ence the interaction between them leading to different or synergic DNA repair capability. A recent molecular epidemiology study has genotyped 44 SNPs in 20 genes involved in four DNA damage repair pathways, showing that homozygous *Gln751Gln* and other gene variants genotyped are highly associated with lung cancer risk^[20]. In the same way, variant *Gln* allele and some nucleotide and base excision repair (NER and BER, respectively) variant gene members are associated with increased level of polycyclic aromatic hydrocarbon-DNA adducts^[15,21].

In conclusion, XPD *Lys751Gln* polymorphism may be an important marker of genotoxicity that can predict the clinical outcome of resected gastric cancer treated with chemo-radiotherapy.

Abstract

AIM: To investigate whether perinatal events, intrauterine or postpartum, are associated with the development of primary sclerosing cholangitis (PSC) later in life.

METHODS: Birth records from 97 patients with adult PSC in Sweden were reviewed. Information on perinatal events including medications and complications during pregnancy, gestation length, birth weight and length were collected. Two control children of the same sex were selected for each subject. Conditional multiple logistic regression was used to assess associations of the perinatal measures with development of PSC.

RESULTS: No significant associations were found between gestational age, birth length, breastfeeding, and the majority of medical complications including infections or medication during pregnancy for the mothers or postpartum for the children. Vaginal bleeding and peripheral oedema showed associations with PSC, with matched odds ratios of 5.70 (95% CI, 1.13-28.83) and 2.28 (95% CI, 1.04-5.03), respectively.

CONCLUSION: The associations of vaginal bleeding and oedema with subsequent PSC cannot readily be

explained, so our findings do not strongly support the hypothesis of a significant role of perinatal events as a risk for the development of PSC later in life.

INTRODUCTION

Primary sclerosing cholangitis (PSC) is a complex disease likely to involve multiple susceptibility genes, environmental and immunological risk factors. PSC can present at any age and is characterised by a long subclinical asymptomatic period in many cases^[1]. The aetiology of the disease is unknown. PSC is closely associated with inflammatory bowel disease (IBD) most commonly ulcerative colitis (UC)^[1,2]. A role for perinatal events in the aetiology of IBD has been suggested. Non-specific exposures such as infections and more specific factors including measles virus infection and vaccination as well as appendectomy have been shown to be associated with later development of IBD^[3-6]. There is evidence of genetic susceptibility in both IBD and PSC^[7,8] and there is a possibility that some immune profiles inherited by the offspring may increase the risk for both these autoimmune diseases as well as for perinatal events and other complications during pregnancy. Since perinatal events represent an increased risk for IBD^[6], some early life events may be a direct risk for PSC. The close association between IBD and PSC has been suggested to be part of the pathogenetic explanation for PSC through the existence of an entero-hepatic circulation of lymphocytes. Some lymphocytes generated in the gut during active IBD may subsequently persist as long-lived memory cells and be activated in the liver resulting in hepatic inflammation and the development of PSC. The molecular basis for this hypothesis is that liver and gut share the same lymphocyte homing receptors^[9]. However,

this hypothesis does not explain why only 5% of patients with IBD eventually develop PSC^[10] and why PSC can precede IBD. Whether perinatal factors play a role for the development of PSC later in life has not been previously evaluated.

The aim of this study was to assess whether perinatal events, intrauterine or postpartum, are associated with an increased risk of PSC.

MATERIALS AND METHODS

All patients with PSC treated at the five largest University Hospitals in Sweden between 1970 and 1998 were selected for this study ($n = 311$). Through the unique national registration number assigned to every Swedish citizen we were able to trace birth parish to identify the hospital where delivery occurred. To trace the medical records associated with delivery and pregnancy from these patients, we searched the respective hospital archives. The detailed medical records from 97 patients with PSC were collected. Individuals born abroad or delivered at home by midwives were excluded. As controls, we selected two children of the same sex as the subject, who were delivered at the same hospital immediately after the subjects. The controls had to be alive and living in Sweden at the date of PSC diagnosis for the case. Controls who had died or emigrated before the diagnosis of their matched case were excluded. One hundred and seventy five controls remained for analysis.

The diagnosis of PSC was based on biochemical, histological and cholangiographic features^[11]. Onset of PSC was defined as first cholangiogram consistent with the diagnosis. Adult PSC was defined as onset of PSC at 16 years of age or later. A diagnosis of UC was based on a typical history and characteristic endoscopic and histological findings^[12]. All 97 patients with PSC had undergone colonoscopy to look for IBD and no endoscopic or histological signs of IBD were found in the non-IBD PSC patients.

For both, subjects and controls, we retrieved information on the age of parents, delivery method, parity and maternal complications including proteinuria, peripheral oedema, hypertension or other diseases during the pregnancy. Other conditions and factors during pregnancy included surgeries, infections, nausea, anemia, varices, constipation, thrombosis or any other disease reported by the patients to the midwife and documented in the patient's record. Information concerning medication during pregnancy, gestational age, birth height and weight, weight of the placenta and medical problems experienced by the mother or child postpartum were also collected. Small and large for gestational age were defined as birth weights two standard deviations below and above normal for the gestational age. All data from the birth records were personally collected by one researcher (U.L). The study was approved by the Ethics committee at Karolinska Institute, Karolinska University Hospital, Huddinge, Sweden.

Statistical analysis

Mean values of continuous measurements were compared

Table 1 Description of perinatal factors in 97 PSC patients and 175 controls

	Patients with PSC ($n = 97$)	Controls ($n = 175$)	<i>P</i>
Age of the mother, yr (mean \pm SD)	27.8 \pm 5.1	27.4 \pm 6.2	NS
Hospital stay days (mean \pm SD)	7.9 \pm 3.2	8.0 \pm 4.7	NS
Birth weight in grams (mean \pm SD)	3501 \pm 537	3557 \pm 480	NS
Birth length in cm (mean \pm SD)	51.0 \pm 2.2	51.0 \pm 1.9	NS
Ponderal index (Weight/height ³)	2.6 \pm 0.3	2.7 \pm 0.3	NS
Vaginal delivery, <i>n</i> (%)	90 (93%)	166 (95%)	NS
Jaundice post partum, <i>n</i> (%)	7 (7%)	14 (8%)	NS
Breastfeeding at discharge from hospital, <i>n</i> (%) ¹	94 (97%)	170 (97%)	NS

¹Missing data in 2 patients.

in order to describe the characteristics of the case and control groups. To assess associations of the perinatal measures with PSC, conditional multiple logistic regression was used. All investigated parameters were modelled as a series of binary dummy variables. After investigation of univariate relationships, all measures associated with PSC ($P < 0.05$) that were statistically significant were included in multivariate analysis using conditional logistic regression. The final conditional logistic regression model excluded redundant measures co-linear with other significant risk factors.

RESULTS

The mean age at PSC diagnosis in the 97 patients was 40 \pm 12 years (\pm SD). 78% (76/97) were men, 80% (78/97) had a concomitant diagnosis of IBD. Sixty eight patients had UC, nine were diagnosed with Crohn's disease and one patient had indeterminate colitis.

A description of maternal and perinatal factors in the 97 PSC cases and the 175 controls is given in Table 1. Birth weight (BWT) was divided into five equally sized groups, where BWT 1 represented the lowest birth weight. Compared with the middle category, only the second lowest birth weight group was associated with PSC in a statistically significant manner. There were no statistically significant differences between the rates of maternal infections in subjects and controls. During pregnancy, maternal infections were reported in four cases (pneumonia ($n = 1$), tuberculosis ($n = 1$), urinary tract infection ($n = 1$), rubella in the first trimester ($n = 1$)). The child born to the rubella-infected mother was female and developed Crohn's disease before PSC was diagnosed. In the control group, one mother suffered from tuberculosis. None of the mothers were diagnosed with IBD or chronic liver disease. 9.3% of the PSC cases and 8.0% of the controls had postpartum medical issues. The most common problems observed in the children were skin lesions and asphyxia-related problems, in both groups. The summated frequency of

Table 2 Matched odds ratios and 95% confidence intervals for the maternal perinatal risk factors studied in 97 patients with PSC and 175 controls

Risk factor	¹ n with PSC (%)	n without PSC(%)	OR (95% CI)	P
Vaginal bleeding	6 (6.2)	2 (1.1)	5.70 (1.13-28.83)	0.035

BWT 1-5, 5ths; 1, lowest ; BWT, body weight. ¹The cases are matched with controls for sex, age and hospital ^aNo estimate due to an empty cell.

all postpartum medical problems for mothers of PSC patients was 11.3% and 12.6% for the controls, dominated by bleeding-anaemia in both groups. This difference is not statistically significant.

The matched odds ratios for perinatal factors are shown in Table 2. Both vaginal bleeding and peripheral oedema are statistically significantly associated with PSC. There was also an association of albuminuria during pregnancy with PSC that is not statistically significant. There was no association between jaundice and the risk of PSC. The non-matched odds ratios did not differ notably from the matched odds ratios shown in Table 2 (data not shown).

A multivariate analysis was conducted for the factors associated with a statistically significant increased risk of PSC: vaginal bleeding, peripheral oedema and birth weight. For vaginal bleeding, the adjusted OR (95% CI) is 6.7 (1.3-34.8), 2.4 (1.1-5.3) for peripheral oedema and 2.24 (1.00-5.02) for the second lowest birth weight category. An additional adjustment for gestational age was conducted separately (data not shown) and did not significantly alter the odds ratios for birth weight, vaginal bleeding or peripheral oedema.

DISCUSSION

To our knowledge, this is the first study investigating the associations of perinatal factors with PSC. The rationale for conducting such a study is that the foetal environment may be a contributing factor in the aetiology of some adult conditions such as diabetes, insulin resistance and rheumatoid arthritis^[13,14]. In addition, IBD (both CD and UC) is closely associated with PSC and “non-infectious

health events” during pregnancy^[4,6]. In celiac disease, which is also associated with PSC^[15], it has been shown that a low birth weight for gestational age and neonatal infections are associated with later development of celiac disease^[16].

We found no associations between PSC and birth length, gestational age, or medical problems for the mother or child, during pregnancy or postpartum. Mothers who had specific infections were identified. Neither individually nor combined were the specific infections associated with PSC risk. However, the number of events is low so detailed analysis was not possible. The association of PSC with birth weight was limited to one part of the birth weight distribution and there was no evidence of a trend. This suggests a chance association that should not be over-interpreted.

Some specific factors, vaginal bleeding during pregnancy and peripheral oedema, proved to be statistically significant in association with higher PSC risk. Interpretation of these data should be cautious. The number of women with vaginal bleeding was small and a clear mechanism to link this event with PSC is not readily apparent. As more women displayed peripheral oedema, its association with PSC is of greater relevance, yet it is a somewhat non-specific symptom, and again, a biologically plausible mechanism linking it with PSC is not obvious. It may be worthwhile to note that peripheral oedema is a symptom of pre-eclampsia; the other important symptoms are hypertension and proteinuria. Only one mother in this study was diagnosed with pre-eclampsia and we could not fully evaluate possible sub-clinical diseases as data were missing for proteinuria in both groups. However, the weak association of proteinuria with the risk for PSC provides further, but limited, evidence that some symptoms of pre-

eclampsia are associated with PSC. If the link between PSC and these maternal symptoms is not due to chance, then they could indicate some inherited characteristics that represent susceptibility to PSC. Alternatively, they might represent foetal exposure, possibly to pro-inflammatory factors, which increase the risk of PSC among susceptible individuals, perhaps through the initiation of an autoimmune process.

Although the detailed aetiology of PSC is unknown, its close association with IBD indicates that these two diseases share important risk factors relevant to exposure or susceptibility.

It is possible that risk factors identified by this study could be intermediates in a causal pathway between IBD and PSC: this could not be investigated here due to the small number of IBD-free subjects. However, it is also possible that the associations are specific to PSC or identify a subset of people with both diagnoses. IBD may indicate greater susceptibility to PSC, but exposure to other risk factors may be required to initiate the pathogenesis of this disease. Given the close association of PSC and IBD, known risks for IBD should be considered.

Bacterial colonisation of the gut is implicated in the aetiology of IBD; this occurs first in early life and the critical stages of early gut colonisation include exposure to bacteria in the birth canal, maternal faecal bacteria and during weaning^[17]. Breastfeeding is important for colonic bacterial colonisation^[17]. Previous studies investigating the association between breast feeding and development of IBD have shown inconsistent results^[18,19]. In the present study, there was a similarly high frequency of breastfeeding among patients and controls (97% in both groups). However, the observation period was short (approximately one week) since breastfeeding was only registered at the time when the mothers were discharged from the hospital and no follow-up was available.

Although the number of subjects included in this study was not large, it includes a high proportion of Swedish PSC patients between the years 1970 and 1998. Differential selection bias is not a concern as subjects and controls were closely matched and the analysis was conditional, such that patients were compared with their matched controls. The controls were selected from the same birth unit (next two consecutive births with the same gender as the subject) and the data was retrieved by the same person. Furthermore, differential information bias is not a determining factor either, as the selection of cases or controls was not influenced by whether perinatal adverse events occurred or not. The general characteristics of the PSC patients in the present study, such as age at onset of PSC, association with IBD and sex distribution, are similar to other studies, suggesting that selection bias among cases is unlikely^[1,2].

In summary, no significant associations with PSC were found for gestational age, birth length, breastfeeding, or most medical complications, including infections, during pregnancy for the mothers or postpartum for the children. The associations with vaginal bleeding and some symptoms of pre-eclampsia could be due to chance,

but should be considered as putative risk factors by further studies. Overall, our findings do not support the hypothesis of a substantial role for perinatal events in the aetiology of PSC later in life.

Abstract

AIM: *Disabled-2 (DAB2)* is a candidate tumor-suppressor gene identified in ovarian cancer that negatively influences mitogenic signal transduction of growth factors and blocks ras activity. In a recent study, we observed down-regulation of *DAB2* transcripts in ESCCs using cDNA microarrays. In the present study, we aimed to determine the clinical significance of loss of *DAB2* protein in esophageal tumorigenesis, hypothesizing that *DAB2* promoter hypermethylation-mediated gene silencing may account for loss of the protein.

METHODS: *DAB2* expression was analyzed by immunohistochemistry in 50 primary esophageal squamous cell carcinomas (ESCCs), 30 distinct hyperplasia, 15 dysplasia and 10 non-malignant esophageal tissues. To determine whether promoter hypermethylation contributes to loss of *DAB2* expression in ESCCs, methylation status of *DAB2* promoter was analyzed in *DAB2* immuno-negative tumors using methylation-specific PCR.

RESULTS: Loss of *DAB2* protein was observed in 5/30 (17%) hyperplasia, 10/15 (67%) dysplasia and 34/50 (68%) ESCCs. Significant loss of *DAB2* protein was observed from esophageal normal mucosa to hyperplasia, dysplasia and invasive cancer ($P_{\text{trend}} < 0.001$). Promoter hypermethylation of *DAB2* was observed in 2 of 10 (20%) *DAB2* immuno-negative ESCCs.

CONCLUSION: Loss of *DAB2* protein expression occurs in early pre-neoplastic stages of development of esophageal cancer and is sustained down the tumorigenic pathway. Infrequent *DAB2* promoter methylation in ESCCs suggests that epigenetic gene

INTRODUCTION

Esophageal cancer is the most aggressive gastrointestinal malignancy ranking as the 6th most common cancer among males and 9th most common cancer among females globally^[1]. Squamous cell carcinoma is the predominant histological subtype of esophageal cancer, characterized by high mortality rate and strong association with dietary habits and life style in India^[2-4]. It is the 2nd most common cancer among males and 4th most common cancer among females in India^[5]. Despite advances in multimodality therapy, due to late stage of diagnosis and poor efficacy of treatment, the prognosis for patients with ESCC still remains poor with an average 5-year survival of < 10% globally^[6,7] and < 12% in India^[8,9].

DOC-2/*DAB2* (differentially expressed in ovarian carcinoma- 2/disabled-2) is a putative tumor suppressor gene that encodes a 96-ku mitogen-responsive phosphoprotein involved in signal transduction^[10-15]. It inhibits mitogenic stimulation via the Ras pathway by binding to Grb2^[13,14]. *DAB2* has been shown to act as a negative regulator of c-Src in normal prostatic epithelium and cancer^[16]. This interaction causes inactivation of Erk and Akt proteins critical for proliferation and survival of prostate cancer cells^[16,17]. *DAB2* is found in association with transforming growth factor- β (TGF- β) type I and II receptors, while directly binding to the TGF- β signaling intermediates Smad2 and Smad3 through the PID domain^[18]. *DAB2* plays an important regulatory role in cellular differentiation and induction of differentiation in the absence of *DAB2* expression commits the cell to apoptosis^[19]. *DAB2* functions as a negative regulator of canonical Wnt signaling by stabilizing the beta-catenin

degradation complex^[20]. Recently, treatment of mouse F9 embryonic carcinoma cells with glycosylceramide synthase inhibitors has been shown to result in depletion of gangliosides and delayed expression of DAB2, suggesting their involvement in F9 cell differentiation^[21]. The aberrant expression of DAB2 has been reported in tumors, such as ovarian, prostate, choriocarcinoma, and breast^[11,22-26]. Histologically, elevated levels of DAB2 are associated with an enriched basal cell compartment, a progenitor cell for glandular epithelium and may be involved in the homeostasis of rat prostate regeneration^[23]. In addition, stable expression of DAB2 in cancer cell line has been shown to significantly reduce its *in vitro* growth rate, concomitant with an increase in cells in G₁ and decrease in anchorage-independent growth on soft agar^[11,22,23]. Therefore, DAB2 appears to be a potent negative regulator of cancer cell growth.

In a recent study, we observed down-regulation of *DAB2* transcripts in ESCCs using cDNA microarrays (data not shown). To our knowledge, the clinical significance of down-regulation of DAB2 in ESCC remains to be determined. In the present study, we analyzed DAB2 protein expression in different stages of development of esophageal cancer viz., primary ESCC and paired non-malignant normal, hyperplasia and dysplasia. Loss of DAB2 protein was observed in high proportion of ESCCs and dysplasia. Therefore, we hypothesized epigenetic silencing of *DAB2* gene in ESCCs. To test this hypothesis, the methylation status of the putative promoter (exon 1) of *DAB2* was analyzed using methylation-specific PCR in ESCC tissues that showed loss of DAB2 protein.

MATERIALS AND METHODS

Tissue samples

The study was approved by Institutional Human Ethics Committee and informed consent was obtained from the patients prior to enrolment in the study. The tissue samples used in this study were collected from Department of Gastrointestinal Surgery, All India Institute of Medical Sciences, New Delhi, India. All the samples were histologically confirmed to be either ESCCs, esophageal hyperplasia, dysplasia or non-malignant tissues by the pathologist (SDG). The samples included 50 histologically confirmed ESCCs, 10 non-malignant esophageal mucosa, 30 hyperplasia and 15 dysplasia.

Immunohistochemistry

Immunohistochemical analysis of DAB2 protein was carried out in paraffin-embedded tissue sections (5 μm thickness). Briefly, the sections were deparaffinized in xylene, hydrated and incubated with 30 mL/L H₂O₂ in methanol for 5 min to inactivate the endogenous peroxidase. Slides were washed with Tris-buffered saline (TBS, 0.1 mol/L, pH7.4) and heated for 15 min at 100°C in 10 mmol/L sodium citrate buffer (pH 6.0). Thereafter, sections were incubated with anti-disabled-2 goat polyclonal antibody (C-20, dilution 1:50, Santa Cruz Biotechnology Inc., Santacruz, CA) at 4°C overnight in humidified chamber. Sections were incubated with biotinylated anti-mouse antiserum with horseradish

peroxidase streptavidin conjugate (DAKO Labs, Glostrup, Denmark). After every incubation step, slides were washed with TBS thrice and color was developed using 3,3'-diaminobenzidine hydrochloride (DAB). Sections were counterstained with Mayer's hematoxylin, and mounted with DPX mountant for evaluation. Normal ovary tissue sections were taken as positive control for DAB2 and in the negative control primary antibody was replaced by isotype-specific IgG (data not shown).

Bisulfite modification

Genomic DNA from tissues was isolated by phenol-chloroform method. Genomic DNA was treated with sodium bisulfite (Sigma-Aldrich, Bangalore, India) as previously described^[27]. Briefly, 1 μg of DNA was denatured with 0.2 mol/L NaOH for 10 min at 37°C. Thirty microliters of 10 mmol/L hydroquinone (Sigma Aldrich) and 520 μL of 3 mol/L sodium bisulfite (pH 5.0) were added, followed by incubation at 50°C for 16 h. The modified DNA was purified using Wizard DNA purification columns (Promega, Madison, WI). The purified DNA was desulphonated with NaOH and precipitated with absolute ethanol in the presence of glycogen and ammonium acetate. DNA was resuspended in 20 μL of 1 mmol/L Tris (pH 8.0) and used for PCR amplification.

Methylation-specific PCR

Bisulfite-treated genomic DNA was amplified with either a methylation-specific or unmethylation-specific primer set for 35 cycles at 95°C for 5 min (hot started by adding Taq polymerase), followed by cycling with denaturation at 95°C for 30 s, primers annealing at 60°C for 30 s, and extension at 72°C for 1 min, as well as a final extension step at 72°C for 5 min. Methylation-specific primers span 6 CpG dinucleotides numbered 19-21 (forward) and 35-37 (reverse) of *DAB2* exon1 (Gene accession No. AF218839). Similarly, unmethylation-specific primers span 8 CpG dinucleotides numbered 19-22 (forward) and 35-37 (reverse). The methylation-specific primers were designed using 5'-TATTTTTCGTCGGGAGTGGTCGC-3' as the forward primer and 5'-ACTAACTATTACCTCCGTAAA ACG-3' as the reverse primer. The unmethylation-specific primers for site S1 were designed using 5'-GAATTATATT TTTTGTGGGAGTGGTTGT-3' as the forward primer and 5'-CCAACTAACTATTACCTCCATAAAAACA -3' as the reverse. These primer sequences were reported by Akiyama *et al*^[28].

RESULTS

Immunohistochemical analysis of DAB2

Immunohistochemical analysis was carried out to determine the expression of DAB2 protein in different stages of esophageal tumorigenesis. Table 1 summarizes the clinicopathological parameters of ESCC patients and expression status of DAB2 protein in the tumors. Strong cytoplasmic staining of DAB2 was observed in epithelial cells of all the 10 non-malignant (histologically normal) esophageal mucosa (Figure 1A). No detectable expression of DAB2 protein was observed in 5/30 (17%) hyperplasia

Table 1 Correlation of DAB2 protein expression with clinicopathological parameters of ESCC patients

Parameters	Total cases <i>n</i>	DAB2	
		Positive <i>n</i> (%)	Negative <i>n</i> (%)
ESCC	50	16 (32)	34 (68)
Age

Node +ve	27	8 (30)	19 (70)
Normal	10	10	
Hyperplasia	30	25 (83)	5
Dysplasia	15	5	10 (67)

(Figure 1B), 10/15 (67%) dysplasia (Figure 1C) and 34/50 (68%) ESCCs (Figure 1D). Only 32% of ESCCs showed weak to moderate DAB2 staining (Figure 1E). Significant loss of DAB2 protein expression was observed from esophageal normal mucosa to hyperplasia, dysplasia and SCC ($P_{\text{trend}} < 0.001$). Significantly higher proportion of dysplastic tissues showed loss of DAB2 expression in comparison with hyperplasia ($P = 0.002$; OR = 9.998; 90% CI = 2.368-42.210).

DAB2 exon1 methylation in ESCCs

To determine the possibility of promoter methylation-mediated gene silencing of *DAB2*, methylation status of putative promoter in exon1 of *DAB2* gene was analyzed in 10 DAB2 immuno-negative ESCC tissues. Burkitt's lymphoma cell line Raji was used as a positive control for hypermethylation of *DAB2* gene, as reported by Akiyama *et al.*^[28]. As shown in Figure 2, 8 of 10 (80%) ESCCs showed signal (PCR amplicon) for the unmethylated *DAB2* alleles, while 2 cases showed the presence of both unmethylated and methylated PCR amplicon, suggesting that *DAB2* promoter hypermethylation may account for loss of DAB2 protein in these two tumors.

DISCUSSION

In this study, we demonstrated, probably for the first time, significant loss of DAB2 protein in different stages of development and progression of ESCC, from normal to hyperplasia, dysplasia and invasive cancer ($P_{\text{trend}} < 0.001$). Strong cytoplasmic expression of DAB2 protein was observed in all the 10 histologically non-malignant esophageal tissues. Loss of DAB2 protein was observed in

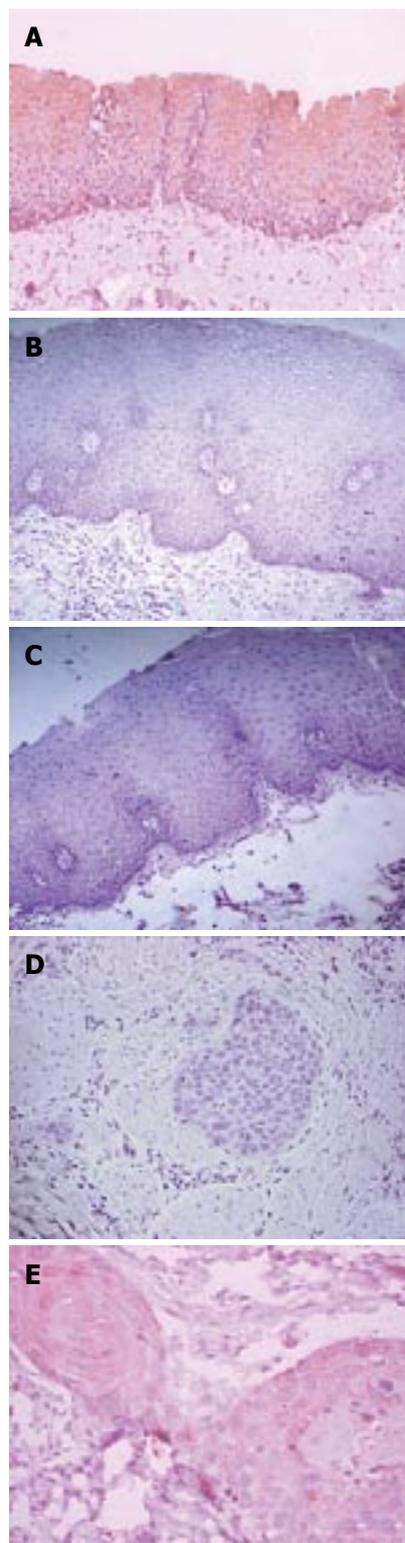

Figure 1 Immunohistochemical analysis of DAB2 in esophageal squamous cell carcinogenesis. **A:** Cytoplasmic expression of DAB2 in non-malignant normal esophageal mucosa; **B:** Hyperplastic esophageal mucosa showing no detectable expression of DAB2 protein; **C:** Dysplastic esophageal mucosa showing loss of DAB2 protein expression; **D:** ESCC section showing loss of DAB2 protein expression; and **E:** ESCC showing faint cytoplasmic DAB2 protein expression (**A-D:** Original magnification x 100; and **E:** Original magnification x 200).

preneoplastic stages, as early as in hyperplasia (in 5 of 30 hyperplastic tissues analyzed), suggesting that deregulation of DAB2 expression is likely to be an early event in esophageal tumorigenesis. Interestingly, loss of DAB2 protein was observed in significantly higher proportion of dysplastic tissues (10/15 cases) in comparison with hyperplasia ($P = 0.002$), indicating a critical impact of loss of this protein in evolution of dysplasia. Furthermore, loss of DAB2 in 34/50 (68%) of ESCCs observed in this study suggests that down-regulation of DAB2 protein is sustained down the tumorigenic pathway. To our

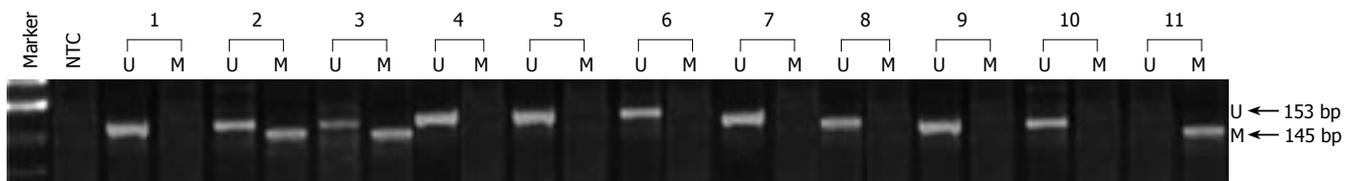

Figure 2 DAB2 exon-1 promoter hypermethylation. Methylation-specific PCR was done to determine the possibility of promoter methylation-mediated gene silencing of *DAB2*. Eight of 10 ESCCs showed signal (PCR amplicon) for the unmethylated *DAB2* alleles (samples 1, 4-10), while 2 cases showed the presence of both unmethylated and methylated PCR amplicon (samples 2 and 3). Burkitt's lymphoma cell line Raji was used as a positive control for hypermethylation of *DAB2* gene (sample 11). In each sample, lane U represents the unmethylated product, while M represents the methylated product, lane NTC refers to the no template control.

knowledge, the clinical relevance of *DAB2* in primary human esophageal tumors remains to be determined. Therefore, our study is important in demonstrating the clinical significance of aberrant *DAB2* expression in primary ESCCs.

The physical interaction of epithelial cells with the basement membrane ensures correct positioning and acts as a survival factor for epithelial cells. Cells that detach from the basement membrane often undergo apoptosis^[29,30]. In tumors, this positional control is absent, resulting in disorganized cell proliferation^[26]. Inactivation of a gene(s) controlling epithelial cell positioning may be a step in tumorigenicity. One of these genes is *DAB2*, which functions in cell positioning control and loss of *DAB2* protein has been suggested to contribute to the basement membrane-independent, disorganized proliferation of tumor cells^[26]. *DAB2* expression in breast cancer cells resulted in sensitivity to suspension-induced cell death (anoikis)^[31]. Loss of *DAB2* expression and the loss of collagen IV and laminin-containing basement membrane are two critical events associated with morphologic dysplastic changes of the ovarian surface epithelium as a step in tumorigenicity^[32,33].

Basement membrane (BM) can regulate differentiation, proliferation and polarity of esophageal epithelium and its integrity is important for carcinogenesis. Studies aimed to explore the effect of the BM changes induced by chronic inflammation on esophageal carcinogenesis have suggested that BM changes with aberrant proliferation of esophageal epithelia^[34]. The most salient finding of our study is the significant loss of *DAB2* protein expression in pre-neoplastic lesions, such as dysplasia in comparison with non-malignant esophageal epithelium and hyperplasia ($P = 0.002$). Based on the studies in ovarian cancer and transitional cell carcinoma and our observations in esophageal dysplasia and ESCC, we hypothesize that down-regulation of *DAB2* protein in dysplasia may be an important step in loss of epithelial cell positioning, aberrant proliferation and tumorigenicity. Therefore, loss of *DAB2* protein may serve as a candidate molecular marker for pre-neoplastic lesions.

Akiyama *et al*^[28] showed epigenetic silencing of *GATA-4* and *GATA-5* but not *GATA-6* transcription factor genes and their potential downstream anti-tumor target genes in colorectal and gastric cancer. *GATA6* and histone deacetylase inhibitor synergistically induce *DAB2* gene expression in transitional cell carcinoma (TCC) cell lines^[35]. Histone acetylation status associated with the 5' upstream regulatory sequence of *DAB2* gene is

one of the key determinants of its activity. *GATA6* can specifically induce *DAB2* promoter activity. Increased histone acetylation and the presence of *GATA6* have a synergistic effect on *DAB2* promoter activity which results in elevation of *DAB2* protein expression. Although the underlying mechanism leading to high *GATA6* and/or acetyl H3 levels in TCC cell lines is still unclear, it is likely that enzymes responsible for epigenetic regulation, such as histone modification or DNA methylation, could play a role. Therefore, we analyzed the methylation status of *DAB2* gene in esophageal tumors that showed loss of *DAB2* protein. Methylation-specific PCR showed methylation of *DAB2* promoter in 2 of the 10 *DAB2* immuno-negative ESCCs analyzed. These findings suggest that epigenetic silencing of *DAB2* is infrequent in ESCCs and accounts for down-regulation of the protein in only a subset of esophageal tumors. Thus, there is a need to investigate other mechanisms that may be responsible for loss of *DAB2* protein in ESCCs harboring the unmethylated *DAB2* promoters. A parallel study on *DAB2* protein expression and promoter methylation in our laboratory showed similar discordance between loss of protein expression and epigenetic silencing of the gene in breast cancer. *In silico* analysis suggested that post-transcriptional, micro RNA-mediated targeting of *DAB2* mRNA may be another mechanism for gene silencing (unpublished data of Bagadi SAR *et al*). It will be worthwhile to determine if micro RNA is involved in targeting of *DAB2* mRNA accounting for loss of *DAB2* protein in ESCCs as well.

In conclusion, our data suggest that loss of *DAB2* protein occurs in early pre-neoplastic stages and is sustained down the tumorigenic pathway of esophageal squamous cell carcinogenesis, underscoring its potential as a candidate molecular marker for pre-neoplastic lesions. Furthermore, *DAB2* exon-1 promoter hypermethylation is an infrequent event in ESCCs.

Abstract

AIM: To observe the inhibition of hepatitis B virus replication and expression by transfecting vector-based small interference RNA (siRNA) pGenesil-HBV X targeting HBV X gene region into HepG2.2.15 cells.

METHODS: pGenesil-HBV X was constructed and transfected into HepG2.2.15 cells *via* lipofection. HBV antigen secretion was determined 24, 48, and 72 h after transfection by time-resolved immunofluorometric assays (TRFIA). HBV replication was examined by fluorescence quantitative PCR, and the expression of cytoplasmic viral proteins was determined by immunohistochemistry.

RESULTS: The secretion of HBsAg and HBeAg into the supernatant was found to be inhibited by 28.5% and 32.2% ($P < 0.01$), and by 38.67% ($P < 0.05$) and 42.86% ($P < 0.01$) at 48 h and 72 h after pGenesil-HBV X transfection, respectively. Immunohistochemical staining for cytoplasmic HBsAg showed a similar decline in HepG2.2.15 cells 48 h after transfection. The number of HBV genomes within culture supernatants was also significantly decreased 48 h and 72 h post-transfection as quantified by fluorescence PCR ($P < 0.05$).

CONCLUSION: In HepG2.2.15 cells, HBV replication and expression is inhibited by vector-based siRNA pGenesil-HBV X targeting the HBV X coding region.

INTRODUCTION

Hepatitis B is a severe infectious disease threatening peoples' health all over the world. There is still no efficient therapy to control HBV persistent replication, which may lead to the development of liver cirrhosis and hepatocellular carcinoma (HCC)^[1]. RNA interference (RNAi) is a highly specific and effective mechanism of post-transcriptional gene silencing mediated by double-stranded RNA of 21-23 nt in size. Several researches have suggested that RNAi could provide a new therapeutic strategy against chronic HBV infection^[2-6]. In the present study, a plasmid leading to the expression of small interfering RNA (siRNA) that targets the HBV X gene was transfected into HepG2.2.15 cells, and HBV DNA replication as well as HBV antigen expression and secretion were monitored.

MATERIALS AND METHODS

Materials

Dulbecco's modified Eagle's medium (DMEM) was purchased from Gibco BRL, USA. Metafectene transfection reagent was purchased from Germany Biontes. Diagnostic kits for HBsAg and HBeAg (time-resolved immunofluorometric assay) were obtained from Suzhou Xinbo Biotechnology Corporation. Mouse monoclonal antibody directed against human HBsAg and rabbit anti-mouse horseradish peroxidase (HRP)-IgG were purchased from Beijing Zhongshan Golden Bridge Biotechnology Corporation. HepG2.2.15 cells were obtained from the Institute of Infectious Disease, Beijing University Medicine School.

Plasmid construction

pGenesil, containing human U6 promoter, was used to generate a series of siRNA expression vectors by inserting annealed oligonucleotides between *Bam*HI and *Hind*III sites. Cell culture and transfection

HepG2.2.15 cells were maintained in DMEM supplemented with 100 mL/L fetal calf serum (FCS), 100 IU/mL penicillin, 100 mg/L streptomycin and 2 mmol/L L-glutamine at 37°C in an atmosphere of 50 mL/L CO₂. The cells were plated in 6-well plates which had been placed sterile cover slips (1×10^6 cells per well). Transfection was performed at about 70% confluence with pGenesil and Metafectene lipofection reagent complex at a ratio of 8 μL :2.5 μg . Under these conditions we obtained a 55% transfection efficiency (data not shown).

Quantitative assay of HBsAg and HBeAg

The levels of HBsAg and HBeAg in culture supernatants were measured at 24, 48 and 72 h after transfection by using time-resolved immunofluorometric assay kits (TRFIA) according to the supplier's instructions.

Assay of HBV DNA replication

HepG2.2.15 cells were harvested at 24, 48, and 72 h post-transfection. Forty μL of the supernatant were mixed with an equal volume of the DNA extractant. Samples were boiled for 10 min and then centrifuged at 10000 $\times g$ for 5 min. Two μL of the samples were transferred into PCR reaction tubes. PCR cycling parameters consisted of denaturation at 93°C for 2 min, followed by 93°C for 45 s; 55°C for 60 s \times 10 cycles and then 93°C for 30 s; 55°C for 45 s \times 30 cycles.

Immunocytochemistry of HBsAg

To examine whether the effects of pGenesil-HBV X on HBsAg production were uniform with the culture media, cytoplasmic HBsAg was visualized by indirect immunocytochemistry 48 h post-transfection. pGenesil-HBV X transfected and control cells were washed with PBS, fixed in 900 mL/L ethanol for 10 min at room temperature and then washed with PBS. The fixed cells were permeabilized with 5 mL/L Triton X-100 in PBS for 15 min at 37°C and washed with PBS. To inhibit endogenous peroxidase, cells were exposed to 3 mL/L hydrogen peroxide for 10 min at 25°C. After washed with PBS, cells were incubated with mouse monoclonal anti-HBsAg antibody for 2 h at 37°C and subsequently with rabbit anti-mouse IgG conjugated horseradish-peroxidase for 30 min at 37°C. Cells were visualized with 3, 3'-diaminobenzidine tetrahydrochloride substrate and examined by light microscopy.

Statistical analysis

All statistical analysis were performed using the Microsoft SPSS 12.0 software. The graphs represented in mean \pm SD and compared using unpaired t-test. $P < 0.05$ was regarded as a significant difference.

RESULTS

pGenesil-HBV X inhibited HBsAg and HBeAg secretion in cultured HepG2.2.15

HBsAg and HBeAg concentrations were measured in cell culture supernatants of pGenesil-HBV X treated and control cells 24, 48, and 72 h post-transfection by using TRFIA (Table 1). At 24 h in the culture media, there was no significant difference between pGenesil-HBV X treated cells and other controls (untreated control, pGenesil-AFP control, pGenesil-HK control, pGenesil alone and Metafectene alone) ($P > 0.05$), while HBsAg was inhibited at 48 and 72 h by 28.47% and 32.16% ($P < 0.01$). HBeAg was reduced at 48 and 72 h post-transfection ($P < 0.05$) by 38.7% and 42.9% in the media of pGenesil-HBV X treated cells compared to the controls.

Inhibited HBV DNA replication in cultured HepG2.2.15

Levels of HBV DNA were examined by fluorescence quantitative PCR. This assay can detect HBV DNA in the range of 10^3 to 10^8 copies. The results revealed a

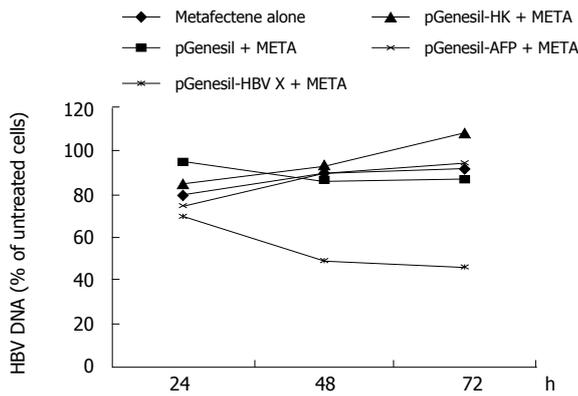

Figure 1 Inhibition of pGenesil-HBV X on HBV DNA in HepG2.2.15.

significant decrease in DNA replication when pGenesil-HBV X treated cells were compared to untreated cells. The number of HBV DNA copies in pGenesil-HBV X treated cells was found to be reduced by 44.9% and 45.9% at 48 and 72 h after transfection, respectively ($P < 0.05$), while the other controls showed no significant difference to the untreated cultures at any time point (Figure 1).

The effects of pGenesil-HBV X on intracellular HBsAg in HepG2.2.15

The effects of pGenesil-HBV X on intracellular HBsAg were visualized by immunocytochemistry 48 h after transfection. Intracellular HBsAg is localized in the cytoplasm of HepG2.2.15 cells at normal. In cells treated with pGenesil-HBV X, HBsAg was either decreased or non-detectable. In contrast, cells of other controls were obviously stained (Figure 2).

DISCUSSION

RNAi is a mechanism of post-transcriptional gene silencing mediated by double-stranded RNA of 21-23 nt in length. RNAi has been applied as a highly specific and efficient tool to interfere with viral replication as it has been shown for HIV^[8-12], hepatitis C virus^[13-16], myetitis virus^[17], gamma herpesvirus^[18] or influenza virus^[19]. HBV DNA replication requires reverse transcription to form a pregenomic RNA that is similar to reverse-transcription virus. 3.2kb pregenomic mRNA is not only translated into HBV proteins including HBeAg, HBcAg and HBV DNAP, but it is also a template for the synthesis of viral DNA to continue replication. Furthermore, all four transcripts include the HBV X protein coding region. Selecting a conserved sequence in the X gene region as a target, we expect to inhibit the expression of HBV antigens and the replication of HBV DNA. To set up an in vitro model which is more stable and more similar to natural condition of viral infection is a base of experiment and is a key prerequisite to evaluate the efficiency of anti-virus therapy. Previous studies were carried out by co-transfecting siRNA or siRNA expression vector and a plasmid cloned with full-length HBV DNA or HBV target region into cells^[7,20,21]. It is obvious that cells transfected with siRNA or siRNA expression vectors must get HBV

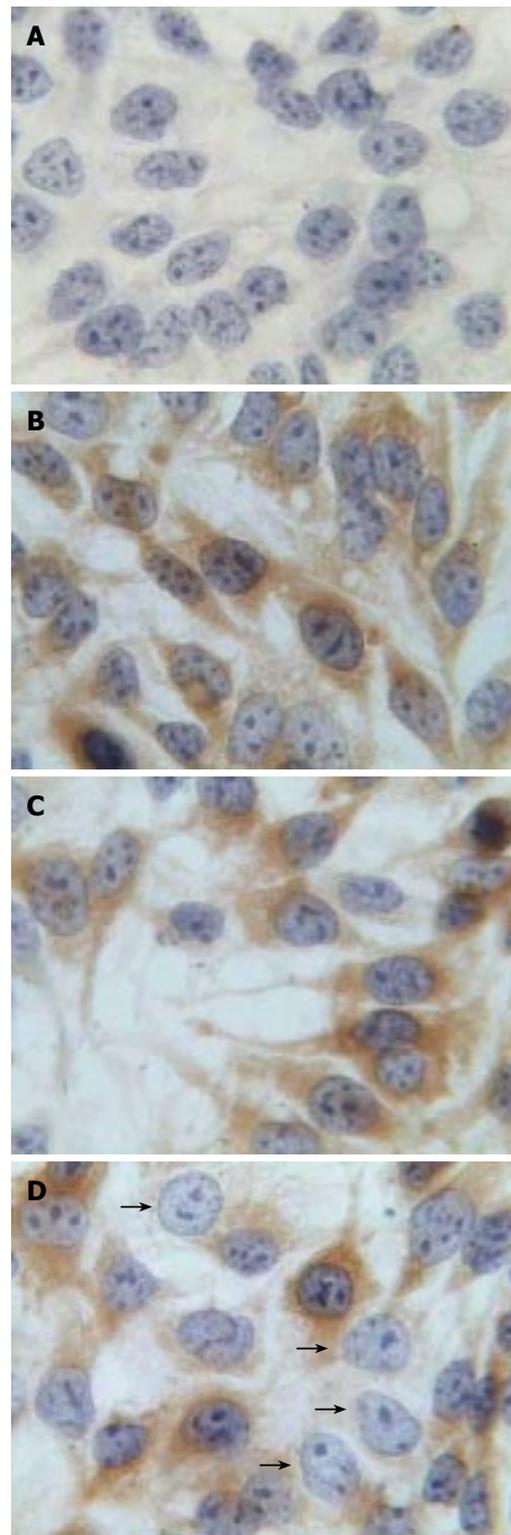

Figure 2 Immunocytochemistry for intracellular HBsAg in HepG2.2.15 (× 400). A: Without monoclonal antibody against HBsAg; B: pGenesil-HK treated cells; C: pGenesil-AFP treated cells; D: pGenesil-HBV X treated cells. Arrows show the cells were transfected and HBsAg expression was suppressed.

expression plasmid at same time, which is better to observe and evaluate the specificity and efficiency by siRNA. But only selecting out the cells co-transfected successfully for research does not coincide with natural conditions of viral infection and will not reflect the exact effects of siRNA on HBV target gene.

The HepG2.2.15 cell line, a derivative of the human HepG2 hepatoma cell line that has been stably transfected with a head-to-tail dimer of HBV DNA^[22], was chosen as a model because it produces HBV infectious particles constitutively and expresses HBV antigens stably. To transfect siRNA expression vector into HepG2.2.15 cells, and culturing transfected cells and untransfected cells under one system, we could simulate the nature condition that virus still replicate and express constitutively in untransfected cells. As a result, we found that HBsAg and HBeAg in the supernatant were inhibited by 28.5% and 38.7% at 48 h, and decreased by 32.2% and 42.9% 72 h post-transfection with pGenesil-HBV X against HBV X. Levels of HBV DNA were also found to be reduced. Moreover, immunocytochemistry revealed that the amount of intracellular HBsAg parallels the decline in HBV serum markers in cultures treated with pGenesil-HBV X. Controls (including untreated cells and treated with Metafectent reagent alone, pGenesil plasmid alone, pGenesil-AFP or pGenesil-HK expressing random siRNA) failed to reduce HBV expression and replication. At the premises of targeting same sequence in HBV X region, the efficiency we got was lower than that of Shlomai^[7] who used a co-transfection approach to Huh-7 cells. At present, there isn't any reagent that achieves 100% transfection efficiency neither to cells nor to animals. Selecting HepG2.2.15 cell line as a model is better for us to evaluate the effects of siRNA in consideration of the efficiency of transfection, and thus it will be valuable for us to evaluate the effects of siRNA on clinical application research in the future.

By measuring the levels of AFP which is constitutively secreted by HepG2.2.15 cells no change was found between pGenesil-HBV X treated cells and other controls except pGenesil-AFP treated cells. This result shows that pGenesil-HBV X specifically inhibits HBV gene expression.

Abstract

AIM: To examine the expression of metalloproteinase-1 (MMP-1) and tissue inhibitor of metalloproteinase-1 (TIMP-1) in the colonic mucosa of patients with ulcerative colitis (UC).

METHODS: Reverse transcription-polymerase chain reaction (RT-PCR) and immunohistochemistry were used to study the expression of MMP-1 and TIMP-1 at both mRNA and protein levels in patients with UC and controls. The relationship between MMP-1 mRNA, TIMP-1 mRNA, MMP-1 mRNA/TIMP-1 mRNA ratio and the severity of clinical symptoms of the patients with UC were also analyzed.

RESULTS: The expression of MMP-1 mRNA and TIMP-1 mRNA in the ulcerated and inflamed colonic mucosa was significantly higher than that in the non-inflamed colonic mucosa ($P < 0.001$), but there was no statistically significant difference in the non-inflamed colonic mucosa of UC patients and normal controls ($P > 0.05$). The mRNA expression of MMP-1 and TIMP-1 in ulcerated colonic mucosa of UC patients was increased by 80-fold and 2.2-fold, respectively when compared with the normal controls. In the inflamed colonic mucosa, the increase was 30-fold and 1.6-fold, respectively. Immunohistochemical analysis showed that among the ulcerated, inflamed, and non-inflamed colonic mucosae of UC patients and the normal controls, the positive rate of MMP-1 expression was 87%, 87%, 40% and 35% respectively, and the positive rate of TIMP-1 expression was 89%, 89%, 80% and 75%, respectively. Furthermore, the expression of MMP-1 mRNA, TIMP-1 mRNA and the MMP-1 mRNA/TIMP-1 mRNA ratio were correlated with the severity of clinical symptoms ($P < 0.05$).

CONCLUSION: Excessive expression of MMP-1 in the diseased colonic mucosa causes excessive hydrolysis of the extracellular matrix (ECM) and ulceration in UC pa-

tients. MMP-1 mRNA, TIMP-1 mRNA and MMP-1 mRNA/TIMP-1 mRNA ratio can be used as biomarkers to judge the severity of clinical symptoms in patients with UC. Exogenous TIMP-1 or MMP-1 inhibitor therapy is a novel treatment for patients with UC.

INTRODUCTION

Ulcerative colitis (UC) is a chronic, non-specific inflammatory disease of the colonic mucosa with unknown etiology and pathogenesis. Pathologically, it is characterized by ulceration in the mucosal and submucosal areas, and degradation of extracellular matrix (ECM) is one of the major events during this process^[1]. Matrix metalloproteinase-1 (MMP-1) produced by cytokine-activated interstitial cells is one of the most important enzymes in degrading ECM, and the activity of MMP-1 is controlled by its natural inhibitor, tissue inhibitor of metalloproteinase (TIMP-1)^[2]. Therefore, in this study we measured MMP-1 and TIMP-1 transcripts and their proteins by using reverse transcription-polymerase chain reaction (RT-PCR) and immunohistochemistry to explore their possible role in patients with UC.

MATERIALS AND METHODS

Patients and samples

Thirty patients with UC confirmed by colonoscopy and biopsy were enrolled in the study. Among these patients, 21 were males and 9 were females with their age ranged from 18 to 76 years and averaged 48 years. Samples were taken from the ulcerated, inflamed and non-inflamed areas of the colonic mucosa during colonoscopy. There were 3 patients with pan-colonic lesions, 2 with hemi-colonic lesions, 13 with recto-sigmoidal lesions, and 12 with rectal lesions. Based on the clinical manifestations, 2 patients

were classified into severe type, 18 into moderate type, and 10 into mild type. Meanwhile, 20 normal subjects were selected as controls; 14 of them were males and 6 were females with their age ranged from 27 to 65 years and averaged 46 years. Biopsy samples were immediately snap frozen in liquid nitrogen and stored at -80°C for RT-PCR. Separate biopsy samples were fixed in formalin and embedded in paraffin for immunohistochemistry.

Total RNA extraction

Total RNA was extracted from the frozen samples using the RNA isolation kit (Invitrogen Company) following the manufacturer's instructions. Five μL of the extracted RNA was run on 1% agarose gel electrophoresis to identify the extracted products.

RT-PCR for MMP-1 and TIMP-1

RT-PCR was performed using the TaKaRa RNA PCR kit 3.0 (AMV) (supplied by Dalian Baosheng Biotechnology Company) following the manufacturer's instructions. Primer sequences^[3] used were as follows: MMP-1: sense: 5'-ATGCGAACAAATCCCTTCTACC-3', antisense: 5'-T'TCCCTCAGAAAGAGCAGCATCG-3'; TIMP-1: sense: 5'-GGACACCAGAAGTCAACCAGCC-3', antisense: 5'-CGTCCACAAGCAATGAGTCC-3'. Primers for β -actin were used as the internal control: sense: 5'-CCTTCCTGGCATGGAGTCCTG-3', antisense: 5'-GGAGCAATGATCTTGATCTTC-3'. Reverse transcription was carried out at 30°C for 10 min, at 42°C for 30 min, at 99°C for 5 min, and at 5°C for 5 min. PCR was performed as follows: initial denaturation at 94°C for 2 min, 35 amplification cycles at 94°C for 30 s, at 53°C for 30 s, at 72°C for 1 min, extension at 72°C for 10 min. Five μL PCR product was run on 2% agarose gel electrophoresis.

