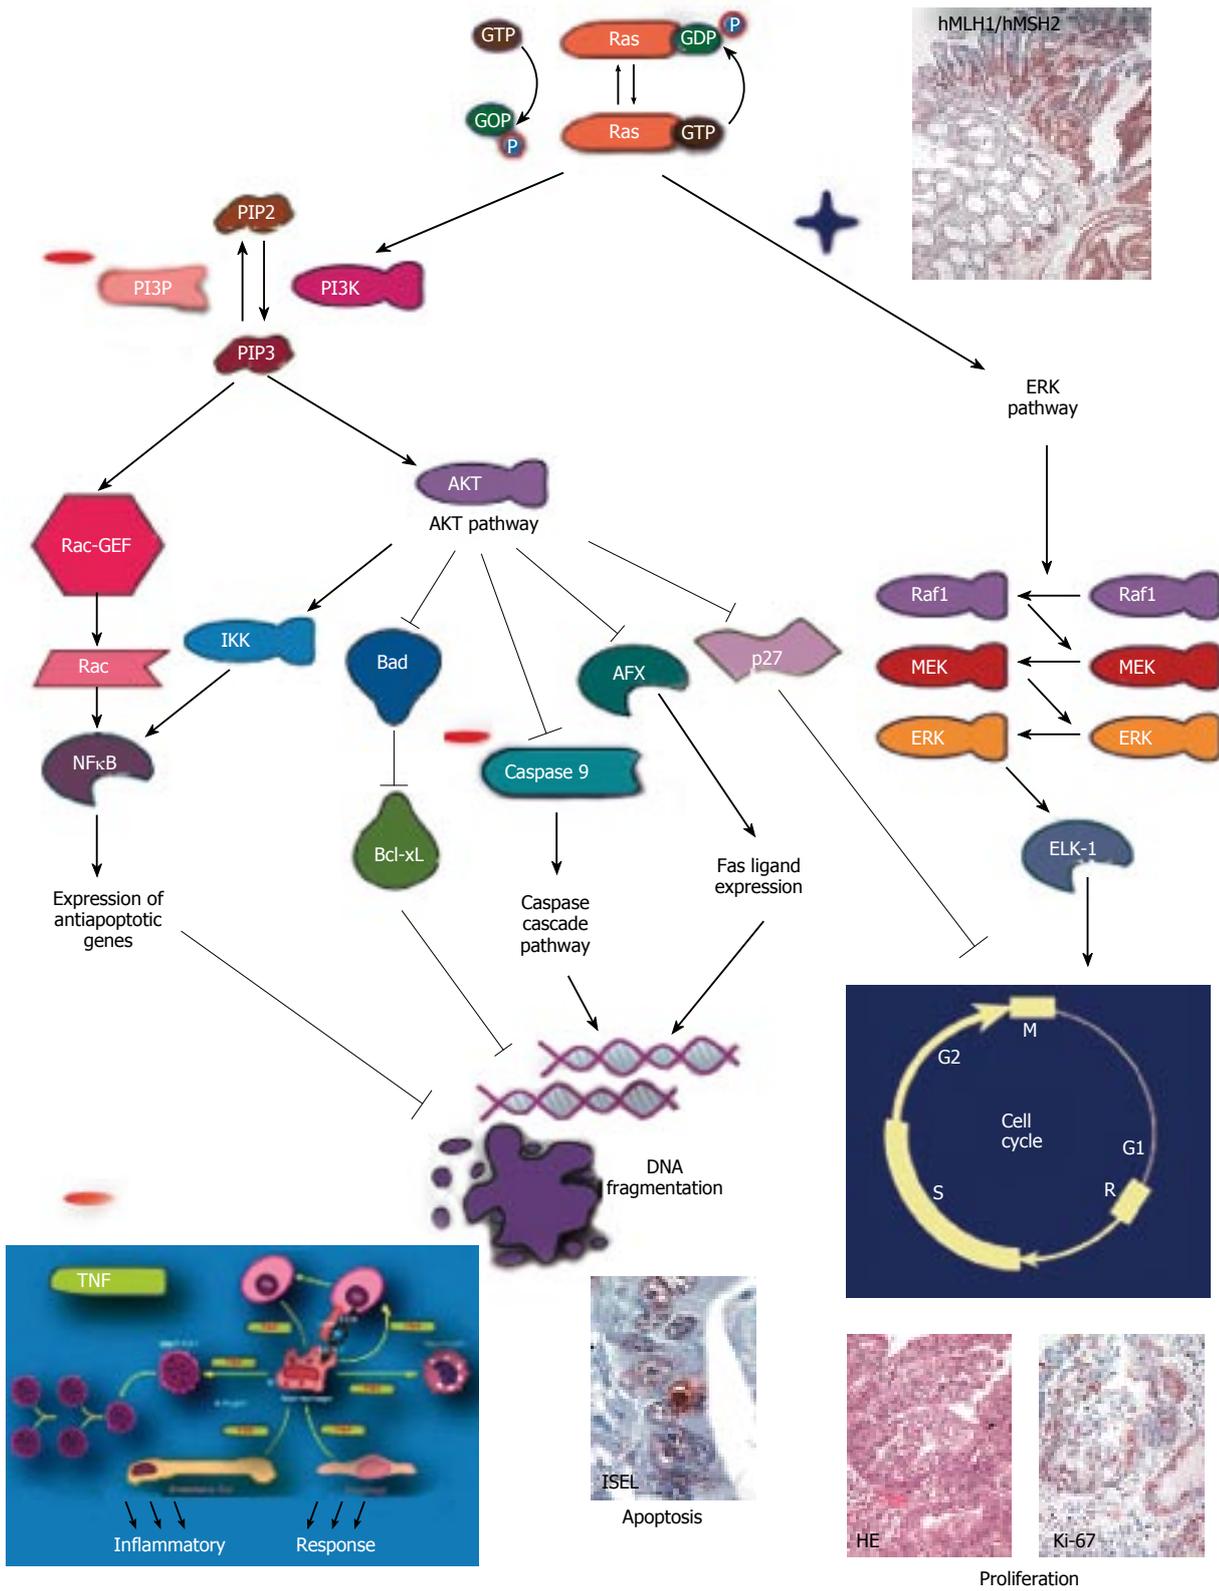

Figure 2 Molecular pathways contributing to the phenotype of microsatellite stable (MSS) CRC. MMR protein expression results in enhanced RAS signaling through ERK pathway (increased proliferation) and down-regulation of PI3P phosphatase, caspase 9 (apoptosis blockade), as well as TNF (decreased inflammation).

associated with Turcot's syndrome^[47]. The original HNPCC diagnostic criteria were established by the International Collaborative Group on Hereditary Nonpolyposis Colorectal Cancer (ICG-HNPCC) and are known as the Amsterdam criteria^[30], but only 50%-70% of HNPCC

families meeting these criteria have been found to have germline *MSH2* or *MLH1* mutations^[48]. The Amsterdam criteria were revised by the ICG-HNPCC in 1999 to include extracolonic cancers. The least stringent criteria are the Bethesda guidelines (more sensitive but less specific

than either the Amsterdam I or Amsterdam II criteria in identifying HNPCC families with pathogenic mutations), which aim to determine which patients should have MSI testing^[48]. These criteria propose MSI testing for:

Individuals with cancer in families that meet the Amsterdam criteria.

Individuals with two hereditary nonpolyposis colon cancer syndrome (HNPCC)-related cancers, including synchronous and metachronous colorectal cancers or associated extracolonic cancers (endometrial, ovarian, gastric, hepatobiliary, or small bowel cancer or transitional cell carcinoma of the renal pelvis or ureter).

Individuals with colorectal cancer and a first-degree relative with colorectal cancer and/or HNPCC-related extracolonic cancer and/or a colorectal adenoma: one of the cancers diagnosed by age 45, and the adenoma diagnosed by age 40.

Individuals with colorectal cancer or endometrial cancer diagnosed by age 45.

Individuals with right-sided colorectal cancer with an undifferentiated pattern (solid/cribriform) on histopathology diagnosed by age 45.

Individuals with signet-ring-cell-type colorectal cancer diagnosed by age 45.

Individuals with adenomas diagnosed by age 40.

The American Gastroenterological Association recommends genetic testing for HNPCC for individuals from families meeting Amsterdam criteria, as well as for individuals with two HNPCC-related cancers (for instance, colorectal and endometrial cancer) and individuals with colorectal cancer who have a first degree relative with an HNPCC-related cancer (or colorectal adenoma) where at least one was diagnosed before age 50^[45,46,49]. Ideally, testing should first be offered to a family member with colorectal or endometrial cancer^[26,45,48,49]. In some individuals, genetic analysis may be offered after prescreening for MSI in an HNPCC-related tumor specimen. Such prescreening should be offered where an HNPCC-related cancer is present in two individuals related by first-degree regardless of age of onset, or individuals with early-onset CRC regardless of family history. Genetic testing is indicated if MSI is present.

The majority (90%) of mutation-positive HNPCC cases are caused by mutations in *MLH1* or *MSH2*^[1,9]. For this reason, the mutation analysis is generally performed for these two genes, *MSH6* being included in the analysis more recently. Although several methods can be used to detect these mutations, direct exon-by-exon gene sequencing is considered the gold standard. The sequencing should analyze each of the protein-coding regions of the *MLH1* and *MSH2* genes in their entirety, with all positive results being repeated for confirmation. Once a specific mutation that has been found in a relative by previous genetic testing, a test examining only the specific portion of the gene containing the known familial mutation can be offered to all family members.

There are some benefits and limitations of genetic testing for HNPCC. Relying solely on family history can underestimate the risk of developing cancer in mutation carriers and over-estimate risk in those who do not

inherit the mutation. When an individual has a personal or family history that suggests the possibility of HNPCC, an important step is to determine whether the person is interested in genetic testing. Genetic testing for HNPCC can have important benefits for members of high-risk families who choose to be tested^[50]. Those who are found to carry deleterious mutations can take steps to reduce their cancer risk, especially through earlier and more intensive surveillance or consideration of prophylactic surgery. Individuals with HNPCC-related CRC can undergo surgical management designed to address the increased risk of a second cancer.

In families in whom a deleterious mutation has been found, those who are mutation-negative can be spared the need for more intensive surveillance and intervention^[50]. However, these individuals remain at risk for sporadic CRC and should be encouraged to adhere to age-appropriate general population screening guidelines.

Before consenting to genetic analysis, patients should also consider the limitations of testing. Currently, genetic testing cannot detect unusual mutations responsible for HNPCC, such as those occurring in MMR genes other than *MLH1* and *MSH2*. Therefore, a negative result in an individual who does not have a family member with a documented mutation must be interpreted cautiously. The test may also detect a variant of uncertain significance whose effect on cancer risk has not yet been established. In such situations, testing other family members for the specific variant to determine if it is associated with cancer may provide clarification of the significance^[50].

Immunohistochemical testing for MMR defects

At the protein level, hMLH1/hMSH2 immunohistochemistry has a role in detecting MMR defects^[51-53], with data suggesting that the effectiveness of immunohistochemical screening of the MMR proteins would be similar to that of the more complex strategy of microsatellite genotyping^[54]. This technique can guide which gene to sequence and can help differentiating sporadic from hereditary mutations: hMSH2 loss is likely to be HNPCC, whereas hMLH1 loss could be HNPCC or sporadic CRC (*MLH1* promoter methylation). MMR proteins heterodimerize to function; the hMSH2 loss almost always accompanies hMSH6 loss and when hMLH1 is lost, generally so is hPMS2^[55-57]. In addition, immunohistochemistry can miss functional loss; i.e. presence of the protein with antigen positivity in the absence of function. Several antibodies have been used for these analyses, but the most widely used are hMSH2 (clone FE11, Oncogene Research), hMLH1 (clones G168 728 and G168-15, BD Pharmingen), hMSH6 (clone 44, BD Transduction Laboratories), and hPMS2 (clone A16-4, BD Pharmingen, and polyclonal C terminus, Santa Cruz Biotechnology).

MMR immunohistochemical studies are based on a complete absence of at least one MMR protein^[5,12,37,51-53,58-61]. But these studies do not consider the immunostaining topographic heterogeneity^[41]. Since the MMR proteins function as heterodimers, it could be advocated to validate the immunohistochemical results of hMSH2/hMSH6 and

hMLH1/hPMS2. More studies are required to clarify the influence of this predictable tumor heterogeneity to select the appropriate sample for immunohistochemical and/or MSI analyses.

PROGNOSTIC AND THERAPEUTIC IMPLICATIONS OF MSI

The CRC microsatellite profile provides useful prognostic information^[6,26,39], showing the patients with microsatellite-unstable neoplasms have a better overall survival rate and a modified response to conventional chemotherapy^[62-67]. MSI also helps in predicting the treatment response of CRC^[63,64,68], and could modify the chemotherapy protocols offered to the patients in the future^[64], but these results should be applied with caution before this predictive tool is verified^[64].

Molecular markers as predictive factors in treatment decisions have been developed in the last few years. The initial studies in sporadic CRC showed that the retention of heterozygosity at one or more 17p or 18q alleles in microsatellite-stable CRCs and mutation of the gene for the type II receptor for TGF- β 1 in CRCs with high levels of microsatellite instability correlated with a favorable outcome after adjuvant chemotherapy with fluorouracil-based regimens, especially for stage III CRC^[63,68]. However, most recent studies have revealed that fluorouracil-based adjuvant chemotherapy benefited patients with stage II or stage III CRC with MSS tumors or tumors exhibiting low-frequency MSI but not those with CRCs exhibiting high-frequency MSI^[64]. The reasons for these responses must be related to the distinctive cell kinetics associated with MMR down-regulation (significantly increased apoptosis and decreased proliferation), which can certainly contribute to tumor cell resistance to conventional chemotherapy^[40,41]. The topographic heterogeneity of sporadic CRC is a key element to explain the discrepant results reported^[41]. This point has not been systematically addressed yet, but a homogeneous selection of the samples from the same topography must be considered in the molecular test design^[25].

CONCLUSIONS

Many CRC show MSI, for which confirmatory analyses are warranted because of prognostic and therapeutic implications. Pathologists play a critical role in identifying microsatellite-unstable CRC, such as occur in young patients with synchronous or metachronous tumors and tumors with classic histologic features. In these cases, MSI testing and/or MMR immunohistochemistry are advisable, along with sequencing and genetic counseling if appropriate. Microsatellite analysis is an excellent functional and prognostic test, whereas MMR immunohistochemistry can guide gene sequencing but can result in false negatives (false negative in antigen positive neoplasms, especially cases with MLH1 promoter methylation). Direct exon-by-exon gene sequencing is considered the gold standard and should be used to analyze each of the protein-coding regions of the *MLH1* and *MSH2* genes in their

entirety, although this technique will miss *MLH1* gene inactivation by promoter methylation. Finally, the selection of samples for molecular tests must be carefully designed considering predictable heterogeneity, such as topographic heterogeneity, to avoid misinterpretations.

Abstract

The prokaryotic and eukaryotic cells of the colon exist in a highly complex, but harmonious relationship. Disturbances in this remarkable symbiosis can result in the development of inflammatory bowel diseases (IBD). Although the etiology of IBD is not entirely understood, it is known that the chronic inflammation of Crohn's disease, ulcerative colitis and chronic pouchitis are a result of an overly aggressive immune response to the commensal intestinal flora in genetically susceptible hosts. Recent studies have enhanced our ability to understand the interaction between the host and its intestinal microflora and the role the microflora plays in maintaining intestinal homeostasis. As we begin to understand the benefits conferred to the intestine by the microflora, the notion of modifying the composition of the bacterial load to improve human health has arisen. A significant body of research now exists investigating the role of probiotics and prebiotics in ameliorating chronic intestinal inflammation. This article will begin with an overview of the role of the commensal microflora in maintaining mucosal immune homeostasis, and how a dysregulated immune response to the intestinal microflora results in IBD. This will be followed by a summary of the use of probiotics and prebiotics in experimental and human IBD.

INTRODUCTION

At birth, the gastrointestinal tract is a sterile environment. Initial exposure of the gut to microbes occurs during the birthing process from the maternal fecal and vaginal flora. Within a few months after birth, a relatively stable microbial population is established^[1]. This abundant, diverse and dynamic intestinal microflora normally lives in a complex, symbiotic relationship with the eukaryotic cells of the mucosa. About 100 trillion bacterial cells benefit from the constant nutrient flow, stable temperature and niches for various metabolic requirements provided by the intestinal environment. Likewise, the host benefits from the ability of the intestinal microflora to synthesize vitamin K, exert trophic effects on intestinal epithelial cells, salvage energy from unabsorbed food by producing short-chain fatty acids, inhibit the growth of pathogens, sustain intestinal barrier integrity and maintain mucosal immune homeostasis. Studies from germ-free animals reveal that the absence of resident intestinal microflora results in significant alterations in intestinal structure and function, including slender villi, shallow crypts, low leukocyte count^[2,3], a decrease in the number and density of Peyer's patches^[4] and decreased stimulation of migrating motor complexes^[5].

In their co-evolution with bacteria, vertebrates develop pattern-recognition receptors, which are activated by specific molecular patterns unique to bacteria, fungi and viruses that are absent in eukaryotes (lipopolysaccharides, peptidoglycan, ssRNA, muramyl dipeptide, flagellins, *etc*). These include the Toll-like receptors (TLRs) and nucleotide oligomerization domains (NODs). TLRs and NODs are critical for the initiation of innate immune defense responses. Activation of their signaling cascades usually results in the production of pro-inflammatory cytokines. TLR signaling also provides a link between innate and adaptive immunity, as TLR signaling results in the maturation of dendritic cells, which activate adaptive immune responses^[6]. Although stimulation of these receptors in most parts of the immune system results in production of inflammatory cytokines, these ligands are not only tolerated by the gut mucosal immune system, but also essential for adaptation to intestinal bacteria and maintenance of homeostasis^[7]. The tolerance to the intestinal microflora is not completely understood, but several aspects of commensal physiology have been defined which contribute to their inability to activate the immune system. Some commensal bacteria can modify

TLR ligands, resulting in a hypoactive immune response. For example, the endotoxic portion of LPS is pentacyclated in many *Bacteroides* species, and has minimal toxicity^[8]. An important feature of commensal bacteria is their inability to penetrate the intestinal epithelial barrier. If some of these organisms do penetrate, they are usually rapidly phagocytosed by the innate mucosal immune system. Indeed, in a healthy host, the systemic immune system appears to be ignorant of the intestinal microflora^[9]. Maintaining tolerance to these intestinal bacteria is a remarkable accomplishment achieved by the mucosal immune system, and disturbances in this bacterial-epithelial homeostasis result in considerable deleterious effects on the host.

Role of the commensal flora in IBD

Although many studies have investigated the possibility of a single infectious agent causing Crohn's disease and ulcerative colitis, also called chronic inflammatory bowel disease (IBD), none has yet been discovered. The intestinal bacteria are now believed to be involved in the initiation and perpetuation of IBD. The prevailing theory explaining the development of IBD is that the adaptive immune system is hyper-responsive to the commensal intestinal microflora in genetically susceptible individuals^[10]. This hypothesis is supported by several observations: most inflammation occurs in areas with the highest density of intestinal bacteria, broad spectrum antibiotics improve chronic intestinal inflammation, and surgical diversion of the fecal stream can prevent recurrence of Crohn's disease. Most importantly, despite differences in the pathogenesis of chronic intestinal inflammation, a consistent feature of many animal models of IBD (such as IL-10 knockout mice and HLA-B27 transgenic rats) is the failure to develop chronic intestinal inflammation when these animals are raised in germ-free conditions^[11,12]. Dysbiosis is also observed in IBD patients. Adherent and intramucosal bacteria, particularly *Bacteroides spp*, *Escherichia coli* (*E. coli*) and *Enterobacterium spp* are more abundant in patients with Crohn's disease (CD) than in controls^[13,14] (Figure 1). Bacterial overgrowth and dysbiosis are also associated with the development of chronic pouchitis, the inflammation of the ileal reservoir created after ileo-anal anastomosis following colectomy in ulcerative colitis (UC) patients^[15]. In addition, several selected commensal bacterial species can induce and perpetuate colitis in genetically susceptible rodent models of chronic intestinal inflammation^[16,17] (Figure 1).

Other immune dysfunctions in IBD include aberrant secretion of pro-inflammatory cytokines and chemokines by intestinal epithelial cells and mucosal immune cells^[18-20], altered TLR4 signaling^[21], defective antigen presenting cell function^[22] and lack of T-cell apoptosis^[23]. It is now clear that ignorance of the systemic immune system to commensal intestinal microflora is lost in IBD patients, as shown by enhanced and persistent cell-mediated and humoral immune responses to these bacteria^[24].

At least 7 genetic loci conferring susceptibility to CD, ulcerative colitis (UC) or both, have been identified^[25]. Interestingly, such susceptibility genes associated with CD

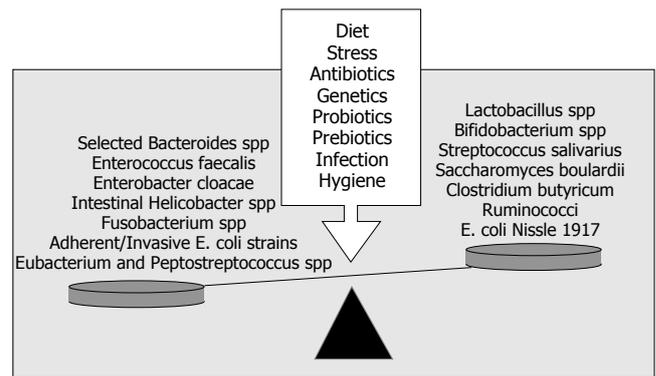

Figure 1 Microbial balance and dysbiosis. The pathogenic immune responses present in IBD are triggered by the presence of luminal bacteria. The balance of beneficial vs aggressive intestinal microbes is responsible for either mucosal homeostasis or chronic inflammation. A number of environmental and genetic factors influence the balance of beneficial vs aggressive microbes. Adapted from^[63].

involve polymorphisms of the NOD2 gene^[26] (the pattern recognition receptor for muramyl dipeptide) which can result in hampered innate immune functions by impairment of TLR function^[27], defective clearance of invasive bacteria by macrophages^[28], and decreased production of defensins^[29].

The recognition of the compelling association between intestinal microflora and the development of IBD has led to an abundance of studies investigating the therapeutic potential of altering luminal bacteria using probiotics and/or prebiotics.

Probiotics, prebiotics and synbiotics

Probiotics are defined as living organisms in food and dietary supplements which, upon ingestion, improve the health of the host beyond their inherent basic nutrition^[30]. Probiotics are typically lactic acid bacteria selected from the gut flora, and are able to survive stomach acid and bile, maintain viability throughout extended periods of storage and are safe for human consumption. Other species have also shown some beneficial effects, such as *E. coli* Nissle 1917 and *Saccharomyces boulardii* (Figure 1). Probiotic bacteria have verifiable beneficial properties, including the ability to improve epithelial barrier function, modulate the mucosal immune system, and alter the intestinal flora.

Prebiotics are non-digestible dietary carbohydrates, e.g., lactosucrose, fructo- and galacto-oligosaccharides, inulin, psyllium, bran, germinated barley (Figure 2), which stimulate the growth and metabolism of endogenous enteric protective bacteria upon consumption. Beneficial effects of prebiotics are also associated with changes in colonic short-chain fatty acids (SCFA) due to fermentation by colonic bacteria^[31]. Synbiotics are combinations of probiotics and prebiotics, and are also an emerging therapeutic modality. Restoration of normal microflora using probiotics, prebiotics or synbiotics has been investigated in numerous gastrointestinal and other disease states, including infectious diarrhea, *H. pylori* infection, irritable bowel syndrome, colorectal cancer, lactase deficiency, pancreatitis, atopy, and IBD.

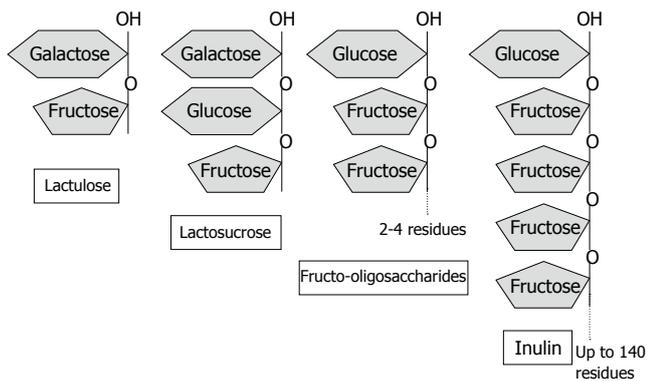

Figure 2 Basic structures of various prebiotic substances. Structurally, prebiotics are a mixture of polymers and oligomers comprising branching chains of fructose units.

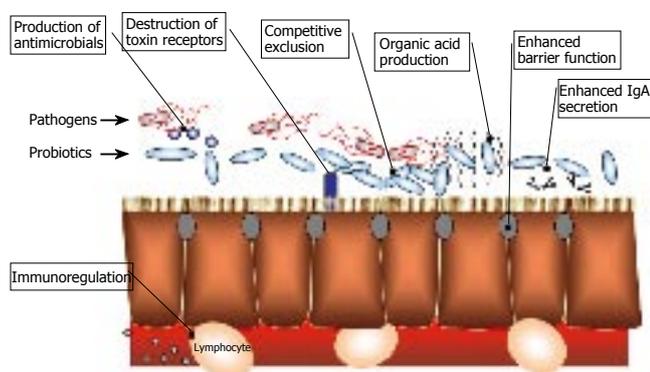

Figure 3 Mechanisms of probiotic activity.

Protective mechanisms of probiotics by ameliorating chronic intestinal inflammation

Probiotic bacteria have beneficial effects on the intestinal epithelia both directly and indirectly, including enhanced barrier function, modulation of the mucosal immune system, production of antimicrobials, and alteration of the intestinal microflora (Figure 3).

Alteration of the mucosal immune system. The presence of probiotics has been shown to result in several modifications in the mucosal immune response, including augmented antibody production^[32,33], increased phagocyte^[34] and natural killer cell activity^[35-38], modulation of the nuclear factor kappa-B (NFκB) pathway^[39-41], and induction of T cell apoptosis^[42]. Generally, probiotics increase the production of intestinal anti-inflammatory cytokines (such as IL-10 and TGF-β), while reducing the production of pro-inflammatory cytokines (e.g., TNF-α, interferon-γ, IL-8)^[43-46]. Several probiotic bacteria, including *B. breve*, *Streptococcus thermophilus*, *B. bifidum* and *Ruminococcus gnavus* have been shown to secrete metabolites that reduce LPS-induced TNF-α secretion^[47]. *L. reuteri* reduces TNF-α and *Salmonella typhimurium* induces IL-8 secretion *in vitro*, by inhibiting nuclear translocation of NFκB and preventing the degradation of IκB^[48]. Administration of the probiotic cocktail VSL#3 (consisting of *L. acidophilus*, *L. bulgaricus*, *L. casei*, *L. plantarum*, *B. breve*, *B. infantis*, *B. longum*, *S. thermophilus*) to IL-10 deficient mice results in

colitis reduction and a concomitant reduction in mucosal secretion of TNF-α and interferon-γ^[49]. *E. coli* Nissle 1917 is able to down-regulate the expansion of newly recruited T-cells into the mucosa and limit chronic intestinal inflammation^[50]. In SAMP1/Yit mice, *Lactobacillus casei* strain Shirota inhibits IL-6 production in LPS-stimulated large intestinal lamina propria mononuclear cells and down-regulates nuclear translocation of NFκB^[51]. Patients with a recent ileo-anal pouch anastomosis who responded to probiotic therapy have reduced mRNA levels of IL-1β, IL-8 and IFN-γ, and fewer polymorphonuclear cells compared with patients who receive placebo^[52]. Probiotic treatment has also been shown to reduce IFN-γ and IL1-α expression and decrease inducible-nitric oxide synthase and gelatinase activities in pouch biopsy samples from patients with pouchitis^[53]. In mucosal explants of ileal specimens from patients with Crohn's disease, probiotics reduced TNF-α release and the number of CD4 cells^[54]. In addition to live probiotics, components of probiotic bacteria can also exert effects on the mucosal immune system. For example, genomic DNA isolated from VSL#3 inhibits TNF-α-induced IL-8 secretion, mitogen-activated protein kinase activation and NFκB activation^[41] in HT-29 cells.

Improved barrier function. Various probiotic bacteria can enhance intestinal epithelial barrier function. For example, oral administration of VSL#3 results in normalization of impaired colonic barrier function and restoration of intestinal epithelial integrity in IL-10 deficient mice and enhancement of epithelial resistance in T-84 cells^[49]. Barrier function was enhanced not only by live bacteria, but also by a proteinaceous secreted product of VSL#3^[49]. Several strains of lactobacilli are also capable of up-regulating intestinal MUC3 mRNA expression, thereby improving barrier function by increasing the mucus layer^[55,56]. *Lactobacillus* GG (*L. GG*) improves barrier function by inhibiting apoptosis of intestinal epithelial cells^[57]. *S. thermophilus* and *L. acidophilus* have been shown to enhance phosphorylation of actinin and occludin in the tight junction, thereby preventing the invasion of enteroinvasive *E. coli* into human intestinal epithelial cells^[58].

Alteration of the intestinal flora. Probiotics suppress the growth and invasion of pathogens in several ways. They competitively exclude pathogenic bacteria by occupying the limited physical space in the mucus layer and on epithelial cells. They also engage pattern-recognition receptors and consume substrate otherwise available to other (pathogenic) microbes. In addition, probiotics render their microenvironment inauspicious for pathogens by secreting antimicrobial substances such as hydrogen peroxide, organic acids, and bacteriocins. For example, both *in vitro* and *in vivo* experiments demonstrate that *B. infantis* suppresses the growth of *Bacteroides vulgatus*^[59]. VSL#3 has been shown to inhibit *Salmonella dublin* invasion into T-84 cells^[49]. Patients with pouchitis treated with VSL#3 have been demonstrated to have increased bacterial diversity in the pouch, and decreased fungal diversity^[60].

Probiotics may also alter the intestinal microflora by changing the fatty acid profile in the colon. VSL#3

Table 1 Clinical studies of probiotics in IBD

Author	Design	Group (Dose/d) (n)		Results
		Probiotic	Comparator	
Induction of remission of ulcerative colitis				
Kato 2004 ^[87]	DB, R, C	Bifidobacterium fermented milk (100 mL) (10)	Placebo (10)	Reduced UCDAI ($P < 0.05$)
Rembacken 1999 ^[85]	DB, R, C	<i>E. coli</i> Nissle 1917 (1×10^{11} cfu) (57)	Mesalamine (59)	As effective as mesalamine at attaining remission
Bibiloni 2005 ^[88]	Open-label	VSL#3 (3.6×10^9 cfu) (32)	None	77% remission or response rate
Ishikawa 2003 ^[86]	R, C	Lactobacillus and Bifidobacterium-fermented milk (100 mL) (11)	Placebo (10)	Reduced exacerbation of symptoms ($P < 0.01$)
Borody 2003 ^[90]	Case reports	Fecal enema (6)	None	100% remission
Maintenance of remission of ulcerative colitis				
Kruis 2004 ^[82]	DB, R, C	<i>E. coli</i> Nissle 1917 ($2.5\text{-}25 \times 10^9$ cfu) (162)	Mesalamine (165)	As effective as mesalamine at maintaining remission ($P = 0.003$)
Zocco 2006 ^[83]	Open-label	Lactobacillus GG (1.8×10^{10} cfu) (65)	Mesalamine (60) Mesalamine + LGG (62)	No difference in relapse rates at 12 mo. LGG more effective than mesalamine at prolonging relapse-free time ($P < 0.05$)
Shanahan 2006 ^[117]	DB, R, C	Lactobacillus salivarius or Bifidobacterium infantus (1×10^9 cfu) (52/group)	Placebo (53)	No improvement of time to relapse
Venturi 1999 ^[84]	Open-label	VSL#3 (1×10^{12} cfu) (20)	None	75% maintained clinical and endoscopic remission
Induction of remission of Crohn's disease				
Schultz 2004 ^[97]	DB, R, C	Lactobacillus GG (2×10^9 cfu) (5)	Placebo (6)	No difference in remission rates
McCarthy 2001 ^[118]	Open-label	Lactobacillus salivarius (1×10^{10} cfu) (25)	None	Reduced disease activity compared with baseline
Gupta 2000 ^[119]	Open-label	Lactobacillus GG (2×10^{10} cfu) (4)	None	Improvement in CDAI scores compared with baseline ($P < 0.05$)
Maintenance of remission of Crohn's disease				
Prantera 2002 ^[95]	DB, R, C	Lactobacillus GG (1.2×10^{10} cfu) (23)	Placebo (22)	No significant difference in remission
Campieri 2000 ^[120]	R, C	VSL#3 (3×10^{11} cfu) (20)	Mesalamine (20)	Equivalent to mesalamine in preventing recurrence
Marteau 2006 ^[94]	DB, R, C	Lactobacillus johnsonii LA1 (2×10^9 cfu) (48)	Placebo (50)	No difference in endoscopic recurrence
Malchow 1997 ^[93]	DB, R, C	<i>E. coli</i> Nissle 1917 (5×10^{10} cfu) (16)	Placebo (12)	No difference in remission rates
Bousvaros 2005 ^[96]	DB, R, C	Lactobacillus GG (2×10^{10} cfu) (39)	Placebo (36)	No difference in time to relapse
Guslandi 2000 ^[91]	R, C 6 mo	Saccharomyces boulardii (1 g/d) + mesalamine (2g) (16)	Mesalamine (16)	Significant prolongation of remission ($P < 0.05$)
Induction of remission of pouchitis				
Kuisma 2003 ^[80]	DB, R, C	Lactobacillus GG (1×10^{10} cfu) (10)	Placebo (10)	No difference in PDAI
Laake 2004 ^[121]	Open-label	Lactobacillus acidophilus and Bifidobacterium lactis-fermented milk (500 mL) (51)	None	Improved PDAI, no difference in histology
Gionchetti 2000 ^[78]	DB, R, C	VSL#3 (6 g) (20)	Placebo (20)	Increased remission time ($P < 0.001$)
Mimura 2004 ^[122]	DB, R, C	VSL#3 (6 g) (20)	Placebo (16)	Increased remission time ($P < 0.0001$)
Gionchetti 2003 ^[79]	DB, R, C	VSL#3 (1×10^{11}) (20)	Placebo (20)	Increased remission time ($P < 0.05$)

DB: Double-blind; R: Randomized; C: Controlled; UCDAI: Ulcerative colitis disease activity index; CDAI: Crohn's disease activity index; LGG: Lactobacillus GG; PDAI: Pouchitis disease activity index.

probiotic strains are also capable of converting linoleic acid to conjugated linoleic acid, a fatty acid with anti-inflammatory and anti-carcinogenic properties^[61].

Use of probiotics in inflammatory bowel disease treatment

Results from various animal studies and clinical trials using probiotics to treat intestinal inflammation have generated considerable excitement. Data are now emerging which suggest that probiotics are capable of preventing relapse of chronic intestinal inflammation. Some probiotics can even treat mild to moderately active IBD^[62,63]. However,

at present there is a relative lack of rigorously designed, randomized, placebo-controlled trials. Level 1 evidence is only available for the use of probiotics in post-operative chronic pouchitis while level 2 and 3 evidence supports the use of probiotics in treatment of CD and UC^[62] (Table 1).

Experimental colitis

More than 20 animal models of IBD are available^[64] and have been widely used to study the efficacy and mechanisms of probiotics in ameliorating inflammation in order to provide support for human clinical trials. In

IL-10 knockout mice, *L. plantarum* 299v^[65], *L. reuteri*^[46], *L. salivarius* subspecies *salivarius* 433118, *B. infantis* 35624^[66], *L. salivarius* subspecies *salivarius* UCC118^[67] and VSL#3^[49] have all been shown to successfully attenuate intestinal inflammation. *L. GG* prevents recurrent colitis in HLA-B27 transgenic rats after antibiotic treatment, whereas *L. plantarum* has no effect^[68]. Both VSL#3 and *L. GG* significantly ameliorate sulfhydryl-blocker iodoacetamide-induced colitis in rats, whereas they have no effect on dinitrobenzene sulfonic acid-induced colitis^[69]. Improved inflammation in 2,4,6-trinitrobenzene sulfonic acid (TNBS)-induced colitis has also been demonstrated after oral administration of *L. salivarius* ssp. *salivarius* CECT5713 and *L. plantarum* NCIMB8826^[70,71]. Dextran sulphate sodium (DSS)-induced colitis in mice is ameliorated by soluble bacterial antigens extracted from *E. coli* (strain *Laves*) or by *Bifidobacterium* strains *breve*, *catenulatum*, and *longum*^[72,73]. Daily administration of live but not heat-killed auto-aggregating *L. crispatus* reduces the severity of DSS-colitis in mice^[74]. *L. reuteri* significantly reduces the colonic inflammation caused by both acetic acid and methotrexate in rats^[75,76]. Interestingly, DNA from VSL#3 has been reported to reduce colonic inflammation, thus improving intestinal barrier function in IL-10 KO mice and DSS-induced colitis^[41,77].

Chronic pouchitis

Probiotics can maintain antibiotic-induced remission in patients with chronic pouchitis after colectomy for refractory UC. Gionchetti *et al.*^[78] have completed placebo-controlled trials using the probiotic cocktail VSL#3 in patients with chronic relapsing pouchitis, showing that the remission rate after 1 year is 90% in the group treated with VSL#3 versus 60% in the placebo group. Another study by the same group also showed that VSL#3 is also capable of preventing the development of chronic pouchitis during the first year after pouch surgery for UC^[79]. Ten percent of patients who took VSL#3 developed pouchitis, compared with 40% of the placebo group. A double-blinded, prospective, randomized placebo-controlled trial was carried out in 20 patients treated with *L. GG* versus placebo for 3-mo^[80]. In contrast to the study with the probiotic cocktail VSL#3, no significant differences were observed in chronic pouchitis disease activity in *L. GG*-treated patients despite an increased total fecal lactobacilli: anaerobe ratio, illustrating the inefficacy of *L. GG* for this condition.

Ulcerative colitis

Numerous studies have investigated the use of probiotics for maintenance of remission of UC in humans. A small study investigating the use of non-pathogenic *E. coli* Nissle 1917 versus low-dose mesalamine showed that it can maintain remission of quiescent UC, with a relapse rate of 16%-67% in those treated with *E. coli* versus 11%-73% in the mesalamine group^[81]. In a double-blind, randomized trial involving 327 patients, Kruis *et al.*^[82] compared the effectiveness of an oral preparation of *E. coli* Nissle 1917 with mesalamine for maintaining remission of UC, and found that at the end of the 12-mo study, there is no significant difference between the two study groups, with

relapses occurring in 36.4% of the *E. coli* Nissle 1917 group and 33.9% of the mesalamine group (significant equivalence, $P = 0.003$). Recently, Zocco *et al.*^[83] investigated the efficacy of *L. GG* in maintaining remission of UC and found that there is no difference in relapse rate between the 3 groups after 6 and 12 mo. However, *L. GG* is more effective than standard mesalamine treatment in prolonging relapse-free time ($P < 0.05$). An open-label study of VSL#3 showed that 15/20 UC patients remain in remission after 1 year^[84].

Several studies have addressed treatment of established UC with probiotic therapy. A study using *E. coli* Nissle 1917 has demonstrated its equivalence to mesalamine for inducing remission of UC^[85]. Ishikawa *et al.*^[86] evaluated *Bifidobacterium*-fermented milk in the treatment of UC, and symptoms of exacerbation were observed in 3 of 11 patients in the treated group versus 9 of 10 patients in the untreated group after 1 year ($P = 0.01$). However, no difference was observed in endoscopic disease activity. A placebo-controlled trial with bifidobacteria-fermented milk for 12 wk in UC patients with active disease showed that endoscopic disease activity index and histological score are significantly reduced in the treatment group compared with those in placebo group^[87]. Uncontrolled administration of daily VSL#3 for 3 mo induces remission in 19 of 30 patients (63%), with a response rate of 87%^[88]. As in all of these reported studies, the increased luminal probiotic bacteria return to baseline levels within one month after stopping probiotic treatment, indicating only transient colonization by these probiotic bacteria. In another small study administration of a combination of 3 bifidobacterium species for 2 mo was superior (20% remission) to placebo (93% remission) in maintaining remission of UC induced by sulfasalazine and glucocorticoids^[89]. This effect correlates with decreased mucosal TNF- α , IL-1 β and increased mucosal IL-10 levels^[89]. An interesting study by Borody *et al.*^[90] showed that altering the gut microflora in UC patients achieved dramatic outcomes by administration of a freshly prepared enema from a healthy donor to six patients with relapsing refractory UC after broad spectrum antibiotics. This results in a remarkable reversal of all symptoms after 4 mo and sustained remission after 1-3 year of treatment.

Crohn's disease

Thus far, the use of probiotics for the prevention and treatment of CD is less substantiated than for the prevention and treatment of UC, although some studies certainly show promise. The effect of probiotics in maintaining remission of CD has been reported in an open-label study in patients receiving mesalamine alone versus mesalamine and *S. boulardii*^[91]. At 6 mo, 37.5% of patients had a clinical relapse in the former group versus 6.3% of patients in the probiotic group. In an open-labeled study, McCarthy *et al.*^[92] reported that oral administration of *L. salivarius* UCC118 significantly reduces disease activity in patients with mild to moderate CD. In a randomized, placebo-controlled pilot study, patients with CD were treated with steroids and randomized to non-

Table 2 Clinical studies of prebiotics in IBD

Author	Design	Group (Dose/d) (n)		Results
		Prebiotic	Comparator	
Induction of remission of ulcerative colitis				
Kanauchi 2003 ^[112]	Open label	Conventional therapy + Germinated barley foodstuff (20-30 g) (21)	Conventional therapy	Improved UCDAI
Furrie 2005 ^[114]	DB, R, C	<i>B. longum</i> (2×10^{11}) + inulin/oligofructose (6 g) (9)	Placebo (9)	Sigmoidoscopy scores reduced ($P = 0.06$) β -defensins, TNF α , IL-1 α levels decreased ($P < 0.05$)
Maintenance of remission of ulcerative colitis				
Hanai 2004 ^[113]	Open label	Conventional therapy + Germinated barley foodstuff (20 g) (22)	Conventional therapy (37)	Improved UCDAI and endoscopic scores
Induction of remission of Crohn's disease				
Lindsay 2006 ^[115]	Open label	Fructo-oligosaccharides (15 g) (10)	None	Increase in IL-10 expressing intestinal dendritic cells

pathogenic *E. coli* Nissle 1917 as probiotic therapy or placebo^[93]. After 1 year, there were fewer relapses in the probiotic group, but this was not statistically significant. Despite these promising studies, there are numerous reports on the inefficacy of some probiotics in CD. A randomized, placebo-controlled study of 98 patients showed that *L. johnsonii* LA1 is ineffective in preventing postoperative recurrence of CD^[94]. A placebo-controlled trial with *L. GG* is also ineffective in preventing postoperative recurrence of CD in patients undergoing bowel resection^[95]. Other studies have failed to detect benefits of *L. GG* in maintaining remission of CD in children^[96] and adults^[97,98]. Although *L. GG* has demonstrated its efficacy in treating rotaviral^[99] and antibiotic-associated^[100] diarrhea, results in IBD patients have been particularly underwhelming for this bacterial species, highlighting the species-specificity of colitis protection by probiotics.

PREBIOTICS IN INFLAMMATORY BOWEL DISEASE

Experimental colitis

Studies using prebiotics have been performed mostly in animal models. Lactulose and inulin have been shown to attenuate inflammation in IL-10 knockout mice and DSS-induced colitis respectively^[46,101]. The combination of inulin and oligofructose (mixture 1:1) is also effective in preventing the development of colitis in HLA-B27 transgenic rats^[102]. This beneficial effect is observed in conjunction with an increase of intestinal bifidobacteria and lactobacilli. Another study in HLA-B27 transgenic rats showed that the effects of the synbiotic "SIM", a combination of lactobacilli, bifidobacteria and the prebiotic inulin, are attributed to the inulin rather than the probiotics. The ingested probiotic bacteria are not detectable in the cecal content, yet the microflora profile of their cecal contents is altered^[103]. In that study, inulin was also shown to specifically stimulate the growth of *Bifidobacterium animalis*. DSS-induced colitis rats fed with goat's milk oligosaccharides maintain their body weight, have reduced colonic myeloperoxidase activity and clinical

symptoms and increased MUC-3 expression compared with control rats^[104]. Goat's milk oligosaccharides also causes decreased anorexia, weight loss, bowel wall thickening and necrotic lesions in TNBS-induced colitis in rats, compared with untreated controls^[105]. In another study of TNBS-induced colitis in rats, a 2-wk feeding of lactulose prior to the induction of colitis reduces myeloperoxidase activity, colonic TNF α and leukotriene B production, in conjunction with an increase of lactobacilli and bifidobacteria species in feces^[106]. Lactulose has also demonstrated a dose-dependent beneficial effect on DSS-induced colitis in rats, including improvements of colonic ulceration areas, body weight changes, diarrhea, bloody stools and a reduction of myeloperoxidase activity and microscopic colitis^[107].

However, not all studies using prebiotics have resulted in positive outcomes. Moreau *et al*^[108] found that fructo-oligosaccharides are ineffective in improving DSS-induced colitis in rats. Holma *et al*^[109] have reported a similar inefficacy of galacto-oligosaccharides in TNBS-colitis rats.

Several studies have investigated the use of an insoluble mixture of glutamine-rich protein and hemicellulose-rich dietary fiber termed germinated barley foodstuff (GBF). Fukuda *et al*^[110] found that feeding GBF to rats with DSS-induced colitis results in significantly reduced colonic inflammation scores, and increased butyrate concentrations in cecal contents. Kanauchi *et al*^[111] have observed similar results in DSS-colitis rats, and further determined that the dietary fiber component rather than the protein component of the GBF is responsible for the beneficial effects of GBF.

Ulcerative colitis

Table 2 lists the clinical trials using prebiotics to treat IBD. Although there is a paucity of human studies using prebiotics, the few emerging studies showed that there is potential for this treatment modality. A multi-centered open-label trial reported that oral administration of GBF to patients with mild to moderately active UC for 24 wk results in a significant decrease in clinical activity index, compared to controls^[112]. An open-label study of 22 UC

patients in remission showed that a daily oral intake of 20 g GBF results in a significantly improved clinical activity index and endoscopic score at 3, 6 and 12 mo, and a reduced relapse rate, compared with controls^[113]. A recent randomized, double-blinded controlled trial by Furrice *et al.*^[114] examined the use of synbiotics in 18 patients with active UC, using a combination therapy of *B. longum*, inulin and oligofructose, and found that sigmoidoscopy inflammation scores are reduced in the synbiotic-treated population when compared to placebo. Intestinal levels of TNF- α and IL-1 β are also reduced. Additionally, rectal biopsies have demonstrated reduced inflammation and greater epithelial regeneration in the synbiotic-treatment group.

Crohn's disease

A small, uncontrolled study of 15 active CD patients reported that 21 d of fructo-oligosaccharide (15 g) intake results in a significant decrease of disease activity, an increase of intestinal bifidobacteria and modifications of Toll-like receptors and IL-10 expression in mucosal dendritic cells^[115].