Immunohistochemistry

Sample sections were washed 3 times with PBS, 3 min each time after initial treatment. Primary antibodies, rabbit anti-human MMP-1 polyclonal antibody and TIMP-1 monoclonal antibody (Beijing Zhongshan Biology Company) were added and incubated at room temperature for 1.5 h, washed again and incubated with peroxidase-conjugated secondary antibody for 15 min and washed again. A brown product was developed in diaminobenzidine (DAB) for 10 min.

Result determination and statistical analysis

Bio-imaging system (PALI Company, USA) was employed to analyze the density of the bands of PCR products. MMP-1 mRNA and TIMP-1 mRNA were semi-quantitatively expressed by the ratios between MMP-1, TIMP-1 and β -actin OD values. All values were expressed as mean \pm SD.

Results of immunohistochemistry were scored according to the degree of staining and percentage of positive cells as no staining: 0 point, mild staining: 1 point, moderate staining: 2 points, heavy staining: 3 points; positive cells $\leq 5\%$: 0 point, 6%-30%: 1 point, 31%-70%: 2 points, 71%-100%: 3 points. Final score was determined by combining points obtained from the above two scoring

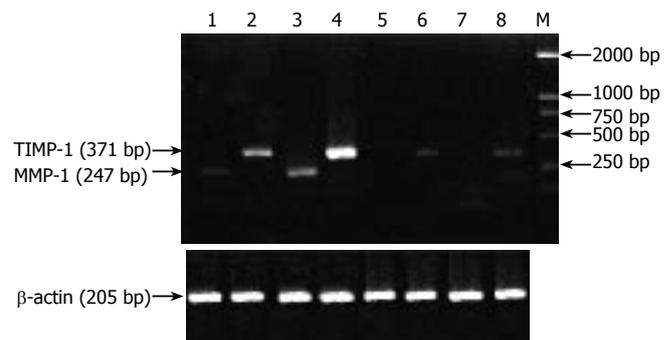

Figure 1 Expression of MMP-1 and TIMP-1 mRNA in UC. Lanes 1, 2: Inflamed area; lanes 3, 4: Ulcerated area; lanes 5, 6: Non-inflamed area; lanes 7, 8: Normal controls; M: DNA marker DL 2000.

systems: 0-1 point: (-), 2 points: (+), 3-4 points: (++), 5-6 points: (+++).

Student-Neuman-Keuls test was used to compare MMP-1 mRNA and TIMP-1 mRNA in different colon biopsy samples. Positive rates were analyzed by χ^2 test and Spearman correlation analysis was used to study the relationship between MMP-1 mRNA, TIMP-1 mRNA, MMP-1 mRNA/TIMP-1 mRNA ratio and the severity of clinical symptoms. $P < 0.05$ was considered statistically significant. All statistical analyses were performed using SPSS 10.0 for Windows.

RESULTS

Expression of MMP-1 mRNA in UC

Expression of MMP-1 mRNA in the ulcerated and inflamed areas of the colon was significantly higher than that in the non-inflamed areas of the colon of UC patients and normal controls ($P < 0.001$). It was 80-fold higher in the ulcerated area and 30-fold higher in the inflamed area when compared with the normal controls, but there was no statistically significant difference in MMP-1 mRNA expression between UC patients and normal controls ($P > 0.05$, Figure 1, Table 1).

Expression of TIMP-1 mRNA in UC

Expression of TIMP-1 mRNA in the ulcerated and inflamed area of colon was significantly higher than that in the non-inflamed area of colon of UC patients and normal controls ($P < 0.001$). It was 2.2-fold higher in the ulcerated area and 1.6-fold higher in the inflamed area when compared with the normal controls, but there was no statistically significant difference in TIMP-1 mRNA expression between UC patients and normal controls (Figure 1, Table 2).

Correlations between MMP-1mRNA, TIMP-1mRNA, MMP-1 mRNA/TIMP-1 mRNA ratio and the severity of clinical symptoms

Expression of MMP-1 mRNA was significantly related to the expression of TIMP-1 mRNA in the tissues of UC patients, the relating coefficient was 0.801 ($P < 0.001$). Based on clinical manifestations, only 2 patients were classified into severe type, so correlation analysis was performed between moderate group (18 patients) and mild group

Table 1 Expression of MMP-1 mRNA in samples from different areas of colon in UC (mean \pm SD)

Samples	MMP-1 mRNA	P value
Ulcerated area	0.4136 \pm 0.2495	< 0.001 ^{b,d}
Inflamed area	0.1491 \pm 0.0891	< 0.001 ^{b,d} < 0.05 ^a
Non-inflamed area	0.0102 \pm 0.0144	> 0.05
Normal controls	0.0051 \pm 0.0086	

^b*P* < 0.001 vs normal controls, ^d*P* < 0.001 vs non-inflamed area, ^a*P* < 0.05 vs ulcerated area.

Table 3 Positive expression rates of MMP-1 in samples from different areas of colon in UC

Samples	Positive cases	Negative cases	Total cases	Positive rate (%)	P Value
Ulcerated area	25	5	30	87	< 0.05 ^{a,c}
Inflamed area	25	5	30	87	< 0.05 ^{a,c}
Non-inflamed area	12	18	30	40	> 0.05
Normal controls	7	13	20	35	

^a*P* < 0.05 vs normal controls, ^c*P* < 0.05 vs non-inflamed area.

Table 5 Positive expression rates of TIMP-1 in samples of different areas of colon in UC

Samples	Positive cases	Negative cases	Total cases	Positive rate (%)	P value
Ulcerated area	26	4	30	89	> 0.05
Inflamed area	26	4	30	89	> 0.05
Non-inflamed area	24	6	30	80	> 0.05
Normal controls	15	5	20	75	

(10 patients). The results showed that MMP-1 mRNA, TIMP-1 mRNA and MMP-1 mRNA/TIMP-1 mRNA ratio were all significantly correlated with the severity of the clinical symptoms, and the relating coefficient was 0.411, 0.328 and 0.552, respectively.

Results of immunohistochemistry

Positive expression rates of MMP-1 in the ulcerated and inflamed areas of the colon were significantly higher than those in the non-inflamed areas of the colon of UC patients and normal controls (*P* < 0.05), but there was no statistically significant difference in non-inflamed areas between UC patients and normal controls (Table 3).

The intensity of MMP-1 expression in the ulcerated and inflamed area of colon was significantly higher than that in the non-inflamed area of colon of UC patients and normal controls (*P* < 0.001), but there was no statistically significant difference in the non-inflamed area between UC patients and normal controls (Table 4).

Positive expression rates of TIMP-1 in the ulcerated and inflamed area of colon were not statistically different when compared with those in the non-inflamed area of colon of UC patients and normal controls (Table 5).

The intensity of TIMP-1 expression in the ulcerated and inflamed area of colon was significantly higher than

Table 2 Expression of TIMP-1 mRNA in samples from different areas of colon in UC (mean \pm SD)

Samples	TIMP-1	P value

that in the non-inflamed area of colon of UC patients and normal controls (*P* < 0.001). The results also showed that the intensity of TIMP-1 expression in the ulcerated area was significantly greater than that in the inflamed area (*P* < 0.05), but there was no statistically significant difference in the non-inflamed area between UC patients and normal controls (Table 6).

DISCUSSION

UC is a chronic and non-specific inflammatory disease of the colon and affects mainly the colonic mucosa and submucosa. Pathologically, it is characterized by ulceration in the mucosa and submucosa and degradation of ECM is involved in this process. In this study, we separately utilized RT-PCR and immunohistochemistry to detect the expression of MMP-1 and TIMP-1 at both mRNA and protein levels. The expression of MMP-1 mRNA and TIMP-1 mRNA in ulcerated and inflamed areas of colon was significantly higher than that in the non-inflamed area of colon of UC patients and normal controls, the same results were also obtained at the protein level, suggesting that expression of MMP-1 and TIMP-1 is correlated to UC severity at both transcription and protein levels^[4]. MMP-1, also termed interstitial collagenase, is able to degrade the

spiral structure of collagen types I, II, III and X, making them more sensitive to the hydrolysis of gelatinase, and thus, play an important role in the degradation of ECM^[5]. RT-PCR showed that the expression of MMP-1 mRNA was greatly increased in the ulcerated and inflamed areas of the colon of UC patients with the ulcerated area being more profound, suggesting that MMP-1 is related to the mucosal damage^[6]. Arihiro *et al*^[7] showed that MMP-1 has something to do with the initial steps of ulceration in UC. von Lampe *et al*^[3] also found that the expression of MMP-1 is increased by 230-fold in the colonic mucosa of patients with UC compared with normal controls. Meanwhile, our immunohistochemical results showed that MMP-1 protein was significantly increased in the ulcerated and inflamed areas of UC patients. Furthermore, MMP-1 protein was mainly expressed in the interstitial cells. This is similar to the result of von Lampe *et al*^[3] who identified that these interstitial cells are macrophages. Mckaig *et al*^[8] identified that myofibroblasts are also MMP-1 producing interstitial cells in the colon of patients with UC.

TIMPs are natural inhibitors of MMPs and exert important regulating functions on MMPs. TIMP-1 mainly inhibits the activity of MMP-1, -3 and -9. Our results showed that the expression of TIMP-1 mRNA in the ulcerated and inflamed areas was significantly higher than that in the normal controls, suggesting that the increased expression of MMP-1 up-regulates TIMP-1, leading to an imbalanced state of MMP-1 mRNA/TIMP-1 mRNA ratio, or in other terms, the increased TIMP-1 mRNA was not able to counteract the increased MMP-1 mRNA, resulting in over degradation of ECM in UC. The similar result was also obtained when TIMP-1 protein was measured. Both MMP-1 and TIMP-1 were expressed in the interstitial cells, indicating that MMP-1 and TIMP-1 come from the same cells^[2]. Immuno-electron microscopy reveals that MMP-1 and TIMP-1 are localized in the rough endoplasmic reticulum of the activated myofibroblasts and smooth muscle cells of the blood vessels^[7], suggesting that MMP-1 and TIMP-1 have something to do with the formation of new blood vessels.

Based on clinical manifestations, only 2 UC patients were classified as severe type in our study. We analyzed the relationship between MMP-1 mRNA and TIMP-1 mRNA expression and the severity of the disease. Our results showed that expression of MMP-1 mRNA and TIMP-1 mRNA in patients with moderate UC was significantly higher than that in patients with mild UC. MMP-1 mRNA, TIMP-1 mRNA and MMP-1 mRNA/TIMP-1 mRNA ratio all were closely related to the severity of the clinical

manifestations. Therefore, it is concluded preliminarily that MMP-1 mRNA, TIMP-1 mRNA and MMP-1 mRNA/TIMP-1 mRNA ratio can be used as the parameters in judging the clinical severity of patients with UC. von Lampe *et al*^[3] found that MMP-1 mRNA expression is correlated with the pathological staging of inflammation. Wiercinska-Drapalo *et al*^[9] found that serum TIMP-1 level is positively correlated with the extent of endoscopic mucosal injury, clinical severity and concentration of C reactive protein in UC patients.

In conclusion, excessive expression of MMP-1 in the diseased colon mucosa of UC patients causes excessive hydrolysis of the ECM and ulceration. MMP-1 mRNA, TIMP-1 mRNA and MMP-1 mRNA/TIMP-1 mRNA ratio can be used as biomarkers to judge the severity of clinical symptoms in patients with UC. Exogenous TIMP-1 or MMP-1 inhibitor therapy is a novel treatment for patients with UC.

Abstract

AIM: To study the expression of HBV enhancer II by transcription factor COUP-TF1.

METHODS: In order to study the regulation of HBV variants in the vicinity of the NRRE we cloned luciferase constructs containing the HBV enhancer II from variants and from HBV genotypes A and D and cotransfected them together with expression vectors for COUP-TF1 into HepG2 cells.

RESULTS: Our findings show that enhancer II of HBV genotype A is also repressed by COUP-TF1. In contrast, two different enhancer II constructs of HBV genotype D were activated by COUP-TF1. The activation was independent of the NRRE because a natural variant with a deletion of nt 1763-1770 was still activated by COUP-TF1.

CONCLUSION: Regulation of transcription of the HBV genome seems to differ among HBV genomes derived from different genotypes. These differences in transcriptional control among HBV genotypes may be the molecular basis for differences in the clinical course among HBV genotypes.

INTRODUCTION

Hepatitis B virus (HBV) is a major health burden for the world^[1]. In an otherwise immune competent host, HBV concentrations of 10^{12} to 10^{13} genome equivalents (GE)/l are frequently found. Thus, in a chronic carrier up to 10^{15} virions are produced per day^[2]. Due to the high replication capacity^[2,3] and the high error rate of the viral polymerase, HBV genomes with all possible single mutations and double mutations of every nucleotide of the HBV genome are produced every day^[3]. Variants of HBV with point mutations, deletions or insertions have been described all over the genome of HBV^[4-7]. In addition to viral variants the variability of the virus is increased by the divergence of HBV into 8 genotypes A-H that differ by at least 8% when comparing whole genomes^[8-10]. The transcription of the hepadnaviral pregenomic (pG) and precore (pC) RNA is regulated by transcription factors binding to a region containing the enhancer II (EII) and the core promoter (Figure 1A)^[11]. The expression of both pG and pC RNA is tightly coupled^[11], however, natural variants^[12] and point mutations^[13] located in this transcriptional element can uncouple the transcription of these RNAs. The variants and artificial point mutations that uncouple the transcription of the pG and pC RNA affect a site in this transcriptional element called the nuclear receptor responsive element (NRRE)^[13,14]. COUP-TF, a member of the nuclear receptor family^[15], binds to the NRRE and has been found to repress transcription from HBV enhancer II/pC/pG promoter^[13].

We have previously characterised an outbreak of HBV in children in a department of oncology^[16,17]. In 1992 we observed a deletion of nt 1763 to 1770 affecting the c-terminus of HBx, enhancer II/pC- and pG promoter^[18] in serum from a single patient. Later on when we examined serum from 20 patients by amplification of the whole genome from different time points after infection, three

additional patients were found to have the deletion of 8 bp in enhancer II^[19]. This deletion was found mainly in sera from time points late after infection. The deletion of nt 1763-1770 was found to increase the ratio of pG to pC RNA, the replication of HBV *in vitro*, and to generate a new binding site for the transcription factor HNF-1^[12]. However, the deletion of nt 1763-1770 also deletes large parts of the binding site for COUP-TF, which was mapped to 1755-1768^[20-22]. We thus analysed whether enhanced replication from variant enhancer II/pC/pG promoter may also be caused by the deletion of the binding site for the repressor COUP-TF1. In contrast to previous studies we used HBV genome isolates with different genotype backgrounds and observed significant differences.

MATERIALS AND METHODS

Transfection and luciferase-assay

All experiments were performed with the differentiated human hepatoblastoma line HepG2^[23] cultivated in RPMI1640/10% FCS. The different expression constructs were used in luciferase assays. Briefly, $1-1.5 \times 10^6$ seeded cells were transfected with 1.5 μ g luciferase construct and 3 μ g of the COUP-TF1 or HNF-1 expression constructs using Lipofectamine (Life Technologies) according to the manufacturers description. All plasmids used were endotoxin free purified (EndoFree, Quiagen). After 48 h the transfected cells were harvested and lysed in Tris-buffer (250 mmol/L, pH 7.8) by 3 cycles of freezing and thawing. Protein concentration of lysates was determined by BCA-assay (Pierce). 15 μ g of lysate protein adjusted to 50 μ L with Tris-buffer were used in the luciferase activity assay^[24]. The results are shown as factors relative to basal luciferase expression and represent the mean values of three independent transfections.

Plasmids

All constructs for reporter assays were cloned into pLuci3 (Promega). The derived constructs were controlled by sequencing. pLEII-A-991 and pLEII-D-Ari: contain the enhancer II/core promoter sequence of genotype A (GenBank: X51970) or D (GenBank: Y07587) from nt 1400 to 1903 and have been described in^[25]. For pLEII-D-2.2.15 nt 1400 to 1903 were amplified from supernatants of the HBV expressing cell line HepG2.2.15^[26] and cloned accordingly. The sequence of this fragment was identical to GenBank U95551. HBV enhancer II, genotype D, with a corresponding truncated construct pL-EII (1730-1822). Derived from this sequence, constructs with an 8bp deletion of nt 1763-1770 or the frequently observed double mutation of 1762 (A/T), 1764 (G/T) have been cloned respectively (pL-EII(1730-1822)d8bp and pL-EII(1730-1822)A/T). For cotransfection expression vectors for HNF1^[27] or COUP-TF1^[28] were employed.

Electrophoretic mobility shift assay (EMSA)

EMSAs were performed as described by^[24] using nuclear extracts from HepG2 cells. For EMSAs the following oligonucleotides with the corresponding binding sites were used: wt (HBV-1755-1805-bs-s): 5'-GAT CCT TAG

GTT AAA GGT CTT TGT ATT AGG AGG CTG TAG GCA TAA ATT GGT CTG CGA-3'; wt (HBV-1755-1805-bs-as) 5'-GAT CTC GCA GAC CAA TTT ATG CCT ACA GCC TCC TAA TAC AAA GAC CTT TAA CCT AAG-3'; 8bp-Deletion (bs-HBVd8-1755-1805-s) 5'-GAT CTT AGG TTA AAT ATT AGG AGG CTG TAG GCA TAA ATT GGT CTG CGC A-3'; 8bp-Deletion (bs-HBVd8-1755-1805-as) 5'-GAT CTG CGC AGA CCA ATT TAT GCC TAC AGC CTC CTA ATA TTT AAC CTA A-3'; 8bp-Deletion (HBVd8-dTBP-1755-1805-s) 5'-GAT CTT AGG TTA AAT ATT AGG AGG CTG TAG GCA TAA ATT GGT CTG CGC A-3'.

RESULTS

To analyse the effect of COUP-TF1 on a frequently found natural variant of the HBV EII/pC/pG promoter we cotransfected expression constructs for HNF1 and COUP-TF1 together with a luciferase reporter construct containing nt 1730-1817 (pL-pC-D-Ari) or nt 1730-1902 (pL-preG-D-Ari) (Figure 1A-C) into HepG2 cells as described^[25].

HNF1 showed a very weak transactivation of both promoter constructs irrespective if wt or the deletion construct were employed. COUP-TF1 showed a strong transactivation of all constructs. It appeared as if the transactivation was higher when constructs that contained the deletion of nt 1763-1770 were used. Two aspects of the latter results were surprising: COUP did not repress transcription from the wt-pG promoter as expected from previously published data^[13] and the deletion of a large part of the binding site for COUP in the Δ 8bp-pG and -pC construct had no effect on the activation by COUP.

Our results for the pG and pC construct (nt 1730-1900) were seemingly in conflict with the data of^[13] who reported a repression of nt 1443 to 1990 of HBV by COUP. Thus, we cloned nt 1400 to 1902 into luciferase constructs. Figure 1C shows that COUP-TF1 also activated expression from the complete enhancer II of the isolates described in^[18,19,29]. No upstream element seemed to influence the activation of enhancer II by COUP-TF1 because all deletion constructs of pLEII-D-Ari and pLEII-D-Ari- Δ 8bp were activated by COUP-TF1 (Figure 1).

Because pLEII-D-Ari was cloned from serum of patients infected during massive immune suppression and HBV genomes from these patients are known to contain many variants^[19], we analysed the effect of COUP-TF1 on enhancer II from an assumed wt-HBV genotype D genome. Figure 2 shows that this construct was also activated by COUP-TF1 even stronger than pLEII-D-Ari. In comparison we analysed a similar construct cloned from genotype A^[25]. Quite in contrast to the activation of pLEII-D-Ari, the genotype A construct pLEII-A991 was repressed by COUP-TF as reported for a construct containing enhancer II of HBV genotype C^[13].

COUP-TF1 is known to exert its repressive effect on HBV enhancer II of HBV genotype C through the NRRE around nucleotide 1755-1768^[13,14]. However, activation of HBV EII by COUP-TF1 also was observed when we tested constructs with a deletion of nt 1763-1770.

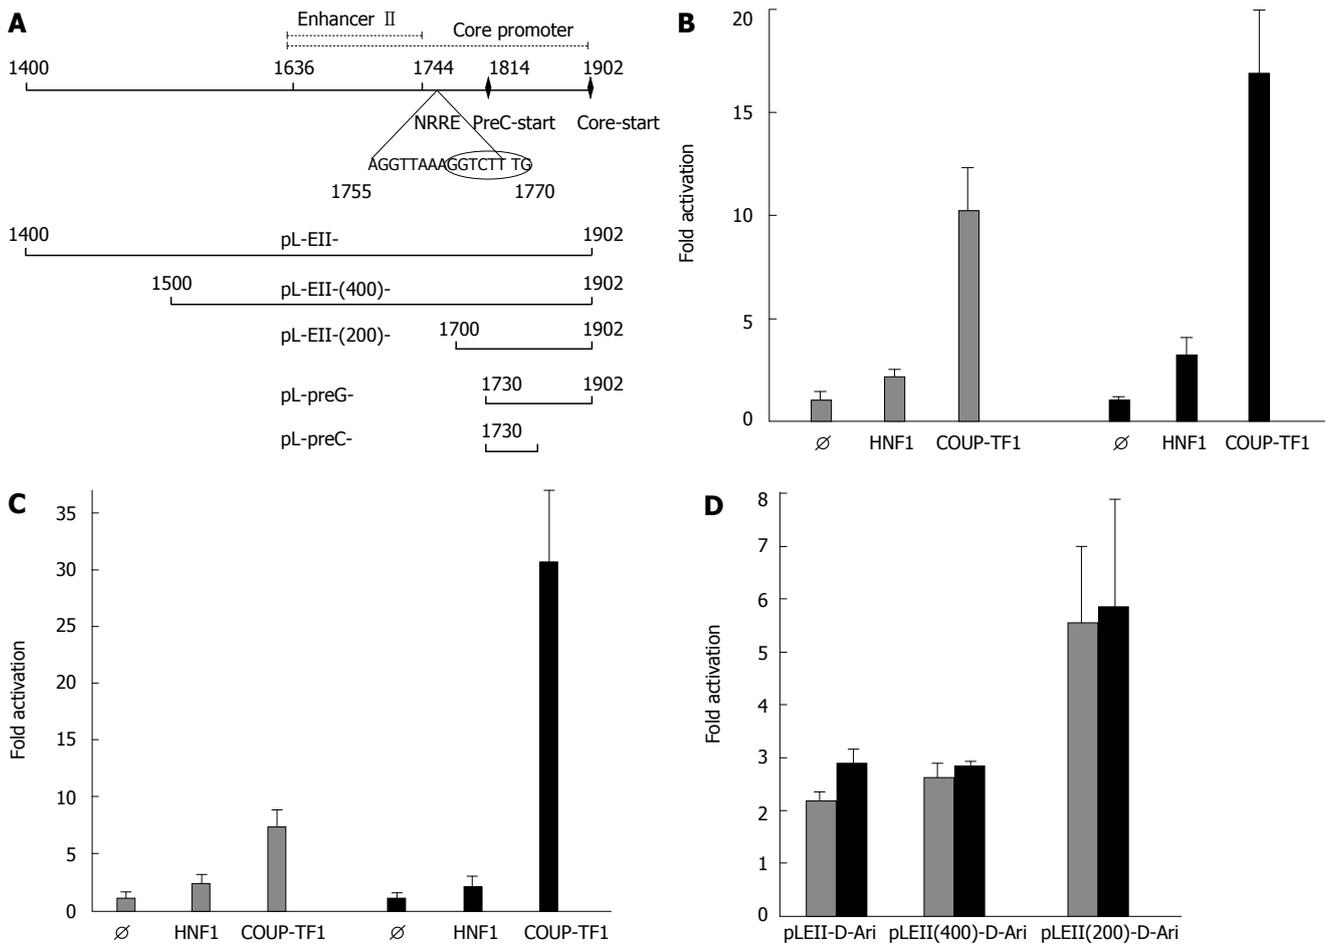

Figure 1 Structure (A) and activation of the precore (B), the pregenomic (C) and enhancer II (D) of HBV genotype D by COUP-TF1. A: Schematic structure of HBV enhancer II and the core promoter. The sequence of the nuclear receptor response element (NRRE) and the natural deletion of nt 1763-1770 (encircled) is indicated. Below the transcriptional elements the HBV fragments cloned into the luciferase reporter vector pGL3 are shown. For cloning the indicated nucleotides from two plasmids containing wt (GenBank: Y07587) and HBV with a deletion of nt 1763-1770^[18] were amplified and cloned. HepG2 cells were transfected with luciferase reporter constructs containing pregenomic promoter (pL-preG-D-Ari, wt in grey); B: Precore promoter (pL-preC-D-Ari, wt in grey) C: The complete and truncated wt enhancer II (pLEII-D-Ari, in grey) corresponding variant constructs with a deletion of nt 1763-1770 (Δ 8bp) in black. For cotransfection the empty expression vector (\emptyset) or expression vectors for HNF1^[27] or COUP-TF1^[28] were employed.

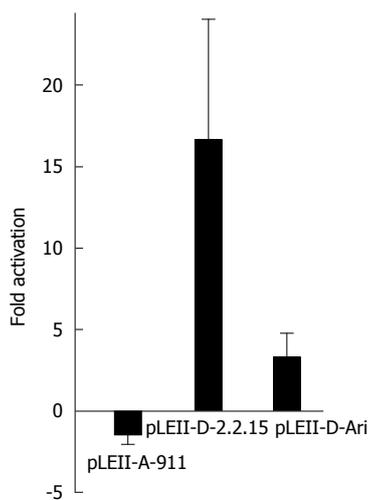

Figure 2 Influence of the nuclear receptor COUP-TF1 on enhancerII/core promoter constructs of different HBV genotypes. HepG2 cells were transfected with luciferase constructs for the complete enhancer II (1400-1902) of genotype A (pLEII-A-991) or two constructs (pLEII-D-Ari and pLEII-D-2.2.15) derived from genotype D and the expression vector for COUP-TF1.

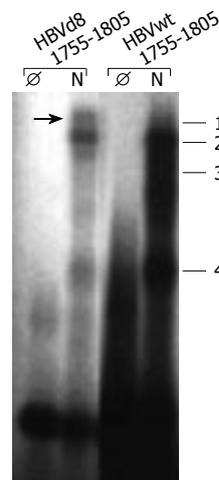

Figure 3 Deletion of nt 1763-1770 leads to altered band shifts in electrophoretic mobility shift assay with oligonucleotides nt 1755-1805. EMSA was performed as described by^[25] with oligonucleotide nt 1755-1805 wt (HBVwt 1755-1805) and with a deletion of nt 1763-1770 (HBVd8 1755-1805) incubated with (N) or without (\emptyset) nuclear extract prepared from HepG2 cells with a method^[25].

Thus, activation by COUP-TF1 may be exerted through other binding sites. To study the binding of the NRRE by cellular proteins we performed EMSAs with nuclear extracts prepared from HepG2 cells as described in^[24]. Figure 3 shows that the wild type oligonucleotide was bound

by several proteins purified from nuclear extracts of the human hepatocyte line HepG2. Four bands could be discerned in the EMSA with nuclear extract. Band 2 and 4 were common to wt and the 8 bp deletion. Band 1 was unique to the variant, band 3 to the wt.

DISCUSSION

Our results show that the ubiquitous transcription factor COUP-TF1 was a strong activator of wt and variant pG, pC promoter and enhancer II constructs (Figure 1 and 2) derived from sera of a single source outbreak^[18,19,29]. This result was surprising because Yu *et al.*^[13] reported that the wt-enhancer II (nt 1443 to 1990) was repressed by COUP-TF1. The involvement of distal elements in enhancer II that may be needed for activation by COUP-TF1 is unlikely because we did not observe a change in activation by deletion of upstream sequences (Figure 1D).

The NRRE seems to be dispensable for activation by COUP-TF1 in our genotype D constructs because all constructs containing a deletion of nt 1763-1770 were activated by COUP-TF1 as well as the wt-constructs (Figure 1). In addition, no binding of COUP-TF1 was observed by EMSA when we used an oligonucleotide containing a frequently found deletion of nt 1763-1770 (data not shown). These data support the findings of Yu and Mertz who reported that two frequently occurring natural point mutations of nt 1764 and 1766 also abolish binding by COUP-TF1^[14].

Our data are compatible with the report from the group of Mertz if HBV genotype differences are taken into consideration. Yu *et al.*^[13] found that the NRRE from nt 1755-1768 was essential for the repression of transcription from HBV enhancer II, pC and pG promoter of genotype C^[13,14]. We have analysed activation of HBV enhancer II, pC and pG promoter of genotype D by COUP-TF1. For activation by COUP-TF1 nt 1763 to 1770 of the NRRE seem to be dispensable. Thus, our data imply that activation of HBV enhancer II, pC and pG promoter is regulated by other elements than the NRRE. We can not rule out the possibility that COUP-TF1 exerts its activation of enhancer II of HBV genotype D by indirect mechanisms not involving direct binding to the promoter as in the activation of the vHNF1 promoter^[30].

Further analyses with constructs containing HBV DNA from other sources showed that very similar constructs of HBV enhancer II reacted differently to COUP-TF1: constructs derived from genotype A (Figure 3) or C^[13] were repressed by COUP-TF1 whereas constructs of genotype D derived from two different sera were activated. A sequence analysis (data not shown) of these four constructs revealed no differences in the NRRE at bp 1755 – 1768, which has been shown to be essential for repression by COUP-TF1^[13,14]. However, the sequences upstream of the NRRE showed sequence variability as expected for HBV isolates of different genotypes. However, we were not able to detect a sequence motif that may be indicative for activation or repression by COUP-TF1.

HBV genotypes influence the course and outcome of preventive and therapeutic measures^[8-10,31-33]. Very limited data are available on the effect of the sequence variability on *in vitro* properties of HBV, which may explain the different outcome of HBV infections depending on the genotype of HBV. In a relatively large analysis using HBV constructs of HBV genotypes A, C, D and E, Sommer *et al.* observed differences in splicing of the HBV pregenome^[34]. Other groups observed higher repression of

apoptosis by HBx derived from genotypes D compared to HBx of genotype C origin^[35]. Using another system, HBx of genotype D also showed a higher activity than HBx of genotype A in the induction of apoptosis^[36].

Thus, the variability induced by HBV genotypes may result in different molecular biology of HBV. However, there is more research to be done because our current results do not answer the question whether the differences described by several groups can be attributed to properties conserved in a given genotype or only represent certain variants that may occur in all 8 HBV genotypes.

Abstract

This case report describes a young female patient presenting with acute intra-abdominal hemorrhage originating from a large tumor in the liver, most likely a hepatocellular adenoma. The bleeding was stopped by selective embolization of right hepatic artery branches. Subsequently, partial hepatectomy was performed after 6 mo. Macro- and microscopic examination showed complete necrosis and absence of tumorous tissue. The patient was discharged without complications, and subsequent follow-up until 22 mo after resection did not reveal any new lesions in the liver. This case emphasizes the significance of selective arterial embolization in the management of bleeding liver tumors and questions the need for (partial) hepatectomy after this procedure in selective cases.

INTRODUCTION

Hepatocellular adenomas are uncommon benign liver tumours that are present mainly in women of reproductive age^[1]. Their existence is associated with the use of oral

contraceptives^[2]. The first clinical presentation of the tumour can consist of abdominal pain, hepatomegaly, or hepatic (subcapsular) hemorrhage and shock^[1]. For the latter presentation, emergency surgery by partial hepatectomy is the current treatment of choice. However, this treatment is associated with high morbidity and mortality rates^[3,4]. Therefore, several groups suggest a role for initial conservative treatment^[1,5].

Selective arterial embolization is a novel method for the management of intra-abdominal hemorrhage without the need for major surgery, and our hospital has gained considerable experience with this procedure. However, the use of this elegant method when coping with liver hemorrhage has only been described incidentally^[1,5,6].

After any initial emergency treatment, secondary partial hepatectomy is generally recommended in patients with lesions ≥ 5 cm, because of increased risk of rupture as well as malignant degeneration^[1,5]. The case we present, however, suggests a role of selective arterial embolization not only in the primary emergency situation, but also as a therapeutic tool to achieve necrosis of an arterially vascularized liver tumor.

CASE REPORT

A 35-year old woman was referred to our hospital with a two-day history of right abdominal pain without any previous trauma. The patient had no medical history, her medication consisted of oral contraceptive treatment only (30 μ g ethinylestradiol, 150 μ g levonorgestrel, taken during eleven years). Despite initial fluid supplementation, her heart rate was elevated (110/min) with normal blood pressure. Further physical examination showed tenderness of the right upper abdomen. Hemoglobin levels were low (78 g/L). INR was 1.0, APTT 21.5 s, PTT 12.5 s and thrombocytes 213×10^9 /L. Serum liver enzyme levels were elevated (ASAT 550 U/L, ALAT 607 U/L, Alk.Fos 75 U/L, γ GT 109 U/L, LDH 758 U/L). She was transfused with 2 units of red blood cells. Computed tomography (CT) scan of the abdomen revealed a large subcapsular hematoma surrounding a tumorous mass in segment IV-VII of the liver, as well as intraperitoneal fluid. Arteriography confirmed hemorrhage originating from the right hepatic artery, which was also responsible for the vascularization of the tumor. Subsequently, selective arterial embolization of the majority of right hepatic artery branches was performed in order to stop the bleeding using both polyvinyl alcohol (PVA) particles and a mixture of enbucrilate (histoacryl) and

Figure 1 Contrast-enhanced computed tomography (CT) scan of the abdomen 6 d after selective arterial embolization, showing liver hemorrhage with a circumscribed mass as its conceivable origin.

Figure 2 Arterial phase CT scan of the abdomen before partial hepatectomy showing remains of the hematoma and the known circumscribed mass, which is not vascularized arterially. Note the arterial deposition of histoacryl and lipiodol along the tumor as a result of selective embolization.

Figure 3 Macroscopic view of the resected tumor (\varnothing 7 cm) consisting entirely of necrotic material.

iodized poppy-seed oil (lipiodol). Contrast-enhanced CT scan 6 d after embolization clearly showed a circumscribed tumorous mass (\varnothing 7 cm) in segment V of the liver, most likely a hepatocellular adenoma (Figure 1). Further hospital stay was unremarkable and the patient was discharged 11 d after admission. Following our department's protocol on liver adenomas with a diameter \geq 5 cm, elective resection of segment V was performed six months later. Preoperative contrast-enhanced CT scan showed the remains of both the hematoma and the known circumscribed mass (Figure 2). Arterial perfusion of segment V of the liver was absent whereas portal perfusion was intact. The resected tumor consisted completely of necrotic material (Figure 3). No clear tumor classification could be made by histological examination due to absence of tumorous material, but the macroscopic signs of necrosis were confirmed. Tumor markers (CEA, CA 19.9 and α -foetoprotein) were in the normal range. The patient was discharged without complications, and subsequent follow-up until 22 mo after resection did not reveal any new lesions in the liver. She was advised to refrain from oral contraceptive medication.

DISCUSSION

The increased chance of rupture of large hepatocellular adenomas makes the presence of such a tumour a

considerable potential hazard. Management of this condition still needs improvement. The presence of a ruptured hepatocellular adenoma cannot be proven by CT scan alone, but is strongly suggested by our patient's clinical presentation. Although hepatocellular carcinoma and focal nodular hyperplasia lesions have also been described as causes of liver hemorrhage^[7], their presence is unlikely in this patient. The presence of liver adenomas in young women is associated with the use of oral contraceptives. In this case no specific histologic tumor classification could be made, since cessation of arterial blood flow by embolization caused necrosis of the tumor. This corresponds with the fact that hepatocellular adenomas are only vascularized arterially. It has to be noted that regression of liver adenomas is possible not only after ischemia, but also after hormone withdrawal^[8], hemodialysis^[9] and dietary therapy for glycogen storage disease^[10].

Embolization is safe and successful in stopping the hemorrhage. The necrosis of the tumor may point to a future role of selective arterial embolization in the management of either bleeding or non-bleeding hepatocellular adenomas. Furthermore, this case argues in favour of conservative follow-up after embolization, regardless of the initial size of the adenoma. This would further limit the indications for surgery in a selected group of patients, resulting in reduction of patient morbidity and mortality.

Abstract

Biliary cystadenomas are rare, cystic neoplasms of the biliary ductal system that usually occur in middle-aged women. They cannot be safely differentiated from cystadenocarcinomas before operation and should always be considered for resection. Cystadenomas have a strong tendency to recur, particularly following incomplete excision, and a potential of malignant transformation. Therefore, complete resection is the therapy of choice and thorough histopathologic evaluation is imperative. A case of benign biliary cystadenoma with mesenchymal stroma is presented along with a review of the relative literature addressing the clinical presentation, histology, histogenesis, differential diagnosis, imaging features, treatment and prognosis of this interesting and rare entity.

<http://www.wjgnet.com/1007-9327/12/6062.asp>

INTRODUCTION

Biliary cystadenomas are rare, benign but potentially malignant, multilocular, cystic neoplasms of the biliary ductal system^[1,2]. They usually arise in the liver (80%-85%)^[2,3], less frequently in the extrahepatic bile ducts^[2,3] and rarely in the gallbladder^[4], accounting for less than 5% of cystic

neoplasms of the liver^[5,6]. Less than 100 reports of intrahepatic biliary cystadenomas are identified in the medical literature^[5,7-10].

They more frequently occur in middle-aged women^[7,10,11]. The patients may be asymptomatic with their tumors discovered incidentally during radiographic evaluation or surgical exploration for other clinical indications^[6]. However, they often have vague abdominal complaints related to extrinsic compression of the stomach, duodenum, or biliary tree^[5,7,12]. The premalignant nature or potential for malignant transformation or degeneration and the tendency to recur, particularly when treated with techniques other than complete excision, are of great concern in these tumors^[7,10,11]. Furthermore, since clinical presentation as well as laboratory and imaging data are highly variable and non specific, cystadenoma cannot be differentiated preoperatively from cystadenocarcinoma^[1,5,6,10,13].

Such entities in surgical pathology are presented mainly as case reports or retrospective collective studies since their rarity prohibits a prospective evaluation. A case of benign biliary cystadenoma with mesenchymal stroma is presented here along with a literature review.

CASE REPORT

A 39-year old woman complained of vague abdominal pain and increasing abdominal girth. No other signs or symptoms were discovered on clinical examination apart from marked hepatomegaly. All blood tests were normal including liver function tests and levels of serous neoplastic markers such as carbohydrate antigen 19-9 (CA 19-9), carcinoembryonic antigen (CEA), carbohydrate antigen 125 (CA 125), and α -fetoprotein (AFP). Anti-echinococcal IgM and IgG antibodies and viral markers for hepatitis B and C were negative. Ultrasound (US) finding of a cystic lesion of the liver led to a computed tomography (CT) scan that revealed a large (19 cm \times 16 cm \times 10 cm), well-encapsulated, binodular, cystic formation of the liver occupying most of the right lobe (Figure 1). The lesion appeared to exceed the limits of the liver, reaching the right iliac fossa. A radiological diagnosis of hydatid cyst was offered.

The patient underwent laparotomy under an extended right subcostal incision that revealed a large cystic formation with no macroscopic resemblance to a hydatid cyst. A decision for right hepatic lobectomy was made and segments V-VIII were excised under proximal vascular control. No intraoperative blood transfusion was required. The postoperative course was uneventful and the patient

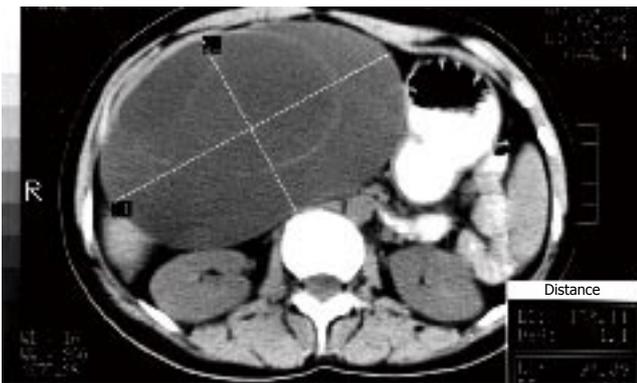

Figure 1 Abdominal CT scan revealing a large binodular cyst occupying most of the right liver lobe.

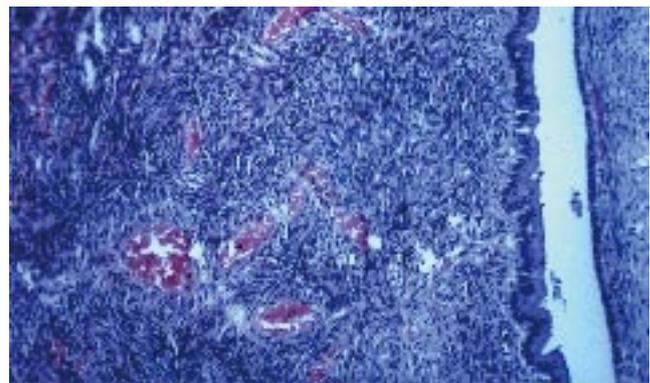

Figure 2 Histologic appearance of the simple columnar and cuboidal epithelium that is typical of biliary cystadenoma. The underlying mesenchymal stroma is densely cellular resembling ovarian.

was discharged six days after operation.

The cytology report of the cystic fluid identified clusters of glandular cells with round nuclei and clear cytoplasm. The most possible diagnosis was biliary cystadenoma. The final histology report referred to an 18 cm × 16 cm gray-white cystic lesion with 0.1-0.3 cm of wall thickness indicating intramural microcystic formation. The lesion was characterized as a hepatobiliary cystadenoma. The epithelium was simple columnar and cuboidal with no atypia and had an underlying densely cellular mesenchymal stroma resembling ovarian (Figure 2). Histological examination showed complete removal of a benign hepatobiliary cystadenoma with mesenchymal stroma.

The patient has remained free of disease for a period of 4 years on repeated CT scans since she was discharged.

DISCUSSION

Cystadenomas are rare, benign but potentially malignant, multilocular, cystic neoplasms of the biliary ductal system^[1,2,7,10], accounting for less than 5% of cystic neoplasms of the liver^[5,6,10]. The incidence of intrahepatic biliary cystadenomas is between one in 20000 to one in 100000 people while the incidence of cystadenocarcinomas approximately one per 10 million patients^[14]. Hepatobiliary cystadenomas can occur at any age^[15], but they are usually seen in middle-aged women^[7,10,11,16]. Approximately 85%-95% of the patients are women^[12,15,17]. Even though they are true proliferative epithelial tumors, their progression is characteristically slow and years are required before they enlarge^[11]. Their size is variable ranging from 1.5 to 30 cm in diameter^[2,5,11,16,18]. They usually arise in liver (80%-85%)^[2,3,7,10,19,20], less frequently in extrahepatic bile ducts^[2,3,7,10,17,19] and rarely in gallbladder^[4]. Approximately 50%-55% of cystadenomas are located in the right lobe with the remaining located in the left lobe or in both lobes (30%-40% in the left lobe and about 15%-20% in both lobes) while few arise from extrahepatic ducts^[2,11,12,21]. Accordingly, the common or the right bile duct can be identified as the origin in more than half of cases.

Although reports of cystadenomas have been increasing due to advances in imaging diagnoses and the

common use of US and CT, less than 100 reports of intrahepatic biliary cystadenomas are identified in the literature^[5,7-10,22] and only 26 extrahepatic cystadenomas have been reported^[17,23]. A review of the literature is provided along with a discussion addressing the clinical presentation, histology, histogenesis, differential diagnosis, imaging features, treatment and prognosis for this rare entity.

Clinical presentation

The patients may be asymptomatic with their tumor discovered incidentally during radiographic evaluation or surgical exploration for other clinical indications or even at autopsy^[6,24]. However, they often have vague abdominal complaints related to extrinsic compression of adjacent structures such as the stomach, duodenum, or biliary tree. Symptomatic patients present with an insidious onset of symptoms due to the slowly growing nature of the neoplasm^[12].

The typical patient is a white female presenting with abdominal discomfort, swelling, gradual increase in abdominal girth and/or pain and a palpable abdominal mass^[5,7,11,12]. Right upper quadrant or epigastric pain along with increasing abdominal girth or awareness of an abdominal mass are the main complaints in about 60% of the patients as reviews of the reported cases have shown^[21]. In another series, complaints include abdominal pain in 74%, abdominal distension in 26%, and nausea/vomiting in 11% of the patients^[25]. The patients may less frequently have gastrointestinal obstruction leading to nausea and vomiting, dyspepsia, anorexia, weight loss or ascites^[11,26].

When complicated, symptoms include biliary obstruction^[5,7,12], rupture^[19], bacterial infection^[19], intracystic hemorrhage^[19,22] or malignant transformation^[7,10]. Biliary obstruction may be either due to the tumor itself^[21,27] or either, rarely, due to the secretion of mucin^[20,28] and is manifested as jaundice, biliary colic, cholangitis, nausea, fever, chills, itching, or steatorrhea^[22]. Such cases represent approximately 35% of the patients with cystadenomas^[24]. Patients may experience intermittent jaundice or repetitive episodes of biliary colic or cholangitis for a long period of time before the diagnosis^[21,22]. Obstructive jaundice,

although not always present^[29], is the most frequent presenting symptom in patients with extrahepatic cystadenomas^[17,19]. Other reported symptoms are right upper quadrant or epigastric pain, nausea, vomiting, skin itching and occasional diarrhea^[29]. On the contrary, in intrahepatic cystadenomas, biliary obstruction is rarely the chief presenting complaint of the patients^[22]. Any patient with clinical or biochemical obstructive jaundice of unknown etiology or recurrence of a liver cyst following surgical treatment should be suspected of having an intrahepatic or extrahepatic cystadenoma^[28-30] or a cystadenocarcinoma^[5,10].

Histology

Biliary cystadenomas are usually large, multiloculated, with internal septation and nodularity and surrounded by a dense cellular fibrostroma. Although it may be extremely rarely be unilocular^[18,22], multilocularity of the tumor is a key feature that distinguishes cystadenomas from developmental cysts^[16]. Biliary cystadenomas are usually globular, with a smooth external surface and a smooth or trabeculated inner surface and contain locules of variable sizes^[10,16]. The internal surface of the cyst may also have papillary infoldings or smaller cysts^[10]. On light microscopy, cystadenoma consists of three layers: a cyst lining of biliary-type epithelium, a moderately-to-densely cellular stroma, and a dense layer of collagenous connective tissue^[31].

The cyst wall consists of a single layer which is typical of biliary-type epithelium containing cuboidal-to-tall columnar and nonciliated mucin secreting epithelial cells with papillary progressions, pale eosinophilic cytoplasm and basally oriented nuclei. The cyst usually contains clear mucinous fluid^[10,19] which raises the possibility of a malignant component when hemorrhage occurs^[4,11], unless there is a trauma history. Rarely, the fluid within the cyst may be bilious, purulent, proteinaceous, gelatinous, clear or mixed. The septa of the tumor may show calcification.

Foci of epithelial atypia or dysplasia consisting of nuclear enlargement and hyperchromasia, multilayer, loss of polarity, and mitotic activity indicate potential malignant changes^[7,16]. Anaplasia or pleomorphism, severe architectural atypia (such as exophytic papillae) and capsular or stromal invasion are features of malignancy^[5,10,16]. The premalignant progression is usually based on the histologic presence of intestinal metaplasia which is characterized by the presence of numerous goblet cells^[7]. Careful pathologic evaluation is emphasized since malignant degeneration or transformation can be detected only after thorough sectioning. Histological differentiation of biliary cystadenoma from other cystic liver lesions is usually based on its multilocularity, columnar epithelium, papillary infoldings, and ovarian-like stroma^[16].

Similar lesions occur in the pancreas and ovary. Two histological variants of biliary cystadenoma are recognized, a serous type and a far more common mucinous type^[16]. The rare serous variety resembles serous cystadenoma of the pancreas and is not known to undergo malignant transformation^[16]. The mucinous type is predominantly a tumor of middle-aged women and is similar to mucinous

cystadenoma of the pancreas^[16].

If the underlying subepithelial stroma is densely cellular resembling ovarian stroma as in our case, it is referred as "mesenchymal stroma"^[5,8]. The stromal cells are spindle-shaped and usually immunoreactive with vimentin, alpha-smooth muscle actin, and muscle-specific actin and less frequently with desmin, estrogen and progesterone receptors^[8,16,27]. Although mesenchyme of these tumors resembles ovarian stroma morphologically, such immunohistochemical features are characteristic of myofibroblasts^[8,31]. Mesenchymal stroma is more often observed in the mucinous type of cystadenoma^[16]. There are two distinct types of cystadenomas based on the presence or absence of "mesenchymal stroma"^[5]. Cystadenoma with mesenchymal stroma occurs exclusively in women^[5,7,8,31,32] while cystadenoma without mesenchymal but with hyaline stroma arises in both men and women and tends to occur in older patients^[5,32]. Cystadenoma with mesenchymal stroma is regarded as a precancerous lesion^[33] but the type without mesenchymal stroma seems to undergo malignant degeneration much more frequently^[32]. Patients with cystadenocarcinoma with mesenchymal stroma have a good prognosis whereas the prognosis of patients with cystadenocarcinoma without mesenchymal stroma is poor, especially in men^[7]. The malignancy arises from the epithelial component in most cases^[33], although sarcomatous transformation of the mesenchymal stroma has been reported^[31,34].

Etiology-histogenesis

The origin of biliary cystadenomas is unclear. Theories on their etiology and histogenesis are not solid since both acquired and congenital origins have been proposed. Experimental studies by Cruickshank *et al*^[34] may support the theory of an acquired lesion. The development of the tumor as a reactive process to some focal injury has also been mentioned^[10]. Mesenchymal stroma, though resembling ovarian microscopically, is more akin to the primitive mesenchyme in embryonic gallbladder and large bile ducts^[8,9], suggesting that the tumor may arise from ectopic embryonal tissue destined to form the gallbladder^[9] or from ectopic embryonic rests of primitive foregut sequestered within the liver^[5,10,33]. Demonstration of endocrine cells in about 50% of hepatobiliary cystadenomas and cystadenocarcinomas could also suggest an origin from intrahepatic peribiliary glands^[35]. The presence of hamartomatous structures and development abnormalities supports the theory of congenital origin in at least some cystadenomas^[10,36].

A possible hormonal dependence of cystadenomas with mesenchymal stroma has also been proposed since immunohistochemical studies showing the characteristics of mesenchymal stromal cells, have revealed myofibroblastic phenotype and expression of progesterone and estrogen receptors^[27,37,38]. In addition, there are reports of this tumor occurring in oral contraceptive users, suggesting that estrogen-containing oral contraceptives may serve as tumor promoters^[11,38]. Ectopic ovarian tissue, however, is considered an unlikely origin of these tumors^[5,8].

It is uncertain whether biliary cystadenocarcinomas are *de-novo* cancer or are derived from cystadenomas. They are generally thought, however, to arise from preexisting benign cystadenomas since many cystadenocarcinomas contain areas of cystadenoma in the same sample^[5,10,33,39].

Differential diagnosis

In the evaluation of cystic hepatic lesions, a high index of suspicion is imperative. Moreover, since these neoplasms have a strong tendency to recur and undergo malignant transformation, differentiating between cystadenomas and other cystic liver lesions is substantially important. Differential diagnosis includes simple liver cysts, parasitic cysts (particularly hydatid cysts), haematomas or post-traumatic cysts, liver abscesses, congenital cysts, polycystic disease, hamartomas, Caroli's disease, and neoplastic lesions such as biliary cystadenocarcinoma, undifferentiated embryonal sarcoma, cystic metastasis, metastatic pancreatic or ovarian cystadenocarcinoma, biliary papilloma, cystic primary hepatocellular carcinoma, cystic cholangiocarcinoma, and hepatobiliary mesenchymal tumors (particularly biliary smooth muscle neoplasms) such as biliary leiomyoma, adenomyoma, and primary hepatic leiomyosarcoma^[2,27,40]. Preoperative and intraoperative diagnosis of biliary cystadenomas and cystadenocarcinomas can be very difficult and differentiation between these two entities can be safely done only after histopathologic evaluation^[1,5,6,10,33,40].