CONCLUSION

The link between intestinal microflora and IBD is now well established, and altering the composition of the microflora using probiotics and prebiotics holds promise as a therapeutic strategy for ameliorating chronic intestinal inflammation. Future developments in this field must include rigorous double-blind, placebo-controlled trials, using probiotics and prebiotics along with a further understanding of their protective mechanisms. Due to their excellent safety profile and lack of serious side effects, there are few contraindications to the consumption of prebiotics, probiotics and synbiotics by IBD patients. Further understanding of the interactions between microbes and gastrointestinal tract will help identify which strains of bacteria and/or which prebiotics may be effective in the treatment of different types of chronic inflammatory disease.

Abstract

Pylorus-preserving pancreaticoduodenectomy (PPPD) is nowadays considered the treatment of choice for periampullary tumors, namely carcinoma of the head, neck, or uncinate process of the pancreas, the ampulla of Vater, distal common bile duct or carcinoma of the peri-Vaterian duodenum. Delayed gastric emptying (DGE) comprises one of the most troublesome complications of this procedure. A search of the literature using Pubmed/Medline was performed to identify clinical trials examining the incidence rate of DGE following standard Whipple pancreaticoduodenectomy (PD) vs PPPD. Additionally we performed a thorough in-depth analysis of the implicated pathomechanism underlying the occurrence of DGE after PPPD. In contrast to early studies, the majority of recently performed clinical trials demonstrated no significant association between the occurrence of DGE with either PD or PPPD. PD and PPPD procedures are equally effective operations regarding the postoperative occurrence of DGE. Further randomized trials are required to investigate the efficacy of a recently reported (but not yet tested in large-scale studies) modification, that is, PPPD with antecolic duodenojejunostomy.

Paraskevas KI, Avgerinos C, Manes C, Lytras D, Dervenis C. Delayed gastric emptying is associated with pylorus-pre-

INTRODUCTION

The introduction of partial pancreaticoduodenectomy for the treatment of carcinoma of the ampulla of Vater dates back to almost a century ago and is credited to Kausch, a German surgeon from Berlin^[1]. Then, in 1935 Whipple and associates redefined this procedure as a two-stage pancreaticoduodenectomy, where the pylorus and proximal duodenum are closed and preserved, while gastrointestinal continuity is re-established via a gastrojejunostomy^[2]. Six years later, the first successful one-stage radical pancreaticoduodenectomy in which the distal stomach, pylorus and duodenum are removed, was reported independently by Whipple^[3] and Trimble and coworkers^[4]. Whipple is credited with popularizing the procedure, which now bears his name. Whipple pancreaticoduodenectomy (PD) has become the standard procedure of choice for many decades for the treatment of benign disorders requiring pancreaticoduodenectomy (such as chronic pancreatitis)^[5], as well as for the treatment of periampullary tumors (carcinoma of the head, neck, or uncinate process of the pancreas, ampulla of the Vater, distal common bile duct, or peri-Vaterian duodenum)^[6,7]. In 1978, Traverso and Longmire^[8] reported a technique by which the whole stomach and 2.5 cm of the duodenum are preserved, restoring the gastrointestinal continuity by duodenojejunostomy. By application of pylorus-preserving pancreaticoduodenectomy (PPPD), the postgastrectomy syndrome (postprandial dumping, diarrhea, dyspepsia, nausea and vomiting) following Whipple resection is reduced and better functional results are achieved^[9]. Although this technique has been initially reported by Watson^[10] more than three decades before, the study by Traverso and Longmire^[8] did not receive enough attention and has not been widely applied. In recent years, PPPD has been used increasingly by many surgeons, and is

considered the treatment of choice in many pancreatic surgery reference centers worldwide, despite the opinion that PPPD does not allow adequate resection of pancreatic or periampullary tumors^[11,12].

A shorter operating time and a reduced intraoperative blood loss as a result of omission of gastric resection requiring the transfusion of fewer units of blood, as well as avoidance of PD-related dumping syndrome, better postoperative weight gain and a better quality of life, are considered advantages of PPPD over PD^[8,13-20]. However, PPPD has been linked with a major drawback, that is, delayed gastric emptying (DGE), which is responsible for prolonged hospital stay and increased associated morbidity^[11,21-23]. DGE has been reported in early studies to occur in up to 70% of patients undergoing PPPD procedure^[11,14,15,22-28]. Although the incidence of DGE appears to be declining in later published reports^[5,29-31], DGE remains a leading cause of PPPD postoperative complications. The concern regarding an increased incidence of DGE following PPPD has prevented the adoption of this technique by some major American pancreatic centers^[32].

Due to the fact that no uniform definition for DGE following pancreatic surgery exists, numerous controversial opinions have been reported regarding the efficacy of these techniques as causative factors for postoperative DGE occurrence. In an attempt to demonstrate which procedure, PD or PPPD, is preferable with regards to post-operative DGE occurrence, we performed a review of randomized, controlled trials in the English literature investigating the incidence of DGE following PPPD compared with PD. We further analyzed the various implicated pathomechanisms leading to the occurrence of DGE.

DEFINITION OF DGE

The occurrence of DGE following PPPD is initially reported by Warsaw and Torchiana^[22]. In their study that included 8 patients undergoing PPPD, only 1 tolerated solid food within 10 postoperative days. Early studies have used a wide variety of definitions for DGE following pancreatic surgery. Some researchers have defined DGE as the inability to tolerate a regular or normal diet by the tenth^[14,22,27] or fourteenth^[26] postoperative day, or the start of a liquid diet after ≥ 7 d^[25]. Others have described DGE as gastric stasis requiring gastric suction for 7 d^[11,15] or ≥ 10 d^[24,28].

In the recent years, although various definitions for DGE exist, 3 seem to be most widely acceptable. (1) According to the first definition^[24], DGE occurs when the nasogastric tube is left in place for ≥ 10 d plus one of the following: emesis after removal of the nasogastric tube, reinsertion of a nasogastric tube, postoperative use of prokinetic agents after the 10th postoperative day, or failure to progress with diet. (2) According to the second definition^[33], DGE occurs when nasogastric intubation is required ≥ 10 d following the operation, or is reinserted due to vomiting. (3) According to the third definition^[34], DGE occurs when nasogastric intubation is required ≥ 10 d following the procedure or when a solid diet cannot be tolerated on or before the 14th postoperative day.

Independent of the correct definition, DGE not only leads to repeated episodes of nausea and vomiting, but also has an impact on postoperative weight gain, duration of hospitalization^[26] and related morbidity, while it may also lead to fatal aspiration and pneumonia^[35]. It is therefore a dangerous and potentially life-threatening complication.

WHAT IS THE PATHOMECHANISM UNDERLYING THE OCCURRENCE OF DGE?

A number of theories have been postulated to explain the occurrence of DGE after PPPD. Physiological gastric emptying and motility of the digestive system are complex processes that are controlled and regulated by complicated physiological mechanisms. Tonic contractions of the proximal stomach are important for the transfer of liquid food from the stomach to the duodenum^[36,37], while peristaltic contractions of the distal stomach are of primary importance for reducing the size of the solid food particles and for the transfer of solid food to the duodenum^[38]. Furthermore, certain properties of ingested food, such as volume, osmolality, pH and nutrient content, may down-regulate the motility of the digestive system, either via vagal and splanchnic sensory pathways which mediate inhibition of gastric motility induced by duodenal distension^[39], or *via* cholecystokin- and secretin-mediated pathways^[40].

Cholecystokinin (CKK) has been shown in animals and humans to inhibit gastric emptying (especially the liquid-phase emptying of the stomach)^[41] *via* a vagal capsaicin-sensitive afferent pathway and by stimulating phasic and tonic pyloric motility^[42-45]. Muller and associates^[46] reported that CCK levels decrease from 1.1 ± 0.2 pmol/L preoperatively to 0.8 ± 0.2 pmol/L 10 d postoperatively, and to 0.5 ± 0.1 pmol/L following PPPD, though no statistical significance could be demonstrated. The decrease in CCK levels is attributed to the resection of the duodenum, because high concentrations of CCK are found in the duodenal mucosa.

An alternative explanation is that the reduction of CCK levels is an adaptive response to DGE. Large amounts of CCK can also be released from the jejunum, as proven by the fact that bypassing of the duodenum in patients with Billroth II gastrectomy does not decrease CCK secretion after ingestion of fats^[47]. A finding that supports this theory is that blockage of CCK receptors with antagonists accelerates gastric emptying^[48].

The role of plasma secretin levels in the development of DGE following PPPD remains controversial and has not yet been fully elucidated^[46,49-50]. Another mechanism that has been demonstrated to influence food transit is CCK-mediated pancreatic polypeptide (PP) release, which is mainly controlled by vagal cholinergic mechanisms^[51-53]. Studies in dogs and humans have shown that the duodenum and vagal innervation are necessary for normal postprandial release of PP from pancreas^[54,55]. PPPD has been shown to be significantly associated with reduction of PP levels compared with the preoperative findings^[46]. This reduction seems to be due to resection of the pancreatic head, where the majority of PP-producing cells

are located^[54].

Other researchers support the theory that DGE occurs as a direct result of the removal of the duodenum, which influences gastric secretion and emptying as well as pancreatic and biliary secretion, thus playing an important role in the regulation of pancreatic hormone release^[56,57]. In addition, duodenectomy disrupts the coordination of gastric and intestinal migrating motor complexes^[58], decreases the postprandial PP release^[59], and abolishes the interdigestive cycles of plasma PP^[54]. Other investigators believe that preservation of the duodenal pacemaker located 0.5-1 cm distally from the pylorus should be the mainstay of the procedure, in order to avoid disturbances in normal gastric peristalsis^[60]. Gastric dysrhythmias probably exacerbated by some intra-abdominal complications such as an anastomotic leak or an abscess have also been thought to be the causative factor for DGE following PPPD^[61]. In addition, problems caused by the surgical procedure itself, namely the injury to the nerve of Latarjet, or placement of suture material through the pyloric muscle resulting in ischemia of the gastroduodenal segments and gastroparesis, have similarly been implicated^[15].

Multiple other causative agents have been implicated as etiological factors for DGE after PPPD, namely intra-abdominal complications, such as a leakage or an abscess^[16,26,61,62], postoperative pancreatitis^[63], pancreatic fibrosis^[64], preoperative cholangitis^[62], pylorospasm secondary to vagal injuries that requires the performance of pyloromyotomy^[65], alternation of the endocrinologic milieu^[15,19], early enteral nutrition commencing on the first postoperative day^[66], and torsion or angulation of the reconstructed alimentary tract^[23,67]. It has been advocated that preservation of the right gastric artery is essential for avoidance of DGE, because of its arterial supply to the pylorus and antrum^[23], although there are other investigators who do not support this theory^[64]. A more recent experimental study suggests that division of neurovascular supply to the pylorus and/or transection of the duodenum may lead to DGE following PPPD^[68]. These investigators underlined that, besides the right gastric artery, additional preservation of the supraduodenal artery, as well as conservation of the pyloric branch of the vagus nerve, are crucial for avoidance of DGE following PPPD.

In an interesting study from two surgical institutes in the Netherlands^[69], the choice of Billroth I (proximal end-to-end duodenojejunostomy) or Billroth II (end-to-side pancreatojejunostomy at the end of the jejunal loop, followed by end-to-side hepaticojejunostomy and an end-to-side duodenojejunostomy) type of reconstruction has been shown to influence DGE after PPPD. Although significantly less procedure-related complications were noted following Billroth I compared to Billroth II type of reconstruction (18% *vs* 42% respectively, $P < 0.05$), DGE occurred in significantly more patients receiving Billroth I compared to Billroth II type of reconstruction (76% *vs* 32% respectively, $P < 0.05$).

The type of reconstruction of pancreaticogastrointestinal continuity following pancreatoduodenectomy has also been implicated to play a significant role in the

development of DGE. A randomized study comparing pancreaticogastrostomy [PG] (69 patients) *vs* end-to-side pancreaticojejunostomy [PJ] (82 patients)^[70], showed that PG is superior regarding DGE rates (2 *vs* 10 patients, or 3% *vs* 12%, respectively, $P = 0.03$). By using the PG reconstructive technique (a single layer of nonabsorbable interrupted stitches on the posterior wall of the stomach)^[71] instead of PJ (single layer pancreaticojejunal or duct to mucosa technique)^[72], the authors found that significantly less complications occur (25% *vs* 68%, respectively, $P = 0.002$). More specifically, the lower rates of biliary fistulae (0% *vs* 8.5%, respectively, $P = 0.01$) and intra-abdominal fluid collections (10% *vs* 27%, respectively, $P = 0.01$) following PG compared with PJ, are the main culprits for the decreased rates of DGE.

Postoperative complications have been reported to correlate significantly with the occurrence of DGE in other trials as well. Horstmann and associates^[73] showed that the incidence of DGE increases from 1% when no postoperative complications occur, to 28% and 43% respectively when moderate (wound infection, temporary cardiopulmonary complications, transient occurrence of amylase/lipase-rich drainage fluid without signs of sepsis) and severe (anastomotic leakage, bleeding, septic complications, reoperation) complications occur ($P < 0.0001$). The results of several other studies lend support to this theory^[16,27,33,74-77].

An in-depth analysis of the physiology of the mechanism underlying the occurrence of DGE has also been reported, showing that the initiation of interdigestive phase III is closely related to the elevation of plasma motilin concentration^[78]. Motilin, a 22-aminoacid residue polypeptide, originates in motilin cells, which are scattered in the duodenal epithelium^[78]. Erythromycin and related 14-member macrolide compounds act as motilin agonists by binding to motilin receptors, which are largely confined to the antrum of the stomach and the upper duodenum^[79], thus initiating phase 3 activity of the interdigestive migratory motor complex (MMC)^[80-81]. An early study^[24] showed that patients administering high doses (200 mg) of erythromycin every 6 h from postoperative d 3 to 10 have a 53% reduction in the incidence of DGE compared with placebo.

Studies in unfed normal patients have shown that high doses of erythromycin (200-300 mg) induce strong, prolonged bursts of antral contraction, which are not propagated to the small intestine^[82,83]. On the contrary, erythromycin administered in low doses (40 mg) induces premature phase 3, commencing in the stomach and migrating through the small intestine, which is similar to spontaneously occurring phase 3^[82]. To test this hypothesis, Ohwada and coworkers^[84] performed a prospective randomized, placebo-controlled trial investigating the effect of low-dose erythromycin *vs* placebo administration on DGE following PPPD and demonstrated that intravenous administration of erythromycin lactobionate (1 mg/kg) in 50 mL of 0.9% saline, given over 15 min through a central venous route every 8 h from postoperative d 1 to 14 results in reduction in the incidence of DGE following PPPD compared with placebo (14.3% *vs* 57.1% for erythromycin and placebo respectively, $P = 0.04$). Use of low-dose

erythromycin is significantly associated with induction of phase 3 of the MMC and initiation of phase 3-like contractions ($P < 0.0001$), earlier nasogastric tube removal ($P < 0.001$) and earlier progression to diet ($P < 0.003$). In contrast, the number of patients who had a nasogastric tube reinserted and emesis after nasogastric tube removal was similar in both groups. Still, erythromycin administration was associated with a 75% reduction in the incidence of DGE. In addition, a stepwise multiple regression analysis using a Cox proportional hazard model, showed that erythromycin and preservation of right gastric artery are significant covariates. Right gastric artery removal is a predictive factor for the effectiveness of erythromycin. The authors concluded that a low dose of erythromycin is not only more effective in reducing DGE after PPPD, but is also associated with a much lower rate of adverse effects compared with a high dose.

Octreotide, a long-lasting somatostatin analogue^[85], administered preoperatively and continued postoperatively for 7 d at a dosage of 100 µg given subcutaneously 3 times a day has been reported to accelerate the rate of gastric emptying^[86]. A randomized, placebo controlled trial in healthy volunteers^[87], showed that administration of octreotide in the above-mentioned dosage can significantly accelerate gastric emptying compared to placebo ($P < 0.05$). It is hypothesized that this occurs as a result of the suppression of postprandial CCK release. A role in the prevention of DGE following pancreatic surgery is thus suggested. A randomized, placebo-controlled report^[88], however, has questioned the role of octreotide in pancreaticoduodenectomy procedures. A similar study^[89] showed that although octreotide use is associated with decreased rates of DGE compared with non-use, its use is significantly associated with the development of pancreatic fistulae. Based on their findings, the authors suggest avoidance of routine use of octreotide after pancreaticoduodenectomies until the development of international guidelines.

IS DGE SIGNIFICANTLY ASSOCIATED WITH PPPD, BUT NOT WITH PD?

We searched the Medline/Pubmed database for clinical studies comparing the efficacy of PD *versus* PPPD with regards to DGE excluding publications not in the English language (Table 1). As a result, a total of 17 trials investigating the incidence of DGE after PPPD compared with PD are identified^[6,12,20,25,34,63,66,73,77,90-97]. On the whole, 910 patients undergoing PD are compared with 1078 patients undergoing PPPD. Therefore, a total of 1988 patients have participated in these 17 studies.

Most early studies^[12,25,63,90] showed that PD is superior to PPPD regarding incidence rates of DGE. However, only one study has demonstrated statistical significance in this outcome^[25]. Another study showed that the difference in the occurrence rates of DGE after the two procedures is not significant because DGE when presents, resolves spontaneously within 6 wk. Later performed studies seem to support that the incidence rates of DGE following either PD or PPPD are comparable^[34,63,66,73,77,91,93,95], although supporters of PD over PPPD regarding DGE

rates also exist^[94]. Some recent trials have even provided significantly lower rates of DGE following PPPD than following PD^[92,96,97].

The reasons behind this diversity are multifactorial. The definition of DGE following pancreatic surgery varies from study to study. Improvement of surgical technique and increased surgical experience as well as advances in perioperative and critical care management, have resulted in decreased rates of DGE in recent years. The degree of lymph node dissection and pancreatic resection as well as the performance of anastomoses vary in different centers. Peri-operative administration of drugs that have been shown to decrease post-operational rates of DGE, like octreotide or erythromycin lactobionate, varies from study to study. The indication for performing PD varies significantly not only between different studies, but also within the same patient cohort. There is therefore a growing need for a multicentre, randomized clinical trial with specific guidelines for peri-operative administration of pharmaceutical agents, standard definition of the term DGE, and specific etiology-based performance of pancreatic surgery, to compare the efficiency of the two methods regarding DGE.

DISCUSSION

A recently reported modification in the classical PPPD procedure is the performance of duodenojejunostomy antecolically instead of retrocolically. Traverso and Kozuschek^[98] reported a decade ago that antecolic duodenojejunostomy seems to be preferred by an increasing number of pancreatic surgery centers worldwide^[61,69,99-101]. The theoretical background for this technique is that decreased blood circulation (especially venous drainage) of the jejunal limb following biliary-pancreato-enteric reconstructions can lead to decreased motility and profound edema of the jejunal limb itself, and eventually edema of the duodenojejunal anastomosis^[27]. Compromised venous drainage of the jejunal limb, which is the peristalsis starting point of the newly constructed intestinal pathway, might lead to delayed recovery of jejunal peristalsis at the site of duodenojejunostomy, which will then cause DGE^[62]. From a theoretical point of view, antecolic duodenojejunostomy avoids mechanical problems, because the descending jejunal loop is more mobile than after retrocolic reconstruction.

Kurosaki and Hatakeyama^[99] evaluated the results of antecolic duodenojejunostomy in 55 consecutive patients undergoing PPPD as the selected mode of therapy for a wide variety of underlying diseases, and demonstrated that by use of the antecolic jejunal reconstruction method, DGE is markedly reduced based on the choice of the definition of DGE selected. According to the definition by Fabre *et al*^[33], DGE occurs in only 5.5% patients. According to the definition by van Berge Henegouwen *et al*^[34], DGE occurs in 29.1% patients, while according to the definition by Yeo *et al*^[24], DGE occurs in 18.2% patients.

These researchers demonstrated that the development of a major complication is correlated significantly with reinsertion of nasogastric tube or emesis ($P = 0.010$), a later initiation of liquid diet ($P = 0.0381$) and a later

Table 1 Association between DGE and PD/PPPD

Study	Yr	Patients (n)	Results
Klinkenbijn <i>et al</i> ^[20]	1992	91 (44 PDs, 47 PPPDs)	No difference with regards to DGE was demonstrated between the two groups (i.e. days to liquid and normal diet)
Roder <i>et al</i> ^[12]	1992	110 (62 PDs, 48 PPPDs)	DGE was noted in 0 (0%) patients after PD and 9 (19%) patients after PPPD (<i>P</i> value not mentioned)
Patel <i>et al</i> ^[25]	1995	67 (52 PDs, 15 PPPDs)	DGE was noted in 41% of the PD group and 61% of the PPPD group (<i>P</i> = 0.04)
Mosca <i>et al</i> ^[90]	1997	218 (61 PDs, 157 PPPDs)	DGE was noted in 1 (4.7%) patient after PD and 14 (8.9%) patients after PPPD (<i>P</i> value not mentioned).
van Berge Henegouwen <i>et al</i> ^[34]	1997	200 (100 PDs, 100 PPPDs)	DGE was noted in 34 patients after PD and 37 patients after PPPD (<i>P</i> = NS) ¹
Lin and Lin ^[63]	1999	30 (15 PDs, 15 PPPDs)	DGE was noted in 1 patient after PD and 6 patients after PPPD (<i>P</i> = 0.08, two-sided Fisher's exact test, NS)
Di Carlo <i>et al</i> ^[91]	1999	113 (39 PDs, 74 PPPDs)	DGE was noted in 6 (15.3%) patients after PD and 9 (12.1%) patients after PPPD (<i>P</i> = NS)
Yeo <i>et al</i> ^[92]	1999	106 (58 PDs, 48 PPPDs) ²	DGE was noted in 9 (16%) patients after PD and 2 (4%) patients after PPPD (<i>P</i> = 0.03)
Seiler <i>et al</i> ^[93]	2000	77 (40 PDs, 37 PPPDs)	DGE was noted in 18 (45%) patients after PD and 12 (32%) patients after PPPD (<i>P</i> = 0.17, NS)
Martignoni <i>et al</i> ^[66]	2000	62 (27 PDs, 35 PPPDs)	DGE was noted in 9 (33%) patients after PD and 13 (37%) patients after PPPD (<i>P</i> = NS)
Yamaguchi <i>et al</i> ^[94]	2001	50 (27 PDs, 23 PPPDs)	DGE was significantly associated with PPPD compared with PD (gastric tube removal, <i>P</i> < 0.0001, oral intake, <i>P</i> = 0.0018)
Yeo <i>et al</i> ^[6]	2002	294 (148 PDs, 146 PPPDs)	DGE was noted in 24 (16%) patients after PD and 9 (6%) patients after PPPD (<i>P</i> = 0.006)
Nguyen <i>et al</i> ^[95]	2003	105 (50 PDs, 55 PPPDs) ³	DGE was noted in 6 of 50 (12%) patients after PD and 4 of 55 (7%) patients after PPPD (<i>P</i> = 0.40, NS)
Horstmann <i>et al</i> ^[73]	2004	132 (19 PDs, 113 PPPDs) ⁴	DGE was noted in 4 of 19 (21%) patients after PD and 13 of 113 (12%) patients after PPPD (<i>P</i> = 0.11, NS)
Tran <i>et al</i> ^[77]	2004	170 (83 PDs, 87 PPPDs) ⁵	DGE was noted in 18 patients after PD and 19 patients after PPPD (<i>P</i> = 0.80, NS)
Seiler <i>et al</i> ^[96]	2005	130 (66 PDs, 64 PPPDs)	DGE was noted in 30 (45%) patients after PD and 20 (31%) patients after PPPD (<i>P</i> = 0.096, NS)
Lin <i>et al</i> ^[97]	2005	33 (19 PDs, 14 PPPDs) ⁶	DGE was noted in 6 (43%) patients after PD and 0 patients after PPPD (<i>P</i> < 0.05)

NS: Not significant. ¹Although nasogastric intubation was prolonged after PPPD *vs* PD (3 *vs* 6 d, *P* < 0.0001), this did not influence DGE rates; ²Initially 114 patients were included in the study. Of these, 58 underwent PD while the remaining 56 were scheduled for PPPD. However, in 8 patients, the pylorus could not be preserved. They were therefore not included in the results; ³In 7 of 55 (13%) patients in the PPPD group, the pylorus could not be preserved; ⁴A total of 150 patients were included in the study but the 18 patients that underwent duodenum-preserving pancreatic head resection were not included here; ⁵Two patients in the PPPD group were converted to the PD group during operation as the surgeon expected duodenal involvement; ⁶Initially 36 patients were included in the study. Three patients with pancreatic head adenocarcinoma initially assigned to the PPPD group, had to undergo PD eventually due to extensive duodenal involvement. These 3 patients were not calculated in either study groups.

progression to solid diet (*P* = 0.0343). Furthermore, a major complication is correlated significantly with DGE but only according to the definition of DGE by Yeo *et al*^[24] (*P* = 0.0006), and not according to the definition of DGE by Fabre *et al*^[33] (*P* = 0.421) or van Berge Henegouwen *et al*^[34] (*P* = 0.103). A major complication is defined as a condition requiring invasive treatment or intensive care, or a pancreatic fistula proved by amylase-rich (> 1000 mg/dL) fluid from drains over 7 postoperative days or radiological examination. In their group, 10 patients developed a major complication (five patients required intensive care or invasive treatment, while another 5 developed a pancreatic fistula).

In addition, division of the left gastric vein (LGV) is correlated significantly with the occurrence of DGE (5.3% *vs* 37%, if the LGV is preserved or divided, respectively, *P* = 0.0016) according to the definition of DGE by van Berge Henegouwen *et al*^[34] but not according to the definition of DGE by Yeo *et al*^[24] (0% *vs* 5%, if the LGV is preserved or divided, respectively, *P* = 0.067). After summing up their results, the authors concluded that, by

setting the stomach vertically in the left abdomen, antecolic duodenojejunostomy improves the occurrence of DGE after PPPD.

The decreased incidence of DGE following antemesenteric instead of retromesenteric jejunal reconstruction has been verified by other researchers as well. Park and associates^[62] demonstrated that antemesenteric jejunal reconstruction is associated with a significantly lower incidence of DGE compared to retromesenteric reconstruction (6.5% *vs* 31.7%, respectively, *P* < 0.05) in terms of duration and amount of nasogastric drainage, as well as diet progression. Sugiyama and associates^[100] also support the superiority of antemesenteric jejunal reconstruction with regards to DGE (8% *vs* 72% incidence of DGE for antemesenteric *vs* retromesenteric jejunal reconstruction respectively, *P* < 0.001). Horstmann and colleagues^[73] demonstrated that performance of antecolic duodenojejunostomy-PPPD is associated with reduced (though not statistically significant) rates of DGE compared with standard Whipple (12% *vs* 21% for antecolic duodenojejunostomy-PPPD and

standard Whipple procedure respectively, $P = 0.11$).

So far, a major drawback of all reported studies is the lack of randomization. Their interpretation has therefore noticeable limitations. Recently however, two randomized controlled trials have verified the positive effect of the antecolic reconstruction method on DGE rates^[102,103]. The first study^[102] reported a significantly lower incidence of DGE after antecolic compared with retrocolic duodenojejunostomy (5% vs 50% respectively, $P = 0.0014$). However, due to the small number of patients included in this study ($n = 20$ patients/group), the authors support that larger-scale studies are needed to confirm the positive results of this new reconstruction method. The second study^[103] demonstrated the same positive results (5.0% vs 24.0% for antecolic and retrocolic duodenojejunostomy, respectively, Odds Ratio: 0.167, 95% CI: 0.054-0.430, $P < 0.001$). Although the number of patients included in this trial was not as small ($n = 100$ patients/group)^[103] as in the first study^[102], a significant drawback is the difference in the time periods of sample collection (from January 1, 1996 until December 31, 2001 for the retromesenteric group, and from January 1, 2002 until December 31, 2003 for the antemesenteric group). Standardization of the operative technique, as well as continuous improvement in perioperative management, could account in part for the difference observed in DGE rates.

CONCLUSION

Pylorus-preserving pancreatic head resection and classical Whipple are equal operations regarding the postoperative development of delayed gastric emptying. Further randomized controlled trials are required to confirm the advantage of antecolic versus retrocolic duodenojejunostomy in PPPD.

INTRODUCTION

Hepatocellular carcinoma is the 5th most common cancer in the world and the 4th most common cause of cancer-associated mortality^[1]. Surgical resection and local treatment are frequently limited, as a result of metastasis, cirrhosis, and other pathological changes in the liver parenchyma. The development of chemotherapeutic or chemopreventive agents for hepatocellular carcinoma is important to reduce the mortality caused by this disease. Since cell homeostasis depends on the balance between proliferation and apoptosis, effective compounds inducing apoptosis appear to be a relevant strategy to suppress tumor growth^[2]. Cytotoxic drugs cause cell death in sensitive cells, at least partly, by induction of apoptosis.

The Anacardiaceae family comprises many medicinal species from which a number of biologically active substances, such as various phenolic lipids (alkylresorcinols, alkylphenols, alkylcatechols), have been isolated. These compounds present antibacterial, fungicidal and cytotoxic properties^[3,4]. In addition, cytotoxic activity on tumor cells (B-16, PC-13, L-5178Y, P-388 and Hep-2) and antitumor activity against S-180 tumors in mice have been reported^[5,6]. *Lithraea molleoides* (Vell.) Engl, a member of the Anacardiaceae family, is a Southamerican tree that grows in Argentina, Brazil and Uruguay^[7,8]. We have previously reported cytotoxic activity for the methanol extract of *L. molleoides* on HepG2 cells^[9]. Further activity-guided fractionation of the dichloromethane extract has led to the isolation of a pure bioactive compound, a new cytotoxic 5-alkyl resorcinol (5-AR) derivative: 1,3-dihydroxy-5-(tridec-4',7'-dienyl) benzene^[10].

The aim of the present study was to analyze the mechanism of cytotoxicity of this compound, by studying apoptosis induction on treated HepG2 and Hep3B hepatoma cell lines.

Abstract

AIM: To study the mechanism of cytotoxicity of a new active 5-alkyl resorcinol [1, 3-dihydroxy-5- (tridec-4', 7'-dienyl) benzene] isolated from *Lithraea molleoides* leaves on liver tumor cells.

METHODS: Human hepatocarcinoma cell lines (HepG2 and Hep3B) in culture were treated with inhibitory concentrations, 50% of the compound, for 24 h. The induction of apoptosis was detected in treated cells by analysis of DNA fragmentation, DNA content, and acridine orange and propidium iodide staining.

RESULTS: After 24 h of 5-alkyl resorcinol treatment, both cell lines showed: (1) the typical morphological alterations of apoptosis; (2) DNA fragmentation, detected by laddering and appearance of a subG0 population by flow cytometry; and (3) condensed and fragmented nuclei by acridine orange-propidium iodide staining.

CONCLUSION: Based on the results, this compound exerts its cytotoxic effect in both hepatocellular cell lines through apoptotic cell death. For Hep3B, cells with mutated p53 and Fas, apoptosis would proceed by p53- or Fas-independent pathways.

MATERIALS AND METHODS

Isolation and identification of the compound

The isolation and characterization of the *L. molleoides*

compound 1, 3-dihydroxy-5- (tridec-4', 7'-dienyl) benzene has been previously described^[10].

Human tumoral cell lines

HepG2 and Hep3B cells, derived from human hepatoma, were obtained from the American Type Tissue Collection (ATCC, HB 8065 and HB 8064, respectively). They were cultured in minimal Eagle's medium (MEM) supplemented with 100 ml/L fetal bovine serum (FBS), 2 mmol/L glutamine, 1.5 g/L sodium bicarbonate, 1.0 mmol/L non-essential aminoacids, 1.0 mmol/L sodium pyruvate, and incubated at 37°C in a humidified atmosphere containing 5% CO₂.

Cytotoxicity assay (MTT assay)

The cytotoxicity assay was carried out as previously described^[9]. Briefly, 5×10^3 of HepG2 or Hep3B cells in growth medium were seeded in each well of a 96 well-microtiter plate, and incubated for 24 h at 37°C. Different concentrations of the 5-AR (in quadruplicates) were added to the exponentially growing cells. Cell controls in absence of the compound were included. After an incubation period of 24 h at 37°C, the MTT assay was performed following the manufacturer's instructions. The absorbance values at 546 nm and 650 nm were recorded in an ELISA plate reader (Meterech 960). The 50% inhibitory concentrations (IC₅₀) for both cell lines were determined by linear regression from dose-response curves.

Analysis of DNA fragmentation

Approximately $1-2 \times 10^6$ of control or treated cells were harvested and washed twice with PBS. DNA was extracted by the Wizard Genomic DNA Purification Kit (Promega), according to the manufacturer's instructions. The DNA pellet was washed, air-dried, resuspended and electrophoresed on 1% agarose gel at 50 volts for 3 h. The gel was visualized under UV transilluminator and photographed.

Analysis of the DNA content by flow cytometry (hypoploid cells)

After a 24-h 5-AR treatment, control or treated cells were harvested and washed twice with 1 g/L bovine serum albumin (BSA) in PBS. They were fixed in 700 mL/L ethanol for 1 h at 4°C, washed twice with 1 g/L BSA in PBS and resuspended in the same buffer. After the addition of a DNA extraction buffer (192 mmol/L PO₄HN₂; 4 mmol/L citric acid; pH 7.8), incubation at room temperature (RT) for 5 min and centrifugation, the cells were stained with propidium iodide (Sigma, 50 µg/mL) and treated with RNase A (Sigma, 0.5 mg/mL) for 30 min at RT. Cells were analyzed on a flow cytometer (FACSCalibur, Becton Dickinson) containing an argon laser (488 nm). The red fluorescence of propidium iodide, proportional to the DNA content, was collected through a 620 ± 15 nm band pass filter. A minimum of 10000 cells per sample was collected and DNA histograms were further analyzed by the WinMDI 2.8 program.

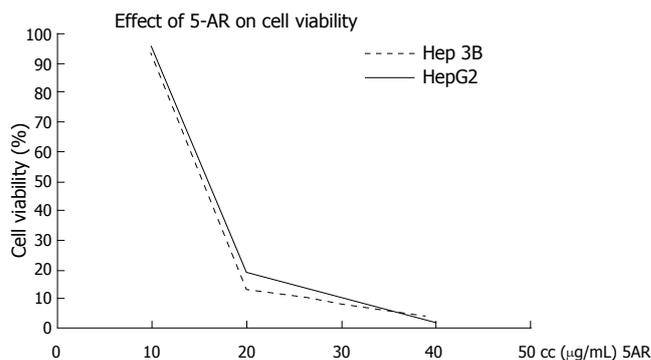

Figure 1 Treatment with 5-AR is highly cytotoxic for HepG2 and Hep3B cells. Cytotoxicity was studied testing cell viability by MTT assay in control or treated cells. The IC₅₀ values for both cell lines were determined by linear regression from dose-response curves.

Acridine orange and propidium iodide staining

Approximately 1×10^6 of control or treated cells were resuspended in 5 mL of PBS containing 5 µg/mL of acridine orange (Sigma) and 5 µg/mL of propidium iodide (Sigma). The cell suspension was immediately dispensed onto slides, viewed under fluorescent microscopy (Nikon Eclipse 400) and photographed (Nikon Coolpix 4500).

RESULTS

Cytotoxicity of 5-AR

The cytotoxicity of 5-AR on HepG2 and Hep3B human hepatoma cell lines was assessed by a cell viability assay, in the presence of different concentrations of the compound for 24 h. Under these experimental conditions, 5-AR exhibited a significant cytotoxic effect on both HepG2 and Hep3B cells. The IC₅₀ values for HepG2 and Hep3B were interpolated from linear regression curves: 13.12 µg/mL (45.49 µmol/L) and 12.45 µg/mL (43.17 µmol/L), respectively (Figure 1). Both viability curves for 5-AR were practically overlapped, suggesting a parallel effect for cell death in both cell lines. This effect is independent of the p53 status of the cells, as cytotoxicity by 5-AR was similar for HepG2, which posses wild-type p53, and Hep3B, which are p53-deficient.

Based on the detected cytotoxic activity, the effect of the compound on cell apoptosis induction was examined in both cell lines by different methods.

Effect of 5-AR treatment on cellular morphology

Apoptosis, characterized by cell shrinkage, membrane blebbing, nuclear pyknosis, chromatin condensation, and genomic fragmentation, represents a universal and exquisitely efficient cellular suicide pathway. The cytoplasm condenses and cells shrink to finally form apoptotic bodies. HepG2 or Hep3B cells were treated for 24 h with the previously determined 24 h IC₅₀ of the compound. After this period, the cells were observed under contrast phase microscopy (Nikon TMS) and photographed (Nikon FDX-35). The observation of cell morphology revealed that 5-AR-treated cells showed significant morphological

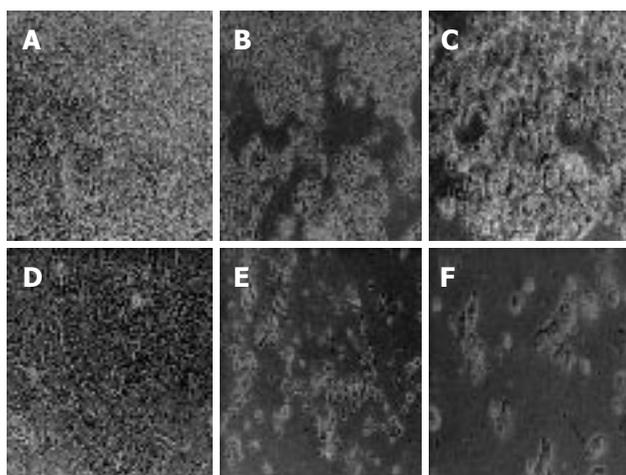

Figure 2 Treatment with 5-AR induces morphological changes typical of apoptosis in HepG2 and Hep3B cells. Control or treated cells were observed under contrast phase microscopy and photographed. **A:** Control untreated HepG2 cells (100 x magnification); **B:** HepG2 cells treated for 24 h with 5-AR IC50 (100 x magnification); **C:** HepG2 cells treated for 24 h with 5-AR IC50 (200 x magnification); **D:** control untreated Hep3B cells (100 x magnification); **E:** Hep3B cells treated for 24 h with 5-AR IC50 (100 x magnification); **F:** Hep3B cells treated for 24 h with 5-AR IC50 (200 x magnification). Results are from one experiment that is representative of three similar ones.

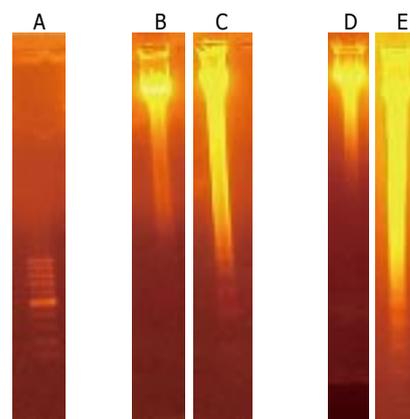

Figure 3 Treatment of HepG2 and Hep3B cells with 5-AR induces the DNA laddering typical of apoptosis. DNA was extracted from control or treated cells and electrophoresed on an agarose gel. Lane A: molecular marker; lane B: control untreated HepG2 cells; lane C: HepG2 cells treated for 24 h with 5-AR IC50; lane D: control untreated Hep3B cells; lane E: Hep3B cells treated for 24 h with 5-AR IC50. Results are from one experiment that is representative of three similar ones.

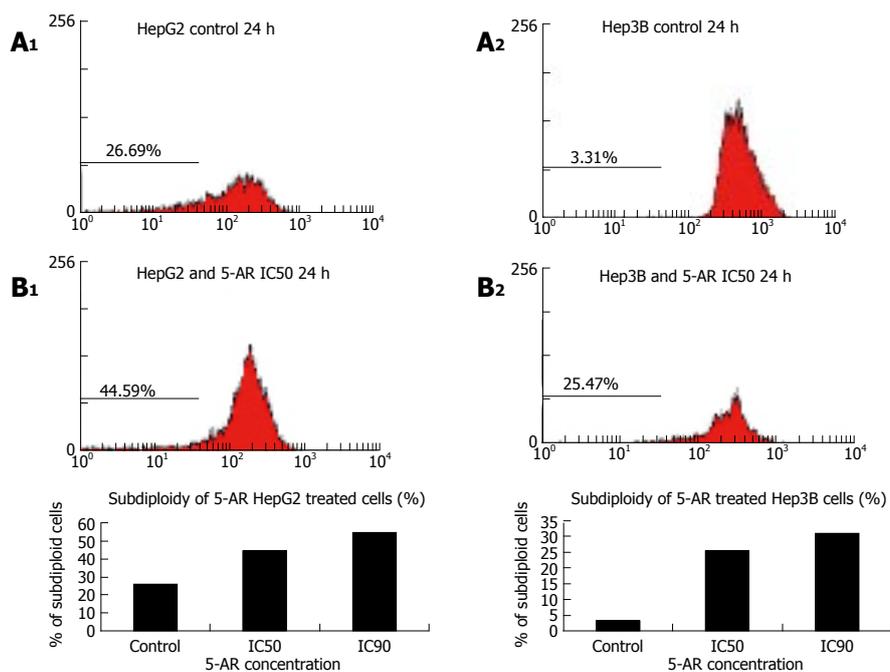

Figure 4 5-AR-treated HepG2 and Hep3B cells showing a subG0 population detected by flow cytometry. Treated or control cells were stained with propidium iodide and analyzed by flow cytometry. Left: **(A₁)** control untreated HepG2 cells, **(B₁)** HepG2 cells treated for 24 h with 5-AR IC50; Right: **(A₂)** control untreated Hep3B cells, **(B₂)** Hep3B cells treated for 24 h with 5-AR IC50. Results are from one experiment that is representative of three similar ones.

changes compatible with programmed cell death (Figure 2). The effects on cell morphology were dose-dependent (data not shown).

Effect of 5-AR treatment on DNA fragmentation

DNA fragmentation, the typical hallmark of apoptosis, was analyzed by DNA laddering on agarose gels and by the appearance of a subdiploid cell population with lower DNA content by flow cytometry.

The apoptotic process leads to fragmentation of cellular DNA in characteristic oligonucleosomal fragments, multiples of 200 base pairs. HepG2 and Hep3B cells, treated for 24 h with 5-AR, showed the typical DNA ladder on agarose gels (Figure 3). The intensity of this typical DNA ladder of multiples of 200 base pairs

fragments was dose- and incubation time-dependent.

These results were further confirmed by flow cytometer histograms obtained from treated cells, stained with propidium iodide. For HepG2 cells, the 5-AR treatment produced a significant increase in the percentage of the subG0 cell population (control cells: 26.09%; IC50: 44.59%). For Hep3B cells, the 5-AR treatment also produced a significant elevation of the subG0 cell population (control cells: 3.39%; IC50: 25.47%). The typical hypodiploid population or subG0 peak, corresponding to cells with low DNA content, is shown in cytometry histograms (Figure 4).

Induction of nuclear condensation by 5-AR treatment

Control or 5-AR-treated HepG2 and Hep3B cells were

stained with acridine orange and propidium iodide. A significant increase in the percentage of red cells and in condensed and fragmented nuclei were observed in treated cells, all these findings compatible with apoptotic cell death (Figure 5).

DISCUSSION

The search for novel anticancer drugs from natural sources has continued through the collaboration of scientists worldwide in looking for new bioactive compounds^[12]. Experimental agents derived from natural products offer opportunities to evaluate not only totally new chemical classes of anticancer agents, but also novel and potentially relevant mechanisms of action^[13].

With the aim of searching for new cytotoxic compounds from Argentine medicinal plants, a 5-AR was isolated from *L. molleoides*. The dose-dependent cytotoxic activity detected on many human tumoral cell lines suggested that it may contain some kind of antitumoral activity^[10]. Due to the relevance of human hepatocarcinoma and the lack of available successful treatments, human hepatocarcinoma cells were selected to study the 5-AR cytotoxicity and to deepen into the mechanism of cell death induced by this compound.

Apoptotic pathways are involved in the cytotoxic mechanism of antitumoral drugs. Some anticancer drugs are known to upregulate Fas ligand, leading to its interaction with Fas and triggering the apoptotic pathway. On the other hand, p53 exerts its effects on cells as a transcription factor. An increase in p53 leads to the expression of pro-apoptotic proteins, which prompt cells to undergo apoptosis. It has been reported that p53-dependent apoptosis modulates the cytotoxicity of anticancer agents^[14].

Considering the importance of Fas and p53 in hepatocyte cell death, two cell lines were selected based on

their differential p53 and Fas phenotype. While HepG2 cells exhibit normal expression of both proteins, Hep3B cells present mutated p53 and Fas^[15]. In this work, the treatment of HepG2 and Hep3B with IC50 doses of the 5-AR induced apoptosis in both cell lines, as evidenced by all the methodologies used in this work. Experiments with lower concentrations of the compounds also showed apoptosis induction in both cell lines (data not shown).

The fact that 5-AR can induce programmed cell death in Hep3B with non-functional p53^[15] and Fas^[16] evidences that the cytotoxic effect of 5-AR in this cell line is independent of their p53 or Fas phenotypic profile. As p53 is the most common mutated gene in hepatocellular carcinomas, it is important to have cytotoxic compounds that exert their apoptotic activity in a p53-independent pathway to treat this kind of tumors.

The induction of apoptosis is known to be an efficient strategy for cancer therapy^[17]. Recently, many plant extracts have demonstrated to possess the ability of triggering the apoptotic pathway^[18,19]. The present study demonstrates that a pure compound isolated from *L. molleoides* is highly cytotoxic and presents apoptogenic activity on human hepatocarcinoma cell lines. The molecular mechanistic pathway involved in this process will be studied in our future experiments. Our results and the previously reported cytotoxic and antitumoral activities of other alkyl resorcinols justify further *in vitro* and *in vivo* studies to evaluate the potential use of this 5-AR as an antitumoral agent for hepatocellular carcinoma.

ACKNOWLEDGMENTS

Abstract

AIM: To evaluate the genotype distribution of hepatitis B virus (HBV) in Eastern India and to clarify the phylogenetic origin and virological characteristics of the recently identified genotype C in this region.

METHODS: Genotype determination, T1762/A1764 mutation in the basal core promoter (BCP) and A1896 mutation in the precore region of 230 subjects were determined by restriction fragment length polymorphism method (RFLP) and the result was confirmed by direct sequencing.

RESULTS: The predominant genotypes D (HBV/D) and A (HBV/A) were detected in 131/230 (57%) and 57/230 (25%) samples. In addition, genotype C (HBV/C) was detected in 42/230 (18%) isolates. Surface gene region was sequenced from 45 isolates (27 HBV/C, 9 HBV/A and 9 HBV/D). Phylogenetic analysis revealed that all of the HBV/C sequences clustered with South East Asian subgenotype (HBV/Cs). The sequence data showed remarkable similarity with a Thai strain (AF068756) (99.5% ± 0.4% nucleotide identities) in 90% of the genotype C strains analyzed. T1762/A1764 mutation in BCP region, associated with high ALT was significantly higher in HBeAg negative isolates than HBeAg positive isolates. Frequency of A1896 mutation leading to HBeAg negativity was low.

CONCLUSION: The present study reports the genotypic distribution and the characteristics of partial genome sequences of HBV/C isolates from Eastern India. Low genetic diversity and confinement of HBV/C in Eastern India possibly indicate a recent, limited, spread in this region. Genotype C with T1762/A1764 mutation has been reported to increase the risk for hepatocellular carcinoma; therefore genotype C carriers in Eastern India should be carefully monitored.