Specific attention should be paid to liver hydatid disease, especially in countries with a high incidence of the disease. Since its imaging features are similar to those of cystadenoma as in our patient, preoperative differentiation may be impossible without serologic tests^[2,24,41]. Anti-echinococcus granulosis and anti-amoebic serologic tests, estimation of CA 19-9, CEA and AFP levels, general evaluation of liver and renal function as well as abdominal US, CT and magnetic resonance imaging (MRI) should be performed. Liver function tests may be normal or elevated in cases of intrahepatic or extrahepatic biliary duct compression^[11,27,29].

Although they do not rule out cystadenoma when normal^[14], serum Ca 19-9 levels are believed to be a valuable marker in the diagnosis and monitoring in the postoperative follow-up since they are reported to return to normal after complete resection^[11,42]. Nevertheless, immunoreactivity for CA 19-9 is lost therefore minimizing the possible benefit of serial follow-up when cystadenoma is transformed to cystadenocarcinoma^[43].

Measurement of cyst fluid CA 19-9 and CEA levels has been advocated as an adjunctive preoperative procedure for enhancing the accuracy of differentiation of cystadenomas and cystadenocarcinomas from other hepatic lesions^[14,44]. High levels of CA 19-9 and CEA can be encountered in cystic fluid or in epithelial lining of biliary cystadenomas, particularly in those with mesenchymal stroma^[5,14,30,41,44] and cystadenocarcinomas^[45]. These elevated cyst fluid tumor markers clearly indicate the neoplastic features and biliary origin of these cysts^[5]. Elevation of CEA may, however, be moderate or not always present^[14]. On the contrary, substantially higher levels of CA 19-9 in

cystic fluid are observed in the majority of cystadenomas compared with those in simple cysts, echinococcal cysts, and polycystic liver disease^[14,30,41,42,44]. Therefore, though not allowing differentiation between cystadenoma and cystadenocarcinoma, measurement of CA 19-9 in cystic fluid obtained by fine needle aspiration as well as in serum may be helpful in the differential diagnosis of hepatic cystic lesions. Moreover, Koffron *et al.*^[14] have proposed a diagnostic and therapeutic algorithm for hepatic cysts and particularly intrahepatic biliary cystadenomas based on CA 19-9 and CEA levels and cytology along with laparoscopic cyst wall biopsy.

Percutaneous fine needle aspiration also provides fluid for bilirubin concentration analysis, which is suggestive of communication of cystadenoma with the biliary tract when it is elevated^[14], and for cytologic evaluation which may be helpful in excluding hepatic abscess, cystic metastases and other cystic lesions. Although there are reports of cystadenocarcinomas arising from cystadenomas diagnosed by percutaneous fine needle aspiration cytology^[45,46], it is not very accurate since this procedure relying on adequate sampling may miss the microscopic foci of the carcinoma in cystadenoma^[44,47,48]. Thus, correlation of aspiration cytology with clinical and radiological data has been suggested^[14,47]. Fine needle aspiration and needle biopsy for diagnosis, however, may also risk dissemination of tumor cells and is not generally recommended, particularly when surgery is planned^[30,48]. Pleural and peritoneal dissemination of tumor cells caused by aspiration has been reported^[48,49].

Furthermore, examination of epithelial cells of several types of hepatic cysts by mucin histochemistry and immunohistochemistry reveals different features of these cells regarding mucus and antigenic expression among the hepatic cysts^[50]. Epithelial cells of non-parasitic simple cysts and adult-type polycystic liver show similar mucin-histochemical and immunohistochemical features, and are characterized by little mucin and weak immunoreactivities to several antibodies. On the contrary, epithelial cells of cystadenoma and cystadenocarcinoma are characterized by much mucin and moderate to strong immunoreactivities to cytokeratins CAM5.2 and AE1 and AE3 as well as to CA 19-9, CEA and epithelial membrane antigen (EMA)^[16,50].

Although frozen sections may be helpful in differentiation of cystadenomas and cystadenocarcinomas from other cystic hepatic lesions^[18], they are not very useful due to the variability in histology of cystadenomas and their inability to rule out cystadenocarcinomas^[48,51,52]. Careful histopathologic evaluation of the resected specimen, therefore, constitutes the only safe diagnostic modality of hepatobiliary cystadenomas and cystadenocarcinomas while malignant degeneration or transformation of a cystadenoma can only be detected after thorough sectioning.

Imaging features

Diagnosis and differential diagnosis of cystadenoma from other cystic hepatic lesions are mainly based on abdominal US, CT scan and MRI. Preoperative US assessment is almost always performed but cannot replace the

diagnostic value of CT. Moreover, the role of US and CT is considered complementary^[53]. By US the tumor appears well-demarcated, thick-walled, noncalcified, anechoic or hypoechoic, globular or ovoid, cystic mass and may present thin internal septations, which are highly echogenic, mural nodules and polypoid or papillary infoldings^[2,11,15,24,53]. Dilatation of intrahepatic or extrahepatic bile ducts may also be disclosed^[27]. In case of intracystic hemorrhage, US may show a hyperechoic mass with no septation^[22].

The need to determine the size, morphology and anatomic relation to surrounding structures, particularly major vessels of the lesion prior to intervention is crucial and CT is of great help for the surgeon. Additionally, CT during arteriography is useful to demonstrate the tumor vascularity^[45]. Common features on CT scan include low-density, well-defined, lobulated, multilocular, thick-walled, cystic masses with internal septa and occasionally mural nodules^[2,12,15,26,53]. Intravenous contrast on CT enhances the cyst wall and septations. CT may sometimes demonstrate dilatation of intrahepatic or extrahepatic bile ducts. Rarely capsular, mural or septal calcification presents on US or CT^[2,15,54]. Although such features can be identified with CT and are essential for differentiating cystadenoma from other cystic liver lesions, a possible preoperative diagnosis is rarely suspected due to the rarity of the disease.

Demonstration of communication between the tumor and the biliary tract is of important diagnostic value both in identifying the site of origin of the tumor and in differentiating biliary cystadenoma/cystadenocarcinoma from other hepatic cystic lesions^[54]. Such a communication can be demonstrated with percutaneous transhepatic cholangiography or cystography (PTC), endoscopic retrograde cholangiopancreatography (ERCP), magnetic resonance cholangiopancreatography (MRCP), intraoperative cholangiography, cyst fluid examination for bile content, or surgical exploration^[12,14,18,45,54,55]. Moreover, since the potential for cystadenomas to extend intraluminally into extrahepatic ducts has been described^[41], preoperative extrahepatic biliary imaging is imperative when surgical management is planned. It is noteworthy that no biliary connection has been identified, even at the time of surgery, in the majority of reported cystadenomas^[11]. In a review of the literature, Sato *et al*^[45] reported that such a biliary fistula was found in only 21 cystadenomas and 16 cystadenocarcinomas.

ERCP or PTC may show an intraluminal filling defect that may be the tumor or represent intraluminal mucin^[20]. An infrequent finding is the endoscopic visualization of mucin being extruded through the ampulla of Vater^[18]. PTC can provide further information on biochemical and cytologic examinations of the cyst fluid^[45]. However, fine needle aspiration cytology is not very accurate^[44,47,48] while aspiration may risk possible tumor pleural or peritoneal seeding^[48,49]. Therefore, it should be avoided in cases of obvious or suspected cystadenocarcinoma, especially when surgery is planned^[48]. ERCP may also be performed in order to reveal or exclude compression or displacement of intrahepatic and extrahepatic bile ducts and is especially important if patients present with jaundice^[19]. Furthermore, diagnosis of a cystadenoma of the

extrahepatic biliary tree can be obtained by intraoperative cholangiography and/or choledochoscopy, PTC, ERCP, MRCP or spiral CT scan^[21,55-57].

MRI is a valuable tool for the diagnosis and differentiation of cystadenoma from other cystic liver lesions while combination of MRI with MRCP is also even more useful^[55]. On T1-weighted images, MRI reveals a fluid-containing, multilocular, septated mass with homogenous low signal intensity, the wall and septa of which become enhanced after administration of Gd-DTPA^[2,54,55]. On T2-weighted images the fluid collections within the tumor demonstrate variable, homogenous high signal intensity while the wall of the mass is represented by a low-signal-intensity rim^[2,54,55]. Variable signal intensities on T1- and T2-weighted images depend on the presence of solid components, hemorrhage, and protein content^[2,54,55]. On T1-weighted images, the signal intensity may change from hypointense to hyperintense while septations may be obscured, and only mild enhancement of the cyst wall is noted after Gd-DTPA administration, as protein concentration and viscosity of the cyst fluid increase. In contrast, on T2-weighted images, signal intensity of the cyst fluid may decrease. Similar changes of the typical MRI appearance of cystadenoma may be caused by internal hemorrhage^[26]. MRI may disclose dilated intrahepatic or extrahepatic bile ducts or demonstrate the relationship of the lesion to vascular structures and, thus, may be helpful in planning the surgical procedure.

Preoperative assumption that the lesion is benign based on US, CT or MR findings is not safe and therefore not recommended^[48]. The presence of irregular thickness of the wall, mural nodules or papillary projections indicates the possibility of malignancy^[2,7,45,53]. Papillary projections in the cyst can be seen on contrast-enhanced CT, and are characteristic of malignant neoplasm^[4]. However, there are cases in which papillary projections are not shown clearly on CT. Hypervascularity of mural nodules on CT during arteriography may also indicate malignancy of the lesion^[45]. Septation without nodularity suggests the diagnosis of cystadenoma whereas septation with mural or septal nodules, papillary infoldings, discrete solid masses, and thick, coarse calcifications is suggestive of cystadenocarcinoma^[47,54]. Changes in appearance of the cyst wall may also suggest malignant transformation^[45]. Despite these features, however, imaging differentiation criteria between biliary cystadenoma and cystadenocarcinoma have not yet been established^[14,17,33].

Angiography is advisable and may be helpful both in clarifying the hepatic arterial anatomy and in differentiating cystadenocarcinoma from benign cystadenoma but seems not essential while the resectability of the tumor is assessed. Common findings include an avascular or hypovascular lesion with a faint rim of contrast-material accumulation in the wall and septa of the mass in the parenchymal phase and, occasionally, a tumor blush at the periphery corresponding to the papillary infoldings along with displacement of regional intrahepatic vessels^[1,11,12,22,26]. Signs raising the suspicion of malignancy are considered to be attenuated intracystic vessels, stretching of thin hepatic arteries, intracystic hypervascular mural nodules,

irregular calibers of the peripheral arteries in the arterial phase, and light stains in the parenchymal phase^[40,45]. Attenuated arteries and tumor stain at the central portion of an avascular or hypovascular lesion are the typical angiographic features of a cystadenocarcinoma^[40].

Although difficult, correct preoperative and/or intraoperative diagnosis of cystadenomas and cystadenocarcinomas is of utmost importance in planning the appropriate surgical procedure. Among all intraoperative diagnostic and surgical procedures intraoperative ultrasound is considered the most sensitive^[58]. Intraoperative US can be helpful for the diagnosis of biliary cystadenoma^[3,18] and determining its resectability^[11]. It may occasionally allow the surgeon to differentiate between the smooth wall of a cystadenoma and the infiltrative wall of a cystadenocarcinoma^[18]. However, it cannot usually confirm the relationship between the tumor and the bile system while it may be difficult to distinguish an extrahepatic cystadenoma from a pancreatic cystadenoma because of their similar appearance on US^[51]. In patients operated laparoscopically, laparoscopic ultrasonography has been reported as an essential supplement to inspection of the lesion via laparoscopy^[14].

Intraoperative cholangiography is also considered very helpful since it can demonstrate both intrahepatic^[12,18] and extrahepatic lesions^[23]. It may allow fluid aspiration for cytology^[18] and may reveal communication between the lesion and the biliary system^[18] although not always^[12]. In addition, it can be performed after the surgical procedure in order to exclude any bile duct injuries or retained cysts^[18]. It has been proposed that intraoperative cholangiography and/or choledochoscopy should be performed to diagnose extrahepatic cystadenomas^[23].

Treatment and prognosis

Resection is the management of choice for all multiloculated cystic hepatic lesions^[19,59]. If a cystadenoma is suspected or has been diagnosed, surgery is indicated even in asymptomatic patients, since cystadenoma and cystadenocarcinoma cannot be reliably differentiated on the basis of radiologic and macroscopic criteria^[1,5,6,10,33,48,54]. The extent of resection remains to be determined since partial resection with occasional ablation of the residual cyst using electrocautery or argon beam coagulation and/or omentopexy^[14,33,60], and lobectomy^[14,61] as well as wedge resection^[14] and enucleation^[14,19,50,62] have been reported.

In cases of communication of an intrahepatic cystadenoma with the biliary tract, biliary fistulae should be confirmed^[45]. When such fistulae are identified, resection of the tumor should be supplemented with suture closure of the fistulae^[14,45] or resection of the affected bile duct and bilioenteric reconstruction particularly if postoperative leak or intrahepatic biliary obstruction after suture control is concerned^[14,41]. In treatment of extrahepatic cystadenomas, resection of the tumor should be supplemented with resection of the affected bile duct and bilioenteric anastomosis^[17]. In cases of compression of intrahepatic or extrahepatic ducts, postoperative cholangiography may be performed to identify resolution of biliary compression^[45].

Incidental finding of a cystadenoma during surgery

for other clinical indications demands a complete surgical resection of the tumor^[6]. Although incidental finding of a cystadenoma after open or laparoscopic fenestration of a hepatic cyst also requires complete resection, it has been proposed that after complete enucleation of the cyst, strict follow-up could be considered as the definitive treatment, demanding the surgical intervention only in case of recurrence or high suspicion of malignancy^[6,63]. However, recurrence of symptoms 8 and 18 months after laparoscopic fenestration of an unsuspected cystadenoma has been reported^[64].

Total tumor extirpation with a wide margin of normal liver provides a chance for cure^[3,7,10,65]. Techniques other than complete excision for treatment of cystic hepatic lesions such as internal drainage, aspiration, marsupialization, sclerosis, Roux-en Y cyst-bowel anastomosis or partial resection should not be performed in cystadenomas because they may result in biliary obstruction, secondary infection or sepsis, rupture, hemorrhage, continued tumor growth, recurrence or late malignant transformation of the tumor^[3,7,10,11,14,17,19,25,45,51]. Benign biliary cystadenomas are believed to transform to cystadenocarcinomas even decades after partial resection although few of these lesions have been reported^[26,36,60]. Moreover, patients with hepatobiliary cystadenomas have been found to be over 10 years younger than those with cystadenocarcinomas^[7]. Cystadenomas should therefore be appreciated as premalignant lesions^[7,10,17,33,45,60] while cystadenoma and cystadenocarcinoma may be considered a different form of the same disease^[15]. Furthermore, cystadenoma cannot be easily differentiated preoperatively or intraoperatively from cystadenocarcinoma and total surgical resection should always be considered^[1,5,6,10,13,33,48,54]. Since complete surgical resection is the only safe way of eliminating such a danger and differentiating the two entities, such tumors should be completely excised^[60,61].

In addition, experience with techniques such as aspiration, fenestration, internal drainage, intratumoral sclerosant application or partial resection of cystadenomas is disappointing since the recurrence rate is extremely high ranging from 90% to 100%^[11,19,21,64,65] compared to 0%-10%^[22,25,26,48,52,60] after radical resection. Similarly, Davies *et al*^[17] reported that the recurrence rate for extrahepatic lesions is 50% after local excision from the bile duct wall compared to no recurrence after formal resection and bilioenteric reconstruction. Moreover, recurrence may be demonstrated even decades after subtotal resection^[51] while consecutive recurrences in the same patient have also been reported^[59].

Though still in evolution, laparoscopic surgery has an expanding role in the treatment of carefully selected patients with liver lesions and can achieve promising results^[66]. There are very few reports on successful laparoscopic treatment of intrahepatic biliary cystadenomas^[14,66] while no case of laparoscopically treated extrahepatic lesion has been reported. Even though laparoscopic treatment of intrahepatic cystadenomas has not been analyzed, provided that it is performed by expert liver as well as laparoscopic surgeons, the patients are carefully selected in terms of tumor size and location, and the tumor is com-

pletely excised, laparoscopic treatment is feasible and safe and may lead to similar results as open surgery^[14,66].

The prognosis of patients with cystadenoma is very good if total excision of the lesion is performed^[5,7,10,25,48,52]. In addition, cystadenocarcinomas may not show aggressive clinical behavior, and usually appear to have a slower growth rate and less frequent metastases or local invasion than other hepatic malignant neoplasms, such as hepatocellular carcinoma and cholangiocarcinoma, and ovarian or pancreatic cystadenocarcinomas^[48]. When treated with radical excision, they also have a generally good prognosis^[48,52], particularly those with mesenchymal stroma, unless the tumor invades the adjacent liver tissue or neighboring organs, or metastases are present^[33,39,48].

CONCLUSION

The natural history of symptomatic progressive tumor enlargement, the inability to preoperatively differentiate cystadenoma from cystadenocarcinoma, the high possibility of recurrence after palliative procedures, and the potential for malignant transformation lend support to the thesis that biliary cystadenoma denotes a potential malignancy. Therefore total resection and a prolonged close follow-up should be performed.

Abstract

Primitive neuroectodermal tumor (PNET) of the pancreas is an extremely rare tumor that usually occurs in children or young adults. We report a case of a 33-year-old male patient with an 18 cm × 18 cm × 16 cm mass arising from the pancreatic body and tail with a one-day history of abdominal pain. Initial CT scan showed no signs of metastatic tumor spread. The tumor caused intrabdominal bleeding and the patient underwent primary tumor resection including partial gastrectomy, left pancreatic resection and splenectomy. Diagnosis of PNET was confirmed by histology, immunohistochemistry and FISH analysis. All neoplastic cells were stained positive for MIC2-protein (CD99). Approximately one month after surgery, several liver metastases were observed and the patient underwent chemotherapy according to the Euro-Ewing protocol. Subsequent relaparotomy excluded any residual hepatic or extrahepatic abdominal metastases. Although PNET in the pancreas is an extremely rare entity, it should be considered in the differential diagnosis of pancreatic masses, especially in young patients. This alarming case particularly illustrates that PNET in the pancreas although in an advanced stage can present with only a short history of mild symptoms.

Welsch T, Mechtersheimer G, Aulmann S, Mueller SA, Buechler MW, Schmidt J, Kienle P. Huge primitive neuroectodermal tumor of the pancreas: Report of a case and review of the literature. *World J Gastroenterol* 2006; 12(37): 6070-6073

INTRODUCTION

Primitive neuroectodermal tumors (PNETs) are small round cell tumors arising from soft tissue belonging to the Ewing's sarcoma family. These neoplasms all exhibit a neural phenotype, express the MIC2-protein (CD99) and display the same chromosomal translocation t(11; 22)(q24; q12) in about 85% of the cases^[1]. While Ewing sarcoma is a primary bone tumor and follows osteosarcoma as the second most common malignant bone tumor in children, PNETs occur most often in soft tissue of the thoracopulmonary region, pelvis and lower extremities of children and young adults. Most of these tumors are diagnosed before the age of 35 years with a slight predominance in male patients^[1]. Although PNETs can occur in numerous solid organs such as the kidney, ovary, vagina, testis, uterus, cervix uteri, urinary bladder, parotid gland, heart, lung, rectum and pancreas, it is an extremely rare tumor entity^[2]. According to the literature there are currently 11 reported cases of PNET originating from the pancreas (Table 1)^[2-6].

Here we report another case of PNET in the pancreas in an otherwise healthy 33-year old man.

CASE REPORT

A 33-year old man presented to the Emergency Department of our hospital with acute abdominal pain which started one day ago. The patient reported one episode of vomiting but no history of diarrhea, peptic ulcer disease or pancreatitis. Laboratory data on admission showed leucocytosis, elevated C-reactive protein, amylase and lipase.

CT-scan of the abdomen revealed a 13.7 cm × 15.0 cm mass arising from the pancreatic tail compressing the stomach and spleen (Figure 1). The mass had solid and cystic characteristics with an inhomogenous contrast enhancement. Furthermore, blood was noted in the subhepatic area and pelvis indicating rupture of the tumor. Numerous mesenteric lymph nodes were enlarged up to 11 mm, while the liver showed no lesions suspicious of metastasis. Until surgery, a significant decline in hematocrit due to tumor bleeding was observed. At

Figure 1 CT-scan showing a huge intra-abdominal mass with solid and cystic areas originating from the pancreas.

laparotomy the tumor was found to be adherent to the stomach and the pancreatic body and tail. The capsule was partially ruptured. An enbloc-resection of the tumor was accomplished by partial gastric resection (Billroth-II), left pancreatic resection and splenectomy. The continuity was restored with gastrojejunostomy and Roux-Y-jejunostomy. The postoperative course was uneventful.

Grossly, the tumor measuring 18 cm × 18 cm × 16 cm was surrounded by an edematous capsule and appeared as cystic with alternating necrotic areas. The tumor was adhered to the pancreatic tail and stomach adjacent to the minor curvature where two small non-neoplastic ulcers were noted.

On microscopic examination, the solid tumor parts were composed of nests of medium-sized round or oval tumor cells with enlarged round or oval nuclei and scant cytoplasm surrounded by fibrovascular septae (Figure 2A). Focally, Homer-Wright rosettes were observed (Figure 2A). Immunohistochemically, the tumor showed a consistent and strong membranous expression of CD99 (Figure 2B) and a strong cytoplasmic staining for vimentin (Figure 2C). NSE-positive and negative neoplastic cells were found in about equal proportions, and smaller neoplastic

subsets were positive for cytokeratin (KL-1; Figure 2D), cytokeratin 18, EMA, synaptophysin, CD56 (Figure 2E) and CD117. The neoplastic cells lacked any detectable cytokeratins (7, 8 and 19), CEA, α 1-fetoprotein (AFP), α 1-antichymotrypsin (α 1ACT), protein S100, melan A and HMB-45. The Ki67 (MIB-1) labeling index was about 20%-30% (Figure 2F). Fluorescence *in situ*-hybridization was performed with a dual-colour DNA probe flanking the EWS gene on chromosome 22q12 (Vysis/Abbott, Wiesbaden, Germany) according to the manufacturer's instructions. Tumour cell nuclei showed one fused signal and one dislocated hybridization signal indicative of a chromosomal translocation involving the EWS gene. Overall, the microscopic findings led to the diagnosis of PNET.

Following primary hospitalization and surgery the patient was scheduled for staging examinations prior to chemotherapy. Thirty-five days after laparotomy, CT and MRI revealed at least two liver metastases in segments 6 and 7 up to 1.5 cm in size that were biopsied and confirmed immunohistochemically. There were no metastases in the lung, bone marrow or in the skeletal system according to staging by CT, bone marrow biopsy and scintigraphy. The patient underwent 6 cycles of induction VIDE chemotherapy (vincristin, ifosfamide, doxorubicin and etoposide), 1 cycle of VAI chemotherapy (vincristin, actinomycin D, ifosfamide) followed by high dose chemotherapy with melphalan and etoposide and autologous stem cell transplantation. During chemotherapy, devitalization and shrinking of the liver metastases were documented. Because CT visualized a residual lesion in segment 6 of the liver, the patient underwent explorative laparotomy with intraoperative ultrasound which did not show any metastasis or residual tumor. One year after diagnosis, there was no evidence of tumor recurrence.

DISCUSSION

Ewing sarcoma (EWS) and PNET belong to a tumor family (Ewing family of tumors) that is characterized

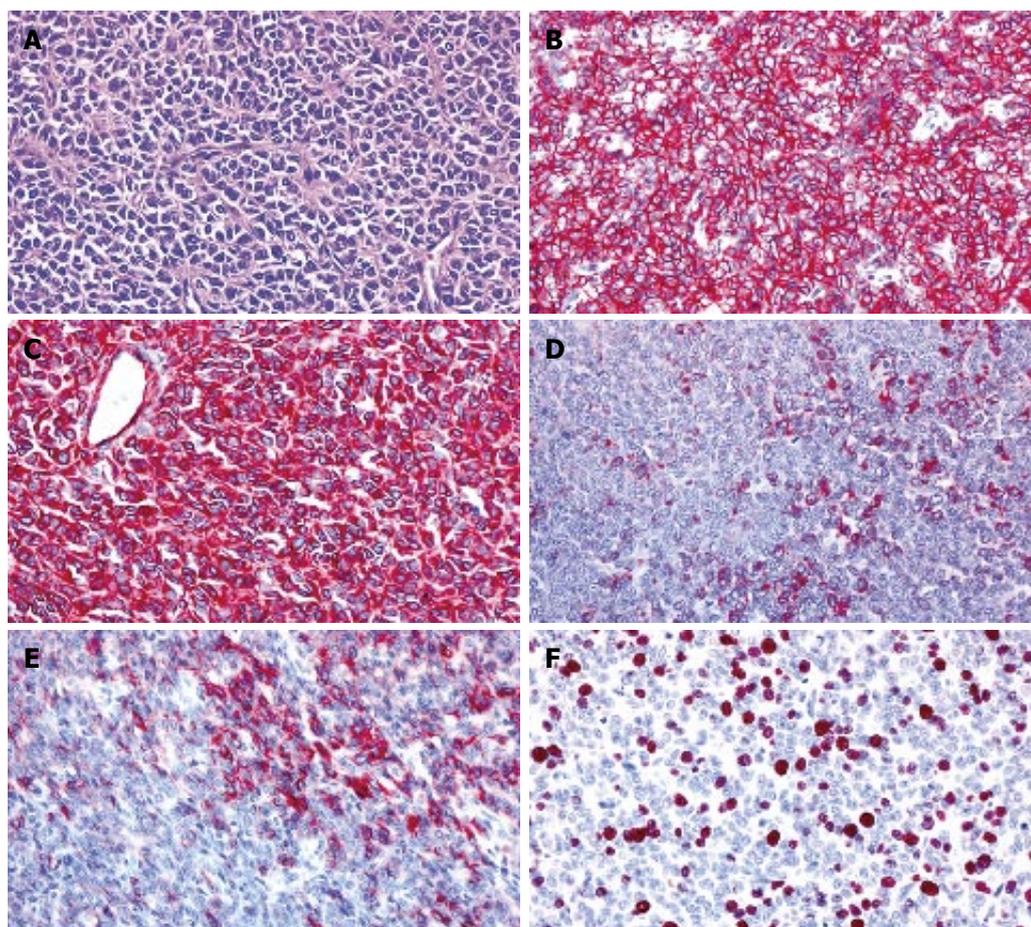

Figure 2 Histomorphological characteristics and immunolabeling of PNET. **A:** Solid tumor cell sheets separated by a delicate fibrovascular stroma; **B:** Strong membranous expression of CD99 (MIC-2) in the entire tumor cell population; **C:** Vimentin-positive neoplastic cells; **D:** Expression of cytokeratins (KL-1) in a minor tumor cell subset; **E:** Partial CD56-positive neoplastic population; **F:** Nuclear staining for the Ki67 proliferation antigen (MIB-1) in about 20%-30% of tumor cells.

by typical chromosomal translocations with subsequent functional fusion of the EWS gene with transcription factor genes thus forming a chimeric protein. Peripheral PNET (pPNET) was first described by Stout^[7] as a tumor of the ulnar nerve with the gross features of a sarcoma but composed of small round cells focally arranged as rosettes in 1918. pPNET makes up approximately 1% of all sarcomas^[2]. EWS and PNET form a subset of the “small-round-cell tumors” in childhood that comprise lymphomas, neuroblastoma and soft tissue sarcomas including rhabdomyosarcomas as well, which at least in undifferentiated forms, are indistinguishable by conventional light microscopy. When PNET is found in the pancreas, the differential diagnosis includes undifferentiated small cell carcinoma, pancreatoblastoma and pancreatic endocrine tumors. Thus the diagnosis of PNET necessitates histopathologic, immunohistochemical and if possible, also genetic analysis. EWS and PNET show a high expression of the cell surface glycoprotein MIC2 (also named CD99 or p30/32^{MIC2}) which is considered to be important in cell adhesion^[1]. However, other neoplasms as well as normal tissue including pancreatic endocrine tumors and pancreatic islet cells express the MIC2 protein, thus limiting specificity of the test.

Cytogenetic and molecular analysis of translocations has been established as a powerful adjunct for sarcoma classification. EWS/PNET show typical chromosomal translocations involving the EWS gene on chromosome 22

and a member of the ETS family of genes which code for DNA-binding transcription factors. The most common translocation $t(11; 22)(q24; q12)$ resulting in the fusion product EWS-FLI1 occurs in 85%-95%, while the second most common translocation $t(21; 22)(q22; q12)$ is seen in 5%-10%^[1].

Once PNET is diagnosed, the standard treatment is a systemic multi-agent chemotherapy combined with surgery and/or radiotherapy. Tumor dissemination at the time of diagnosis is associated with a poorer outcome compared to localized disease^[8]. However, a retrospective study on 24 patients younger than 16 years old with extraskeletal EWS reported that age and surgical treatment, but not size of tumor and metastatic disease at the time of diagnosis are significant prognostic factors^[9]. In this study the overall 5-year survival rate was 61% and the disease free survival rate was 54%. In various series including patients with extraskeletal EWS, the 5-year survival rate ranges from 61% to 77%^[8]. Intensive preoperative multi-agent chemotherapy may further improve the prognosis of EWS family tumors^[10]. There are only few data focusing on the prognosis of patients with PNET in the pancreas. Movahedi-Lankarani *et al*^[2] reported 2 patients with chemotherapy after primary Whipple procedure. One was alive at 33 mo with no evidence of disease, while the other died of disease 4 years after diagnosis.

In conclusion, PNET of the pancreas is an extremely rare pancreatic tumor and mainly affects children or young adults. To our knowledge, this is the 12th-reported case so

far. Although uncommon, PNET has to be considered in the differential diagnosis of atypical pancreatic tumors in young patients.

Abstract

Most of the foreign bodies detected in adult gastrointestinal systems are accidentally swallowed pins. In this study, we presented a case with intracolonic multiple pebbles. A 20-year-old man was admitted to emergency surgery policlinic for abdominal pain for 2 d without any alleviation or aggravation. His upright plain abdominal radiographic imaging revealed about 30-40 overt dense opacities in lumen of colonic segments, with oval and well shaped contours, each approximately 1 cm x 1 cm in size. The multiplanar reconstructions and three-dimensional images combined with sectional screening showed that all pebbles had passed completely into the colon and no foreign bodies had remained in the ileal segments. On psychiatric assessment, he was found to have immature personality features, difficulty in overcoming stressors and adaptation disorder. He recovered by conservative management and radiographic monitoring applied during his follow-up. Thus, it can be concluded that, in differential diagnosis of abdominal pain in adult ages, though less frequently seen than in children, gastrointestinal system foreign bodies should always be kept in mind and it should be considered that ingestion of pebbles may be one of the factors contributing to abdominal pain particularly in young adults with psychiatric problems. In such cases suspected of having foreign bodies which cannot be detected by plain films, abdominal tomography can be an alternative for diagnostic imaging.

Eryilmaz M, Ozturk O, Mentesh O, Soylu K, Durusu M, Oner K. Intracolonic multiple pebbles in young adults: Radiographic imaging and conventional approach to a case. *World J Gastroenterol* 2006; 12(37): 6074-6076

INTRODUCTION

The frequency of foreign body detection in gastrointestinal system is less in adulthood compared to childhood. Accidentally swallowed pins account for most of the foreign bodies found in adult gastrointestinal systems. Oral dental implants, bezoars, chicken-fish bones, packages of medications and drugs are among the other foreign bodies commonly seen to be swallowed^[1]. Incidence of foreign bodies swallowed by an individual with mental defect or due to conversive reaction is relatively rarer. Regardless of the types of the objects, foreign bodies are very rare to result in a serious clinical condition in intestinal lumen. If it does not develop an emergency surgical indication, there is no need to hospitalize the cases. Conservative follow-up approach is a generally preferred method. Out-patient follow-up through serial physical examination and plain films will be enough. A good observation and quick radiographic monitoring is suggested for the follow-up of such patients. As long as the objects do not get stuck in intestinal transition points such as pylorus or ileo-caecal valve, they are generally passed rectally out within a few days^[2]. We present herein a young adult case of intracolonic multiple pebbles, who was managed successfully by serial radiographic imaging and conventional approach, without surgical intervention.

CASE REPORT

A 20-year-old male presented in a peripheral hospital with the complaint of abdominal pain. With a provisional diagnosis of "intestinal foreign body", based on his upright abdominal plain film, he was referred to our hospital. The abdominal pain had been continuing for 2 d, with mild severity without any alleviation or aggravation. His physical examination revealed soft abdomen, no guarding and rebound tenderness, and normal bowel sound. However, tenderness was found at right lower quadrant on deep palpation. No abnormality was detected in rectal examination. Complete blood count and urine test were within normal limits. His upright abdominal plain film showed about 30-40 overt dense opacities in the colonic segments, with oval and well shaped contours, each approximately 1 cm x 1 cm in size (Figure 1). In addition to these multi-opacities, an image of a pin was detected in the region consistent

Figure 1 An upright plain abdominal radiographic imaging revealing 30-40 overt dense opacities in lumen of colonic segments, with oval and well shaped contours, each approximately 1 cm x 1 cm in size.

Figure 2 CT showing dense opacities in lumen of colonic segments, with oval and well shaped contours.

Figure 3 A multiplanar reconstruction and three-dimensional image combined with sectional screening showing all pebbles had passed completely into the colon and no foreign bodies were remained in the ileal segments.

with the right lower quadrant. In abdominal ultrasound, there were not any obvious abnormalities supporting the findings of the plain film. However, a minimal amount of smear-like fluid was present around the ileal segments in right lower quadrant. Low-dose computed abdominal tomography was applied without administering contrasting substance to see whether there is a foreign body which is unable to pass into the colon and poses the risk of obstruction, to be able to detect other foreign bodies which might not show any opacity, to evaluate the ileo-caecal valve better, and to better analyze the smear-like fluid shown by ultrasonography. In the lumen of colon, about 30-40 hyperdense images, suspicious of being pebbles, were detected (Figure 2). The multiplanar reconstructions and three-dimensional images combined with sectional screening revealed that all pebbles had passed completely into the colon and no foreign bodies had remained in the ileal segments (Figure 3). After computed abdominal tomography, rectal enema was applied to the patient and a few pebbles were passed out the body through defecation. He was managed conservatively and monitored with physical examination and abdominal plain film on follow-up in surgical out-patient clinic, until all the pebbles and pin were discharged within one week *via* defecation without any difficulty.

DISCUSSION

Intestinal foreign body cases resulting from foreign body ingestion accidentally or due to a convulsive reaction are seen less frequently in adulthood when compared to childhood. Types of the intestinal foreign bodies taken orally

by adults differ from those taken by children. In literature, plastic pipe, metal pin, nail, screw, spoon, bamboo stick and paper clip have been reported in adults as gastrointestinal system foreign bodies^[3-5]. Some case reports are available regarding Meckel's diverticulum perforations caused by swallowed fish bone^[6-8], foreign bodies^[9-11], chicken bone^[12] and alkaline battery^[13]. In the relevant literature, Selivanov *et al.*^[14] published a series of 101 and Steven *et al.*^[15] a series of 75 foreign body ingestion cases. In addition, Losanoff *et al.*^[5] presented a series of 9 prisoners who swallowed metal parts shaped like a cross.

Orally ingested foreign bodies are the cases that are not seen frequently in emergency surgery polyclinic. The basic approach is physical examination and imaging techniques. Patients considered not having acute abdominal syndrome after physical examinations are followed up with a serial upright abdominal plain film and physical examination. In case the foreign body cannot be visualized in conventional films, it should be kept in mind that the patient did not swallow the object or conventional techniques remained inadequate to visualize it. When the presence of other foreign bodies is suspected although one is observed on plain films, computed abdominal tomography can be considered as a proper alternative^[16-20]. Plain film findings of our case were evaluated in accordance with literature. Abdominal ultrasonography was applied considering that there might be foreign bodies which cannot be seen on plain films. Pebbles and the pin detected on plain films could not be seen on ultrasonography. Then computed abdominal tomography was applied to the case, which revealed multiple opacities that were suspected of being pebbles with intracolonic localization.

Intestinal foreign body cases, regardless of being in adulthood or childhood, do not reveal any symptoms as long as the object does not cause obstruction. If they lead to any obstruction or perforation, the main symptom to emerge will be abdominal pain, as was found in our case. Data have shown that majority of the cases are normal adults who swallowed fish or chicken bones while eating or mentally retarded patients who swallowed foreign bodies unconsciously.

His physical examination revealed soft abdomen, no guarding and rebound tenderness, and normal bowel sound. However, tenderness was found at right lower quadrant on deep palpation. No acute abdominal symptom or a clinical condition requiring an emergency surgi-

cal intervention could not be obtained in the case. The swallowed foreign bodies were clearly seen on his upright abdominal plain film. Literature points out that metal and glass objects can be seen on plain films, but not wooden objects, so abdominal USG may be obtained when deemed necessary^[21]. It will be very helpful to evaluate the abdomen through computed tomography in addition to plain films particularly in cases with psychiatric problems, suspicious of swallowing objects such as drugs, posing the risk of harming themselves and in those trying to conceal the truth, as seen in our case. Computed tomography and three-dimensional imaging were applied to the case in order to reveal other foreign bodies that might be present although they could not be monitored on plain films and to eliminate the foreign bodies that might remain in ileal segments and lead to ileo-caecal obstruction. Since there might be some other foreign bodies that cannot be detected by plain films, computed tomography and three-dimensional imaging are applied as the appropriate alternative for the detailed assessment of the intestinal lumen in suspected problematic cases and in the elimination of probable future complications.

While approaching to the intestinal foreign body cases, location of the foreign body has a great importance in terms of management. According to the localization and shape of the object, it is decided on whether an out-patient treatment or surgical intervention will be applied^[17,20,21]. Although sharp objects pass through gastrointestinal tract without difficulty in 90% of the cases, they may also be removed using fiberoptic gastroscopy without waiting. Early endoscopic intervention, in general, may be required and applied for objects wider than 2 cm and longer than 6 cm, since their passage through pylorus and duodenum will become difficult. Once these foreign bodies pass beyond pylorus and ileo-caecal valve, they are easily removed out of the lumen^[2]. Losanof *et al*^[12] operated all cases since the foreign bodies have pointed and sharp edges. Our case was managed conservatively and monitored on out-patient polyclinic follow-up, in the light of the literature. He was informed about the probable progress of his condition and suggested to be admitted to the clinic as soon as possible in case of acute abdominal pain and/or any other complaints.

In conclusion, in differential diagnosis of abdominal pain seen in adult ages, gastrointestinal system foreign bodies should always be kept in mind although they are seen less frequently than in children. It should be considered that intestinal system foreign bodies may be one of the factors contributing to abdominal pain particularly in young adults. In such cases suspected of having foreign bodies which cannot be detected by plain films, abdominal

tomography can be a sound alternative for diagnostic imaging.

Abstract

We report a case of sigmoid colonic carcinoma associated with deposited ova of *Schistosoma japonicum*. A 57-year old woman presented with a 10-mo history of left lower quadrant abdominal pain and a 2-mo history of bloody stools. She had a significant past medical history of asymptomatic schistosomiasis japonica and constipation. A colonoscopy showed an exophytic fragile neoplasm with an ulcerating surface in the sigmoid colon. During the radical operative procedure, we noted the partially encircling tumor was located in the distal sigmoid colon, and extended into the serosa. Succedent pathological analysis demonstrated the diagnosis of sigmoid colonic ulcerative tubular adenocarcinoma, and showed deposited ova of *Schistosoma japonicum* in both tumor lesions and mesenteric lymph nodes. Three days after surgery the patient returned to the normal bowel function with one defecation per day. These findings reveal that deposited schistosome ova play a possible role in the carcinogenesis of colorectal cancer.

INTRODUCTION

Schistosomiasis is a trematode parasitic infection in which terminal hosts are humans or other mammals with freshwater snails as intermediate hosts^[1]. Schistosomiasis

japonica is endemic mainly in China, and remains a major public health problem today although remarkable successes in schistosomiasis control have been achieved over the previous four decades^[2].

The life cycle of *Schistosoma japonicum* (*S. japonicum*) starts when cercariae in the freshwater infect humans or other mammals. After maturing, male and female worms pair up in the hepatic portal vein system, and produce ova in the mucosal branches of the inferior mesenteric and superior hemorrhoidal veins. Many ova are discharged in the feces, hatch, and release free-swimming miracidia, which in turn reinfect receptive freshwater snails and asexually produce larval cercariae^[2]. However, some ova deposit in the tissues of the host, cause host inflammatory responses, and lead to granuloma formation which is the principal pathology associated with schistosomiasis^[3]. Periovarian granulomas have been found in many types of tissue, including the liver, intestine, skin, lung, brain, adrenal glands, and skeletal muscle. Ova retained in the gut wall induce inflammation, hyperplasia, ulceration, microabscess formation, polyposis, and carcinogenesis^[3].

Successes in schistosomiasis control in China have prolonged the life of patients with schistosomiasis japonica in which the chronic pathological process may occur due to deposited schistosome ova.

Here we report a case of sigmoid colonic carcinoma associated with deposited ova of *S. japonicum*, with their possible role in carcinogenesis discussed.

CASE REPORT

A 57-year old woman presented with a 10-mo history of left lower quadrant abdominal pain and a 2-mo history of bloody stools. She had a sense of pain in the left lower quadrant abdomen when she had bowel movements about 10 mo ago. The pain was relieved after defecation, so that she did not think much of it. Two months ago, she noted that dark red blood adhered to the surface of stools without blood drops from anus. The symptom of hematochezia persisted until hospitalization. She had no other complaints. She had a significant past medical history of asymptomatic schistosomiasis japonica and constipation. She came from the rural area in Zhejiang Province, where schistosomiasis japonica was prevalent several decades ago. She had the experience of swimming in a local river in her childhood. At the age of 13, she was diagnosed with schistosomiasis through a thick smear stool examination by the county public health workers

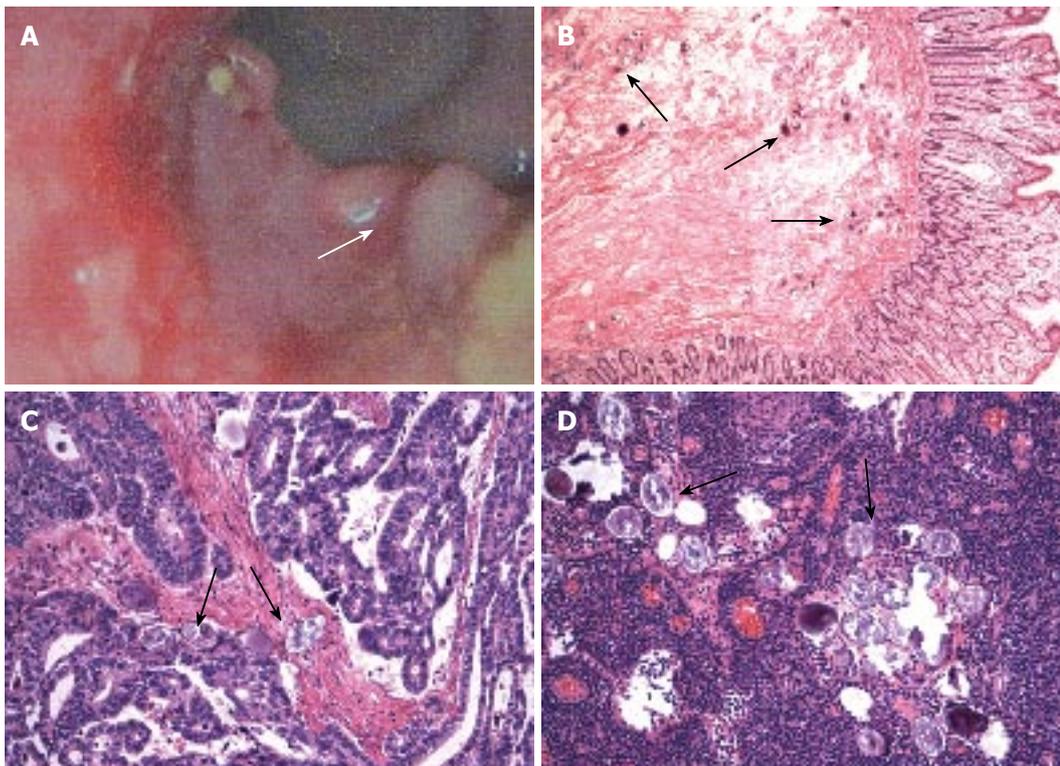

Figure 1 Colonoscopy showing an exophytic fragile neoplasm with an ulcerating surface (as indicated by the white arrow head) in the sigmoid colon (A), pathological analysis revealing deposited *S. japonicum* ova and granuloma formation as well as fibrotic deposition in the submucosa of the sigmoid colon (B) (HE \times 50), moderately-differentiated tubular adenocarcinoma (HE \times 200) and deposited *S. japonicum* ova in the tumor (C), and deposited *S. japonicum* ova in the mesenteric lymph node (D) (HE \times 200). Black arrow heads indicate *S. japonicum* ova.

for schistosomiasis control, and given the appropriate antischistosomiasis therapy which was not terminated until repeated stool examinations were negative. At the age of 20, she suffered from constipation which was not improved by adequate fiber intake. Usually, she had about two bowel movements with hard stools per week. The symptom began to become worse ten years ago and she had defecation once per week.

She was in good general condition. No supraclavicular lymph nodes were palpable. On abdominal palpation, there was a discomfortable sense in the left lower quadrant without palpable masses. Her peripheral blood cell count showed leucopenia (white blood cells: $3100/\text{mm}^3$) and mild thrombocytopenia (platelets: $72000/\text{mm}^3$), without anemia and eosinophilia. Three stool tests were all negative for *S. japonicum* ova. Liver function, renal function and electrolyte concentration were all normal. Tumor markers (AFP, CEA, and CA-199) were 2.41 ng/mL, 0.72 ng/mL, and 5.88 U/mL, respectively, which were within normal limits. The abdominal ultrasonography revealed echodense areas scattered within the parenchyma with typical fish-scale pattern, representing the trait of liver schistosomiasis. The computed tomographic scan showed that the bowel wall of sigmoid colon was incrassated and irregular in shape. The colonoscopy showed an exophytic fragile neoplasm with an ulcerating surface in the sigmoid colon (Figure 1A), which was diagnosed as adenocarcinoma through biopsy.

After definite diagnosis was made, the radical operative procedure was performed. During laparotomy, the entire peritoneal cavity was examined, with a thorough inspection of the liver, pelvis, and hemidiaphragm. Neither metastatic lesions nor enlarged mesenteric lymph nodes were found. The partially encircling tumor was located in the distal

sigmoid colon, and extended into the serosa. Pathological analysis of the operative specimen revealed deposited *S. japonicum* ova, granuloma formation, and fibrotic deposition in the submucosa of the sigmoid colon (Figure 1B), and demonstrated a grade 2 moderately-differentiated sigmoid colonic ulcerative tubular adenocarcinoma, 3 cm \times 2 cm in size, penetrating the serosa without lymph node involvement (Figure 1C). Deposited *S. japonicum* ova were found in both tumor lesions (Figure 1C) and mesenteric lymph nodes (Figure 1D).

Three days after surgery the patient returned to the normal bowel function with one defecation per day.

DISCUSSION

The relation between colorectal cancer and schistosomiasis japonica has not been well established. However, researchers in China have noted the coincidence of colon cancer and schistosomiasis japonica at the patient level during the 1970s^[4]. Another case-control study in Jiangsu Province showed that rectal cancer is associated with schistosomiasis japonica^[5]. A recent matched case-control study showed that previous *S. japonicum* infection is significantly associated with both liver cancer and colon cancer^[6]. It was also reported that schistosomiasis japonica correlates with colorectal cancer^[7].

The mechanism of schistosome infection-induced colorectal cancer was explored in our study. The mutations in p53 tumor suppressor gene in Chinese patients with schistosomiasis japonica-related rectal cancer and a high proportion of base-pair substitutions at CpG dinucleotides and a higher frequency of arginine missense mutations were observed, suggesting that the mutations are the result of genotoxic agents produced endogenously

through the course of schistosomiasis japonica^[8]. Another study showed that *S. japonicum* ova-induced colorectal epithelial proliferative polyps have a high percentage of atypical hyperplasia (64.9%) and CEA (90%)^[9]. Thus the epithelial proliferative polyp, especially that with atypical hyperplasia, is the transition during deposited ova-induced carcinogenesis. It was reported that the majority of colorectal cancer cases associated with *Schistosoma mansoni* (*S. mansoni*) infection have a significant expression of Bcl-2 while p53 and C-Myc expressions are insignificantly different in colorectal cancer cases associated with *S. mansoni* infection compared with those without *S. mansoni* infection^[10]. In a word, the mechanism of schistosome infection-induced carcinogenesis remains unclear.

In our present case, both chronic constipation and sigmoid colonic adenocarcinoma were induced by deposited *S. japonicum* ova, revealing that ova can interact with the host microenvironment. Asymptomatic schistosomiasis in our patient was cured as neither eosinophilia nor ova in her stools were observed. However, many old ova deposited in sigmoid colonic submucosa, tumor lesions, and mesenteric lymph nodes. Furthermore, the anatomic location of adenocarcinoma corresponded to the colorectal area with most deposited ova. These findings indicate that deposited *S. japonicum* ova play a possible role in the carcinogenesis of colorectal cancer^[7].

Another important aspect of this case is that chronic constipation was improved after operation. In this case, granuloma formation and fibrotic deposition around deposited ova perhaps disturbed the sensory function of the sigmoid colon, and resulted in constipation.

Additionally, we noted deposited ova in the mesenteric lymph nodes, leucopenia, and thrombocytopenia in this case. However, their pathological significance remains unclear.

In conclusion, sigmoid colonic carcinoma is associated with deposited ova of *S. japonicum*. Therefore, screening

for colorectal cancer should always be thoroughly performed with routine endoscopy in patients with previous *S. japonicum* infection, and the mechanism of deposited *S. japonicum* ova-induced carcinogenesis should be further investigated.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents[®]/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch[®]) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology

Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China

E-mail: wjg@wjgnet.com

<http://www.wjgnet.com>

Telephone: +86-10-85381901

Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5

line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

Key words

Please list 6-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P*<0.05, ^b*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, ^c*P*<0.05 and ^d*P*<0.01 are used. Third series of *P* values can be expressed as ^e*P*<0.05 and ^f*P*<0.01. Other notes in tables or under

illustrations should be expressed as ¹F, ²F, ³F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (<http://www.wjgnet.com/cgi-bin/index.pl>), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Patent (list all authors)

- 16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 µg/L; CO₂ volume fraction, 50 mL/L CO₂ not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please download CAF from <http://www.wjgnet.com/wjg/help/9.doc>.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to *WJG* all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The *WJG* requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1) direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3) supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The *WJG* does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to *WJG* if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Final check list for authors

The format is at: <http://www.wjgnet.com/wjg/help/13.doc>

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: <http://www.wjgnet.com/wjg/help/10.doc>

Abstract

The application of gene transfer technologies to the treatment of cancer has led to the development of new experimental approaches like gene directed enzyme/pro-drug therapy (GDEPT), inhibition of oncogenes and restoration of tumor-suppressor genes. In addition, gene therapy has a big impact on other fields like cancer immunotherapy, anti-angiogenic therapy and virotherapy. These strategies are being evaluated for the treatment of primary and metastatic liver cancer and some of them have reached clinical phases. We present a review on the basis and the actual status of gene therapy approaches applied to liver cancer.

INTRODUCTION

Knowledge of molecular mechanisms governing malignant transformation brings new opportunities for therapeutic intervention against cancer using novel approaches. One of them is gene therapy. This new discipline is based on the transfer of genetic material to an organism with the aim of correcting a disease. The genes can be delivered directly into the subject, using a variety of vehicles named vectors (*in vivo* gene therapy), or delivered into isolated cells

in vitro that are subsequently introduced into the organism (*ex vivo* gene therapy).

Cancer is the most frequent application of experimental gene therapy approaches^[1] for several reasons.

First, the genetic alterations that give rise or contribute to the malignant transformation of cells are being unravelled with increasing detail in the last two decades, and this provides multiple candidate targets for gene therapy intervention^[2]. Nevertheless, the genetic and epigenetic alterations that lead to an established tumor are complex and require special approaches that often differ from gene therapy applied for hereditary monogenic diseases. In many cases, the transfer of genes into malignant cells is not performed with the intention of correcting a genetic deficiency related to cancer. To be efficient, this would require that the selected gene plays a dominant role in the malignant phenotype. In addition, a technique would be needed that achieves successful modification of virtually every cell in the tumor, something that is far from being realistic in the near future. Therefore, different strategies have been developed to introduce genes that cause the destruction of the tumor by indirect mechanisms, as will be discussed below.

Second, some tools initially developed as gene therapy vectors, such as certain viruses, are being exploited as oncolytic agents by themselves. This means that the development of gene therapy approaches against cancer is activating other fields such as virotherapy and cellular therapies.

Finally, the lack of safe and efficient therapeutic options against many types of cancer is fostering the development of new gene therapy applications for these diseases. Liver cancer is a good example of this situation. Hepatocellular carcinoma (HCC) accounts for 80% of primary liver tumors in adults, has an increasing incidence^[3] and a poor 5-year survival rate of about 7% despite treatment^[4]. In addition, the liver is the most frequent site of metastasis, especially from gastrointestinal cancer. Potentially curative therapies such as liver transplantation and surgical resection can only be applied to a minority of subjects because of advanced disease at the time of diagnosis and the lack of suitable organ donors. Other regional treatments may be beneficial for unresectable HCC, but recurrence is frequent and the long term survival rate remains poor. These treatments include transarterial embolization (TACE), percutaneous Ethanol injection, radiofrequency thermal ablation, microwave coagulation therapy, laser-induced thermotherapy and radiotherapy. New protocols based on combinations of regional treatments (with or without previous surgery) are being investigated for the management of HCC, and they are showing a clear advantage when compared to single treatments^[5]. In this context,

gene therapy could be considered as a potential adjuvant to other therapies. The clinical trials performed so far have shown that the side effects are acceptable in most of the cases, and that the mechanism of action is different from standard treatments^[6]. Therefore, choosing the right combination among gene therapy approaches and conventional treatments may achieve a synergistic effect. Furthermore, the refinement of interventional therapies for HCC such as TACE and PEI provides new possibilities for the delivery of gene therapy vectors into hepatic tumors, increasing the effective dose and minimizing potential side effects derived from non-target cell transduction.

In this review we present an insight into gene therapy strategies against liver cancer and discuss the latest developments in the field.

RESTORATION OF TUMOR SUPPRESSOR GENES

This strategy is the most intuitive application of gene therapy for the treatment of HCC and other cancers. It is clear that the loss of function of certain genes (caused by deletions, mutations, promoter inactivation or other epigenetic changes) is associated with malignant transformation of cells^[7]. These tumor suppressor genes control cell proliferation and apoptosis in order to maintain an equilibrated turnover of cells in each tissue. Under experimental conditions (mostly *in vitro*), it has been demonstrated that the restoration of tumor suppressor genes can revert the malignant phenotype of cells^[8]. However, the therapeutic application of this observation faces enormous difficulties. Cancer cells often suffer some degree of genetic instability. When they lose their capacity to sense and repair damaged genes, mutations accumulate and cells with higher proliferation rate and lower sensitivity to apoptotic stimuli are selected sequentially. Under these circumstances, they may become insensitive to the restoration of a particular tumor suppressor gene. On the other hand, this approach requires the introduction of the gene and the expression of the antitumoral protein in virtually all cancer cells, or at least in those responsible for tumor maintenance. This is technically impossible with current gene therapy vectors, especially for solid tumors like HCC.

Despite all these considerations, the transfer of p53 tumor suppressor gene has shown effect in several animal models of cancer, including HCC^[9,10]. This proof of concept has stimulated the use of p53 as a therapeutic gene. Mutations in p53 or alterations in its pathway have been described in more than 50% of human cancers^[11,12]. When cells lack functional p53, they are unable to stop the cell cycle or trigger apoptosis in response to DNA damage. They accumulate mutations that lead to malignant initiation, progression and resistance to treatments. Thus, the restoration of p53 may render tumor cells sensitive to apoptotic stimuli, even if they have accumulated other mutations. This may explain the therapeutic effect observed in pre-clinical models, and suggests a potential role of p53 as an adjuvant to conventional therapies that induce apoptosis in cancer cells.

In contrast, several clinical trials based on delivery of the wild type p53 gene using different vectors have observed variable, and often less positive results in different types of cancer such as lung, head and neck, bladder, ovarian and breast cancer^[13]. However, a first-generation adenoviral vector expressing the p53 cDNA under the control of the CMV promoter became the world's first commercially licensed gene therapy product (Gendicine) for the treatment of head and neck squamous cell carcinoma in China^[14]. In a clinical trial performed on 30 HCC patients, Partial Response (PR) was reported in 2 cases, Stabilized disease (SD) in 24 patients and Progressive Disease (PD) in 4 of them. The virus was administered at doses of $1-2 \times 10^{12}$ VP/wk for 4 wk. In another HCC clinical trial, Gendicine was used in combination with TACE (5FU, HCPT and ADM). The viral doses were similar ($1-4 \times 10^{12}$ VP/wk for 4 wk), starting 2-5 d after TACE. The authors reported 67.6% PR in the combination group versus 51.2% in the TACE-only group (reviewed by Peng^[14]). The clinical significance of these results is controversial at this time, but the availability of a gene-based therapy in the market with potential effect on HCC will probably extend its use in combination with other therapies and allow the identification of synergistic effects. Optimization of the vectors and the therapeutic regimes may be needed to increase gene transfer. For instance, weekly injections of a first-generation adenoviral vector are most likely eliciting a strong immune response that blocks the infectivity of repeated doses after 2 wk. A better understanding of genetic alterations in each particular case of cancer will help to predict the response to the restoration therapy and aid in the selection of candidate patients.

In addition, new strategies are being developed to address the limitations of this approach. One of them relies on the fusion of p53 with VP22, a tegument protein from Herpes Simplex Virus-1 (HSV-1)^[15]. VP22 is exported from the cytoplasm of the expressing cell and gets incorporated by neighbouring cells by poorly defined mechanisms. The fusion of VP22 with other polypeptides enables the intercellular spread of the chimeric protein. It has been demonstrated that an adenoviral vector expressing the p53-VP22 fusion construct achieves higher transduction efficiency and therapeutic effect on a rat model of HCC when compared with wild type p53^[16]. In addition, the combination of p53 with other tumor suppressor genes like p16 can cooperate to induce apoptosis in cancer cells^[17].

The suppressor of cytokine signalling 1 (SOCS-1) gene has been recently identified as a potential tumor suppressor for HCC. Its promoter is frequently inhibited by methylation in HCC, causing activation of the JAK/STAT pathway^[18]. At least *in vitro*, the restoration of SOCS-1 function induces apoptosis in cancer cells.

INHIBITION OF ONCOGENES

The rationale of this approach is in line with the previous one. In this case the correction of the imbalance between positive and negative proliferation signals is attempted by inhibiting the function of genes implicated in the mainte-

nance of unrestricted cell proliferation and acquisition of metastatic phenotype. Many of the drawbacks mentioned above can be applied here, like the need for a highly efficient gene transfer method and a dominant role of the target gene in malignant transformation. The number of candidate oncogenes is continuously expanding as the knowledge of cancer at the genomic and proteomic levels advances^[2].

Hopefully, the inhibition of oncogene expression will not only decrease cell proliferation, but also restore sensitivity of cells to apoptotic stimuli. For instance, it is known that the inhibition of the Ras oncogene, apart from blocking a cascade of mitotic signals, relieves the repression exerted on the p53 pathway and predisposes cells to apoptosis^[19]. This may be the case for other oncogenes such as the pituitary tumor transforming gene 1 (PTTG1)^[20].

Another example is the catalytic subunit of Telomerase (Telomerase Reverse Transcriptase, TERT). Since telomerase function is necessary to maintain telomere length in each cell division, cancer cells undergoing unrestricted cell proliferation present activation of TERT expression^[21]. Therefore, inhibition of TERT is hypothesised to cause inhibition of cell growth after several divisions, when telomeric repeats finally run out. However, efficient inhibition of telomerase expression is able to induce apoptosis in a few days, and this is irrespective of its telomere-lengthening function^[22]. New data indicate that telomerase is also necessary to protect chromosome ends from being recognized as DNA disruptions, which would trigger apoptosis^[23].

Different methods are used to inhibit expression of oncogenes. One of them is based on the transfer of antisense nucleotides, artificial sequences complementary to the mRNA corresponding to the gene whose inhibition is attempted^[24]. These can be short sequences (antisense oligonucleotides, ASO), or the full cDNA. Several mechanisms account for the blocking of gene expression, with the most widely spread and studied being the degradation of RNA-DNA hybrids by cell nucleases such as RNase H. A more recent approach is RNA interference, another posttranscriptional gene silencing mechanism based on the production of double-stranded stretches of RNA complementary to the target mRNA^[25]. Using the endogenous cell machinery, the double-stranded RNA is processed into 21 to 23-nucleotide short interfering RNAs (siRNAs) that recognize the cognate mRNA and trigger its degradation. Alternatively, the siRNAs can be transfected directly. In the "triple helix" strategy, the inhibitory oligonucleotides (triplex-forming oligonucleotides, TFOs) are targeted to the cellular double-stranded DNA^[26]. They interact with polypurine-polypyrimidine sequences in the minor or major groove of genomic DNA and block gene expression at different levels depending on the localization of the complementary sequence. They could be potentially used not only for gene expression modification, but also in gene correction strategies^[27]. Finally, the expression of secreted or intracellular antibody-based molecules has been proposed to block the function of oncogenes^[28,29].

In the case of HCC, the inhibition of several genes has shown potential antitumor effect. Most reports provide

proof of concept showing growth inhibition or induction of apoptosis using HCC-derived cell lines in cell culture. The *in vivo* studies performed in animal models show growth retardation in tumors, especially when cancer cells are transfected *ex vivo*, but complete eradication is difficult when *in vivo* gene therapy is tested on pre-existing tumors.

Since telomerase and Wnt pathway activation are frequently associated with HCC, different approaches including antisense molecules and siRNA have been used to inhibit them^[30-32]. Antisense technology was also used against FGF-2^[33], VEGF^[34] and COX-2 genes^[35]. The triplex helix approach showed similar results as antisense technology for the inhibition of IGF-I and induction of apoptosis in HCC cells^[27]. When the cells were injected into mice, an immune-mediated antitumor protection was observed. The inhibition of PTTG1 and urokinase-type plasminogen activator (u-PA) has been accomplished using siRNA on HCC cells^[20,36]. The p28-GANK oncoprotein, which induces hyperphosphorylation and increases degradation of pRB was found to be overexpressed in the majority of HCCs^[37]. The repeated administration of an adenoviral vector that induces the production of siRNA against p28-GANK caused a dramatic decrease in the growth of human HCC xenografts in nude mice^[38]. This shows that the continuous inhibition of an oncogene may have a strong impact on the progression of tumors. The clinical application of this approach is challenging, because highly efficient long-term expression vectors will be needed instead of first generation adenoviruses.

GENE-DIRECTED ENZYME/PRO-DRUG THERAPY (GDEPT)

This approach is based on the transfer of exogenous genes that convert a non-toxic pro-drug into a cytotoxic metabolite in cancer cells^[39]. Once the pro-drug is administered systemically, transduced cells expressing the converting enzyme die and, in some cases, provoke the destruction of surrounding cells (bystander effect). Unlike other gene therapy strategies, GDEPT lacks intrinsic tumor specificity, and relies on tumor targeting at the levels of cell transfer (depending on the vectors and the route of administration) and gene expression (depending on tumor-specific promoters)^[40]. The efficacy of a GDEPT system is highly influenced by the extent of the bystander effect, because the fraction of transduced cells in a tumor is generally low with current gene therapy vectors^[41].

The thymidine kinase gene from HSV-1 (HSV-TK) used in conjunction with the pro-drug ganciclovir (GCV) was the earliest and most used GDEPT system applied to HCC and other cancers^[42]. It has shown significant antitumor effect in relevant animal models of HCC, such as carcinogen-induced HCC in rats^[43]. HSV-TK converts ganciclovir into the monophosphate intermediate that is subsequently transformed into the triphosphate form by cellular enzymes. This is a highly polar molecule that cannot diffuse outside the cell. The bystander effect of this system has been explained by gap junction transfer of the toxic metabolite and phagocytosis of neighbouring cells^[44], but this local effect is weak compared to other

GDEPT modalities. The fusion of TK with the VP22 protein can amplify the effect by transferring the enzyme to surrounding cells^[45]. Ganciclovir-triphosphate is incorporated into the DNA and causes apoptosis in a cell cycle-dependent manner, but it can cause mitochondrial toxicity in normal hepatocytes if the expression of HSV-TK is not restricted to HCC cells^[46,47]. Apart from the therapeutic purpose, HSV-TK can be considered a reporter gene for PET analysis. It has been successfully used to visualize transduction of HCC with adenoviral vectors in humans^[48]. So far, the good antitumor efficacy of the HSV-TK system observed in different animal models of HCC has not been demonstrated in the clinical setting^[42]. Clinical and pre-clinical studies performed on other cancers suggest that HSV-TK can act as an immunogen that cooperates in the establishment of a systemic or at least local response against the tumors^[49,50]. Nevertheless, combination with other therapies will be needed. In pre-clinical studies the radiation-inducible Egr-1 promoter was used to control the expression of HSV-TK in combination with radioisotopes (I^{131} lipiodol)^[51]. Thus, the expression of HSV-TK was stimulated by the internal radiation, and the antitumor effect of both treatments was synergistic.

The yeast Cytosine Deaminase converts the antifungal drug 5-fluorocytosine (5-FC) into the cytotoxic thymidylate synthetase inhibitor 5-fluorouracyl (5-FU)^[52]. This metabolite can diffuse locally and cause a wider bystander effect than phosphorylated ganciclovir, but the cytotoxicity is also cell cycle-dependent. The system has been used in animal models of primary and metastatic liver cancer with good results^[53,54]. The efficacy of 5-FU on HCC patients is very low, but this strategy could achieve high local concentrations of the drug. In this context, toxicity in normal liver should be carefully evaluated. In addition, the conversion of 5-FC to 5-FU by the cytosine deaminase present in habitual enterobacteria can contribute to toxicity^[55].

Other GDEPT approaches generate very potent DNA cross-linking agents whose effects are largely cell cycle-independent. These include the cytochrome P450/cyclophosphamide^[56] and the Nitroreductase/dinitrobenzamide CB systems. Palmer *et al*^[57] reported that the intratumor administration of a first generation adenoviral vector expressing Nitroreductase in HCC patients is safe and feasible. Transgene expression was dose-dependent and is supposed to be clinically relevant, although no pro-drug was administered to patients in this study. Strong immune responses against the vector and the therapeutic gene were observed, indicating that re-administration of the treatment may not be beneficial. Assessment of the antitumor effect and toxicity of this approach in patients receiving the pro-drug requires new clinical trials.

An approach closely related to GDEPT consists on the delivery of the sodium iodide symporter (NIS) gene to cancer cells^[58]. Since NIS is necessary for the internalization of I^{131} in the cell, a higher dose is accumulated in cells expressing NIS, as happens in thyrocytes, resulting in cell cycle blockade and death. Using this method, the extent and location of gene transfer can be detected by tomography. An adenovirus vector

expressing NIS under the control of the CMV promoter has been used for the treatment of HCC in a model of chemically induced tumors in rats^[59]. After injection of the vector in pre-existing nodules, specific accumulation of I^{131} and significant reduction in tumor volume was observed.

TARGETED EXPRESSION OF CYTOTOXIC/PRO-APOPTOTIC GENES

This strategy is based on the selective transfer of genes that will cause the destruction of the cancer cells by different mechanisms. The concept is similar to GDEPT, but in this case the effect does not depend on any exogenous drugs. This can be an advantage in some circumstances, but on the other hand it lacks the possibility of pharmacologically modulating the cytotoxicity. This means that the system relies mostly on the targeting of gene transfer and expression into cancer cells, using specific surface ligands or promoters. The promoters for α -fetoprotein (AFP) and TERT have been used to control the expression or the diphtheria toxin fragment A and other cytotoxic genes in HCC cells^[60,61], but the toxicity of these treatments in relevant animal models is unclear.

Alternatively, the mechanism of action of the lethal gene can provide some tumor specificity. This is the case for TNF-related apoptosis inducing ligand (TRAIL). Unlike other members of the TNF ligand family, such as FASL and TNF- α , TRAIL induces apoptosis preferentially on cancer cells and may have reduced hepatotoxicity^[62]. The extracellular domain of TRAIL works as a soluble cytokine (sTRAIL) and induces apoptosis of cancer cells at distant locations from the producing cell. In fact, an AAV vector expressing sTRAIL fused with a human insulin signal peptide has shown potent antitumor effect on subcutaneous liver cancer xenografts after oral or intraperitoneal administration of the vector^[63]. This systemic effect was achieved without significant liver toxicity. Other vectors developed for the expression of TRAIL include first generation and oncolytic adenoviruses with enhanced infectivity in cancer cells^[64,65]. Interestingly, the adenoviral E1A protein sensitizes cells to TRAIL-induced apoptosis^[66].

IMMUNOGENE THERAPY

The transfer of genes with the aim to elicit an immune response against tumors is one of the most extensively used strategies in the field of cancer gene therapy. It is based on the observation that cancer cells modify their characteristics and their environment in order to avoid being detected and rejected. If this can be reversed, the specificity and systemic nature of the immune system offers the possibility of controlling the primary tumor and block its dissemination, which is the ultimate goal of all oncologic treatments. The wide repertoire of immunogene therapy approaches can be grouped as follows.

Expression of immunomodulatory cytokines

Cytokines are key mediators in the function of the immune system. They have been extensively used to

stimulate the immune response against tumors, including interleukin 2^[67], 7^[68], 12^[69], 15^[70], 18^[71], 21^[72], 23^[73] and 24^[74]; interferon α ^[75], β ^[76], and γ ^[77]; tumor necrosis factor α ^[78]; granulocyte-macrophage colony stimulating factor (GM-CSF)^[79], and others. Their effects on different cell components of the immune system and their influence on the expression of endogenous factors are extremely complex. Most of these cytokines do not have an intrinsic tumor-specific effect, but they may enhance the precarious immune response against tumors if the dose, location and timing are carefully controlled. For example, interleukin-12 (IL12) promotes a T-helper cell type 1 (Th1) response with activation of cytotoxic T lymphocytes and natural killer cells (NK)^[80], together with an antiangiogenic effect^[81,82]. These effects are largely dependent on the induction of IFN- γ . The systemic administration of recombinant IL12 showed potential antitumor effects in humans^[83], but severe toxicity was observed^[84] and this modality of treatment was discarded. The use of gene therapy vectors enables the localization of IL12 expression to the tumor, especially if vectors with liver tropism such as those derived from adenovirus are used^[85]. The antitumor effect of this strategy on different animal models of HCC has been demonstrated by several groups^[86,87]. Tumor eradication and immunologic protection against relapse is achieved in a significant proportion of cases, including implanted tumors in syngenic animals and chemically-induced HCC in rats. These results led to a phase I clinical trial that demonstrated the safety and feasibility of intratumor injection of a first generation adenoviral vector expressing IL12 in primary and metastatic liver cancer patients^[88]. Using these vectors, the expression of IL12 was very low and transient. No complete responses were observed, but patients with HCC had a better outcome than other histological groups in this trial. Based on these results, improvements in the vectors are being investigated. The use of high-capacity adenoviral vectors carrying a liver-specific inducible system for the expression of IL12 allows the long-term expression of the cytokine in response to the inducer mifepristone. Using this vector, the levels and duration of cytokine expression can be modulated to achieve antitumor effect and avoid toxicity^[89]. Further improvement can be achieved by using a version of IL12 in which the p35 and p40 subunits are fused in a single protein using a short linker peptide^[90]. Experiments performed in rats bearing HCC indicate that the single chain IL12 is about 1000 times more potent than the native protein when an equivalent adenoviral vector is used to deliver the gene intratumorally^[87].

Other cytokines that deserve special attention are TNF- α and IL24 (also know as mda-7). These molecules have shown antitumor effect on animal models of HCC^[78,91], and ongoing clinical trials suggest the potential therapeutic effects on other malignancies in humans^[92,93]. IL24 is especially promising, because apart from its immune-regulatory activities it induces apoptosis preferentially in cancer cells^[94].

Taking into account the natural mechanism of immune response activation, pro-inflammatory cytokines and co-stimulatory signals should be combined to achieve an effective response and avoid anergy. It is possible that

the accessory signals are already present in the tumor, but there is evidence of enhanced antitumor effect when IL12 is transferred together with 41BB agonists^[95] or B7.1^[96] in animal models of HCC. The intratumoral injection of an adenoviral vector expressing CD40L achieved tumor eradication on a significant proportion of pre-existing HCC in a rat model^[97]. This molecule is normally expressed on activated T cells and interacts with CD40 on the surface of antigen-presenting cells.

A combination of different cytokines may be more effective and less toxic than the expression of a single cytokine at high levels. The injection of adenoviral vectors expressing IL12 and IP-10 (interferon- γ inducible protein-1) exerted a synergistic antitumor effect in a murine model of colon cancer when both molecules were expressed locally^[98]. This is in agreement with the "attraction and activation hypothesis", in which colocalization of immunostimulatory (IL12) and chemoattractant factors (IP10) is needed. Some pre-clinical data indicate that IL15 can increase the antitumor effect IL12 on HCC models^[99]. Interestingly, this could happen in the absence of IFN- γ function. Other combinations proposed for the treatment of HCC include IL12+GM-CSF^[100], IL12+MIP3 α ^[101], and IL21+IL15^[72]. An alternative to co-expression of individual cytokines is the construction of fusion proteins. You *et al.* used a retroviral vector to deliver an IL2/IL12 fusion gene and demonstrated enhanced survival of tumor-bearing rats compared with rats treated with the individual cytokines^[102]. The antitumor effect of cytokines can be enhanced by other gene therapy approaches like GDEPT using HSV-TK, as demonstrated by several groups that employed adenoviral or retroviral vectors for gene delivery in HCC models^[103,104].

Vaccination with tumor antigens and genetically modified cells

The transfer of genes encoding tumor-specific antigens such as AFP has been used with the aim to break the immune tolerance against HCC^[105]. The pre-clinical efficacy of this approach depends on the particular animal model employed^[106], suggesting that high variability could be expected in patients. A different approach consists on the administration of activated effector or antigen-loaded presenting cells to fight cancer. The efficacy of these cells can be increased if they are manipulated genetically to express antigens, cytokines or co-stimulatory molecules (*ex vivo* gene therapy). Syngenic fibroblasts or cancer cells expressing IL12^[107] or IL2 plus B7^[108] can trigger an immune response against HCC in murine models. However, the use of cancer cells as a source of antigens and cytokines poses obvious technical difficulties in the clinical setting. An attractive alternative is the use of autologous dendritic cells (DC), professional antigen presenting cells that express the co-stimulatory molecules (CD80, MHC class I and II, *etc.*) necessary for efficient activation of effector cells. DCs expressing AFP^[109], cytokines^[110] or co-stimulatory molecules^[111] have been successfully used in animal models of HCC and gastrointestinal cancer^[112]. These results encouraged the initiation of a phase I clinical trial in which DCs expressing IL12 after *ex-vivo* infection with an adenoviral

vector were injected into the tumor mass^[113]. However, it was demonstrated that the cells were unable to migrate to lymph nodes because they were sequestered into the tumor by local factors^[114], preventing an efficient activation of effector cells and the establishment of relevant antitumor immune responses.

Adoptive cell therapy consists on the infusion of autologous T cells or killer cells that have been expanded and activated *in vitro*. In animal models, it has been demonstrated that T cell expansion occurs *in vivo* in tumor-bearing mice that were treated with IL12^[115]. The infusion of these cells has antitumor effect on recipient mice, in synergy with *in vivo* gene therapy by an adenoviral vector expressing IL12. This suggests that immunogene therapy can be used in combination with adoptive T-cell therapy in order to increase the efficacy observed in clinical trials that used either strategy alone.

An important aspect that is becoming more relevant in recent years is the inhibition of regulatory signals that control the duration and intensity of the immune response, because this could enhance the efficacy of anticancer immunotherapy. For instance, the blockade of the B7-H1/PD-1 pathway by soluble PD-1 expression improved the immune response against an implanted HCC in mice^[116].

ANTI-ANGIOGENIC GENE THERAPY

The realization that tumor growth requires intense neo-vascularization is the basis for a series of approaches aimed to specifically block the cancer-induced formation of new vessels^[117]. Anti-angiogenic factors such as endostatin have been identified and have demonstrated the ability to inhibit tumor growth *in vivo*^[118,119]. This strategy is supposed to be safe because it does not affect the mature vessels of normal tissues. Since HCC is known to be much vascularized, antiangiogenic therapies may have a strong therapeutic benefit, probably in combination with other standard or experimental treatments. Gene therapy may play an important role in this field, because anti-angiogenic factors need to be delivered for long period of times to control the progression of tumors. In fact, an adenoviral vector carrying the endostatin cDNA was more effective than the direct injection of the protein^[120]. The combination of endostatin delivered by an AAV vector and chemotherapy (etoposide) achieved antitumor effect on metastatic liver cancer in mice^[121]. Of note, several strains of bacteria have been engineered as vectors to deliver endostatin into liver tumors. *Bifidobacterium longum* administered orally increased the survival of tumor-bearing mice^[122], whereas attenuated *Salmonella choleraesuis* accumulates in hypoxic tissues and has shown antitumor effect after intraperitoneal administration^[123].

Other anti-angiogenic approaches are focused on blocking the VEGF receptor, which is an important mediator of angiogenesis. This can be achieved by expressing the soluble form of VEGF receptor (KDR/Flk-1), which sequesters VEGF^[124]. The same approach has been used to block the endothelium-specific receptor Tie2, which affects direct tumor growth and neovascularization^[125]. The Pigment Epithelium Derived Factor (PEDF) has been recently discovered as an anti-

angiogenic protein expressed in normal liver^[126] that is downregulated in HCC patients, suggesting a possible role in tumor progression. The transfer of PEDF has antitumor effects in a murine model of HCC^[127]. NK4 is a fragment of the Hepatocyte Growth Factor (HGF) that acts as a HGF antagonist and blocks angiogenesis. The intrasplenic administration of an adenoviral vector expressing a secreted form of NK4 caused reduction in the vascularization and growth of pancreatic metastasis in the liver of mice^[128]. Finally, it should be mentioned that the inhibition of angiogenesis may be one of the most important mechanisms by which IL12 exerts its antitumor effect^[129].

ONCOLYTIC VIRUSES

Using the cytopathic effect of certain viruses to destroy cancer cells is an old idea, but the advances in viral vector design and production have renewed interest in the field of virotherapy. The objective is to obtain a virus that replicates and preferentially kills cancer cells, leaving the surrounding normal tissues relatively intact^[130]. This property is intrinsic to some viruses. For instance, Vesicular Stomatitis Virus (VSV), Measles Virus (MV) and Newcastle Disease Virus (NDV) are very sensitive to the inhibitory effects of IFN and replicate only in cancer cells that have developed mechanisms to counteract IFN pathways. Other viruses like reovirus replicate better in cells that present activation of the Ras oncogene^[131].

On the other hand, other viruses such as Adenovirus or HSV can be genetically modified to make their replication cancer-specific. One of the methods to achieve cancer specificity is the deletion of viral functions necessary for replication in normal cells, but not in cancer cells. For instance, the adenoviral protein E1A blocks pRB in the cell to force activation of the cell cycle, whereas E1B 55K blocks p53 to inhibit apoptosis at early times. Since both p53 and pRB pathways are commonly altered in cancer cells, adenoviruses lacking these functions will replicate preferentially in tumors^[132,133]. Another method to restrict the replication of viruses is to use tumor-specific promoters to control the transcription of viral genes important for replication, such as E1A and E4 for adenovirus^[134]. Parallel strategies have been used to achieve oncolytic herpes viruses^[135,136]. The control of the γ 134.5 gene expression determines the efficacy of HSV-1 replication in different cells, and the deletion of the ribonucleotide reductase function attenuates the virus in normal cells^[137].

An important property of oncolytic adenoviruses is the possibility of accommodating therapeutic genes and the ability to act as gene therapy vectors with the advantage of tumor-specific amplification of gene expression^[138]. These genes code for pro-drug converting enzymes, immunostimulatory cytokines or pro-apoptotic proteins that enhance the oncolysis and/or achieve a systemic effect.

The mutant dl1520 adenovirus (also called ONYX-015 or CI-1042 later on) was described in 1996 as the first oncolytic adenovirus^[139]. It contains a deletion in the E1B 55K gene that achieves preferential replication in

cancer cells by different mechanisms^[140]. Although recent advances have yielded viruses with improved potency and specificity, the experience accumulated with ONYX-015 in the laboratory and in the clinic has been extremely useful for the advance of the field. The virus has shown partial antitumor effect on murine models of HCC^[141], and clinical trials for other cancers indicate a potential benefit when used in combination with chemotherapy^[142]. In the case of liver cancer, a clinical trial on HCC patients showed no evident antitumor effect. The first dose of ONYX-015 was administered intravenously and then by direct ultrasound-guided intratumoral injection on d 2, 15, 16, 29 and 30^[143]. The rationale of this regime was to elicit an immune response against the virus that causes a local reaction in the tumoral site. In a separate phase II trial in patients with metastatic colorectal cancer the virus was administered intravenously, and only transient stabilization of the disease could be observed in some cases^[144]. When the virus was administered intratumorally in a different clinical trial for hepatobiliary tumors, transient reduction of tumor markers in serum (CEA, AC19-9 or AFP) was observed in 50% patients, although radiological responses were less than 10%^[145]. These results support the notion that ONYX-015 has limited therapeutic effect as monotherapy on HCC patients, especially if systemic routes are used. When the virus was administered intravenously in combination with 5-Fluorouracil and leucovorin in patients with liver metastases of gastrointestinal cancers, 25% of cases presented partial or minor (< 50%) radiological responses, with good tolerance and evidence of adenovirus replication in tumors^[146]. An independent trial in patients who had failed previous treatment with 5-FU suggested increased survival when the virus was injected in the hepatic artery in combination with 5-FU^[147]. Interestingly, an early radiological increase in tumor volume was attributed to virus-induced necrosis rather than tumor progression in several patients. This should be taken into account in order to evaluate efficacy and avoid removal of responding patients in clinical trials. To this end, PET can be a more reliable technique. Now clinical trials with a virus similar to ONYX-015 (H101) are being conducted in China. A phase III trial in squamous cell cancer patients showed increased response rate in combination with chemotherapy, and the virus has recently obtained approval in that country^[148].

Other oncolytic adenoviruses have been developed, and show promising results (usually better than ONYX-015) in animal models of HCC. However, their performance in clinical trials has not been tested so far. The AFP promoter was used to control the expression of the E1A viral gene, with or without E1B 55K deletion, and this achieved preferential replication in AFP-producing HCC cells^[149,150]. The same effect is observed in metastatic gastrointestinal cancer using a virus controlled by the CEA promoter^[151]. A broader cancer spectrum is achieved when other tumor-specific promoters such as human TERT^[152,153] and E2F-1^[154] are used. The efficacy of these agents can be increased if they are adapted as gene therapy vectors for therapeutic genes ("armed" viruses), because viral oncolysis usually cooperates with the effect of the gene. Oncolytic adenoviruses expressing GM-

CSF^[155], TRAIL^[65,156], Smac^[157], Cytosine Deaminase^[158] and endostatin^[159] have demonstrated better performance than the previous versions.

The field of virotherapy has been enriched by the incorporation of oncolytic agents derived from different viruses, which may solve some of the limitations observed with adenovirus. For instance, HSV-1 exerts a potent oncolytic effect and its large genome can accommodate different exogenous genes, apart from the endogenous TK^[160]. The complex genome of HSV-1 allows multiple modifications that can be exploited to achieve tumor specificity. The G207 mutant contains a disruption in the UL39 gene that eliminates the ribonucleotide reductase function and determines preferential replication in cancer cells^[161]. It is attenuated by deletion of a single copy of the ICP6 gene and both copies of the γ 134.5 neurovirulence gene, but efficient elimination of HCC cells has been reported^[162]. The NV1020 virus harbours a deletion over the joint region of the genome, but retains the ICP6 gene and one copy of γ 134.5^[163]. A clinical trial using this virus is ongoing for patients with gastrointestinal cancer metastatic to the liver. The rRp450 HSV-1 variant carries the cytochrome p450 gene as a pro-drug converting enzyme^[164]. This virus has shown promising antitumor effect on HCC models, although complete eradication of metastatic liver cancer was not observed after single or multiple intraportal administrations. In addition, significant antitumor effect has been obtained in liver cancer models using herpes virus expressing Cytosine deaminase^[165] or IL12^[166].

VSV-derived viruses are emerging as a new class of oncolytic agents. A single injection of a recombinant VSV virus into the hepatic artery increased the survival of rats bearing multifocal HCC, and multiple doses achieved long term survival and tumor eradication in nearly 20% of the animals^[167]. This strategy is being investigated in human patients. Interestingly, experiments performed in rats indicate that a prophylactic treatment with IFN- α reduces the toxicity of the virus on normal tissues and elevates its therapeutic index^[168].

CONCLUSION

The treatment of hepatic malignancies (both primary tumors and metastatic cancer of the liver) remains a challenge that needs new approaches. Gene therapy is an experimental discipline in continuous evolution that offers interesting opportunities for the treatment of liver cancer. Following early excitement about gene therapy possibilities, the field soon realized its limitations and is now systematically addressing fundamental issues to solve them. The transfer of genes to the majority of cancer cells is still unrealistic for solid tumors, even with the best vectors available to date. Immunogene therapy approaches try to circumvent this limitation and extend the antitumor effect to distant metastases. Pre-clinical studies have validated the concept, but at the same time the results in animal models reveal that the efficacy of immunotherapy is very limited in advanced liver cancer. Hence, it is not surprising that the results of early phase clinical trials are apparently deceiving. Oncolytic adenoviruses were envisioned as autonomous

therapeutic agents that would seek and destroy cancer cells, amplifying the initial load until the tumor is eradicated. Now we know that they find important physical barriers that limit their distribution inside the tumor. Moreover, the immune system will control the spread of the viruses in a few days and neutralize further administrations, leaving a narrow time frame for them to display their oncolytic activity. An additional obstacle for the clinical application of most gene therapy approaches is the cost and technical difficulties of large scale production of the vectors.

Despite all these difficulties, gene therapy may play an important role as an adjuvant to other standard or experimental treatments against liver cancer in the near future. There is evidence that different gene therapy approaches like GDEPT or oncolytic viruses have synergistic effects when combined with chemotherapy or radiotherapy. The different mechanisms of action favour these combinations and may prevent the development of resistance to the treatment. As the knowledge of tumor immunology advances, more rational immunogene therapy approaches are designed. In addition, the improvement of invasive techniques for locoregional treatment of HCC can be used to deliver gene therapy vectors inside the tumor, increasing their safety and efficacy.

In summary, gene therapy will improve the management of liver cancer patients in the future, probably as part of an individualized multimodal therapy. This will require close collaboration and a continuous flow of information between basic, applied researchers and health care professionals.

Abstract

Smoking causes a variety of adverse effects on organs that have no direct contact with the smoke itself such as the liver. It induces three major adverse effects on the liver: direct or indirect toxic effects, immunological effects and oncogenic effects. Smoking yields chemical substances with cytotoxic potential which increase necroinflammation and fibrosis. In addition, smoking increases the production of pro-inflammatory cytokines (IL-1, IL-6 and TNF- α) that would be involved in liver cell injury. It contributes to the development of secondary polycythemia and in turn to increased red cell mass and turnover which might be a contributing factor to secondary iron overload disease promoting oxidative stress of hepatocytes. Increased red cell mass and turnover are associated with increased purine catabolism which promotes excessive production of uric acid. Smoking affects both cell-mediated and humoral immune responses by blocking lymphocyte proliferation and inducing apoptosis of lymphocytes. Smoking also increases serum and hepatic iron which induce oxidative stress and lipid peroxidation that lead to activation of stellate cells and development of fibrosis. Smoking yields chemicals with oncogenic potential that increase the risk of hepatocellular carcinoma (HCC) in patients with viral hepatitis and are independent of viral infection as well. Tobacco smoking has been associated with suppression of p53 (tumour suppressor gene). In addition, smoking causes suppression of T-cell responses and is associated with decreased surveillance for tumour cells. Moreover, it has been reported that heavy smoking affects the sustained virological response to interferon (IFN) therapy in hepatitis C patients which can be improved by repeated phlebotomy. Smoker's syndrome is a clinico-pathological condition where patients complain of episodes of facial flushing, warmth of the palms and soles of feet, throbbing headache, fullness in the head, dizziness, lethargy, prickling sensation, pruritus and arthralgia.

INTRODUCTION

Lighting a cigarette creates over 4000 harmful chemicals with hazardous adverse effects on almost every organ in the body. The impact of heavy smoking on the pathogenesis of liver disease and response to interferon therapy among chronic hepatitis patients has been overlooked. Before we begin this article; it is necessary to define who is a heavy smoker and to shed light on the common toxic constituents of cigarette smoking.

WHO IS A HEAVY SMOKER?

Heavy smokers are variably defined, some studies suggest exposure to two or more packets (≥ 40 cigarettes) a day for 10 years or more^[1]. On the other hand, Marrero *et al*^[2] have defined heavy smokers as those exposed to greater than 20 pack-years.

COMMON CONSTITUENTS OF CIGARETTE SMOKE

The constituents of smoke are contained in either the particulate phase or gas phase.

Particulate phase

Particulate phase components include tar, polynuclear hydrocarbons, phynol, cresol, catechol and trace elements (carcinogens), nicotine (ganglion stimulator and depressor), indole, carbazole (tumor accelerators)^[3], and 4-aminobiphenyl^[4].

Gas phase

Gas phase contains carbon monoxide (impairs oxygen transport and utilization), hydrocyanic acid, acetaldehyde, acrolein, ammonia, formaldehyde and oxides of nitrogen

(cilitoxin and irritant) nitrosamines, hydrazine and vinyl chloride (carcinogens)^[3].

ADVERSE EFFECTS OF SMOKING ON THE BODY

Smokers are at greater risk for cardiovascular diseases (ischaemic heart disease, hypertension), respiratory disorders (bronchitis, emphysema, chronic obstructive lung disease, asthma), cancer (lung, pancreas, breast, liver, bladder, oral, larynx, oesophagus, stomach and kidney), peptic ulcers and gastroesophageal reflux disease (GERD), male impotence and infertility, blindness, hearing loss, bone matrix loss, and hepatotoxicity^[5,6].

ADVERSE EFFECTS OF SMOKING ON THE LIVER

Beside the hazardous effects mentioned before; smoking causes a variety of adverse effects on organs that have no direct contact with the smoke itself such as liver. The liver is an important organ that has many tasks. Among other things, the liver is responsible for processing drugs, alcohol and other toxins to remove them from the body. Heavy smoking yields toxins which induce necroinflammation and increase the severity of hepatic lesions (fibrosis and activity scores) when associated with hepatitis C virus (HCV)^[7] or hepatitis B virus (HBV) infection^[8]. Cigarette smoking increases the risk of developing HCC among chronic liver disease (CLD) patients^[9] independently of liver status. Association of smoking with hepatocellular carcinoma (HCC) irrespective of HBV status has been reported^[10,11].

How does smoking affect the liver?

Smoking induces three major adverse effects on the liver: toxic effects either direct or indirect, immunological effects and oncogenic effects.

Toxic effects of smoking on the liver

Direct toxic effect: Smoking yields chemical substances with cytotoxic potentials^[12]. These chemicals created by smoking induce oxidative stress associated with lipid peroxidation^[13,14] which leads to activation of stellate cells and development of fibrosis. In addition, smoking increases the production of pro-inflammatory cytokines (IL-1, IL-6 and TNF- α) involved in liver cell injury^[15]. It has been reported that smoking increases fibrosis score and histological activity index in chronic hepatitis C (CHC) patients^[7] and contributes to progression of HBV-related cirrhosis^[8].

Indirect toxic effects (concomitant polycythemia)

Heavy smoking is associated with increased carboxyhaemoglobin and decreased oxygen carrying capacity of red blood cells (RBCs) leading to tissue hypoxia. Hypoxia stimulates erythropoietin production which induces hyperplasia of the bone marrow. The latter contributes to the development of secondary polycythemia

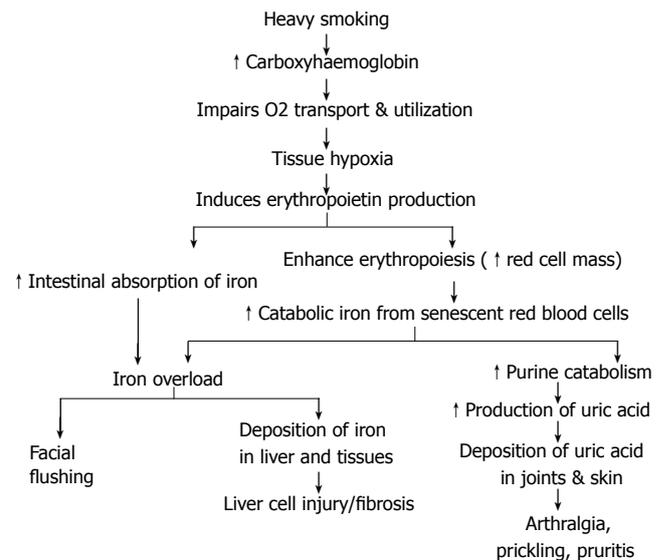

Figure 1 Development of smoker's polythycemia and its adverse effects.

and in turn to increased red cell mass and turnover. This increases catabolic iron derived from both senescent red blood cells and iron derived from increased destruction of red cells associated with polycythemia^[16,17]. Furthermore, erythropoietin stimulates absorption of iron from the intestine. Both excess catabolic iron and increased iron absorption ultimately lead to its accumulation in macrophages and subsequently in hepatocytes over time, promoting oxidative stress of hepatocytes^[18]. Accordingly, smoking might be a contributing factor to secondary iron overload disease in addition to other factors such as transfusional haemosidrosis, alcoholic cirrhosis, thalassemia, sideroplastic anemia and porphyria cutanea tarda.

In the meantime, increased red cell mass and turnover are associated with increased purine catabolism which promotes excessive production of uric acid. Eventually uric acid is deposited in tissues and joints as manifested clinically by prickling sensation, pruritus and arthralgia^[19] (Figure 1).

Smoker's syndrome: Smoker's syndrome is a clinicopathological condition reported in patients smoking \geq 40 cigarettes or 10 stones of popular shisha (water-pipe) in Egypt per day, over a long time. These patients suffer from episodes of facial flushing, warmth of the palms and soles, throbbing headache, fullness in the head, dizziness, lethargy, prickling sensation, pruritus and arthralgia^[20]. However, the majority of patients who smoke less than the described level are subject to biochemical changes rather than clinical manifestations.

Facial flushing, the most prominent symptom, is explained by capillary vasodilatation associated with increased blood flow through the skin. The vasodilatation may be attributed to the direct action of vasodilator constituents of the smoke as well as to excess haemoglobin saturation^[21] reported among heavy smokers^[20].

On examination of these smokers, the face appears dusky-red and/or pigmented, the pulse is full. The smokers suffer from hypertension, joint stiffness and swelling.

Some of them have experienced cerebrovascular and cardiovascular strokes. Laboratory studies have revealed an increased Hb level (> 160 g/L) and haematocrit (> 55 mL/100 mL) in almost all the patients and raised ALT (> 2 fold), uric acid (> 6 mg/dL), serum iron (> 165 μ g/dL) and ferritin in most of the patients. Histopathological examination reveals hepatic necro-inflammation, apoptotic necrosis, fibrosis, and deposition of iron in hepatocytes as demonstrated by Perl's stain.

IMMUNOLOGICAL EFFECTS OF SMOKING

Smoking affects both cell-mediated and humoral immune responses^[22]. Nicotine blocks lymphocyte proliferation and differentiation including suppression of antibody-forming cells^[15,23] by inhibiting antigen-mediated signaling in T-cells^[15,23,24] and ribonucleotide reductase^[25]. Furthermore, smoking induces apoptosis of lymphocytes^[26] by enhancing expression of Fas (CD95) death receptor which allows them to be killed by other cells expressing a surface protein called Fas ligand (FasL). Smoking induces elevation of CD8+ T-cytotoxic lymphocytes^[14], decreased CD4+ cells, impaired NK cell activity^[27] and increases the production of pro-inflammatory cytokines (IL-1, IL-6, TNF- α)^[15].

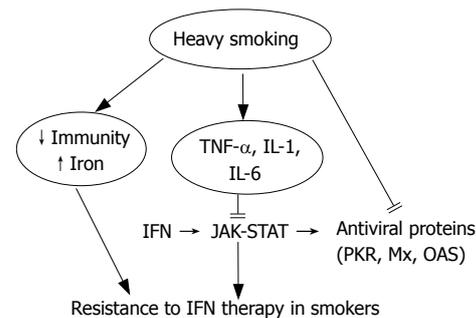

Although smoking has long-term adverse effects; cessation of smoking reversed these effects, such as elevation of NK activity which is detectable within one month of smoking cessation^[28], elevation of both antibody- and cell-mediated immune responses as well as decreased proinflammatory cytokines and increased antioxidant activity.

ONCOGENIC EFFECTS OF SMOKING

Smoking yields chemicals with oncogenic potentials such as hydrocarbons, nitrosamine, tar and vinyl chloride^[29]. Cigarette smoking is a major source of 4-aminobiphenyl, a hepatic carcinogen which has been implicated as a causal risk factor for HCC^[4]. Smoking increases the risk of HCC in patients with viral hepatitis^[9,30,31]. Furthermore, recent data from China and Taiwan have shown an association of smoking with liver cancer independent of HBV status^[10,11]. Tobacco smoking is associated with reduction of p53, a tumour suppressor gene^[32,33] which is considered "the genome guardian". Suppression of T-cell responses by nicotine and tar is associated with decreased surveillance for tumour cells^[25]. El-Zayadi *et al*^[20] reported that heavy smokers accumulate excess iron in hepatocytes which induces fibrosis and favours development of HCC. Smoking is considered a co-factor with HBV and HCV for hepatocarcinogenesis^[31]. In addition, suppressed mood, a common feature among heavy smokers, increases the risk for development of cancer^[25].

SMOKING AND LIVER CELL INJURY AMONG CHRONIC HEPATITIS C PATIENTS

El-Zayadi *et al*^[20] have reported an association between heavy smoking and liver cell injury in the form of necroinflammation, apoptosis and excess iron deposition

El-Zayadi A, 2005

Figure 2 Possible mechanisms of resistance to IFN- α therapy for viral hepatitis among heavy smokers.

in the liver. These effects are attributed to iron overload with consequent iron deposition in hepatocytes^[20,34]. Excess hepatic iron induces oxidative stress and lipid peroxidation^[13,14]. However, iron overload will not correct itself and the only exit of iron from the body is by bleeding or frequent chelation^[35]. Therapeutic phlebotomy allows excess iron to be removed from the body and chelation of labile iron from the liver.

SMOKING AND THE RESPONSE TO IFN THERAPY AMONG CHRONIC HEPATITIS C PATIENTS

El-Zayadi *et al*^[36] reported that smokers suffering from chronic hepatitis C tend to have a lower response rate to IFN therapy. Therapeutic phlebotomy among chronic hepatitis C patients improves the response rate to IFN therapy^[37,38]. Furthermore, the authors recommended that chronic hepatitis C patients should be advised to avert smoking before embarking on IFN therapy^[36].

Several mechanisms have been implemented in resistance to IFN therapy in heavy smokers which are summarized in Figure 2. First, heavy smoking causes immunosuppression^[22] such as reduction in CD4+ cells, impaired NK cytotoxic activity^[27] and recognition of virus-infected cells, and induces apoptosis of lymphocytes^[26]. Second, heavy smoking increases hepatic iron overload which is involved in resistance to IFN^[20]. Third, smoking induces pro-inflammatory cytokines (IL-1, IL-6, TNF- α)^[15] that mediate necroinflammation and steatosis. Fourth, smoking directly modifies IFN- α -activated cell signaling and action^[39].

The present article sends a message indicating that smoking is an underestimated risk factor for liver disease. In this respect, further well-designed studies are needed to clarify this issue.

Abstract

Inflammatory bowel disease (IBD) is traditionally considered to be common in the Western world, and its incidence has sharply increased since the early 1950s. In contrast, until the last decade, low prevalence and incidence rates have been reported from other parts of the world including Eastern Europe, South America, Asia and the Pacific region. Recent trends indicate a change in the epidemiology of IBD with previously low incidence areas now reporting a progressive rise in the incidence, while in West European and North American countries the figures have stabilized or slightly increased, with decreasing incidence rates for ulcerative colitis. Some of these changes may represent differences in diagnostic practices and increasing awareness of the disease. The quality of studies is also variable. Additional epidemiologic studies are needed to better define the burden of illness, explore the mechanism of association with environmental factors, and identify new risk factors.

INTRODUCTION

The pathogenesis of ulcerative colitis (UC) and Crohn's disease (CD) is only partly understood. Inflammatory bowel disease (IBD) is a multifactorial disease with probable genetic heterogeneity. In addition, several environmental risk factors contribute to the pathogenesis. During the past decades, the incidence pattern of both diseases has

changed dramatically, showing some common but also quite distinct characteristics of the two disorders. Differences in geographic distribution, and particularly changes in incidence over time within one area, may provide insight into possible etiological factors^[1].

Several studies have been conducted on the epidemiology of IBD^[1-3]. The geographical incidence of IBD varies considerably. The highest incidence rates are traditionally reported in Northern and Western Europe as well as North America, whereas lower rates are recorded in Africa, South America and Asia, including China^[2]. It is more common in developed, more industrialized countries, pointing at urbanization as a potential risk factor. The incidence rate of UC varies greatly between 0.5-24.5/10⁵ inhabitants, while that of Crohn's disease varies between 0.1-16/10⁵ inhabitants worldwide, with prevalence rates of IBD reaching up to 396/10⁵ inhabitants. Recent data from South Europe^[3], East Europe^[4] and Asia^[5] in the mid-1990s report a rise in incidence values in some areas already comparable to rates reported from Northern Europe or North America. The gap between areas with conventionally high and low incidence rates is diminishing. A further difference is that the previously reported predominance of UC is diminishing, as CD is becoming more prevalent^[6].

INCIDENCE IN THE WESTERN WORLD: NORTH/WEST EUROPE AND NORTH AMERICA

The first assessment of the incidence of IBD was carried out retrospectively in Rochester, Minnesota^[7]. The reported incidence of Crohn's disease was 1.9/10⁵ in 1935-1954. The incidence rates began to increase in the late 1930s in the United States and in the 1950s in North and Western Europe. From the 1960s onwards, an increasing number of studies of Crohn's disease and ulcerative colitis have been published. Most of these studies investigated the incidence retrospectively over rather short time periods and in small populations. Many of these studies were limited by incomplete case ascertainment.

The increase in the incidence of ulcerative colitis precedes the increase in the incidence of Crohn's disease by about 15-20 years. In the late 1990s, the incidence of UC leveled off to a plateau or even decreased^[6], while the incidence of CD was still increasing in most European countries. Recent data, however, suggest a further increase in the incidence of IBD, at least in some North European countries. The prevalence of Crohn's disease in North America ranges from 26.0 to 198.5 cases per 10⁵ persons.

The incidence rates range from 3.1 to 14.6 cases per 10^5 persons^[1,7]. That of UC varied between 6.0 and 14.3 from 1981 to 1994. Both ulcerative colitis and Crohn's disease appear to be more frequent in the northern parts of the US than in the south.