INTRODUCTION

Hepatitis B virus (HBV) belongs to the *Hepadnaviridae* family of enveloped viruses with double-stranded DNA genome of nearly 3200 bp lengths. The HBV genome consists of four major overlapping open reading frames named surface (S), core (C), polymerase (P), and X.

HBV that infects humans has been classified into mainly eight genotypes, A-H based on the sequence divergence over the entire genome exceeding 8%^[1-4] and S gene sequence analysis^[5]. HBV genotypes have distinct geographical distributions and according to various studies seem to have different biological properties affecting, thus, the clinical outcome of HBV disease. Subgroups have been identified within different HBV genotypes, on the basis of > 4% (but < 8%) difference in the complete nucleotide sequence. In HBV genotype A, two subgroups have been defined; one is prevalent in Europe (Ae), and the other is prevalent in Africa and Asia (Aa)^[6]. Similarly, genotype C has been classified into four subgroups with characteristic

geographical distributions. Subgroup C1 (Cs) is common in Southeast Asian countries like Thailand, Myanmar and Vietnam, C2 (Ce) in East Asian countries like Japan, Korea and China^[7,8], C3 in Oceania comprising strains specifying *adrq*-, and C4 specifying *aym3* is encountered in Aborigines from Australia^[9,10].

Based on antigenic typing and further analysis of sub determinants HBV has been classified into 9 subtypes^[11]. Subtypes correlate broadly with genotypes. Some subtypes can be found in more than one genotype, which confer additional heterogeneity within the genotypes.

It is now recognized that mutations in the basal core promoter (BCP) and precore region regulate hepatitis B e antigen (HBeAg) expression. It was reported in an *in vitro* study that the double mutations in BCP A1762T and T1764A (T1762/A1764A) down regulate precore mRNA and slightly increase the efficiency of pregenome mRNA and core mRNA^[12]. Recently HBV genotypes have been partially clarified as influencing the clinical manifestation of chronic liver disease in hosts. A higher disease inducing capacity of HBV/C than HBV/B has been observed in Asia. Moreover, HBV/C with T1762/A1764 mutation has been reported to increase the risk for hepatocellular carcinoma^[13].

India is a vast country with an ethnically diverse population. With more than 40 million carriers of HBV, this is the major etiology of chronic liver diseases in India. Analyses of genomic sequences of HBV isolates from India are limited. Most reports are from Western India and Northern India, where genotypes D and A are found^[14,15]. Eastern India is a geographical area where genotypes D and A of mainland India and genotypes B and C of China and Southeast Asia converge. Recently genotype C has been reported from Eastern India^[16-18]. However, data regarding genotype distribution as well as molecular and virological characteristics of genotype C in Eastern India remain undefined.

Therefore the present study was undertaken to investigate the distribution of HBV genotypes in Eastern India and the molecular and virological features of HBV/C circulating in Eastern India.

MATERIALS AND METHODS

Patients

A cross sectional study was performed on 230 HBV DNA positive serum samples from patients with HBV infection who were referred to Indian Council of Medical Research (ICMR) Virus Unit for HBV DNA detection. Among them, 200 samples came from the outpatient clinics of Kolkata hospitals during the period of March 2001 to February 2004. All patients were known to have been positive for surface antigen (HBsAg) for > 6 mo. In addition 30 HBsAg positive asymptomatic carriers found during a community based epidemiological point prevalence study carried out by Institute of Post Graduate Medical Education & Research (IPGMER) in the rural areas, about 150 km away from Kolkata, were also included in this study^[19]. These samples were sent to our Unit for HBV DNA detection and for genotyping.

Only pretreatment samples were included in the study. Informed consent was obtained from the patients, and the Institutional Ethical Committee approved of the study protocol.

Serological testing

HBsAg, HBeAg, antiHBe were tested by using commercially available enzyme linked immunosorbent assay kits (Organon Teknika, Boxtel, The Netherlands).

HBV DNA preparation and amplification

The sera were stored at -80°C until analysis. Viral DNA was extracted from 200 µL serum by phenol/Chloroform extraction after incubation with Proteinase K^[20]. HBV DNA was detected using in-house nested polymerase chain reactions (PCR) targeting the DNA sequences encoding the surface and the precore/core regions by the method described earlier^[16,17]. Instructions to prevent cross contamination were followed strictly^[21] and the results were considered valid only when they were consistently obtained in duplicate.

Genotyping and Sequencing of HBV

HBV genotyping was done in 230 HBV DNA isolates by Restriction Fragment Length Polymorphism (RFLP) using the methods described earlier^[5] and reconfirmed on the basis of phylogenetic analysis of the 440 nt fragment of S gene of 45 randomly chosen isolates. Of these 45 isolates, 27 were from genotype C, 9 from genotype A and 9 from genotype D. The nested PCR products were sequenced from both directions on an ABI Prism 377 (Applied Biosystems, Foster City, California, USA), using the PCR primers. BCP and precore core region were sequenced using primers as described earlier^[17].

Subgenotypes of HBV/C were assigned as described previously, C1 (Cs), C2 (Ce)^[7,8] and C3, C4^[10].

Phylogenetic analysis

For sequence alignment as well as phylogenetic analysis, we selected the GenBank sequences with the best and the high scoring matches with our sequences in a NCBI BLAST search. Sequences were edited, aligned and analyzed using Bioedit version 7.0.4.1^[22]. Genetic distances were calculated using the Kimura two parameter algorithm and phylogenetic trees were constructed by the neighbor joining (NJ) method. To confirm the reliability of the pair wise comparison and phylogenetic tree analysis, bootstrap resampling and reconstruction were carried out 1000 times. Phylogenetic analysis was done using MEGA version 2.1^[23].

RESULTS

The clinical and demographic characteristics of 230 HBV carriers are shown in Table 1. Among them 200 patients (age between 5-68 years, 77 HBeAg+ and 123 HBeAg-) were native resident of Kolkata and its neighborhood, while 30 (age between 2-50 years, 3 HBeAg+ and 27 HBeAg-) were from rural areas. All the patients were ethnic Bengali. Median serum HBV DNA load of the patients was 5.37 (range 5.15-9.15) log copies/mL.

Table 1 Clinical and demographic characteristics of 230 HBV carriers from Eastern India

	HBV carriers from		Total
	Kolkata (n = 200)	Rural areas (n = 30)	
Age (yr)	32.56 ± 12.98	26.03 ± 14.14	31.71 ± 13.29
Sex (M/F)	173/27	21/9	194/36
Genotype (A/C/D)	57/40/103	0/2/28	57/42/131
ALT (IU/L)	83.24 ± 75.15	37.63 ± 21.73	77.29 ± 72.15
HBeAg positive	77	3	80
HBeAg negative	123	27	150

Table 2 Characteristics of 42 HBV/C isolates of Eastern India

	HBeAg positive (n = 23)	HBeAg negative (n = 19)
Age (yr)	32.67 ± 13.04	32.47 ± 13.01
Sex (M/F)	19/4	15/4
ALT (IU/L)	75.13 ± 39.50	85.84 ± 54.14
Subtype adrq+/adw2	23/0	18/1
T1762/A1764	12 (52%)	17 (89%)
A1896	2 (9%)	4 (21%)

Genotype distribution

Three HBV genotypes (A, C and D) could be detected among the 230 HBV DNA positive samples studied by RFLP method. Majority of the samples belonged to Genotype D, 131/230 (57.0%), followed by genotype A, 57/230 (24.8%) and 42/230 (18.2%) isolates were identified as genotype C, the majority of which (40 of 42) were from outpatient clinics of Kolkata. Out of the 30 samples from incidentally detected asymptomatic carriers from rural areas, only 2 (2/30, 6.7%) were of genotype C, while the rest were of genotype D (93.3%) (Table 1). The banding pattern of all the genotype C samples was similar to that of genotype C pattern found among Southeast Asian carriers by Lind *et al* 1997.

Characteristics of 42 HBV/C isolated from Eastern India

Among the 42 HBV/C strain, 23 (53%) were HBeAg positive and rest 19 (47%) were antiHBe positive. In order to clarify the clinical characteristics of HBV/C carriers in this region clinical and laboratory data between HBeAg positive and antiHBe positive patients were compared (Table 2). There was no significant difference between the mean age of HBeAg positive and antiHBe positive group. The mean ALT level was slightly high in antiHBe positive (85.84 ± 54.14 *vs* 75.13 ± 39.50) cases but the difference was not statistically significant. T1762/A1764 double mutation in the BCP region was more frequent in antiHBe positive than HBeAg positive group (17/19, 89% *vs* 12/23, 52%) with elevated ALT level, whereas the frequency of A1896 mutation that creates a stop codon in the precore region was low 6/42 (14%). To examine the correlation between age and HBeAg/antiHBe status, the age specific prevalence of the HBeAg/antiHBe status in 42 HBV/C

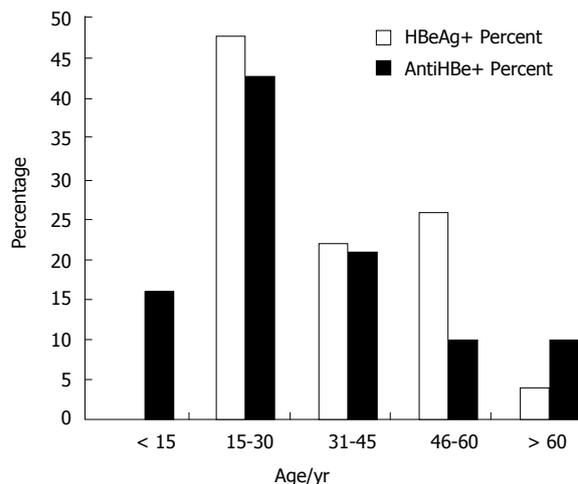

Figure 1 Age specific prevalence of HBeAg/antiHBe status in 42 HBV/C strain isolated from Eastern India.

subjects was analyzed (Figure 1). About 19/42 (45%) of subjects were in the age group of 16-30 years irrespective to HBeAg status. After that the infection rate gradually decreased.

Phylogenetic analysis

Phylogenetic analysis based on nucleotide (nt.) 256-696 of the Surface (S) gene region of HBV isolates was used to confirm the presence of these three genotypes from 45 isolates. The 45 S gene fragments were analyzed along with 39 reference sequences of different genotypes retrieved from GenBank in the phylogenetic tree presented in Figure 2. Genotypes A with adw2 subtype and D with ayw2 and ayw3 subtype from the present study clustered with the genotype A and D sequences previously reported from India. However, genotype C isolates with adrq+ and adw2 subtype from Eastern India clustered with HBV/Cs subgroup found in South East Asian countries rather than HBV/Ce subgroup found in the Far East like China, Japan, and Korea. Overall percent nucleotide identity (PNI) for HBV genotype C isolates from Eastern India with HBV/Cs varied from 98.4 to 100%. In addition to the above observation, 24 strains were most closely related to the Thai strain, AF068756 in the NCBI BLAST search. The PNI for these 24 sequences with AF068756 was found to be 99.5% ± 0.4%, across the 440 nt fragment in the S gene region. EI01343 and EI01329 were two HBV/C strain isolated from rural areas. Sequences have been submitted under GenBank accession numbers AY879184-AY879228.

Figure 3 represents the phylogenetic relatedness based on core sequences of the HBV/C strain from Eastern India. In this study, the core gene sequences were obtained from 19 HBV/C strain, 12 in this present study (accession no AY967430, AY967435, AY967442, AY967456-62, AY967465, AY967467) and 7 from previous study^[17]. The phylogenetic tree was also constructed using the core gene sequences (nt. 1900 to 2350) of 39 reference sequences of different genotypes retrieved from GenBank along with 19 HBV/C strain from Eastern India. It was evident that all

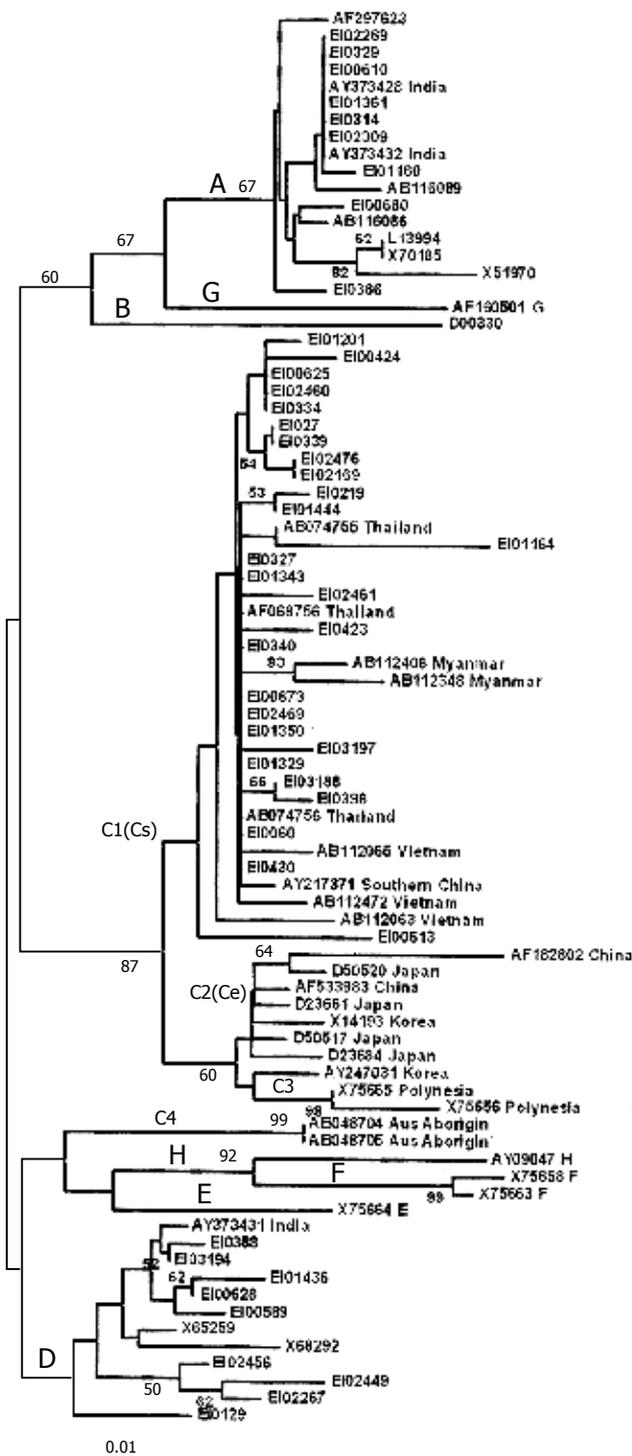

Figure 2 Neighbor joining phylogenetic of S gene region (codon 35-180) of HBV isolates from eastern India (denoted with EI) along with other genotypes derived from Genbank.

the HBV/C strain isolated from Eastern India clustered with South East Asian strain (HBV/Cs) and also found to be most closely related to Thailand sequences.

Mutation in S gene region

Amino acid sequences of the part of S protein (codon 41-180) of 27 HBV/C isolates from our study were compared with sequences retrieved from GenBank. Subtyping of the HBV isolates was done on the basis of presence of amino acid residues at codon 122, 127 and

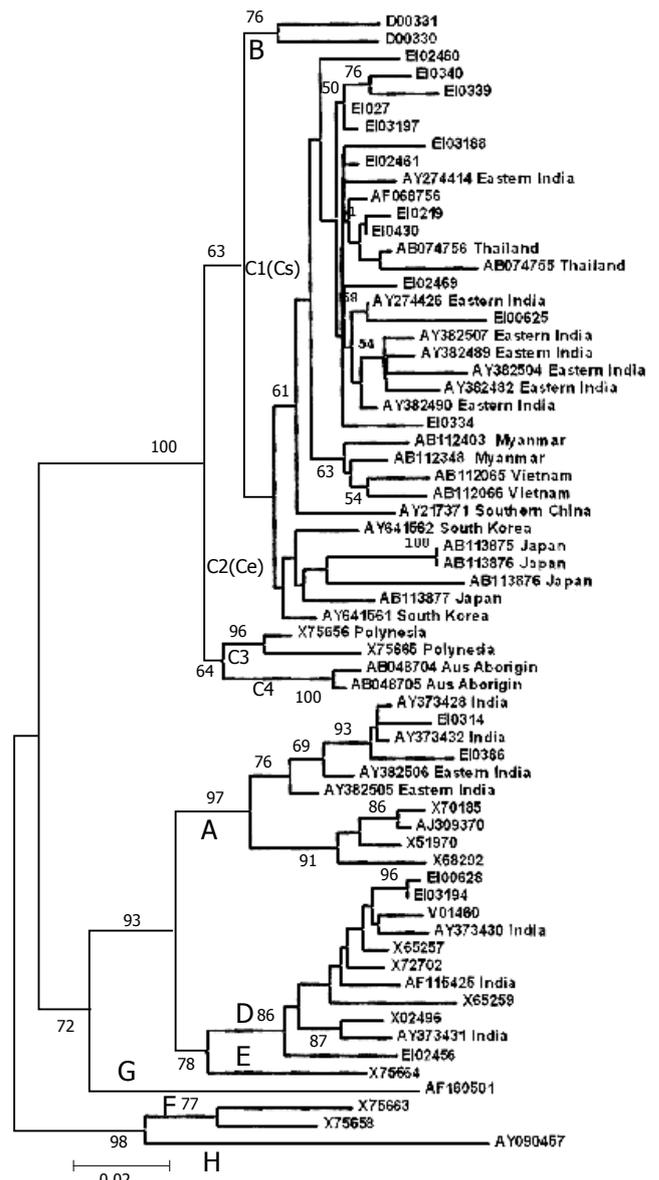

Figure 3 Neighbor joining phylogenetic analysis using the core gene region (nt. 1900-2300) of HBV isolates from Eastern India (denoted with EI).

160 of the S gene region (Figure 4A and B). The sub determinant q⁺ and q⁻ was differentiated on the basis of amino acid residue at codon 177 and 178. Among the genotype C isolates 26 out of 27 isolates had amino acid Lys122 and Arg160 as well as Val177 and Pro178 indicating that they were adr^{q+} subtype. However, only one isolate (EI01164) was classified as adr^{q-} subtype on the basis of amino acid Lys122 and Lys160 and Pro127 present in the antigenic determinant.

Comparison of amino acid sequences showed that most of the sequences were conserved (Figure 4A and B). Consensus amino acid substitution at codon 53 and 126 was observed within HBV/Cs and HBV/Ce. Out of 27 genotype C sample studied 20 were shown to have Ser to Leu amino acid substitution at codon 53, which was also found in all genotype HBV/Cs sequence from the database. The remaining 7 samples had Ser at 53 codon, which was the characteristic of genotype Ce. Most of the samples from Far East (HBV/Ce) had amino acid Ile at

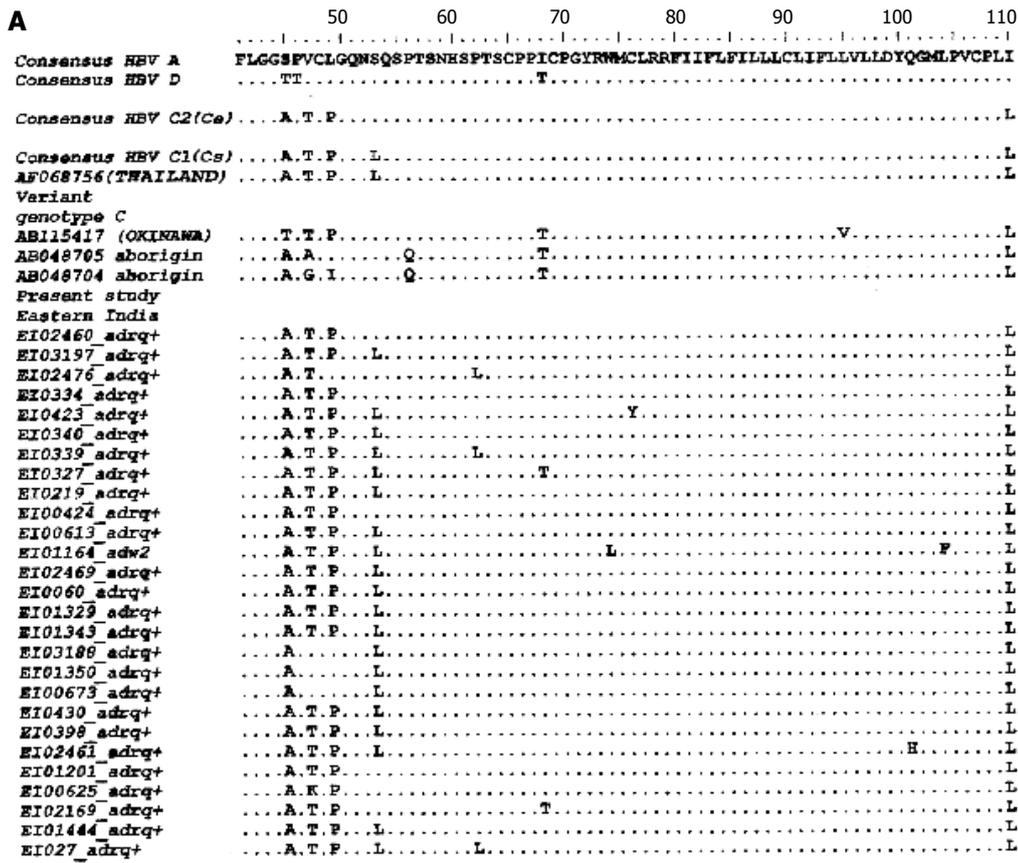

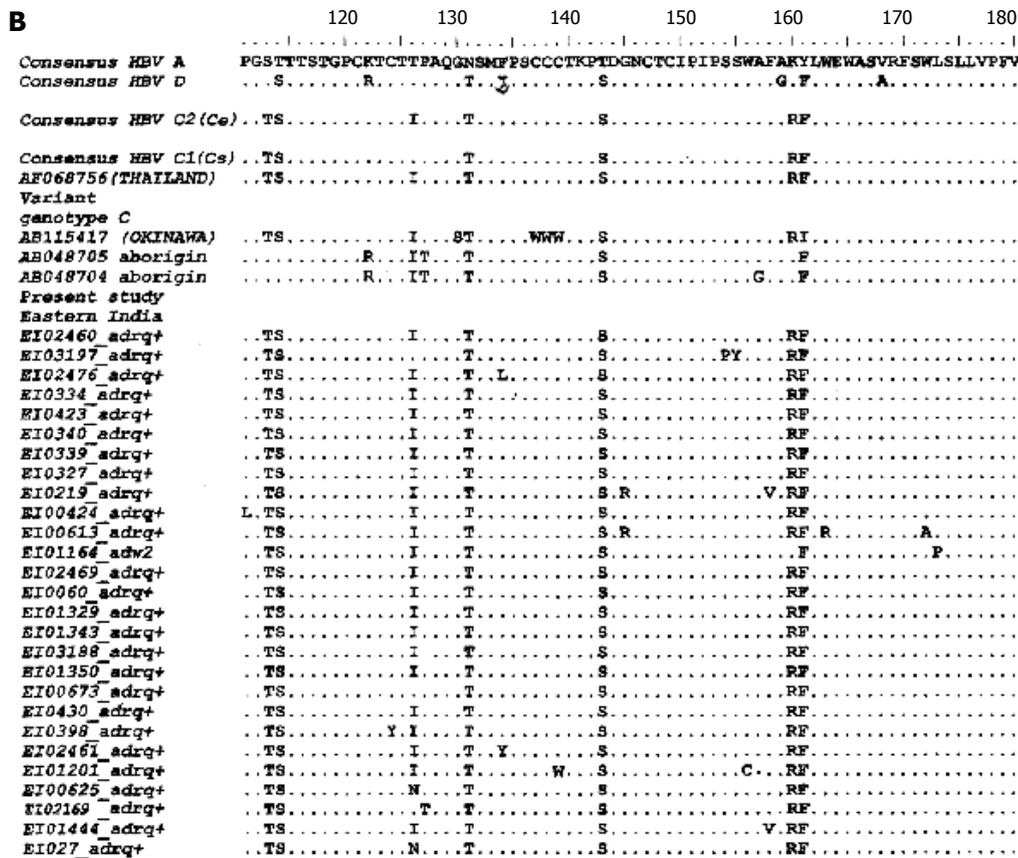

Figure 4 A, B: Alignment of amino acid sequences (41-180) of the partial S protein of HBV/C isolated from Eastern India.

codon 126, whereas most of the samples from Southeast Asia had either Asn or Thr at codon 126. However the isolate AF068756 from Thailand had Ile at codon 126. Major-

ity of the genotype C isolates studied by us also had Ile at codon 126. Only three isolates had Thr and two had Asn in that position.

DISCUSSION

Except for the HBV sequences from two studies that focused on Western and Northern India^[14,15], there are hardly any HBV sequences available from our vast country. In this study, HBV DNA sequencing and phylogenetic analysis of S gene and core region established the presence of genotype C among the HBV carriers in addition to HBV/A and HBV/D from Eastern India. This is in contrast to Western and Northern India where genotypes D and A are prevalent^[14,15]. Moreover, genotype C could be detected both from Kolkata as well as from the incidentally detected asymptomatic carriers from the rural population. Vivekanandan *et al* 2004 reported the presence of genotype C (by RFLP) only among chronic patients who went to their hospital for treatment from Eastern India. However, they could not detect HBV/C among their asymptomatic relatives who were incidentally detected HBsAg positive during blood donation. On the other hand, HBV genotypes found among patients who came from Southern India to that hospital were of genotype D excepting one case. However they have not characterized the molecular features of the genotype C strains of Eastern India. Taking into consideration their report, our findings, as well as other reports from Western and Northern India, it seemed likely that genotype C is at present confined mostly to Eastern India. Similar significant difference in the geographic distribution of HBV genotypes was recently reported from Japan and USA^[24,25].

Four subtypes adrq-, ayr, adw, adrq+ were associated with genotype C. Recently, association of serotype ayw3 was also found with genotype C variant, among Australian aborigines^[9]. In our study, in addition to adrq+ subtype, one (EI01164) of the genotype C HBV isolates showed adw2 subtype. High prevalence of this adw2 subtype within genotype C was already reported from Tibet, East Asia^[26] which borders Northern India. Genotypes A and D in our study group were of adw2 and ayw2, ayw3 subtype respectively which is consistent with the previous study reported from other parts of India^[14,15].

In places where well-known waves of migration have occurred over time, prevalence of HBV genotypes is known to reflect anthropological history of human migration, origin of immigrants and other patterns of migration. Thus, an apparent south-to-north gradient of genotypes C and B in Japan is considered to reflect anthropological history of migration from Asian countries to Japan^[24]. In contrast, the presence of genotype D HBV among primitive tribes of Andaman and Nicobar islands is thought to be due to introduction of HBV from mainland India in the past century^[27]. However, carrying the HBV/Cs strain among Jarwas (an isolated tribe from Andaman and Nicobar islands) correlate with the anthropological history of migration of this tribes from Southeast Asia^[28].

Population groups of Northern, Western and Eastern India ethnically are of Caucasoid origin, who speak Indo-European languages and show close genetic affinities with populations of Eurasia and Europe^[29] where HBV genotypes A and D are prevalent. It is therefore not surprising that HBV genotype D and A is most predominant in India. On the other hand genotype C is predominant in countries

neighboring Eastern part of India, where the population groups (of Mongoloid origin) are believed to have originated from Tibeto-Burman language subfamily. Genetic study showed that the Bengali population group of Eastern India had close ethnic affiliation with Caucasoids^[30] and formed clusters distinctly different from the North East population groups (ethnic affiliation to Mongoloid) who are possibly descendents of ancestral population of China, where genotype C and B are prevalent. Since our study population is not of Mongoloid origin, therefore it is quite unlikely that presence of genotype C in Eastern India reflects the history of population migration long ago.

This is further supported from the fact that when the sequences from the present study were compared to GenBank sequences in a BLAST search, the best matches and the high-scoring matches were from Southeast Asian Countries, especially from Thailand and not from China. Phylogenetic analysis both from Surface and core gene also revealed that almost all sequences from our study group clustered with Southeast Asian HBV/Cs subgroup and not with HBV/Ce found in East Asia and predominant in China. Of the 27 genotype C isolates sequenced, 24 (90%) had percent nucleotide identity (PNI) of 99.5% \pm 0.4%, with Thai genotype C sequence (Accession No. AF068756), in the S gene region.

There are several reports available where low genetic diversity of HBV strains has been considered to suggest limited and relatively recent spread of the strain over the geographical region. Arankelle *et al*^[27] reported a recent introduction of the virus, on the basis of low genetic diversity of partial S gene (PNI varied from 1.6% to 2.0%), of genotype D isolates from mainland India to tribal population of Andaman and Nicobar islands. For similar reason, HBV/E was considered as relatively recent introduction in West Africa^[31]. Thus considering low genetic diversity of HBV/C strain in Eastern India with Thai sequences, we presumed that the genotype Cs in Eastern India possibly might have spread from Southeast Asia, particularly from Thailand, rather recently. It is noteworthy that the prevalence of genotype C is much higher in urban population (20% *vs* 6.7%) than in rural population. Moreover, genotype C HBV samples have not been reported from Northern and Western parts of India^[14,15]. In the Southern Indian Tertiary hospital^[18], genotype C was detected in a significantly higher proportion of patients from Eastern India compared with those from Southern India (16.8% *vs* 0.9%, $P < 0.0001$). This selective confinement of genotype C to Eastern India especially to the urban population suggests that perhaps sufficient time has not yet passed since its introduction to Eastern India for its subsequent spread to the rest of the country. However, we must admit that this introduction of genotype C in Eastern India would have been best addressed if sequential study showing changing HBV genotype pattern could have been documented in Eastern India.

Kolkata is the most important port city of Eastern India and proximal to Southeast Asia. Increased trade relationship with Thailand suggests that spread of genotype Cs to Eastern India is possible, but the infectious source and the route of transmission are not clear. Previous reports showed presence of Thai HIV strains as well as Thai

HCV strains^[32,33] from North Eastern and Eastern India. Heroin trafficking routes have been associated with IDU and HIV infection in Thailand, Myanmar, China and India^[34]. HBV and HIV share common modes of transmission. There is possibility of co transmission of HBV from Southeast Asia to Eastern India, *via* this route. This might have been followed by spread to general population via unsafe injection practices, which is common in developing countries including India^[35,36]. The presence of HBV/Cs is known in our neighboring country Bangladesh, however the proportion of HBV/C among HBV carriers in Bangladesh, is unknown^[10]. People from Bangladesh come to Kolkata for treatment. This population might also have some influence in the presence of genotype C in Kolkata. Whatever may be the source, this study confirmed the presence of Cs in the Eastern Indian population.

In an era of frequent international travel and human migration, introduction of new HBV genotype to a community might have far reaching effects, including recombination between genotypes^[37] or replacement of one genotype by another^[38]. HBV genotype C is associated with delayed hepatitis B e antigen (HBeAg) seroconversion^[39], more-active hepatitis^[40], lower response to antiviral therapy^[41], more advanced liver disease and a higher risk of hepatocellular carcinoma^[42], compared with HBV genotype B. Furthermore, HBV/C with T1762/A1764 mutation in BCP region has been reported to be an increased risk factor for hepatocellular carcinoma^[13]. In our study, at least 45% of the subjects were in the age group of 16-30 years. In addition, 29/42 (69%) of genotype C isolates had T1762/A1764 mutation in BCP region, most of them associated with elevated ALT. Thus, the patients infected with genotype C need to be carefully monitored to assess their clinical outcome in future.

In conclusion, the present study reports the genotypic distribution and partial genome sequences of HBV/C isolates from Eastern India in addition to most predominant HBV/A and HBV/D. These isolates clustering with HBV/Cs genotype found in South East Asia, is prevalent in considerable proportion (18%) of Eastern Indian HBV carriers. Low genetic diversity and confinement of HBV/C in Eastern India possibly indicates a recent, limited, spread of HBV/Cs in this region. Several studies have suggested that HBV genotype C is associated with more active or severe sequelae of liver disease in Southeast Asia compared with genotype B. Therefore, the presence of HBV genotype C in Eastern India should be carefully monitored by further studies including epidemiological, clinical and virological assessment.

ACKNOWLEDGMENTS

We thank Dr. Abhijit Chowdhury of IPGMER for providing sera samples from HBsAg positive asymptomatic carriers of rural areas included in this study. We also thank Sri Tapan Chakraborty and Sri Sreekanta Deb for excellent technical assistance.

Abstract

AIM: To explore the mechanism by which *H pylori* causes activation of gastric epithelial cells.

METHODS: A VacA (+) and CagA (+) standard *H pylori* line NCTC 11637 and a human gastric adenocarcinoma derived gastric epithelial cell line BGC-823 were applied in the study. MTT assay and ³H-TdR incorporation test were used to detect the proliferation of BGC-823 cells and Western blotting was used to detect the activity and existence of related proteins.

RESULTS: Incubation with *H pylori* extract increased the proliferation of gastric epithelial cells, reflected by both live cell number and DNA synthesis rate. The activity of extracellular signal-regulated protein kinase (ERK) signal transduction cascade increased within 20 min after incubation with *H pylori* extract and appeared to be a sustained event. MAPK/ERK kinase (MEK) inhibitor PD98059 abolished the action of *H pylori* extract on both ERK activity and cell proliferation. Incubation with *H pylori* extract increased c-Fos expression and SRE-dependent gene expression. *H pylori* extract caused phosphorylation of several proteins including a protein with molecular size of 97.4 kDa and tyrosine kinase inhibitor genistein inhibited the activation of ERK and the proliferation of cells caused by *H pylori* extract.

CONCLUSION: Biologically active elements in *H pylori* extract cause proliferation of gastric epithelial cells through activating tyrosine kinase and ERK signal transduction cascade.

INTRODUCTION

H pylori is an important pathogen associated with gastritis and peptic ulcers^[1]. It has also been defined as a carcinogen^[2]. The mechanisms of pathogenic and carcinogenic effects of *H pylori* infection are under intensive investigation. Research data suggest that *H pylori* might stimulate the proliferation of gastric epithelial cells both *in vitro* and *in vivo*^[3-5]. This effect of *H pylori* has an important pathogenic significance because increased cell proliferation may elevate the gastric mutation rate and is a predisposing factor for neoplasia. The mechanism, especially the intracellular signal transduction pathway associated with the stimulating effect of *H pylori* on the proliferation of gastric epithelial cells, is under extensive study.

Protein kinases, which regulate the protein phosphorylation, are considered to play the most important role in regulating protein function and cell activity. Mitogen-activated protein kinase (also known as MAP Kinase) is a crucial member of the protein kinase family. So far, four MAP Kinase cascades have been characterized in mammalian cells. Among them, extracellular signal-regulated protein kinase (ERK) cascade is most well characterized. The activation of signal transduction pathways by growth factors, hormones and neurotransmitters is mediated through ERK cascade^[6,7]. It is the basic signal transduction pathway regulating cell proliferation and differentiation. Recent research data indicate that activation of ERK cascade is involved in *H pylori*-induced proliferation of gastric epithelial cells^[8-10]. However, more details of *H pylori*-induced activation of ERK cascade are needed to be explored.

MATERIALS AND METHODS

Materials

Human gastric epithelial cell line BGC-823 (ICLC

HTL98007) was provided by Institute of Tumor Research of Beijing. VacA (+) and CagA (+) international standard *H. pylori* strain NCTC11637 was provided by Institute of Microbiology and Epidemiology of China, Beijing. DMEM culture medium was from Gibco (Grand Island, NY). Brucella broth was from Becton Dickinson (Franklin Lakes, NJ). New born calf serum (NBCS) was from No.2 Factory of Beijing Milk Company (Beijing, China). Antibody against phosphorylated ERK was from Sigma (St. Louis, MO). All other primary antibodies were from Santa Cruz Biotechnology (Santa Cruz, CA). HRP-conjugated secondary antibody was from Jackson ImmunoResearch Laboratories (West Grove, PA). ECL chemoluminescence reagents were from Amersham (Buckinghamshire, England). Tyrosine kinase inhibitors genistein and luciferin were from Sigma (St. Louis, MO). MAPK/ERK inhibitor PD98059 was from Calbiochem (San Diego, CA). Plasmid DNA constructs encoding SRE-luciferase and CRE-luciferase were kind gifts from Dr. Renate Pilz in University of California, San Diego.

Cell culture

Human gastric cancer cell line BGC-823 was kept in DMEM containing 100 mL/L serum and incubated in 5% CO₂ at 37°C. The medium was changed every second day and the cells were sub-cultured at 80%-90% confluence.

Preparation of *H. pylori* extract

Healthy *H. pylori* was scraped down from horse serum agar plate and transferred into Brucella broth containing 100 mL/L serum. The bacterial suspension was incubated in micro-oxygen environment (80% N₂, 15% CO₂, 5% O₂) at 37°C for 24 h with continuous shaking. The growth of *H. pylori* was confirmed by Gram staining before harvest. *H. pylori* cells were precipitated by centrifugation at 5000 r/min for 15 min at 4°C and washed with PBS. The bacteria were re-suspended in serum free cell culture medium (DMEM) and sonicated (100 W, 15 s × 6, at 30 s interval). The breakdown of the bacteria was confirmed by microscopy. The suspension was centrifuged at 10000 r/min for 30 min at 4°C. The supernatant (*H. pylori* extract) was adjusted to protein concentration of 1 g/L and kept at -20°C until use.

Preparation of protein samples

The harvested cells (1 × 10⁷) were washed three times with PBS and re-suspended in 40 μL suspension buffer containing 100 mmol/L NaCl, 10 mmol/L Tris-HCl (pH7.6), 1 mmol/L EDTA (pH8.0), 1 mg/L aprotinin, 100 mg/L PMSF. The same volume of boiled 2 × SDS protein loading buffer containing 100 mmol/L Tris-HCl (pH6.8), 200 mmol/L DTT, 4% SDS, 0.2% bromophenol blue, 20% glycerol was added into the cell suspension. The sample was boiled for 10 min to lyse the cells and sonicated for 1 min to break down the DNA. After centrifugation at 12000 r/min for 10 min, the supernatant was kept at -20°C until use. For preparation of membrane protein samples, the cells were harvested, washed with PBS, and lysed with extract buffer containing 20 mmol/L HEPES (pH7.4), 10

mL/L Triton X-100, 5 mmol/L EDTA, 50 mmol/L NaCl, 30 μmol/L β-glycerophosphate, 50 mmol/L sodium fluoride, 50 mg/L aprotinin, 10 mg/L leupeptin. The lysate was centrifuged at 100000 × *g* for 1 h at 4°C and the supernatant was kept at -20°C until use.

Western blotting

The protein sample was loaded with 30 μg protein per lane on SDS-PAGE gel. After electrophoresis, the proteins on the gel were transferred onto nitrocellulose (NC) membrane as described previously. The NC membrane was blocked with 50 g/L milk in TBS-T for 1 h at room temperature (RT), incubated with first antibody for 2 h and with secondary antibody for 50 min at RT and finally washed three times after each incubation. ECL chemoluminescence reagent was used to show the positive bands on the membrane.

MTT assay

A total of 1 × 10⁴ trypsin-dispersed BGC-823 cells in 0.1 mL culture medium were seeded into each well of the 96-well plates and cultured for 24 h. Then, the cells were incubated with medium alone or with medium plus *H. pylori* extract at different concentrations. After 24 h of further incubation, 10 μL of MTT (6 g/L, Sigma) was added to each well and the incubation was continued for 4 h at 37°C. Finally, the culture medium was removed and 200 μL of dimethylsulphoxide (DMSO) was added to each well. The absorbance was determined with an ELISA reader at 570 nm. The "change percentage" of the absorbency (*A*) value of the cells treated with *H. pylori* extract compared with *A* value of the cells without treatment was calculated as:

$$\text{Change (\%)} = \frac{A \text{ value (} H. pylori \text{ group-control)}}{A \text{ value of control group}} \times 100\%$$

³H-TdR incorporation

The cells were cultured in the same way as described in MTT assay. When the culture medium was changed and *H. pylori* extract was added, 0.2 μCi of ³H-TdR was also added into each well. After further incubation for 24 h, the medium was discarded and the cells were trypsin-dispersed and collected onto a membrane. The membrane was heated dry at 65°C and put into a plastic vial containing 6 mL of scintillation liquid. The count per minute (CPM) was calculated with a Beckman scintillation counter. The "change percentage" of CPM of the cells treated with *H. pylori* extract compared with CPM of the cells not treated with *H. pylori* extract was calculated as:

$$\text{Change (\%)} = \frac{\text{CPM (} H. pylori \text{ group-control)}}{\text{CPM of control group}} \times 100\%$$

Reporter gene assay

The cells were transfected with plasmid DNA encoding SRE-luciferase or CRE-luciferase, and β-galactosidase. After incubation with *H. pylori* extract for 8 h, the cells were harvested and the activity of luciferase and β-galactosidase was measured by luminescence-based assays. The luciferase activity was calculated as the fold of increase after normalized by the β-galactosidase activity.

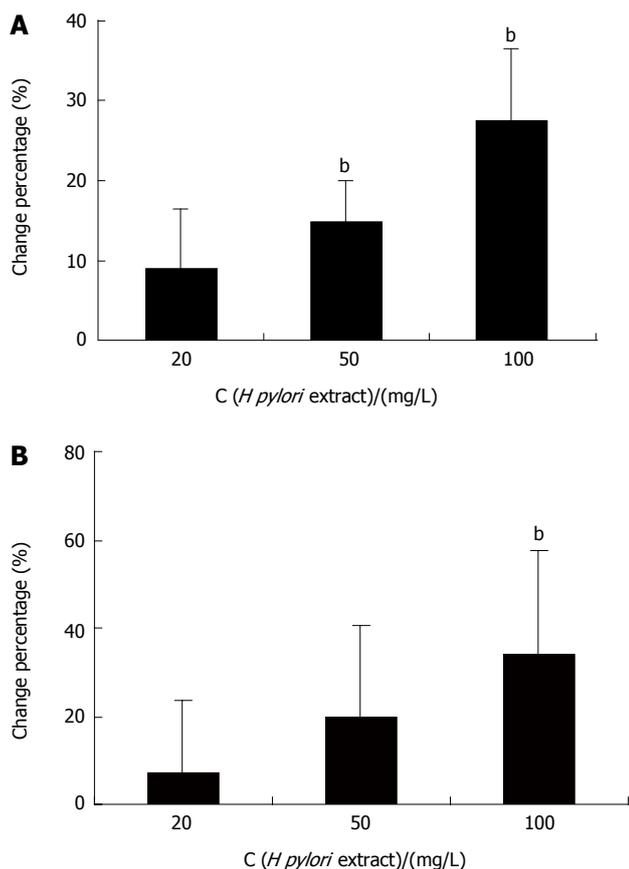

Figure 1 MTT assay (A) and ³H-TdR-incorporation test (B) showing *H pylori* extract-stimulated proliferation of BGC-823 cells. ^b*P* < 0.01 vs control.

Statistical analysis

The results of MTT assay, ³H-TdR incorporation test and reporter gene assay data were expressed as means ± SD. The significance of the difference between control group and experimental group was evaluated by Student's *t*-test.

RESULTS

***H pylori* extract stimulated proliferation of BGC-823 cells**

The MTT assay showed that *H pylori* extract could stimulate the proliferation of BGC-823 cells. The *A* value reflecting the number of viable cells, increased significantly in the cells incubated with 50 mg/L and 100 mg/L *H pylori* extract for 24 h (Figure 1A). Similar result was also obtained in ³H-TdR-incorporation test. The ³H incorporation increased dose-dependently when the cells were incubated with 20 mg/L, 50 mg/L, and 100 mg/L *H pylori* extract respectively for 24 h (Figure 1B).

***H pylori* extract activated extracellular signal-regulated kinase in BGC-823 cells**

The separated protein samples from cells incubated with 50 mg/L *H pylori* extract for different periods of time were first probed with antibody against phosphorylated ERK to analyze the activity of ERK and re-probed with anti-ERK2 antibody to show the protein content of this kinase. The results showed that in serum-starved cells, the activity level of ERK was very low. During incubation with *H pylori* extract, the activity of ERK increased obviously

Figure 2 Western blotting showing phosphorylated ERK (A) and total ERK (B) in serum-starved BGC-823 cells incubated with *H pylori* extract. M: Protein molecular marker; 0: Control; 1-7: Incubation with 50 mg/L *H pylori* extract for 20, 40, 60 min and 3, 6, 12, 24 h.

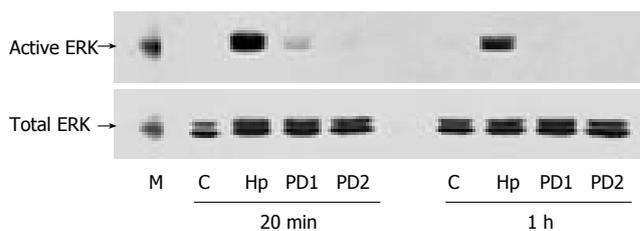

Figure 3 Western blotting showing PD98059-blocked stimulating effect of *H pylori* extract on ERK activation in BGC-823 cells. M: Molecular marker; C: Control; Hp: 50 mg/L *H pylori* extract; PD1: 25 μmol/L PD98059 + 50 mg/L *H pylori* extract; PD2: 50 μmol/L PD98059 + 50 mg/L *H pylori* extract.

within 20 min and stayed at a high level (about 5 times of control) for more than 8 h (Figure 2).

PD98059 blocked the stimulating effect of H pylori extract on ERK activity and proliferation of BGC-823 cells

PD98059, an inhibitor of MAPK/ERK kinase (MEK) activating ERK directly, was used to confirm the specificity of ERK activation induced by *H pylori* extract. Western blotting showed that PD98059 abolished the stimulating effect of *H pylori* extract on ERK activity (Figure 3). MTT assay showed that the inhibitor also blocked the stimulating effect of *H pylori* extract on proliferation of the cells (Figure 4).

Genistein inhibited ERK activation induced by H pylori extract

Genistein is an inhibitor of tyrosine kinase. Western blotting with antibody against phosphorylated ERK showed that treating the cells with genistein inhibited the ERK activation induced by *H pylori* extract (Figure 5).

H pylori extract caused tyrosine phosphorylation of membrane protein

An antibody against pan-tyrosine phosphorylation of proteins was used to detect the tyrosine phosphorylation caused by *H pylori* extract. Western blotting showed that during incubation with *H pylori* extract, several proteins were phosphorylated on tyrosine within 20 min of incubation (Figure 6). A tyrosine-phosphorylated protein with molecular size around 97.4 kDa was especially arrested because it also existed in membrane protein sample extracted from the cells (Data not shown).

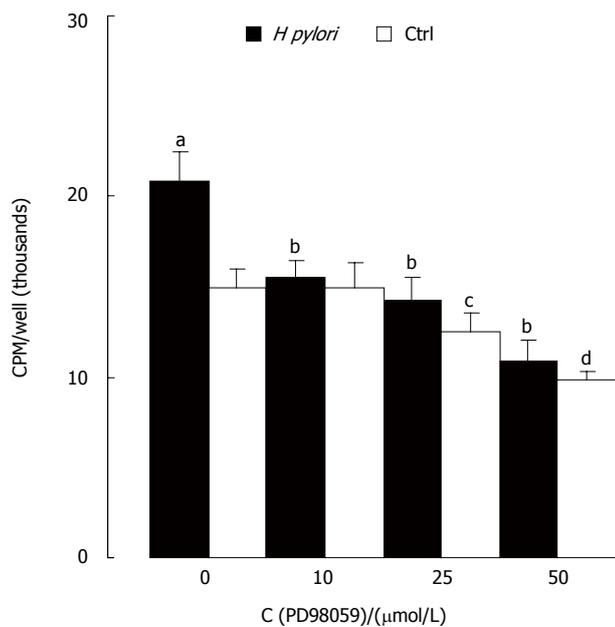

Figure 4 MTT assay showing PD98059-blocked proliferation-stimulating effect of *H. pylori* extract. ^a*P* < 0.05, ^c*P* < 0.05, ^d*P* < 0.01 vs control only; ^b*P* < 0.01 vs Hp only.

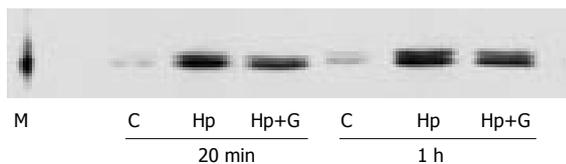

Figure 5 Western blotting showing genistein-prevented ERK activation by *H. pylori* extract. M: Molecular marker; C: Control; Hp: *H. pylori* extract; Hp + G: Genistein and *H. pylori* extract.

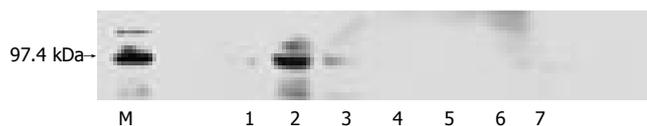

Figure 6 Western blotting showing *H. pylori* extract-caused tyrosine phosphorylation of cell lysate of BGC-823. M: Molecular marker; 1: control; 2-7: *H. pylori* extract incubated for 20, 40 min and 1, 3, 6, 12 h.

H. pylori extract increased expression of c-fos

Western blotting showed that when the cells were incubated with 50 mg/L *H. pylori* extract, the expression of c-Fos protein increased obviously. During incubation, the expression of c-Fos started to increase around 40 min after incubation, reached its peak around 1 h and lasted for 6 h (Figure 7).

H. pylori extract stimulated SRE-dependent reporter gene expression

Reporter gene assay showed that *H. pylori* extract specifically stimulated SRE-dependent expression of luciferase while it had no effect on CRE-driven luciferase expression (Figure 8), indicating that *H. pylori* extract could increase c-Fos expression through SRE cis-element of the promoter.

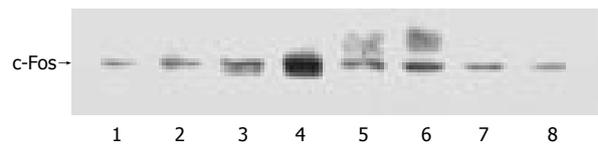

Figure 7 Western blotting showing *H. pylori* extract-increased expression of c-Fos. 1: Control; 2-8: *H. pylori* extract incubated for 20, 40 min and 1, 3, 6, 12 and 24 h.

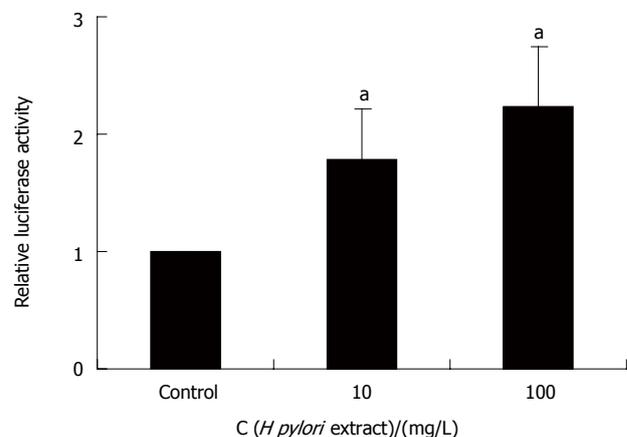

Figure 8 *H. pylori* extract-stimulated SRE-dependent reporter gene expression. ^a*P* < 0.05 vs control.

DISCUSSION

Gastric *H. pylori* infection is the most common infection in humans. It is responsible for virtually all cases of gastritis and most cases of peptic ulcers^[1]. Moreover, *H. pylori* is defined as a group 1 carcinogen in humans by International Agency for Research on Cancer, a working party of WHO^[2]. The conclusion is, however, mainly based on the epidemiological data and clinical investigations. Even though laboratory data on carcinogenesis of *H. pylori* are accumulating during recent years^[11-13], more efforts are still needed to elucidate the mechanism of *H. pylori*-induced malignant diseases. Gastric carcinoma develops through a sequence of events from normal mucosa to gastric carcinoma^[14]. *H. pylori* might be closely associated with this process. Several mechanisms have been proposed by which *H. pylori* infection might lead to predisposition for gastric cancer^[15]. One explanation is that *H. pylori*-associated chronic inflammation may increase the rate of cell turnover in gastric mucosa. Rapidly replicating DNA is more susceptible to damage. Alongside increased reactive oxygen species and decreased ascorbic acid content during inflammatory reactions, *H. pylori*-induced proliferation may be the major factor for gastric dysplasia and gastric cancer^[16,17]. In *H. pylori* hosts with gastritis, increased proliferation of gastric epithelial cells has been confirmed^[3,4]. Laboratory data have also shown that *H. pylori* might directly stimulate proliferation of gastric epithelial cells^[5,10,11]. The former reveals an increased cell turnover rate in *H. pylori* host and the latter suggests that increased proliferation of gastric epithelial cells might be a direct effect of *H. pylori*.

Probing separated proteins with anti-phosphorylated ERK antibody and re-probing them with anti-ERK2

antibody provide a sensitive way to detect ERK activity^[18]. With this method, our study showed that during incubation with *H pylori* extract, the activity of ERK increased obviously in serum-starved cells and the activation of ERK was a sustained event. This is significant because sustained activation of ERK appears to be required for many cells to pass the gastrointestinal restriction point to enter S phase, in which cellular DNA is replicated^[19,20]. MTT assay and ³H-TdR-incorporation test confirmed the stimulating effect of *H pylori* extract on cell proliferation in our study. Since ERK-mediated cascade is the basic signal transduction pathway regulating cell proliferation, this pathway can mediate proliferation-stimulating effects of *H pylori*.

ERK is in the middle of the signal transduction pathway. Currently, it is believed that ERK may be activated through several pathways^[21]. One is the receptor tyrosine kinase-Ras-MEK pathway. Growth factor ligand binds to membrane receptor and causes tyrosine-phosphorylation of the receptor. Consequential action of Ras and then Raf, which are components of the cascade, causes the activation of MEK (also known as MAP kinase), a direct upstream regulator of ERK^[22]. PD98059 is a specific inhibitor of MEK^[23]. Our results showed that PD98059 could block both ERK activity-stimulating and proliferation-stimulating effects of *H pylori* extract. Ras activity was not investigated in this experiment. However, we used tyrosine kinase inhibitor genistein to explore the possible involvement of tyrosine kinase in *H pylori* extract-induced signaling. The results showed that genistein inhibited *H pylori* extract-induced activation of ERK. Then, we used antibody against pan-tyrosine phosphorylation to detect tyrosine phosphorylation in both whole cell lysate and membrane protein from the cells. The results showed that in samples from the cells treated with *H pylori* extract, there was obvious tyrosine phosphorylation of a membrane protein with molecular size around 97.4 kDa, suggesting that it is very likely that *H pylori* extract activates ERK through receptor tyrosine kinase-Ras-MEK pathway.

As to the down-stream events of ERK activation, it was reported that some ERK activated by MEK can translocate to the nuclei and phosphorylate at least two transcription factors, c-Myc and Elk-1^[24,25]. The phosphorylated factors may lead to increased production of c-Fos mRNA and finally lead to cell activation^[26]. Mitsuno *et al*^[27] reported that co-culturing human gastric cancer cells with Cag-positive *H pylori* strains can activate c-fos gene through SRE. Our results showed that *H pylori* extract stimulated SRE-dependent gene transcription and increased the expression of c-Fos protein, indicating that the signaling process behind activation of ERK by *H pylori* can derive biological elements.

Several methods, including co-culture of live *H pylori* with target cells, use of water extract and sonication extract to stimulate target cells, have been used to study the effect of biologically active components of *H pylori* on the activity of target cells. For example, during co-culture, *H pylori* may secrete active factors or act on the target cells through type IV secretion system^[28], water extracting can get the surface component of the bacteria^[29], and sonication extracting can efficiently release

active components from the body of bacterial cells^[30,31]. In this experiment, sonication of *H pylori* extract showed that soluble component from the bacteria activated the MAPK cascade of gastric cells. Further work is needed to identify the molecular features of the component in our laboratory.

In summary, *H pylori* extract has direct proliferation-stimulating effects on gastric epithelial cells and the activation of gastric epithelial cells can be induced by *H pylori* through MAPK-mediated signal transduction pathway, suggesting that biologically active elements in *H pylori* contribute to the tumorigenesis effect of the bacteria.

Abstract

AIM: To investigate whether the stimulation of peripheral blood mononuclear cells (PBMNC) with the cell debris and cell extraction of different probiotic strains is similar or species specific.

METHODS: Three strains of *bifidobacteria*, 4 strains of *lactobacilli*, and *E. coli* nissle were sonicated and centrifuged in order to divide them into cell extract and cell debris. PBMNC were separated by density gradient and incubated for 36 h with either the cell debris or the cell extract of single strains of probiotic bacteria in doses from 10² to 10⁸ CFU/mL. Cell supernatants were taken and interleukin (IL)-10, IL-1 β , and tumor necrosis factor (TNF)- α were determined by ELISA.

RESULTS: Depending on the species super-family, the strains had different stimulation patterns. Except for both *L. casei* strains, the cell extract of *bifidobacteria*

and *lactobacilli* had less stimulating capacity than cell debris, whereas the cell extract of *E. coli* nissle had similar stimulating properties to that of the cell debris of the strain and significantly more stimulating capacity than that of *bifidobacteria* and *lactobacilli*. The cell debris of *bifidobacteria* stimulated more cytokine release than the cell debris of *lactobacilli*. The cell debris of *lactobacilli* did not have a stimulating capacity when lower concentrations were used. Neither cell extraction nor cell debris had an inhibitory effect on the production of the tested cytokines by stimulated PBMNC.

CONCLUSION: The incubation of probiotic strains, which have been used in clinical trials for inflammatory diseases, with immunocompetent cells leads to different species specific reactions. High IL-10 response to cell debris of *bifidobacteria* and *E. coli* nissle can be found. This corresponds to positive effects of *bifidobacteria* and *E. coli* nissle in clinical trials for inflammatory bowel disease compared to negative outcomes obtained with *lactobacilli*.

INTRODUCTION

There is no doubt that the relationship between intestinal microflora and immune system is complex. The host has to distinguish between pathogenic bacteria and harmless commensal and must react in an adequate and not self-destructive manner^[1]. There is an increasing body of evidence that chronic intestinal inflammations such as

inflammatory bowel disease (IBD) are due to a disturbed relationship within the host's immune response to the enteric microflora^[2-4]. Based on these proposals the relationship between micro-flora and intestinal immune response has been intensively studied by manipulation of the enteric micro-flora with probiotic bacteria^[5-11]. These are by definition "A preparation of or a product containing viable, defined products in sufficient numbers which alter the microflora (by implantation or colonization) in a compartment of the host and by exerting beneficial health effects in the host"^[12]. The efficacy of *E. coli* nissle in therapy for ulcerative colitis^[5-6] has been shown and our own clinical experience has been focused on a highly concentrated probiotic preparation (VSL#3) in preventing pouchitis, an unspecific inflammation of an ileal pouch anal anastomosis after colectomy for ulcerative colitis^[9-10]. *Lactobacillus* GG instead has no influence on clinical outcome in Crohn's disease^[7-8]. Besides clinical findings, different studies have also shown the influence of probiotic bacteria on the local and systemic immune response in experimental colitis^[13-15]. The mechanisms underlying this effect are still under investigation. One hypothesis is based on modulating pro- and anti-inflammatory cytokines^[16-17]. Pro-inflammatory cytokines such as interleukin (IL)-1 β and tumor necrosis factor (TNF)- α play an important role in gut inflammation^[17]. In Crohn's disease and ulcerative colitis these cytokines are elevated in local inflammation area and peripheral blood cells^[18-19], whereas the anti-inflammatory cytokine IL-10 is decreased in patients suffering from IBD^[20]. IL-10 produced by gene manipulated bacteria, reduces toxic colitis that is associated with pro-inflammatory cytokines^[21-22]. Further arguments have been found in the absence of IL-10. IL-10 deficient (KO) mice do not show any symptoms of intestinal inflammation as long as they are kept in sterile conditions, but spontaneously develop chronic colitis with a histological distribution similar to that found in Crohn's disease after termination of the sterile conditions^[23]. If the mice are fed with different lactic acid bacteria before finishing the sterile conditions, this chronic inflammation can be prevented^[24]. Recently, during preventive therapy for chronic pouchitis using different probiotics as mentioned above, we investigated the cytokine tissue levels of patients with pouchitis and after induction of remission and during the following probiotic application. It is interesting to find that cytokine tissue levels of IL-10 increase during the application of the probiotic preparation, whereas anti-inflammatory cytokine-levels such as TNF- α and IL-1 remain low after the application^[25].

The aim of our study was to set up an *in vitro* model to compare the immunomodulatory effects of different probiotic strains that have previously been evaluated in different clinical trials. For this purpose we used peripheral blood mononuclear cells (PBMNC), which are a combination of different immunogenic cells.

MATERIALS AND METHODS

Subjects

Blood samples were taken from 12 healthy blood

Table 1 List of the bacterial strains

<i>Bifidobacterium breve</i> : Y 8
<i>Bifidobacterium infantis</i> : Y 1
<i>Bifidobacterium longum</i> : Y 10
<i>E. coli</i> : Stamm Nissle 1917 (Mutaflor, Ardeypharm, Herdecke, Germany)
<i>Lactobacillus azidophilus</i> : MB 443
<i>Lactobacillus casei</i> subspecies <i>rhamnosus</i> : Lactobacillus GG (LGG, Valio, Helsinki, Finland): ATCC 53103
<i>Lactobacillus casei</i> : MB 451
<i>Lactobacillus delbrueckii</i> subspecies <i>bulgaricus</i> : MB 453
<i>Lactobacillus plantarum</i> : MB 452

donors (7 females, mean age: 44 years; 5 males, mean age: 52 years). Blood from the same donor was used for each co-incubation with all tested bacteria in different concentrations. Incubation experiments were repeated 4 to 6 times with blood from different donors. The study was performed in accordance with the Declaration of Helsinki and the local ethics committee.

Separation of PBMNC

PBMNC from healthy donors were separated according to Boyum^[26]. Briefly, peripheral blood diluted with Hank's balanced salt solution (HBSS) (without Ca²⁺ or Mg²⁺) (GIBCO, Karlsruhe, Germany) containing 100 U/mL heparin, was layered over a ficoll (Lymphoprep, Progen, Biotechnik, Heidelberg, Germany; specific gravity: 1.077) and centrifuged for 40 min at 400 r/min without using a frame. Cells harvested from the interface were washed in HBSS (without Ca²⁺ or Mg²⁺) and centrifuged for 10 min at 400 r/min. Supernatant was discarded and the pellet was resuspended in HBSS (without Ca²⁺ or Mg²⁺), which was repeated four times. Finally, resuspension was performed in RPMI 1640 (GIBCO, Karlsruhe, Germany) with 10% fetal calf serum, 100 U/mL penicillin, 100 μ g/mL streptomycin, and 50 μ g/mL gentamycin (all Sigma, St. Louis, MO). Viability of cells was tested by trypan-blue, which was more than 97%. After calculation of the cells per volume, the cell count was adjusted to 500 000 cells per well and per mL.

Bacteria and culture conditions

The bacteria species and strains used in this study are listed in Table 1. Strains in bold type originated from the pharmaceutical probiotic VSL#3 (Sigma Tau, Promezia, Italy). *Bifidobacterium* and *Lactobacillus* strains were grown in MRS broth (Difco, Detroit, MI) with the addition of 0.05% L-cysteine hydrochloride monohydrate (Merck, Darmstadt, Germany). All strains were incubated anaerobically at 37°C. Mid log cultures counted by plating technique on the above mentioned media, were collected by centrifugation (8000 \times g for 3 min), washed and resuspended in 5 mL RPMI 1640 Medium (GIBCO, Karlsruhe, Germany). The bacterial suspensions were subsequently sonicated (Branson Sonifier W-250, Heinemann, Schwäbisch, Germany) at power levels 5-6 at 30% duty for 5 min to destroy cellular membranes. The sonicated suspension was centrifuged at 8000 \times g for 30 min to separate cell debris from crude cell extract. After centrifugation the supernatant containing the

cell extract and the pellet containing the cell debris were taken for further investigation.

Bacterial incubation with PBMNC

Bacterial cell debris and extract were applied at concentrations ranging from 1×10^3 to 1×10^{10} colony forming units (CFUs)/mL. One hundred μL at specific concentration was transferred to 900 μL medium containing 500000 mononuclear cells and co-incubated at 37°C and 50 mL/L CO_2 for 36 h. Supernatants were collected and stored at -20°C until assay. The viability of PBMNC was checked by the trypan blue test. On each incubation plate a positive control with LPS added to PBMNC and a negative control without stimulus were investigated. The same set-up was used in order to examine the ability of probiotics to inhibit LPS-induced cytokine release. PBMNC were incubated with bacterial cell extract and debris for 10 min, then LPS was added in a concentration of 100 ng/ μL .

Cytokine quantification in culture supernatant

Cytokine quantification in culture supernatant was analysed by commercially available sandwich enzyme linked immunosorbent assay (ELISA).

TNF- α was detected using anti-human TNF- α monoclonal "capture" antibody (MAB 610, R&D Systems, Minneapolis, MN, USA) and biotinylated "detection" antibody (BAF 210 R&D Systems, Minneapolis, MN, USA) with o-phenylenediamine buffer/ H_2O_2 (Sigma, Steinheim, Germany) as substrate. Standard procedure was performed by using recombinant human TNF- α (210-TA, R&D Systems, Minneapolis, MN, USA). The absorbance values of the sample were read at 490 nm on an ELISA plate reader. ELISA measurements were performed in duplicates or triplicates.

IL-1 β was detected using anti-human IL-1 β monoclonal "capture" antibody (MAB 601, R&D Systems, Minneapolis, MN, USA) and biotinylated "detection" antibody (BAF 201 R&D Systems, Minneapolis, MN, USA) with o-phenylenediamine buffer/ H_2O_2 (Sigma, Steinheim, Germany) as substrate. Standard procedure was performed by using recombinant human IL-1 β (201-LB, R&D Systems, Minneapolis, MN, USA). The absorbance values of the sample were read at 490 nm on an ELISA plate reader. ELISA measurements were performed in duplicates or triplicates.

IL-10 was detected using anti-human IL-10 "capture" antibody (18551A Pharmingen, San Diego, CA, USA) and biotinylated "detection" antibody (18562D, Pharmingen, San Diego, CA, USA) with o-phenylenediamine buffer/ H_2O_2 (Sigma, Steinheim, Germany) as substrate. Standard procedure was performed by using recombinant human IL-10 (19701V, Pharmingen, San Diego, CA, USA, USA). The absorbance values of the sample were read at 490 nm on an ELISA plate reader. ELISA measurements were performed in duplicates or triplicates.

Statistical analysis

Data of cytokine concentration were presented as mean \pm SE and expressed in pg/mL. For quantification of

stimulating capacity of bacteria at different concentrations, cytokine concentration was resumed as an area under the curve (AUC) and described as (mean \pm SE) AUC. Statistical significance was calculated by the Mann-Whitney-Rank test and expressed as *P*-value.

RESULTS

Positive and negative controls

Results from cytokine production in PBMNC after stimulation with LPS (100 ng/mL) were pooled (144 samples from 12 different donors). The mean cytokine production in stimulated PBMNC was 186.5 ± 125.6 pg/mL for IL-10, 1875.6 ± 1381.2 pg/mL for IL-1 β and 356.0 ± 249.1 pg/mL for TNF- α . Cytokine production in non-stimulated PBMNC was under detection limit of the ELISA.

Cytokine production in PBMNC after incubation with cell debris and extract

Generally, cytokine production in PBMNC induced by bacteria differed in cell debris and extract between bacteria and depended on the applied concentration used (Figure 1).

IL-10 concentration

Lactobacilli: Cell extracts from all applied *lactobacilli* induced IL-10 concentration only weakly, whereas no difference was found between species (data not shown). The stimulation by cell debris of these strains led to higher concentrations of IL-10 whereas significance only reached in *L. azidophilus* MB443, *L. delbrueckii* subsp. *bulgaricus* MB453 and *L. plantarum* MB452 (AUC: *L. azidophilus* MB443: 1.0 ± 1.5 pg/mL; *L. delbrueckii* subsp. *bulgaricus* MB453: 3.8 ± 4.65 pg/mL; *L. plantarum* MB452: 9.9 ± 13.8 pg/mL). The stimulation by cell debris of both *L. casei* subs. (MB 451 and *L. GG*) did not differ from that of cell extract of these strains. As shown in Figures 2 and 3, the cell debris of *lactobacilli* had a weak stimulation capacity at concentrations less than 10^5 CFU/mL.

Bifidobacteria: Cell debris of each *bifidobacteria* strain stimulated IL-10 production in PBMNC more significantly than their cell extracts (AUC: *B. breve* Y8 cell debris: 1062.7 ± 889.9 pg/mL; cell extract: 182.6 ± 177.5 pg/mL; AUC *B. longum* Y10 cell debris: 682.7 ± 466.9 pg/mL; cell extract: 30.5 ± 28.9 pg/mL; AUC *B. infantis* Y1 cell debris: 1095.6 ± 925.3 pg/mL; cell extract: 228.3 ± 233.0 pg/mL; *P* < 0.05) (Figure 1). No difference was found between different *bifidobacteria* species when the stimulation capacity of cell extracts or cell debris was compared. Cell debris from *bifidobacteria* stimulated IL-10 production in PBMNC more significantly than *lactobacilli* (AUC cell debris of *bifidobacteria*: 710.1 ± 795.5 pg/mL; AUC cell debris of *lactobacilli*: 219.6 ± 174.7 pg/mL; *P* < 0.02) (Figure 4).

As shown in Figure 2 and Figure 3, the cell debris of *bifidobacteria* had a weak stimulating capacity at the concentration lower than 10^3 CFU/mL. Moreover, the highest concentration (10^8 CFU/mL) of *bifidobacteria* had a less stimulating capacity than the lower concentration (10^7 CFU/mL), whereas the viability measured by trypan blue test was over 97%.

E. coli nissle: Cell extracts and debris of *E. coli* nissle led

to similar IL-10 concentrations (AUC cell debris: 1270.7 ± 210.9 pg/mL; cell extract: 1154.8 ± 264.0 pg/mL) (Figure 1). The stimulation ability of cell extract to produce IL-1 β in PBMNC was significantly higher in *E. coli* nissle than in *lactobacilli* or *bifidobacteria* ($P < 0.05$). The cell debris of *E. coli* nissle had a similar stimulating capacity to *bifidobacteria* but a more significant capacity than *lactobacilli* ($P < 0.02$) (Figure 4). The cell debris and extract of *E. coli* nissle even had a stimulating capacity at low concentrations (Figure 3). The highest concentration (10^8 CFU/mL) of *E. coli* nissle had a less stimulating capacity than the lower concentration (10^7 CFU/mL), whereas the viability measured by trypan blue test was over 97%.

IL-1 β concentration

Lactobacilli: As shown in Figure 1 cell extracts from all applied *lactobacilli* induced IL-1 β concentration only weakly, whereas no difference was found between species (data not shown). The stimulation by cell debris of *L. acidophilus*, *L. delbrueckii* subsp. *bulgaricus* and *L. plantarum* led to higher concentrations of IL-1 β (AUC: *L. azidophilus* MB443: 1282.2 ± 987.9 pg/mL; *L. delbrueckii* subsp. *bulgaricus* MB453: 4881.5 ± 893.8 pg/mL; *L. plantarum* MB452: 3390.8 ± 288.9 pg/mL) ($P < 0.05$) (Figure 1). The stimulation by cell debris did not differ from cell extract of *L. casei* subs. *rhamnosus* (L.GG) and *L. casei* MB451. As shown in Figures 2 and 3, the cell debris of *lactobacilli* had only a weak stimulating capacity at concentrations of less than 10^6 CFU/mL.

Bifidobacteria: Cell debris of each *bifidobacteria* strain stimulated IL-1 β production in PBMNC more significantly than their cell extract (AUC: *B. breve* Y8 cell debris: 11152.9 ± 2547.7 pg/mL; cell extract: 1488.3 ± 454.0 pg/mL; AUC *B. longum* Y10 cell debris: 12364.0 ± 192.5 pg/mL; cell extract: 491.0 ± 190.6 pg/mL; AUC *B. infantis* Y1 cell debris: 9018.8 ± 2190 pg/mL; cell extract: 2142.3 ± 925.0 pg/mL; $P < 0.05$) (Figure 1). No difference was found between *bifidobacteria* species when the stimulating capacity of cell extracts or cell debris was compared. The cell debris from *bifidobacteria* led to higher IL-1 β concentrations in supernatant of PBMNC than cell debris of *lactobacilli* (AUC cell debris of *bifidobacteria*: 11692.8 ± 2283.2 pg/mL; AUC cell debris of *lactobacilli*: 3143.3 ± 2689.0 pg/mL; $P < 0.02$) (Figure 4). As shown in Figure 2, the cell debris of *B. breve* Y8 and *B. longum* Y10 even had a stimulating capacity at low concentrations (10^3 CFU/mL and 10^2 CFU/mL), whereas the IL-1 β production in PBMNC was weak when incubated with *B. infantis* Y1 at a concentration of less than 10^4 CFU/mL. The highest cell debris concentration (10^8 CFU/mL) of *bifidobacteria* had a less stimulating ability to produce IL-1 β in PBMNC than its lower concentration, whereas the viability measured by trypan blue test was over 97%.

E. coli nissle: Cell extracts and debris of *E. coli* nissle led to similar IL-1 β concentrations (AUC cell debris: 9334.8 ± 2486.1 pg/mL; cell extract: 7875.0 ± 1595.3 pg/mL) (Figure 1). The stimulating ability of the cell extract of *E. coli* nissle to produce IL-1 β in PBMNC was significantly higher than that of *lactobacilli* or *bifidobacteria* ($P < 0.05$). The cell debris of *E. coli* nissle had a similar stimulating

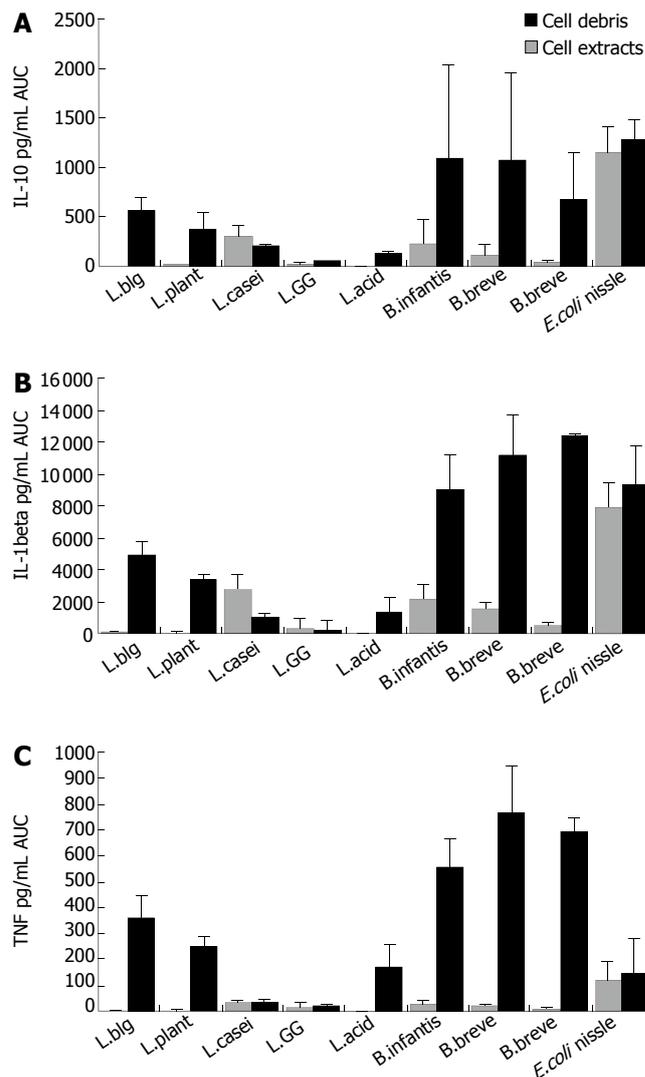

Figure 1 Concentration of IL-10 (A), IL-1 β (B) and TNF α (C) by PBMNC (area under the curve of mean \pm SE) after incubation with cell debris (■) or cell extract (▒) of different strains.

capacity to *bifidobacteria* but a more significant capacity than *lactobacilli* ($P < 0.02$) (Figure 4). The cell debris and extract of *E. coli* nissle even had a stimulating capacity at low concentrations (Figure 3). The highest concentration of debris of *E. coli* nissle had a less stimulatory capacity than lower concentration.

TNF-concentration

Lactobacilli: Cell extracts from *L. azidophilus* MB443, *L. delbrueckii* subsp. *bulgaricus* MB453, and *L. plantarum* MB452 induced TNF- α concentration only weakly. The stimulation by cell debris of these strains led to higher TNF- α production (AUC: *L. azidophilus* MB443: 1695.3 ± 879.3 pg/mL; *L. delbrueckii* subsp. *bulgaricus* MB453: 3593.2 ± 822.1 pg/mL; *L. plantarum* MB452: 2466.5 ± 433.3 pg/mL) ($P < 0.05$) (Figure 1). The stimulation by cell debris did not differ from cell extract of *L. casei* subs. *rhamnosus* (L.GG) and *L. casei* MB451. As shown in Figures 2 and 3, the cell debris of *lactobacilli* only had a weak stimulating capacity at concentrations of less than 10^7 CFU/mL.

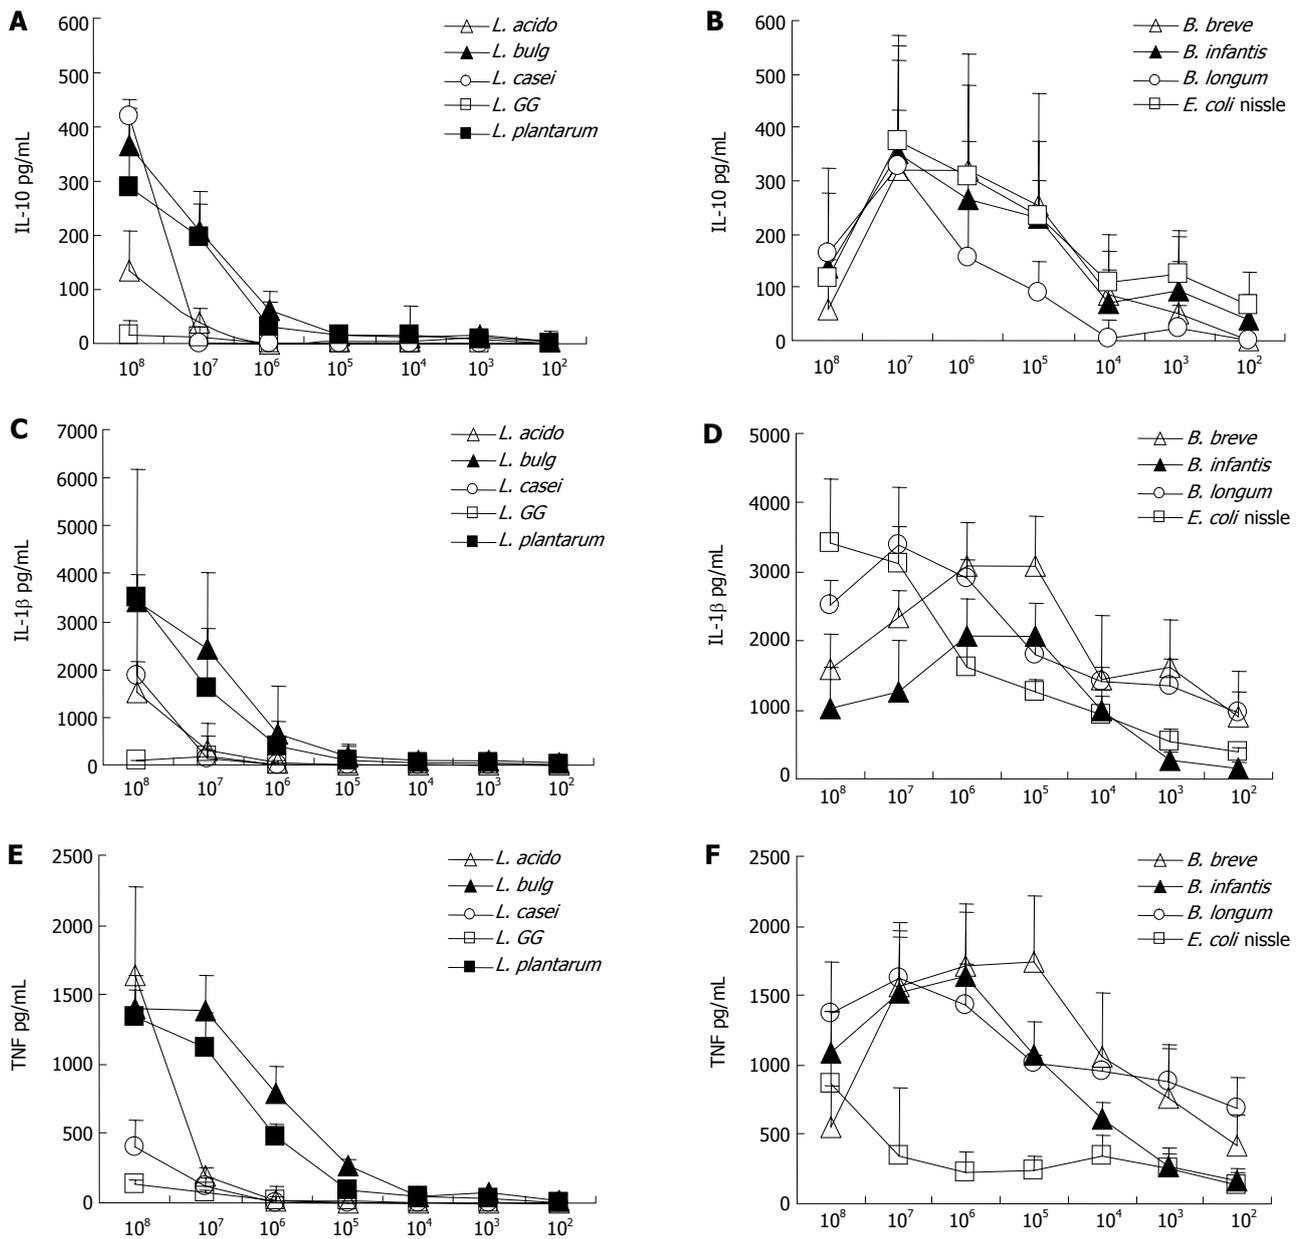

Figure 2 Cytokine concentration of supernatant after incubation of PBMC with cell debris of bacteria in different concentrations. **A** and **B**: supernatant concentration of IL-10 in pg/ml (mean ± SE); **C** and **D**: supernatant concentration of IL1β in pg/ml (mean ± SE); **E** and **F**: supernatant concentration of TNFα in pg/mL (mean ± SE). *Lactobacilli* are described on the left side and *bifidobacteria* are described on the right side.

Bifidobacteria: Cell debris of each *bifidobacteria* strain led to higher TNFα concentrations in supernatant of PB-MNC than their cell extract (AUC: *B. breve* Y8 cell debris: 7645.5 ± 1823.1 pg/mL; cell extract: 180.1 ± 85.5 pg/mL; AUC *B. longum* Y10 cell debris: 6951.2 ± 522.7 pg/mL; cell extract: 83.6 ± 40.0 pg/mL; AUC *B. infantis* Y1 cell debris: 5584.8 ± 1098.8 pg/mL; cell extract: 290.5 ± 103.6 pg/mL) (*P* < 0.05). No difference was found between *bifidobacteria* species when the stimulating capacity of cell extract or cell debris was compared. The cell debris from *bifidobacteria* led to higher TNFα concentrations in supernatant of PB-MNC than cell debris from *lactobacilli* or *E. coli nissle* (AUC cell debris of *bifidobacteria*: 6882.4 L ± 1355.0 pg/mL; AUC cell debris of *lactobacilli*: 1630.8 ± 1265.1 pg/mL; AUC cell debris of *E. coli nissle*: 1466.6 ± 1356.0 pg/mL) (*P* < 0.02)

(Figure 4). As shown in Figure 2, the cell debris from *B. breve* Y8 and *B. longum* Y10 even had a stimulating capacity at low concentrations (10³ CFU/mL and 10² CFU/mL), whereas the TNF-α production in PBMC was weak when incubated with *B. infantis* Y1 at a concentration of less than 10⁴ CFU/mL. The highest concentration (10⁸ CFU/mL) of *bifidobacteria* had no strong stimulating ability to produce TNF-α in PBMC, whereas the viability measured by trypan blue test was over 97%.

E. coli nissle: High concentrations (10⁸ CFU/mL) of cell debris of *E. coli nissle* led to high concentrations of TNF-α, whereas lower concentrations of cell debris and extracts led to lower concentrations of TNF-α (Figure 3) (AUC cell debris: 1466.6 ± 1356 pg/mL; cell extract: 1153.0 ± 748.4 pg/mL) The cell debris of *E. coli nissle*

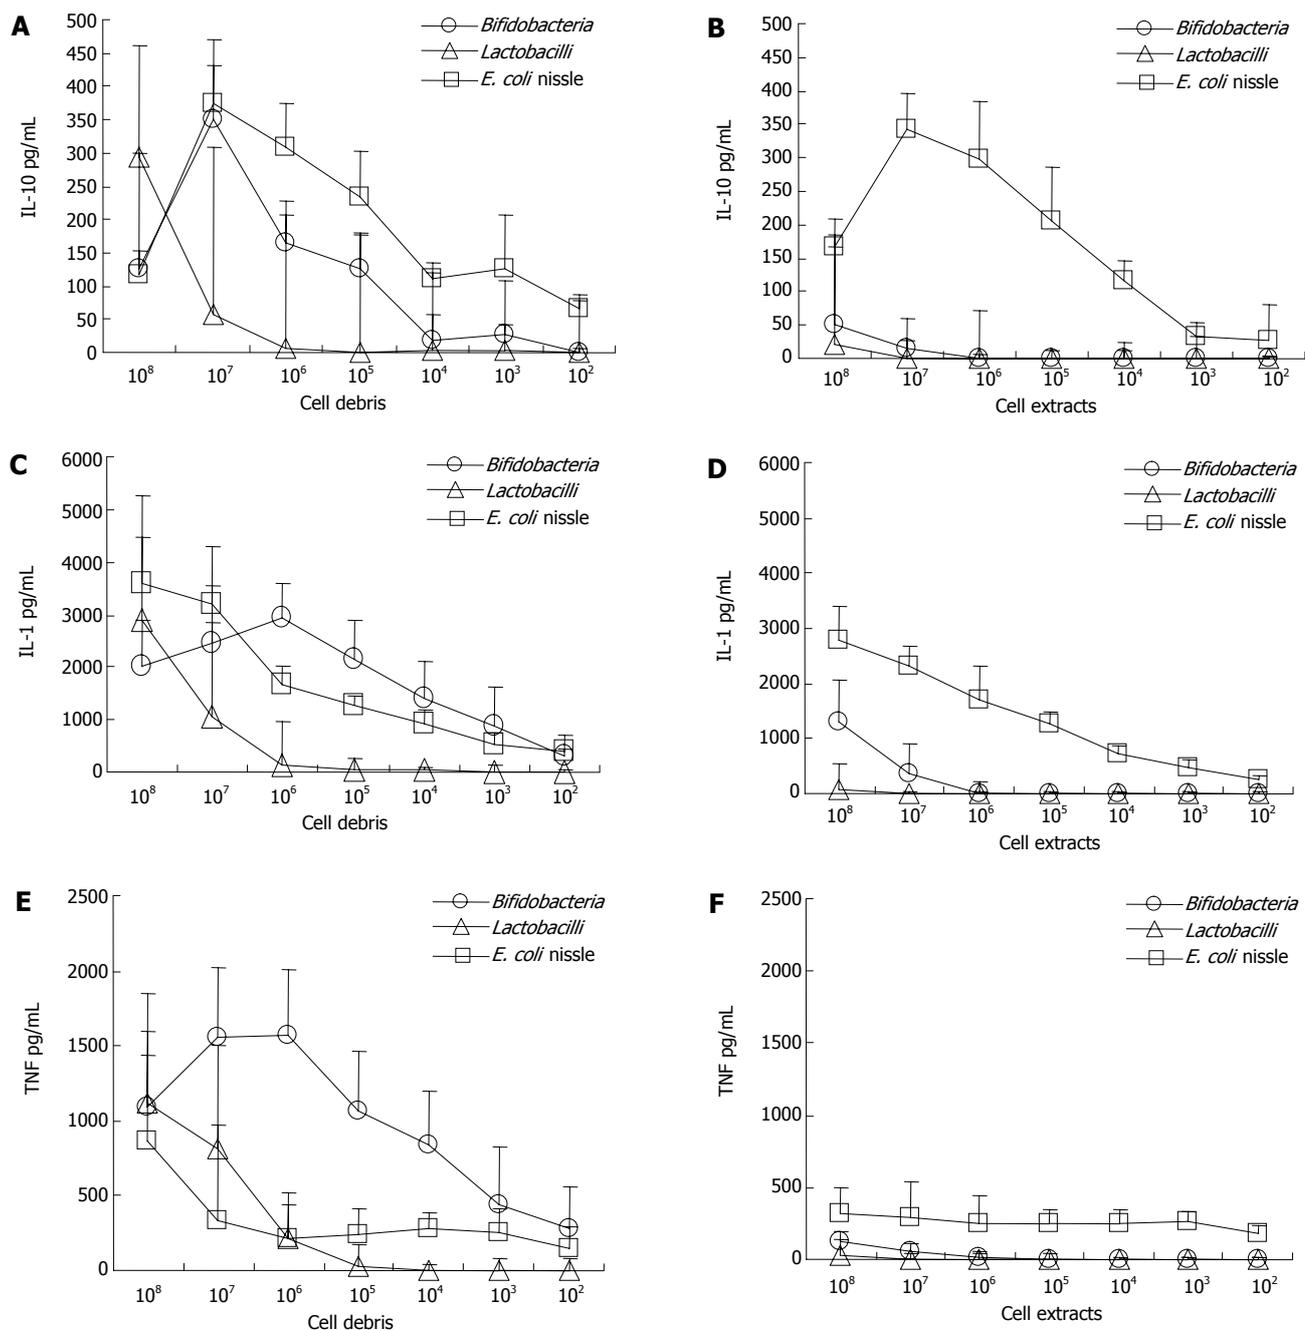

Figure 3 Cytokine concentrations of supernatant after incubation of PBMC with cell debris (left side) or cell extracts (right side) of bacteria from different species families in different concentrations. **A** and **B**: supernatant concentration of IL-10 in pg/ml (mean \pm SE); **C** and **D**: supernatant concentration of IL-1 β in pg/ml (mean \pm SE); **E** and **F**: supernatant concentration of TNF α in pg/mL (mean \pm SE).

had a similar stimulating capacity similar to *lactobacilli* but a significantly less capacity than that of *bifidobacteria* ($P < 0.02$) (Figure 4).

Inhibition of stimulated PBMC by bacterial cell debris and extract

None of the bacterial cell debris and extract of *lactobacilli*, *bifidobacteria* or *E. coli nissle* had an inhibitory effect on the cytokine production in PBMC. Pre-incubation with cell debris or with cell extract and stimulation with LPS led to similar cytokine production of LPS alone or cell debris alone (data not shown).