Similarly, previous studies in Northern and Western Europe in the 1970s and 1980s suggested that the incidence is decreasing from north to south^[8-11], but in the early nineties, the European IBD Study Group found comparable rates between Southern and Northern Europe^[3]. During the period between October 1991 and October 1993, twenty European centers in twelve countries prospectively collected all newly diagnosed IBD patients, in a population-based manner using a standard protocol for case ascertainment. The overall incidence was $10.4/10^5$ for ulcerative colitis (northern centers: $11.8/10^5$ vs southern centers: $8.7/10^5$) and $5.6/10^5$ for Crohn's disease ($7.0/10^5$ vs $3.9/10^5$). For UC, the highest incidence was found in Iceland and the lowest in southern Portugal. For CD, the highest incidence rates were observed in the southeastern Netherlands and in northwestern France. Nonetheless, the excess in northern centers was less pronounced than previously reported. Similarly, gradually increasing incidence values were reported from Italy between 1978 and 1992 (from $3.8/10^5$ to $9.6/10^5$ for UC and from $1.9/10^5$ to $3.4/10^5$ for CD) in the well-known Florence study^[8]. In addition, in recent publications, the incidence rate of UC in Central Greece has been reported to be as high as $11.2/10^5$, similar to that observed in high incidence North European centers^[9].

In addition, we have to note that continuously increasing incidence values are still reported from some high incidence areas, e.g. Denmark and Sweden. Earlier studies have reported an incidence of $4.1/10^5$ for CD and $9.2/10^5$ for UC from the 1980s^[10], while recent data in 2003-2005 indicate even higher incidence rates (CD: $8.6/10^5$, UC: $13.4/10^5$)^[11]. In Stockholm, the corresponding incidence data for CD in 1990-2001 were $4.9/10^5$ in 1985-89 and $8.3/10^5$ in 1990-2001^[12]. In contrast, data from the UK indicate a plateau with an incidence around $10.0/10^5$ - $13.9/10^5$ for UC, while it is still increasing ($3.9/10^5$ - $8.3/10^5$) in CD^[13].

A further difference is that the previously reported predominance of UC is diminishing, as CD is becoming more prevalent. Furthermore, decreasing incidence values in 1988-1999 were reported from Northern France. The incidence of CD was increased slightly from $5.2/10^5$ - $6.4/10^5$, while that of UC decreased from $4.2/10^5$ to $3.5/10^5$ ^[12].

INCIDENCE OF IBD IN OTHER PARTS OF THE WORLD: EAST EUROPE, ASIA AND SOUTH AMERICA

Until recently, only limited data was available on the epidemiology of IBD from other parts of the world. Most of these data are retrospective, hospital based surveys. One of the few exceptions is the study by Vucelic *et al*^[14] from Croatia, who conducted a prospective study on the incidence of IBD in Zagreb in 1980-1989. The study was population-based, including inpatient and outpatient data, as well as general practitioners' reports. The reported

incidence rate is $1.5/10^5$ inhabitants for UC and $0.7/10^5$ for CD. The prevalence of UC and CD was $21.4/10^5$ and $8.3/10^5$ respectively at the end of 1989.

In the last few years, a significant number of papers and reviews have been published on the epidemiology of IBD from Eastern Europe and Asia^[4,5]. However, there is still a significant lack of data from Latin America, Africa and Australia. Most of these studies have reported a change in the epidemiology of IBD. The rise in incidence began in the early 1990s, in parallel with changes in governing systems and social environment. In Eastern Europe, a population-based epidemiology survey from Hungary^[15] reported a sharp increase in incidence of UC from $1.7/10^5$ during 1977-1981 to $11.0/10^5$ during 1997-2001. In CD, a similar trend was observed (from $0.4/10^5$ to $4.7/10^5$). The ratio of UC/CD incidence rates decreased from 4.0 to 2.3 during the observed periods. The prevalence of UC and CD was $142.6/10^5$ and $52.9/10^5$ inhabitants respectively at the end of 2001. Similarly, in a prospective study Mijandrusic Sincic *et al*^[16] reported much higher rates in Croatia ($7.0/10^5$ for CD and $4.3/10^5$ for UC) in 2000-2004 compared to previous reports.

In contrast, a questionnaire-based nationwide epidemiological survey^[17] from Romania, over a period of one year between June 2002 and June 2003, still reported low incidence of both UC ($0.97/10^5$) and CD ($0.50/10^5$). Corresponding prevalence data were also very low ($2.25/10^5$ in UC and $1.51/10^5$ in CD). Similarly, low incidence was reported in a population-based prospective study from Estonia^[18]. The data were collected between 1993 and 1998 in Tartu country (151 301 inhabitants) from the internal medicine, paediatrics and surgery departments. A total of 16 UC and 13 CD patients were diagnosed, equalling an average incidence of $1.7/10^5$ for UC and $1.4/10^5$ for CD. However, the relative small area and small absolute number of patients might have biased the data.

Similar trends in UC have been observed in Asia. Although both incidence and prevalence rates of IBD are still low compared with Europe and North America, they are rapidly increasing. An emergence of UC is apparent. In contrast, the incidence of CD is still low. An analysis of UC patients from China reported a total of 10 218 cases from 1981 to 2000^[19]. Of these, 2506 were diagnosed between 1981 and 1990, and 7512 between 1991 and 2000, a three-fold increase. The most recent review^[11] of Chinese literature reveals that 143 511 cases of IBD (140 120 of UC and 3391 of CD) were described during the last 15 years, with an 8.5-fold increase during the last 5 years compared with the first 5 years. In addition, though figures are still low, Leong *et al*^[20] reported a three-fold increase in the incidence of CD in the Chinese population of Hong Kong, from $0.3/10^5$ in 1986-1989 to $1.0/10^5$ in 1999-2001. A hospital-based study came to the same conclusions. An estimated incidence of $0.28/10^5$ and a prevalence of $1.38/10^5$ were reported between 1950-2002 from 22 provinces of China^[21].

Recent reviews from Japan also report an increase in the incidence and prevalence of IBD. Hospital-based investigations reported that the incidence of UC was $1.95/10^5$, and the prevalence was $18.12/10^5$ in 1991^[21]. In a retrospective study from Seoul, South Korea, the

prevalence of UC was $7.57/10^5$, with a significant increase in incidence rates from $0.20/10^5$ in 1986-1988 to $1.23/10^5$ in 1995-1997^[21]. In Thailand, UC is still uncommon, with only 40 cases reported between 1988 and 2000^[22].

Singapore is also witnessing a higher prevalence of IBD, recently estimated at $6/10^5$ ^[23]. The current prevalence of UC is $17/10^5$, whereas that of CD is lower, at $3.6/10^5$. The impact of ethnicity in various Asian populations has also been studied in Singapore, a multiracial city-state composed of Chinese, Malay and Indian groups^[24]. The prevalence of UC in the three races has been calculated to be $6.2/10^5$ for Chinese, $4.8/10^5$ for Malay and $16/10^5$ for Indian subjects. Similar prevalence data were reported from a recent retrospective hospital-based study from Kuala Lumpur, Malaysia. The prevalence of UC was $17.9/10^5$ in Indians, followed by $11.2/10^5$ in Chinese and only $3.7/10^5$ in Malays between 1985 and 1998. No such marked difference was seen in CD. The prevalence rates in Chinese, Malays and Indians were $4.0/10^5$, $2.9/10^5$ and $4.9/10^5$, respectively^[23].

The lower prevalence and incidence of IBD in Asia compared with the West are not universal. A population-based study from Northern India found that the prevalence rate of UC is $42.8/10^5$ ^[25]. This unexpectedly high prevalence has been recently confirmed by another population-based study in Punjab, also in Northern India, revealing a prevalence of $44.3/10^5$ and an incidence of $6.02/10^5$ ^[26]. However, a major limitation of these studies is that they only screened a population sample of around 22 000 and 52 000 inhabitants, respectively. Thus, the results rely on a very small number of definite cases extrapolated to the whole population of the area.

IBD in Middle-East is traditionally reported to be high among Jews from the United States and Northern Europe. In Israel, the incidence is somewhat lower and Ashkenazi Jews have a higher incidence than Sephardic Jews. In 2000, Niv *et al*^[27] reported an annual incidence of $5.04/10^5$ for UC for a ten-year follow-up period between 1987-1999. The prevalence rate rose from $121.0/10^5$ to $167.2/10^5$.

In contrast, Arab countries in the Middle East still report low incidence rates. A prospective hospital-based study from Saudi Arabia^[28] reported an estimated incidence of $0.5/10^5$ and prevalence of $5.0/10^5$ for IBD in children in 1993-2002. Similarly, a retrospective study from the same region estimated a $0.94/10^5$ mean incidence of CD in 1983-2002, with a gradual increase in incidence from $0.32/10^5$ to $1.66/10^5$ ^[29]. In contrast, in Turkey the incidence of UC was as low as $0.59/10^5$ - $0.69/10^5$ between 1998 and 2001, in a hospital-based study^[30]. Finally, a recent case series from Teheran, Iran suggests very low incidence rates, since authors reported that only 448 IBD patients were referred to or diagnosed in two university hospitals and two private GI clinics between 1992 and 2002^[31].

Only limited data are available from Central and South America. A recent prospective study has reported the incidence of IBD in Puerto Rico^[32]. The total incidence of IBD increased significantly between 1996 and 2000 ($3.07/10^5$ to $7.74/10^5$), being significantly higher than CD. In contrast, much lower incidence rates were reported from a population-based survey from Panama and

Argentina^[33] in 1987-1993. The annual incidence of UC was $1.2/10^5$ in Panama and $2.2/10^5$ in Argentina, with only a single case of CD being identified. Similarly, the incidence of both UC and CD admissions is low in Brazil with only 257 new cases (126 CD and 131 UC) diagnosed in 1980-1999^[34].

Finally, Gearry *et al*^[35] have recently reported one of the highest incidence rate of CD from New Zealand in 2004. The reported incidence of CD is $16.5/10^5$ and the incidence of UC is lower ($7.6/10^5$). Corresponding prevalence rates are $355.2/10^5$ and $145.0/10^5$.

INFLAMMATORY BOWEL DISEASE IN CHILDREN AND ELDERLY

It is important but difficult to study the epidemiology of IBD in children. Although both UC and CD are rare below the age of 11 years, the incidence of these diseases increases rapidly after adolescence. In the pediatric age group, several epidemiologic studies have been published with some evidence suggesting that the incidence of IBD (in particular, CD) has increased over the last ten years.

The explanation for the differences in incidence between studies is further complicated by different definitions of childhood. The upper age limit varies between 14 and 17 years of age. Furthermore, upper gastrointestinal involvement is reported to be more common in children with CD. In addition, we have to note that new diagnostic tools may lead to overinterpretation of IBD emergence, since the clinical importance of minute lesions such as small erosions diagnosed during capsule endoscopy or double-balloon enteroscopy, which may be often diagnosed as IBD in children with abdominal pain, is still to be determined. To exclude this possibility, new uniform criteria have been developed for the diagnosis of IBD in children by ESPGHAN^[36].

Most of the published data come from the United States and Western Europe. The largest prospective study from the United Kingdom and Ireland has reported a well-characterized cohort of 739 children with IBD^[37]. The mean incidence of CD and UC is $3.0/10^5$ and $1.5/10^5$. Higher values were reported in a prospective study from Wisconsin, United States between 2000 and 2001^[38]. The mean incidence of CD and UC is $4.5/10^5$ and $2.1/10^5$, respectively.

A further population-based study from Copenhagen^[39] reported that 7% of the 1161 patients diagnosed with UC and 6% of the 373 patients with CD had an onset before 15 years of age. The median age at diagnosis was 12 years (range 0-14 years), indicating a steep increase in incidence around puberty. During the 26 years of the study, no significant change in incidence was found, the mean incidence of IBD was $2.2/10^5$ (UC: $2.0/10^5$ and CD: $0.2/10^5$). In another study of a large area of Sweden, Lindberg *et al*^[40] prospectively studied all patients below 16 years of age with a diagnosis of definite or probable UC and CD in 1984-1995. An increase in the incidence of UC was found (from $1.4/10^5$ to $3.2/10^5$), but only in the age group of 11-16 years, not in early childhood. The incidence of CD did not change over the time studied.

In contrast, other studies have reported a marked increase in the incidence of pediatric IBD. A slight increase in the incidence of juvenile onset CD was reported from Scotland between 1981 and 1995 with marked differences in the incidence of CD between north and south^[41]. The incidence of UC and CD increased over the observed period in both south (UC: 0.9-1.6/10⁵ and CD: 1.8-2.5/10⁵) and north (UC: 0.9-1.8/10⁵ and CD: 2.8-3.5/10⁵) territories. Similarly, an increase in the incidence of CD was reported in a prospective study from northern Stockholm between 1990 and 2001^[42]. The incidence in CD rose from 1.5/10⁵ to 8.4/10⁵ (mainly in the age group of 10-15 years), while that of UC was relatively stable at approximately 1.8-1.9/10⁵, except for 1990-1992. One of the largest studies has been reported from Northern France^[43]. In a prospective follow-up study, a total of 7066 patients were diagnosed, 509 (7.2%) of them were under the age of 17 years at the time of diagnosis. During follow-up, a trend for an increase in the incidence of CD was observed (from 2.1/10⁵ to 2.6/10⁵), while the incidence of UC remained unchanged (0.8/10⁵).

In Eastern Europe, Pozler *et al*^[44] have recently published the results of a retrospective study investigating the incidence of CD in the Czech Republic in children diagnosed under the age of 15 years between 1990 and 2001. A marked increase in the incidence of CD was reported from 0.25/10⁵ in 1990 to 1.25/10⁵ in 2001.

The same trend has been reported from Melbourne, Australia^[45] in a retrospective, hospital-based study in children diagnosed under the age of 16 years. The incidence of CD rose from 0.13/10⁵ to 2.0/10⁵ between 1971 and 2001.

An interesting question is the incidence of IBD in elderly populations. At least according to the published data from Western Europe, it may not be as uncommon as previously suspected. A prospective Belgian study^[46] between 1993 and 1996 reported that the incidence of IBD in the elderly population (age at diagnosis > 60 years) is high (UC:4.5 and CD:3.5), was comparable to the figures for younger age groups (UC: 3.4 and CD: 4.8).

Similarly, comparable incidence rates for CD have been reported from France between 1994 and 1997^[47]. The annual incidence rate is 2.5/10⁵, with a higher proportion of colonic disease.

HOW CAN WE EXPLAIN THE RECENT EPIDEMIOLOGICAL TRENDS?

The incidence of IBD varies greatly worldwide. Genetic and environmental factors are assumed to play a significant role in the aetiology of the disease. The role of genetic factors is supported by ethnic and familial differences as well as twin studies^[1,4], while the differences in incidence rates among various geographical areas suggest a role of certain environmental factors. It is known that the incidence differs among different ethnic groups living in the same geographic region. This fact is mostly observed in Asian countries^[5,24]. Similarly, the genetic predisposition may have led to the observation that the risk for IBD in Asian immigrants surpassed that observed in UK's native

population with an odds ratio of 6.1^[48]. In addition, disease phenotypes may also vary among different races, e.g. in a recent study from the United States^[49] reported that African American CD patients are more likely to develop upper gastrointestinal, colorectal or perianal disease, uveitis and sacroileitis compared to whites, while Hispanics are at higher risk of developing perianal disease or erythema nodosum, supporting a role of underlying genetic variations. Finally, the prevalence of identified genetic risk factors (e.g., NOD2 in CD) is also different in the different populations.

An important change in the incidence of IBD has taken place in the last few decades. In most of the Western Europe countries, the incidence rate remains relatively stable or even decreased. In contrast, continuously increasing incidence rates of CD have been recently reported from other high incidence areas such as Denmark^[11] and Sweden^[12]. There is also an important change in the diagnosis of CD. A new classification system has been developed^[50], as well as new tools which are readily available for the investigation of the small-bowel (e.g., capsule endoscopy^[51,52] and double balloon enteroscopy^[53]), which may lead to a further increase in reported incidence rates. As a consequence, an unusually high upper gastrointestinal involvement (as high as 55%) has been reported in recent genetic studies in pediatric settings^[54]. A similar trend is also apparent in the adult cohorts. Nonetheless, it is important to note that the clinical importance of minute lesions still needs to be determined. Capsule endoscopic examinations due to abdominal pain can reveal small lesions (angiodysplasias and small erosions) in similar percentages of subjects^[55]. Since the penalty for false-positive testing is very high (unnecessary use of toxic and expensive medications, and the stigma of being diagnosed with a serious chronic disease), at present, capsule endoscopy and double balloon enteroscopy should be used only in limited clinical situations rather than routinely. In addition, the interpretation of microscopic disease, especially in children is rather controversial. Nonetheless, this still does not explain the higher incidence values reported in recent studies.

In previously low-incidence areas, especially in Eastern Europe^[4,15,16] and some regions in Asia^[26], the disease has become more prevalent. Until now, the role of private practice is limited in Eastern Europe and most Asian countries and the majority of patients are managed in the public health care system, enabling population-based epidemiological investigations. The diligent collection of data and case ascertainment is, of course crucial.

The increased incidence rates of both UC and CD observed in Eastern Europe and Asia raise further questions. What could be the cause of this change? In the 1970s and early 1980s the lower incidence rates could be partially explained by the use of fewer up-to-date diagnostic procedures (e.g., the relative low availability of selective enterography or colonoscopy). It is also possible that greater awareness, either by physicians or by patients, may result in the diagnosis of mild cases that might have been previously unnoticed. There has also been an important change in patients' behaviour, at least in Eastern Europe, as patients tend to seek medical advice more often and with milder

symptoms than they did two decades ago. In contrast, in Eastern Europe, due to various and multiple causes, the access to health care services has not improved much. The reported incidence rates of IBD in Hungarian^[15] and Croatian^[16] are in a similar range, as previously observed in Nordic countries^[3,56,57]. In contrast, other countries (e.g., Czech Republic, Poland, Romania and Slovakia) still report low incidence rates. These studies however, have several limitations. Some of them were retrospective surveys^[44], while others were based solely on the in- and outpatient records of a single hospital, extrapolating the results to the investigated area^[4]. Patients might have been unnoticed, thus the incidence rate is clearly underestimated. We believe that the increase in the incidence of IBD in Eastern Europe in the late 1980s and 1990s is real and not solely due to improved diagnosis, better health care access or more extensive search. This notion is also supported by the increase in more severe cases, which can only be interpreted as real.

The observed changes may be at least partially explained by the differences in study design. Most of the earlier studies from Eastern Europe, and still the majority of studies from Asia^[19,23], Middle-East^[29,30] and Central America^[33] are biased by methodological shortcomings. A great majority of them were retrospective, hospital-based surveys, which may have at least partly been responsible for the low incidence rates reported. In contrast, recent prospective, population-based studies, especially from Eastern Europe with extensive search for IBD cases^[25,32] have reported much higher incidence rates from the same regions with some exceptions^[20]. The situation is somewhat different in India. Though papers are prospective^[25,26], results might have been biased by methodological problems. Only questionnaire-based surveys were conducted and only a limited population sample was screened. Thus, the results rely on a very small number of definite cases extrapolated to the whole population of the area.

Diet, as a luminal antigen, is thought to be an important factor in the pathogenesis of IBD^[1,58]. In the last two decades, there has been a change in the lifestyle in Eastern Europe, Asia and Central America, as the standard way of living, including the diet, has become more "Westernized". This possibility is further supported by the differences in incidence and prevalence found within one region. In Eastern Europe^[4,15], the change in the incidence is parallel to the change in governing system and the prevalence is clearly different between the more "Western"-type living in the western regions, as opposed to the less rapidly changing eastern parts.

This raises the possibility that the prevalence of IBD, e.g., in the eastern parts of Europe and Asia is also capable of changing in the next one or two decades. An early signal of this change might be the reported increase in the incidence of UC in many of the Asian countries. Since the change in incidence of UC precedes that in CD in most countries, it is possible that different environmental factors are responsible for the increase in the incidence of UC and CD. Alternatively, the same environmental factors may act differently in the two diseases, resulting in different epidemiological patterns. This is supported by the recent trends in the incidence of UC in Asia and the similar changes in

the late 1980s and early 1990s in Eastern Europe, where the increase in the incidence of UC precedes that of CD. It is therefore, of outstanding interest to follow the temporal trends of IBD epidemiology in Asia, Eastern Europe and Central America. In addition, these studies offer a unique possibility to extensively study the role of possible environmental risk factors in the susceptibility of IBD.

Other possible environmental factors, such as perinatal events, childhood infections or measles have not been investigated outside North America and Western and Northern Europe^[59,60]. Measles vaccination is however universal in Eastern Europe making the disease very rare, in addition to a low birth rate. Early childhood hygiene is also well developed, supporting a possible role of the "oversheltered child" theory^[61]. The hygiene hypothesis suggests that skewing of the Th1/Th2 balance in early life is a major cause for the recent increase in allergic and autoimmune diseases. Recent data from different regions of Canada have controversial results^[62,63]. Nonetheless, since early and high level of childhood hygiene has existed, at least in Eastern Europe since the early 1970s, it does not explain the epidemiological trend observed in the late 1990s. In addition, the reported prevalence of other known environmental factors (e.g., smoking, frequency of appendectomy, contraceptive and use of NSAID and antibiotics) did not change significantly in the last decades, thus it is unlikely that these factors are essential in evolution of the epidemiology trends.

The incidence of IBD varies greatly worldwide. In traditionally high incidence areas, e.g. in West European and North American countries the figures have stabilized or slightly increased, with even decreasing incidence rates for ulcerative colitis. In contrast, low prevalence and incidence rates have been reported from other parts of the world including Eastern Europe, South America, Asia and the Pacific region. Recent trends however, also indicate a change in the epidemiology in these countries, since previously low incidence areas are now reporting a progressive rise in the incidence. Some of these changes may represent differences in diagnostic practices and increased awareness of the disease. The quality of the surveys is also variable. Most probably, inadequately identified environmental factors or a combination of these factors may be responsible for the recent rapid changes. Additional epidemiologic studies are needed to better define the burden of illness, explore the mechanism of association with environmental factors, and identify new risk factors.

Abstract

The number of patients with gastric cancer has more than doubled since 1985 in developing countries. Thus, the questions of whether it can be predicted from gastritis morphology, who is at risk and who has a lower risk of developing gastric carcinoma are raised. *H pylori*-infection leads to erosions, ulcerations, carcinoma, mucosa associated lymphoid tissue (MALT)-lymphoma and extragastric diseases only in some individuals. The frequency of ulcerations among *H pylori*-infected individuals is estimated to be 13%, gastric cancer about 1% and MALT lymphoma around 0.1%. In the literature a multistep model from chronic active *H pylori*-infection through multifocal atrophy, intestinal metaplasia, dysplasia (intraepithelial neoplasia) and carcinoma has been described. But this model cannot be applied to all routine cases. Since risk factors such as metaplasia and atrophy are precancerous rather than precancerous conditions, this raises the question whether there is a better morphological marker. Differences in topography, grade and activity of Helicobacter gastritis in the antrum and corpus might be good markers for identifying those who are at risk of developing gastric cancer. It is known that the so-called corpus dominant *H pylori* gastritis is found more frequently among individuals with early and advanced gastric cancer and within high risk populations. This is valid both for first-degree relatives of gastric cancer patients and for patients with gastric adenoma and hyperplastic polyps. In conclusion, corpus-dominant *H pylori* gastritis is significantly more common in patients with advanced and early gastric cancer, first-degree relatives of patients with gastric cancer, patients with gastric adenoma and gastric hyperplastic polyps. Therefore, all these patients are at risk of developing gastric cancer. Next, the question of who is at risk of developing corpus-dominant gastritis is raised. It appears that patients with a low acid output more frequently develop gastric cancer. Eradication therapy is never performed too early but probably sometimes too late after the patients pass a "point of no return". Large prospective long term studies

are necessary to prove this and identify new reliable markers for gastric cancer development.

INTRODUCTION

H pylori is recognized as the major pathogenetic factor in chronic active gastritis. Chronic active gastritis not only leads to gastric inflammation in various degrees but also can be the cause of gastric and duodenal ulcer disease and might give rise to gastric mucosa associated lymphoid tissue (MALT) lymphoma (marginal B-cell lymphoma). Interestingly, low grade MALT lymphoma regresses after antibiotic treatment for *H pylori* eradication in a high percentage of cases.

HISTORICAL BACKGROUND

Prior to the morphological identification of *H pylori* as the causative agent, gastric inflammation had already been considered a risk factor for gastric carcinoma. Correa postulated in 1988^[1] that chronic gastritis may lead *via* a multistep process to intestinal metaplasia and atrophy as an additional morphological risk factor for the development of carcinoma since these are frequently found to be closely related to the intestinal type of gastric cancer. In addition, today it has become clear that at least 50% of all cases of autoimmune atrophic gastritis which is considered to some varying degree as a precancerous condition, are probably induced by *H pylori*^[2].

EPIDEMIOLOGICAL EVIDENCE

Mortality of gastric cancer is a significant burden not only on patients but also on the whole health system. There are regional differences depending on the geographical location (Table 1). For example, about 360 000 deaths

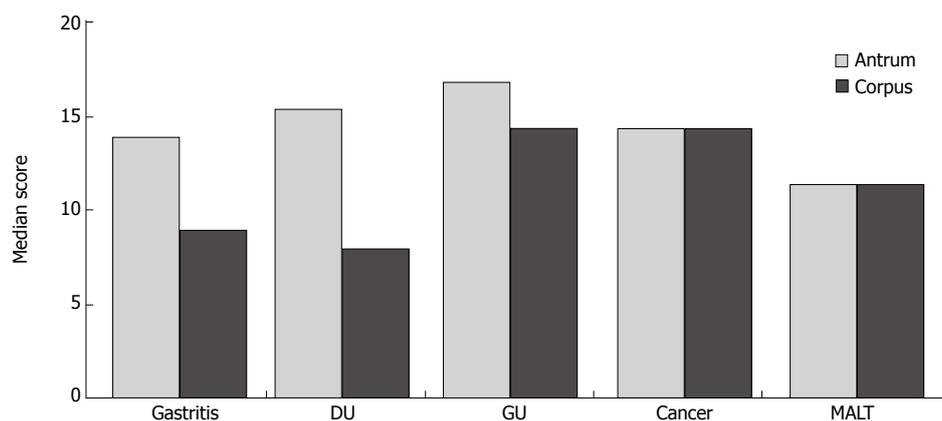

Figure 1 Median gastritis scores in antrum and corpus mucosa of patients with chronic active *H pylori* gastritis alone, duodenal ulcer (DU), gastric ulcer (GU), gastric cancer or MALT lymphoma ($n = 50$) (Modified from Meining *et al*^[16]).

Table 1 Gastric cancer mortality in different populations (Modified from Winawer *et al*^[31])

Countries	Yr	Yr
	2000	2020
Developed	334.000	440.000
Developing	543.000	983.000

occur due to gastric cancer each year in China with the world largest population^[3]. This means that every 2 min one patient dies of gastric cancer in China.

The knowledge on a pathogenetic association between gastric carcinoma and *H pylori* infection is mainly based on retrospective studies by observing resected stomachs. *H pylori* gastritis is usually present in gastric mucosa adjacent to cancerous lesions. Furthermore, a statistically significant correlation between the rate of infection and the incidence of gastric cancer has been observed in a number of populations, although in some populations, especially in Africa, such a correlation is not found^[4]. Thirdly, case-control studies demonstrated that the risk of developing gastric carcinoma is significantly higher in the presence of *H pylori*. Such an association is only described for the distal stomach but not for carcinomas in the proximal stomach, that may arise due to an increasing number of Barrett's esophagus^[5,6]. Many of these studies have methodological problems and weakness of data strength. The situation has improved nowadays. At least some prospective studies are available showing that if certain morphological features are present the patients are at risk of developing gastric carcinoma.

In Germany with 80 million inhabitants, more than 26 000 patients suffer from gastric carcinoma^[7]. Approximately 50% of them will not survive for 5 years, which underlines the importance of this disease for the health system.

WHO has classified *H pylori* as a class 1 carcinogen for the development of gastric carcinoma, but only a minority of individuals infected with *H pylori* develop gastric carcinoma. It is not clear up till now how the complex interaction occurs between host development of neoplasia in some patients but not in the majority of all others. It has long been known that nutritional factors, high salt intake, smoked meat, few vitamins might increase the risk

of gastric carcinoma^[8]. From our routine practice we know that cancer develops very rarely in normal gastric mucosa. It is of particular interest to identify risk markers capable of predicting the risk of developing gastric carcinoma. Healing of such high risk gastritis can then decrease the risk of developing gastric adenocarcinoma. Before *H pylori* was re-introduced into medicine as the causative agent for gastritis, it has been known that the presence of multifocal atrophic gastritis with intestinal metaplasia is a risk factor for gastric carcinoma^[1]. Interestingly, the diffuse (signet ring cell) type of carcinomas is not covered by such a hypothesis that gastric cancer might develop even in normal gastric mucosa, especially in very young adults, indicating a genetic background in those patients.

MORPHOLOGICAL FEATURES OF GASTRITIS WITH HIGHER RISK OF DEVELOPMENT OF ADENOCARCINOMA

Initial investigations on the topographic aspects of *H pylori* showed that *H pylori* colonization is less frequent and activity is less marked in the gastric corpus compared to the gastric antrum^[9-12]. Recent studies including the gastric cardia also suggest that *H pylori* colonization is denser in the gastric cardia than in the gastric corpus, in turn leading to more pronounced gastritis in this region^[13]. Nowadays it is well accepted that *H pylori* colonizes in the whole gastric mucosa. The infection induces chronic active inflammation anywhere in the gastric mucosa. An important task is therefore, to search for bacteria- and host-related factors that favor the development of gastric carcinoma. The results of studies carried out by our group at the end of the 1980s^[14] have prompted us to carry further studies in this field.

Comparison of gastritis scores in antrum and corpus biopsies

In a matched control study, our group has compared the gastritis score^[15] of individuals with NUD, duodenal ulcer, gastric ulcer, MALT-lymphoma and gastric carcinoma. These studies show that patients with chronic active *H pylori* gastritis, gastric ulcer and duodenal ulcer have significantly lower scores in the corpus than in the antrum, compared to cases of gastric cancer and MALT-lymphoma (Figure 1)^[15], but the scores are significantly lower in MALT lymphoma than in gastric cancer.

Table 2 Gastric cancer risk index in patients with active *H pylori* gastritis

Grade of gastritis (infiltration by lymphocytes and plasma cells) is more severe in the corpus compared to the antrum or at least equally distributed
Activity of gastritis (infiltration by neutrophilic granulocytes) is more severe in the corpus compared to the antrum or at least equally distributed
Intestinal metaplasia present in the antrum and/or in the corpus

Each feature is scored with one point. Values between 0 and 3 and a total sum of 3 are possible (Adapted from Meining *et al*^[16]).

Table 3 Prevalence of *H pylori*-associated high risk gastritis (3-index-points) in relation to age ($n = 845$) (Modified from Leodolter *et al*^[19])

Age	<i>n</i>	3-index-points
< 35 yr	114	0.9%
35-54 yr	116	2.7%
55-64 yr	186	6.5%
65-74 yr	145	12.7%
> 74 yr	83	12.6%

Comparison of antral and corpus gastritis in patients with gastric carcinoma or duodenal ulcer

In a next step, our group compared the grade and activity of *H pylori* gastritis in the antrum of 215 patients with gastric carcinoma or patients suffering from duodenal ulcer, showing that there are no differences in the grade and activity of antrum mucosa between the two patient groups, but significant differences in the corpus mucosa. The activity and grade of gastritis in the gastric corpus are significantly higher than those in the antrum of patients with gastric carcinoma, but only in a few patients with duodenal ulcer (Figure 2)^[16]. An additional study showed that intestinal metaplasia occurs significantly more often both in antrum and in corpus of patients with gastric carcinoma^[17]. According to Hattori *et al*^[18], intestinal metaplasia might only be a paracancerous condition and just an expression of prior or ongoing severe inflammation, but does not cause cancer.

Gastric carcinoma risk index

In 1998, our group proposed a gastric carcinoma risk index based on previously described results. This index score consists of the presence of intestinal metaplasia (1 point) and the grade and activity of gastritis in the corpus. The maximum point is 3 when all features are present (Table 2). The maximum point is 3 when all features are present (Table 2). The positive predictive value for the presence of gastric carcinoma is 79% for score 2 and 94% for score 3^[16]. Leodolter *et al*^[19] found that there is a strong relationship between age and the prevalence of so-called high risk gastritis with a score of 3 (Table 3).

Comparison of grade and activity in first degree relatives of gastric carcinoma patients

Due to the lack of large prospective studies, it can be argued that analyses of the topographic grading of *H pylori*-infected gastric mucosa in patients with gastric carcinoma do not allow transfer of the findings to individuals

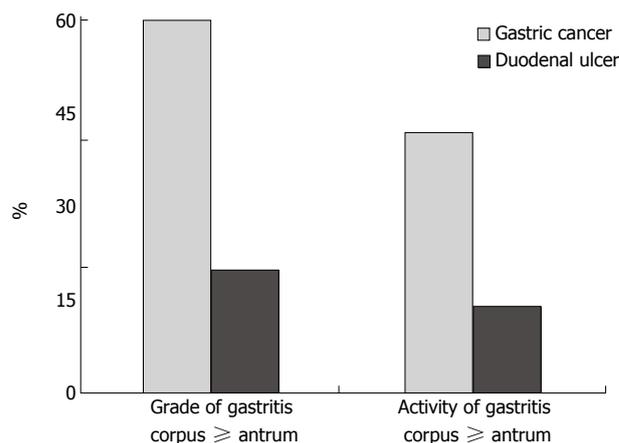

Figure 2 Topographic distribution of grade and activity of *H pylori* gastritis in individuals with early gastric cancer or duodenal ulcer (Modified from Meining *et al*^[16]).

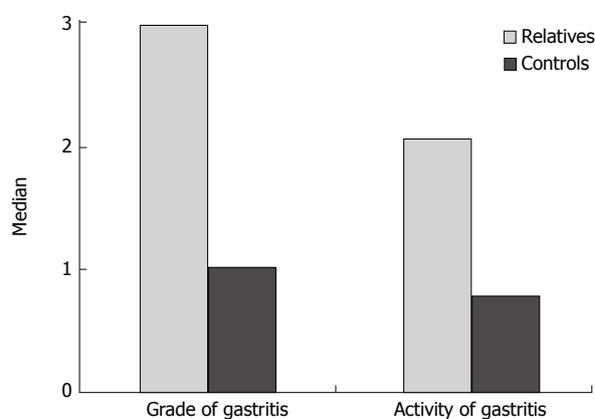

Figure 3 Median grade and activity of *H pylori* gastritis in the corpus in relatives of gastric cancer patients ($n = 237$) and matched control patients ($n = 237$) (Modified from Meining *et al*^[20]).

without gastric cancer since it might influence the status of gastric mucosa. Therefore, our group has analyzed a set of 237 first degree relatives of gastric cancer patients and 237 controls with *H pylori* infection alone^[20]. The updated Sydney System for histological classification of gastritis^[21] consists of a four-scale semiquantitative grading system with values being not present, slight, moderate and marked.

When the risk profile is analyzed by grading the grade and activity of gastritis according to the updated Sydney System, it becomes clear that the first degree relatives of gastric cancer patients do have more severe grade and activity of gastritis (Figure 3), supporting the familial background of gastric cancer.

Gastritis status in patients with gastric adenomas and hyperplastic polyps

Adenomas of the stomach are unequivocal intraepithelial neoplasms that are limited to the gastric epithelium and can be subdivided into low-grade (adenoma) and high grade intraepithelial neoplasia (formerly dysplasia). From our routine practice, we know that the diagnosis of high grade intraepithelial neoplasia is very rare, and that most

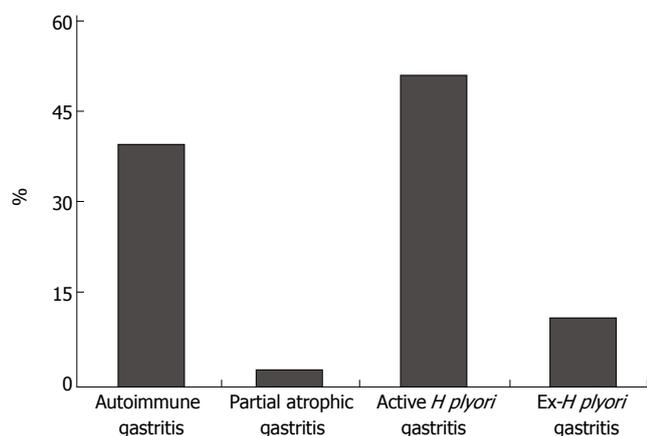

Figure 4 Prevalence of different gastritis in 118 individuals with gastric adenomas (Adapted from Meining *et al*^[25]).

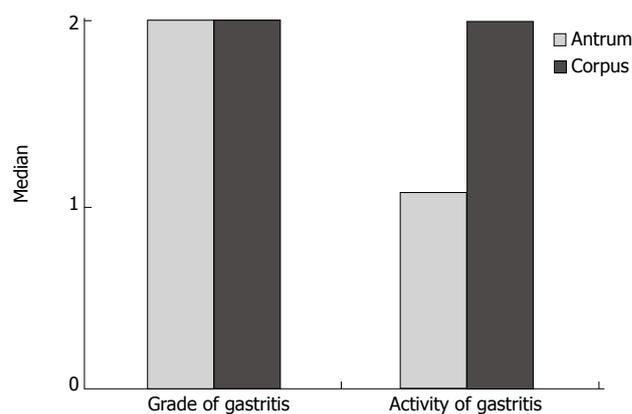

Figure 5 Grading of gastritis according to the updated Sydney System for classification of gastritis in the antrum and corpus of 91 patients with hyperplastic polyps (Adapted from Oberhuber^[27]).

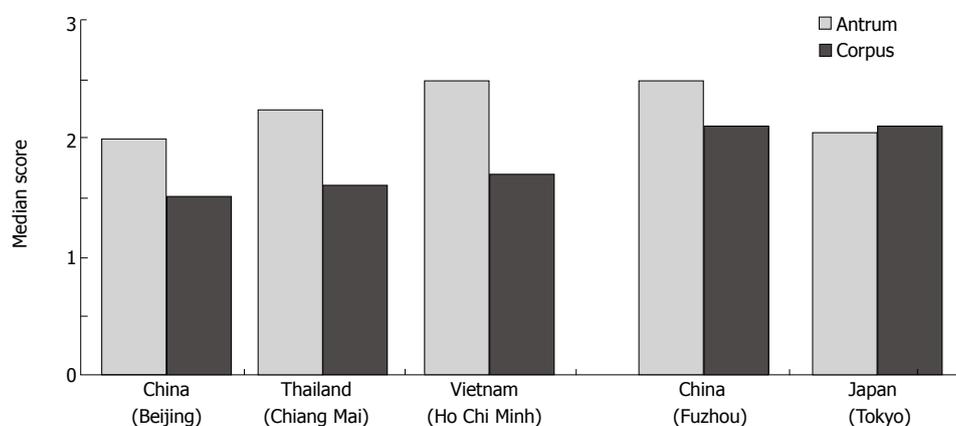

Figure 6 Mean scores of active gastritis (neutrophilic granulocytes) in the antrum and corpus in different Asian populations (Modified from Matsuhisa *et al*^[29]).

reports on follow-up studies of such lesions show that most of these “high grade lesions” are invasive cancers within a few months^[22], which probably contribute more to diagnostic uncertainty in biopsy specimens than real neoplastic progression. Adenomas can show a polypoid or a flat growth within the gastric epithelium. For gastric adenomas, the adenoma-carcinoma-sequence^[23] can also be used to represent a precancerous lesion that should be removed completely to avoid progression to cancer^[24].

In a series of 118 patients with gastric adenomas, our group showed^[25] that adenomas occur more frequently in patients with autoimmune gastritis but also in patients with *H pylori* gastritis (Figure 4), and a subsequent analysis showed that patients with gastric adenoma have the same distribution of corpus dominant *H pylori* gastritis like patients with early gastric cancer. In a further study, our group analyzed the gastritis status of gastric pyloric gland adenomas which is also a precancerous condition (approximately 30% show invasive carcinoma at the time of first diagnosis), and found that the proportion of atrophic autoimmune gastritis and corpus dominant *H pylori* gastritis is high in elderly women^[26] (data not shown).

Hyperplastic polyps are also considered a precancerous lesion. A few case series in the literature and our own data^[27] indicate that hyperplastic polyps bear a risk of malignant transformation between 0.6% and 6.6%. Therefore, these polyps belong to the group of

precancerous lesions and should be removed completely. Follow-up studies showed that gastric carcinoma may develop in 8.6% of the patients at other gastric sites^[28]. As adenomas, hyperplastic polyps arise quite often in autoimmune gastritis. *H pylori* infection is present in 37% of the cases of hyperplastic polyps. Most of these cases also show corpus-dominant *H pylori* gastritis (data not shown) (Figure 5).

Gastritis status in populations with different risks of developing gastric carcinoma

A high incidence of gastric carcinoma is present in Fuzhou in China and in Japan, compared to Beijing in China, Thailand and Vietnam. Corpus dominant gastritis is present in Japan and China (Fuzhou), especially in the elderly whereas antrum predominant gastritis is present in Beijing (China), Thailand and Vietnam. These results correlate with the low incidence of gastric adenocarcinoma in Thai, Vietnamese and certain Chinese populations^[29] (Figure 6). Interestingly, the activity of corpus gastritis increases with age in Japanese individuals while antrum predominant *H pylori* gastritis does not shift to more severe corpus gastritis in Vietnamese, Thai and certain Chinese populations. This is followed by a more severe colonization of *H pylori* in cases of corpus dominant *H pylori* gastritis. In contrast to the literature, we could not confirm the finding of improved antrum gastritis after proton-pump inhibitor

(PPI) therapy. We have found aggravated corpus gastritis as described in the literature but decreased colonization in the antrum and corpus^[30]. This might explain why increased incidence of gastric carcinoma is not reported among the millions of individuals who use acid-suppressive therapy, although corpus dominant *H pylori* gastritis is treated with PPI. Future prospective studies especially in China with its large background of individual genetic differences and environmental conditions are necessary to investigate the topography of gastritis in different Chinese populations searching for explanations for different incidences of gastric cancer in China as reported in the literature^[31]. It has been speculated that differences in environmental factors might provide a crucial clue to all these questions rather than genetic backgrounds^[32].

DISCUSSION

Corpus dominant *H pylori* gastritis is found more frequently in patients with advanced gastric carcinomas, or early gastric carcinomas and even in first degree relatives of patients with gastric cancer than in patients with duodenal ulcer or functional dyspepsia. While more than 90% of patients with gastric carcinoma are *H pylori* positive. Combined autoimmune gastritis and gastric cancer is very rarely found. On the other hand, 30% of patients with hyperplastic polyps and gastric adenoma of the intestinal or gastric type (pyloric gland adenoma) suffer from autoimmune gastritis^[16,26]. Corpus dominant *H pylori* gastritis is mainly diagnosed in cases infected with *H pylori*. All the above studies have confirmed that corpus dominant *H pylori* gastritis bears a higher risk developing gastric neoplasms rather than other forms of *H pylori* gastritis.

It is difficult to explain the different incidences of gastric cancer in patients with corpus dominant *H pylori* gastritis and autoimmune gastritis, because at least 50% of autoimmune gastritis are probably induced by *H pylori*^[2], indicating that more than one risk exists in patients with precancerous lesions and patients with corpus dominant *H pylori* gastritis have a higher risk than those with autoimmune gastritis. Corpus dominant *H pylori* gastritis is a risk factor for gastric carcinoma in individuals with precancerous conditions and in the first degree relatives of gastric carcinoma patients^[20,25]. The predictive value of corpus dominant *H pylori* gastritis needs to be investigated in future prospective studies.

Lee *et al.*^[33] are the first to consider the possibility of differences in acid secreting capacity in answering the underlying causes of corpus dominant *H pylori* gastritis. According to their hypothesis that low acid output leads to more severe gastritis, which has been confirmed later^[34,35]. Moreover, it is important to emphasize that the proposed gastritis-atrophy-intestinal metaplasia-dysplasia-carcinoma sequence by Correa^[1] is an ideal model only and fails to be proven in most cases^[18]. But intestinal metaplasia (as a paracancerous phenomenon) is frequently picked up in biopsy specimens from individuals with corpus dominant *H pylori* gastritis, indicating a close relationship.

Whether *H pylori* eradication is capable of preventing gastric cancer is to be clarified in prospective studies such as the German PRISMA study^[36]. Eradication stops at least

the progression of intestinal metaplasia and atrophy^[37] and improves gastritis^[38]. However, it has been indicated that "a point of no return" might have been reached before *H pylori* eradication cures the infection. This possibility is demonstrated by the development of 3 early gastric carcinomas in 92 patients 4 and 5 years after *H pylori* eradication and complete remission of MALT lymphomas in our German MALT lymphoma study^[39] and 3 additional cases having a similar clinical history (Malfertheiner's personal communication). Further proof is given by the study of Wong *et al.*^[40] who showed that the incidence of gastric carcinoma is similar in individuals receiving eradication therapy or placebo during a 7.5-year follow-up period. It was reported that if no precancerous lesions (atrophy/dysplasia/intestinal metaplasia) are present, eradication of *H pylori* leads to no gastric cancer^[40-42]. Another factor that should not be disregarded is a genetic background shown by the analysis of first-degree relatives of individuals with gastric carcinoma^[43-46]. Whether metaplasia and atrophy are precancerous or paracancerous lesions^[18], they may not have a great clinical impact since these lesions occur especially in individuals with an elevated risk of gastric cancer^[47]. Large prospective studies are needed to further analyze the risk factors for gastric cancer and to clarify whether and when eradication therapy is capable of preventing gastric carcinoma.

Abstract

Mesalazine is a safe drug, although adverse events may be seen in a minority of patients. This applies also to pregnant women and children. The role of mesalazine in combination therapy to improve efficacy and concomitant drug pharmacokinetics, or in chemoprevention against inflammatory bowel disease (IBD)-related colonic carcinoma has not yet been completely elucidated. Therapeutic success of mesalazine may be optimized by a combination of high dose and low frequency of dosage to improve compliance. Therefore, due to its superior safety profile and pharmacokinetic characteristics, mesalazine is preferable to sulphasalazine. This paper reviews the literature concerning mechanisms of action, indications and off-label use, pharmacokinetic properties and formulations, therapeutic efficacy, compliance, paediatric indications, chemoprevention, and safety issues and adverse event profile of mesalazine treatment *versus* sulphasalazine. It also highlights these controversies in order to clarify the potential benefits of mesalazines in IBD therapy and evidence for its use.

INTRODUCTION

In the late 1970s, elegant studies revealed that 5-aminosalicylate is the active moiety of sulphasalazine in patients suffering from ulcerative colitis (UC) and Crohn's disease (CD)^[1,2]. Since then, 5-aminosalicylate has become the gold standard first line therapy for patients with UC, although its use in CD remains controversial. After 25 years, discussion of monocomponent 5-aminosalicylate with regard to its efficacy in comparison with sulphasalazine^[3,4], drug profile^[5,6], precise indications^[7,8], and adverse events^[9,10] continues to be ongoing and lively. This review highlights these controversies in order to clarify the potential benefits of mesalazines in inflammatory bowel disease (IBD) therapy and evidence for its use.

CONSIDERATIONS 1 AND 2

How efficacious is mesalazine in comparison with sulphasalazine in patients with ulcerative colitis and which is the most effective mesalazine?

The therapeutic efficacy of salicylazosulphapyridine (SASP) in inducing and maintaining remission in patients with UC has been recognized for over 60 years^[11]. SASP is a conjugate of 5-aminosalicylate and sulfapyridine. 5-aminosalicylate was identified as the principal effective component of this conjugate in the 1970s^[1,2], and remains the starting point for the clinical use of monocomponent 5-aminosalicylate or mesalazine. Although the exact mechanism of action of mesalazine/SASP has still to be elucidated^[12,13], several potential mechanisms have been suggested, including 5-aminosalicylate-induced inhibition of inflammation by interfering with the metabolism of arachidonic acid, prevention of mucosal generation of leukotrienes and prostaglandins^[14], scavenging of free radicals^[14,15] and mechanisms only recently identified involving inhibition of nuclear factor-kappaB (NFκB) and induction of apoptosis^[16-20]. Further properties include changes in the production of immune globulins and diminished production of interleukin-1 and partial inhibition of platelet activating factor (PAF) expression, resulting in a decrease in leucocyte trafficking^[21].

5-aminosalicylate is believed to act in the damaged epithelial intestinal layer, where it is transformed into the inactive acetylated 5-aminosalicylate, which is subsequently filtered and excreted by the kidneys. As a result, the therapeutic activity and efficacy of 5-aminosalicylate are related to its intraluminal concentration^[6,13,22,23]. It has been argued that increasing dosages of oral mesalazine are

not correlated with enhanced efficacy. Although this has never been the subject of an extensive study^[3], a double-blind study in 321 patients has found no significant dose response between mesalazine (1.5 g/d, 3.0 g/d and 4.5 g/d)^[24]. Theoretically, however, dosing of mesalazine above the enzymatic (acetylating) capacity of the epithelial layer increases the subepithelial concentration of mesalazine^[25], thereby increasing its potential efficacy^[14], a finding that is corroborated by studies demonstrating a dose-response relationship of oral formulations^[26-29]. These findings have been recently corroborated by a post-hoc analysis of 423 patients out of the original 687 patients from the ASCEND I and II studies, in which daily oral use of 4.8 g mesalazine (Asacol[®]) was compared to 2.4 g mesalazine, showing that the higher dosage is superior in patients with moderately active UC^[30]. There is little doubt that registered doses of oral mesalazine are effective in treatment of active UC^[31]. Indeed, the recent (2004) British Society of Gastroenterology (BSG) guidelines^[32], recommend a combination of topical and oral mesalazine as first line therapy in the treatment of distal mild to moderate UC.

More contentiously, recent Cochrane meta-analyses of the capacity of mesalazine to induce or to maintain remission^[3] in UC patients are not in favour of mesalazine over SASP, particularly in maintaining remission. However, SASP is not as well tolerated as 5-aminosalicylate^[3]. Therefore, these authors question whether there is a clinical advantage of monocomponent preparations. However, it should be noted that mesalazine and SASP are equally effective in the 12-mo trials. It is only the 6-mo data that differ. The conclusions made from this meta-analysis are further flawed due to the following reasons. Although the authors have made considerable efforts to group studies with the same patients and outcome variables, these meta-analyses are based on different patient groups from various hospital settings. Moreover, meta-analyses may lead to incorrect conclusions, in particular when smaller studies are added to perform the analysis, as has been shown by the challenging and controversial findings of LeLorier *et al*^[33]. They showed that performing well-conducted meta-analyses with available data from small-scale studies leads to incorrect conclusions as exemplified by contradictory findings in properly designed and statistically powered prospective trials, performed to verify the conclusions from these prior meta-analyses. In addition, there is a lack of trials using high-dose mesalazine, with intention-to-treat analysis, and including registered compliance rates. Notwithstanding these limitations, and others posed by the authors (such as lack of standard UC-index of severity and different, partly obscured, treatment strategies), it could be concluded that these Cochrane-analyses showed that efficacy of oral SASP or mesalazine in induction and maintenance treatment in UC is more or less equivalent^[3,4]. Therefore, a final decision as to the choice of therapy depends largely on other factors such as adverse events and drug profile, patient's preference, and costs. Knowledge of drug profile and pharmacokinetic characteristics may be helpful in determining the correct choice in oral therapy for UC, although all compounds have proven their efficacy in colonic disease^[31,34]. In the

early trials, somewhat surprisingly, oral balsalazide therapy was shown to be superior over mesalazine^[35,36], in addition to more expected results such as better tolerability than SASP^[37,38]. However, it has since been contested that the interpretation and clinical implications of these findings are ambiguous^[34,39-41]. Direct comparative studies with well-defined clinical presentations (pancolitis versus left-sided colitis), and well-defined consistent primary study goals, such as number of patients in remission after 8 or 12 wk, are necessary to prove the therapeutic superiority primarily and secondarily, to justify preferences^[31,40].