DISCUSSION

Different probiotic strains used in clinical trials have shown prophylactic properties in different inflammatory diseases of the gastrointestinal tract, such as Crohn's disease, ulcerative colitis, pouchitis, antibiotic-associated colitis and traveller's diarrhoea^[27-28]. Recently, we have shown that the IL-10 concentration in the mucosa of ileo- anal pouch tissue is elevated after administration of probiotics^[25]. In this *in vivo* approach we used a highly concentrated probiotic preparation containing different lactic acid bacteria. Our hypothesis is that a high concentration of bacteria contributes to these clinical results and

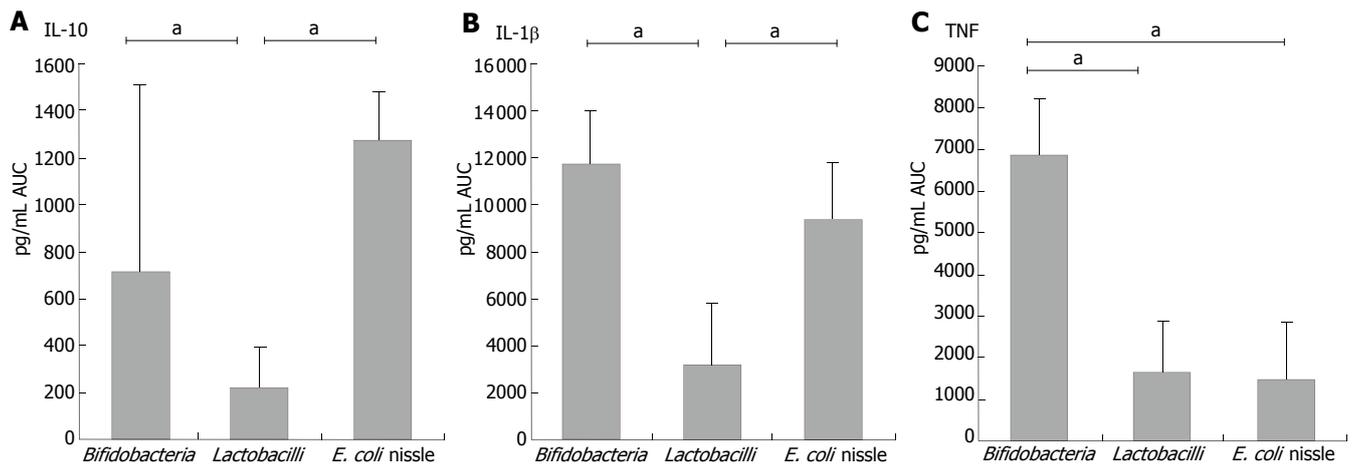

Figure 4 Supernatant concentrations of different cytokines after co-incubation of PBMC with cell debris of bacteria from different species families. With regard to *lactobacilli* results are pooled from *L.acidophilus*, *L.bulgaricus*, *L.casei*, *L.GG*, *L.plantarum*. With regard to *bifidobacteria* results are pooled from *B.breve*, *B.infantis*, *B.longum*. IL-10, IL-1 β and TNF α shown as area under the curve (mean \pm SE) ($^{\circ}P < 0.05$).

immunologic findings^[3]. However, the specific property of different strains remains unclear. Therefore, we investigated an *in vitro* model in order to test different probiotic strains and species, which are used in clinical practice to prevent inflammatory diseases, in order to understand the pro- and anti-inflammatory properties of specific strains. There are several studies on the induction of cytokines by cell components of lactic acid bacteria to induce cytokines^[29,31]. However, systematic analysis of probiotic bacteria used in clinical practice for the prevention of inflammatory disease, has not been performed until now in a human cell model. For this purpose we used PBMC which are easily available and express toll-like-receptor (TLR) 2 and TLR 4 as well as CD14 which are shown to mediate immune response to microbial components as peptidoglycan and lipoteichoic acid^[32-33]. Until now there is no report on comparison of dose response over a broad range of different concentrations of probiotic bacteria used in clinical practice for prevention of inflammatory bowel disease. Our findings on PBMC indicate that stimulation by *lactobacilli* works in a dose-dependent way. High doses of cell debris could stimulate PBMC to produce pro- and anti-inflammatory cytokines. The cell extract has a less stimulating capacity in a dose-dependent manner. An interesting finding is that the cell debris of *L. delbrueckii* subsp. *bulgaricus* MB453 and *L. plantarum* MB452 stimulates PBMC when used at concentrations higher than 10^4 CFU/mL, while both *L. azidophilus* MB443 and *L. casei* MB451 strains only require concentrations higher than 10^6 and 10^5 CFU/mL. Cell debris of *L. casei* subsp. *rhamnosus* (*L.GG*) had a very low stimulating capacity compared to other strains (Figure 1). The weak or even absent reaction at high concentrations of *lactobacilli* (10^6 or 10^5 CFU/mL) is not suspected. This phenomenon is reproducible in different blood donors and exists in all different *lactobacilli* strains when used for this examination. Schultz and co-workers^[34] recently showed that *L. casei* subsp. *rhamnosus* (*L.GG*), which had the lowest stimulating capacity in our study, induces immunologic tolerance to granulocytes after oral administration for several weeks. Since *lactobacillus*

strains normally are early inhabitants of the human gastrointestinal tract, oral tolerance to low concentrations of *lactobacillus* strains might generally develop^[35]. Although this is expected for *bifidobacteria*, they stimulate pro- and anti-inflammatory cytokines more significantly than *lactobacilli*. But the stimulation pattern is different. The highest concentration of *bifidobacteria* induces PBMC to produce less pro- and anti-inflammatory cytokines than lower concentrations of the strain. Whether the lower induction of cytokine release in incubation with highly concentrated cell debris is due to deletion or apoptosis of PBMC remains unclear. Toxic reaction or a reaction resulting in direct cell death can be excluded by the trypan blue control test which provides information about the functionality of cell membrane but not about the metabolic condition of cells. Recently, it has been proposed in a different model that *bifidobacteria* strains induce oral tolerance^[36] but also induction of oral tolerance to *E. coli* and *lactobacilli* has been reported^[37-38]. The stimulating capacity of *E. coli nisse* shows a different pattern. The cell extract and debris of *E. coli nisse* have a similar ability to produce cytokines. Interestingly, the cell debris and extract of *E. coli nisse* at low concentrations can stimulate epithelial HT29/19 cells to produce the chemotactic factor interleukin-8 (IL-8), whereas the cell debris and extract of *lactobacilli* and *bifidobacteria* do not stimulate epithelial HT29/19 cells to release IL-8^[38]. *E. coli nisse*, which has been shown to be effective in maintaining remission of ulcerative colitis, has a high stimulating capacity for IL-10 and IL-1 β compared to other strains, but a low capacity for TNF- α . *Bifidobacteria* of the probiotic composition VSL#3 of *bifidobacteria*, which can prevent inflammatory bowel disease, can stimulate PBMC to produce IL-10^[9,10]. *L. GG* can weakly stimulate PBMC to produce IL-10 and has no positive effect on inflammatory bowel disease^[7-8]. This is consistent with the findings in another study^[25]. *L. GG* has been primarily used in trials for prevention of relapses in Crohn's disease. It has been recently reported that Crohn's disease is associated with the polymorphism of the nucleotide-binding oligomerization domain 2

(NOD 2)^[39-40]. NOD 2 is a regulator of TLR 2-mediated response to microbial agents^[41] and Gram-positive bacteria like *lactobacilli* are typical ligands for TLR 2^[32]. Since the function of mutations in the NOD 2 gene in Crohn's disease is not clear^[42], explanation about the lacking effect of probiotics on Crohn's disease is warranted.

In conclusion, the ability of probiotic bacteria to stimulate PBMC is different. Compared to *E. coli* nissle and *bifidobacteria*, *lactobacilli* debris exerts effects only at high concentrations. Whereas the extract of *lactobacilli* and *bifidobacteria* has only weak effects, while the cell extract and debris of *E. coli* nissle have similar effects. The higher IL-10 response to *E. coli* nissle and *bifidobacteria* corresponds to the positive effect of these probiotic strains on inflammatory bowel disease compared to negative outcomes obtained with *lactobacilli*.

Abstract

AIM: To evaluate the intestinal motility changes evoked by 8 bacterial strains belonging to *Bifidobacterium*, *Lactobacillus* and *Streptococcus* genera within the probiotic preparation VSL#3.

METHODS: Ileum and proximal colon segments isolated from guinea-pigs were used as a study model. Entire cells and cell fractions (cell debris, cell wall fraction, cytoplasmatic fraction, proteinaceous and non-proteinaceous cytoplasmatic components) of VSL#3 strains and, as controls, *Escherichia coli*, *Salmonella aboni* and *Bacillus licheniformis* were tested in this *in vitro* model.

RESULTS: Among the bacterial cell fractions tested, only the cytoplasmatic fraction modified intestinal motility. *Lactobacillus* strains stimulated the contraction of ileum segment, whereas all probiotic strains tested induced proximal colon relaxation response. The non-proteinaceous cytoplasmatic components were responsible for the colon relaxation.

CONCLUSION: The results obtained in this study suggest that the proximal colon relaxation activity showed by the probiotic bacteria could be one of the possible mechanisms of action by which probiotics exert their positive effects in regulating intestinal motility.

INTRODUCTION

Probiotics are viable microbial cells that upon ingestion in specific numbers appear to have beneficial effects on the health and well-being of the host, beyond inherent basic nutrition^[1]. These health-promoting effects are predominantly related to reinforcement of the intestinal mucosal barrier against enteropathogens' colonization, immunostimulation and immunomodulation, anticarcinogenic and antimutagenic activities, improvement of lactose utilization, and reduction of serum cholesterol^[2].

Most probiotics are bacteria members of the genera *Lactobacillus* and *Bifidobacterium*, which represent important components of human gastrointestinal flora. However, other nonpathogenic bacteria, such as *Streptococcus*, some strains of *Escherichia coli* and *Enterococcus faecium*, and yeasts, such as *Saccharomyces boulardii*, have been used in probiotic preparations^[3].

Experimental and clinical studies support the use of probiotics in the treatment of intestinal disorders such as infectious diarrhea^[4-7], antibiotic diarrhea^[8-10], traveller's diarrhea^[11-13], irritable bowel syndrome or functional diarrhea^[14-18] and inflammatory bowel disease^[19-23]. In recent double-blind placebo controlled trials the efficacy of the probiotic preparation VSL#3 has been shown as maintenance treatment and prophylactic therapy in patients with diarrhea-predominant irritable bowel syndrome and pouchitis^[18,22-24]. VSL#3 (VSL Pharmaceuticals, Ft. Lauderdale, FL, USA) contains a mixture of eight different bacterial species at very high concentrations (450 billions/sachet of viable lyophilized bacteria). The preparation consists of three strains of *bifidobacteria* (*Bifidobacterium longum*, *Bifidobacterium breve*, *Bifidobacterium infantis*), four strains of *lactobacilli* (*Lactobacillus acidophilus*, *Lactobacillus casei*, *Lactobacillus delbrueckii* subsp. *bulgaricus*, *Lactobacillus plantarum*) and one strain of *Streptococcus thermophilus*.

To the best of our knowledge, there are no experimental data evaluating the effects of probiotic bacteria on

the intestinal motility. Functional assays could represent useful tools to investigate the effects evoked by the entire probiotic cells and/or their fraction on different segments of the intestinal tissue.

The aim of this study was to evaluate the effect of the eight strains within the probiotic preparation VSL#3^[18,21-23] on intestinal motility using ileum and proximal colon segments isolated from guinea-pigs. Entire bacterial cells, cell fractions of VSL#3 strains, and, as controls, *Escherichia coli*, *Salmonella aboni* and *Bacillus licheniformis*, were tested in this *in vitro* model.

MATERIALS AND METHODS

Bacterial strains and culture conditions

The following bacterial strains were used in this study: *Bifidobacterium breve*, *Bifidobacterium infantis*, *Bifidobacterium longum*, *Lactobacillus acidophilus*, *Lactobacillus casei*, *Lactobacillus delbrueckii* subsp. *bulgaricus*, *Lactobacillus plantarum* and *Streptococcus thermophilus*.

Bifidobacterium and *Lactobacillus* strains were grown anaerobically (Anaerobic System, Model 2028, Forma Scientific, Marietta, OH, USA) in MRS medium (Difco, Detroit, MI, USA) supplemented with 0.05% L-cysteine hydrochloride monohydrate (Merck, Darmstadt, Germany), at 37°C. *S. thermophilus* was cultured anaerobically in M17 medium (Difco) at 37°C. *Salmonella aboni* NCTC 6017, *Escherichia coli* ATCC 11105 and *Bacillus licheniformis* BGSC 5A24 were used as controls and grown aerobically in LB medium (Difco) at 37°C.

Preparation of bacterial cell fractions

Ten milliliter of the bacterial mid log cultures, counted by plating technique on the previously mentioned media, was collected by centrifugation (5000 × *g* at 4°C for 5 min), washed, and resuspended in 1 mL of De Jalon buffer (155 mmol/L NaCl, 5.6 mmol/L KCl, 0.5 mmol/L CaCl₂, 6.0 mmol/L NaHCO₃, 2.8 mmol/L glucose)^[25], obtaining a final bacterial concentration of 1 × 10⁹-1 × 10¹⁰ colony forming units (CFUs/mL). Subsequently the bacterial suspensions were sonicated (Bronson Sonifier W-250, Heineman, Schwäbisch, Germany) at power level 2 at 20% duty for 8 min and centrifuged at 8000 × *g* for 30 min to separate cell debris from crude extract. Cell debris was resuspended in 1 mL of De Jalon buffer. The crude extract was ultracentrifuged at 250 000 × *g* at 4°C for 2 h: the supernatant represents the cytoplasmatic fraction while the pellet, resuspended in 1 mL of 50 mmol/L TRIS.HCl pH 7.6, represents the fraction enriched in membrane proteins.

In order to obtain the bacterial cell wall fraction, bacterial cultures were centrifuged at 5000 × *g* at 4°C for 5 min, washed in 50 mmol/L Tris HCl pH 7.6, resuspended in 1 mL of protoplast buffer [50 mmol/L Tris HCl pH 7.6, 1 mol/L sucrose, 50 mL of completeTM protease inhibitor (Roche, Mannheim, Germany), 15 mg/mL lysozyme] and incubated at 37°C for 20 min. The supernatant was recovered by centrifuging at 5000 × *g* at 4°C for 5 min.

Proteinaceous components were precipitated by addition of 9 volumes of acetone:HCl (10:0.1) to one

volume of the cytoplasmatic fraction and collected by centrifuging at 12000 × *g* at 4°C for 5 min. Supernatant (non-proteinaceous fraction) and protein pellet were dried on ice under vacuum for removing acetone and resuspended in the initial volume of 50 mmol/L TRIS.HCl pH 7.6. The very low value of pH (about 1) of the non-proteinaceous fraction was adjusted to a value of 7.4 to overcome the unspecific colonic contractile response due to the acid pH. Similarly, the cytoplasmatic fraction was incubated with proteinase K (500 mg/mL) at 50°C for 1 h for the enzymatic digestion of the proteins. All the bacterial fractions of cell debris (i.e., cell wall fraction, membrane proteins, cytoplasmatic fractions, proteinaceous and non-proteinaceous cytoplasmatic components) were aliquoted and stored at -80°C before to be used in the *in vitro* stimulation of ileum and proximal colon.

SDS PAGE

Ten μL of *B. infantis* cytoplasmatic fraction, non-proteinaceous fraction and cytoplasmatic fraction deprived of proteins by proteinase K digestion was analyzed by SDS-PAGE, as described by Laemmli^[26], using a 12% polyacrylamide running gel. The gels were stained with silver nitrate.

Bacterial DNA preparation

Isolation of genomic DNA from pure cultures of the probiotic bacteria was performed as previously described^[27]. In order to obtain the complete cell disruption, the method was slightly modified by prolonging the enzymatic lysis for 1 to 3 h and grinding with glass beads (150-212 μm, Sigma, St. Louis, MO, USA). Concentration and purity of all DNA preparations were determined by measuring OD₂₆₀ absorbance and OD_{260/280} ratio, respectively. Only DNAs with an OD_{260/280} ratio > 1.8 were used.

Animals and preparation of Guinea-pig ileum and proximal colon

Guinea-pigs of either sex (200-400 g) obtained from Charles River (Calco, Como, Italy) were used. The animals were housed according to the ECC Council Directive regarding the protection of animals used for experimental and other scientific purposes. All procedures followed the guidelines of The Animal Care and Use Committee of The University of Bologna (Bologna, Italy). The animals were sacrificed by cervical dislocation, and the organ (ileum or proximal colon) required was set up rapidly under a suitable resting tension in 15-mL organ baths containing appropriate physiological salt solution (PSS) consistently warmed (see below) and buffered to pH 7.4 by saturation with 950 mL/L O₂ and 50 mL/L CO₂ gas.

Preparation of ileum

The terminal portion of ileum (3-4 cm near the ileo-caecal junction) was cleaned with Tyrode solution of the following composition: 118 mmol/L NaCl, 4.75 mmol/L KCl, 2.54 mmol/L CaCl₂, 1.20 mmol/L MgSO₄, 1.19 mmol/L KH₂PO₄·2H₂O, 25 mmol/L NaHCO₃, and 11 mmol/L glucose. The mesenteric tissue was removed. The ileum tissue was cut in two segments of 2-3 cm taken in the lon-

gitudinal direction along the intestinal wall. The segments were set up upright under 1-g tension in a jacketed tissue bath (15 mL, 37°C) containing Tyrode solution buffered to pH 7.4 by saturation with 950 mL/L O₂ and 50 mL/L CO₂ gas. Tissues were allowed to equilibrate for at least 30 min, during which time the bathing solution was changed every 10 min. After stabilization, the strips were challenged with 1 μmol/L carbachol (Sigma, Italy) to assess the responsive capacity of the tissue^[28].

Preparation of proximal colon

Starting approximately 1 cm distal from the caecocolonic junction, a segment of about 3 cm was excised, cleansed by rinsing it with De Jalon solution^[25], and the mesenteric tissue was removed. The proximal colon segment was cut in two segments of about 1 cm each taken in the longitudinal direction along the intestinal wall. The segments were set up upright under 1-g tension at 37°C in a jacketed tissue bath (15 mL, 37°C) containing De Jalon solution buffered to pH 7.4 by saturation with 950 mL/L O₂ and 50 mL/L CO₂ gas. Tissues were allowed to equilibrate for at least 30 min during which time the bathing solution was changed every 10 min. After stabilization, the strips were challenged with 5 μmol/L 5-hydroxytryptamine (5-HT) (Sigma, Italy) in the presence of 1 μmol/L atropine (Sigma, Italy) to assess the responsive capacity of the tissue.

Functional assays on ileum and proximal colon

After stabilization and assessment of the responsive capacity of the tissue in the organ bath, concentration-response curves were constructed by cumulative addition of the above described bacterial preparations (1 to 1500 μL). Each successive addition of bacterial preparations was performed after the response to the previous addition reached its maximum level and remained steady. Longitudinal muscle contractions or relaxations were recorded isometrically by securing one end of the tissue segments to a tissue holder and the other end to a force displacement transducer (FT. 03, Grass Instruments, Quincy, MA) using Power Lab software (ADInstruments Pty Ltd, Castle Hill, Australia). Each tracing was obtained by using separate intestinal strips.

Statistical analysis

Experiments were performed in duplicate with tissue from the same animal, and mean values were recorded. All data are presented as mean ± SE ($n = 3-5$ for ileum and $n = 5-7$ for proximal colon). Differences between means were calculated with Student *t*-test and *P*-values < 0.05 were considered statistically significant^[29-31].

RESULTS

Bacterial effect on motility response in guinea-pig ileum

The motility response of the guinea-pig ileum segment was investigated with increasing concentrations of the following components of the probiotic VSL#3 mixture: live bacteria, bacterial cell debris, and crude extracts. VSL#3 live bacteria and cell debris did not modify the guinea-pig ileum motility (data not shown), whereas crude

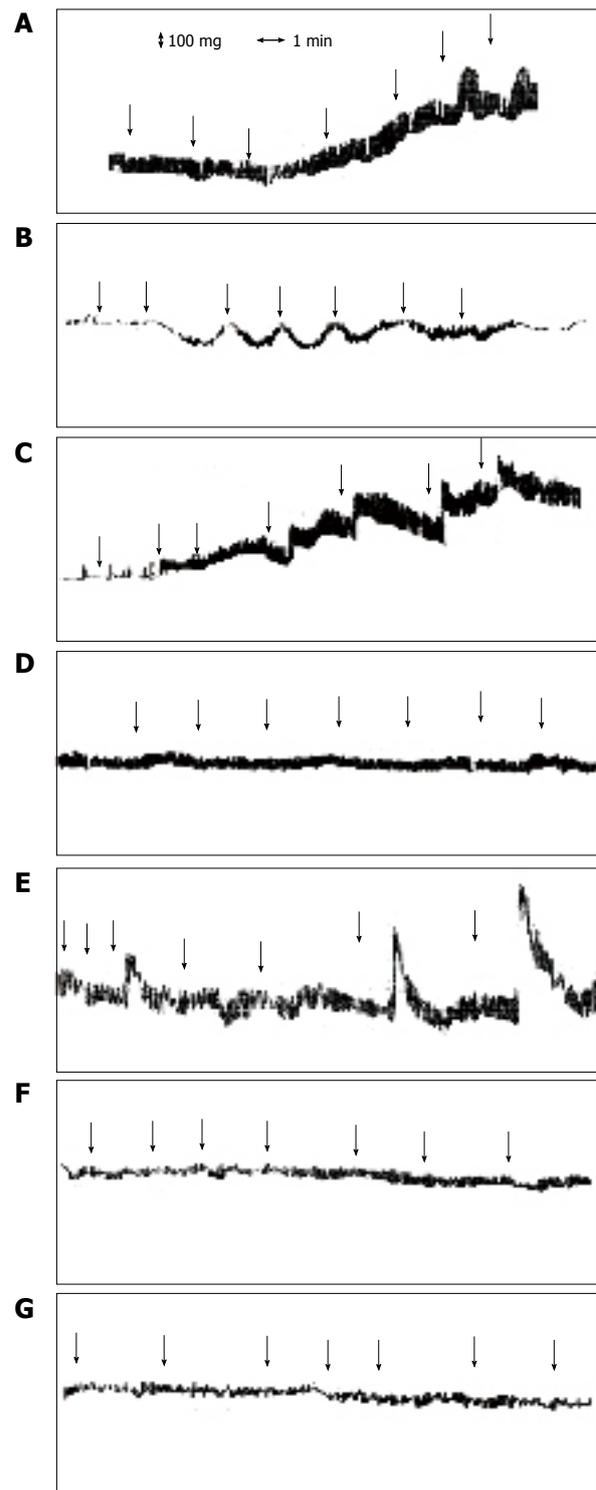

Figure 1 Recorder tracing of the cumulative dose of VSL#3 (A), *Bifidobacterium* (B), *Lactobacillus* (C), *Streptococcus thermophilus* (D), *Salmonella aboni* (E), *Escherichia coli* (F), and *Bacillus licheniformis* (G) crude extracts on the contractility of Guinea-pig isolated ileum. Arrows indicate the addition of 50, 100, 150, 200, 250, 300 and 350 μL of each crude extract tested.

extracts dose-dependently increased both spontaneous phasic and tonic contractions of the ileum (Figure 1A). The effects on motility induced by crude extracts persisted even after adjusting the pH of the solution from around 5.0, as found in the crude extract, to pH 7.4 and were reversible as the basal tone returned to initial values after

several washing steps (data not shown).

To identify the microbial genera within the VSL#3 cocktail responsible for the effects on motility in the guinea-pig ileum, crude extract mixtures of *Bifidobacterium* (*B. longum*, *B. infantis*, *B. breve*), *Lactobacillus* (*L. acidophilus*, *L. casei*, *L. plantarum*, *L. bulgaricus*), and *Streptococcus thermophilus* were individually tested. The following differences in the motility response by the crude extracts of the three probiotic genera were observed: (1) *Lactobacillus* strains induced a concentration-dependent contraction of the ileum, which was rapid in onset; (2) *Bifidobacterium* promoted a weak and transient stimulation of the ileum in a non concentration-dependent manner; (3) *Streptococcus* did not promote any significant response (Figures 1B-D).

The intestinal bacteria *Salmonella aboni* and *Escherichia coli* and the non-intestinal bacterium *Bacillus licheniformis* were used as controls to verify the specificity of the probiotic effects on gut motility (Figures 1E-G). Ileum motility was not affected by the exposure to *E. coli* and *B. licheniformis* crude extracts (Figures 1F, G), whereas *S. aboni* crude extracts were able to trigger the ileum contraction in a dose-dependent manner (Figure 1E). Furthermore, the amplitude of contraction induced by *S. aboni* was significantly higher than that promoted by the VSL#3 mixture and *Lactobacillus* crude extracts.

In order to verify the involvement of muscarinic receptors in the observed contraction response, the muscarinic antagonist atropine (1 $\mu\text{mol/L}$) was added to the organ bath. Atropine did not modify the motility response of ileal tissue exposed to all the bacterial crude extracts tested (data not shown).

Bacterial effect on motility response in guinea-pig proximal colon

The motility response of guinea-pig proximal colon segment was investigated using a similar protocol as with the guinea-pig ileum by adding identical concentrations of the bacterial cell preparations tested in the ileum stimulation study. Similar to the guinea-pig ileum, only the crude extracts of the probiotic VSL#3 mixture showed a significant effect on colon motility. However, the effect on the guinea-pig proximal colon was opposite to that observed in ileum (Figure 2A). In particular, the crude extract of the VSL#3 mixture elicited a rapid and sustained relaxation of the colon tissue, characterized by peaks in response to each addition, together with a progressive lowering of the basal tone. As previously carried out with the ileum, crude extract preparations at pH 5 and 7.4 were tested obtaining the same colon relaxation response (data not shown).

The VSL#3 extract mixtures of the genera *Bifidobacterium*, *Lactobacillus*, and *S. thermophilus* were assessed (Figures 2B-D). All the bacterial groups provoked a dose-dependent relaxation of the colon tissue, but no significant motility effect was observed by exposure to the control bacteria (Figures 2E-G). Clear colon relaxation effects were promoted by the crude extracts of *Bifidobacterium* strains and *S. thermophilus* and were quite similar to those induced by the crude extracts of the VSL#3 mixture (Figure 3). *Lactobacillus* strain's crude extract showed a lower relaxation

successive additions of all crude extracts tested restored the basal tone of the tissue (data not shown). A further investigation was carried out with the crude extracts of VSL#3 *B. infantis* and *L. casei* strains, representative of *Bifidobacterium* and *Lactobacillus* genera. Colon relaxation patterns induced by these samples were identical to those obtained with the crude extracts of *Bifidobacterium* and *Lactobacillus* mixtures (data not shown).

Effects of *B. infantis* cell components on colon motility

To confirm that bacterial cytoplasmatic components are mainly responsible for colon relaxation, a more refined fractioning of the *B. infantis* cells was performed by separating cell wall fraction, membrane proteins, and cytoplasmatic fraction. A concentration-response curve was constructed for each of these bacterial portions (Figure 4). Indeed, the cytoplasmatic fraction showed a sustained relaxation of the colon segment equal to that demonstrated by the *B. infantis* crude extract. As expected, the cell wall fraction and the membrane proteins did not produce any significant effect.

The cytoplasmatic fraction of *B. infantis* was further refined in proteinaceous and non-proteinaceous components. The absence of protein in the non-proteinaceous fraction was verified by SDS PAGE analysis (Figure 5). As reported in Figure 6, the effect on colon relaxation was induced by the non-proteinaceous components, which showed a motility response similar to

that exerted by the cytoplasmatic fraction. The relaxation effect exerted by the non-proteinaceous components was confirmed by colon motility experiments carried out with a *B. infantis* cytoplasmatic fraction deprived of proteins by proteinase K digestion. This preparation, in which the enzymatic protein degradation was demonstrated by SDS PAGE analysis (Figure 5), evoked a significant colonic relaxation response similar to that obtained with the buffered non-proteinaceous preparation (Figure 6). To further characterize the *B. infantis* non-proteinaceous cytoplasmatic components, the possible involvement of bacterial genomic DNA fraction was tested. Addition to the organ bath of *B. infantis* DNA ranging from 0.5 μg to 10 μg did not modify the colon motility (data not shown).

DISCUSSION

The gut represents a complex and dynamic microbial ecosystem in which intestinal microflora has important and specific metabolic, trophic, and protective functions. Normal gut structure and function are the end-point of a complex set of interactions between the host and microorganisms colonizing the gut^[2]. Several studies have shown that probiotics restore mucosal integrity and regulate the immune response. However, the effects of probiotics on the enteric nervous system and the intestinal musculature have not been systematically studied. This study was designed to investigate the motility response evoked by the probiotic preparation VSL#3 on the ileum and proximal colon isolated from guinea-pigs.

The choice of VSL#3, a formulation with a high viable concentration of *Bifidobacterium*, *Lactobacillus* and *Streptococcus thermophilus*, was based on the reported efficacy in bowel diseases associated with changes in propulsive motility of the gut, including diarrhea-predominant irritable bowel syndrome^[18]. Furthermore, in clinical trials these exogenous probiotic bacteria have been shown to transiently colonize the human gut^[19, 21, 22].

The data from this study show that the motility of isolated ileum is not influenced by the addition of either entire cells or cell debris of the VSL#3 mixture, whereas its crude extracts induce a dose-dependent contraction. It is noteworthy that VSL#3 crude extracts, which have a pH of about 5, and crude extracts in which the pH was increased up to physiologic value of 7.4 showed

similar contractile responses. These results demonstrate that the ileum motility response is not related to the pH of the bacterial fraction and suggest that some bacterial metabolites could be involved in the contractions. Furthermore, as the presence of atropine ($1 \mu\text{mol/L}$) in the organ bath throughout the experiments did not determine a decrease of contraction induced by the addition of the VSL#3 crude extracts, the mechanism of action of the bacterial fractions does not involve muscarinic receptors.

Crude extracts of the different bacterial groups within the VSL#3 preparation provoke different motility response patterns. *Bifidobacterium* and *Streptococcus* strains did not change the basal tone of the ileum tissue, while *Lactobacillus* strains induced relevant ileum contractions. However, this contractile response is observed with volumes of cell extracts corresponding to *lactobacilli* concentration values of at least 10^7 CFU/mL, a value that is generally not detectable at ileum level of healthy humans^[27]. This result suggests that the contractile effect evoked in ileum by VSL#3 cell extracts will be of minor importance *in vivo* at ileum level, as the rapid transit of ileum content and the low bacterial titer do not allow it to reach sufficient bacterial lysis or metabolic secretion. Furthermore, it is noteworthy that the contractile response induced by *Lactobacillus* is lower than that promoted by crude extracts of intestinal *S. aboni* added at the same concentration.

Like the guinea-pig ileum, the motility of guinea-pig proximal colon segment is modified by crude extracts of the VSL#3 mixture, while entire bacterial cells and cell debris do not exert any effect. The crude extract of all the probiotic strains (*Bifidobacterium*, *Lactobacillus* and *S. thermophilus*) included in VSL#3 induced dose-dependent relaxation of the proximal colon tissue, whereas the crude extracts of the control strains did not influence colon motility. These results suggest that the ability to induce a colon relaxation response is specific for these probiotic bacteria. Furthermore, the proximal colon relaxation response induced by probiotic bacteria cell extracts is reversible as successive washings abolished the colon relaxation. The restoration of the basal tone of the proximal colon tissue after removing the stimuli by several washings suggests that colonic tissue is not damaged. Volumes of cell extracts from *Bifidobacterium*, *Lactobacillus* and *Streptococcus* inducing the relaxation response correspond to bacterial titer values that are in the range of the physiological concentrations measured in colon^[19].

Since *B. infantis* has been shown to colonize the human gut more efficiently than the other VSL#3 bacterial strains^[22], we used this strain to further investigate the components of probiotic bacteria involved in the guinea-pig colon relaxation. Interestingly, only the cytoplasmatic fraction of the cell showed a pronounced colon relaxation activity. The bacterial cytoplasmatic fraction may well have physiological implications, because its specific components reach the intestinal lumen as metabolites actively secreted by the viable bacteria colonizing the intestinal epithelium. In addition, the entire bacterial cytoplasm is released in the gut lumen following cell lysis. Further, subdivision of the bacterial cytoplasm allowed us to demonstrate that the

non-proteinaceous cytoplasmatic portion was responsible for the colon relaxation, whereas protein factors had no effect on proximal colon relaxation. This result has been confirmed by challenging the colon tissue with bacterial cytoplasmatic fractions digested with proteinase K.

Since the cytoplasmatic fraction deprived of the protein component contains significant amounts of genomic DNA, which in prokaryotic microorganisms is not confined to a nucleus, the proximal colon segment was tested with the bacterial genomic DNA. The DNA preparation extracted from *B. infantis* did not cause any changes in colonic motility, indicating that other unidentified non-proteinaceous factors may be involved.

In conclusion, this is the first study performed in isolated tissues that deals with the effects of probiotic bacteria on intestinal motility. Our results suggest that *Bifidobacterium*, *Lactobacillus* and *Streptococcus* strains in VSL#3 mediate proximal relaxation activity. This could be one of the possible mechanisms of action by which probiotic bacteria exert their effects in ameliorating diarrhea by reducing stool frequency and restoring a disturbed microbial balance. Based on these data, further studies to elucidate the implication of a large array of receptor families and subtypes known to affect gut function and to characterize the non-proteinaceous bacterial molecules involved in intestinal motility are warranted.

Abstract

AIM: To investigate the role of genes and kinetics of specific transcription factors in liver regeneration, and to analyze the gene expression and the activity of some molecules crucially involved in hepatic regeneration.

METHODS: USING gel-shift assay and RT-PCR, transcription factors, such as NF- κ B, STAT-3, SMAD3 and AP-1, and gene expression of inducible nitric oxide synthase (iNOS), hepatocyte growth factor (HGF) and c-met were analyzed in an animal model of chemically induced hepatectomy.

RESULTS: Gene expression of HGF and its receptor c-met peaked at 3 h and 24 h after acute CCl₄ intoxication. iNOS expression was only observed from 6 to 48 h. Transcriptional factor NF- κ B had an early activation at 30 min after acute liver damage. STAT-3 peaked 3 h post-intoxication, while AP-1 displayed a peak of activation at 48 h. SMAD3 showed a high activity at all analyzed times.

CONCLUSION: TNF- α and IL-6 play a central role in hepatic regeneration. These two molecules are responsible for triggering the cascade of events and switch-on of genes involved in cell proliferation, such as growth factors, kinases and cyclins which are direct participants of cell proliferation.

INTRODUCTION

The liver is a unique organ with with ability to regulate its growth. This capacity can be altered at various different conditions like tissue dismissal and cell loss caused by chemical or viruses^[1]. Specific molecules are involved in the molecular events originated from these processes. One of these molecules is IL-6 which is an important factor for liver regeneration and repair after injury^[2]. IL-6-deficient mice fail in regenerating its hepatic gland presenting liver necrosis, functional failure, blunted DNA response in hepatocytes, absence of STAT-3 and NF- κ B activation, and selective dysfunction in AP-1, c-myc and cyclin D1 gene expression^[3]. IL-6 signals via STAT-3, and STAT-3 activation increase in an IL-6-dependent manner post-hepatectomy (PH) and post acute CCl₄ intoxication peaking at 2 h^[4,5] and returning to basal levels at 12 h^[6]. IL-6 is also an activator of AP-1 expression in liver regeneration^[3]. AP-1 and STAT-3 act in a synergistic fashion enhancing transcription^[7]. In our previous study IL-6 was strictly detected only at 24 h after acute CCl₄ intoxication. We could not detect IL-6 mRNA in rats intoxicated with turpentine, indicating the need of the presence of acute phase response for hepatocyte proliferation^[8]. On the other hand, TNF- α has also been shown as a major effector of signal pathways of liver regeneration^[9]. Several lines of evidence invoke the role of TNF- α in the regulation of IL-6 secretion through a previous induction of NF- κ B^[10]. Our previous results showed that induction of TNF- α gene expression takes place as early as 6 h, peaking at 48 h post-acute CCl₄ intoxication and this expression might induce IL-6 production^[8]. In correlation with our results, others have shown that TNF- α activates NF- κ B in many cells within 30 min after intra-peritoneal injection^[11]. TNF- α and IL-6 also induce iNOS transcription through NF- κ B activity^[12] which occurs principally in hepatocytes due to NO production,

and is detected in these cells just after partial hepatectomy and before cell proliferation^[13]. HGF, the major growth factor involved in hepatocyte proliferation, signals through its receptor c-met, a transmembrane tyrosine kinase protein product of the proto-oncogene with the same name^[14]. HGF is produced by hepatic stellate cells (HSCs) and acts on cultured hepatocytes in a paracrine manner as a potent mitogen^[14,15]. HGF production is induced in animals by partial hepatectomy and hepato-toxin^[16], detecting the mature form in significant levels^[17]. The results in animal models correlate with the elevated levels of serum HGF in patients with hepatic disorders^[18]. In this study, we aimed to elucidate the kinetic of activation of several transcription factors and molecular mechanisms involved in hepatic regeneration in an animal model. Furthermore, we shed light on how these transcription factors are involved in the resolution of this process. The early activation of NF- κ B, STAT-3 and AP-1 along with the expression of iNOS, HGF and c-met observed in this study suggested that induction of events like production of TNF- α , IL-6, HGF and some proteins are involved in cell proliferation. Knowledge obtained regarding activation of these transcription factors might enable us to propose new pharmacological strategies of treatment for induction of hepatic regeneration in some cases of cirrhosis.

MATERIALS AND METHODS

Animals

Forty male Wistar rats (Charles Rivers Inc., Boston, MA), weighting 200 g, were used in this study and housed according to the principles and procedures outlined by the National Institute of Health's Guide for the Care and Use of Laboratory Animals. For acute intoxication experiments, five rats for each time point were intragastrically administered a single dose of a mixture 1:1 (v/v) of CCl₄ (Merck Company, Darmstadt, Germany) and mineral oil (Sigma Chemical Company, St Louis MO, USA) at 5 mL/kg of body weight. Control animals were administered a same volume of vehicle. Animals were sacrificed at 0.5, 1, 3, 6, 12, 24, and 48 h after CCl₄ intoxication. Livers were removed, immediately frozen in CO₂-acetone and stored at -70° until use.

Extraction and quantification of RNA

Isolation of total RNA from rat livers was carried out according to the modified method described by Chomczynski *et al*^[19]. Briefly, liver tissue was taken from three different lobes to obtain a representative sample and homogenized using a Polytron System (Brinkmann, Switzerland) in the presence of Trizol (Invitrogen). Chloroform was added, the aqueous phase was obtained and the RNA was precipitated from the aqueous phase by isopropanol at 4°C overnight. Quantity and intactness of RNA were routinely tested by determining absorbance (*A*) at 260/280 and ethidium bromide fluorescence of RNA electrophoresis on 10 g/L formaldehyde-containing agarose gels.

Analysis of iNOS, c-met and HGF gene expression

Expressions of iNOS, c-met and HGF gene were detected

using RT-PCR as previously described^[8]. We amplified the target genes iNOS, c-met, HGF and the constitutive gene HPRT in different reaction tubes. RNA from liver samples was isolated with Trizol and 2 g of total RNA was reverse transcribed into complementary DNA (cDNA) using 0.05 mol/L Tris-HCl (pH 8.3), 0.04 mol/L KCl, 0.007 mol/L MgCl₂ buffer containing 0.05 g/L random hexamers (Invitrogen), 0.001 mol/L dNTPs mix (Invitrogen), 50 U/L RNase inhibitor and 400 U of Moloney murine leukemia virus reverse transcriptase (M-MLV) (Invitrogen). Samples were incubated for 10 min at 25°C and then for 60 min at 37°C. Reverse transcriptase was further inactivated by heating the sample tubes at 95°C for 10 min. The cDNAs were used to perform PCR reaction according to the optimal amplification conditions for each gene. Amplification was performed in a PCR buffer of 0.05 mol/L Tris-HCl (pH 9.0) and 0.05 mol/L NaCl containing a mixture of 1×10^{-4} mol/L dNTPs and 1 unit of Taq DNA polymerase (Invitrogen). Amplification reactions were overlaid with light mineral oil and held at 94°C for "hot-start" PCR for 3 min and then run in an automated thermal cycler for different number of cycles and incubation temperatures according to each gene. Each PCR reaction was repeated at least in triplicate. Annealing temperature, number of cycles and primer sequence for each gene are shown in Table 1.

Nuclear extract isolation

Isolation of nuclear proteins was carried out according to the methods described by Andrews *et al*^[20], with a few modifications. Briefly, 1 g of liver from CCl₄-treated and controls rats was homogenized in 5×10^{-4} L of buffer A (0.01 mol/L Hepes-KOH (pH 7.9), 250 g/L glycerol, 0.420 mol/L NaCl, 0.0015 mol/L MgCl₂, 2×10^{-4} mol/L EDTA, 5×10^{-4} DTT, 2×10^{-4} PMSF) to disrupt extracellular matrix and cellular membranes. Homogenates were centrifuged at 1200 r/min for 10 s at 4°C. The pellet was resuspended in 2.5×10^{-4} L of buffer C (0.02 mol/L Hepes-KOH (pH 7.9), 250 g/L glycerol, 0.42 mol/L NaCl, 15×10^{-4} mol/L MgCl₂, 2×10^{-4} mol/L EDTA, 5×10^{-4} mol/L DTT, 2×10^{-4} mol/L PMSF), homogenized and incubated at 4°C for 20 min. Cellular debris was removed by centrifugation at 4°C for 2 min. Supernatant fraction containing DNA binding proteins was recollected and quantified as described by Bradford^[21]. Supernatant was stored at -70°C in aliquots until use.

Gel mobility shift assays

Electrophoretic mobility shift assay (EMSA) was performed as described elsewhere^[3]. Binding reactions were prepared using 2 g of nuclear extracts from either acutely damaged rat livers or from control animals. Additionally, 100000 cpm of radioactive probe and 1.2 g of poly (DI-DC) as a non-specific DNA competitor were included in the binding reactions. Mixtures were incubated for 30 min at room temperature in binding buffer containing 0.01 mol/L Hepes (pH 7.5), 0.05 mol/L NaCl, 0.001 mol/L EDTA and 100 g/L glycerol. For competition assays, a 100-fold excess of unlabeled probe was added to the reactions concomitantly with the hot probe. For supershift experiments, 1 mL of antibody against NF- κ B,

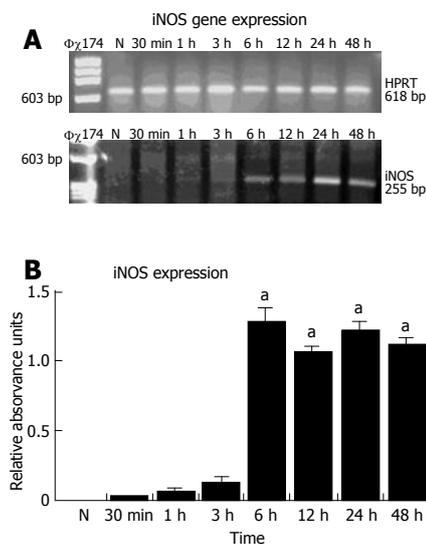

Figure 1 Semiquantitative RT-PCR analysis for iNOS expression. **A:** PCR products analyzed by agarose electrophoresis; **B:** normalized values of iNOS expression with respect to the housekeeping gene HPRT in all analyzed groups of three different PCR reactions performed.

STAT-3, AP-1 or SMAD3 (Santa Cruz Biotechnology) was incubated with the reaction mixture for 1 h at room temperature before regular incubation. The reactions were analyzed on 5% acrylamide non-denaturing gels in $0.5 \times$ Tris-borate-EDTA buffer, dried and exposed. Intensity of each band, as the measure of DNA binding activity, was assessed by densitometric scanning Kodak ID 3.6 program. For gel retardation experiments, single-stranded oligonucleotides were obtained from Sigma and annealed

in water. For annealing of complementary oligonucleotide pairs, 5 μ g of each single-strand oligonucleotide was adjusted to a final volume of 5×10^{-5} L and placed on a heating blocker at 95°C for 5 min. Then the blocker was turned off and left to reach room temperature. Double-strand probe end labeling was performed using T4 polynucleotide kinase (Gibco) in the presence of (γ -32P) ATP. Each gel-shift experiment was performed in triplicate. Probe sequences for NF-κB, STAT-3, SMAD3 and AP-1 are shown in Table 2.

Statistical analysis

Results were expressed as mean \pm SD. Student's *t* test was used to analyze the data. $P < 0.05$ was considered statistically significant.

RESULTS

After normalization against the housekeeping gene HPRT, iNOS expression was detected at 6 h after acute liver damage and continued up to 48 h, being statistically different at these times ($P < 0.05$). However, iNOS expression was not detected before 6 h (Figure 1).

The hepatocyte growth factor (HGF) and its cognate receptor c-met mRNAs after CCl₄ acute intoxication are presented in Figure 2. Two peaks of gene expression were observed in both genes: one at 3 h and another at 24 h where significant difference was seen only at 24 h ($P < 0.05$).

It has been shown that transcription factors are

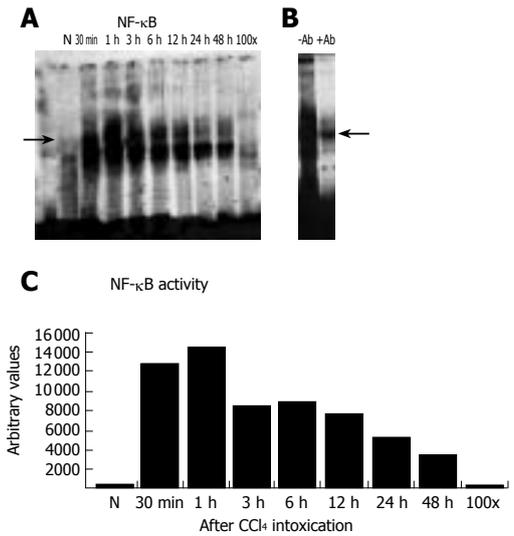

Figure 3 Binding activity of NF-κB in acute liver damage. Wistar rats were intoxicated acutely with CCl₄ and then sacrificed at different time points. activated during hepatic regeneration in different hepatectomy models^[9,22,23]. To determine the role and kinetic of activation of transcription factors critically involved in hepatic regeneration after acute CCl₄ injury, we performed gel-shift assays to evaluate the binding activity of NF-κB, STAT-3, SMAD-3 and AP-1 on DNA probes containing consensus sequences. We performed a chronological analysis between 0.5 h and 48 h after liver damage, since it has been reported by others and us, that the inflammatory process has declined and cell proliferation has concluded by this time^[24]. Transcriptional

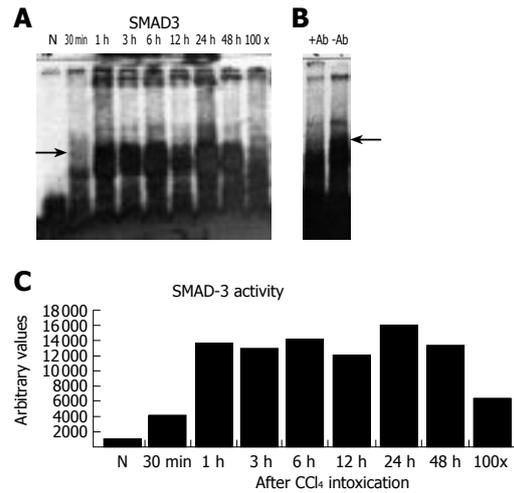

Figure 5 Binding activity of SMAD3 in acute liver damage. Gel-shift and supershift assays were performed to analyze SMAD3 DNA binding activity. **A:** Binding DNA activity of SMAD3 after CCl₄ intoxication; **B:** supershift assay using 24-h sample; **C:** densitometric analysis of results of EMSA assay.

factor NF-κB presented strong DNA binding activity from 30 min after CCl₄-induced injury, peaking at 1 h and decreasing thereafter. Nevertheless, 48 h after CCl₄-induced injury, NF-κB activity did not return to normal levels (Figure 3A). To confirm the specific binding activity of NF-κB, we performed supershift assay using specific anti-NF-κB antibodies. The use of a polyclonal antibody against the p65 subunit of NF-κB decreased the binding of this transcription factor to the labeled probe, suggesting the binding of the antibody to the DNA binding site of the transcription factor (Figure 3B). Furthermore, almost complete elimination of the radiolabeled band, when a 100-fold cold DNA probe was used, confirmed the specificity of our results. These results were confirmed by densitometric analysis (Figure 3C).

With respect to STAT-3 activity, our results showed an increase at 30 min after intoxication, presenting the maximum activity at 3 h, and then decreasing and disappearing completely by 48 h (Figure 4A). We also made a supershift assay for this transcription factor obtaining a clear DNA binding reduction. The data suggest that, in our experimental conditions, this antibody preferentially binds to the DNA binding site on the transcriptional factor, thus hindering formation of STAT-3-DNA consensus site complex. This piece of data verifies that the results corresponded to this transcription factor (Figure 4B). These results were confirmed by densitometric analysis (Figure 4C).

On the other hand, SMAD3 showed a strong binding activity in this animal model at all analyzed times, as was confirmed by densitometric analysis at 1 h after CCl₄ intoxication until 48 h (Figures 5A and C). The specificity of the binding activity was analyzed by supershift assay (Figure 5B).

The transcription factor AP-1 showed a basal activity in normal animals. This activity increased as early as 30 min after CCl₄-induced injury and increased progressively showing the maximum peak in the last analyzed time in

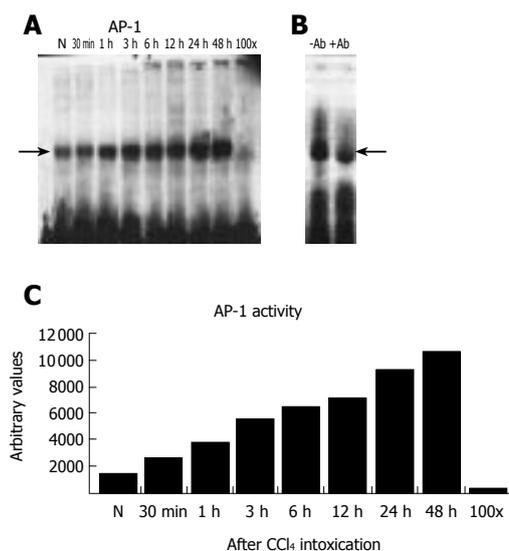

Figure 6 Binding activity of AP-1 in acute liver damage. EMSA and supershift assays, similar to Figures 3 and 4, were performed to analyze AP-1 activity in the same samples. **A:** Binding DNA activity of AP-1 after CCl₄ intoxication; **B:** supershift assay using 24-h sample; **C:** densitometric analysis of results of EMSA assay.

this study, 48 h after intoxication. Figures 6A-B clearly show the specificity of AP-1 DNA-binding activity when an excess of cold probe and specific anti-AP-1 antibody were used to override the binding of nuclear factor to the radiolabeled DNA-consensus sequence. These results were confirmed by densitometric analysis (Figure 6C).