Another important issue relates to the use of topical therapy. Where possible, topical therapy, either as an enema or a suppository, can be an excellent alternative to oral therapy, both for active^[42-44] and quiescent disease^[45,46]. To adequately cover the extent of the diseased distal colon, enema volume has to be varied^[47], whereas all rectal dosages above 1 gram seem equipotent^[48]. In addition, new entities such as gels and foams may be a patient friendly alternative^[49-51]. Furthermore, regarding combination therapy, it has recently been reported that the combination of oral (4 g/d) and rectal (1 g/d) mesalazine therapy significantly improves remission and improvement rates in extensive mild to moderate active UC^[52]. Combination therapy may, in addition, protect against progressive extension of distal disease^[53].

The ideal dosage for maintenance treatment of UC has never been studied, and most studies included in the most recent Cochrane analysis have used relatively low dosages of mesalazine^[4]. The authors concur that the ability to make general conclusions is limited due to the lack of standard indices, and treatment specifications. A dose-response rate could not be found, probably due to the small number of patients included in this subanalysis. However, it should be noted that the use of olsalazine (Dipentum[®]) may be limited owing to its diarrhoea-inducing capacity^[4]. Nowadays many clinicians believe that the same dose of mesalazine required to induce remission should be continued as maintenance therapy, particularly if higher doses are required to induce remission^[34].

CONSIDERATIONS 3 AND 4

Is mesalazine effective in Crohn's disease and is the pharmacokinetic (mesalazine release) profile of importance?

The use of 5-aminosalicylates in patients with CD is more controversial than its use in UC. The landmark study of Singleton *et al* in 1993^[54], has demonstrated a dose-response relationship with high dose (4 g/d) mesalazine. However, mesalazine therapy appears clinically beneficial only in specific subgroups, such as patients who have recently undergone ileocecal resection to prevent relapses^[55,56]. The efficacy of mesalazine in the overall heterozygous CD population is inconsistent, both in literature and in practice. Several authors advocate the use of mesalazines in mildly active CD^[8,57], although a more critical approach, namely mesalazine is not efficacious in CD, is equally contested by others^[7,58]. One meta-analysis, including data from unpublished studies, has shown a significant effect of mesalazine (4 g/d) compared to placebo in reducing CDAI

score 63 *vs* 45 (ITT) ($P = 0.04$) and 83 *vs* 57 per protocol, ($P = 0.02$)^[8]. The clinical relevance of these differences has been questioned^[58]. Nevertheless, in early studies of mesalazine use in CD, beneficial effects have been observed, which could not be reproduced in larger studies in referral centres^[8,54,55,59,60].

The therapeutic effects of mesalazine (1 g t.i.d), 6-mercaptopurine (50 mg/d), and placebo were studied for 2 years following surgery, which revealed that the relapse rate in the 6-mercaptopurine group was 50% compared with 58% and 77% in the mesalazine and placebo groups, respectively, showing a statistical significance only for 6-mercaptopurine^[61]. In another open randomized study, comparing properly dosed azathioprine and mesalazine (1 g t.i.d), no statistically significant difference was observed in the cumulative risk of clinical relapse between the two treatment regimens ($P = 0.2$), which may be due to a type 2 error^[62]. A potential role of mesalazine in maintenance therapy of CD following medically induced remission is questioned^[63].

Others believe that only SASP and not mesalazine, may be indicated for but strictly limited to mildly active colonic CD^[7]. This may reflect the colonic release profile of SASP, which clearly differs from the release profile of mesalazine delivered in microgranules, which has been shown to reduce postoperative recurrence in CD patients with small bowel involvement only (mesalazine 22% *vs* placebo 40%, $P = 0.002$)^[56,64]. Localization of the disease differs considerably between patients. This clinical heterogeneity may lead to differences in efficacy between mesalazine formulations. Drug release profiles of mesalazine moieties noticeably vary^[6]. Mesalazine incorporated in ethylcellulose microgranules (Pentasa[®]) releases mesalazine from the duodenum through the colon in a gradual manner at all pH levels^[6,22,65]. Conversely, mesalazine with a Eudragit-L-coating (Salofalk[®]) releases mesalazine exposed to a pH level of 6 to 6.5, limiting its action to the mid small intestine and onwards, whereas a similar formulation with Eudragit-S-coating (Asacol[®]), releases when exposed to pH levels of 7, corresponding approximately to the last part of the small intestine. The prodrugs sulphasalazine (Azulfidine[®]), balsalazide (Colazal[®]) and olsalazine (Dipentum[®]) release 5-aminosalicylate in the azoreductase containing bacteria-rich colon. Thus, there exist formulations which release 5-aminosalicylates in specific regions of the intestine, while others continuously release 5-aminosalicylates in both the small and large intestine^[6,65]. Regionalization of mesalazine delivery is further influenced by enteral motility and anatomy, as exemplified by various recurrence rates after mesalazine use in Crohn's disease patients with different anastomotic configurations following resection^[66]. The pharmacokinetics of various mesalazine moieties has recently been reviewed more extensively^[5,67].

Since intraluminal concentrations of mesalazine appears to determine therapeutic efficacy, regional targeting of mesalazine is considered to be important^[6,60,64]. Remarkably, several generic oral formulations of mesalazine-containing preparations have been approved based on bibliographic files, without conductance of thorough bio-equivalence studies^[6]. Clearly, generic preparations with undocumented release profiles cannot be compared with well-documented

formulations^[5,6]. Nevertheless, "it is as yet unclear whether any specific formulation has shown site specificity for Crohn's disease"^[8], and this pharmacokinetic issue has yet to be the subject of a clinical trial. Aside from these pharmacokinetic considerations, the potential of mesalazine in CD has yet to be fully determined although the recent BSG guidelines stated that high-dose (4 g/d) mesalazines could be used as an initial therapy for mild-ileocolonic CD^[32]. However, a critical approach is warranted, as concluded by the authors of a Cochrane review concerning any use of 5-aminosalicylates in Crohn's disease patients^[63].

CONSIDERATION 5

Does non-compliance contribute to insufficient efficacy of mesalazine in maintenance therapy?

Another often overlooked issue in therapeutic efficacy is lack of compliance with therapeutic regimens. This problem has been recognized as a pitfall in conducting IBD maintenance therapy trials as early as 1982^[68]. Although reported compliance in clinical trials is usually in excess of 90%, such high levels of compliance are not necessarily continued in everyday practice. Indeed, a high rate of non-compliance up to 50%, has been reported in IBD-patients^[68-70] with a significant impact on treatment outcome which in UC at least is the most important predictor for relapse^[71]. Although medication compliance is generally good in acute disease, compliance rates in maintenance therapy decrease considerably once remission is achieved. The interpretation of maintenance studies without measurements of drug levels may therefore be difficult^[68]. One of the key risk factors for non-compliance is the number of pills and multiple medications, a risk factor that is common in IBD patients, and in particular in those taking high dosages of mesalazine in multiple dosing regimens^[70]. Reduction of the number of dosages, preferably with patient friendly formulations such as granules, without decreasing the dosage would be expected to improve the outcome of mesalazine therapy, particularly during maintenance therapy^[72].

CONSIDERATION 6

What are the safety considerations for mesalazine versus SASP?

The short-term use of mesalazine is perceived to be relatively safe^[73]. However, specifically olsalazine has been shown to induce diarrhoea in up to 17% of treated patients, probably induced by the release-profile modifying azo-bond which is also used in balsalazide and SASP, the latter two showing similar prosecretory effects in elegant *in vitro* studies^[74]. To estimate the more severe potential risks of mesalazine, most data are obtained from case reports concerning adverse events that have been published, especially relating to renal damage^[75-79] and pancreatitis^[76,80-84], both are idiosyncratic phenomena^[85]. Interestingly, 4-ASA enemas may be used when 5-ASA-induced pancreatitis occurs^[86]. Predictably, SASP containing 5-aminosalicylate, has also been associated with pancreatitis^[83,87], nephrotic syndrome^[88,89], and many other

detrimental events. The latter is reportedly associated with the sulfa component of SASP^[90,91]. In a recent report on the usage of SASP and mesalazine for ≥ 5 years in nearly 700 patients, side effects are reported most frequent in SASP-treated patients (20% *vs* 6.5%)^[92]. Evaluation of the number of prescriptions *versus* the number of central adverse events has ascribed superior safety to SASP^[9]. The methodology of this observation remains controversial^[93-95]. For short term therapy, mesalazine is widely perceived to be better tolerated than SASP, as has been measured by several methods^[73,92]. Moreover, mesalazine is a good alternative when SASP has to be withdrawn due to adverse events^[96]. In addition, other adverse events occur less commonly, or are less reported, a known flaw in epidemiological data obtained from spontaneous reporting. Therefore, many of the well-known adverse events ascribed to SASP are expected to be underreported^[95]. Overall, mesalazine is a safe drug, but its use bears a small risk for idiosyncratic renal damage and pancreatitis^[10,97-99].

CONSIDERATION 7

Should off-label use of mesalazine be considered?

Fertility, pregnancy and nursery: Conception and pregnancy are common events in the cohort of IBD patients, owing to the fact that many patients with IBD are of child-bearing age without diminished fertility, although SASP and anecdotically mesalazine have been associated with reversible, decreased male fertility^[100,101]. Ideally, conception and pregnancy take place during periods of IBD remission, without use of medication^[100,102,103]. However, this is not always feasible. Of note is that the progression of pregnancy and foetal development are more endangered by active, insufficiently treated IBD, than by the majority of pharmacological agents^[102,104]. Many drugs including mesalazine, that are used for IBD may cross the placenta^[65,105]. Therefore, toxicity and teratogenicity cannot be ruled out completely. However, the safety of mesalazine is very well documented^[103,105-110], although the safety of oral dosages above 3 g mesalazine per day during gestation has not been documented^[105]. In addition, concerns about the rate of stillbirth remain, although this may be due to activity of the disease^[110]. One incidence of renal affection in uteri in a foetus where the mother received 4 g mesalazine/day has been reported^[111]. In addition, the topical use of mesalazine in enemas appears to be safe^[112]. In contrast, SASP is associated with several congenital abnormalities. Although causality has not been proven, the concomitant use of folic acid is recommended^[113-115]. Pregnancy outcome in patients using mesalazine is equivalent to that in the non-IBD population^[102,103,105,109].

Lactation is not considered to be a contraindication for mesalazine use, although minor concentrations of mesalazine have been detected in breast milk^[116]. One case of diarrhoea in a breast-fed child of a 5-aminosalicylate treated mother has been reported^[117] and cerebral thrombosis has been recently reported in the child of a breast-feeding mother on mesalazine therapy^[118]. However, it is uncertain whether mesalazine contributes to the latter

condition.

Paediatric use of mesalazine: The incidence of IBD in children appears to rise in Eastern and Western countries^[119-122]. However, not all authors agree^[123]. Although the medical approach to IBD in children is largely similar to that of adults, its treatment aims differ from the adult population^[124,125]. Mesalazine may be used in mild to moderate or severe UC, alone or in combination with steroids^[125] and dosages in children above 12 years of age are similar to those of adults. Therapy for younger children is usually 20-50 mg mesalazine per kilogram bodyweight given in two to three separate dosages per day^[126]. The pharmacokinetic profile of mesalazine pellets is comparable to that for adults in these young patients^[127]. Maintenance therapy is habitually half that dose with a minimum of 750 mg mesalazine daily. The incidence of adverse events in children is similar to that observed in adults, although rare observations such as IBD-mimicking^[128] and pericarditis^[129] have been reported. In a paediatric study comparing SASP with mesalazine, the majority of patients prefer mesalazine, due to its superior properties regarding ease and frequency of administration and its better safety profile^[130]. The problems regarding acceptance of the disease and its treatment in this patient group supports mesalazine use over SASP^[130,131]. In contrast to treatment in adults, paediatricians tend to use mesalazine in non-stenotizing CD and if necessary, concomitant enteral nutritional therapy can be used in active disease or as a maintenance therapy^[127,132]. However, none of these indications has been subjected to large controlled trials in children.

Chemoprevention of IBD-related colonic cancer: Traditionally UC and more recently CD have been associated with enteral adenocarcinoma, although the risk appears to be limited to patients with chronic inflammation^[133,134]. Interestingly, several studies and reviews refer to potential chemoprotective properties of mesalazine moieties in prevention of this type of cancer^[18,19,135-139], similar to the alleged chemoprotective properties of acetylsalicylic acid, although the latter remains contraindicated in patients with IBD. Laboratory and other findings support the hypothesis of mesalazine as a chemoprotective agent^[138]. These chemopreventive properties include selectively inducing apoptosis in colorectal cancer (CRC) cells and stabilising effects on micro-satellites^[139]. In addition, the incidence of CRC has been demonstrated to be reduced in a case-control study (odds ratio 0.19, 95% confidence interval: 0.06%-0.61%) if patients use mesalazine doses above 1.2 g daily^[137]. Nevertheless, it could be argued that the decreasing relative risk for development of colonic carcinoma in patients with IBD is related to successful therapy of chronic active disease *per se*, and is thus unrelated to mesalazine therapy^[27,138]. In short, prospective and comparative data are lacking, but the indication for mesalazine as a chemopreventive agent looks promising, as recently concluded in a meta-analysis^[140].

CONSIDERATION 8

Does mesalazine have a role in combination therapy?

Concomitant use of mesalazine formulations may be beneficial, as its efficacy seems related to intraluminal

concentrations. Combination therapy of oral and rectal mesalazine has been investigated. Interestingly, higher mucosal concentrations of mesalazine^[27] have been associated with the decreased relapse rates but not with higher remission rates^[141]. Prior studies have reported that earlier remission can be achieved using combination therapy in left-sided UC^[142], and that a longer duration of remission has been observed when enemas are combined with low oral dosages of mesalazine^[143]. In addition, recent studies have also demonstrated the benefits of combining high-dose oral mesalazine with topical therapy in terms of remission and improvement rates in patients with UC^[52], and protection against increase of disease extent^[53]. Again, extensive well-designed dose-response trials are lacking and no final conclusion can be drawn from these sparse data.

Another interesting approach to the treatment of UC patients may be dual therapy with a combination of mesalazine and another inflammation-modifying drug such as butyrate^[144,145], fraxiparin^[146], or allopurinol^[147]. Also, preliminary studies investigating combination therapy with mesalazine and probiotics support their use^[148]. It should be noted, however, that as these reports are open-label studies, conclusions may not be as valid as those obtained from studies using classical approaches such as increasing mesalazine dosage or switching of type of drugs. Although the combination of mesalazine and steroids may, theoretically, have synergistic effects, this concept has yet to be substantiated by clinical trials, although for topical therapy, the combination of beclomethasone and mesalazine has been proved beneficial in a small open-label study of patients with mesalazine-refractory ulcerative proctitis^[149]. The combination of azathioprine (a potent immunosuppressive drug) with mesalazine (a milder agent) seems counter-intuitive. Proper studies are lacking once again, although one study has suggested that mesalazine may interfere with azathioprine metabolism, inducing a higher concentration of supposedly active metabolites, such as 6-thioguaninenucleotides^[150]. After 25 years of mesalazine use, it is clear that the value of combination therapy, whether beneficial or detrimental, remains to be fully elucidated.

SUMMARY

Decisions regarding treatment options for IBD must be carefully weighed following a careful benefit-risk analysis. The immediate goal of controlling active diseases must be balanced against the long-term goal of keeping patients asymptomatic on a therapy with acceptable toxicity. Large prospective and retrospective cohorts demonstrate that mesalazine is a safe drug, although adverse events may be seen in a minority of patients. Overall, in UC, mesalazine is beneficial in mild to moderate active diseases^[31,151-153]. Maintenance therapy with mesalazine is also well documented^[151], although it remains contentious as to which dosage and dosing frequency are optimal. With respect to a high compliance and good therapeutic success, the combination of high dose and low frequency is ideal and mesalazine preparations which can provide this are optimal. Indeed, preliminary studies support this type of therapeutic regimen although further studies are

needed to confirm these findings^[154,155]. Topical therapy is safe and effective and can be used to reduce systemic concentrations of mesalazine or its methylated metabolite, particularly in those prone to develop adverse events^[43]. The alleged potential of mesalazine therapy in CD requires further clarification, but the use of mesalazine delivered in microgranules postoperatively including small bowel CD only, and SASP in colonic disease, is scientifically corroborated^[56,58,61]. The limited data available support the use of the low toxicity mesalazine agents in children. The use of mesalazine in pregnancy and during breast-feeding, indicates that mesalazine is very likely to be safe. Preliminary studies suggest that 5-aminosalicylate also plays a role as a chemoprotective agent in reducing the risk of developing colorectal cancer, although further studies are needed to confirm this effect. The combination of various inflammation-modifying drugs with mesalazine is a sparsely investigated field, but initial data are encouraging.

Overall, mesalazine is a safe and effective drug with a pivotal role in UC patients and a limited role in CD patients. Although clinical superiority in comparison with SASP has yet to be proven, the superior safety profile and pharmacokinetic characteristics of mesalazines definitely advocate their use as the treatment of choice when treatment with 5-ASAs is indicated.

Abstract

Pseudomyxoma peritonei (PMP) is a rare disease. It refers to a progressive disease process within the peritoneum which originates from the appendix or ovaries and is characterised by the production of copious amounts of mucinous fluid resulting in a "jelly belly". If untreated the condition is fatal. The traditional approach to PMP is based on repeated surgical debulking procedures, often associated with intraperitoneal or systemic chemotherapy. The natural history of this disease has been drastically modified since the introduction of a new surgical approach defined as a peritonectomy procedure. This paper is to review the literature on this treatment strategy.

INTRODUCTION

Pseudomyxoma peritonei (PMP) is a rare disease^[1]. It refers to a progressive disease process within the peritoneum which originates from the appendix or ovaries and is characterised by the production of copious amounts of mucinous fluid resulting in a "jelly belly". If untreated the condition is fatal. With the progress of immunohistochemistry, PMP should be considered as a border line malignant disease because of its inevitable persistence and progression. PMP is an indolent disease, which is most prevalent in women aged between 50 and

70 years. The cases of ovarian origin outnumber those of appendiceal origin. A large proportion of ovarian tumours are secondary to appendiceal tumours. More women appear to suffer from this condition than men. However, the appendix is the primary source of most PMPs, which may then spread to other sites like the ovaries^[2]. Clinically, although painless, deterioration of general health begins long before diagnosis. Acute presentation during advanced stage of the disease is common. The main complaints are abdominal pain and distension besides a host of non-specific symptoms. Inflammatory changes associated with peritoneal tumour implants can lead to fistula formation and adhesions, which in turn can cause intermittent or chronic partial bowel obstruction. Localized masses are frequently present in PMP of appendiceal origin. Surprisingly, signs and symptoms of cancer such as cachexia are rare. The characteristic PMP dissemination within the peritoneal cavity is defined by Sugarbaker^[3] as a complete redistribution phenomenon, indicating a complete and sequential invasion of the peritoneal cavity with large tumor volume localization at predetermined anatomical sites and minimal invasion at other sites. The modalities of dissemination are strongly influenced by the histopathology of the primary tumor^[4,5]. The traditional approach to PMP is based on repeated surgical debulking procedures, often associated with intraperitoneal or systemic chemotherapy. The natural history of this disease has been drastically modified since the introduction of a new surgical approach, proposed by Sugarbaker^[3] who defines it as a peritonectomy procedure consisting of the complete removal of the tumor. Surgery is followed by local drug administration aimed at eliminating microscopic and/or minimal residual disease left in the abdominal cavity following surgical manipulations^[6]. The additional effects of hyperthermia, through the use of a special pump, increase local tissue drug concentration and consequently antitumour drug activity^[7]. This technique has been defined as hyperthermic intraperitoneal chemotherapy (HIPEC). These methods can achieve satisfactory results in patients with PMP^[8-12]. We here review the application of peritonectomy and hyperthermic intraperitoneal chemotherapy in the treatment of PMP.

PERITONECTOMY PROCEDURE

This fundamental technique requires the removal and stripping of all tumour tissues involving the parietal and visceral peritoneum. Small cancer deposits on the visceral peritoneum, especially on the surface of tubular structures, are individually electroevaporated. Large tumour nodules

in the small bowel must be resected and all visible tumors must be removed to maximize the benefits of peri-operative intraperitoneal chemotherapy. The surgical technique has been described in detail previously and is based on the Sugarbaker principles of peritonectomy^[13,14] with a few modifications. In brief, peritonectomy procedures are performed on the basis of disease extension by the following steps: (1) greater omentectomy and right parietal peritonectomy with or without right colon resection, (2) pelvic peritonectomy with or without sigmoid colon resection as well as hysterectomy and bilateral salpingo-oophorectomy, (3) lesser omentectomy and dissection of the duodenal-hepatic ligament with or without antrectomy and cholecystectomy, (4) right upper quadrant peritonectomy and glissonian capsule resection, (5) left upper quadrant peritonectomy and left parietal peritonectomy with or without splenectomy, and (6) other intestinal resection and/or abdominal mass resection.

HIPEC

Intraperitoneal chemotherapy is only required to eradicate microscopic residual disease for its complete success. The pharmacokinetic advantage of the intraperitoneal route of drug administration is not compromised when used as a planned part of a surgical procedure. The high molecular weight of chemotherapy agents and their water solubility (hydrophilic) cause a prolonged retention in the peritoneal space. Also, use of selected drugs under hyperthermic conditions can increase cytotoxicity on the peritoneal surface but not systemic (bone marrow) toxicity. Hyperthermia can improve drug penetration into tumor tissue and optimize the dose intensity of chemotherapy on the abdominal and pelvic surfaces. The combined use of hyperthermia and intraperitoneal chemotherapy enhances the cytotoxicity of chemotherapeutic agents and increases tissue penetration by chemotherapy in cancerous tissue as compared to normal tissue. HIPEC is performed after completion of the anastomosis. The closed-abdomen technique is used for all patients. Two inflow catheters are inserted, one in the right subphrenic space, the other deep in the pelvic cavity. Two outflow catheters are inserted, one in the left subphrenic space, the other more superficially in the pelvic cavity. Six thermocouples are used to continuously monitor the inflow, outflow, and intraperitoneal cavity temperatures. Temporary abdominal skin closure is carried out following a tight continuous nylon stitch. The catheters are then connected to an extracorporeal perfusion circuit. The intraperitoneal temperature is maintained at 42.5°C during the perfusion. Different chemotherapeutic agents are used depending on the tumor histological characteristics. Intraperitoneal chemotherapy regimens are as follows: (1) cisplatin (CDDP; 25 mg/m² per liter) and mitomycin C (MMC; 3.3 mg/m² per liter)^[15] for pseudomyxoma peritonei and colorectal and gastric carcinomatosis, (2) CDDP (43 mg/L of perfusate) and doxorubicin (15.25 mg/L of perfusate)^[16,17] for mesothelioma, ovarian carcinomatosis, and sarcomatosis. The perfusate is then instilled into the peritoneal cavity at a mean flow rate of 600 mL/min.

CURRENT STRATEGY FOR COMBINED TREATMENT

Peritonectomy in combination with hyperthermic intraperitoneal chemotherapy is divided into four major steps: electrosurgery for tumour resection and peritonectomy, hyperthermic intraperitoneal chemotherapy, reconstruction, and early post-operative intraperitoneal chemotherapy. Dedicated instruments and specific surgical techniques are essential to achieve optimum results^[18-22].

Intra-abdominal dissection is facilitated by electroevaporative surgery using a 0.3 cm ball-tipped diathermy. The electrosurgical generator is set at a very high voltage between 200 MW and 250 MW. A maximal pure cut that evaporates the tissues on contact is used for dissection, which minimizes blood loss from small vessels up to 1.5 mm in diameter. Larger vessels are electrocoagulated or ligated in continuity and divided. Heat damage can be reduced by a frequent intermittent saline irrigation at the site of dissection. Heat necrosis at the tumour's margin of resection could reduce the likelihood of cancer dissemination and local recurrence.

The selection of agents for peri-operative intraperitoneal chemotherapy is based on the drug's ability to produce a cytotoxic effect over a short time period and to show heat synergy. Mitomycin C, doxorubicin and cisplatin have a slow clearance from the peritoneal cavity. The effects of these agents are potentiated by hyperthermia to achieve a maximum cancer cell kill. Intraoperative intraperitoneal chemotherapy can absorb 75%-90% of mitomycin C and cisplatin within the first hour. Despite the greatly enhanced drug cytotoxicity because of high concentrations and heat synergy, the technique is effective only in treating small volume peritoneal disease. The use of early post-operative intraperitoneal chemotherapy may be restricted due to the co-morbidity state of patients.

EFFECTIVENESS OF PERITONECTOMY AND HIPEC

Several prospective studies have shown promising results when peritonectomy and HIPEC were used to treat peritoneal carcinomatosis^[23-26]. Verwaal *et al*^[27] demonstrated that this new treatment strategy can prolong the survival time of patients with carcinomatosis of colorectal origin. The institution that has a program to treat peritoneal carcinomatosis requires not only highly specialized human resources, but also complex technological facilities to perform the peritonectomy plus HIPEC^[28], which minimizes treatment-related morbidity and mortality and maximizes results in terms of survival and quality of life. In this context, identification of risk factors for postoperative complications is of major concern. Small-bowel perforations and anastomotic leaks are the most common complications associated with a surgical procedure unusually involving a long operative time, numerous and complex resections, peritoneal stripping, and a heated intraperitoneal chemotherapy component. Bryant *et al*^[29] showed that patients with PMP may benefit

from the Sugarbaker procedure and have an estimated 5-year and 10-year survival of approximately 50% and 18%, respectively. In contrast, the 2-year, 3-year and 10-year survival rates of patients after HIPEC are 90%, 60%-90%, and 60%-68%, respectively. The percentage of patients with no evidence of disease at the end of follow-up after the Sugarbaker procedure ranges from 41% to 82%. Similarly, the percentage of patients alive with disease at the end of follow-up after HIPEC ranges from 9% to 35%. Mortality of the disease ranges from 2% to 31% after the Sugarbaker procedure.

DISCUSSION

Pseudomyxoma peritonei is a rare disease which is characterized by a large amount of mucinous ascites with peritoneal and omental implants. A clear understanding of its natural history has been hampered by the fact that tumors of various sites under the heading of PMP have significantly different biologic behaviours leading to dilemma in diagnosis and management. PMP is referred to an extensive mucinous accumulation within the peritoneal cavity associated with a malignant cystic neoplasm arising commonly from the appendix or ovary. Other sites include pancreas, bile duct, colon, gall bladder and urachus. No controlled clinical studies have been conducted on PMP because of its rarity (1 case/million per year), and up until now, treatment has been directed at palliation and delaying the lethal outcome that seems inevitable for these patients. Peritonectomy and hyperthermic intraperitoneal chemotherapy can prolong the survival of these patients. Peritonectomy is a complex approach and leads to postoperative complications. This technique is also employed in the treatment of other malignancies, such as gastric, ovarian, and colon cancer and peritoneal mesothelioma, in which peritoneal dissemination remains an important cause of surgical treatment failure^[30-31]. Understanding the treatment and mastery of surgical skills to manage the peritoneal surface spread of cancer can prolong the survival of selected patients. Combination of this treatment strategy with proper patient selection has reduced the mortality and morbidity. The success of peritonectomy and hyperthermic intraperitoneal chemotherapy depends on a long-term dedication to achieve the full potential of a curative outcome.

In conclusion, peritonectomy in combination with hyperthermic intraperitoneal chemotherapy is a feasible treatment for pseudomyxoma peritonei.

Abstract

AIM: To investigate the behaviour of total plasma homocysteine (tHcy) and its most common genetic determinant defect, the methylenetetrahydrofolate reductase C677T (C677TMTHFR) polymorphism in patients with early stage colorectal carcinoma.

METHODS: tHcy was quantified by Abbott IMx immunoassay; screening for C677TMTHFR substitution was performed by PCR and restriction analysis.

RESULTS: The frequency of the C/T and T/T genotypes of the C677TMTHFR gene polymorphism did not differ between the groups. The mean tHcy was statistically higher in cancer patients than in control subjects carrying the same C/C or C/T genotype, whereas there was no difference in the T/T homozygous carriers of the two groups. tHcy was significantly higher in the T/T homozygous carriers than in C/C and C/T genotype carriers.

CONCLUSION: The statistically significant increase of tHcy observed in C/C and C/T genotype carriers among our cancer patients is related to substrate consumption dependent on the tumor cell proliferation rate, whereas the tHcy increase observed in T/T genotype carriers of both groups probably depends on the enzymatic deficit of the homocysteine conversion to methionine and/or on the folate deficiency.

INTRODUCTION

Homocysteine, a sulfur-containing amino acid produced by the adenylation and subsequent demethylation of dietary methionine, is an essential intermediate in folate metabolism. Two enzymes and three vitamins play a key role in the regulation of circulating homocysteine levels. Of the enzymes, cystathionine- β -synthase controls the breakdown of homocysteine to cystathionine in the transsulfuration pathway, while methylene tetrahydrofolate reductase (MTHFR) is involved in the remethylation pathway, in which homocysteine is converted back to methionine. Homocysteine is present in human plasma in four forms: 1% as free thiol, 20%-30% as disulfur with itself and others thiols, 70%-80% as disulphide bound to plasma proteins. The sum of all the forms of homocysteine existing in plasma is referred as "total plasma homocysteine" (tHcy)^[1,2].

Folic acid, vitamin B₆ and vitamin B₁₂ are essential cofactors in homocysteine metabolism and a lack of them due to a deficient diet or disease can produce elevated plasma homocysteine^[2,3]. Increased homocysteine concentrations are thought to directly affect carcinogenesis by diminishing DNA methylation in critical tissues through a simultaneous increase in intracellular S-adenosylhomocysteine^[4]. Inclusion of homocysteine in the assessment of folate in carcinogenesis is important because we may deal with an issue of inadequate folate metabolism, which is indicated by the reduced function of enzymes involved in homocysteine metabolism, rather than merely a state of folate deficiency. However, to our knowledge, only one study has reported that there is no significant positive association between serum homocysteine and colorectal cancer^[5]. Despite the substantial amount of published data related to folate and colorectal carcinogenesis, the mechanisms responsible for this effect remain unclear.

Plausible mechanisms described in the literature include the role of folate in the metabolism of one-carbon units, such as methyl, methylene, and formyl groups involved in various substrates and a variety of enzymatic reactions that are intimately related to DNA and RNA synthesis and cell proliferation^[4,6]. It was recently proposed that an imbalance between biological methylation and nucleotide synthesis is a key to clarifying the mechanisms responsible for the role of folate in carcinogenesis^[4-7]. In addition, lower folate intakes, compared with higher supplements, have been shown to be associated with a significantly higher risk of *Ki-ras* mutations (prominent in colorectal neoplasia) in adenomas^[8] and carcinomas^[9].

Homocysteine metabolism has been shown to be dependent on genetic factors as well as acquired factors^[10]. Of the gene defects, the most common is the C-to-T substitution at nucleotide 677 in the coding region of the gene for MTHFR, the so-called thermolabile variant. There are an elevated homocysteine concentration and a decreased plasma folate concentration in the homozygous mutant genotype of C677TMTHFR gene. An adequate folate intake is thus required to decrease the elevated homocysteine concentration^[11,12]. The C677TMTHFR polymorphism might modulate the risk of developing neoplasia through its effects on folate metabolism. It regulates the production of thymidylate and purines for DNA synthesis and supply of methyl groups for the synthesis of methionine and DNA methylation^[4]. It has also been proposed that the protective effect of folate against the risk of colon cancer is stronger among subjects with a positive family history of colorectal cancer than among those without such a history^[13]. This study was to investigate the pattern of tHcy levels and the C677TMTHFR polymorphism in a group of neoplastic patients with non metastatic colorectal cancer, who were eligible for curative surgery, by determining tHcy levels in neoplastic patients and then clarifying whether this was due to a genetic enzymatic defect or was a consequence of cancer cell proliferation if the levels were increased.

MATERIALS AND METHODS

Subjects

Ninety-three consecutive colorectal carcinoma patients (51 men and 42 women, mean age 62 years, range 48-78 years), admitted to our surgery department for elective and curative surgery, were enrolled in the study. The criteria for exclusion from the study were as follows: malnutrition, serum creatinine level > 13 mg/L, assumption of vitamin supplements or other drugs which might interfere with plasma tHcy levels, pernicious anaemia, skin diseases, heavy smoking, and alcohol abuse. The subsite distribution of the 93 colorectal cancers showed 19 in right colon, 6 in transverse colon, 45 in left colon, and 23 in rectum. Diagnosis of adenocarcinoma was confirmed in all patients by histology and cytologic investigations. TNM stages of resected tumors were as follows: stage 1 = 6 cases (28%), stage 2 = 25 cases (27%) and stage 3 = 42 cases (45%). Histopathological grading of adenocarcinoma was: 2% well differentiated, 81% moderately differentiated, or 17% poorly differentiated (Table 1). The control group included

Table 1 Characteristics of control subjects and cancer patients

Group	Sex (M/F)	Mean age \pm SD (yr) (range)	TNM staging
Controls	100 (56/44)	64 \pm 6 (46-79)	//
Cancer patients	93 (51/42)	62 \pm 8 (48-78)	T ₁₋₃ , N ₀₋₂ , M ₀

100 healthy individuals (56 men and 44 women, mean age 64 years, range 46-79 years), enrolled with the same exclusion criteria as the cancer patients, selected from the hospital staff and people attending our out-patient surgery (Table 1). The study was approved by the local ethical committee and informed consent was obtained from all participants.

Homocysteine determination

Blood samples were collected from the antecubital vein, after overnight fasting. They were drawn into vacuum tubes containing K3-EDTA, immediately put on ice and centrifuged at 2200 r/min for 20 min at 4°C. The supernatant platelet-poor plasma was stored at -80°C until assay. Total Hcy was quantified using the fluorescence polarization immunoassay (FPIA) on the IMx analyzer from Abbott Laboratories (Abbott Park, IL, USA). The Imx Hcy assay is based on reduction of the plasma samples with dithiothreitol and subsequent conversion of free Hcy to S-adenosyl homocysteine by hydrolase in the presence of added adenosine. The sample and the tracer compete in binding to the monoclonal antibody. This reaction is followed by detection of S-adenosyl homocysteine by a fluorescence polarization immunoassay. The concentration of tHcy in plasma is inversely related to the intensity of the polarized light. The within-run CV for fasting tHcy was 2.2%-1.5% and the between-run CV was 2.2%-3.0%^[14].

Genotyping of C677T MTHFR mutation

Genomic DNA was isolated from peripheral blood leukocytes. Screening for the MTHFR 677C→T substitution was performed by polymerase chain reaction (PCR) of genomic DNA, followed by *Hinf* I digestion and agarose gel electrophoresis. The region surrounding position 677 in the MTHFR gene was amplified by PCR technique, and the alleles were identified through restriction enzyme digestion as previously described^[15]. PCR reactions of 15 μ L contained 30 ng template genomic DNA and 1.5 U AmpliTaqGold DNA polymerase and the following concentrations of reagents: 0.16 μ mol/L of each oligonucleotide primer, 1.6 mol/L of each dNTP, 15 mmol/L Tris-HCl (pH 8.0), 50 mmol/L KCl and 1.5 mmol/L MgCl₂. Verification of amplification was achieved by comparing the 173-bp products with molecular weight standards in a gel made from a combination of 3% BibcoBRL ultrapure agarose and 1.5% NuSieve GTG agarose run for 1 h at 150 V and visualized with ethidium bromide. Reaction products (5 μ L) were digested for 1 h at 37°C with 2.5 U of *Hinf* I in buffer at pH 7.9 of 10 mmol/L Tris-HCl, 10 mmol/L MgCl₂, 50 mmol/L NaCl and 1 mmol/L dithiothreitol. Genotypes were determined by analysis of restriction patterns after electrophoresis on

Table 2 tHcy plasma levels according to C677T MTHFR polymorphism [mean \pm SD (μ mol/L) (*n*)]

Group (<i>n</i>)	CC genotype	CT genotype	TT genotype
Control subjects (100)	9.01 \pm 2.76 (30)	9.71 \pm 2.34 (51)	17.56 \pm 10.81 ^{d,f} (19)
Cancer patients (93)	11.82 \pm 3.09 ^a (32)	12.45 \pm 4.46 ^b (40)	16.88 \pm 9.25 ^{d,f} (21)

^a*P* < 0.05, ^b*P* < 0.01 vs control; ^d*P* < 0.01 TT vs CC; ^f*P* < 0.01 TT vs CT.

Table 3 tHcy plasma levels according to CC + CT genotype of C677T MTHFR polymorphism [mean \pm SD (μ mol/L) (*n*)]

Group	(CC + CT) genotype
Control subjects	9.45 \pm 2.51 (81)
Cancer patients	12.17 \pm 3.90 ^b (72)

^b*P* < 0.002 vs control.

agarose gels (as above) with T at position 677, resulting in fragments of 125 and 48 bp in length and with C at position 677, resulting in a single fragment of 173 bp. We referred to the C/C genotype as wild-type, the C/T genotype as the heterozygous variant and the T/T genotype as the homozygous variant.

Statistical analysis

Normally distributed continuous variables were analysed using the Student's *t* test. To assess the normal distribution we applied the Kolmogorov-Smirnov test on each sample data. Non-normally distributed variables were analysed using the Mann-Whitney test. We used the χ^2 test for group comparison frequencies. Continuous variables were compared by Student's *t* test or the ANOVA when multiple statistical hypotheses were assumed. All *P* values were two-sided. A significance level of 95% (*P* < 0.05) was assumed. Statistical analysis was performed by SPSS (v. 11.0).

RESULTS

In the control group there were 51 heterozygous and 19 homozygous carriers of the C677T MTHFR polymorphism (Table 2), with a prevalence of 51% of the C/T genotype and 19% of the T/T genotype that corresponded to a T allele frequency of 44.5%. Among the colorectal cancer group we found 40 heterozygous and 21 homozygous carriers of the C677T MTHFR polymorphism, with a prevalence of 45.5% of the C/T genotype and 23.8% of the T/T genotype that corresponded to a T allele frequency of 46.5%. The prevalence of both the genotypes (Table 2) like the frequency of the T allele was not statistically different between the groups.

When patients were subdivided according to cancer stage (regional *versus in situ*/localized), the prevalence of T/T genotype was 21.42% (9 cases) in stage 3 and 23.5% (12 cases) in stage 1/2, while the prevalence of T/T genotype according to cancer location (colon *versus* rectum) was 21.42% (15 cases) in colon and 26.08% (6 cases) in rectum. The prevalence of T/T genotype was not statistically different when both stage and location

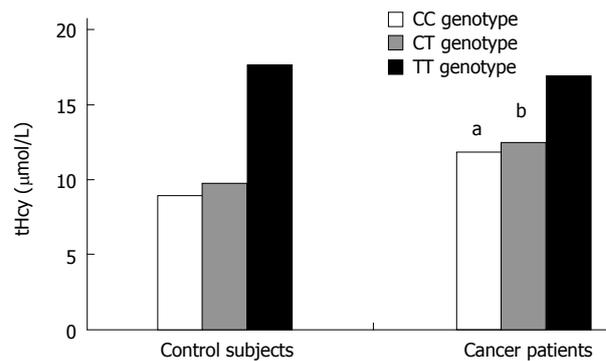

Figure 1 Mean tHcy plasma levels according to C677T MTHFR genotype, ^a*P* < 0.04, ^b*P* < 0.01 vs control.

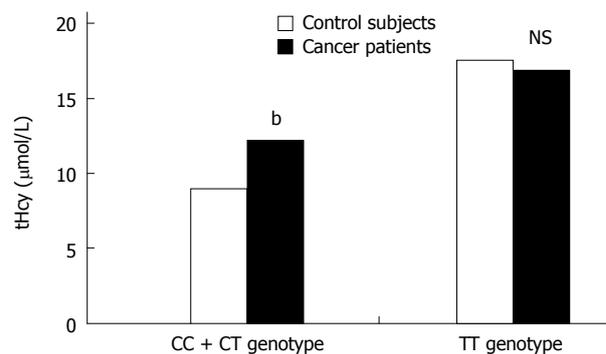

Figure 2 Mean tHcy plasma levels according to C677T MTHFR polymorphism, ^b*P* < 0.002 vs control; NS: Not significant.

were considered. The mean total Hcy level was statistically higher in cancer patients than in control subjects carrying the same C/C or C/T genotype (Table 2 and Figure 1, *P* < 0.04 and *P* < 0.01 respectively). In addition, when all the C/C and C/T carriers were considered together and the two study groups were compared, tHcy was still more significantly higher in the cancer group (12.17 \pm 3.90 vs 9.45 \pm 2.51, *P* < 0.002, Table 3, Figure 2). In contrast there was no difference in the mean total Hcy concentrations among the T/T genotype carriers of the two study groups (*P* = 0.6). In both groups tHcy was significantly higher in the T/T genotype than in the C/C and C/T genotypes, although there was no difference between the C/T and C/C genotype carriers (Table 2, Figure 2). Total plasma Hcy was not associated with tumor stage (regional *versus in situ*/localized) or location (colon *versus* rectum): 12.53 \pm 6.43 μ mol/L in colon, 13.82 \pm 6.08 μ mol/L in rectum, 12.62 \pm 5.21 μ mol/L in stage 3 and 12.97 \pm 7.15 μ mol/L in stages 1 and 2.

DISCUSSION

In our group of colorectal cancer patients the T allele frequency, like the prevalence of the C/T and T/T genotypes of the C677T MTHFR polymorphism, was similar to that in the control subjects, whereas the mean tHcy concentration was significantly increased in the cancer patients carrying the C/C or C/T genotype. This difference was even more evident when the C/C plus

C/T genotype carriers of each group were compared. This finding is difficult to explain because the increase of tHcy was not simply due to the decreased MTHFR enzyme activity, but rather due to a more complex disorder of folate metabolism, probably partly related to the methionine-dependency of the proliferation rate of colorectal tumor cells. It is well known that most malignant cells, including colon cancer cell lines in primary histoculture need methionine, but endogenous methionine conversion from homocysteine does not meet the increased metabolic demand of these cells^[16]. Insufficient methionine synthesis in cancer cells can result from a lack of reduced folate as a cofactor in the homocysteine 5-methyl-tetrahydrofolate methyltransferase reaction. In fact the reduced folates may be drained into other pathways that are enhanced in proliferating cells, such as the synthesis of purines and pyrimidines. As a consequence there is an increase of homocysteine in dividing cells, resulting in a greater egress of it from such cells. High tHcy levels may therefore be a phenotypic expression of malignancy, as well as a marker for cancer cell activity.

Serum concentration of homocysteine increases with folate deficiency because the metabolic disposal of homocysteine depends on a remethylation reaction in which N-5-methyltetrahydrofolate serves as a co-substrate with homocysteine^[17]. In practice, an elevation of this amino acid has been found to be a more sensitive indicator of cellular folate depletion than its blood folate concentrations^[18]. The importance of homocysteine concentration as a biological marker is highlighted by Kim *et al.*^[19], who found that blood folate and homocysteine are correlated with colonic mucosal folate concentration.

Since we did not measure plasma folic acid, vitamin B12 and B6 concentrations, if the increase of tHcy observed in our cancer patients is a consequence of nutritional deficiency or substrate consumption induced by active neoplastic proliferation remains unknown. Assuming that our cancer patients had the same nutritional habits as our control subjects, the hypothesis is that more active consumption of substrates is more likely secondary to the metabolism of one-carbon units related to DNA and RNA synthesis^[5-8].

According to previous reports regarding the Italian population^[20], we found a similar and increased prevalence of T/T genotype carriers, in both our cancer and control groups (21% and 22.4% respectively). The total Hcy concentration in these subgroups was similar both in cancer patients and in control subjects, suggesting that the T/T genotype has a stronger influence on tHcy concentration, thus overcoming the biochemical cancer effect.

It has been reported that the T/T genotype of the C677T MTHFR gene polymorphism is associated with a decreased risk of colorectal cancer^[21,22]. We can argue that in our subjects, both in the control and cancer groups, there is a depletion of folate. In the folate deficiency, the high activity of the enzyme or the C/C genotype may be disadvantageous because 5, 10-methylenetetrahydrofolate is converted and the thymidylate pool is depleted. Increased risk for T/T genotype *versus* C/C genotype would be seen in the folate-depleted situation if aberrant

DNA methylation is a primary mechanism, but no such increase has been observed^[23]. We have no data about serum folate, but the increase of total Hcy observed in our T/T genotype carriers may also be an index of low folate status, a condition that confers no protection against cancer risk, as reported by Ulvik *et al.*^[24]. Moreover, because the number of individuals carrying the T/T genotype in both our groups is low, it is possible to hypothesize that a modest influence of cancer on tHcy exists, although it was not shown by our data. Of note is that a previous study investigating a large cohort of Caucasian colorectal cancer cases and matched controls, reported that C677T MTHFR polymorphism is associated with total Hcy^[24]. It cannot be excluded that the difference found in our study may have been biased by the relatively small number of patients and controls with different genotypes. The relatively high SD value for T/T genotype carriers supports this possibility. The T/T genotype of the C677T MTHFR variant has less than one third of the functional activity of the normal MTHFR enzyme and is associated with reduced cellular folate and methionine levels, reduced cellular ratio of S-adenosylmethionine to S-adenosylhomocysteine, as well as elevated homocysteine levels^[25]. Based on Frosst's data, a normal C/C homozygote has 100% activity, a C/T homozygote approximately 65% activity, and a T/T homozygote approximately 30% activity^[26]. Finally, it is important to emphasise that hyperhomocysteinaemia is a well-known and independent risk factor for thrombosis^[27]. Moderately elevated levels of tHcy are associated with an increased risk of thrombosis, through mechanisms that are incompletely understood. In particular, there is evidence that hyperhomocysteinemia increases the risk of venous thromboembolism approximately two to four-folds^[28-30], contributing to the hypercoagulable state that characterises the malignant disease^[31].

In summary, the results of our study suggest that the modest but significant increase of plasma tHcy observed in the C/C and C/T genotype carriers in our cancer group, may be related to the methionine-dependent proliferation rate of colorectal cancer cells and moreover, may act as a permissive factor for thrombosis in the context of cancer thrombophilia. The tHcy increase observed in T/T genotype carriers in both groups, on the other hand, is probably dependent on the enzymatic deficit associated with the homocysteine conversion to methionine and/or the depletion of folate.

expressing cells were increased in *H pylori*-infection and correlated with epithelial apoptosis. Perforin-expressing cells were also increased in GU compared with *H pylori*-gastritis.

CONCLUSION: Epithelial apoptosis is increased in *H pylori*-infection and correlates to FasL- and perforin-expression by T cells. Expression of perforin is correlated with the tissue damage, and may represent the enhancement of a distinct cytotoxic pathway in GU. Increased expression of FasL not paralleled by Fas on T-cells and macrophages may indicate a reduced susceptibility to the Fas/FasL-mediated apoptosis of lymphoid cells in *H pylori*-infection.

Abstract

AIM: To analyze the level of apoptosis in different mucosal compartments and the differential expression of Fas/Fas-ligand and perforin in *H pylori*-associated gastric ulcer.

METHODS: Antral specimens from patients with *H pylori*-related active gastric ulcer (GU), *H pylori*-related gastritis, and non-infected controls were analysed for densities and distribution of apoptotic cells determined by the TdT-mediated dUDP-biotin nick-end-labelling method. GU patients were submitted to eradication therapy with follow-up biopsy after 60 d. Fas, FasL, and perforin-expressing cells were assessed by immunoperoxidase, and with anti-CD3, anti-CD20 and anti-CD68 by double immunofluorescence and confocal microscopy. Quantitative analysis was performed using a computer-assisted image analyser.

RESULTS: *H pylori*-infected antrum showed greater surface epithelial apoptosis which decreased after eradication therapy. In the lamina propria, higher rates of mononuclear cell apoptosis were observed in *H pylori*-gastritis. Co-expression of Fas with T-cell and macrophage markers was reduced in GU. FasL- and perforin-

INTRODUCTION

Infection with *H pylori* induces chronic gastritis in virtually all infected hosts and it has been implicated as the major etiologic factor in peptic ulcer disease, chronic atrophic gastritis^[1,2], gastric carcinoma, and gastric lymphoma^[3,4]. An important feature of *H pylori* infection relies on the fact that the gastric mucosal immune response is not capable of eliminating the organism, and the infection persists indefinitely^[5]. The local inflammatory process is constituted by immunocompetent cells, including a large number of T cells in the lamina propria and an increased expression of T-helper type 1 (Th1) proinflammatory cytokines^[6,7].

H pylori has been reported to increase apoptosis of gastric epithelial cells which has been associated with gastric atrophy and also peptic ulcer^[8]. Although the mechanisms by which the infection with *H pylori* may

result in abnormal apoptosis are still unclear, there is some evidence indicating a major role for the host immune response. Results from an *in vitro* study demonstrated that interferon gamma (IFN-gamma) increases the attachment of the bacteria as well as the induction of apoptosis in gastric epithelial cell lines exposed to *H pylori*^[9]. In another *in vitro* study, proinflammatory stimuli such as tumor necrosis factor alpha, IFN-gamma, and a receptor-activating CD95/APO-1/Fas antibody, were shown to potentiate *H pylori*-induced apoptosis both directly and indirectly through sensitization of epithelial cells^[10].

Alterations in apoptosis have been associated with the pathogenesis of diseases such as cancer, viral infections, autoimmunity^[11], and inflammatory bowel disease^[12,13]. The increased apoptosis of epithelial cells triggered by *H pylori* has been related to the enhancement of the Fas/Fas ligand signaling pathway in the gastric mucosa^[14,15]. Results from *in vitro* studies have demonstrated a possible role for the Fas-mediated cytotoxicity of activated gastric T-cell lines in the apoptosis of gastric epithelial cells during the infection with *H pylori*^[16,17].

Apoptosis mediated by cytotoxic T lymphocytes (CTLs) is thought to constitute an essential mechanism of recognition of auto-reactive cells and of target-cell destruction. Although increased gastric epithelial apoptosis has been associated with the expansion of mucosal T-helper type 1 cells, the role of T-cell mediated cytotoxicity in that process is still unclear. Therefore, this study was designed to evaluate the rate of apoptosis in different mucosal compartments of *H pylori*-associated gastric ulcer disease. In addition, distinct pathways of cytotoxicity were assessed through the differential expression of Fas and Fas ligand, and of perforin in the gastric mucosa of patients in different clinical conditions including after eradication therapy.

MATERIALS AND METHODS

Patients

Fifteen consecutive patients with *H pylori*-positive active gastric peptic ulcers, and 14 *H pylori*-positive and 14 *H pylori*-negative patients both with endoscopically normal gastroduodenal mucosa were enrolled in this study. None of the patients studied had received any antibiotics, nonsteroidal anti-inflammatory drugs, bismuth compounds, H₂-receptor antagonists, proton pump inhibitors, anticancer drugs, or corticosteroids at least 6 mo before the beginning of the study. *H pylori* infection was confirmed by positive results in both rapid urease test and histological examination, while *H pylori*-negative patients were defined by the absence of bacteria in both tests.

Patients with gastric ulcers consisted of 7 women and 8 men, with a mean age of 44.4 years (range 18-71 years). All peptic ulcers were located in the antrum and lesions were at the Sakita A1-A2 stages. After biopsy specimens were obtained, all patients were submitted to eradication therapy consisting of a 2 wk course of lansoprazole 30 mg, amoxicillin 1 g, and clarithromycin 500 mg given twice daily. Control endoscopy with gastric biopsies was undertaken at least 60 d after completion of eradication therapy.

As controls, biopsy samples were obtained from

benign normal mucosa of consecutive patients undergoing diagnostic upper endoscopy for various clinical indications. Patients with *H pylori*-positive gastritis (without peptic ulcer) comprised 10 women and 4 men, with a mean age of 33.9 years (range: 20-58 years). The group of *H pylori*-negative patients consisted of 5 women and 9 men, with a mean age of 39.1 years (range: 20-63 years).

The study protocol was approved by the Ethical Committee of the University Hospital, Federal University of Rio de Janeiro, and informed consent was obtained from all patients.

Mucosal specimens

Gastric biopsy specimens were endoscopically obtained from the antrum (2 cm away from the pyloric ring) of all patients in the study. From patients with gastric ulcer biopsy samples were collected from the antrum both at the ulcer margins and at the opposite wall of the lesion.

Biopsy specimens were taken for urease test, histology, and immunohistochemical studies. One specimen was used for the urease test. Two specimens were fixed in 10% normal saline, embedded in paraffin, cut into 5 µm sections and stained with hematoxylin and eosin (HE) and with Giemsa for histopathological examination. Another two antral specimens were immediately covered with Tissue Tek O.C.T. compound (Miles Scientific Laboratories Ltd, Naperville, IL, USA) and snap frozen in isopentane in a liquid nitrogen bath. These specimens were subsequently stored at -80°C before processing, and cut into 5 µm sections in a cryostat maintained at -20°C. Tissue sections were mounted onto slides pre-treated with poly-L-lysine (Sigma Chemical Co., St Louis, MO, USA), air-dried and fixed for 10 min in acetone at room temperature.

Histologic analysis

Formalin-fixed gastric sections were stained with hematoxylin and eosin for the evaluation of gastritis and with Giemsa stain to detect *H pylori*. The histological assessment of inflammation was performed according to the updated Sidney system^[18]. Briefly, the parameters evaluated were inflammation (mononuclear leukocyte infiltration) and activity (polymorphonuclear neutrophil infiltration) of gastritis, density of *H pylori* colonization, atrophy, and intestinal metaplasia, which were graded as absent (0), mild (1), moderate (2), and severe (3), respectively.

Immunohistochemistry

For this set of experiments, frozen sections were used to characterize different cell subsets and for the study of apoptosis, which were performed by using the indirect immunoperoxidase technique.

Immunohistochemical staining was carried out using the following primary mouse monoclonal antibodies: anti-CD3 (1:50), anti-CD68 (1:50), anti-CD20 (1:50), anti-CD95/APO-1 (1:50) (Dako A/S, Glostrup, Denmark), anti-Fas ligand (1:1000), and anti-perforin (1:100) (Pharmin-gen, San Diego, CA, USA).

Briefly, frozen sections were immersed in 3% hydrogen peroxide in methanol for 10 min to block endogenous peroxidase activity. After being rinsed in phosphate buffered

saline (PBS) containing 0.5% Tween 20 for 10 min, tissue sections were incubated with non-immune horse serum for 30 min and, subsequently, with the respective monoclonal antibody in a humidified chamber overnight, at room temperature. Two sections from each sample were incubated with either PBS alone or mouse monoclonal IgG1 (concentration-matched) (Dako A/S, Glostrup, Denmark) and served as negative controls. After being rinsed in PBS for 10 min, all tissue sections were incubated for 30 min with a goat anti-mouse peroxidase conjugate (1:200) (Zymed Laboratories, Inc., San Francisco, CA, USA).

To determine apoptosis, fragmented DNA was stained by the terminal deoxynucleotidyltransferase (TdT)-mediated dUDP-biotin nick end labelling (TUNEL) assay, with the TACS™ TdT kit-*in situ* apoptosis detection kit (R&D Systems, Minneapolis, MN, USA). Frozen sections were first incubated with proteinase K solution for 15 min at room temperature, and then immersed in hydrogen peroxide to block endogenous peroxidase activity, as described above. After washing, slides were incubated with the TdT labeling buffer for 5 min. This step was followed by the incubation with the labeling reaction mix containing TdT enzyme for 1 h at 37°C. The biotinylated nucleotides incorporated into DNA fragments were detected using streptavidin horseradish peroxidase conjugate. A second section of each sample, incubated without TdT enzyme, constituted the negative controls. Positive controls were prepared by treating samples with TACS-nuclease.

After being rinsed in PBS, all sections were developed with a solution containing hydrogen peroxide and diaminobenzidine. Preparations were lightly counterstained in Harris's hematoxylin, dehydrated, and mounted in Permount (Fisher Scientific, Pittsburgh, PA, USA).

Morphologically preserved TUNEL-positive cells and apoptotic bodies were referred to as apoptotic cells and determined using predefined measurements in the computer-assisted image analyser in conjunction with careful evaluation of morphologic criteria.

Immunofluorescence and confocal microscopy

In a double direct or indirect immunofluorescence study, the frozen sections were incubated overnight at 4°C with 2.5% bovine serum albumin (BSA), 2.0% skimmed milk, 8.0% fetal calf serum (FCS) blocking buffer under shaking. The sections were rinsed once with PBS and 0.05% Tween 20 and then incubated with appropriately diluted primary antibodies in PBS and 1.0% FCS for 1 h in a humidified atmosphere at 37°C. The primary antibodies used were the anti-CD3 FITC (1:50), anti-CD68 FITC (1:50), anti-CD20 FITC (1:50), anti-CD95 (Fas/APO-1) R-PE (1:50) (Dako A/S, Glostrup, Denmark), anti-Fas ligand (1:1000), and the anti-perforin R-PE (1:100) (Pharmingen, San Diego, CA, USA). After rinsing three times in PBS containing 0.05% Tween 20 for 5 min each, tissue sections incubated with anti-Fas ligand were incubated for 1 h with TRITC-conjugated Fab fraction of goat anti-mouse IgG antibody (Dako A/S, Glostrup, Denmark), as appropriate for indirect immunolabelling. Slides were rinsed three times and mounted in an anti-fading medium containing buffered

glycerol and *p*-phenylenediamine (Sigma Chemical Co., St Louis MO, USA), and then observed with a Zeiss LSM 510 META confocal laser scanning microscope. At least four representative images from each slide were captured at distinct excitation wavelengths (488 nm for FITC conjugate, and 543 nm for TRITC or R-PE conjugates), creating excitation lambda stacks. Using the META detector, excitation lambda stacks were separated into individual images corresponding to the signal from distinct dyes, eliminating autofluorescence and crosstalk between fluorochromes. Two sections from each sample were incubated with either PBS alone or FITC- or TRITC-conjugated anti-mouse IgG antibody, and served as negative controls.

Quantitative assessment

Quantitative analysis of tissue sections (under light microscope at $\times 400$ magnification) and of captured images of immunofluorescence (under confocal laser scanning microscope) was carried out using a computer-assisted image analyser (Image-Pro Plus Version 4.1 for Windows, Media Cybernetics, LP, Silver Spring, MD, USA). Any epithelial and lamina propria cells exhibiting identifiable reactivity distinct from background were regarded as positive.

In the immunoperoxidase studies, percentages of the different cell subsets or apoptotic cells were defined by the number of immunoreactive cells in relation to total cells (immunoreactive and non-immunoreactive cells) in the lamina propria per millimetre squared (counted in at least 10 different areas), or in at least 500 epithelial cells in the crypts and in the surface epithelium of longitudinally sectioned gastric pits.

In the double immunofluorescence studies, the immunoreactive cells were counted in the lamina propria per millimetre squared. Co-localization was defined as the numbers of double-positive cells (yellowish colour) in relation to one of the single-positive cells (green colour), in the lamina propria per millimetre squared (counted in at least 4 different areas). Co-expression was further confirmed with confocal LSM co-localization tool (data not shown). Two independent observers who were unaware of the patients' data examined all tissue sections and captured images.

Statistical analysis

Statistical analysis was performed using the statistical software SPSS for Windows (Version 10.0.1, SPSS Inc., 1989-1999, USA). Statistical differences among the experimental groups were evaluated with the one-way ANOVA test in which pairwise multiple comparisons were carried out using the Dunnett's T3 test, and the Wilcoxon signed rank test for comparisons between patients with gastric ulcers (before and after treatment; gastric antrum and marginal zone of the ulcer). Correlations between the densities of positive cells measured by immunohistochemistry and the co-localization studies were assessed using the Spearman rank correlation coefficient. Values are expressed as medians (1st quartile, 3rd quartile). The level of significance was set at $P < 0.05$.

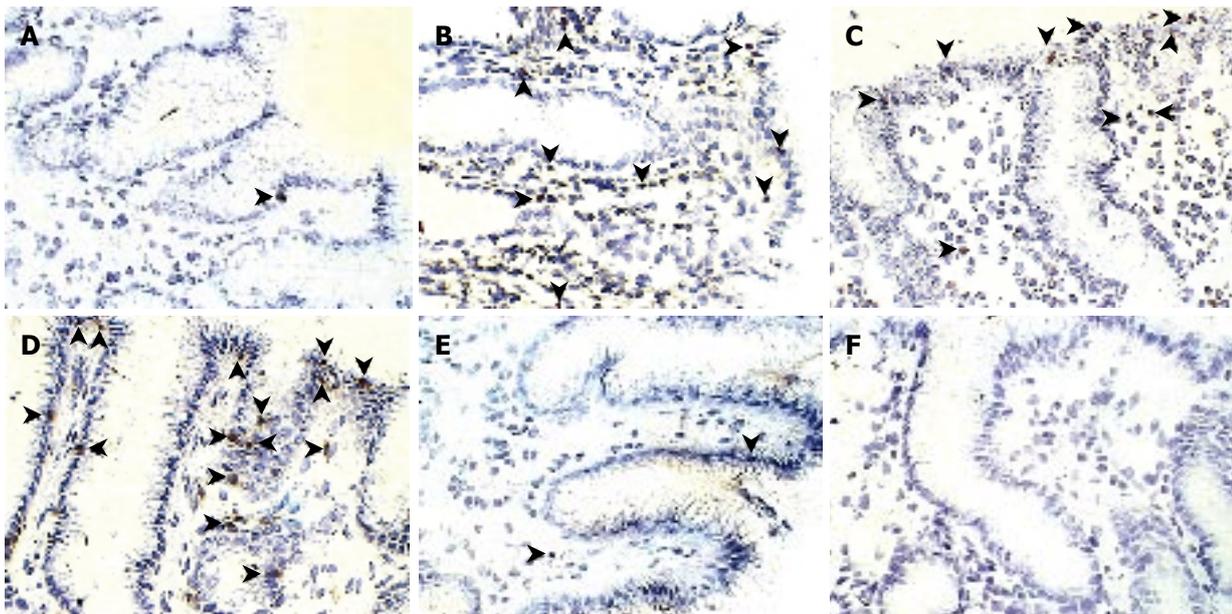

Figure 1 Terminal deoxynucleotidyltransferase (TdT)-mediated dUDP-biotin nick end labelling (TUNEL)-positive apoptotic cells. Photomicrographs show tissues obtained from the antral mucosa of: a non-infected control patient (A), a patient with *H. pylori*-associated gastritis (B), a patient with active gastric ulcer (C), at the ulcer margin of the same patient (D), and after eradication therapy (E), and a negative control, without TdT enzyme (F), respectively. Arrowheads show positive cells in the epithelium and in the lamina propria (Original magnification $\times 400$).

RESULTS

Inflammatory scores in gastric mucosa

Higher inflammatory scores were found in the mucosa of gastritis and GU patients infected with *H. pylori* compared to the normal mucosa of control patients free of infection and the mucosa of the same patients after eradication therapy. Scores in the GU patient group were 5.0 (3.3-5.0) at the ulcer margins, while the antrum scored 4.0 (3.0-5.0) before and 2.0 (1.0-2.0) after eradication therapy. In the antrum of untreated *H. pylori*-associated gastritis the score was 3.0 (3.0-3.0), and in the control group of normal non-infected mucosa the score was 0.5 (0.0-1.0). Atrophy and intestinal metaplasia were not detected in any specimens.

Proportions of T and B cells, and macrophages

A significantly higher number of T cells was found at both the ulcer margin and antrum of patients with GU (12.7% and 17.7%, respectively) compared with the normal non-infected control group (7.1%) ($P = 0.027$ and $P < 0.001$, respectively). After eradication therapy, rates of T cells in the antrum significantly decreased from 17.7% to 13.1% ($P = 0.046$). The number of macrophages was also significantly higher in the antrum of GU patients before treatment (12.0%) compared with that of the control group (6.9%) ($P = 0.029$). In addition, in the GU patient group, the number of macrophages in the ulcer margin and antrum (11.1% and 12.0%, respectively) decreased after eradication therapy (6.8%) ($P = 0.028$ and $P = 0.043$, respectively). In *H. pylori*-positive patients with gastritis, the number of T cells (13.9%) and macrophages (12.7%) was not significantly different from those in the GU and control group. The proportions of B cells were similar in all groups.

Proportions of apoptotic cells in the epithelium and lamina propria

In the GU group, the location of epithelial cell apoptosis was predominant in the superficial layer, both at the ulcer margin and the opposite wall of the antrum. In contrast, in the infected mucosa from patients with gastritis, apoptosis was more frequent in the crypts (Figure 1). When the proportion of apoptotic cells was assessed, patients who were *H. pylori*-positive contained a significantly ($P < 0.03$) greater number of apoptotic cells in the mucosa, regardless of the diagnosis, than in the same group after eradication and in non-infected controls (Figure 2). In the GU group, the number of apoptotic cells was significantly ($P < 0.003$) higher than in the gastritis group. The proportion of apoptotic cells in the crypts was similar in all groups.

When the lamina propria was assessed, apoptosis of inflammatory cells was seen more frequently ($P < 0.01$) in the mucosa of patients with gastritis compared to that of treated GU patients and non-infected controls (Figure 2). A significant correlation was found between the inflammatory scores and the number of apoptotic cells in the surface epithelium ($r = 0.71$, $P < 0.001$), but not the crypt epithelium or the lamina propria.

Expression of Fas and Fas L by gastric inflammatory cells

Immunohistochemistry revealed that Fas was constitutively expressed by all epithelial cells, with no differences detected among all groups. In the lamina propria, the percentage of Fas-positive cells was significantly increased in patients with GU, both at the ulcer margin and the antral mucosa, compared with the mucosa of the same patients after eradication therapy ($P < 0.01$) and those of non-infected controls ($P < 0.04$) (Figure 3). A significant correlation was

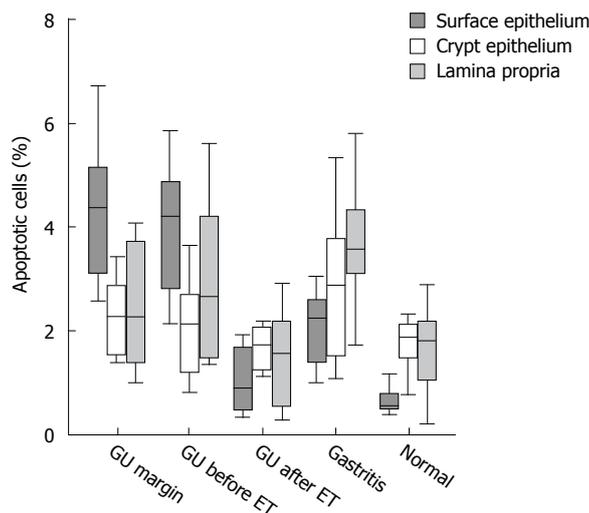

Figure 2 Percentages of apoptotic cells in the surface and crypt epithelium, and in the lamina propria of patients with gastric ulcer (GU) [at the ulcer margin, and the antrum before and after eradication therapy (ET)], *H pylori*-associated gastritis, and non-infected controls, respectively. Horizontal bars represent medians, boxes represent the 25th and 75th percentiles, and vertical bars represent ranges. In the surface epithelium values were significantly different compared to GU after ET ($P = 0.018$; $P = 0.003$; $P = 0.027$); gastritis ($P = 0.003$; $P = 0.002$), and the control group ($P < 0.001$; $P = 0.001$). In the lamina propria values were significantly different compared to GU after ET ($P = 0.001$), and the control group ($P = 0.001$). In the crypt epithelium values were not significantly different among groups (n : GU = 12, *H pylori*-associated gastritis = 11, control = 10). Differences were analysed using one-way ANOVA with the Dunnett's test for multiple comparisons. The Wilcoxon signed rank test was used for comparisons between GU patients.

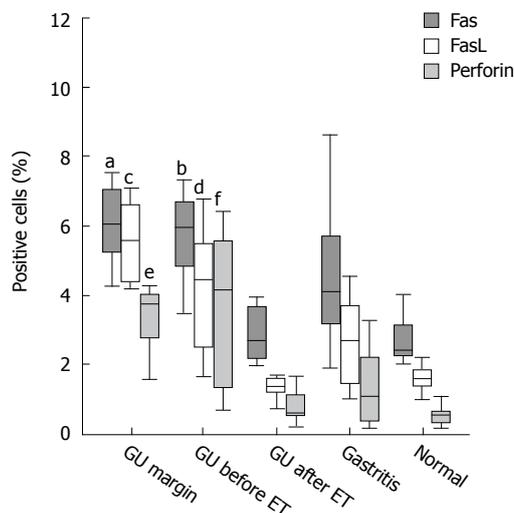

Figure 3 Quantitative analysis of apoptosis-related proteins in the gastric lamina propria of patients with gastric ulcer (GU) [at the ulcer margin, and the antrum before and after eradication therapy (ET)], *H pylori*-associated gastritis, and non-infected controls, respectively. Horizontal bars represent medians, boxes represent the 25th and 75th percentiles, and vertical bars represent ranges. Values of Fas were significantly different compared with the antral mucosa after ET ($^aP = 0.005$, $^bP = 0.008$), and the normal group ($^cP < 0.001$, $^dP = 0.031$). Values of FasL were significantly different compared to GU after ET ($^eP = 0.003$, $^fP = 0.008$), gastritis ($^gP < 0.001$), and the control group ($^hP < 0.001$, $^iP = 0.018$). Values of perforin were significantly different compared to GU after ET ($^jP = 0.005$, $^kP = 0.008$), gastritis ($^lP = 0.004$, $^mP = 0.033$), and the control group ($^nP = 0.001$, $^oP = 0.006$) (n : GU = 12, *H pylori*-associated gastritis = 11, control = 10). Differences were analysed using one-way ANOVA with the Dunnett's test for multiple comparisons. The Wilcoxon signed rank test was used for comparisons between GU patients.

found between the number of Fas-positive cells within the lamina propria and inflammatory scores ($r = 0.62$, $P < 0.001$).

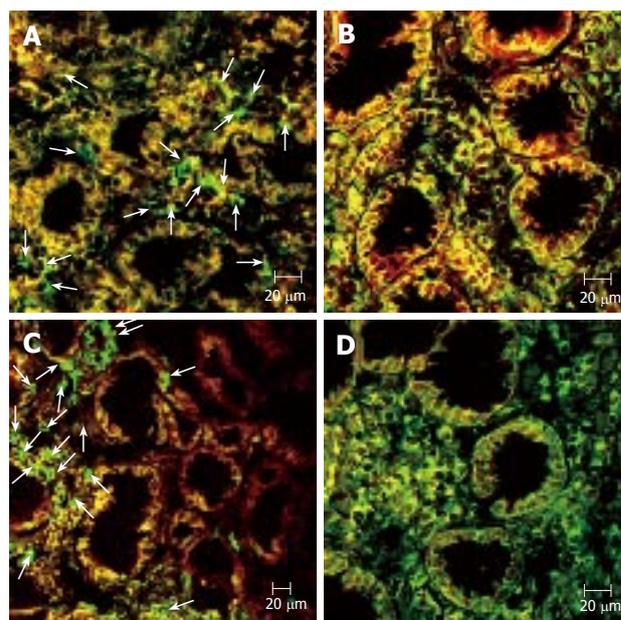

Figure 4 Double immunofluorescence analysis. Expression of CD3 (FITC) and Fas (R-PE) in the ulcer margin of a patient with gastric ulcer (A) and a non-infected control (B). Expression of CD68 (FITC) and Fas (R-PE) in the antrum of a patient with gastric ulcer (C) and a patient with *H pylori*-related gastritis (D). Images obtained by confocal microscopy. Arrows show CD3 or CD68 (FITC)-single-positive cells (green) without correspondent Fas (R-PE)-positive cells in the lamina propria of the same tissue section.

Next, we tried to identify the type of inflammatory cells co-expressing Fas by confocal double immunofluorescence. The expression of Fas by lamina propria T cells from the ulcer margin and the untreated antral mucosa was significantly reduced compared with both cells in the antrum after treatment ($P < 0.05$) and in non-infected controls ($P < 0.02$) (Figures 4 and 5). Essentially the same results were obtained when co-expression of Fas by macrophages was evaluated (Figures 4 and 5). In regard to B cells, no significant differences were found in the gastric mucosa among all groups.

Immunostaining for FasL was predominantly located in the lamina propria, and rarely seen in intraepithelial lymphocytes. The percentage of FasL-positive cells was increased in the mucosa of patients with GU, both at the ulcer margin and the antrum before treatment, compared with that observed after treatment and in the non-infected control group (Figures 3 and 6). We further investigated the co-localization of FasL in the gastric lamina propria and, as expected, essentially all FasL-positive cells co-expressed CD3 (data not shown). Of note, a significant correlation existed between the expression of FasL by gastric mucosa T cells and the percentages of apoptotic cells in the surface epithelium ($r = 0.71$; $P < 0.001$) and the histological inflammatory scores ($r = 0.63$, $P < 0.001$).

Expression of perforin by gastric inflammatory cells

Immunostaining for perforin was essentially restricted to the lamina propria, with occasional staining in intraepithelial lymphocytes. Perforin-positive cells were significantly more frequent in the lamina propria of patients with GU, both at the ulcer margin and the untreated antrum, compared to the antrum of gastritis patients ($P < 0.04$),

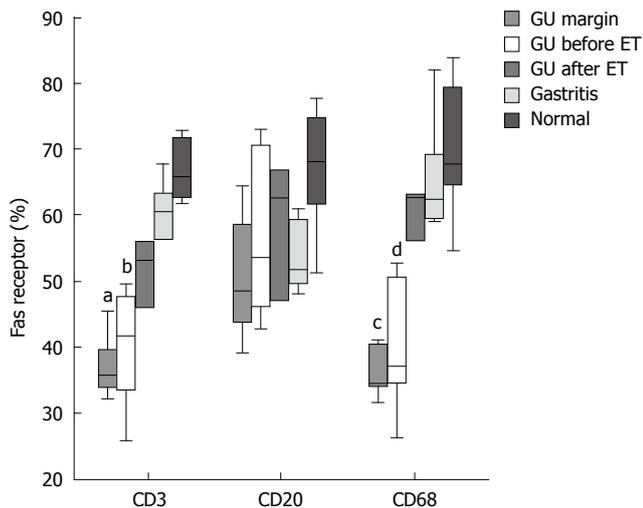

Figure 5 Percentages of the expression of Fas by CD3, CD20, and CD68 positive cells in the antral lamina propria of patients with gastric ulcer (GU) [at the ulcer margin, and at the antrum before and after eradication therapy (ET)], patients with *H pylori*-associated gastritis, and from non-infected controls, respectively. Horizontal bars represent medians, boxes represent the 25th and 75th percentiles, vertical bars represent ranges. In regard of the expression of Fas with CD3 values were significantly different compared to GU after ET (^a*P* = 0.043), gastritis (^b*P* = 0.021); and the control group (^c*P* < 0.001; ^d*P* = 0.012). For Fas expression with CD20 values were not significantly different among groups. For Fas expression with CD68 values were significantly different compared to GU after ET (^e*P* = 0.043), gastritis (^f*P* = 0.007; ^g*P* = 0.034); and the control group (^h*P* = 0.012; ⁱ*P* = 0.027) (*n* = 6, in each group). Differences were analysed using one-way ANOVA with the Dunnett's test for multiple comparisons. The Wilcoxon signed rank test was used for comparisons between GU patients.

treated GU patients (*P* < 0.01), and normal non-infected controls (*P* < 0.01) (Figures 3 and 6). Confocal microscopy confirmed that all perforin-positive cells were also CD3-positive (data not shown). A significant correlation was detected between the number of perforin-expressing cells in the gastric mucosa and the percentage of apoptotic cells in the surface epithelium (*r* = 0.61; *P* < 0.001) as well as the inflammatory scores (*r* = 0.59, *P* < 0.001).

DISCUSSION

In the current study, we detected increased rates of apoptosis in the surface epithelium of the gastric mucosa infected with *H pylori*, predominantly of GU patients. Increased rates of apoptosis were also observed among lamina propria mononuclear cells of patients with *H pylori*-associated gastritis. The expression of Fas, FasL, and perforin in the *H pylori*-infected gastric mucosa was increased compared with normal non-infected controls and with patients after eradication therapy. The higher expression of apoptosis-related molecules was found in the antral mucosa of patients with gastric ulcer, and this result was significantly correlated with the levels of apoptosis at the surface epithelium. In addition, we showed for the first time an *in situ* analysis of the densities and co-localization of apoptosis-related molecules in the antral mucosa from patients with gastric ulcer, before and after eradication therapy, and both at the ulcer margin and at the opposite antral wall. The results demonstrated that there was a reduction in the expression of Fas by both T cells and macrophages in the antral lamina propria of GU

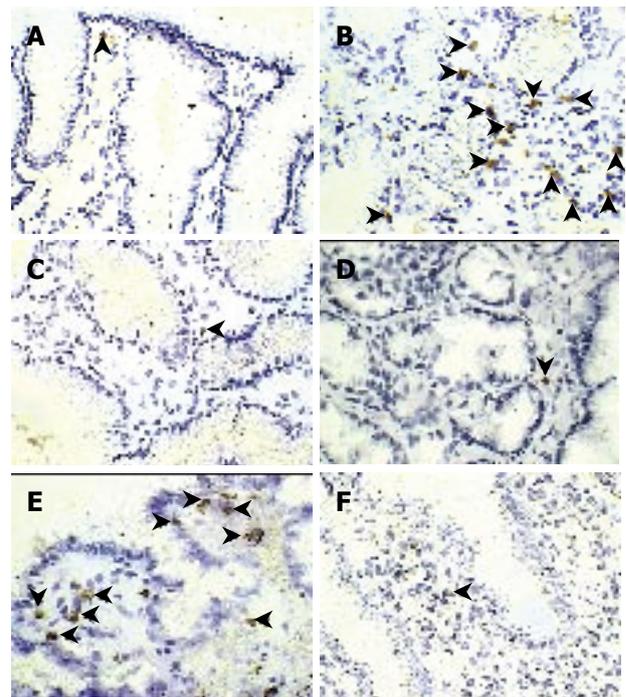

Figure 6 Apoptosis-related proteins in the gastric mucosa stained with immunoperoxidase. Photomicrographs show the antral mucosa stained for FasL in a non-infected control patient (A), at the ulcer margin (B), and after eradication therapy of the same patient (C). Immunostaining for perforin is shown in a patient with *H pylori*-associated gastritis (D), and in a patient with gastric ulcer before (E), and after eradication therapy (F), respectively. Arrowheads show immunoreactive cells (Original magnification × 400).

patients.

Although *H pylori*-related gastritis continues to constitute one of the most common human infections, only a subset of patients will develop severe complications of the infection such as peptic ulcer disease. Histological findings of the chronically infected stomach reveal a dense cellular infiltration throughout the mucosa, whereas *H pylori* locates predominantly in the overlying mucous layer. Several studies have provided evidence that activated T-helper type 1 cells are increased in *H pylori*-associated gastritis^[6,7], and the consequent pro-inflammatory stimuli have been associated with the sensitization and induction of epithelial apoptosis^[9,10]. However, in normal conditions epithelial apoptosis appears to be an infrequent event in the gastric mucosa. In the present work, the results of *in situ* analysis suggest that increased rates of epithelial apoptosis are related to *H pylori* infection, in agreement with previous *in vivo* and *in vitro* studies^[8,19,20]. Significantly higher rates were found in patients with peptic ulcer and decreased significantly after eradication therapy reaching normal levels. In addition, the localization of epithelial apoptosis differed among groups. In the peptic ulcer group apoptotic cells were found predominantly in the superficial epithelium, whereas in the gastritis group the phenomenon was mostly located at the crypts. Distinct localization patterns of epithelial apoptosis seem to be in accordance with either the most likely outcome of peptic ulcer whenever surface epithelial damage prevails or with atrophy in chronic *H pylori*-associated gastritis.

The induction of macrophage apoptosis has been

considered as a possible method employed by multiple pathogens to escape the host immune response^[21]. In fact, apoptosis of immunocompetent cells such as macrophages^[22], and B cells^[23] has been reported in association with *H pylori* infection. Furthermore, *H pylori* may also evade the host immune response through the impairment of antigen-specific T cell proliferation^[24], or inducing T cell apoptosis^[25]. Therefore, at least in theory, apoptosis of immunocompetent cells is likely to decrease the local inflammatory process, but on the other hand it may reduce the effective immune response against *H pylori* as well. Apoptosis of mononuclear leukocytes in the gastric mucosa infected by *H pylori* was also reported after eradication therapy^[26]. Although in the present study the rates of apoptosis in the lamina propria after eradication therapy were comparable to normal controls, the mucosa showed a concomitant reduction in the number of inflammatory cells. Thus, it was possible that the number of those cells could have been reduced by induction of apoptosis after therapy. However, if this was the case in our study, the effect would be likely to have decreased to the normal levels by the time of the follow-up biopsy. On the other hand, a relative resistance to *H pylori*-induced apoptosis was detected in neutrophils^[27], and dendritic cells^[28] *in vitro*. In this study, we found significantly increased rates of apoptosis in the lamina propria mononuclear cells of patients with *H pylori*-related gastritis compared to the non-infected mucosa. The fact that this phenomenon has not been observed in the antral mucosa of GU patients may reflect the existence of a defect in the control of local host responses. It is possible that apoptosis of lamina propria mononuclear cells might constitute a mechanism by which the host may down-regulate the inflammatory response associated with chronic *H pylori* infection.

Apoptosis constitutes the primary mechanism of target-cell destruction mediated by cytotoxic T lymphocytes, and one of the pathways involved in this process is the Fas/FasL. Increased rates of apoptosis reported in *H pylori*-infected gastric mucosa has been associated with the Fas/FasL pathway^[15,17,29]. *In vitro* studies have demonstrated that the sensitivity of gastric epithelial cells to Fas-mediated apoptosis could be increased by the up-regulation of the Fas-receptor expression consequent to *H pylori* infection^[14] or triggered by inflammatory cytokines^[30]. In addition, it was demonstrated that increased expression of Fas by gastric epithelium renders cells sensitive to apoptosis by adjacent FasL-expressing T cells^[16].

In contrast to T cell responses, the epithelial expression of FasL is low or undetectable^[31], and blocking the Fas receptor cannot protect those cells from apoptosis^[29]. Therefore, it seems that *H pylori* may be capable of inducing apoptosis in different cell lineages using diverse but possibly overlapping mechanisms. Nevertheless, in T cells the response appears to be mostly dependent on Fas/FasL interactions^[25]. In the present study, we found that the levels of FasL-positive cells in the lamina propria were positively correlated with surface epithelial apoptosis. However, increased numbers of FasL-positive cells were present in all patients infected with *H pylori*, without any significant difference between the results of gastritis and

GU patients. These findings suggest that FasL might participate in the inflammatory process associated with *H pylori* infection, but may not be directly and specifically related to ulcerogenesis.

Fas/FasL-mediated apoptosis is regulated mostly by the cellular expression of both molecules, since Fas is activated almost exclusively by the membrane-bound form of its natural ligand, FasL^[32]. However, cellular mechanisms that control the expression of Fas and FasL appear to be independent. Fas is more universally distributed and is thought to be expressed later in the course of cellular activation^[33], while the up-regulation of FasL is regarded as an early event of T-cell activation^[34]. Hence, the expression of Fas on T-cells and other lamina propria mononuclear cells could have an effect of down-regulation of gastrointestinal immune responses through apoptosis, upon binding with FasL. In accordance with the findings of the present study, Fas is expressed constitutively in the epithelial cells of the human stomach^[30], where it has been considered as a key molecule in the control of apoptosis. In the lamina propria infected with *H pylori* we observed increased numbers of Fas-expressing cells. However, since the numbers of inflammatory cells were also significantly increased in the infected mucosa, the expression of Fas could actually be proportionally altered. In fact, the expression of Fas was shown to be reduced by both T cells and macrophages in the lamina propria of GU patients. Taken together, these results suggest that the increased numbers of FasL-expressing cells might result in increased epithelial cytotoxicity not paralleled by lamina propria mononuclear cell apoptosis mediated by the Fas/FasL system in GU patients. It is hypothesized that an uncoordinated regulation of Fas and FasL could possibly result in decreased apoptosis of inflammatory cells, including auto-reactive cells in the lamina propria of GU patients.

In conjunction with T cells, macrophages are recognized as fundamental elements of the chronic inflammatory process of GU. Therefore, it is reasonable to suppose that mechanisms to eliminate activated macrophages should also be required for the maintenance of peripheral tolerance. Results from an *in vitro* study demonstrated that in addition to T-T and T-B lymphocyte cytotoxicity, the Fas/FasL system is also capable of mediating T-macrophage cytotoxicity^[35]. Hence, in the current study the reduced expression of Fas on macrophages shown in the gastric mucosa from patients with gastric ulcer could possibly explain the accumulation and persistence of those cells in sites of gastric inflammation.

Increased levels of granzyme B mRNA, introduced through the action of perforin, have been found in cells adjacent to apoptotic epithelial cells of specimens obtained from the marginal zone of active gastric and duodenal ulcers. But interestingly, in that study the findings were shown also in patients with peptic ulcer in the absence of *H pylori* infection^[26]. In the current study, perforin was detected at increased rates in GU patients, both at margins and tissues away from the lesion, compared to both non-infected controls and *H pylori*-related gastritis. Moreover, the levels of perforin were significantly correlated with the

rates of surface epithelial apoptosis. This fact may support the contribution of distinct pathways to the cell-mediated cytotoxicity against innocent bystander targets such as the gastric epithelium, but possibly with a greater role for perforin in the development of peptic ulcer disease. On the other hand, the positive correlation between the rates of perforin-expressing cells and apoptotic cells in the lamina propria of patients with *H pylori*-associated gastritis may indicate the enhancement of an alternative pathway as a mechanism to circumvent the resistance to apoptosis and chronic mucosal inflammation.

In conclusion, the results indicate that increased apoptosis in the surface epithelium may contribute to the pathologic process of gastric ulcer. The lamina propria Fas/FasL expression may reflect the state of inflammation secondary to *H pylori* infection. However, the consistently increased percentage of perforin-expressing cells in the antrum of GU patients suggests a distinct role of perforin in ulcerogenesis.

Abstract

AIM: To evaluate the therapeutic effect of Chunggan extract (CGX), a modified traditional Chinese hepatotherapeutic herbal, on the dimethylnitrosamine (DMN)-induced chronic liver injury model in rats.

METHODS: Liver injuries were induced in Wistar rats by injection of DMN (ip, 10 mg/mL per kg) for 3 consecutive days per week for 4 wk. The rats were administered with CGX (po, 100 or 200 mg/kg per day) or distilled water as a control daily for 4 wk starting from the 15th d of the DMN treatment. Biochemical parameters (serum albumin, bilirubin, ALP, AST and ALT), lipid peroxides, hydroxyproline, as well as histological changes in liver tissues were analyzed. In addition, gene expression of TNF- α , TGF- β , TIMP-1, TIMP-2, PDGF- β , and MMP-2, all of which are known to be associated with liver fibrosis, were analyzed using real-time PCR.

RESULTS: CGX administration restored the spleen weight to normal after having been increased by DMN treatment. Biochemical analysis of the serum demonstrated that CGX significantly decreased the serum level of ALP ($P < 0.05$), ALT ($P < 0.01$), and AST ($P < 0.01$) that had been elevated by DMN treatment. CGX administration moderately lowered lipid peroxide production and markedly lowered hydroxyproline generation caused by DMN treatment in accordance with histopathological examination. DMN treatment induced a highly up-

INTRODUCTION

Several pathologic conditions, including chronic alcohol consumption, viral B or C hepatitis, and constant cholestasis, induce chronic injury to liver tissue. Moreover, these chronic liver disorders lead progressively to fibrosis or liver cirrhosis, which is an extreme form of chronic liver disease that reduces the quality of life and life span of the patients^[1]. Therefore, a crucial step in treating chronic liver disease involves preventing the development of cirrhosis. One of the best therapeutic strategies involves removing the underlying causes of liver damage^[2], and major findings on the epidemiological and pathogenic features that involve various cytokines or the transformation of stellate cells in the progression of chronic liver disease have recently been reported^[3-5]. Currently, however, no universally effective therapeutics exist, and chronic liver disease remains a major concern for global public health.

Medical research on natural products for treating chronic liver disease has been increasing in recent years^[6-8]. Chunggan extract (CGX), also called *Qinggan* extract, which means "cleaning liver" is a modified herbal drug based on a traditional Chinese hepatotherapeutic formula. It has therapeutic properties particularly for hyperlipidemia,

alcohol-induced liver damages in animal models, and other chronic liver diseases, including chronic viral B type hepatitis in clinical tests^[9-11]. Nevertheless, further studies are needed to evaluate the pharmaceutical efficacy based on scientifically controlled experiments before an appropriate clinical application can be implemented for treating various liver diseases.

We herein investigated the therapeutic effect of this drug on a chronic liver injury model in rats caused by dimethylnitrosamine (DMN).

MATERIALS AND METHODS

Components of CGX and fingerprinting analysis

The ingredients of CGX include 5 g each of *Artemisia capillaris* Herba, *Trionycis* Carapax, *Raphani* Semen; 3 g each of *Atractylodis Macrocephalae* Rhizoma, *Poria*, *Alismatis* Rhizoma, *Atractylodis* Rhizoma, *Salviae Miltiorrhizae* Radix; 2 g each of *Polyporus*, *Amomi Fructus*, *Aurantii Fructus*, and 1 g of *Glycyrrhizae* Radix or *Helenii* Radix. The 10.71% (w/w) lyophilized water-extract was obtained from the initial dried mixture according to the Korean standard over-the-counter (OTC) monographs, and its high-performance thin layer chromatography (HPTLC)-based fingerprint was produced by the CAMAG application system (Muttenez, Switzerland) (Figure 1A and 1B). For the HPTLC analysis, water extracts of CGX, *Artemisia capillaris* Herba, *Aurantii Fructus*, and their standard components, 6, 7-dimethoxycoumarin (Sigma Chemical Co., St. Louis, MO, USA) and Poncirin (Fluka, St. Louis, MO, USA), were dissolved in HPLC-grade methanol and applied to pre-washed silica gel 60 F254 HPTLC plates (size 10 cm × 10 cm, thickness of the silica gel 0.2 mm; Merck, Darmstadt, Germany) with an automated applicator (Linomat IV; CAMAG). The samples were then separated (migration distance 75 mm) using HPLC-grade ethyl acetate/formic acid/acetic acid/water (15:1:1:2). The migrated components were visualized under UV radiation at 366 nm using Reprostar 3 with a digital camera (CAMAG).

Animals and reagents

Specific pathogen-free 4-wk-old male Wistar rats were purchased from a commercial animal breeder (Samtako, Osan, Korea). Forty rats were acclimated for 3 wk and housed in an environmentally controlled room at 22 ± 2°C, 55% ± 10% relative humidity, and 12-h light/dark cycles, and fed commercial pellets (Samtako) and tap water *ad libitum*. Animal experiments were conducted in accordance with the Use of Laboratory Animals as adopted and promulgated by the U.S. National Institutes of Health.

Dimethylnitrosamine (DMN, *N*-Nitrosodimethylamine) and other reagents, including hydroxyproline, *p*-dimethylaminobenzaldehyde, and chloramine-T were purchased from Sigma, and perchloric acid was obtained from GFS Chemical Co. (Columbus, OH, USA).

Induction of chronic liver damage and administration of CGX

Forty Wistar rats with average body weight 210 ± 15 g were randomly divided into 5 groups (8 rats per group) as follows: naive (no treatment); DMN 4 wk (4-wk DMN treatment and sacrificed following the treatment

period); control (4-wk DMN treatment and 4-wk water administration from the third week of DMN treatment); and CGX 100 or CGX 200 (4-wk DMN treatment and 4-wk CGX administration from the third week of DMN treatment). DMN diluted in saline was intraperitoneally injected at 10 mg/mL per kg for 3 consecutive days during each week for the DMN 4 wk, control, CGX 100, and CGX 200 groups. The DMN 4 wk group was sacrificed at the end of the 4-wk DMN treatment. The CGX 100, CGX 200, and control groups were administered CGX with (100 or 200 mg/kg per day) or distilled water as a control daily for 4 wk starting from the third week of DMN-treatment. This experimental model is presented in Figure 1C.

Measurement of the relative organ weights, and histomorphologic examination of the liver

The changes in body weight for all animals were recorded weekly throughout the experimental period. The animals were sacrificed on the last day of experimentation or following the 4-wk induction for the DMN-4 wk group; the liver and spleen were removed and weighed to determine changes in the organ weights by treatment. The liver was removed and separately stored for histomorphologic examination, RNA expression analysis, as well as hydroxyproline and lipid peroxide determination.

For the histomorphological evaluation, a portion of liver tissue was fixed in Bouin's solution. The paraffin-embedded liver was sectioned (4-μm thickness), and Hematoxylin & eosin staining and Masson's trichome staining were performed. The representative histopathological features, such as necrosis or inflammatory cell infiltration and fibrosis, were examined under microscopy.

Complete blood count and serum biochemical analysis

The rats were bled via abdominal aorta after ether anesthesia on the final day of the 4-wk induction for the DMN 4 wk group or on the final day of full experimentation for others. Complete blood counts were performed by blood cell counter (HEMAVET; CDC Technologies Inc., Oxford, CT, USA) using small amounts of blood mixed in EDTA.

Once sera were prepared from the remaining blood, the levels of total protein, albumin, total bilirubin, alkaline phosphatase (ALP), aspartate transaminase (AST), and alanine transaminase (ALT) were determined in the serum using an Auto Chemistry Analyzer (Chiron Ltd., Emeryville, CA, USA).

Lipid peroxidation measurement by malondialdehyde determination in liver tissues

Lipid peroxidation in liver tissues was examined using the method of thiobarbitric acid reactive substances (TBARS) as previously described^[12]. The concentration of TBARS was expressed as n moles of malondialdehyde (MDA) per milligram of tissue using 1.1.3.3-tetraethoxypropane (TEP) as a standard. Briefly, 0.2 g of liver tissue was homogenized in 2 mL of ice-cold 11.5 g/L KCl; then 0.13 mL of homogenate was mixed with 0.08 mL of 10 g/L phosphoric acid and 0.26 mL of 0.67% thiobarbituric acid. After heating the mixture for 45 min at 100°C, 1.03 mL of *n*-butanol was added into the mixture, followed

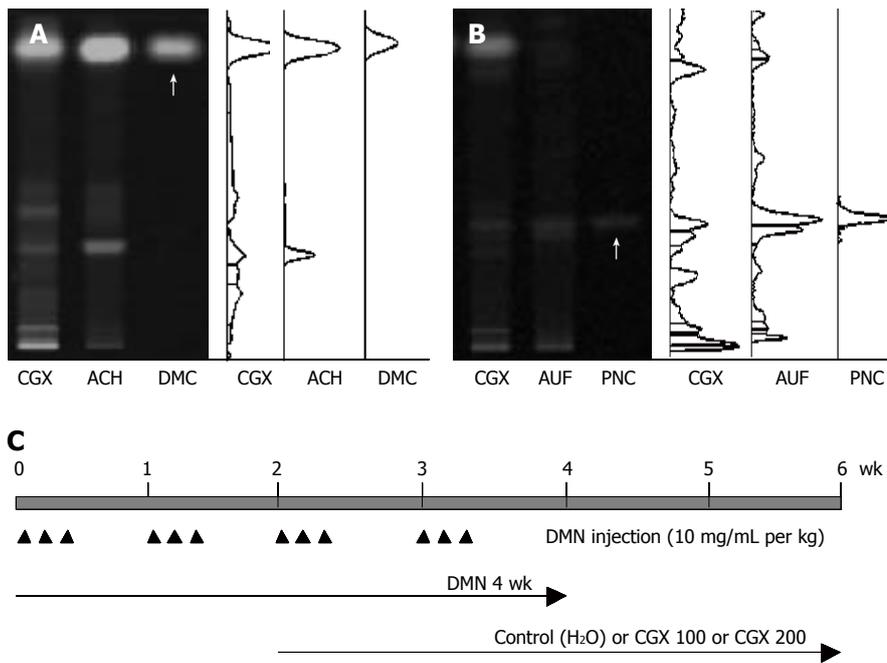

Figure 1 HPTLC-based fingerprint for CGX and scheme for the experiment. HPTLC analysis was performed to characterize CGX and its two major components (extracts from *Artemisia capillaris* Herba and *Aurantii Fructus*) with reference components, 6,7-dimethoxycoumarin and Poncirin. **A:** 2 µL of CGX (200 mg/mL) and 1 µL of the extract from *Artemisia capillaris* Herba (50 mg/mL) were subjected to HPTLC with 1 µL of 6, 7-dimethoxycoumarin (0.1 mg/mL); **B:** 2 µL of CGX (200 mg/mL) and 1 µL of the extract from *Aurantii Fructus* (50 mg/mL) were subjected to HPTLC with 1 µL of Poncirin (5 mg/mL). Arrows indicate 6,7-dimethoxycoumarin and Poncirin, respectively; **C:** Simplified scheme summarizing the experimental design: DMN treatment (ip, 3 consecutive days per week, 10 mg/mL per kg for 4 wk) and CGX administration (po, 100 or 200 mg/mL per kg, for 4 wk from 2 wk after DMN treatment). ACH: *Artemisia capillaris* Herba; AUF: *Aurantii Fructus*; DMC: 6,7-dimethoxycoumarin; PNC: Poncirin.

by vigorous mixing and centrifugation at 3000 r/min for 15 min. The absorbance of the upper organic layer was measured at 535 and 520 nm with a spectrophotometer, and compared to the value from freshly prepared TEP as a standard.

Collagen measurement by hydroxyproline determination in liver tissues

Hydroxyproline assays were performed as previously described with a slight modification^[13]. Briefly, liver tissues (0.2 g) stored at -70°C were homogenized in 2 mL of 6 mol/L HCl and incubated overnight at 110°C. After filtering the acid hydrolysates using filtering paper (Toyo Roshi Kaisha, Tokyo, Japan), 50 µL of samples and standard hydroxyproline in 6 mol/L HCl were incubated to dry out the HCl; 50 µL of methanol, 1.2 mL of 500 mL/L isopropanol, and 200 µL of chloramine T solution were sequentially added to the samples, followed by incubation at room temperature for 10 min. Next, 1.3 mL of Ehrlich's solution was added to the mixtures and incubated further at 50°C for 90 min. At the end of incubation, absorbance of the reaction mixtures was read at 558 nm. A standard curve was constructed using 0-1.0 mg/50 µL of hydroxyproline solutions.

Gene expression analysis using real-time PCR

Total RNA was extracted from liver tissue samples with Trizol (Invitrogen, Carlsbad, CA, USA), RNAlater (Ambion, Inc., Austin, TX, USA), and RNA easy column (Qiagen, Inc., Valencia, CA, USA). Complementary DNA (cDNA) was synthesized using 10 pmol of oligo dT and 10 pmol/L of random hexamer (Bioneer, Daejeon, Korea). After cDNA synthesis, quantitative real-time PCR was performed using SYBR green supermix reagent (Bio-Rad, Hercules, CA, USA) with the primers (forward and reverse, respectively) for β-actin: 5'-GTGGGGCGCCCCAGGCACCA-3' and 5'-CTCCTTAATGTCACGCACGATTTC-3'; tumor

necrosis factor-α (TNF-α): 5'-CTCCCAGGTTCTC TTCAAGG-3' and 5'-TGGAAGACTCCTCCAGGTA; transforming growth factor-β (TGF-β): 5'-TGAGTGGCTGTCTTTTGACG-3' and 5'-TTCTCTGTGGAGCTGAAGCA; platelet-derived growth factor beta (PDGF-β): 5'-GAGTCGAGTCGG AAAGCTCA-3' and 5'-CTGCTGCAGCCAGAGACC; matrix metalloproteinase-2 (MMP-2): 5'-GCGCTTT TCTCGAATCCAT-3' and 5'-GGGTATCCATCTCC ATGCTC-3'; tissue inhibitor of metalloproteinase-1 (TIMP-1): 5'-CGGACCTGGTTATAAGGGCT-3' and 5'-ACTCTCCAGTTTGCAAGGGA; and tissue inhibitor of metalloproteinase-2 (TIMP-2): 5'-GCATCACCCAG AAGAAGAGC-3' and 5'-GTTTCCAGGAAGGGATG TCA-3'. Reactions were performed with 12.5 µL of iQ SYBR green supermix, 1 µL of 10 pmol/L primer pairs, 10.5 µL of distilled water, and 1 µL of cDNA. Each PCR run was performed under the following conditions: initial denaturation at 95°C for 5 min, 40 amplification cycles including denaturation at 95°C for 1 min, annealing at 58°C for 40 s, and elongation at 72°C for 40 s, followed by a single fluorescence measurement.

Statistical analysis

The results were expressed as the mean ± SD. Statistical analysis of the data was carried out using Student's *t* test. *P* values less than 0.05 were considered statistically significant.

RESULTS

Relative liver and spleen weights

As shown in Figure 2, 4-wk DMN treatment decreased relative liver weights compared to the control group, while it increased relative spleen weight. A 2-wk cessation of DMN following the 4-wk DMN treatment slightly restored these changes as seen in the control groups. These restorations were augmented by CGX administration (200 mg/kg), especially the spleen weights, compared to the

After just 4-wk DMN treatment (DMN 4 wk), and after 6-wk full experiment for or control group including naïve group, complete blood count analysis was performed using EDTA-mixed blood. ^a*P* < 0.05 vs control group; ^c*P* < 0.05, ^b*P* < 0.01 vs naive group.

control group (*P* < 0.05; Figure 2).

Hematological analysis

DMN treatment for 4 wk decreased the level of erythrocytes, hemoglobin, hematocrit and platelets, and decreased the lymphocyte population in peripheral blood compared to the naïve group (Table 1). Most of these hematological changes, however, had almost completely recovered to normal levels by cessation of the treatment for 2 wk (control group). These hematological improvements may, therefore, not have been due to the effect of CGX, with the exception of the decreased monocyte population of leukocytes in CGX 100 and CGX 200 groups (*P* < 0.05).

Serum biochemical analysis

Four-week treatment with DMN induced liver dysfunction, including lowered levels of total protein and albumin along with elevated level of total bilirubin, ALP, AST, and ALT (Figure 3A-3C). Although these biochemical parameters were partially restored after the 2-wk cessation period in the control group, AST and ALT levels still differed significantly from their normal values.

CGX treatment (100 mg/kg) showed significant restoring effects on serum level of total proteins and albumin (*P* < 0.01 and *P* < 0.05, respectively; Figure 3A). However, bilirubin, which was rapidly reduced by cessation of DMN treatment for 2 wk, was not affected by CGX administration. The elevated ALP level significantly decreased with treatment by both concentrations of CGX (Figure 3B), and the CGX treatment significantly lowered the of AST back to nearly normal level and moderately reduced the level of ALT (*P* < 0.01; Figure 3C), while no

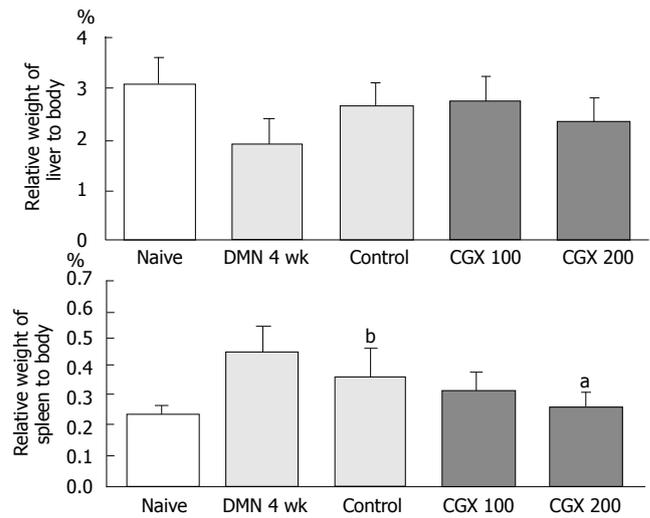

Figure 2 Weight of the liver and spleen relative to total body weight. Eight male Wistar rats per group were treated with DMN together with or without CGX as described in Figure 1C. At the end of the total treatment period, the liver and the spleen were removed from the rats and the relative organ weight with respect to total body weight was examined. ^a*P* < 0.05 vs control group; ^b*P* < 0.01 vs naive group.

significant changes were observed after 2-wk cessation of DMN following the 4-wk DMN treatment without CGX.