DISCUSSION

The increase in DNA binding activity of the transcription factors NF- κ B, STAT-3 and AP-1 analyzed in this study indicates that hepatic regeneration process in response to CCl₄-induced acute liver damage requires the switch on and the switch off of many genes. These genes include cytokines, growth factors, kinases and cyclins which regulate cell cycle and induce hepatocyte proliferation. Our previous study demonstrated that expression of IL-6 is strongly associated with hepatic regeneration^[8]. We observed IL-6 gene expression in acute liver damage between 6 and 24 h, and disappeared thereafter. Other pro-inflammatory cytokines like IL-1 β and TNF- α also show strong expression around 24 h after liver damage^[24,25]. Because NF- κ B is required for TNF- α and iNOS production^[12], our results suggest that the strong inflammatory response present in CCl₄-intoxicated animals causes oxidative stress manifested as an increase in NF- κ B activity which induces iNOS expression. Although the maximum activity of NF- κ B was detected at 1 h post-CCl₄ intoxication, and iNOS expression was not observed before 6 h, suggesting that some hours are required for iNOS RNA to be detected. This inflammation is accompanied with damage and death followed by hepatocyte proliferation where TNF- α plays an important role^[26]. The activation of NF- κ B, STAT-3, SMAD3 and AP-1 allows their migration to the nucleus, where they can bind to their consensus sequence and induce the

expression of several genes involved in inflammation and cell proliferation^[27]. TNF- α promoter contains multiple binding sites for NF- κ B being a vital component for its expression and a ubiquitous oxidative stress-sensitive transcription factor^[28]. NF- κ B is found in almost all cell types, including hepatocytes and non-parenchymal cells^[29]. In absence of NF- κ B, TNF- α functions as an apoptotic agent in liver development. The NF- κ B inhibitor (I κ -B) degradation is enhanced by reactive oxygen species that can be generated by TNF and many other agents and cellular processes^[30].

Evidence indicates that blockade of NF- κ B in the regenerating liver by expression of NF- κ B super-repressor in an adenovirus vector leads to apoptosis after the cells have replicated their DNA^[31]. Similarly, introduction of I κ -B in an adenovirus vector after partial hepatectomy in mice results in increased liver injury and decreased hepatocyte cell proliferation.

On the other hand, transcription factor STAT-3 is also activated after partial hepatectomy but its activation is delayed compared to NF- κ B. STAT-3 becomes activated mainly by IL-6 type cytokines^[32]. Binding of IL-6 causes dimerization of the receptor, activation of tyrosine kinases which phosphorylate gp130 and create docking sites for STAT-3 binding. IL-6/STAT-3 signaling pathway is involved in cell proliferation through the induction of cyclins D1, D2, D3, A, cdc25A and concomitant down-regulation of cyclin-dependent kinase (cdk) inhibitors p21 and p27^[33,34]. p53, mdm2, p21, cyclins and cdk genes are also activated. STAT-3 activation observed in this study is in agreement with previous reports which demonstrated binding activity as early as 30 min using partial hepatectomy model to induce liver regeneration^[1,23]. SMAD3 have been found to be involved in hepatic stellate cell activation and collagen production after liver damage^[34], since high level of transcription factor SMAD3 could be detected even after 48 h of CCl₄ intoxication. These results suggest that liver damage caused by CCl₄ intoxication has not resolved at this time and some genes involved in the damage resolution activated by SMAD3 like TGF- α and collagen I are being expressed.

The role of AP-1 in the expression of molecule participants in cell proliferation, such as c-myc, D1 cyclin and cell growth factors, have been reported^[25]. The results obtained with AP-1 support, in fact, the role of AP-1 in hepatic regeneration. In this study, we observed a higher activity of AP-1 and also the maximum hepatocyte proliferation between 24 h and 48 h after CCl₄-induced liver damage, which are in agreement with previous studies^[35,36]. The initiation step called "priming step" appears to be mediated by TNF- α and IL-6 and their downstream pathways involving activation of NF- κ B, STAT-3 and AP-1^[1,37]. Activation of these transcription factors leads the progression to G1 phase of the cell cycle^[33]. "Priming" of hepatocytes induces them to respond to extra- and intra-hepatic growth factors, such as epidermal growth factor (EGF), transforming growth factor- β (TGF- β) and HGF^[1]. In this study, we found HGF gene expression and its receptor c-met peaking at 1 and 24 h after the liver damage. These results allow to us think that HGF expression could be induced by two

different pathways involving two different molecules, first TNF- α and then IL-6. Since HGF strongly stimulates DNA synthesis in damaged hepatocytes, an increase in HGF and its receptor mRNA expression suggests that liver regeneration is taking place^[15,17].

TNF- α signals through two distinct receptors: TNFR-1 and TNFR-2^[38]. Mice lacking functional TNFR-2 show completely normal DNA replication after hepatectomy and CCl₄ treatment. In contrast, lack of signaling through TNFR-1 greatly inhibits DNA replication after partial hepatectomy and cause significant mortality 24-40 h after the operation^[39]. In TNFR-1-knockout mice, activation of NF- κ B and STAT-3 is inhibited and AP-1 activation is decreased. The signal transduction pathway starting from TNF- α required for liver regeneration involves TNFR-1 with NF- κ B activation. The sequence of events proposed for liver regeneration after CCl₄-intoxicated acute liver damage is similar to that observed with different animal models like partial hepatectomy. However, the time of activation seems to be more delayed. The sequence of these events is as follows: TNF- α binds to TNFR-1 and induces activation of NF- κ B, NF- κ B binds to IL-6 promoter and the protein is produced. IL-6 activates STAT-3, which in turn activates AP-1. AP-1 participates in expression of the genes involved in hepatocyte proliferation, such as D1 cyclin, c-myc and kinases^[7,9].

In conclusion, TNF- α and IL-6 are responsible for triggering the cascade of events and switch-on of genes involved in cell proliferation, such as growth factors, kinases and cyclins which are direct participants of cell proliferation.

be of lesser importance for regulation of SERCA than in heart. Lower expression of Ca²⁺ storage proteins (CSQ and CRT) might contribute to increased lower esophageal sphincter pressure in achalasia, possibly by increasing free intracellular Ca²⁺.

Abstract

AIM: To compare expression of Ca²⁺-regulating proteins in upper gastrointestinal (GI) tract of achalasia patients and healthy volunteers and to elucidate their role in achalasia.

METHODS: Sarcoplasmic reticulum Ca²⁺ ATPase (SERCA) isoforms 2a and 2b, phospholamban (PLB), calsequestrin (CSQ), and calreticulin (CRT) were assessed by quantitative Western blotting in esophagus and heart of rats, rabbits, and humans. Furthermore, expression profiles of these proteins in biopsies of lower esophageal sphincter and esophagus from patients with achalasia and healthy volunteers were analyzed.

RESULTS: SERCA 2a protein expression was much higher in human heart (cardiac ventricle) compared to esophagus. However, SERCA 2b was expressed predominantly in the esophagus. The highest CRT expression was noted in the human esophagus, while PLB, although highly expressed in the heart, was below our detection limit in upper GI tissue. Compared to healthy controls, CSQ and CRT expression in lower esophageal sphincter and distal esophageal body were significantly reduced in patients with achalasia ($P < 0.05$).

CONCLUSION: PLB in the human esophagus might

INTRODUCTION

Intracellular Ca²⁺ regulates contractility in striated, smooth, and heart muscle. In the heart, expression of the most important proteins for intracellular Ca²⁺ homeostasis has been studied extensively. β -adrenoceptor agonists elevate Ca²⁺ by activation of cAMP-dependent protein kinase (PKA) and subsequent phosphorylation of regulatory proteins. The predominant protein phosphorylated in cardiac sarcoplasmic reticulum (SR) by PKA is phospholamban (PLB). The best characterized function of phospholamban is the regulation of the activity of the SR or endoplasmic reticulum (ER) Ca²⁺-pump (SERCA). In isolated guinea-pig hearts, β -adrenergic stimulation leads to phosphorylation of PLB and, at the same time, Ca²⁺-uptake into the SR is increased^[1]. PLB in its dephosphorylated state lowers the Ca²⁺ affinity of SERCA, while phosphorylation of PLB reduces the affinity of SERCA for Ca²⁺. Therefore, PLB phosphorylation increases the rate of Ca²⁺-transport into the SR. As a consequence, the rate of cardiac relaxation as well as contraction increase^[2,3]. SERCA itself is coded by three genes in mammals: SERCA 1, 2, and 3^[4]. SERCA 1 usually is expressed in fast-twitch skeletal muscle and SERCA 3 in non-muscle cells. For SERCA 2, two splice variants are known: SERCA 2a and SERCA 2b, the latter containing 49 additional amino acids at the carboxyterminal end^[5]. In the heart SERCA 2a

is the predominant isoform, whereas SERCA 2b is found mainly in smooth muscle, but smaller amounts have been recognized also in other tissues like heart^[6].

Intracellular rapidly exchanging Ca^{2+} stores provide the possibility for release, uptake, and storage of Ca^{2+} transported into SR by SERCA. Ca^{2+} -binding proteins with high capacity and low affinity for Ca^{2+} -binding permit rapid Ca^{2+} release. At least two families of these Ca^{2+} -binding proteins have been described, namely calsequestrin (CSQ) and calreticulin (CRT). CSQ is found in skeletal muscle and heart, while CRT is more widely distributed^[7,8]. CSQ is coded by two genes, the skeletal muscle isoform (CSQ1) coding for a 62-ku protein, and the cardiac isoform (CSQ2) coding for a 51-ku protein^[9,10]. Differences within the amino acid sequences might be functionally relevant, because the deduced amino acid sequence of cardiac calsequestrin is consistent with its ability to bind larger amounts of Ca^{2+} ^[10]. In contrast, CRT is coded by one gene and splice variants have not yet been reported^[11].

In heart, regulation of SERCA2a activity by expression and phosphorylation of PLB is well established, and disturbances of this system might be involved in pathophysiological events leading to heart failure^[3,12,13]. Indeed, targeted over-expression of CSQ or CRT in the heart of transgenic mice led to cardiac hypertrophy, dilated cardiomyopathy, and heart failure^[14-16]. However, expression, function, and pathophysiological role of Ca^{2+} -processing proteins in the human gastrointestinal (GI) tract and their alterations in diseased states have not been examined before.

There are few diseases of the GI tract where altered Ca^{2+} homeostasis might be involved. One of the possible entities is achalasia. Achalasia is a rare motility disorder characterized by increased pressure of the lower esophageal sphincter (LES) and simultaneous contractions of the esophageal body (EB) leading to impaired swallowing. There is evidence that gastric motility is also impaired in achalasia^[17,18]. Common treatments of achalasia are invasive procedures like pneumatic dilatation and laparoscopic myotomy. For medical therapy, smooth muscle relaxants as nitrates and Ca^{2+} -channel blockers of the dihydropyridine-type are effective in the treatment of achalasia^[19]. Hence, we tested the hypothesis that the expression of SR-proteins involved in Ca^{2+} handling in the GI tract is altered in achalasia in humans.

MATERIALS AND METHODS

Animals

Male Wistar rats (body weight, 150-250 g) and rabbits which had fasted overnight were sacrificed. Organs (esophagus, heart) were prepared and immediately frozen in liquid nitrogen.

Human cardiac tissue

Samples were taken from left ventricles of non-failing hearts which were obtained from prospective organ donors whose hearts could not be used. The study was performed in accordance with the guidelines from the Local Ethics Committee.

Patients

Manometrically proven 9 patients with achalasia (age, 19-52 years), and 6 healthy controls (age, 22-49 years) participated in the study. None of the control group had a history of GI disease or complained of any symptom of a GI disease. All patients underwent gastroduodenoscopy and ¹³C-urea breath test to exclude gastroduodenal disease or infection with *H. pylori*. During endoscopy, biopsies of esophagus and LES were taken. Biopsies were immediately frozen in liquid nitrogen. The study had been approved by the Local Ethics Committee, and all patients gave written informed consent.

Esophageal manometry

Patients were fasted overnight before manometric examination was performed using a low-compliance, water-perfused system. The Arndorfer catheter-with four side-holes oriented radially, 0.5 cm apart, located distally for LES (lower esophageal sphincter) examination and four more orifices located every 5 cm above the distal ones thus allowing for the assessment of the motility pattern in the middle and distal part of the EB (esophageal body)-was attached to force transducers. The recorded signals were amplified (Polygraph VIII, Synectics, Stockholm, Sweden) and stored for further analysis with a specially designed software (Gastrosoft, Irving, Texas, USA). The motility patterns of distal esophagus were examined with (wet swallows) and without (dry swallows) swallowing of 5 mL of water bolus and expressed as mean values of the amplitude (mm Hg), duration (s) and propagation (cm/s) as calculated for five wet and five dry swallows. The LES resting tone was assessed by pull-through technique and the mean value, expressed in mm Hg above the mean intragastric pressure, was calculated from three consecutive measurements. The LES relaxation was measured in response to 5 mL of water bolus, while the distal catheter orifices were located in the LES high-pressure zone and results were documented as complete or incomplete relaxation of the LES.

SDS-PAGE and Western blot analysis

Gel electrophoresis was performed according to the method described by Laemmli^[20]. Briefly, samples were homogenized in 10 mmol NaHCO_3 /50 g/L SDS using a microdismembrator (Braun, Melsungen, Germany) and the protein content of homogenates was measured according to Lowry *et al.*^[21]. After SDS polyacrylamide gel electrophoresis, the separated proteins were transferred onto nitrocellulose membranes (Schleicher and Schüll, Dassel, Germany) as described previously^[22]. For immunostaining, the following primary antibodies were used: monoclonal anti-PLB (2D12), monoclonal anti-SERCA 2a (2A7-A1), polyclonal anti-CSQ (all kindly provided by L.R. Jones, Krannert Institute of Cardiology, Indianapolis, USA), polyclonal anti-SERCA 2b (kindly provided by L. Raeymaekers and Wuytack, University of Leiden, Belgium), and polyclonal anti-calreticulin (Alexis, Grünberg, Germany). Thereafter, bound primary antibodies were detected with [¹²⁵I]-labeled protein A (ICN, Meckenheim, Germany). Visualization and

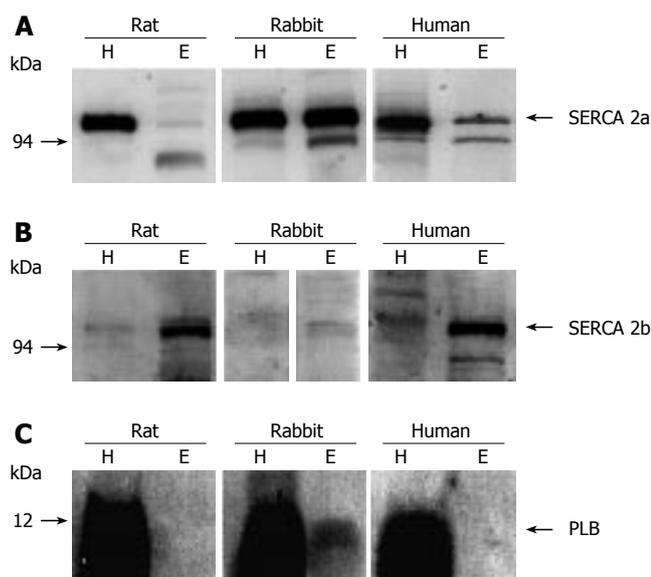

Figure 1 Protein expression of SERCA 2a (A), 2b (B), and PLB (C) in esophageal and ventricular homogenates of rat, rabbit, and human. Protein loading for esophagus (100 μ g) was 5 times higher than for heart (20 μ g). For documentation of PLB, sensitivity of the PhosphorImager was optimized for detection of very weak signals. Therefore, signals in heart samples are overexposed. H: heart; E: esophagus.

quantification of protein bands were performed with a PhosphorImager system (Molecular Dynamics, Krefeld, Germany). Differences in protein loading were corrected by densitometric quantification of Ponceau-stained membranes.

Statistical analysis

Results were presented as mean \pm SE. The significance of differences between means was evaluated using Mann-Whitney test with a confidence value at $P < 0.05$.

RESULTS

First, we studied the expression of Ca^{2+} -regulatory proteins in the upper GI tract. For comparison, we used cardiac tissues where the distribution of Ca^{2+} -regulatory proteins has been established before^[23,24]. Finally, we were interested in their putative pathophysiological role in man. Of note, to our knowledge, expression of these proteins has not been studied before in the human GI tract. However, as more data on expression are available for animal tissues than for human tissues, we studied, where possible, human and animal tissues in parallel. First, we analyzed the expression of SERCA in homogenates from various tissues. Figure 1 depicts protein expression of SERCA 2a and 2b in the esophagus and heart of different species (human, rat, and rabbit). Although, only 20 μ g of ventricular protein was loaded compared to 100 μ g for esophagus, it is obvious that SERCA 2a protein expression was highest in the cardiac ventricle in all three species analyzed (Figure 1A). In rabbit esophagus, the SERCA 2a signal was quite pronounced, whereas in human and rat esophageal expression of SERCA 2a was hardly detectable (Figure 1A). Although, primary sequences of SERCA 2a

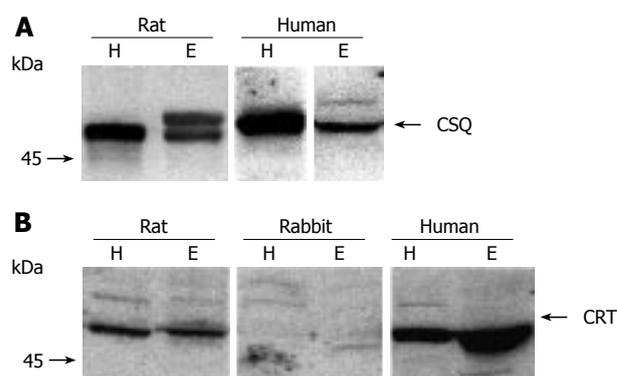

Figure 2 Protein expression of CSQ (A) and CRT (B) in esophageal and ventricular homogenates of rat, rabbit, and human. Protein loading was 50 μ g/lane for CSQ and 100 μ g/lane for CRT. H: heart; E: esophagus.

are somewhat different between rat, rabbit, and human, these expressional differences are valid, as comparisons only were done within one species^[4]. However, the SERCA 2a protein sequence expressed in esophagus and heart of a given species is identical. In rat and human, where SERCA 2a expression was barely detectable in 100 μ g of esophagus protein, a strong signal was visible in 20 μ g of cardiac proteins (Figure 1A). This strongly argues for tissue differences in expression between esophagus and heart at least in rat and, more importantly, in human. In contrast, SERCA 2b expression could be found predominantly in rat and human esophagus, while rabbit esophagus did contain only very low levels of SERCA 2b (Figure 1B). Only a very weak signal for SERCA 2b was detectable in heart, as expected (Figure 1B). For subsequent quantification, it was important to establish the linearity of protein detection by Western blotting. Detection of SERCA 2b in human left ventricle and esophagus as well as in rat samples was linear over a range of 50 to 200 μ g of protein loaded per lane (data not shown).

Next, we compared PLB expression in rat, rabbit, and human samples (Figure 1C). Strong signals could be detected in all homogenates of cardiac ventricles, while in rat and human esophagus, expression of PLB was below our detection limit (defined as 5% over background). Only in rabbit esophagus, a weak PLB signal was detectable (Figure 1C).

Both CSQ isoforms were expressed in esophagus of human and rat (Figure 2A). In the heart, only the low molecular weight isoform was present (Figure 2A). The high molecular weight band was identified as the skeletal muscle isoform and the lower band as the cardiac isoform of CSQ, based on the literature^[7].

We studied protein expression of CRT in all tissues. Expression of CRT in rat was nearly the same in esophagus and cardiac ventricle (Figure 2B). In humans, CRT expression was lower in heart than in esophagus (Figure 2B). In rabbit, CRT signal was much weaker in both tissues compared to human and rat. Conceivably this was a problem of the specificity of the antibody we used for detection of CRT.

After determination of protein expression of SERCA, PLB, CSQ, and CRT in different species, we posed the

Table 1 Ratios of CRT/CSQ and CRT/SERCA 2b in esophageal body (EB) and lower esophageal sphincter (LES) and LES pressure of achalasia patients and healthy controls (mean \pm SE)

	EB		LES	
	Control (n = 6)	Achalasia (n = 9)	Control (n = 6)	Achalasia (n = 9)
Pressure (mm Hg)	ND	ND	31.2 \pm 2.9	49.2 \pm 3.8 ^a
CRT/CSQ	0.63 \pm 0.08	0.61 \pm 0.04	0.88 \pm 0.10	0.78 \pm 0.08
CRT/SERCA 2b	1.07 \pm 0.20	0.77 \pm 0.10	1.47 \pm 0.09	1.07 \pm 0.08 ^a

CRT: Calreticulin; CSQ: Calsequestrin; SERCA: Sarcoplasmic reticulum Ca²⁺ ATPase; ND: Not done. ^aP < 0.05 vs controls.

question, whether expression of these proteins might be altered during GI disease. Ca²⁺ plays an important role in GI motility. Hence, we compared SERCA 2b, CSQ, and CRT expression in healthy controls and patients with achalasia (LES pressure was elevated by 58%, Table 1). In biopsies from LES and EB, SERCA 2b expression was not obviously different between controls and patients (Figure 3). However, CSQ expression in LES and EB was found to be significantly reduced in patients with achalasia (LES reduced by 19%, and EB by 22%) (Figure 3). CRT expression was reduced by 26% in LES as well as in EB of patients with achalasia (Figure 3). CRT/CSQ ratio was not markedly different between both groups, while CRT/SERCA 2b ratio was significantly reduced by 27% in LES of achalasia patients (Table 1).

DISCUSSION

For phasic smooth muscles, it was shown that SR Ca²⁺ cycling can play a major role in modulating mechanical activity^[25]. As achalasia, a human GI motility disorder, can be treated with drugs modulating intracellular Ca²⁺, one can speculate that impaired Ca²⁺-homeostasis might be involved in development or deterioration of this disease. Therefore, aim of this study was to compare protein expression of Ca²⁺-regulating proteins in upper GI tract from different species and moreover, to ascertain if they could play a role in human diseases of the upper GI tract. In rats, as well as in humans, SERCA 2a was predominantly expressed in cardiac tissue, while expression was hardly detectable in esophageal tissue. However, rabbit esophagus contained high amounts of SERCA 2a, while SERCA 2b was not detectable in both, cardiac and esophageal, homogenates of this species. Our data concerning the relative expression of SERCA 2a and SERCA 2b in rat cardiac and esophageal homogenates are in accordance with observations by Wu *et al.*^[26] who reported a similar ratio of SERCA 2a/2b expression in rat heart (30:1) and esophagus (1:4) at the mRNA level. Similar distribution of SERCA 2a and 2b RNAs in rat stomach and heart have been described^[27]. However, esophagus was not analyzed in this study. Another study, using the sensitive nuclease protection assay, determined a SERCA 2a/2b mRNA ratio of 20:1 in rabbit cardiac tissue, whereas in most smooth muscle and non-muscle tissues SERCA 2b was expressed predominantly^[28]. Surprisingly, in rabbit esophagus, SERCA 2a accounted for 80% of SERCA 2 content^[28].

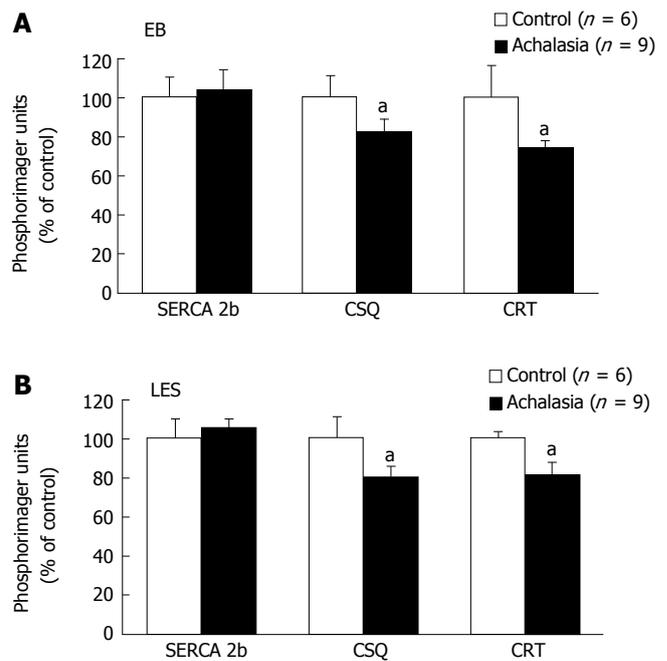

Figure 3 Protein expression of SERCA 2b, CSQ, and CRT in biopsies of esophageal body (EB, **A**) and lower esophageal sphincter (LES, **B**) from patients with achalasia or healthy controls. Protein expression was quantified using [¹²⁵I]-labeled protein A for detection of primary antibodies. Radioactive bands were visualized and quantified using a PhosphorImager. Data are presented as mean \pm SE of n patients. ^aP < 0.05 vs control.

These data are in accordance with our observation that in rabbit esophagus SERCA 2a expression was much more pronounced than in esophagus of rats and humans (compared to heart of the same species). Correspondingly, the SERCA 2b signal was significantly weaker in rabbit than in rat and human esophagus. Although, species specificity of the antibody (the alternatively spliced 50 amino acid carboxy terminal tail exhibits 10 differences between rabbit and man, 3 between rat and human and 10 between rabbit and human, most of these changes being conservative replacements^[28]) might contribute to this phenomenon, it is conceivable that the weaker expression of SERCA 2b might be due to a lesser importance of this isoform in rabbit esophagus. In summary, there are differences in the relative expression of SERCA 2a and 2b. Hence, splicing of SERCA 2 exhibits distinct tissue and species differences. Similar results at the protein level had been published elsewhere^[29]. But esophageal tissue was not analyzed so far.

In our study, expression of PLB was abundant in cardiac tissue of all species analyzed. A weak PLB signal could be obtained in rabbit esophagus. In the esophagus of rats and humans, PLB was below the detection limit. Only sparse data on PLB expression in the GI tract are available. Varying amounts of PLB mRNA and protein with a strong signal in gastric smooth muscle of pigs, but no signal in aorta were noted^[30]. In canine smooth muscle cells of ileum, PLB was detected by immunogold microscopy, but only ileum, not esophagus, was analyzed^[31]. Another group detected PLB in pig stomach, rat aorta and dog aorta, but not in pig aorta. They concluded from their experiments that PLB might exist in many, but not all muscle tissues^[32].

However, in our experiments, we failed to detect PLB in human and rat esophagus. This has not been studied and reported before. Our observation might be due to the fact that PLB is only of minor functional importance for SERCA regulation in these tissues.

May these discrepancies have functional consequences? Some studies have addressed the question of how SERCA 2a and 2b interact with PLB in different muscle tissues. The effect of cAMP- and cGMP-dependent protein kinases on Ca^{2+} uptake of ER vesicles is smaller in smooth muscle than in cardiac tissue^[33]. Using transfection experiments with COS-1 cells, a slower turnover rate for SERCA 2b was found and a higher apparent affinity for Ca^{2+} was reported for SERCA 2b compared to SERCA 2a. Ca^{2+} -affinity was decreased in both cases by co-expression with PLB^[5,34]. John *et al*^[35] reported similar functional differences of SERCA 2a and 2b isoforms. Additionally, they described the ability of CRT to modulate SERCA 2b-, but not SERCA 2a-activity, most likely by a binding to the additional eleventh transmembrane segment and luminal carboxy terminus of SERCA 2b. Since PLB expression in human and rat esophagus was below the detection limit, in contrast to cardiac PLB expression, esophageal PLB (at least in rats and humans) seems to be of lesser importance for regulation of SERCA than in heart. It is tempting to speculate that regulators other than PLB, possibly CRT, might control SERCA 2b and Ca^{2+} -handling in these tissues. In agreement with this speculation, we detected PLB expression only in rabbit esophagus, where a high amount of SERCA 2a, but no CRT was present, while CRT was detectable in rat and human esophagus, where SERCA 2b, but not PLB, was expressed.

In accordance with the literature, we found two isoforms of CSQ in rat, a low and high molecular weight isoform. In the heart exclusively the low molecular form was expressed, while smooth muscle tissue contained both isoforms^[7]. Here we have demonstrated that human esophagus also contains both isoforms of CSQ. To the best of our knowledge, CSQ protein expression in human upper GI tract has not been described before.

CRT protein expression was found in esophagus of rat and man and, to lesser extent, in cardiac tissue of these species, while it was missing in rabbit tissue. CRT expression, although being detectable in high amounts in various tissues, has not been analyzed in human esophagus. The expression patterns, presented here, encourage the speculation that CRT might be involved in the regulation of esophageal SERCA 2b.

Finally, we found decreased expression of CSQ and CRT in LES and EB of patients with achalasia. Although, antagonists of L-type Ca^{2+} -channels like nifedipine have proven effective in treatment of achalasia, studies on free intracellular Ca^{2+} levels in achalasia have not been published. It might be speculated that decreased CRT and CSQ levels might lead to increased intracellular free Ca^{2+} and therefore to elevated LES pressure. Interestingly, over-expression of CSQ decreases the free Ca^{2+} in the cytosol of cardiac myocytes^[13]. This finding may explain why contractility of CSQ-over-expressing cardiac cells was diminished compared to wild-type cells. In contrast, one can speculate that reduced expression of CSQ might

be accompanied by increased free cytosolic Ca^{2+} followed by enhanced contractility. If this mechanism comes true for smooth muscle cells, reduced expression of CSQ might lead to elevated free Ca^{2+} levels and hence increased tension and therefore to achalasia in patients. Reduced CRT expression might contribute to achalasia by similar mechanisms like PLB. For instance, in PLB-knockout mice, cardiac contractility was enhanced, because loss of PLB relieved any inhibition of SERCA function by PLB: Ca^{2+} is more effectively removed from the cytosol and more Ca^{2+} can be released during the systole leading to enhanced force generation in these hearts^[36]. A similar mechanism might hold true for CRT in esophagus: lower levels of CRT should also loosen its inhibitory modulation of SERCA function in the esophageal cells and more tension might be generated.

In conclusion, our results provide new insights to understand the mechanisms leading to achalasia. Further studies will be necessary to elucidate the role of impaired Ca^{2+} regulation for development of diseases like achalasia. Some questions which have to be answered are why the Ca^{2+} -regulatory proteins CSQ and CRT are down-regulated, and does down-regulation occur before or after manifestation of the disease.

ACKNOWLEDGMENTS

We thank Dr. LR Jones (Krannert Institute of Cardiology, Indianapolis, USA) for providing antibodies against PLB, SERCA 2a, and CSQ and Dres. F. Wuytack and L. Raeymaekers (University of Leuven, Belgium) for providing antibodies against SERCA 2b.

Abstract

AIM: To study the relationship between the patterns of postprandial peristalsis and transduodenal bolus transport in healthy subjects.

METHODS: Synchronous recording of chyme transport and peristaltic activity was performed during the fasting state and after administration of a test meal using a special catheter device with cascade configuration of impedance electrodes and solid-state pressure transducers. The catheter was placed into the duodenum, where the first channel was located in the first part of the duodenum and the last channel at the duodenojejunal junction. After identification of previously defined chyme transport patterns the associated peristaltic patterns were analyzed.

RESULTS: The interdigestive phase 3 complex was reliably recorded with both techniques. Of 497 analyzed impedance bolus transport events, 110 (22%) were short-spanned propulsive, 307 (62%) long-spanned propulsive, 70 (14%) complex propulsive, and 10 (2%) retrograde transport. Short-spanned chyme transports were predominantly associated with stationary or propagated contractions propagated over short distance. Long-spanned and complex chyme transports were predominantly associated with propulsive peristaltic patterns, which were frequently complex and comprised multiple contractions. Propagated double wave contraction, propagated contraction with a clustered contraction, and propagated cluster of contractions have been identified to be an integrated part of a peristaltic sequence in human duodenum.

CONCLUSION: Combined impedancometry and manometry improves the analysis of the peristaltic patterns that are associated with postprandial transduodenal chyme

transport. Postprandial transduodenal bolus transport is regulated by propulsive peristaltic patterns, which are frequently complex but well organized. This finding should be taken into consideration in the analysis of intestinal motility studies.

INTRODUCTION

The spatial and temporal organization of gastrointestinal contraction waves seems to be a more important determinant of the flow of luminal contents than their number and amplitude^[1,2]. Therefore, significant advances in understanding intestinal motility disorders could be made by analysis of bolus movement together with peristaltic activity within the gastrointestinal lumen. With manometry alone small intestinal motility patterns can be obtained^[3]. However, up to date there are limited observations on the relationship between intestinal chyme transport and peristaltic activity in humans because fluoroscopic studies are limited due to radiation exposure.

Multichannel impedancometry is a newly developed technique to study chyme transport^[4]. We performed human studies and demonstrated that multichannel impedancometry is a reliable technique to obtain detailed information about spatial and temporal chyme movements, both in the human esophagus and duodenum^[5-9]. Simultaneous impedancometry and pH-monitoring have also been used for characterisation of patterns of gastroesophageal reflux^[10,11].

In previous studies we have characterized postprandial duodenal chyme transport patterns^[5,6]. Recently, we developed the technique of combined impedancometry and manometry (CIM)^[12] and applied it for motility testing in healthy subjects and reflux patients^[13-15]. In the present study we used this approach in order to systematically

study the relationship between intestinal chyme transport patterns and peristaltic patterns and to obtain detailed information about peristaltic mechanisms regulating postprandial transduodenal bolus transport.

MATERIALS AND METHODS

Subjects

Ten subjects (7 males and 3 females, mean age 34 years, range 26-36 years) were studied after written informed consent. All healthy volunteers were recruited from the medical staff. They took no medication and had no history of gastrointestinal disease. The study protocol was approved by the local ethical committee of Aachen University.

Methods

Combined impedance and pressure recording: A custom-made combined catheter consisting of 11 impedance segments (each 2 cm long) and 4 semiconductor pressure transducers was used (prototype developed by Dr. Nguyen RWTH-Aachen, Ref. 13). The pressure transducers were located between the impedance channels 1-2, 4-5, 7-8 and 10-11 (intertransducer distance 6 cm) (Figure 1). The cascade configuration of the impedance electrodes allows continuous monitoring of chyme movement and is particularly suitable for analysis of chyme transport patterns^[5,6].

Study protocol: After an overnight fast from 10 pm, the catheter was placed transnasally into the duodenum under fluoroscopic control. All channels were placed in the duodenum. The proximal end of the catheter was located in the first part of the duodenum and the last channel at the duodenojejunal junction (Figure 1). This catheter position yielded information about bolus transport along the whole duodenum. The final position was confirmed by fluoroscopy at the beginning of the studies.

Synchronous recording of chyme transport and peristaltic activity was started after a resting period of at least 20 min following catheter placement. After identification of a phase 3 migrating motor complex, a standard test meal consisting of 500 g of commercially available yogurt with small pieces of fruit (450 kcal, 400 mL, 5.5 g fat, 12.5 g protein, 75 g carbohydrate) was administered, and data were collected for a further 2 h.

Statistical analysis

Impedance and manometry tracings were reconstructed on screen and the patterns were consecutively analyzed. Since we studied transduodenal bolus transport, only impedance signals related to a complete chyme transport over at least 6 cm beginning at the first impedance channel were included and analyzed as previously described as a bolus transport event (BTE)^[5,6]. This definition was used to exclude transpyloric movement of gastric contents into the duodenum bulb without initiation of duodenal peristalsis. BTE were classified according to (a) site of onset (proximal *vs* distal), (b) propulsion direction (propulsive *vs* retropropulsive), (c) propagation distance (short-spanned ≤ 8 channels or ≤ 16 cm *vs* long-spanned > 8 channels or > 16 cm), (d) number of components (simple = one

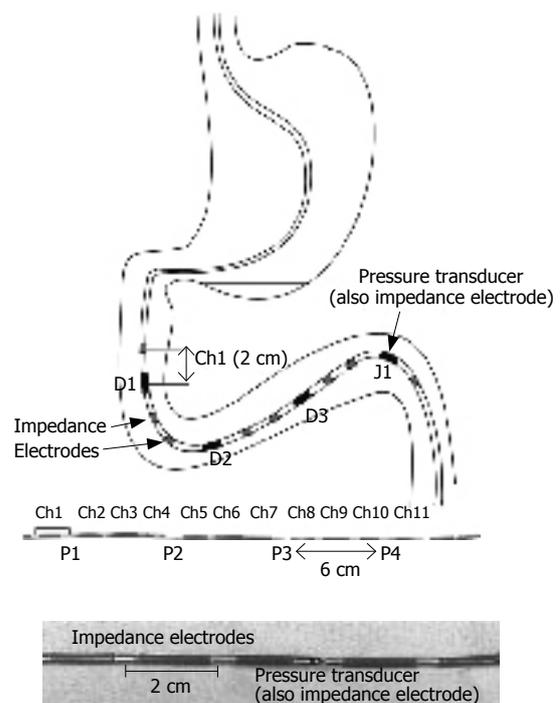

Figure 1 Modified manometry catheter for concurrent impedance-manometry procedure. The 4 semiconductor solid-state pressure transducers (P1-P4) serve also as impedance electrodes and are placed at 6 cm distance each. The 8 impedance electrodes (4 mm length) are arranged between the pressure transducers at a distance of 16 mm. Together with the pressure transducers, they form 11 impedance segments, each 2 cm long (Ch1-Ch11). The solid-state pressure transducers are located exactly between the impedance channels 1-2, 4-5, 7-8, and 10-11, respectively. The first channels were located at the first part of the duodenum.

component *vs* complex = multiple components). Thus the transport patterns were: (a) short-spanned propulsive, (b) retrograde, (c) long-spanned propulsive, and (d) complex propulsive^[5,6,8]. Of note, our previous validation study^[6] demonstrated that long-spanned BTE are associated with a significant drop of intraluminal pH and change of electrical conductivity, thus indicating real chyme movement originating from the stomach.

After identification and classification of the chyme transport patterns the corresponding peristaltic sequences were analyzed. Firstly, the peristaltic nature of the associated contractions was characterized as (a) stationary (isolated contraction observed in only one channel) or (b) propagated (contraction detected over 2, 3 or 4 pressure channels = 6, 12 and 18 cm). Secondly, propagated contractions were classified according to Summers *et al.*^[16] to be: (a) propagated contraction with single wave contraction (1 contraction), (b) propagated contraction with a double wave contraction (2 contractions) or propagated contraction with a clustered contraction (> 2 contractions occurring at a rate of 5 s) (c) propagated cluster of contractions (clustered contractions occurring at more than one pressure channel) as shown in Figure 2. A double spike wave was considered to be single wave. Contractions that were observed between the BTEs were not included for analysis. Data are expressed as total number of events counted.

RESULTS

Combined impedance-manometry during the interdigestive state

During the interdigestive phase 2 there were irregular motility activities as recorded by manometry and irregular chyme transport events as recorded by impedance-manometry (Figure 3, upper panel). Both impedance and manometry recorded the same features of the phase 3 complex (Figure 3, lower panel).

Combined impedance-manometry during the postprandial state

The postprandial manometry tracings showed irregular peristaltic activity, which is difficult to analyse (Figure 4, upper panel). However, with combined impedance and manometry the relationship between transduodenal bolus transport event and associated peristaltic activity could be investigated in more detail (Figure 4, middle panel). Plotting the tracings at high resolution, the patterns of chyme transport as recorded by impedance and of peristalsis as recorded by manometry were analysed systematically (Figure 4, lower panel).

Impedance bolus transport patterns

A total number of 564 BTEs were counted. Sixty seven BTEs (12%) were excluded, because they could not be clearly classified according to the impedance criteria. Of the remaining 497 BTEs the distribution of the impedance patterns was: (a) short-spanned propulsive transport, 110 events (22%), long-spanned propulsive transport, 307 events (62%), and (d) complex transport, 70 events (14%) and retrograde transport events, 10 (2%).

Relationships between impedance transport patterns and manometry peristaltic patterns

The relationship between impedance transport patterns and manometry peristaltic patterns could be classified as followed (Figure 5): (a) of the short-spanned propulsive chyme transports (110 events) the majority of them was associated either with a stationary contraction (43 events or 39%) or a single contraction propagated over only 2 pressure channels (64 events or 58%); (b) all long-spanned propulsive chyme transports (307 events) were associated with a propagated contractions; (c) all complex chyme transport patterns (70 events) were associated with propagated contractions, particularly over 4 pressure channels; (d) retrograde chyme transport was rare (10 events) and are associated either with a stationary contraction (7 events) or retrograde propagated single wave contraction (3 events).

Of the long-spanned bolus transport events (307 events), 92 BTEs (30% of them) were associated with a propagated contraction over 2 or 3 pressure channels (6-12 cm), and 215 BTEs (70% of them) were associated with a propagated contraction over 4 pressure channels (18 cm).

Of the long-spanned propulsive chyme transports over 4 channels (215 events), 61 events (28% of them) were associated with a propagated single wave contraction, and 154 events (72% of them) were associated with a propagated double wave contraction or a propagated

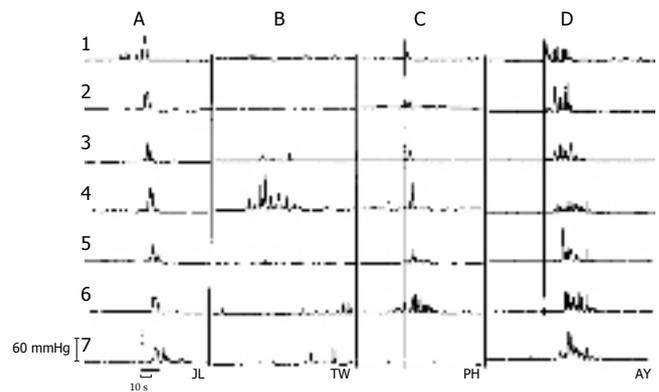

Figure 2 Classification of the peristaltic patterns according to Summers *et al*^[16]. The peristaltic pattern can be classified to be (A) propagated single (double spike) wave contraction, (B) isolated (stationary) cluster of contractions, (C) propagated contraction with a clustered contraction, and (D) propagated cluster of contractions.

contraction with a clustered contraction. None of these bolus transport was associated with a propagated cluster of contractions.

All complex propulsive chyme transports (70 events) were associated with propagated contractions over 4 channels (18 cm): 48 events (68% of them) were associated with a propagated double wave contraction or a propagated contraction with a clustered contraction, and 22 events (32% of them) were associated with a propagated cluster of contractions. None of these bolus transport was associated with a propagated single wave contraction.

Examples of the bolus transport events and their associated peristaltic patterns are shown in Figures 6-8.

DISCUSSION

Only few studies in man have directly analysed the spatial and temporal relationship between the patterns of chyme flow and patterns of peristaltic contraction waves in the duodenum, particularly during the postprandial state and in details. This study was performed to directly address this issue using the newly developed and validated technology of combined impedance and manometry for motility testing^[12-15]. The daisy-chained configuration of the impedance electrodes in the present system differ significantly from other systems^[17-19], where the impedance electrode pairs are located far from each other. As shown in previous impedance studies^[5,6] this catheter configuration offers a high spatial resolution for detailed monitoring of bolus transport patterns. The incorporated solid state pressure transducers allow the concurrent analysis of the corresponding contractile events.

As shown in Figure 3, the phase 3 complex is recorded identically by both techniques, showing the well-known characteristics of the migrating motor complex, similar to recent findings by Imam *et al*^[17]. During the postprandial phase, chyme transport and associated peristaltic activity can be accurately monitored, and thus a large number of bolus transport event (BTE) was obtained for detailed analysis.

Considering the manometry tracings alone, it has been

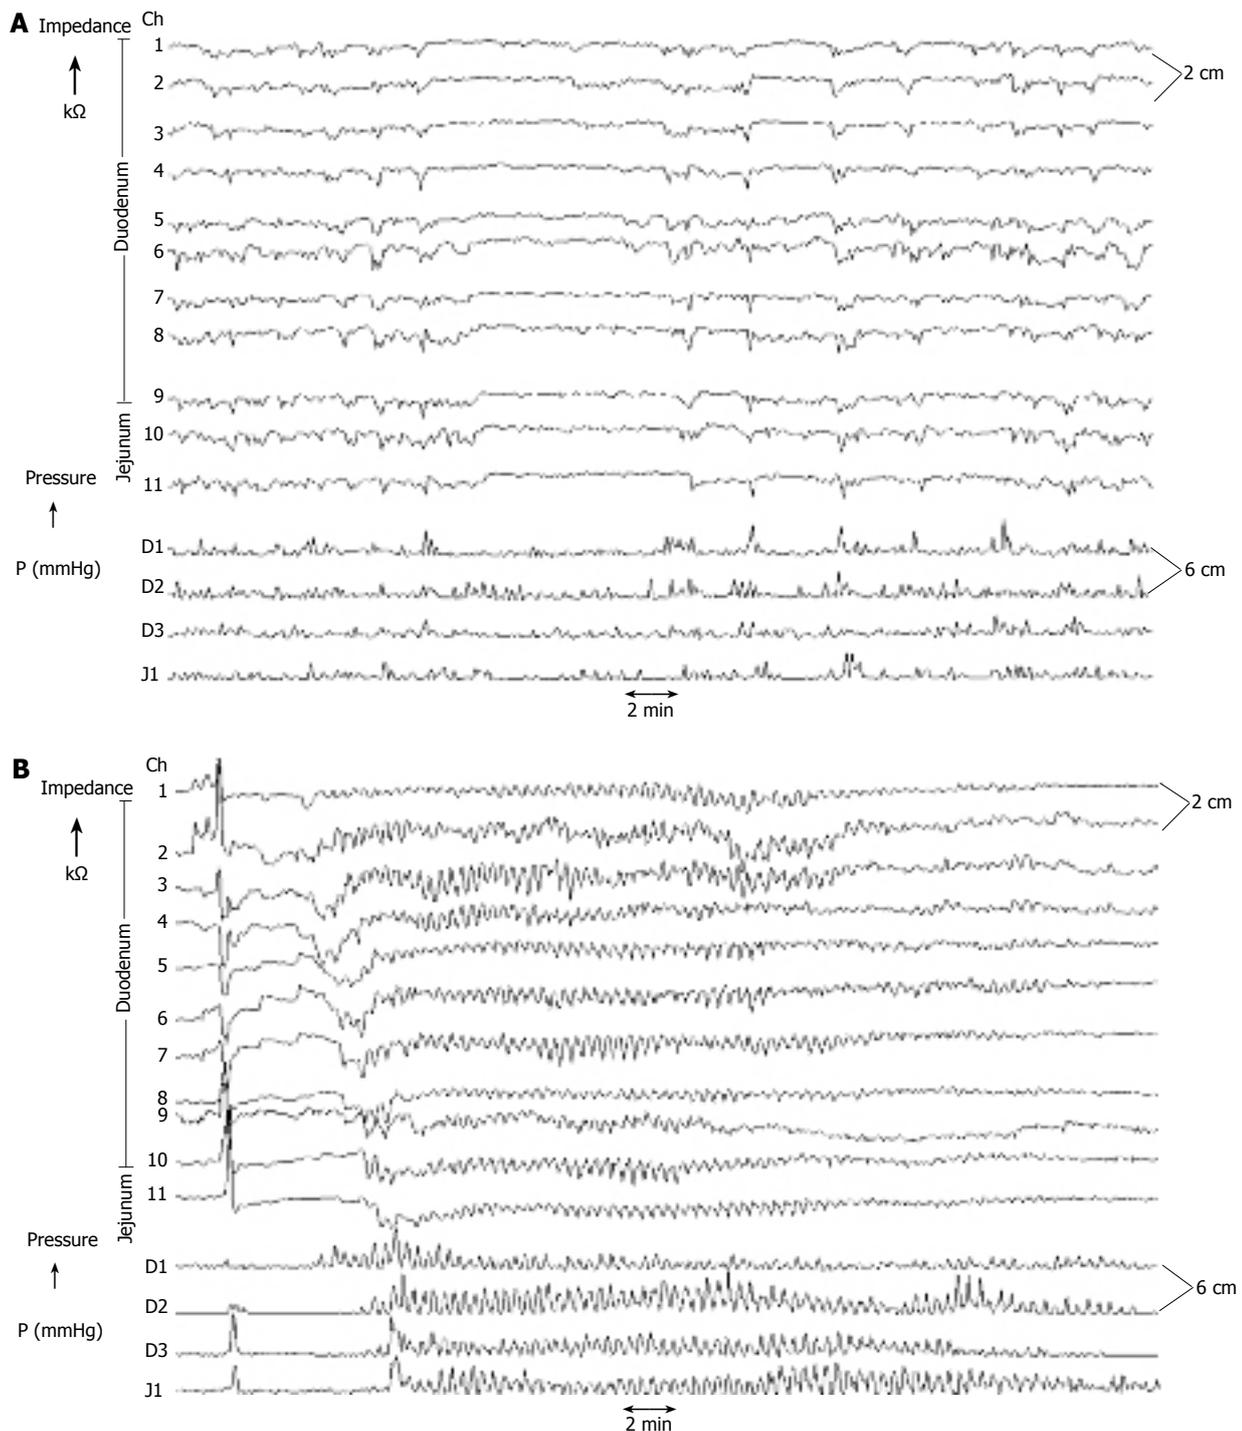

Figure 3 Concurrent Impedance Manometry (CIM) tracings. Upper panel: During the interdigestive phase irregular chyme transport at the impedance channels and irregular motor activities at the pressure channels are observed. Lower panel: A phase 3 complex displays nearly identical features with frequent changes of both pressure and impedance.

shown to be difficult to characterize contraction waves to be stationary or propagated^[20]. As shown in Figure 4 this problem can be overcome by the combined technique as shown in the recent study. After a bolus transport event (BTE) had been identified with impedance in the present study, the organization of the associated contraction waves could be analyzed. We did not include contraction waves that occurred between the bolus transport events, as compared to previous studies^[1,3,20], which analyzed the overall motility activity. Therefore, the results are not comparable. As only impedance events representing

a bolus transport over at least 6 cm were analysed, the present results provide data about the postprandial organization of peristaltic activity in association with a transduodenal bolus transport. Transpyloric chyme movement was not included in the present studies.

A major finding of the present study is the close relationship between transduodenal bolus transport patterns and peristaltic contraction patterns. The results showed that long-spanned chyme transport patterns are predominantly associated with propagated peristaltic patterns, whereas short-spanned chyme transport patterns

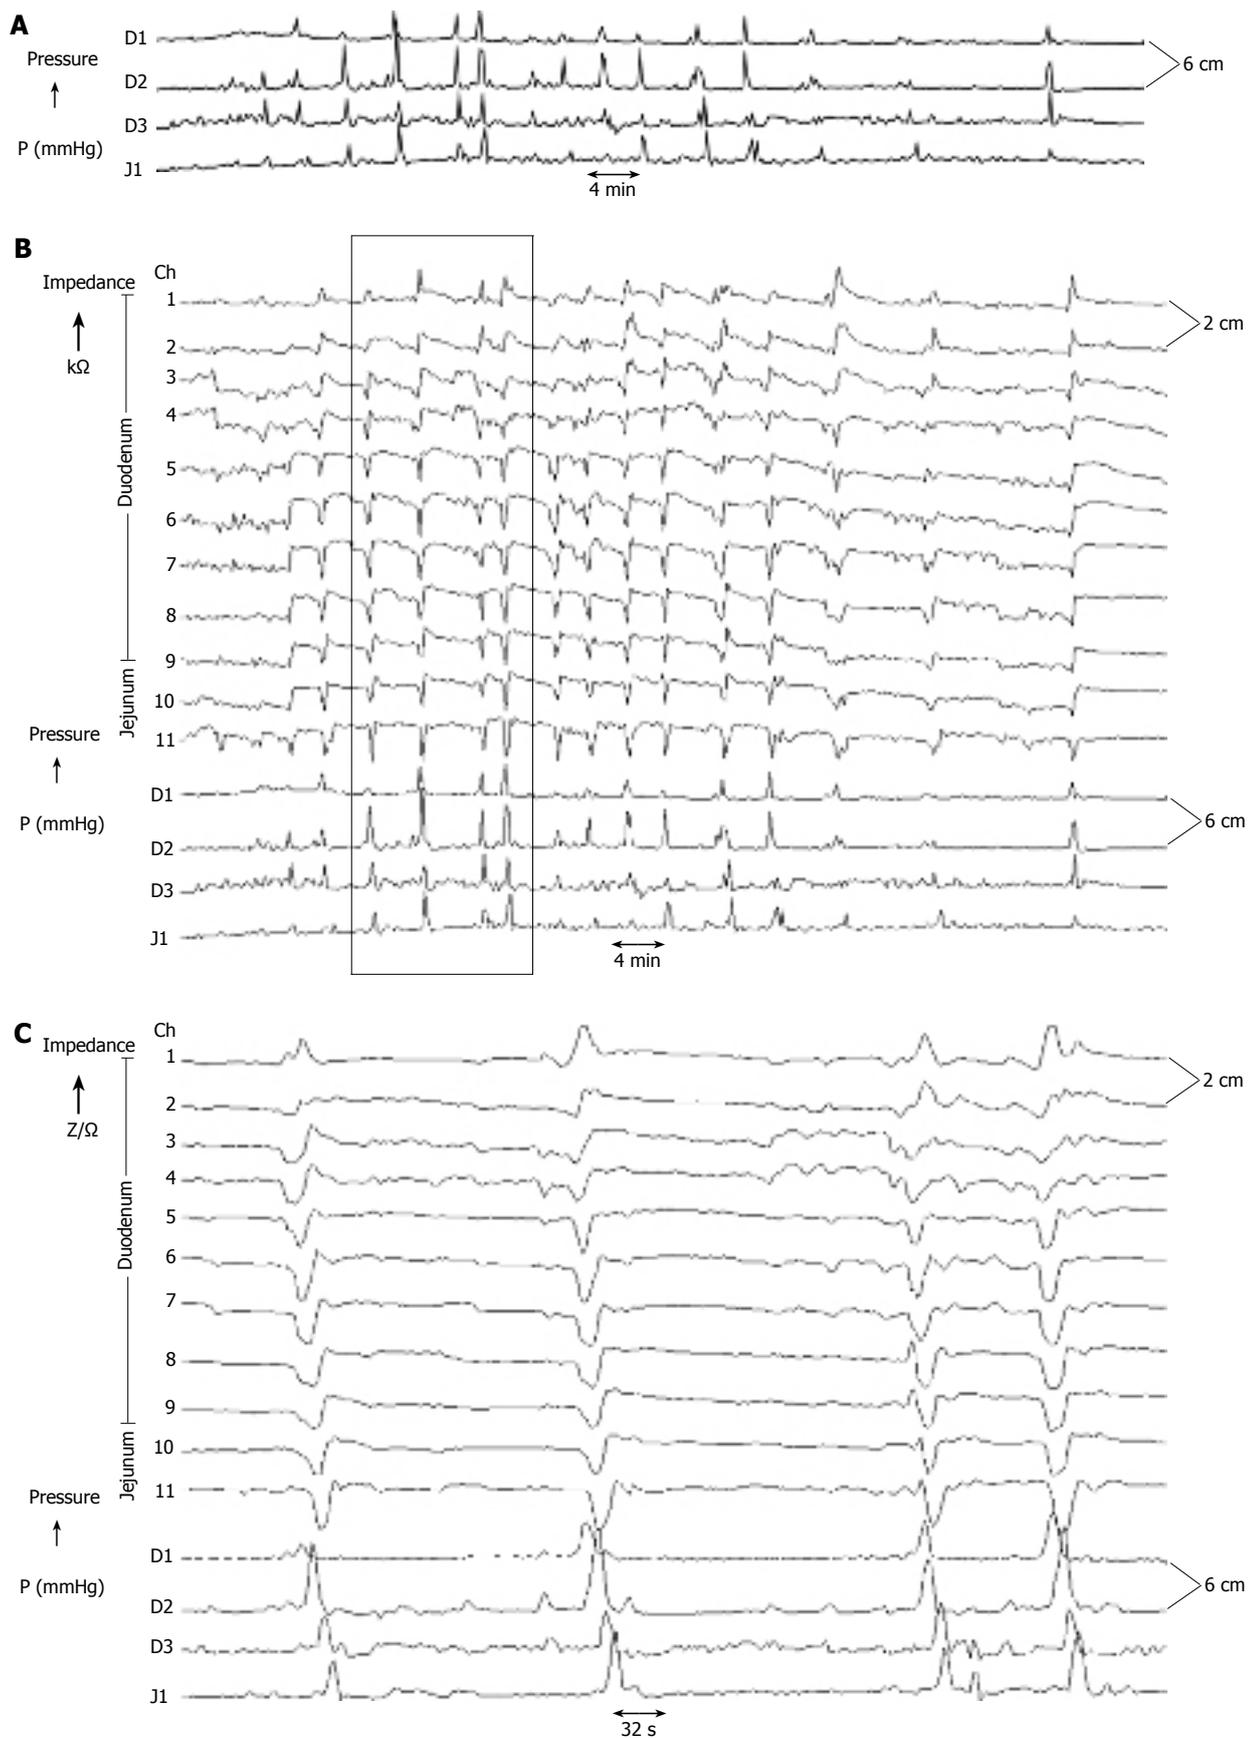

Figure 4 Concurrent Impedance Manometry (CIM) tracings after a test meal. Upper panel: Low time scaled manometry tracings of the postprandial state. Middle panel: Low time scaled impedance manometry tracings of the same period as above showing several bolus transport events with associated peristaltic activities. Lower panel: High time scaled impedance manometry tracings of the box allowing identification and classification of bolus transport patterns as well as analysis of associated peristaltic patterns.

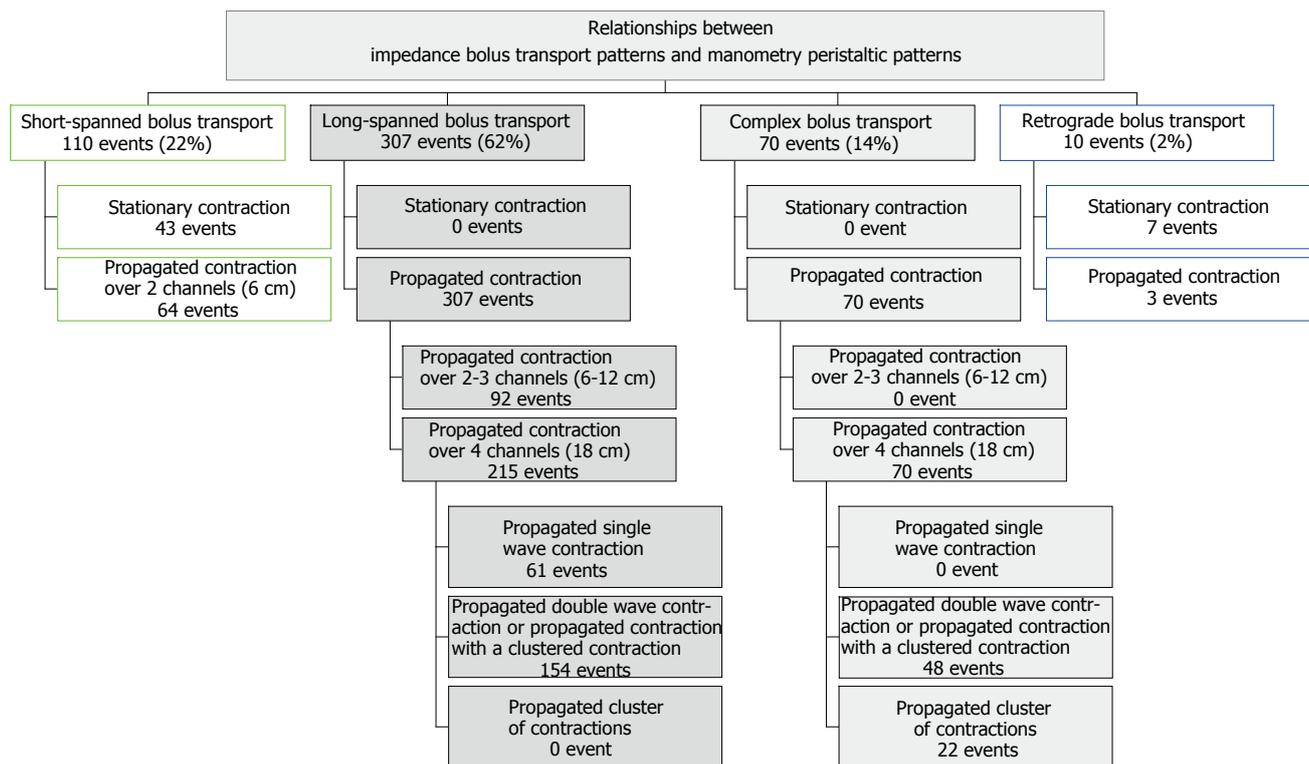

Figure 5 Distribution of bolus transport patterns and associated peristaltic patterns (see text for details).

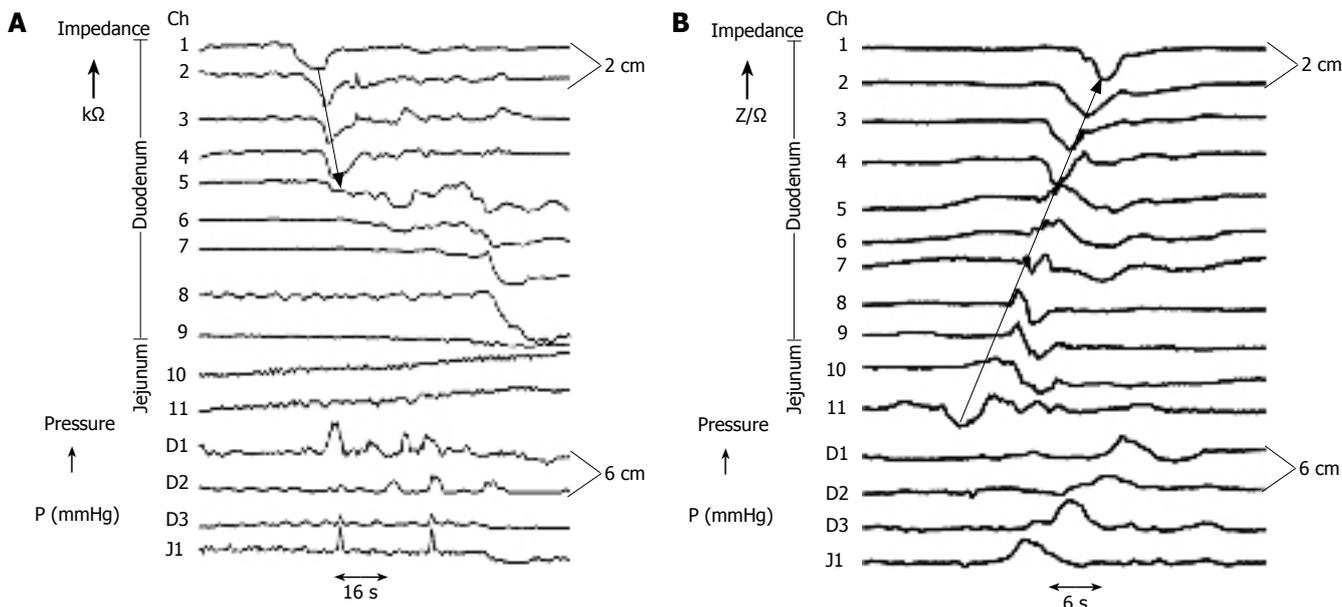

Figure 6 Examples of simple bolus transports and associated peristalsis. Upper panel: Short-spanned bolus transport with associated stationary contraction. Lower panel: Retrograde bolus transport with associated retrograde peristalsis.

are frequently related to stationary contractions or propagated contractions over short distance (6 cm). The data are consistent with results of a recent study^[17] showing that impedance corresponds better with fluoroscopic flows than manometry and that recording of pressure events can underestimate even flow events of substantial length. However, the quantitative data of this study are not comparable to ours because there are important differences with respect to study design and analysis algorithm: (a) in this study the impedance segments were spaced 5 cm apart

from each other as compared to the cascade configuration in our study, thus, the recording of impedance patterns differs substantially; (b) all impedance events with a drop of 12% or more below baseline, even if detected in only one impedance segment (spread distance < 5 cm), were included as compared to impedance signals of a complete bolus passage over 6 cm in our study. Since an impedance drop only indicates arrival of a bolus front but not always a complete bolus passage, it might represent transpyloric chyme movement into the proximal duodenum, which is

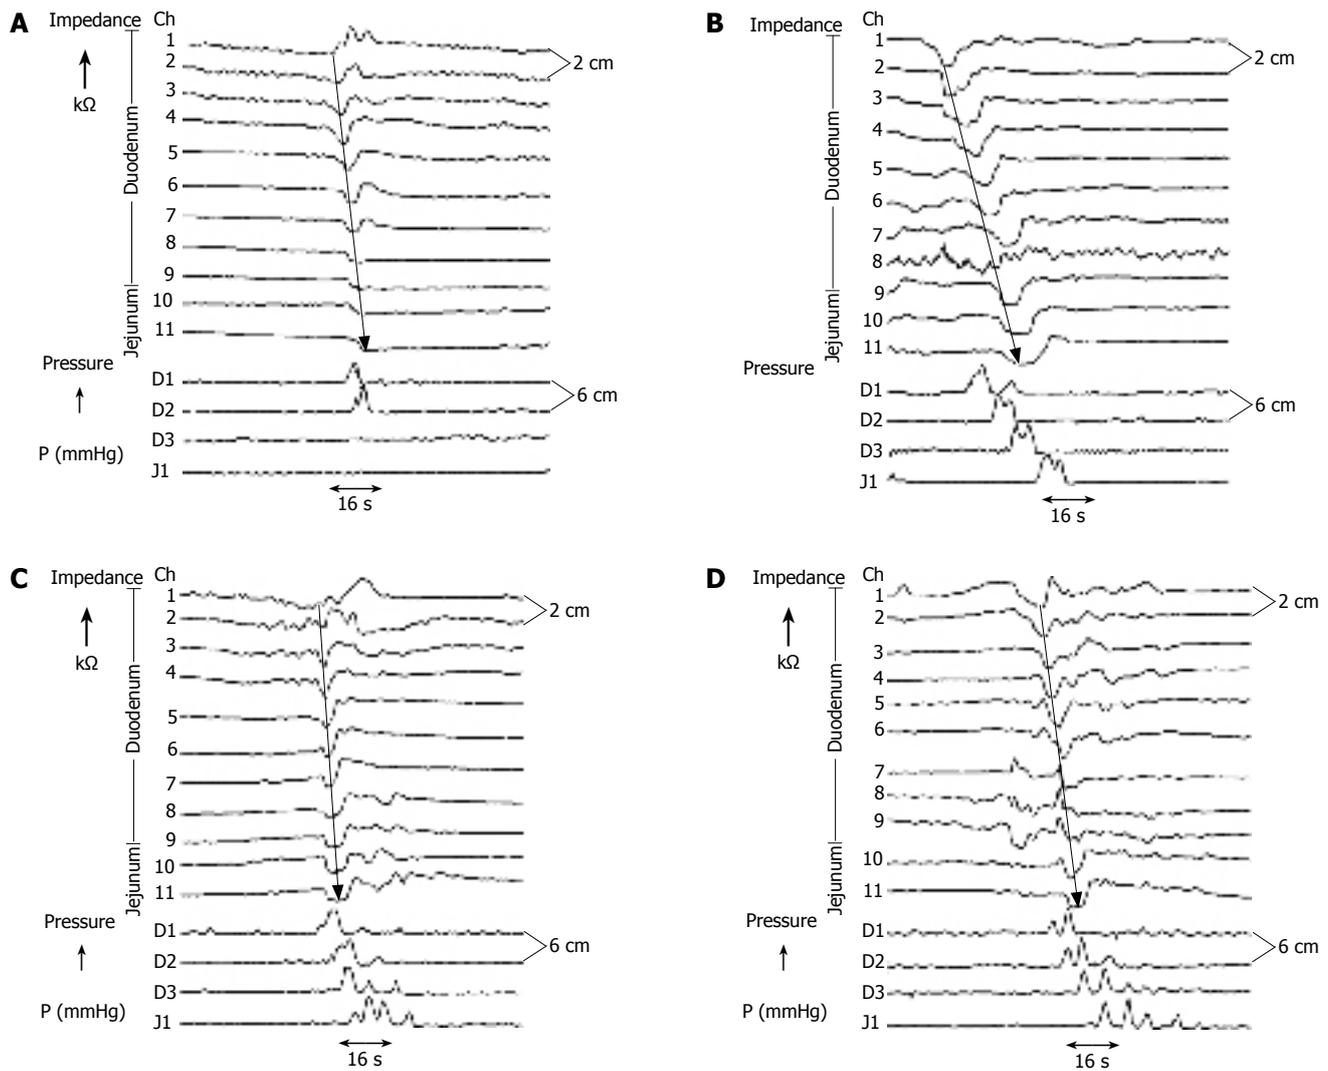

Figure 7 Examples of long-spanned bolus transports and associated peristalsis. (A) A long-spanned bolus transport with the bolus front traversing the whole duodenum. The associated peristaltic sequence displayed a propagated single wave contraction from D1 to D2. This peristaltic pattern was classified to be simple (propagated single wave contraction). (B) A long-spanned bolus transport traversing the whole duodenum. The associated peristaltic sequence displayed a propagated contraction with a double wave contraction at channel D1 and double spike contractions at D2, D3 and J1. This peristaltic pattern was classified to be complex (propagated contraction with a double wave contraction). (C) A long-spanned bolus transport with the bolus front traversing the whole duodenum. The associated peristaltic sequence displayed single wave contractions at channel D1-D3 and a clustered contractions at J1. This peristaltic pattern was classified to be complex (propagated contraction with a clustered contraction). (D) A long-spanned bolus transport with the bolus front traversing the whole duodenum. The associated peristaltic sequence displayed double wave contractions at channel D1 and a clustered contractions at D2, D3 and J1. This peristaltic pattern was classified to be complex (propagated cluster of contractions).

detected at the first duodenal channel as compared to a transduodenal bolus transport over at least 6 cm.

Another major finding is related to the motor mechanisms regulating transduodenal bolus transport. Distinct peristaltic patterns have been identified. Our data showed, that if a bolus is propelled over a long distance (> 4 pressure channels or 18 cm), it is frequently associated with a complex peristaltic sequence, which can be either a propagated contraction with double wave contraction, a propagated contraction with a clustered contraction, or rarely, a propagated cluster of contractions. The finding that cluster of contractions (double wave contraction, clustered contraction) are an integral part of a peristaltic sequence associated with a transduodenal bolus transport is new. The retrospective analysis of these contraction patterns without the associated impedance tracings frequently fails to clearly identify the clustered contractions to be a part of bolus-associated peristaltic sequence. These results may

explain the facts that the analysis and classification of all contraction waves in human small intestine is difficult, and most of them have been classified to be stationary^[20].

The dominant patterns of propulsive bolus transports with associated propulsive peristaltic patterns support the existence of a precise spatial and temporal organization of the contraction waves in human duodenum during the postprandial state^[21-24]. Two recent studies investigating the relationships between antral contraction, transpyloric fluid flow and duodenal motility observed that transpyloric fluid transport is associated with duodenal propagation^[18,21]. The results of the present study strongly support previous reports showing that coordinated duodenal contraction waves are an important determinant regulating antroduodenal chyme flow^[22,24,25], as well as gastric emptying^[26].

The recent finding of different propulsive bolus transport patterns associated with different propulsive

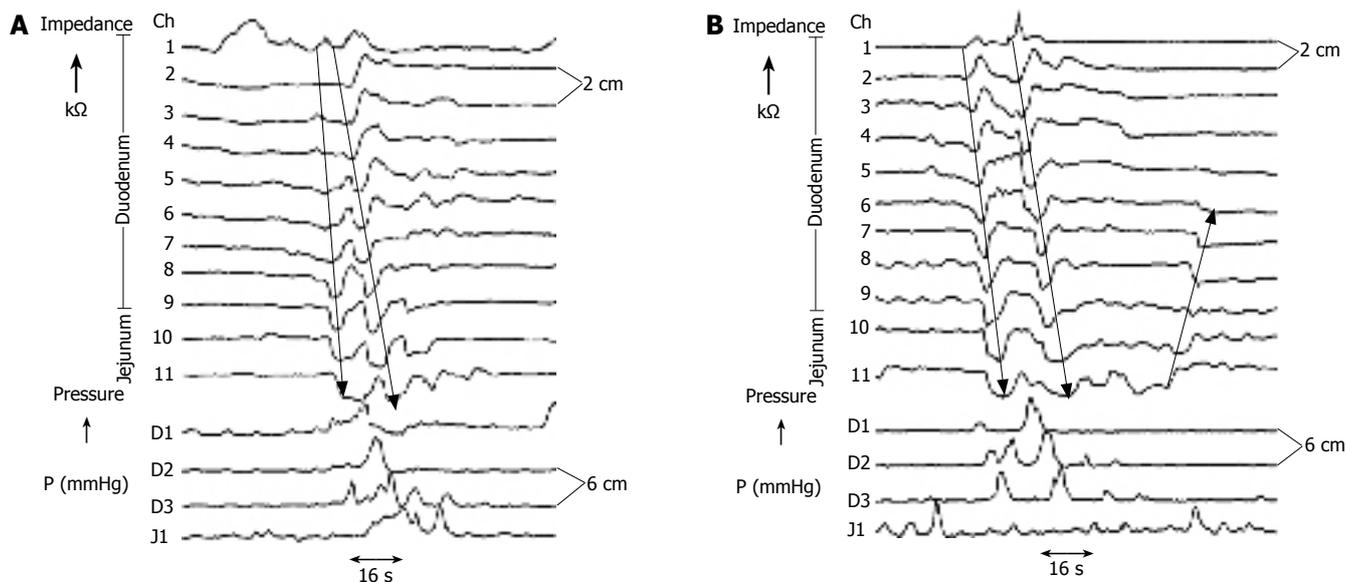

Figure 8 Examples of complex bolus transports and associated complex peristalsis. (A) A complex bolus transport with two components propelling with different propulsion velocity as illustrating by the arrows. The associated peristaltic sequence is complex showing a long lasting double spike contraction at D1, a single wave contraction at D2, a clustered contraction at D3 and a multispike double wave contraction at J1. (B) A complex bolus transport comprising two boluses following each other very rapidly as illustrating by the anterograde arrows. The associated peristalsis showed two separate peristaltic sequences which seemed to be connected together by an interpolate contraction wave at D2. A retrograde bolus movement (retrograde arrow) seemed to be derive from a retrograde peristaltic sequence with a single contraction wave seen at J1.

peristaltic patterns underlines the physiological difference between the duodenum and the esophagus, where the bolus transport patterns are highly uniform and the peristaltic sequences are predominantly simple^[17,131]. This finding support the view that the duodenum is not only a conduit but also an active segment, which is able to generate contractions transporting and mixing gastric contents together with duodenal juices into the jejunum^[27-31]. Since previous studies^[32,33] indicated that contraction patterns in the duodenum are quite different from those in the jejunum, further studies should examine, if similar bolus transport patterns and peristaltic patterns will be found in other segments of the gut.

The answers about the question regarding how complex peristaltic sequences can be regenerated during a bolus transport can be sought in results of electrophysiological studies. Intestinal motility is considered to be controlled by interaction between myogenic, neural and humoral factors^[34-35]. In recent studies several motility patterns have been characterized as peristaltic or pendular, stationary or propagating, or twitch or segmental^[36-37]. Furthermore, several electrical signals have been shown to be associated with different types of contractions including slow waves, spikes, or bursts^[36-38]. Therefore, peristalsis with associated propagated peristaltic waves should not be regarded as a simple reflex, but rather as a co-ordinated locomotor pattern, which can be induced either by fluid distension, local stretch, or mucosal stroking^[56]. Careful examination of the spatial and temporal relationship between spontaneous slow waves and peristaltic waves showed that they seem to constitute two separate electrical events that may drive two different mechanisms of contractions^[59]. Slow waves are not in rhythm with peristaltic waves and they may occur in different groupings and patterns. These waves may travel in the same or in opposite directions from each other and may

propagate in the oral or caudal direction, and therefore, may modulate each other. Similarly, slow waves and spikes seem to be propagated by different mechanisms through different cell networks^[52]. Thus, the spatial and temporal characteristics of contraction in the small intestine seem to be determined not only by the direction of the slow wave but also whether or not spikes are generated after these slow waves^[32,40].

There are 2 limitations of the recent studies, which should be evaluated in further studies: (a) since the composition of the test meals significantly affect small intestine motility, it remains to be determined, if the recent bolus transport and peristaltic patterns will be the same by using different test meals; (b) since the intertransducer distance significantly affect the recognition of propagated pressure waves, it remains to be determined, if more closely spaced recording points with 1-2 cm apart may provide more accurate data.

In summary, combined impedancometry and manometry in human duodenum provides detailed data about the relationship between the organization of contraction waves and the patterns of chyme flow during the postprandial state. This technique improves the analysis of intestinal motility. Several postprandial peristaltic patterns associated with transduodenal bolus transport have been identified showing that cluster of contractions constitutes an integral part of the peristaltic sequence associated with transduodenal bolus transport. The results provide new insights into the peristaltic mechanisms that are associated with transduodenal chyme transport and maintain the physiological function of the duodenum. The present results clearly indicate that comprehensive motility testing in the small intestine, particularly during the postprandial state, should be performed using the combined technique. The present data will serve as basis

findings forwarding clarifying small intestinal motor dysfunction.

Abstract

AIM: To compare the efficacy and tolerability of S-pantoprazole (20 mg once a day) versus racemic Pantoprazole (40 mg once a day) in the treatment of gastro-esophageal reflux disease (GERD).

METHODS: This multi-centre, randomized, double-blind clinical trial consisted of 369 patients of either sex suffering from GERD. Patients were randomly assigned to receive either one tablet (20 mg) of S-pantoprazole once a day (test group) or 40 mg racemic pantoprazole once a day (reference group) for 28 d. Patients were evaluated for reduction in baseline on d 0, GERD symptom score on d 14 and 28, occurrence of any adverse effect during the course of therapy. Gastrointestinal (GI) endoscopy was performed in 54 patients enrolled at one of the study centers at baseline and on d 28.

RESULTS: Significant reduction in the scores (mean and median) for heart burn ($P < 0.0001$), acid regurgitation ($P < 0.0001$), bloating ($P < 0.0001$), nausea ($P < 0.0001$) and dysphagia ($P < 0.001$) was achieved in both groups on d 14 with further reduction on continuing the therapy till 28 d. There was a statistically significant difference in the proportion of patients showing improvement in acid regurgitation and bloating on d 14 and 28 ($P = 0.004$ for acid regurgitation; $P = 0.03$ for bloating) and heart burn on d 28 ($P = 0.01$) between the two groups, with a higher proportion in the test group than in the reference group. Absolute risk reductions for heartburn/acid regurgitation/bloating were approximately 15% on d 14 and 10% on d 28. The relative risk reductions were 26%-33% on d 14 and 15% on d 28. GI endoscopy showed no significant difference in healing of esophagitis ($P = 1$) and gastric erosions ($P = 0.27$) between the two groups. None of the patients in either group reported any adverse effect during the course of therapy.

CONCLUSION: In GERD, S-pantoprazole (20 mg) is more effective than racemic pantoprazole (40 mg) in improving symptoms of heartburn, acid regurgitation, bloating and equally effective in healing esophagitis and gastric erosions. The relative risk reduction is 15%-33%. Both drugs are safe and well tolerated.

INTRODUCTION

The primary treatment goals in patients with gastroesophageal reflux disease (GERD) are relief of symptoms, prevention of symptom relapse, healing of erosive esophagitis, and prevention of complications of esophagitis^[1]. Proton pump inhibitors (PPIs) block the final step in acid production and hence are the most effective inhibitors of acid secretion^[2]. Recent advances in analytical methods for the separation of enantiomers of PPIs have led to a considerable interest in the stereoselective pharmacokinetics of PPI enantiomers^[3].

Pantoprazole, a selective and long acting PPI, is a chiral sulfoxide that is used clinically as a racemic mixture of S-pantoprazole and R (+) pantoprazole. The pharmacokinetics of R and S isomers of pantoprazole vary widely in extensive and poor metabolizers^[4]. The use of a single isomer avoids this variation and offers predictable pharmacokinetics. Animal studies have shown that S-pantoprazole is more potent (1.5 to 1.9 times) and effective (3 to 4 times) than racemate in inhibiting gastric lesions in different pre-clinical models^[3,5], suggesting that in human patients 20 mg of S-pantoprazole would be at least equivalent in efficacy to 40 mg of racemic pantoprazole. The present study was to compare the efficacy and tolerability of S-pantoprazole (20 mg) *versus* racemic pantoprazole (40 mg) in the treatment of gastro-oesophageal reflux disease (GERD) in adult patients.

MATERIALS AND METHODS

Materials

S-pantoprazole was synthesized by Emcure Pharmaceuticals Ltd. Tablets of S-pantoprazole (20 mg) and racemic pantoprazole (40 mg) were provided by the same source in coated opaque packets containing 28 tablets each without labeling the identity of the contents.

Methods

This multi-centre, randomized, double blind comparative study permitted by Drugs Controller General of India (DCGI) was conducted in compliance with the 'Guidelines for Clinical Trials on Pharmaceutical Products in India-GCP Guidelines' issued by the Central Drugs Standard Control Organization, Ministry of Health, Government of India (<http://www.cdsc.nic.in/html/GCP1.html>). The Ethical Committee approval was taken from Sharada Clinic Ethical Committee, Karad for Dr. S Erram, Independent Ethical Committee for Dr. H Thacker, Independent Ethical Committee of Surya Hospital, Pune for Dr. V Pai, Dr. V Mandora and Dr. J Shinde. Written informed consent was obtained from the subjects. The study was initiated on November 7, 2004 and completed on February 25, 2005.

Subjects

Patients of either sex, aged 18-65 years, with clinically confirmed GERD, were enrolled in the study after providing written informed consent. Patients with known hypersensitivity to pantoprazole and any major hematologic, hepatic, metabolic, gastrointestinal or endocrine disorder requiring any other anti-GERD medication and women who were pregnant or lactating or child bearing potential and not practicing effective method of contraception were excluded from the study.

Patients were randomized in blocks of ten, as per the computer generated randomization chart (www.randomization.com) into two treatment groups: one group receiving 20 mg S-pantoprazole once daily for 28 d (test group) while the other group receiving 40 mg racemic pantoprazole once daily (reference group) for the same period. The identity of the treatment allocated was unknown to either investigators or patients. The reference and test medications had a similar appearance, shape and size and could not be distinguished from each other based on their external appearance. All the patients completed the 28 d therapy during which they were followed up twice on d 14 and 28. Medication compliance was checked by counting the number of tablets left in the packet, if any.

Scoring of symptoms

Heartburn, regurgitation and dysphagia are symptoms of GERD. Although nausea and bloating are symptoms of dyspepsia which can be an overlapping condition in patients with GERD, this study included patients with symptoms of nausea and bloating also in order to capture the overall clinical benefit. The severity of heartburn, acid regurgitation, bloating and nausea was scored as follows: 0 = none, no symptom; 1 = mild, occasional symptoms that did not affect normal activities; 2 = moderate, frequent symptoms or symptoms that affected normal activities; 3

Table 1 Baseline demographic variables

Variable	Reference group	Test group
n	182	187
Male: Female	115:67	114:73
Mean age \pm SD (yr)	42.3 \pm 11.7	42 \pm 12.3

= severe, constant symptoms. The severity of dysphagia was scored as follows: 0 = normal; 1 = occasional sticking of solids; 2 = swallowing semisolids and Pureed food; 3 = swallowing liquids only. Scores were recorded for all the patients at the initiation of the study and then on d 14 and 28. Improvement in symptoms was defined as reduction in baseline symptom score. Assessment of within-group efficacy was done by comparing symptom scores on d 14 and 28 with baseline value on d 0 of the study. Assessment of between-group efficacy was done by comparing the proportions of patients showing improvement in symptoms in each group. GI endoscopy was done in 54 patients enrolled at one of the study centers on d 0 and 28. Tolerability profile was assessed by comparing the incidence of possible drug-related adverse effects in each group on d 14 and 28 of the study.

Statistical analysis

The results were analyzed using Fisher's exact test (two sided) for difference in proportions, Friedman's test (non-parametric repeated measures ANOVA) for comparison of between-days score (variation amongst column medians). For this, $P < 0.05$ was considered statistically significant. Individual differences between columns (d 0 vs d 14 and d 0 vs d 28) were assessed by Dunn's multiple comparisons test. The GraphPad InStat (version 3.06, 32 bit for Windows, September 11, 2003, GraphPad Software, San Diego California USA, www.graphpad.com) and WINPEPI suite (Abramson JH (2004) WINPEPI (PEPI-for-Windows) computer programs for epidemiologists as well as Epidemiologic Perspectives & Innovations (2004, 1:6) softwares were used for statistical analysis. UBC clinical significance calculator (<http://www.healthcare.ubc.ca/calc/clinsig.html>) was used to calculate the absolute risk reduction (ARR), relative risk reduction (RRR) and number needed to treat (NNT). ARR is the absolute arithmetic difference in rates of bad outcomes between experimental and control participants in a trial, calculated as experimental event rate minus control event rate. RRR is the proportional reduction in rates of bad outcomes between experimental and control participants in a trial, calculated as experimental event rate minus control event rate divided by control event rate. NNT is the number of patients who need to be treated to achieve one additional favorable outcome, calculated as $1/ARR$.

RESULTS

Three hundred and sixty-nine patients (229 males and 140 females) with symptoms of GERD were enrolled in the study after providing written informed consent. Baseline demographic variables of the two groups are shown in Table 1. There was no statistically significant difference between the two groups at baseline.

Fisher's test, P	0.19		0.01		0.004		0.004		0.004		0.03	

No significant differences were present in the baseline symptom scores in both groups. In both treatment groups, significant reductions in the mean and median scores for heart burn ($P < 0.0001$), acid regurgitation ($P < 0.0001$), bloating ($P < 0.0001$), nausea ($P < 0.0001$) and dysphagia ($P < 0.001$) were achieved on d 14 with further reduction on continuing the therapy till d 28 (Table 2). The percentage of patients in the reference group, achieving improvement in heart burn, acid regurgitation, bloating, nausea and dysphagia was 57.0%, 58.2%, 51.0%, 66.4% and 58.6% respectively at the end of 14 d therapy, and 74.4%, 82.4%, 76.5%, 81.3% and 79.3% respectively at the end of 28 d therapy. The percentage of patients in the test group, achieving improvement in heart burn, acid regurgitation, bloating, nausea and dysphagia was 64.3%, 73.5%, 67.8%, 72.7% and 67.8% respectively at the end of 14 d of therapy, and 85.5%, 92.9%, 86.7%, 81.3% and 84.7% respectively at the end of 28 d of therapy. There was a statistically significant difference in the proportion of patients showing improvement in acid regurgitation and bloating on d 14 and 28 ($P = 0.004$ for acid regurgitation; $P = 0.03$ for bloating), and heart burn on d 28 ($P = 0.01$) between the two groups, with a higher proportion in the test group than in the reference group (Table 3, Figure 1).

Of the 54 patients who underwent GI endoscopy, baseline findings of esophagitis and erosions were present in 17 (68%) and 6 (2.4%) patients out of 25 patients in the reference group and 21 (72.4%) and 2 (0.7%) patients out of 29 patients in the test group respectively. Twenty-eight days after therapy, esophagitis and erosions were present in 7 (28%) and 6 (2.4%) patients out of 25 patients in the

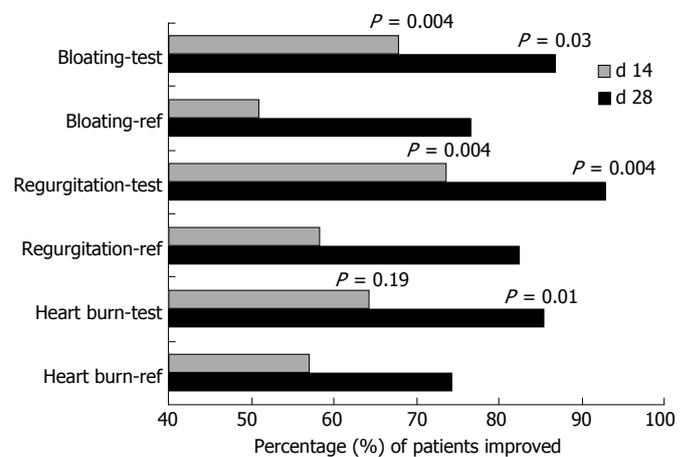

Figure 1 Percentage of patients showing improvement in heartburn, acid regurgitation and bloating in two treatment groups on d 14 and 28.

reference group and 9 (31%) and 3 (1.03%) patients out of 29 patients in the test group respectively. There was no significant difference in both treatment groups in healing of esophagitis ($P = 1$) and erosions ($P = 0.27$) (Table 5).

None of the patients in either group reported any adverse effect during the course of the study. Both drugs were well tolerated.

DISCUSSION

All PPIs are chiral compounds. Chirality can introduce marked selectivity and specificity into the way the drug is handled by the body and how the compound interacts

Table 4 Absolute risk reduction (95% CI for differences between proportions), relative risk reduction (RRR) and number needed to treat (NNT)

Symptoms, d	Absolute risk reduction ¹ (95% CI for difference in improvement) (%)	RRR (%)	NNT
Heartburn, d 28	+ 11.1 (2.7-19.4)	15	9
Acid regurgitation, d 14	+ 15.3 (5.3-25.0)	26	7
Acid regurgitation, d 28	+ 10.5 (3.6-17.5)	13	10
Bloating, d 14	+ 16.8 (5.7-27.9)	33	6
Bloating, d 28	+ 10.2 (1.4-19.0)	13	10

¹Significant differences in favor of test group were analyzed.

with the receptor or enzyme binding sites in some cases. Overall, this may lead to variations in pharmacokinetic and pharmacodynamic properties and differences in safety and toxicity profiles^[6].

The present study showed that symptoms of GERD *viz* heart burn, acid regurgitation, bloating, nausea and dysphagia improved significantly in both treatment groups. The results also showed that a significantly higher proportion of patients treated with 20 mg S-pantoprazole achieved improvement in heart burn, acid regurgitation and bloating as compared to patients treated with 40 mg racemic pantoprazole (Table 3, Figure 1). The absolute risk reduction was approximately 15% on d 14 and 10% on d 28. The relative risk reduction was approximately 15% on d 28 and at least 26% on d 14. This translates to a NNT of approximately 6-7 patients on d 14 and 9-10 patients on d 28 (Table 4). The findings of GI endoscopy showed that 20 mg S-pantoprazole was equally effective compared to 40 mg racemic pantoprazole in healing esophagitis ($P = 1$) and gastric erosions ($P = 0.27$). Both drugs were well tolerated with no adverse effects. These findings confirm that S-pantoprazole is the more active component of racemic pantoprazole that can be used even at half the dose of racemate to achieve a better efficacy in the treatment of GERD.

Table 5 Findings of GI endoscopy

	Number of patients with findings (n)			
	d 0		d 28	
	Esophagitis	Erosions	Esophagitis	Erosions
Ref	17	6	7	6
Test	21	2	7	3
Fisher's test, P	0.77	0.12	1	0.27

In summary, 20 mg S-pantoprazole is more effective than 40 mg racemic pantoprazole in improving symptoms of heart burn, acid regurgitation, bloating of GERD. Both drugs are safe and well tolerated.

ACKNOWLEDGMENTS

The authors thank Emcure Pharmaceuticals Ltd for providing S-pantoprazole and racemic pantoprazole tablets.

Abstract

AIM: To investigate the relationship between mucin 6 (MUC6) VNTR length and *H pylori* infection.

METHODS: Blood samples were collected from patients visiting the Can Tho General Hospital for upper gastrointestinal endoscopy. DNA was isolated from whole blood, the repeated section was cut out using a restriction enzyme (*Pvu* II) and the length of the allele fragments was determined by Southern blotting. *H pylori* infection was diagnosed by ¹⁴C urea breath test. For analysis, MUC6 allele fragment length was dichotomized as being either long (> 13.5 kbp) or short (≤ 13.5 kbp) and patients were classified according to genotype [long-long (LL), long-short (LS), short-short (SS)].

RESULTS: 160 patients were studied (mean age 43 years, 36% were males, 58% *H pylori* positive). MUC6 *Pvu* II-restricted allele fragment lengths ranged from 7 to 19 kbp. Of the patients with the LL, LS, SS MUC6 genotype, 43% (24/56), 57% (25/58) and 76% (11/46) were infected with *H pylori*, respectively ($P = 0.003$).

CONCLUSION: Short MUC6 alleles are associated with *H pylori* infection.

INTRODUCTION

H pylori has the unique ability to colonize the human stomach. Infection with *H pylori* invariably leads to gastritis and in many instances to peptic ulcer disease^[1]. Additionally, *H pylori* infection has been associated with gastric cancer^[2]. It is a common infection throughout the world, with prevalence ranging from below 20% in developed countries to over 80% in developing countries. Some risk factors for *H pylori* infection have been identified, such as low socio-economic status or poor hygiene^[3]. However, there is remarkable inter-individual variability in susceptibility to the infection that cannot be explained by differences in environmental factors.

Another factor that may be related to *H pylori* infection susceptibility is the composition of the mucus gel layer in the stomach, in which *H pylori* resides. This layer protects the underlying epithelium from acid, proteases, mechanical trauma, and pathogenic micro-organisms and its main constituents are high molecular weight glycoproteins named mucins. These mucins consist of a polypeptide backbone with O-linked oligosaccharide side chains, which largely determine the properties of the mucins^[4]. Interestingly, there is substantial inter-individual variation in the number of these side chains. This is caused by a variable number tandem repeat (VNTR) polymorphism in the genes encoding for the mucins. VNTRs consist of repeated DNA sequences and the number of repeats is highly variable. The resulting repeated amino acid sequences are located in the central part of the mucin polypeptide backbone, to which the oligosaccharide side chains are attached^[5]. Therefore, this polymorphism leads to the production of mucin polypeptides that substantially differ in both length and glycosylation^[6,7]. Thus, this VNTR polymorphism may affect the protective properties of the mucins and consequently the susceptibility to *H pylori* infection.

Normal gastric mucosa is characterized by the expression of mucins MUC1, MUC5AC and MUC6. MUC1 is of the membrane-bound type, whereas MUC5AC and MUC6 are of the secreted, gel-forming type^[8]. MUC6 and MUC1 show extensive VNTR variation,

MUC5AC only moderate^[6,9]. Furthermore, the length of the repeated sequence differs: a single MUC6 tandem repeat sequence consists of 507 base pairs whereas single MUC1 and MUC5AC tandem repeat sequences consist of only 60 and 24 base pairs, respectively^[6]. Therefore, the VNTR polymorphism has the most profound impact on allele length and protein structure of MUC6.

Despite the significant structural consequences of these VNTR polymorphisms, few studies investigated their pathophysiological consequences. In a study comparing gastric cancer patients with healthy blood donors, shorter VNTR sections were associated with gastric cancer for MUC6^[10] and MUC1^[11]. This effect may be mediated by an altered susceptibility to *H pylori* infection which is an important factor in gastric carcinogenesis, since Vinall *et al*^[9] showed that short VNTR sections were associated with *H pylori* infection for MUC1. However, there are no data available regarding the relationship between *H pylori* infection and VNTR polymorphism in MUC6, which is abundant in the stomach and has the most extensive VNTR variation^[12].

Therefore, the aim of this study was to investigate the hypothesis that susceptibility to *H pylori* infection is related to MUC6 VNTR length. We studied a sample of 160 patients referred for upper gastrointestinal endoscopy and found that patients with short MUC6 allele fragments have a significantly higher risk of being infected with *H pylori*, which suggests that mucin 6 protein length modifies susceptibility to *H pylori*.

MATERIALS AND METHODS

Subjects

From September to December 2003, all patients with upper gastrointestinal symptoms visiting the Gastroenterology Outpatient Clinic of the Can Tho General Hospital for upper gastrointestinal endoscopy were asked to participate in this study. Patients who had not been treated for *H pylori* infection in the past and who gave written informed consent were included in the study. At baseline, data regarding age, gender, smoking habits and alcohol consumption were registered.

Diagnosis of *H pylori* infection

All patients had a ¹⁴C urea breath test (HeliprobeTM, Noster system AB, Stockholm, Sweden). Patients were not allowed to use proton pump inhibitors/H₂-receptor antagonists or antibiotics during the two weeks preceding the breath testing. After an overnight fast patients took a HeliCapTM capsule (containing 1 μCi of ¹⁴C urea) with 50 mL of water. Ten minutes later, a breath sample was collected (Breath-CardTM) and analyzed during 4 min. Measuring more than 50 counts was regarded as proof of *H pylori* infection, measuring fewer than 25 counts was regarded as proof of absence of *H pylori* infection^[13].

Determination of MUC6 allele length

Blood samples were collected for DNA isolation (PuregeneTM kit, Gentra systems, Minneapolis, USA). MUC6 allele fragment length was measured using Southern blot

analysis. The DNA samples were digested with the *Pvu* II restriction enzyme as described previously by Vinall *et al*^[6]. This enzyme cuts just outside the tandem repeat domain and clearly reveals the MUC6 VNTR polymorphism. The resulting DNA fragments were separated by agarose gel electrophoresis (0.7% agarose in 0.04 mol/L Tris, 0.001 mol/L EDTA, pH 8.0) at 35 V for 18 h. We used λ -*Hind* III digest as a marker of DNA fragment length. DNA fragments were then transferred onto nylon membranes (Gene Screen PlusTM hybridization transfer membrane, Boston, USA). Afterwards, the nylon membranes were treated with ultraviolet radiation and prepared for hybridization by Church buffer. The probe, which consisted of two MUC6 tandem repeats, was produced by polymerase chain reaction with forward primer 5'-ACCTCTTTGGT-GACTCCAATTA-3' and reverse primer 5'-AACGT-GAGTGGGAAGTGTGGT-3' and randomly labelled with α -³²PdCTP. The resulting PCR product was verified by sequencing. After 18 h of hybridization of the probe in 0.5 mol/L phosphate buffer containing 7% SDS and 0.001 mol/L EDTA, SSPE/SDS-solutions were used to remove non-specifically bound probe. Using the λ -*Hind* III digest as a reference, the individual MUC6 allele fragment lengths were calculated.

Statistical analysis

The primary outcome of this study was the presence or absence of *H pylori* infection. For analysis, MUC6 allele fragment length was dichotomized as being either short (\leq 13.5 kb) or long ($>$ 13.5 kb) and patients were classified according to genotype [long-long (LL), long-short (LS), short-short (SS)]. Baseline characteristics for *H pylori* positive and negative patients were compared. MUC6 genotype and baseline characteristics were related to *H pylori* infection by means of unadjusted and adjusted logistic regression analyses, using the SAS[®] statistical software package (SAS Institute Inc., USA). Statistical significance was defined as a $P < 0.05$. Missing values were excluded from analysis.

RESULTS

Population

During the study period, 160 patients [mean age 43 years, 58 (36%) males, 92 (58%) *H pylori* infected] were included. Table 1 shows that *H pylori* positive and negative patients were comparable for all baseline characteristics except age.

MUC6 allele fragment length

Using the restriction enzyme *Pvu* II, a clear length polymorphism was detected. Minimum fragment length difference was 0.5 kb, reflecting the length of a single MUC6 tandem repeat that consists of 507 base pairs. MUC6 was found to be highly polymorphic with *Pvu* II-restricted fragment lengths ranging from 7 to 19 kb [mean 13.8 kb (SD: 2)] (Figure 1).

Factors associated with *H pylori* infection (Table 2)

Mean MUC6 allele fragment length was shorter for *H pylori* positive patients than for *H pylori* negative patients (13.4

Gender (male vs female)	0.62	0.3-1.2	0.47	0.2-1.9
Currently smoking	0.94	0.5-2.0	1.46	0.5-4.3
Current alcohol consumption	0.89	0.4-2.0	1.39	0.5-3.9

^a*P* < 0.05. ¹Adjusted for MUC6 genotype, age group, gender, current smoking and current alcohol consumption.

vs 14.2, *P* = 0.001). Since there were too many different allele fragment lengths to analyse separately, MUC6 allele fragment length was dichotomized as being either short (≤ 13.5 kb) or long (> 13.5 kb). Furthermore, patients were grouped according to genotype [long-long (LL), long-short (LS), short-short (SS)].

Patients with two short allele fragments were more often infected with *H pylori* than patients with one long and one short allele fragment [Odds ratio (95% CI): 2.41 (1.0-5.7)] or patients with two long allele fragments [4.24 (1.8-10.0)]. Figure 2 shows that there seems to be a gradual increase in prevalence of *H pylori* infection from 43% (24/56) for patients with two long allele fragments, through 57% (25/58) for patients with one long and one short allele fragments, to 76% (11/46) for patients with two short allele fragments.

Additionally, Table 2 shows that of the other patient characteristics measured, only age was associated with *H pylori* infection, and that the influence of MUC6 genotype remained virtually unchanged after adjusting for age group, gender, smoking and alcohol consumption.

DISCUSSION

The aim of this study was to investigate the relationship between MUC6 VNTR polymorphisms and *H pylori* infection. We were able to confirm that MUC6 VNTR length is

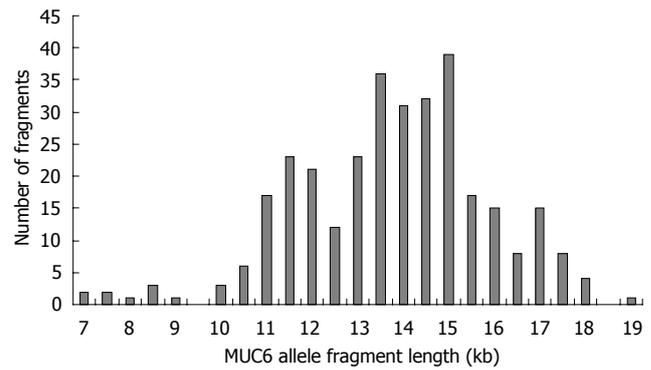

Figure 1 Distribution of MUC6 allele fragment lengths after *Pvu* II restriction enzyme digestion.

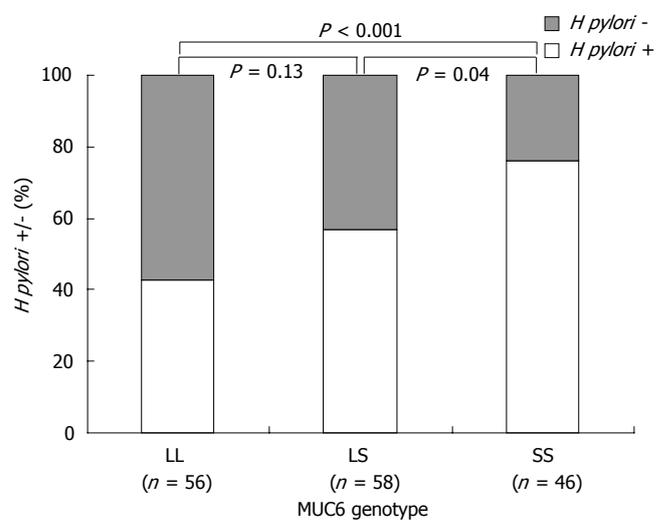

Figure 2 Percentage of *H pylori* infected patients according to MUC6 genotype.

highly polymorphic and our data suggest that *H pylori* infection is more frequent in patients with short MUC6 alleles.

Few other studies investigated the MUC6 VNTR polymorphism. Vinall *et al*^[6] found 11 different allele fragment lengths for MUC6, ranging from 8 to 13.5 kb. This degree of variation is considerably lower than in our study. It is unlikely that this difference in VNTR length variation is inherent to the Southern blotting technique, as we used the same restriction enzyme. However, the aforementioned study used the Centre d'Étude du Polymorphisme Humain (CEPH) series of families in France and these may be much more homogeneous than our study population.

The relationship between *H pylori* infection and mucin VNTR length has been investigated for another mucin gene, MUC1, and the results were similar to ours. Like other mucins, MUC1 lubricates epithelial structures and constitutes a barrier against acid, proteases and pathogenic organisms. Vinall *et al*^[9] showed that short MUC1 alleles were associated with *H pylori*-induced gastritis. Therefore, MUC1 and MUC6, although arising from different families of mucins, may be involved in the same mechanism regarding *H pylori* infection^[14].

Our results are also compatible with research focusing

on the relationship between mucin allele length and gastric cancer. In a study investigating 157 gastric cancer patients, it was found that short MUC6 alleles were more frequent in patients with gastric cancer than in healthy blood donors^[10]. This seems to be in line with our results that short MUC6 alleles are associated with *H pylori* infection. In fact, because *H pylori* has been classified as a class I carcinogen, the higher prevalence of *H pylori* infection among patients with short MUC6 alleles may (partly) explain the higher prevalence of gastric cancer in these patients. Again, the same goes for MUC1 since Carvalho *et al*^[11] stated that short MUC1 alleles were associated with gastric cancer. More research is necessary to determine whether these relationships are independent.

However, other researchers claimed that MUC5AC, and not MUC6, is important in *H pylori* infection: Van den Brink *et al*^[15] stated that *H pylori* co-localised with MUC5AC but not with MUC6, and Van de Bovenkamp *et al*^[6] stated that MUC5AC, and not MUC6, was the most important receptor for *H pylori*. However, in the study by Van den Brink *et al*, antibodies recognizing the MUC6 precursor rather than mature MUC6 were used. Therefore, it seems plausible that the precursor MUC6 is only found in neck and gland cells, where MUC6 is synthesized. However, the mature MUC6, which is secreted, may be found throughout a much larger area. In fact, Ho *et al*^[17] recently confirmed that the mucin within the glands consisted entirely of MUC6, but they also showed that, although the mucus layer on the gastric surface consisted primarily of MUC5AC, layers of MUC6 were interspersed between the layers of MUC5AC.

Regarding the receptor function of the mucins, MUC5AC is the primary source of Lewis B (Le^b), a terminal carbohydrate chain that acts as a ligand for the bacterial adhesion molecule BabA^[16,18]. However, although other receptor sites may be present on MUC6^[19], mucins may be involved in many other processes besides bacterial binding.

In fact, recently, Kawakubo *et al*^[20] showed that secretions from the glands (consisting of MUC6) may have an antibiotic effect on *H pylori*, while secretions from the superficial epithelium (primarily consisting of MUC5AC) may have a pro-biotic effect, thereby limiting *H pylori* infection to the superficial epithelium and protecting the deeper layers of the gastric mucosa. This is consistent with the geographical distribution of *H pylori* described by Van den Brink *et al*^[15]. The antibiotic effect was mediated by terminal α -1, 4-linked *N*-acetylglucosamine (α -1,4-GlcNAc) residues, which are present on the variable region of MUC6. Furthermore, the presentation of multiple terminal α -1,4-GlcNAc residues as a cluster may be important for achieving optimal activity. This may explain our finding that shorter MUC6 molecules, which have fewer α -1,4-GlcNAc residues and therefore lower antimicrobial activity, are associated with *H pylori* infection. More research is necessary to further elucidate the functions of the mucins.

Abstract

AIM: To evaluate the effect of resistance to activated protein C (aPCR), the most common known inherited thrombophilic disorder, on the risk of intestinal operation of fibrostenosis in patients with Crohn's disease (CD).

METHODS: In a previous study, we assessed the prevalence of aPCR in CD. In a retrospective case-controlled study, 8 of these CD patients with aPCR were now compared with 24 CD patients without aPCR, matched by gender, age at diagnosis and duration of disease in a 1:3 fashion. The primary end point was the occurrence of an intestinal CD-related operation with evidence of fibrostenosis in the bowel resection specimen.

RESULTS: The Kaplan-Meier analysis revealed that patients with aPCR had a lower probability of remaining free of operation with fibrostenosis than patients without aPCR ($P = 0.0372$; exact log-rank test) resulting in a significantly shorter median time interval from diagnosis of CD to the first operation with fibrostenosis (32 vs 160 mo). At 10 years, the likelihood of remaining free of operation with fibrostenosis was 25% for patients with aPCR and 57.8% for patients without aPCR.

CONCLUSION: CD patients with aPCR are at higher risk to undergo intestinal operation of fibrostenosis than those without aPCR. This supports our hypothesis of aPCR being a possible risk factor for fibrostenosis in CD.

INTRODUCTION

Fibrostenotic lesions of the bowel are frequent and serious complications in Crohn's disease (CD). They often require surgery, which may lead to short bowel syndrome in case of repeated bowel resections^[1-4]. Intestinal fibrosis in CD as a consequence of chronic transmural inflammation is characterized by increased production of extracellular matrix, including fibrillar collagen, by activated mesenchymal cells, such as fibroblasts and smooth muscle cells^[5,6]. However, the exact pathophysiological mechanism explaining variable disposition of CD patients to develop fibrostenotic lesions is unknown. But some risk factors have been discovered. For example, NOD2/CARD15 variants^[7-9] and smoking have been associated with fibrostenosis^[10,11]. Moreover, CD patients with antibody responses against *Saccharomyces cerevisiae* (ASCA), CD-related bacterial sequence (I2), *E. coli* outer membrane porin C (anti-OmpC), and neutrophil nuclear antigen (pANCA) have also been reported as being more likely to develop fibrostenotic lesions^[12-15].

Resistance to activated protein C (aPCR)^[16], representing the most common known inherited thrombophilic disorder^[17], has been shown to increase the rate of fibrosis in other inflammatory diseases, such as chronic viral hepatitis^[18]. Activated protein C serves as a natural anticoagulant by cleavage and inactivation of factor V a. Factor V plays a central regulatory role in hemostasis, since it contributes to the conversion of prothrombin to active thrombin, which, on the other hand, transforms fibrinogen into fibrin. A single-point mutation in the gene encoding factor V, also known as factor V Leiden, results in a form of factor Va that is resistant to degradation by activated protein C, leading to a relative hypercoagulation state^[19].

The increase of the rate of fibrosis in chronic viral hepatitis caused by aPCR was explained by thrombotic obliterations of small portal and hepatic veins resulting in local hepatocyte death and increased development of fibrosis and by the effect of thrombin through activation of stellate cells, which are the mediators of fibrosis in the liver^[20]. However, the role of aPCR in the development of fibrostenotic lesions in CD has not been elucidated till now. The potential role of the clotting system in CD has already been shown. Granulomatous vasculitis, intravascular fibrin deposition and capillary microthrombi have been reported in CD lesions^[21,22]. Additionally, CD has been observed less frequently in patients with inherited haemophilic disorders^[23]. On the other hand, aPCR as a thrombophilic disorder may favor intravascular fibrin deposition and thrombotic obliteration of the small vessels of intestinal lesions in CD, resulting in increased local cell death and fibrosis.

We, therefore, hypothesized that aPCR increases the rate of fibrosis in CD patients. We expected that CD patients with aPCR are more likely to have fibrostenotic lesions of the bowel than patients without aPCR, resulting in a lower probability of remaining free of operation with fibrostenosis.

MATERIALS AND METHODS

Patients and study design

This is a retrospective case-control study on the influence of aPCR on the presence of fibrostenotic lesions found at intestinal CD-related operations in CD patients. In a previous study on risk factors for thromboembolism in inflammatory bowel disease (IBD), we assessed the prevalence of aPCR in patients with IBD, including 77 patients with CD^[24]. We had detected 8 CD patients with aPCR who were now compared with CD patients without aPCR selected from the same database. CD patients with aPCR ($n = 8$) and without aPCR ($n = 24$) were matched by gender, age at diagnosis (± 10 years) and duration of disease (± 3 years) in a 1:3 fashion. A colleague blinded for the clinical course of the patients performed the matching. All patients included in the study were Caucasians and had been in routine care at our institution (Medical University of Vienna, Department of Internal Medicine IV, Division of Gastroenterology and Hepatology, Vienna). The diagnosis of CD was based on established criteria of clinical, radiological, endoscopic, or histological findings^[25]. The location of CD was determined according to the Vienna classification^[26]. The information on the clinical course, smoking habits, and the medical and surgical management was reviewed from the charts of the patients. A "smoker" was defined as a patient who had smoked at least seven cigarettes weekly for at least one year^[11]. Immunosuppressants, such as azathioprine, were considered for analysis if the duration of treatment had been at least 3 mo.

The primary end point of the study was the presence of fibrostenosis found at intestinal CD-related operations documented by the pathological and/or surgical report, respectively. The secondary end point was the occurrence of intestinal CD-related operations regardless of fibroste-

nosis. Only intestinal operations, such as bowel resections, stricturoplasties and gastrointestinal bypass-surgery, were included in the analysis. Creations of a stoma, intestinal reconstructions, exploratory laparotomies, and surgery of complicated perianal CD were excluded from the analysis. Two observers blinded for the aPCR status of the patients (W.R. and J.P.) reviewed the pathological and surgical reports of the patients for the presence of fibrostenosis. The Ethics Committee of the Medical University of Vienna approved this study.

Definition of fibrostenotic lesions

Strictureing disease is defined by the Vienna classification as the occurrence of constant luminal narrowing demonstrated by radiologic, endoscopic, or surgical examination combined with prestenotic dilatation and/or obstructive signs or symptoms but without evidence of penetrating disease^[26]. In our retrospective analysis, for the purpose of defining fibrostenotic lesions at the time of surgery, we modified this definition for four reasons. First, strictures of the bowel in CD may result not only from fibrostenotic lesions but also from inflammatory obstruction without fibrosis. Second, internal fistulas are often associated with strictures and such mechanical factors may even favor the development of fistula, which might explain the coexistence of fibrostenotic lesions and perforation^[27]. Third, radiologic, endoscopic, and surgical examination may report contradictory results. The most reliable data on complicated disease are available after resection from surgical and pathological reports. In these reports, fibrostenotic lesions were defined as luminal narrowing and bowel wall thickening on naked-eye examination of the surgical resection specimen. Histologically, strictures were recognized by thickening of the muscularis mucosa and by fibrosis of the submucosa^[27]. And fourth, we excluded "obstructive symptoms" from the definition, since it may be difficult to differentiate clinically from other disease-related complications (e.g. inflammation, fistula and abscess).

We, therefore, defined fibrostenotic lesions as the occurrence of bowel wall thickening and luminal narrowing on naked eye examination in the pathological and surgical report found at intestinal CD-related surgery as well as the occurrence of thickening of the muscularis mucosa and of fibrosis of the submucosa in the histological part of the pathological report. In case of discrepancies between pathological and surgical examination, the pathological report of the surgical resection specimen was rated with higher priority than the surgical report. In case of stricturoplasties and gastrointestinal bypass surgery, if a surgical resection specimen was not available, the assessment of fibrostenosis was based solely on the surgical report. The diagnosis of a fibrostenotic lesion was irrespective of evidence of penetration.

Assay system

aPCR was determined as described previously using the assay Coatest[®] aPCTM Resistance (Chromogenix, Mölndal, Sweden) according to the manufacturer's instructions^[24]. The normal range of the aPC ratio was > 1.9 and aPCR, therefore, was diagnosed if the aPC ratio was ≤ 1.9 . This

Table 1 Characteristics of 32 patients with Crohn's disease (frequencies, %, median values with range)

	With aPCR (n = 8)	Without aPCR (n = 24)
Sex ratio (M/F)	3/5	9/15
Age at diagnosis (yr)	30 (13-53)	31 (10-46)
Duration of disease (mo)	140 (86-257)	145 (65-272)
aPC ratio ¹	1.52 (1.19-1.64)	2.31 (2.08-2.66)
Patients with VTE in the history	5 (63%) ^b	2 (8%)
Smokers	4 (50%)	19 (79%)
Patients under azathioprine	4 (50%)	15 (63%)
Location of CD ²		
Terminal ileum	2 (25%)	4 (17%)

aPCR: resistance to activated protein C; CD: Crohn's disease; VTE: venous thromboembolism. ¹The patients were divided into the two groups according to the value of the aPC ratio: \leq (diagnosis of aPCR) and $>$ 1.9 (normal range), respectively. ²The location of disease was classified according to the Vienna classification^[26]. ^b $P < 0.01$ vs patients without aPCR.

test with predilution of samples with factor V-deficient plasma has been shown to have a very high sensitivity and specificity of nearly 100% for the diagnosis of factor V Leiden, including a discrimination between heterozygous and homozygous subjects^[28-30].

Statistical analysis

All computations were performed with the use of SAS software, version 9 (SAS Institute Inc., Cary, NC, USA). Data were presented as frequencies, percentages and median values with range, respectively. Differences between groups were analyzed using the fisher's exact test for categorical data and the Mann-Whitney *U*-test for continuous data. Survival time methods were used to analyze the time from diagnosis of CD to the first intestinal CD-related operation with fibrostenosis and from diagnosis of CD to the first intestinal CD-related operation, respectively, (uncensored observations) or the duration of follow-up among patients without intestinal CD-related operation with fibrostenotic lesions and without intestinal CD-related operation, respectively (censored observations)^[31]. The probability of survival free of intestinal CD-related operation with fibrostenosis and survival free of intestinal CD-related operation regardless of the presence of fibrostenosis, respectively, was estimated according to the Kaplan-Meier method^[32]. Differences between Kaplan-Meier curves of both groups were analyzed using the exact log-rank test for unequal follow-up^[33]. The study design included 1:3 matching (CD with aPCR : CD without aPCR) with regard to gender, age at diagnosis and duration of CD. Differences were considered significant if *P* was $<$ 0.05.

RESULTS

Study population

The clinical data of both patient groups are summarized

Table 2 Intestinal CD-related surgery in 32 patients with Crohn's disease (frequencies, %, median values)

	With aPCR (n = 8)	Without aPCR (n = 24)
Patients having undergone an operation ¹	6 (75%)	16 (67%)

aPCR: resistance to activated protein C; CD: Crohn's disease. ¹Operations: intestinal CD-related operations; ²Operations with fibrostenosis: intestinal CD-related operations with fibrostenosis; ³The location of fibrostenosis was classified according to the Vienna classification for location of Crohn's disease^[26]. ^a $P < 0.05$ vs patients without aPCR.

in Table 1. Eight patients had an aPC ratio below 1.9 and were diagnosed as having aPCR: one patient had an aPC ratio of 1.19 consistent with homozygous for factor V Leiden and the other 7 patients had aPC ratios ranging from 1.46 to 1.64 consistent with heterozygous for factor V Leiden^[30]. Twenty-four patients had values of the aPC ratio within the normal range. Neither patient group differed in terms of location of disease, and percentage of smokers and patients who had been treated with azathioprine (Table 1). Furthermore, the number of cigarettes per day, the duration of smoking, and the dosage and duration of treatment with azathioprine did not differ between either patient group (data not shown). No immunosuppressants other than azathioprine had been administered. None of the patients had received infliximab or any other biological agent. Patients with aPCR had a history of venous thromboembolic complications diagnosed by imaging procedures significantly more often than the patients without aPCR ($P < 0.01$). Most of the thromboembolic events had been deep venous thromboses of the legs and pulmonary emboli.

Intestinal CD-related surgery

Six of 8 patients with aPCR and 16 of 24 patients without aPCR underwent intestinal surgery. Altogether, 44 intestinal CD-related operations (13 in patients with aPCR and 31 in patients without aPCR) had been performed. All operations had been intestinal resections, except for one case of gastroentero-anastomosis, which was necessary to circumvent the obstructed duodenum in a patient with CD of the upper gastrointestinal tract. A strictureplasty and a resection of another bowel segment performed at the same surgical procedure in a patient with aPCR were counted as one operation. The location of the bowel resections did not differ between both patient groups and was most likely of the terminal ileum (Table 2). In addition to bowel resections, three balloon dilations of fibrostenotic

lesions had been performed in two patients with aPCR but not in patients without aPCR. These interventions were not included in the analysis.

Operations with fibrostenosis: primary end point

There was a clear tendency for fibrostenosis to be found more often in the presence of aPCR. At the first intestinal CD-related operation, fibrostenotic lesions were found in all 6 (100%) patients with aPCR, but only in 10 out of 16 (62.5%) patients without aPCR ($P = 0.079$). The Kaplan-Meier analysis revealed that patients with aPCR had a significantly lower probability of remaining free of operation with fibrostenosis compared to patients without aPCR ($P = 0.0372$; exact log-rank test). This was also represented by the median time from diagnosis to the first operation with fibrostenosis being significantly shorter in patients with aPCR than in patients without aPCR (32 *vs* 160 mo; Table 2). In a further step, the calculation was limited to 120 mo, since this time interval was just below the median observation time of the patients (140 and 145 mo, respectively) and, therefore, more than half of the patients were under follow-up during the first 10 years after diagnosis of CD ($P = 0.0216$; exact log-rank test) (Figure 1). At 10 years, the likelihood of remaining free of operation with fibrostenosis was 25% for patients with aPCR and 57.8% for patients without aPCR.

Both observers who reviewed the pathological and surgical reports of the patients for fibrostenotic lesions agreed on the presence or absence of fibrostenosis in all operations. In 4 out of 44 operations, a fibrostenosis was described in the pathological report but was not mentioned in the surgical report. In all these four cases (1 patient with aPCR and 3 patients without aPCR), the surgeons described inflammatory masses that made it difficult to diagnose fibrostenosis in the surgical situation.

Overall operations: secondary end point

Concerning any intestinal CD-related operation without regard to whether it revealed fibrostenosis or not, patients with aPCR did not undergo operations more often than patients without aPCR. Six of 8 (75%) patients with aPCR and 16 of 24 (67%) patients without aPCR had undergone intestinal surgery ($P = 0.32$) (Table 2). Furthermore, the median time interval from diagnosis of CD to the first operation (Table 2), and the probability of remaining free of intestinal surgery (Kaplan-Meier survival curve not shown) did not significantly differ between the two patient groups ($P = 0.24$).

DISCUSSION

To our best of knowledge, this is the first report on an association between resistance to activated protein C and fibrostenosis in Crohn's disease. In a case-controlled study setting, aPCR increased the risk of fibrostenotic lesions found at intestinal surgery as described by surgical and/or pathological reports. CD patients with aPCR had a significantly lower probability of remaining free of intestinal operations with fibrostenosis. These data support our hypothesis that aPCR accelerates the development of

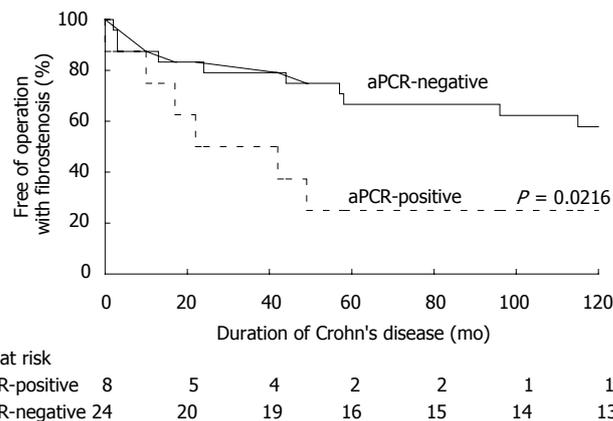

Figure 1 Kaplan-Meier curves for CD patients with and without aPCR, for remaining free of intestinal CD-related operation with fibrostenosis. A significantly lower proportion of patients with aPCR remained free of operation with fibrostenosis as compared to CD patients without aPCR ($P = 0.0216$; exact log-rank test). The calculation was limited to a period of 120 mo.

fibrosis in intestinal lesions in CD patients.

The primary end-point in the present study was the occurrence of an intestinal CD-related operation with fibrostenosis. Fibrostenotic lesions were referred to bowel wall thickening and luminal narrowing on naked-eye examination and to patho-histological features. This definition of fibrostenosis was modified from the definition of disease behavior used in the Vienna classification^[26] and was irrespective of evidence of penetration. The most important reasons for modification were the association of internal fistula and fibrostenosis in multiple bowel resection specimens^[27] as well as the possible occurrence of inflammatory bowel obstruction without fibrostenosis. It is difficult or sometimes impossible to distinguish inflammatory from fibrostenotic strictures by current diagnostic techniques, including imaging procedures and endoscopy, leaving the question of what is the gold standard for the differential diagnosis? Is there any method, which is superior to direct visualization by the surgeon and the pathologist as well as to patho-histological investigation? From the literature, good evidence cannot be retrieved. Thus, we based our evaluation of fibrostenosis on the assumption that surgical and pathological reports deliver the most reliable data on the presence of fibrostenosis and are, therefore, superior to imaging procedures in the diagnosis of fibrostenotic strictures on expert opinion.

aPCR is the most common known inherited thrombophilic disorder known until now^[16,17]. The genetic basis of aPCR is a single-point mutation in the gene encoding for coagulation factor V, also known as factor V Leiden. Factor V Leiden has a 2%-7% prevalence in most Caucasian populations and is identified in 20%-50% of patients with venous thromboembolism^[17,34-36].

In addition to the increased risk of venous thromboembolism, aPCR and other thrombotic risk factors have also been shown to accelerate the rate of fibrosis in inflammatory diseases, such as chronic viral hepatitis^[18,37,38]. Thrombotic obliterations of small portal and hepatic veins and activation of the stellate cells by

thrombin were assumed to cause increased fibrosis in the liver^[20]. The effect of thrombin is mediated through activation of thrombin receptors on the stellate cells, which are up-regulated during chronic liver injury^[39]. Furthermore, aPCR significantly increased pulmonary fibrosis in bleomycin-induced inflammatory lung injury in mice^[40]. Additionally, an association between aPCR and fibrosis has been described in a transgenic factor V Leiden mouse model with enhanced fibrin deposition in multiple tissues^[41]. In CD, an influence of the clotting system on the pathomechanism has been assumed based on the finding of intravascular fibrin deposition and capillary microthrombi^[21,22] and a reduced frequency of CD in patients with inherited haemophilic disorders^[23].

The association between aPCR or any other thrombotic risk factor and fibrosis in CD has not been previously investigated. An increased rate of fibrosis may lead to fibrostenotic lesions of the bowel, which often require surgery. Intestinal fibrosis and fibrostenosis are caused by uncontrolled proliferation of mesenchymal cells and excessive production of extracellular matrix proteins, including fibrillar collagen^[5,6]. Fibroblasts cultured from fibrostenotic lesions in CD patients, for instance, have been shown to synthesize an increased amount of collagen type III^[42]. A precondition for the development of fibrosis is a chronic transmural inflammation, which is a typical feature of CD. Infiltrating immune cells are considered to secrete cytokines and growth factors, such as transforming growth factor beta (TGF- β), in the mesenchymal layers, which might lead to activation of fibroblasts^[6,43].

Some risk factors predispose to fibrostenosis in CD. Several studies reported that CD-associated NOD2/CARD15 variants are associated with fibrostenotic lesions^[7-9] and, furthermore, that CD patients who are positive for ASCA, I2, anti-OmpC or pANCA are also more likely to develop fibrostenosis^[12-15]. Additionally, smoking has been shown to predispose to ileal localization of CD and to fibrostenotic lesions^[10-11]. But for all the itemized risk factors, it remains to be determined whether the association with fibrostenosis is independent or secondary to association with ileal involvement.

Immunosuppressive drugs do not seem to prevent the formation of fibrostenosis. Azathioprine has been shown to improve mucosal healing but not the development of fibrostenosis in CD, especially in the ileocecal region^[44-46]. A recent retrospective study on the use of immunosuppressive drugs and the need for intestinal surgery described only a tendency of reduced probability of formation of fibrostenosis over the time, despite a significant increase of the use of azathioprine in the same time period^[4]. However, the only immunosuppressive drug given to the patients in the present study was azathioprine, which was equally frequently administered to the patients of both groups. We can, therefore, exclude any influence of medical treatment on the results of our study.

Furthermore, there was no difference in smoking habits between the two patient groups. But all the other risk factors for fibrostenosis, such as NOD2/CARD15 variants, ASCA, I2, anti-OmpC, and pANCA, were not fully available and, therefore, not included in the analysis. It was thus not possible to investigate the influence of

these risk factors on our results. A further limitation might be the small number of patients included in the study. Since the effect of aPCR on fibrostenosis in CD was unknown prior to the present investigation, a calculation of the sample size was not possible. Our aim was to perform a pilot study on an association between aPCR and fibrostenosis in CD and by this way to generate the basis for a working hypothesis.

aPCR did not significantly influence the number of overall intestinal CD-related operations regardless of fibrostenosis. Therefore, we have no evidence that other indications for surgical treatment in CD except fibrostenotic strictures are influenced by aPCR.

In summary, our results give rise to this hypothesis that aPCR may be a risk factor for fibrostenosis in CD. The effect of aPCR might not be specific and coagulation might generally be involved in the development of fibrosis in CD, disposing patients with any thrombophilic disorder also to have an increased tendency to fibrostenosis. We are aware that our data should be verified by further larger trials, including data about other known risk factors for fibrostenosis. However, our study contains the first reference to an association between aPCR and fibrostenosis in CD and may provide a new insight in the pathogenesis of fibrostenosis in CD.

Abstract

AIM: To evaluate the potential association of xeroderma pigmentosum group D (XPD) codon 751 variant with outcome after chemo-radiotherapy in patients with resected gastric cancer.

METHODS: We used PCR-RFLP to evaluate the genetic XPD *Lys751Gln* polymorphisms in 44 patients with stage III (48%) and IV (20%) gastric cancer treated with surgery following radiation therapy plus 5-fluorouracil/leucovorin based chemotherapy.

RESULTS: Statistical analysis showed that 75% (12 of 16) of relapse patients showed *Lys/Lys* genotype more frequently ($P = 0.042$). The *Lys* polymorphism was an independent predictor of high-risk relapse-free survival from Cox analysis (HR: 3.07, 95% CI: 1.07-8.78, $P = 0.036$) and Kaplan-Meier test ($P = 0.027$, log-rank test).

CONCLUSION: XPD *Lys751Gln* polymorphism may be an important marker in the prediction of clinical outcome to chemo-radiotherapy in resected gastric cancer patients.

INTRODUCTION

The xeroderma pigmentosum group D (XPD) gene encodes a protein required for nucleotide excision repair (NER). This product recognizes and repairs a wide range of structurally unrelated lesions such as bulky adducts caused by UV light, environmental agents, cross links and oxidative damage^[1,2]. Moreover, XPD gene is one of the components of basal transcription factor IIIH (TFIIH), participating also in transcription initiation. Since XPD is involved in both transcription and NER, it may be able to repair other types of damage, such as radiation therapy-induced damage. Because XPD interacts with many different proteins as part of TFIIH transcription factor, amino acid variants in different domains of XPD, such as 683 and 751, may affect different protein interactions, and result in expression of different phenotypes^[3,4].

Intrinsic and acquired resistance to cancer chemotherapeutic agents results from polymorphisms in genes encoding DNA repair enzymes. Differences in responsiveness of cancer cells to anticancer agents can be differently affected by changes in repair efficiency. Clinical outcomes after chemotherapy may be influenced by pharmacogenetic polymorphisms in DNA repair enzymes. In this sense, three single nucleotide polymorphisms (SNP) in the XPD gene (in codons 156, 312, and 751) are related with different DNA repair capacity^[5-7]. Thus, variants generated by amino acids can change *Asp312Asn* (exon 10, G > A substitution) and *Lys751Gln* (exon 23 A > C substitution) located in conserved regions of the XPD protein, and are associated with lower efficiency of damage repair and significantly higher background frequency of apoptotic cells in irradiated lymphocytes^[8].

Although gastrectomy is the only potentially curative treatment in gastric-cancer patients, the overall survival results remain unsatisfactory. The main factor accounting for high mortality is relapse after surgical resection. During the past few decades, the principle of combined treatment modality has been developed and applied in various solid tumors including gastric cancer. In order to prevent recurrence and increase the cure rate of gastric-cancer after surgery, multiple studies using variable treatment modalities

ties have been undertaken. One of the landmark studies reported that chemo-radiotherapy can significantly improve survival after resection of stage IB to stage IV gastric cancers^[9]. Chemo-radiotherapy has been increasingly recognized as a standard of care since then^[10,11]. However, whether adjuvant chemo-radiotherapy can prolong the survival of patients with extensive lymph node dissection remains debatable. In this paper, we evaluated the potential role of XPD codon 751 variant in the outcome of 44 patients with resected gastric cancer after chemo-radiotherapy.

MATERIALS AND METHODS

Patients

Characteristics of the patients are listed in Table 1. From October 1992 to January 1999, 44 patients consisting of 32 men (73%) and 12 women (27%) with a median age of 60 years (range: 33-77 years) with diagnosis of gastric cancer after having undergone gastrectomy were treated with radiation plus 5-fluorouracil (5-FU) and leucovorin. Thirty-two percent of the patients had stage I - II and 68% stage III-IV gastric cancer at the time of diagnosis (Table 1). The median follow-up time was 46.9 mo (range: 5.33 to 124.06 mo). The median time to progression was 37.5 mo (range: 2.3 to 95.4 mo). This study was conducted in Navarra Hospital Center, and informed consent was obtained from all the patients for using their tissues. The clinicopathological information of each subject was obtained from the tumor registry at Navarra Hospital.

Treatment schedule

The patients received postoperative treatment with 5-FU plus leucovorin and local radiation 20-40 d after gastrectomy. This chemotherapy regimen developed by the North Central Cancer Treatment Group^[12] was used before and after radiation. Chemotherapy (fluorouracil, 425 mg/m² per day, and leucovorin, 20 mg/m² per day) was initiated on d 1 followed by chemo-radiotherapy on d 28 after the initial cycle of chemotherapy. Chemo-radiotherapy consisted of 4500 cGy of radiation at 180 cGy/d, 5 d/wk for 5 wk, with 5-FU (400 mg/m² per day) and leucovorin (20 mg/m² per day) on the first four and the last three days of radiotherapy. One month after radiotherapy, two 5-d cycles of 5-FU (425 mg/m² per day) plus leucovorin (20 mg/m² per day) were given every other month.

The 4500 cGy of radiation was delivered in 25 fractions (5 d/wk) to the tumor bed, regional nodes and 2 cm beyond the proximal and distal margins of resection. The adjuvant treatment was performed as previously described^[9].

Samples and DNA extraction

Surgical specimens (paraffin blocks) were cut into 5 µm-thick sections for molecular analysis.

Three tissue sections were transferred into a micro centrifuge tube and 1.2 mL of xylene was added. After centrifugation at 14 000 r/min for 5 min at room temperature (RT), the supernatant was removed. Subsequently, the tissue samples were washed in 1.2 mL of 96 mL/L

ethanol. After centrifugation at 14 000 r/min for 5 min at RT, the supernatant was discarded. The washing procedure was repeated another time. The samples were dried for 3-5 min, in a vacuum pump (any letter between were and dried).

DNA was extracted using the QIAamp DNA Mini Kit (Qiagen-IZASA- Barcelona Spain). The deparaffinized samples were re-suspended in 180 µL of ATL buffer plus 20 µL of proteinase K and incubated overnight at 56°C. The samples were processed according to the provided protocol. The purified DNA was finally eluted in a total volume of 150 µL. DNA yield was quantified by NanoDrop 3.0.0 (Nucliber, Wilmington, Delaware USA).

About 7-509 mg/L of DNA was extracted and 45-200 ng of genomic DNA was used as template. PCR/RFLP-based assays were performed as described previously^[5] with slight modifications. The PCR product (20 µL) was digested with 25 units of Pst I enzyme (New England BioLabs, -IZASA, S.A, Barcelona-, Spain) in 50 µL reaction mixture for 1 h. The digestion product was visualized in 3% agarose gel (Pronadisa, Madrid, Spain). The wild-type homozygote was defined by 104- and 220-bp banding patterns; the heterozygote by 63-, 104-, 157-, and 220-bp fragments; and variant homozygote

by 63-, 104-, and 157-bp fragments. Some samples were noted as “unknown” because they could not be amplified due to a relatively frequent occurrence of PCR inhibitory substances in samples prepared with this DNA extraction method (Table 1). Furthermore, three DNA samples corresponding to each genotype selected by direct sequencing were used. The results were in concordance with RFLP genotyping.

Statistical analysis

This study was designed to analyze the role of XPD polymorphism in the prediction of relapse. Relapse free-survival (RFS) was defined as the time from the start of chemotherapy to the first evidence of disease progression. RFS was calculated using the Kaplan-Meier method. Contingency tables and chi-square test (χ^2) were used to summarize the association of relapse with XPD polymorphism. All *P* values were two-sided. Cox proportional hazards models were also used to evaluate the different variables considered. All statistical tests were conducted by SPSS software 11.0 version for Windows (SPSS, Inc. Chicago). *P* ≤ 0.05 was considered statistically significant.

RESULTS

Thirty-seven patients were evaluated for the *Lys751Gln* polymorphism. Seven patients were not assessed due to poor sample extraction quality. Fifty-one percent (19 of 37) of the patients were homozygous for the *Lys/Lys* genotype, 38% (14/37) heterozygous for *Lys/Gln*, and 11% (4 of 37) homozygous for the glutamine variant (Table 1). The *751Gln* allele frequency was 0.33, similar to that observed in other studies^[5,7].

Sixteen patients (36%) developed grade III-IV toxicity. Hematological toxicity was found in 62% (10/16) patients compared with gastrointestinal and other toxicity in 19% (3/16) patients (Table 2). However, there was no

association between XPD genotype and toxicity (data not shown).

Gastrectomy with D1 lymphadenectomy was performed in all patients. Of the 44 patients, 20 (45.5%) had relapse and 17 (85%) of them died. The first relapse site was local in 5, distant in 10, and both local and distant in 5 (Table 3).

Statistical analysis showed that 75% (12 of 16) of relapse patients showed *Lys/Lys* genotype more frequently (*P* = 0.042, Table 4).

Other clinico-pathological features such as histology, grading and localization were not significant (data not shown).

The relative risk of progression (with *Lys/Lys* genotype used as the reference) was 0.35 (95% CI: 0.11-1.09) for patients carrying the *Lys/Gln* genotype and 0.25 (95% CI: 0.03-1.96) for the *Gln/Gln* group (Table 5).

Only XPD genotype and stage to diagnosis showed a significant relation with cancer relapse and were evaluated as potential predictors of RFS by Cox test. We used the combined genotypes *LysGln/GlnGln* as reference in these analyses and found that the *Lys/Lys* genotype was more strongly associated with disease progression (*P* = 0.036) than the combined *LysGln/GlnGln* genotype (adjusted HR: 3.07, 95% CI: 1.07-8.78) (Table 6, Figure 1).

DISCUSSION

Most cases of gastric cancer are diagnosed at an advanced stage with poor prognosis. Surgery remains the only potentially curative treatment, but it is associated with a high rate of local recurrence and distant metastases. When irradiation is combined with surgical resection for all or a

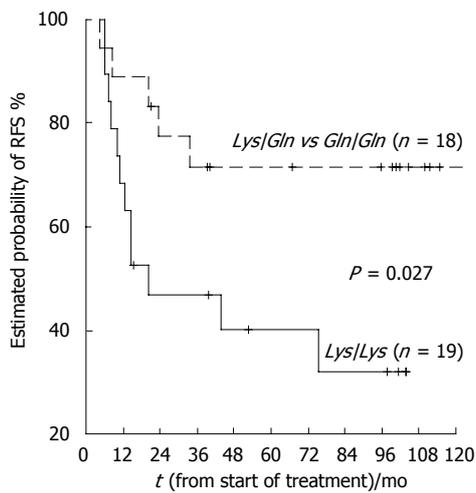

Figure 1 XPD751 polymorphism and RFS under radio-5Fu/Lv treatment.

majority of tumors, both survival and local control appear to be better than those for the unresected patients^[13]. Epidemiological studies have shown that *Gln* variant at XPD-751 polymorphism is partially able to repair DNA in lung cancer^[7,14]. In this sense, cancer treatment is to cause DNA damage and tumor cell apoptosis. *Gln* variant seems to show a lower ability to repair DNA damage and cancer patients are more sensitive to chemo-radiotherapy. In contrast, the presence of allele *Lys* represents a positive effect in different DNA repair pathways and a possible poor response to cancer treatment. In this study, we found a significant relationship between clinical response to chemo-radiotherapy and the XPD *Lys751Gln* polymorphism. Patients with the *Lys/Lys* genotype were more likely to have relapse compared to those with the combined *Lys/Gln* and *Gln/Gln* genotype.

Scientific publications are available but with diverging results in the XPD751 polymorphism and cancer risk or treatment efficiency^[3,5-7]. Thus, decreased DNA repair has been associated with *Lys* allele^[6]. Epidemiological study has reported association of this allele with a higher risk of basal cell carcinoma^[5] even though no significant relationship between this polymorphic gene and DNA repair proficiency has been reported^[15,16]. Spitz *et al*^[7] and other research group^[17] reported a suboptimal DNA repair capacity (DRC) particularly in subjects who were homozygous for 751*Gln* alleles. Moreover, a recently study has found a tendency toward a higher background frequency of apoptotic cells in irradiated lymphocytes carrying variant homozygote *Gln* at XPD codon 751^[8]. Our results are in agreement with these studies, suggesting that heterozygote and homozygote *Gln* alleles may therefore increase their clinical response to suboptimal DNA damage repair after treatment.

Repair of DNA damage is a complex process^[1,18,19]. Functional protein of XPD could be affected by a structural change (*Lys* → *Gln*) from a basic to a polar amino acid change located at about 50-base upstream from the poly (A) signal^[5]. Moreover, close proximity in the genome between XPD and other polymorphic DNA repair genes such as X-ray repair cross complementing (XRCC1) and excision repair cross complementing (ERCC1) may influ-