Lipid peroxide and hydroxyproline

To examine the effects of CGX on lipid peroxidation and fibrosis in liver tissue, lipid peroxide and hydroxyproline were determined from frozen tissues. Prominent lipid peroxidation occurred during the 4-wk DMN treatment and progressed further during the 2-wk cessation period (control group), but 200 mg/kg CGX administration lowered it significantly (*P* < 0.01). Hydroxyproline, however, rapidly increased with DMN treatment but then dropped dramatically 2 wk later (control group), and CGX administration (100 and 200 mg/kg) significantly augmented its concentration (*P* < 0.01; Figure 4).

Histopathological findings

Four-week DMN treatment (DMN 4 wk) appeared to shrink the liver and cause it to become blunt and congested with blood, whereas the CGX treatment reversed these changes. These gross findings were supported by microscopic examination after hematoxylin & eosin and Masson's trichrome staining. DMN treatment for 4 wk caused severe local necrosis, inflammatory cell infiltration, hemorrhagic regions, and serious septal fibrosis. Although these pathologic features partially recovered by stopping the DMN treatment for 2 wk, CGX administration led to notable recovery effects (Figure 5).

Fibrosis-related gene expression analysis

To inspect the changes in gene expression of cytokines linked to liver fibrosis and the anti-fibrotic effects of CGX, gene expressions of TNF- α , TGF- β , PDGF- β , MMP-2, TIMP-1, and TIMP-2 were analyzed using real-time PCR. As shown in Figure 6, DMN treatment induced high expression of all these genes compared to the naïve group.

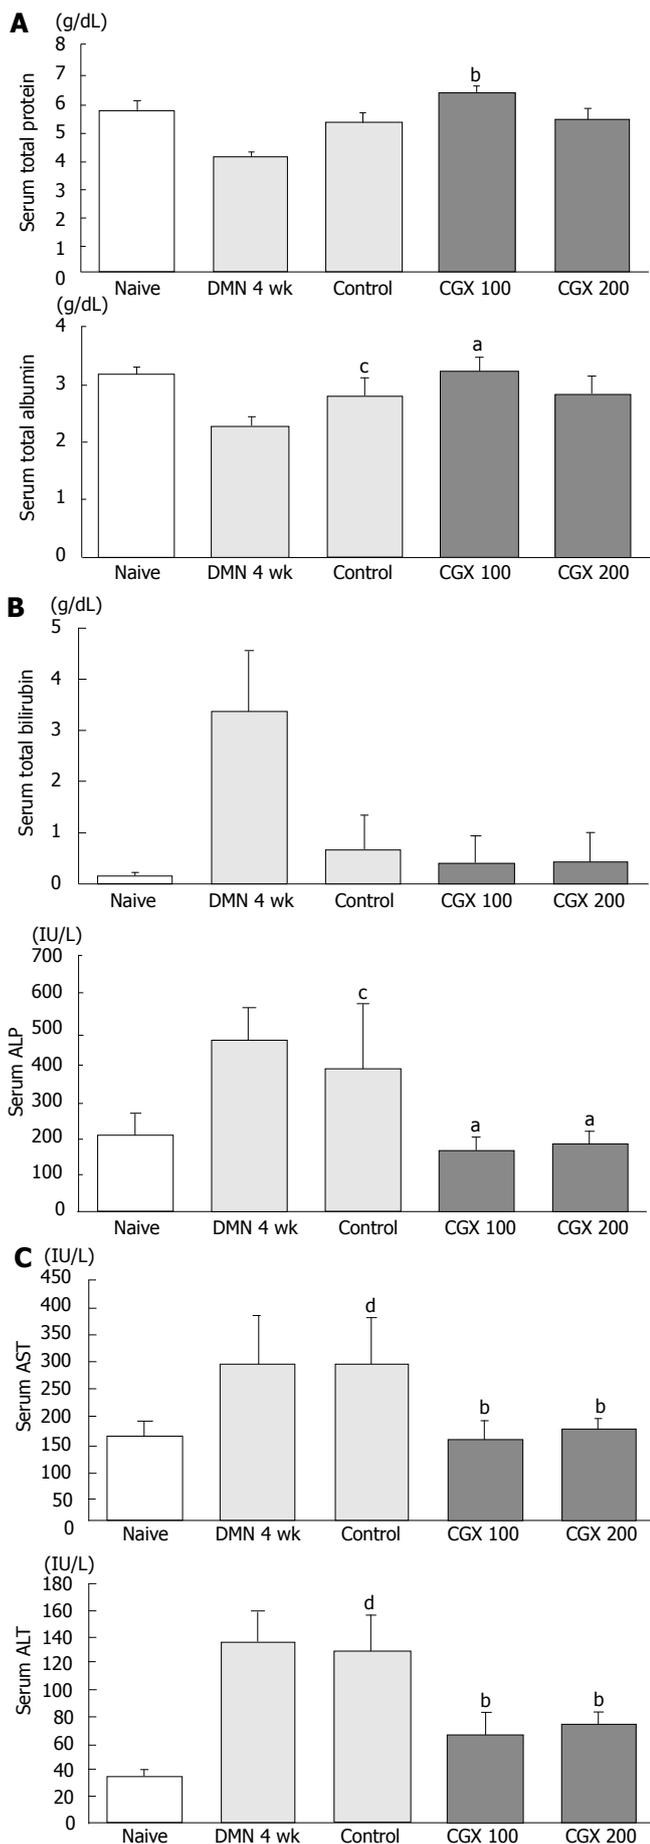

Figure 3 Serum biochemical analyses. At the end of the total treatment period, sera were prepared from blood collected via abdominal aorta of ether-anesthetized rats to measure (A) total protein and albumin, (B) total bilirubin and ALP, and (C) AST and ALT. ^a*P* < 0.05, ^b*P* < 0.01 vs control group; ^c*P* < 0.05, ^d*P* < 0.01 vs naive group.

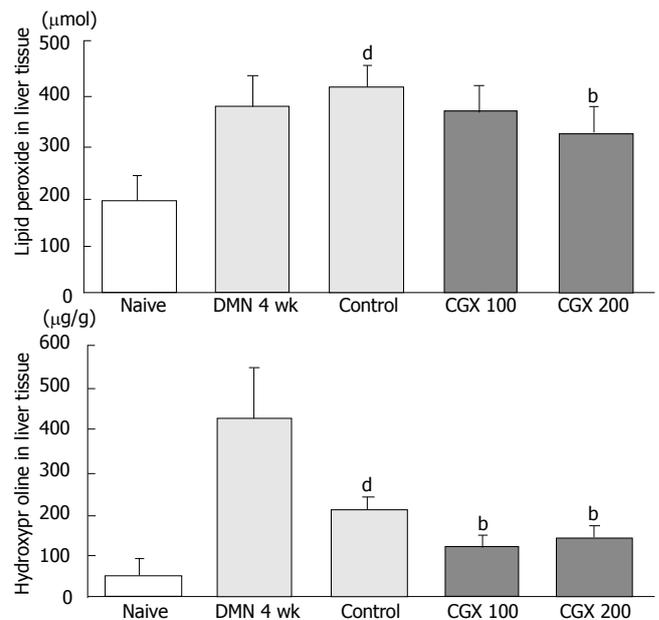

Figure 4 Measurement of lipid peroxide and hydroxyproline levels in liver tissues. Eight male Wistar rats per group were treated with DMN together with or without CGX as described in Figure 1C. At the end of the total treatment period, malondialdehyde and hydroxyproline were determined in the liver tissues. ^b*P* < 0.01 vs control group; ^d*P* < 0.01 vs naive group.

The DMN-induced high expression of TNF- α , TGF- β , TIMP-1, and TIMP-2 were spontaneously reduced to basal levels by cessation of the DMN treatment. However, the expression of genes encoding PDGF- β and MMP-2 was further activated during the 2-wk cessation period (control group). These patterns of over-expressed genes prominently subsided following CGX administration.

DISCUSSION

Liver tissue is generally characterized by its vigorous ability to completely regenerate when damaged during short periods, whereas chronic liver injury can cause gradual progression of fibrotic or cirrhotic changes or sometimes cancerous transformation, resulting in dysfunction of the liver itself with whole-body consequences^[14]. Disorders with persistent destruction of liver tissue, known as chronic liver diseases, include chronic types of viral or alcoholic hepatitis, autoimmune hepatitis, liver cirrhosis, and liver cancer, and are a leading cause of death worldwide^[15]. The development of cirrhosis is a critical step impacting the clinical outcome or mortality of patients suffering from chronic liver diseases. Because cirrhotic changes consisting of fibrosis and nodulation are often a consequence of the wound-healing response to chronic liver injury, treating the underlying pathogenic conditions, such as chronic inflammation, before the onset of fibrogenesis is an important strategy for the management of these disorders^[16,17].

Despite the lack of well-designed clinical evidence, herbal medicines are becoming popular among patients with liver disease, and are attractive as putative anti-fibrotics or hepatotherapeutics^[18-22]. CGX has shown some hepatoprotective properties or anti-hyperlipidemic effects in previous studies^[9-11], so we further examined whether

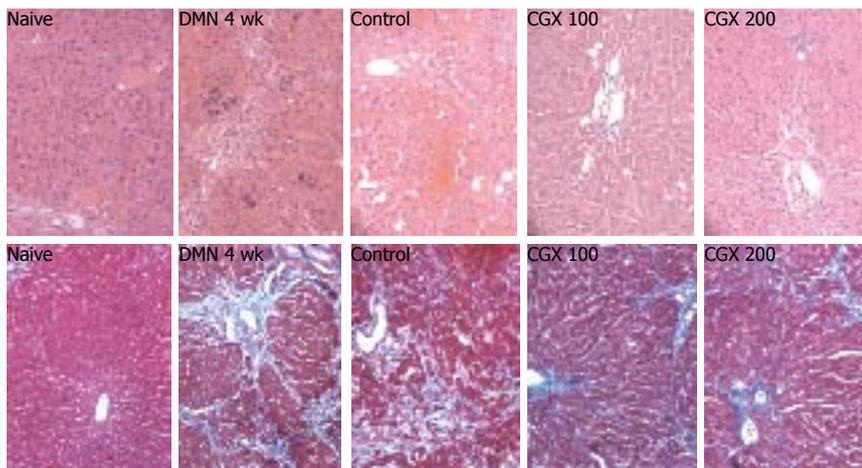

Figure 5 Histopathologic examination of liver tissues. Eight male Wistar rats per group were treated with DMN together with or without CGX as described in Figure 1C. At the end of the total treatment period, the liver was removed, fixed in Bouin's solution, and stained with hematoxylin and eosin (top, x 200 magnification) or Masson's trichrome (bottom, x 200 magnification) for histological examination under a light microscope.

this drug has therapeutic effects in a chronic liver damage model, including anti-fibrotic effects.

We constructed a chronic liver injury model using Wistar rats as in previous studies^[23-25], showing marked liver dysfunctions, such as low serum albumin, high level of bilirubin, ALP, AST, and ALT, and increased lipid peroxidation and hydroxyproline accumulation in liver tissues. In our experiments, the values of relative organ weights, serum albumin and bilirubin, and hydroxyproline in liver tissues moderately recovered to normal levels after 2-wk cessation of DMN without any treatment, whereas the levels of ALP, AST, and ALT remained dangerously out of normal physiologic conditions.

CGX administration showed major reducing effects on the increased levels of ALP, AST, and ALT induced by DMN treatment, and slight restorative effects on organ weight, serum albumin and bilirubin, and hydroxyproline concentration in liver tissues. In contrast to other biomarkers, the production of lipid peroxidation, measured as malondialdehyde (MDA), accelerated continuously up to the endpoint of this experiment in spite of stopping DMN treatment in the control group. This was partially restored by the administration of CGX (Figure 4). Because oxidative stress in DMN-treated animal models is known to be a major cause of hepatocellular damage and fibrosis^[26], it is likely that CGX has some hepatotherapeutic effects as a result of reducing DMN-induced oxidative stress.

As expected, DMN treatment for 4 wk resulted in the development of fibrosis, thus causing shrunken livers and the accumulation of hydroxyproline and extracellular matrix. Any chronic types of hepatocellular injury generally lead to hepatic fibrosis and cirrhosis, and investigation of anti-fibrotics and anti-cirrhosis have been a central issue due to their importance in the clinical outcome of patients. Thus far, no effective anti-fibrotic or anti-cirrhosis treatments are available for clinical use^[2,27]. This experiment demonstrated some anti-fibrotic effects of CGX administration, as shown by reduced hydroxyproline concentration in tissues and histological examination (Figure 5).

In order to determine the molecular mechanisms of these effects, we examined the change in expression of several fibrosis-associated genes in liver tissues. It has

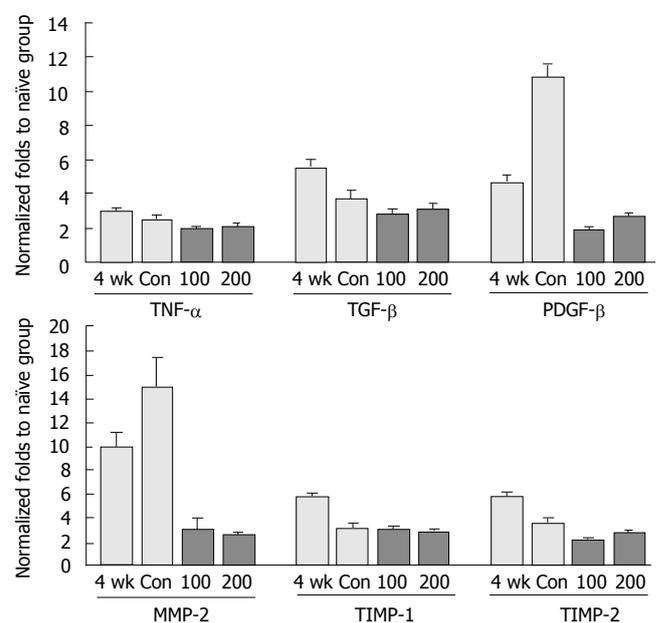

Figure 6 Expression of fibrosis-related genes using real-time PCR. Eight male Wistar rats per group were treated with DMN together with or without CGX as described in Figure 1C. At the end of the total treatment period, total RNA was prepared from liver tissues and used for cDNA synthesis. Quantitative real-time PCR was then performed using SYBR green supermix reagent with the gene-specific primers. The results are expressed in terms of fold increase in the expression levels relative to the naive control group. Con: Control.

already been established that stellate cells and various cytokines work as key factors in the pathogenic process of liver fibrosis^[2]. Among these, TGF- β and PDGF are considered the prominent profibrogenic cytokines^[28-31]. As shown in Figure 6, CGX administration moderately inhibited TGF- β expression compared to four- and five-fold over-expression in the DMN 4 wk and control groups, respectively. In particular, PDGF- β was obviously over-expressed by DMN treatment, whereas it was markedly inhibited by CGX administration. In addition, the unbalance between synthesis and degradation of the extracellular matrix is an important feature of liver fibrosis, and increased expression of several matrix metalloproteinases, including MMP-2 and tissue inhibitors of metalloproteinases (TIMPs), is well-known to occur during fibrogenesis^[32,33]. CGX administration also

noticeably decreased the expression of MMP-2 that had been highly over-expressed during or after DMN treatment, similar to previous reports^[34].

Among the many drugs derived from herbal medicines, silymarin is the most clinically popular for patients with various liver disorders, and is known to have hepatotherapeutic and anti-fibrotic properties^[35-37]. We also used silymarin (50 mg/kg) as a positive control in this experiment, and observed that CGX exhibited greater anti-fibrosis effects than silymarin (data not shown).

Based on these results, we conclude that CGX possesses hepatotherapeutic properties against chronic hepatocellular destruction and consequential liver fibrosis. The mechanism of these therapeutic effects of CGX on liver diseases, however, should be further clarified so that CGX can be used as effectively as possible as a means of treatment.

following HBT results in the formation of large endothelial gaps. These gaps, though important in the transfer of DNA molecules from the blood to the space of Disse are not enough to provide the appropriate conditions for hepatocyte transfection. Hydrodynamics based injection is applicable in fibrotic rats provided that ECM load is reduced.

Abstract

AIM: Hydrodynamics based transfection (HBT), the injection of a large volume of naked plasmid DNA in a short time is a relatively simple, efficient and safe method for *in vivo* transfection of liver cells. Though used for quite some time, the mechanism of gene transfection has not yet been elucidated.

METHODS: A luciferase encoding plasmid was injected using the hydrodynamics based procedure into normal and thioacetamide-induced fibrotic Sprague Dawley rats. Scanning and transmission electron microscopy images were taken. The consequence of a dual injection of Ringer solution and luciferase pDNA was followed. Halofuginone, an anti collagen type I inhibitor was used to reduce ECM load in fibrotic rats prior to the hydrodynamic injection.

RESULTS: Large endothelial gaps formed as soon as 10' following hydrodynamic injection; these gradually returned to normal 10 d post injection. Hydrodynamic administration of Ringer 10 or 30 m prior to moderate injection of plasmid did not result in efficient transfection suggesting that endothelial gaps by themselves are not sufficient for gene expression. Gene transfection following hydrodynamic injection in thioacetamide induced fibrotic rats was diminished coinciding with the level of fibrosis. Halofuginone, a specific collagen type I inhibitor, alleviated this effect.

CONCLUSION: The hydrodynamic pressure formed

INTRODUCTION

The ability to introduce foreign genes has paved the way for elucidating the physiological functions of genes and their therapeutic potential in the context of the entire organism^[1,2]. A crucial yet unresolved issue in successfully implementing gene delivery as an effective procedure is the methodology by which genes can be introduced. In recent years naked DNA rather than synthetic vectors or viruses were applied to animal models. In doing so, various procedures were used including direct injection to liver vessels or bile duct^[3-7].

The introduction of the hydrodynamics based transfection (HBT) by Liu *et al*^[2] and Zhang *et al*^[1] presented new opportunities in the field owing to its relatively straightforward manner, eliminating the need for surgical procedures. The technique has been widely used ever since, reaching beyond the goals of treating liver diseases. Gene suppression by RNAi or defining regulatory DNA sequences^[8,9] are among the topics investigated using this approach. Two parameters influence more than any other the outcome of the hydrodynamic injection, the volume administered and the rate of injection. In the mouse model up to 10% of body weight is administered within 5 s. Under these harsh conditions the output of the heart fails to cope with the heavy load of fluid, leading to excessive blood flow into the hepatic vein circulation and consequent transfection of hepatocytes^[10].

Attempts to elucidate the mechanism underlying the HBT have yielded conflicting reports. These reports

include receptor mediated endocytosis^[11], non specific entry to hepatocytes through transient small pores caused by high pressure^[12] or transient inversion of intrahepatic flow associated with massive endocytosis^[10]. Regardless of the mechanism, it is obvious that the sinusoids and associated cells, i.e., sinusoidal endothelial cells, hepatic stellate cells and Kupffer cells are influenced by the high pressure created by the procedure.

The current study follows the fate of the reporter gene luciferase in fibrotic rats undergoing HBT. Such animals demonstrated lower levels of transfection compared to healthy control rats, yet the outcome of the HBT could be improved by halofuginone, an anti collagen type I inhibitor. We also bring evidence demonstrating that the morphological alterations in the form of fused fenestrae, gaps, inflicted on the membrane of sinusoidal endothelial cells following HBT are either not involved or not sufficient to achieve transfection of liver cells.

MATERIALS AND METHODS

Plasmid

pGL3-Control vector (Promega, Madison, WI) encoding for the luciferase gene was purified using a commercial kit (Qiagen, Valencia, CA). The purity of the plasmid was checked by Nanodrop (Wilmington, DE) and agarose gel electrophoresis.

Hydrodynamic injection and thioacetamide administration

Sprague-Dawley rats (250-280g) were injected via the tail vein with luciferase encoding plasmid using a 22G venflon cannula in a volume equivalent to 5.25% of the body weight and a rate of 5-8 s. The amount of DNA administered throughout this study, 400 µg/injection, was deduced from a preliminary study in which various amounts of naked DNA were used. In all experiments the DNA was dissolved in Ringer solution (117 mmol/L NaCl, 2.5 mmol/L KCl, 2 mmol/L CaCl₂, 9.1mmol/L HEPES, 5 mmol/L D-glucose pH 7.4). Prior to injection rats were anesthetized using Ketamin HCl (90 mg/kg) and Acepromazine Maleate PB (2.5 mg/kg). The amount of Acepromazine Maleate PB was reduced to 1 mg/kg in fibrotic rats. Liver fibrosis was induced by injection of 0.2 mg/g thioacetamide (TAA) intraperitoneally twice weekly for the designated time. The level of fibrosis was determined using the Ishak scoring system^[13] following staining with Sirius Red. Halofuginone (Collgard, Petach Tikva, Israel) was supplied in the food at a concentration of 5 ppm.

Histochemistry

Liver samples were fixed in 4% paraformaldehyde, dehydrated in gradual ethanol solutions and embedded in paraffin. Five µm thick sections were blocked for endogenous peroxidase and stained with Sirius Red^[14].

Luciferase assay

Two hundred mg of liver tissue were homogenized by Polytron homogenizer (Kinematika, Lucerne, Switzerland) in 1ml Reporter lysis buffer (Promega Corp., Madison, WI). Luciferase activity was determined using a commercial assay kit (Bright-Glo Luciferase Assay System, Promega,

Madison, WI) according to manufacturer's instructions. Luciferase was expressed as Relative Light Units per mg protein ± standard deviation.

Cell proliferation

BrdU labeling was used to determine cell proliferation. Briefly animals were intraperitoneally injected one and two hours before sacrifice with PBS containing 5-bromo-2-deoxyuridine (Sigma, St. Louis, MO) at a dose of 50 mg/kg body weight. Liver samples were fixed, dehydrated, embedded in paraffin and cut to 5 µm slices. Staining was performed using the BrdU kit (Zymed, South San Francisco, CA).

Electron microscopy

Liver tissue samples were prepared according to standard protocols^[15]. Briefly, liver tissue was prefixed, cut to 1 mm³ samples and stored in 1.5% glutaraldehyde in 0.12 mol/L cacodylate buffer at pH 6.9. Following glutaraldehyde fixation, tissue blocks were postfixed in 1% Osmium tetroxide. Dehydrated tissue blocks were dried with hexamethyldisilazane and subsequently broken in liquid nitrogen, mounted on stubs and sputter coated with a thin layer of 20 nm gold^[16]. Scanning electron microscopy (SEM) samples were studied in a Philips XL-20 at 30 kV. Morphometric analysis was performed on randomly acquired digitized SEM images at magnifications × 5000 or × 20000 as previously described^[17]. The UTHSCSA Image Tool 2.0 software was used to trace the number and diameter of liver sinusoidal endothelial gaps. Gaps were discriminated from fenestrae based on their morphology and size as described^[15,16,18]. Each experimental variable was repeated three times (3 animals) using 10 images in the periportal and pericentral zone (regions up to 100 µm in diameter) randomly selected and captured at both magnifications. All experiments were repeated three times and data were expressed as mean ± standard deviation of the mean.

Statistical analysis

Statistical analysis was performed with the Mann Whitney two-sided *U*-test for endothelial gap sizes and one way ANOVA for plasmid distribution in the liver lobes. The *t*-test was used for plasmid expression in the different experimental groups.

RESULTS

Luciferase gene distribution in rat liver lobes following HBT

Given the conflicting reports as to the distribution of naked DNA in the liver following HBT^[19-21] we first addressed the above, using the pGL3-Control vector. Following HBT, random segments from each of the four liver lobes were thus picked, minced in Reporter lysis buffer (Promega, Madison, WI) supplemented with Complete Mini Protease Inhibitor (Roche Diagnostics, Mannheim, Germany) and tested for luciferase. Surprisingly, variations in luciferase expression were noted between segments of the same lobe. To avoid false interpretation in all further experiments, liver lobes were chopped into small pieces and a 200 mg representative sample was collected and

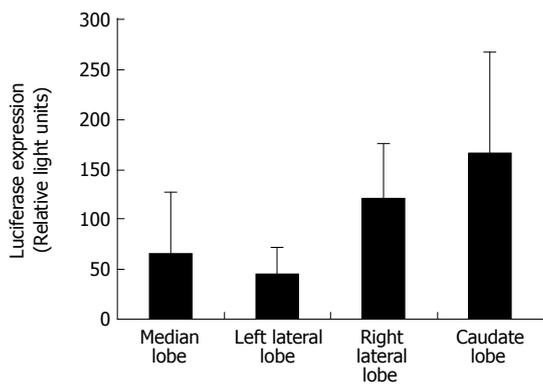

Figure 1 400 μ g of pGL3-Control plasmid DNA was injected in 5.25% (volume per animal weight) Ringer to healthy rats by the hydrodynamics based injection (5 to 8 s). 24 h later the liver was excised, the lobes minced and 200 mg samples of each of the four lobes homogenized in reporter lysis buffer and luciferase activity monitored ($n = 10$).

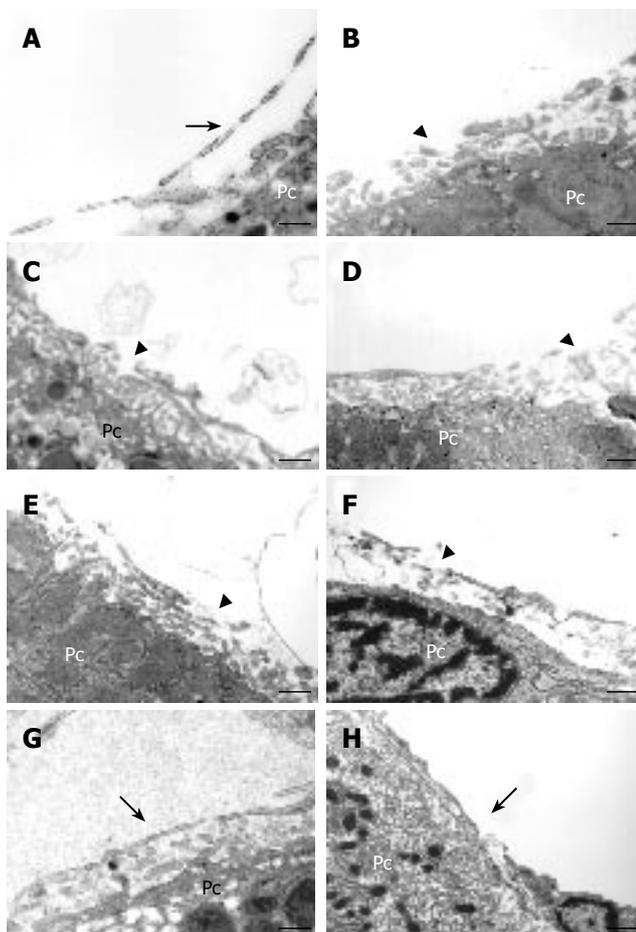

Figure 2 High magnification electron micrographs of liver sinusoids following hydrodynamic injection. **A:** Control image illustrates intact histological relationship between liver sinusoidal endothelial and neighboring liver parenchymal cells (Pc). Note the fenestrated processes (arrow) of endothelial cells; **B:** Ten minutes after hydrodynamic injections, severe damage of the endothelial lining in the form of gaps is noted (arrowhead). Similar features were observed at 1 (**C**), 8 (**D**), 24 (**E**), and 72 (**F**) h, i.e., a disrupted endothelial lining with the presence of large structural rearrangement in the form of gaps (arrowheads). The architecture of hepatocytes remained intact when compared to the control. Between seven (**G**) to ten (**H**) days post injection, the number of gaps decreased significantly. Interestingly, the hepatic sinusoidal endothelial lining is less fenestrated when compared to the control (arrow). Scale bars, 1 μ m.

Table 1 Number of gaps along the sinusoidal endothelial lining after hydrodynamic injections (mean \pm SD, $n = 30$)

	n gaps/10 μ m ² (periportal)	n gaps/10 μ m ² (pericentral)
Control	0.14 \pm 0.15	0.18 \pm 0.21
10 min	3.04 \pm 0.62 ^{ac}	0.86 \pm 0.42 ^e
1 h	3.02 \pm 0.35 ^{ac}	0.76 \pm 0.42 ^e
8 h	3.08 \pm 0.64 ^{ac}	1.39 \pm 0.46 ^e
24 h	2.98 \pm 0.55 ^{ac}	1.07 \pm 0.39 ^e
72 h	1.42 \pm 0.32 ^{ac}	0.72 \pm 0.27 ^e
168 h	0.92 \pm 0.33 ^{ac}	0.49 \pm 0.21
240 h	0.45 \pm 0.19	0.39 \pm 0.20

Scanning electron microscopy based morphometric analysis of gaps per area along the sinusoidal endothelial lining cells. Significance of data was determined using the Mann Whitney two-sided U-test. Significant differences between the number of gaps in the periportal and pericentral zones were noted at all time points indicated (^a $P \leq 0.05$) following hydrodynamic injections. Significant differences between control and time points indicated following hydrodynamic injections were evident at both periportal (^b $P \leq 0.05$) and pericentral (^c $P \leq 0.05$) areas of the liver. A gap is defined as a hole with a diameter size of 300-2000 nm.

used to give a reliable representation of the expression in the lobe (Figure 1). Comparison between the four lobes showed statistical difference in expression (d.f. = 3, $F = 6.78$, $P < 0.001$). The left lateral lobe was found by post hoc analysis to express significantly less plasmid ($P < 0.05$).

HBT is associated with the formation of large endothelial gaps

An enlargement in liver fenestrae was reported when high pressure was used in liver perfusion^[22]. We have demonstrated an increase in blood flow to the liver following partial hepatectomy which was associated with the formation of "fused" fenestrae (gaps)^[23]. The number of these gaps gradually decreased, reaching baseline level 10 d post surgery. To test the effect of hydrodynamic injections on cells occupying the space of Disse, both scanning and transmission electron microscopy were utilized. Prior to HBT injection, normal ultrastructure of liver sinusoids and the surrounding hepatocytes was noted, with patent lumen delineated by endothelial cells with thin processes containing a few fenestrae. These fenestrae ranged in size between 120-140 nm. Microvilli extending from the parenchymal cell surface could be readily seen. Hepatocytes show normal ultrastructure displaying a cytoplasm rich in rough endoplasmic reticulum, glycogen and multiple membrane bound vesiculo-organelles such as lysosomes, lipid droplets and coated pits. As early as ten minutes after hydrodynamic injections, endothelial-associated changes were noted in the form of fused fenestrae, i.e., gaps, ranging in diameter between 0.3 μ m and 2 μ m. These gaps were more prominent in periportal areas than pericentral areas (Figure 2 and Table 1). Increasing values were noted in subsequent times, i.e., 1 to 24 h post-hydrodynamic injection in both areas. The number of gaps decreased gradually reaching almost pre-hydrodynamic injection levels 240 h post injection (Table 1). Scanning electron microscopy revealed similar results (Figure 3). Control tissue demonstrated intact relationship between sinusoidal endothelial cells and neighboring liver parenchymal cells. Ten minutes after injections the

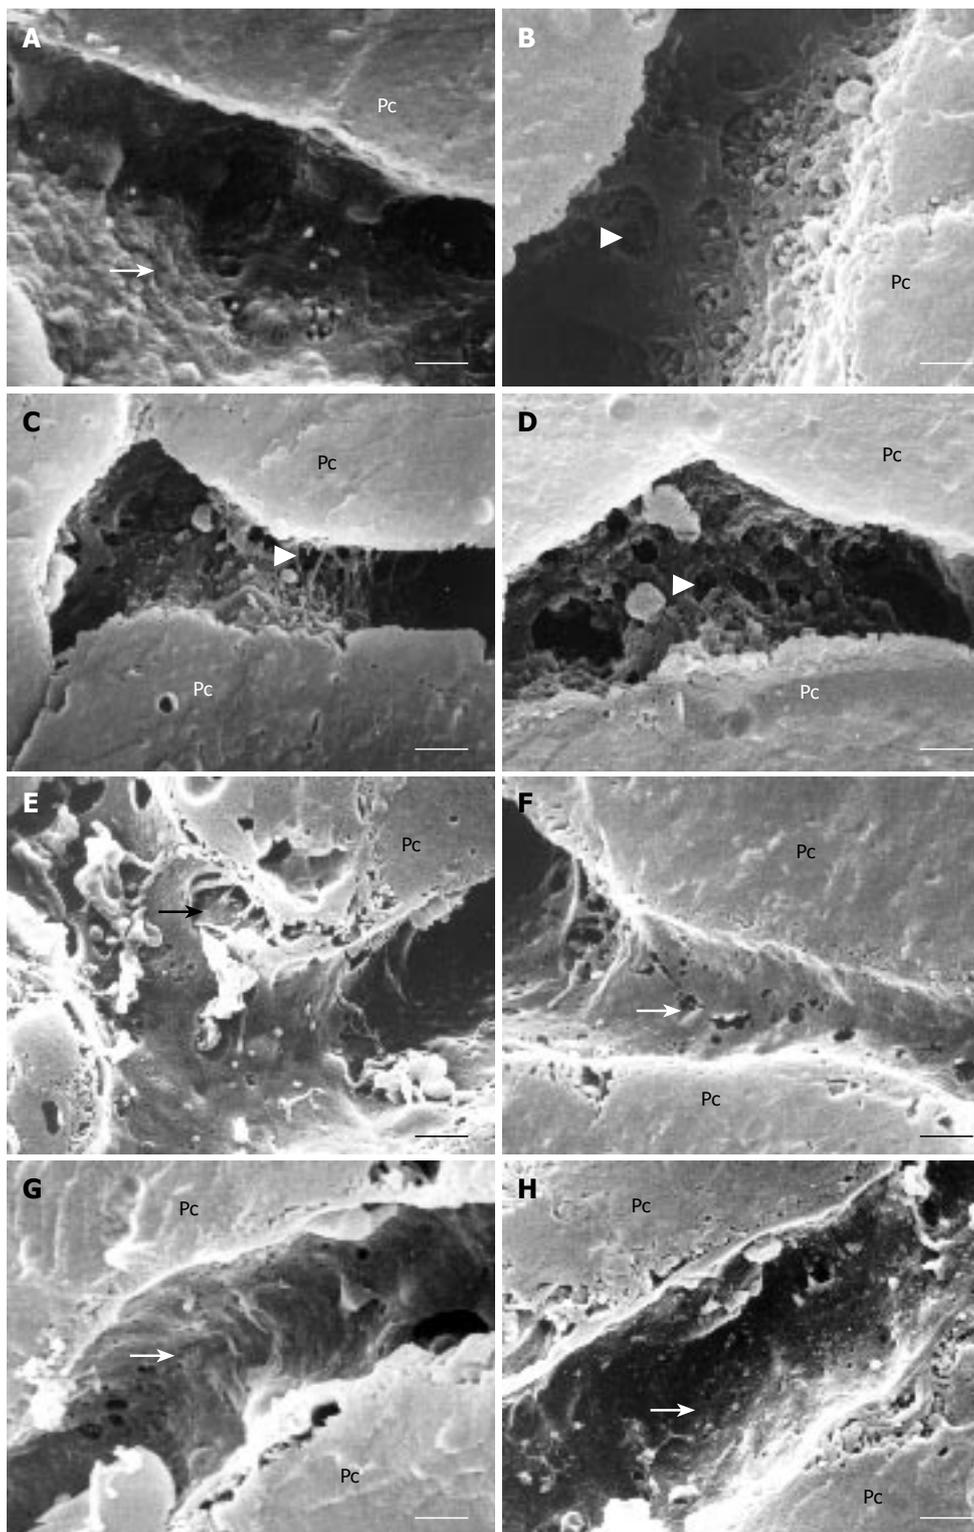

Figure 3 Scanning electron micrographs of liver sinusoids following hydrodynamic injections. **A:** Control liver demonstrates an intact endothelial wall with numerous small pores perforating the endothelial lining (fenestrae) (arrow) and undisrupted bordering parenchymal cells (Pc); **B:** Numerous gaps (arrowhead) are observed as early as ten minutes after hydrodynamic injections and persist at one (**C**) and eight (**D**) hours after injection. From twenty four hours post HBT and onwards the number of gaps (arrowhead) decreases, yet a significant number are still present (**E**, **F**). Between seven (**G**) and ten (**H**) days following HBT, the endothelial lining reveals similar features as described under Figure 2G-H: i.e., less fenestrated appearance. Scale bars, 2 μm .

endothelial lining was disrupted by gaps and microvilli facing toward the sinusoidal lumen. Ten days after HBT liver morphology returned to normal with very few fenestrae.

No increase in BrdU cell labeling was evident in HBT injected rats (data not shown) suggesting that in spite of the morphological damage mentioned above no cell proliferation was associated with our protocol.

Hydrodynamic administration of Ringer solution prior to transfection does not facilitate plasmid transfection

Given the fact that endothelial cell fenestrae undergo major

changes resulting in a significant increase in the number of gaps as early as 10 m following HBT we examined whether the induction of gaps by itself enables plasmid DNA transfection. Normal rats were thus injected with Ringer solution in a volume equal to 5.25% of their body weight followed by a moderate injection of 400 μg of pGL3-Control plasmid 10 or 30 m post HBT. Two control groups of rats were injected either hydrodynamically or moderately with the same plasmid. While hydrodynamic administration of the plasmid resulted in a remarkably high level of luciferase expression, hydrodynamic administration of Ringer followed by moderate injection

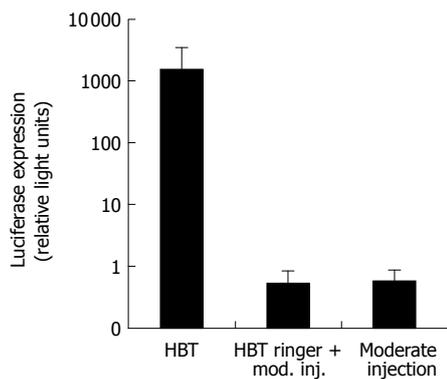

Figure 4 400 μ g of pGL3-Control plasmid DNA were injected in the following variations: (1) HBT: 5.25% (volume per animal weight) Ringer solution with plasmid DNA in 5 to 8 s; (2) HBT Ringer + moderate injection: 5.25% (volume per animal weight) Ringer solution in 5 to 8 s followed by 400 μ g of plasmid DNA in 500 μ L 10 or 30 m later; (3) moderate injection: 500 μ L Ringer solution with 400 μ g plasmid DNA. Twenty four hours post injection the liver was excised. 200 mg liver sample were then homogenized in reporter buffer and luciferase activity monitored ($n = 5$).

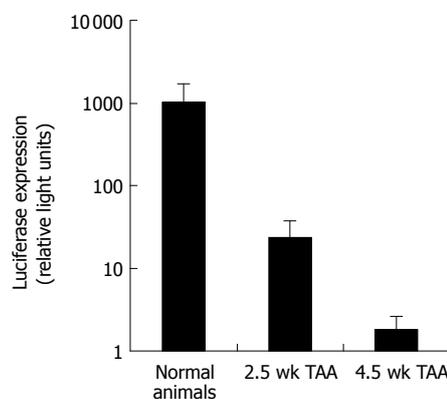

Figure 5 400 μ g of pGL3-Control plasmid DNA was injected in 5.25% (volume per animal weight) Ringer in 5-8 s to normal rats, and rats injected intraperitoneally (IP) twice weekly with thioacetamide (TAA) for either 2.5 or 4.5 wk. 24 h later the liver was excised and 200 mg samples of the median lobe were homogenized in reporter lysis buffer and the activity of luciferase monitored ($n = 5$).

of the plasmid 10 or 30 m after HBT yielded significantly lower expression levels ($P < 0.05$), similar to those of moderate injection ($P > 0.5$ between these two groups) (Figure 4).

Transfection efficiency of HBT in fibrotic rats is reduced

HBT is associated with an increase of hydrodynamic pressure in the liver, leading to an efficient transfection. It follows therefore that "blocking" endothelial sinusoids would lead to gradual decrease in the efficiency of transfection. To test this assumption we followed the fate of pGL3-Control in rats treated with thioacetamide for 2.5 or 4.5 wk. Such treatment results in fibrotic expansion of most portal areas along with the formation of incomplete septa (Ishak scoring 1-2) and portal to portal and portal to central septa including occasional nodules (Ishak scoring 5) respectively. HBT in both fibrotic groups resulted in a significant reduction in the expression of luciferase ($P < 0.000$). Between the two fibrotic groups there was also significant difference in expression ($P < 0.005$) (Figure 5). Furthermore, luciferase expression strongly correlated

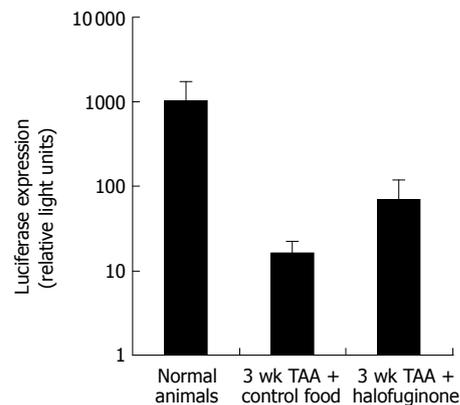

Figure 6 400 μ g of pGL3-Control plasmid was injected in 5.25% (volume per animal weight) Ringer in 5-8 s to normal rats, and rats previously injected intraperitoneally twice weekly with thioacetamide (TAA) for 3 wk. Prior to the hydrodynamic injection the rats were fed for 3 wk with either control food or food containing halofuginone at a concentration of 5 ppm. Twenty four hours post HBT the liver was excised and 200 mg samples of the median lobe were homogenized in reporter lysis buffer and the activity of luciferase monitored ($n = 5$).

inversely with the severity of fibrosis as quantitated by Ishak ($r = -0.77$). Halofuginone is a specific collagen type I inhibitor. In previous studies^[24,25] we have shown its beneficial usage in reducing collagen deposition in fibrotic rats. When given to rats with established fibrosis prior to hydrodynamic injection, an increase in the level of luciferase expression following HBT was evident ($P < 0.05$ between the treated and untreated groups) (Figure 6). Such animals also demonstrated a reduced level of fibrosis as determined by Sirius Red staining.

DISCUSSION

Hydrodynamics based transfection allows efficient delivery of plasmid DNA to the liver. This simple procedure has been used to test the potential benefits of certain genes like the hemophilia Factor IX or for screening novel elements *in vivo*^[26-28]. Yet in spite of the intense usage of the methodology, the mechanism underlying the entry and expression of the targeted gene is still unclear. The present study elucidates basic features associated with the technique, which are of fundamental importance when the technique is being implemented. It also demonstrates the potential usage of halofuginone, a collagen type I inhibitor in the event that the HBT technology is used in fibrotic rats. Conflicting reports exist as to the number of cells expressing the desired gene following HBT. Song and colleagues identified close to 40% positively stained cells most of which are hepatocytes^[29]. Others^[3] reported significantly lower numbers of 10% or less. It is obvious that incorrect sampling of the liver may lead to a wrong conclusion. Our current analysis using samples representing the complete lobe previously cut into small pieces was reliable and reproducible. In that context, it is worth noting that variations in gene expression between the four liver lobes were noted, though these differences were not significant except for the left lateral lobe which showed lower expression ($P < 0.05$). We conducted all experiments using the median lobe which is the largest.

The term "liver sieve" is used to describe the endothelial

cells that line the hepatic sinusoids. These fenestrated endothelial cells which have no basement membrane allow free transfer from the sinusoidal lumen of various substrates including growth factors, hormones, proteases and chylomicrons^[15]. Evidence points to the availability of receptors responsible for the removal of soluble molecules via sinusoidal endothelial cells (SEC)^[30]. Fenestration of sinusoidal endothelial cells is a dynamic process whose size and density may be affected by various factors ranging from physical factors to soluble substances^[31]. The formation of large gaps following an increase in hydrodynamic pressure in the liver has been documented in different set-ups. Fraser and colleagues have shown enlarged fenestrae when high pressure was applied in a liver perfusion model^[22]. Wack and colleagues^[31] reported increased porosity and fenestration diameters following 70% partial hepatectomy. We have recently been able to demonstrate the formation of large gaps ranging in diameter between 0.3 μm and 2 μm following 70% partial hepatectomy^[23]. These gaps are most probably formed by the increased shear stress associated with elevated blood flow following hepatectomy. Though gaps are evident 10 m post hepatectomy, it is likely that these are formed concomitantly with the elevation in blood flow. We now show a similar pattern of gap formation following hydrodynamic injection. In both cases, the increase in the number of gaps was more prominent in periportal areas than pericentral areas. These differences cannot be simply explained by higher pressure formed close to portal zones as increased pressure in the inferior cava vein and therefore in central veins has been described with the hydrodynamic injections^[10]. The reported increase in the number of gaps was evident 10 m post HBT, peaking between 8 and 24 h. Gradual recovery was thereafter recorded approaching normal values ten days post injection.

For naked pDNA to be expressed following HBT it needs to overcome the obstacle of the lining endothelial cells, and reach the hepatocytes which constitute the majority of cells transfected under hydrodynamic pressure, penetrate the membrane and arrive in the nucleus. The formation of gaps, sized up to 0.3 μm following HBT seems to facilitate the crossing of DNA from the blood to the space of Disse. Further, such gaps may also help clear pDNA from the blood instantaneously, thereby avoiding exposure to nucleases and rapid degradation^[12,32]. The importance of the space of Disse and the state of its ECM components on the expression of naked pDNA using the hydrodynamic technology was proven in rats previously administered with thioacetamide.

HBT in fibrotic rats was less effective compared to healthy control rats. Further, the expression of luciferase correlated with the level of fibrosis. Liver fibrosis is associated with both qualitative and quantitative changes in the composition of hepatic ECM. In the healthy liver the endothelium expresses very little collagen thus minimizing the barrier to substrate diffusion^[30,33]. Following injury, the total content of ECM increases 3-5 times and the sub-endothelial type of ECM shifts from normal low density basement membrane like matrix to interstitial type matrix containing fibril forming collagen^[34]. These changes have been reported to also be associated with

the closure of HSC fenestrae^[35]. The low expression of luciferase achieved in fibrotic rats undergoing HBT thus seems to coincide with the deposition of ECM and the blocking of the fenestrae. Given the fact that collagen type I may account for 5%-30% of the deposited ECM components in fibrotic liver, drugs inhibiting collagen synthesis or supporting collagen degradation should be used to help gene expression following HBT. In the present study we used halofuginone to reduce ECM content induced by thioacetamide. Halofuginone is a well known collagen I inhibitor. The drug has been proven effective in various models^[36-40] including fibrotic rats using either dimethylnitrosamine or thioacetamide^[25,40]. In rats exhibiting moderate levels of fibrosis halofuginone treatment resulted in a decrease in the level of fibrosis. The expression of luciferase in this group was higher than the control group, demonstrating its efficacy.

The mechanism underlying the HBT technology is still unresolved. The formation of endothelial gaps associated with the hydrodynamic pressure developing in the liver following HBT may account for the transfer of pDNA from the blood to the space of Disse, yet it does not explain why liver cells, mainly hepatocytes, are transfected by the same pDNA. Indeed when a moderate injection of pGL3-Control (500 μL) was performed 10 or 30 m following hydrodynamic injection of Ringer solution, the level of luciferase expression was the same as that obtained following moderate injection only. The increase in the number of endothelial gaps as early as 10 m post injection suggests that they are either not involved in the transfection procedure or are not the only event occurring following HBT.

In a separate study^[19,41] an interval longer than 10 s between the two injections results in a significant and gradual decrease in the number of cells expressing the desired gene.

Isolated hepatocytes shortly after HBT demonstrate maximal pDNA expression, suggesting that DNA molecules have been taken up soon after injection. While our data on the formation of gaps generally coincide with that reported by others^[32] we found no evidence for the formation of membrane pores following HBT. If indeed DNA molecules enter hepatocytes through pores, then a certain concentration of DNA should be achieved within a short time and the number of pores should be sufficient to allow entry. Based on experimental data and theoretical assumptions Budker and colleagues^[11] are not in favor of the membrane pore mechanism but rather support the involvement of a receptor mediated process. Regardless of the unresolved mechanism underlying the hydrodynamic injection our study paves the way for using the technology in fibrotic animals as well. The usage of halofuginone in partially resolving some of the accumulated ECM components in the liver should encourage the search for drugs that might be used in future combined therapy.

Abstract

AIM: To investigate the effects and mechanisms of vasoactive intestinal peptide (VIP) and nitric oxide (NO) in the modulation of electroacupuncture (EA) on gastric motility in restrained-cold stressed rats.

METHODS: An animal model of gastric motility disorder was established by restrained-cold stress. Gastric myoelectric activities were recorded by electrogastroenterography (EGG). VIP and NO concentrations in plasma and gastric mucosal and bulb tissues were detected by radioimmunoassay (RIA). VIP expression in the gastric walls was assayed using avidin-biotin-peroxidase complex (ABC) and image analysis.

RESULTS: In cold restrained stressed rats, EGG was disordered and irregular. The frequency and amplitude of gastric motility were higher than that in control group ($P < 0.01$). VIP and NO contents of plasma, gastric mucosal and bulb tissues were obviously decreased ($P < 0.01$). Following EA at "Zusanli" (ST36), the frequency and amplitude of gastric motility were obviously lowered ($P < 0.01$), while the levels of VIP and NO in plasma, gastric mucosal and bulb tissues increased strikingly ($P < 0.01$, $P < 0.05$) and expression of VIP in antral smooth muscle was elevated significantly ($P < 0.01$) in comparison with those of model group.

CONCLUSION: VIP and NO participate in the modulatory effect of EA on gastric motility. EA at "Zusanli" acupoint (ST36) can improve gastric motility of the stressed rats by increasing the levels of VIP and NO.

INTRODUCTION

In recent years, along with the extensive research into enteric nerve system (ENS), increasing evidence shows that peptidergic neurotransmitters are the key factors regulating the gastric motility. Our previous research^[1-3] showed that electroacupuncture (EA) at acupoints of the Stomach Meridian of Foot-Yangmin may regulate gastric movement, increase blood flow in the microvessels in the gastric mucosa, and exert a protective effect on gastric mucosa. Nitric oxide (NO) and vasoactive intestinal peptide (VIP) participate in the protective effect of EA against gastric mucosal damage. It has been demonstrated that the increase or decrease of NO can lead to electrogastric dysrhythmias^[4]. Regular gastric motility in antrum was abolished after traumatic stress in rats. Plasma VIP contents were increased significantly within 2 h after stress^[5]. The restraint plus water-immersion stress in rats induced obvious enhancement in gastric motility. NO levels of gastric mucosa were decreased significantly, and the gastric mucosal lesion was obvious^[6]. VIP may be important in the prevention of gastric mucosal damage induced by cold-restraint stress^[7]. Therefore, the aim of this study was to investigate the modulative effect of EA on gastric motility and its relation to NO and VIP in the animal model of restrained-cold stress, in an effort to explore the mechanisms of EA.

MATERIALS AND METHODS

Animal treatment

Eighty Wistar rats (weighing 220 ± 30 g), provided by the Experimental Animal Center of Anhui Medical University, were randomly divided into normal control group, model

group, EA group and non-acupoint group, with 20 animals in each. Each group was further divided into two parts: 10 rats measured by radioimmunoassay, and another 10 rats measured by immunohistochemistry. Rats of the last 3 groups were subjected to 24 h of fasting (including water-intake), then anesthetized with 20% urethane (1.0 g/kg), and fastened to an animal board and put into a refrigerator at 4°C for 2 h after awaking. Bilateral “Zusanli” (ST36) were punctured with filiform needles and stimulated with an EA therapeutic apparatus and using parameters such as frequency of 20-100 Hz, dense-sparse waves, electrical current of 2-3 mA and duration of 30 min. The non-acupoint group was located at the site of the buttock on the bilateral sides. The treatment was given once daily, for 7 consecutive days.

Gastric myoelectric activity

Rats were anesthetized with 20% urethane (1.0 g/kg) and an Ag-AgCl electrode was fixed on the body surface at the projection spot of antrum (1.5 cm below xiphoid process, 0.5 cm leftward). The positive electrogastroenterography (EGG) electrode was connected with the lead column of the surface electrode and the negative electrode was connected with right lower limb, then connected to earth. Gastric myoelectric activities were measured by EGG^[8]. Frequency and amplitude of EGG were recorded and analyzed by computer^[9].

Measurement of VIP and NO concentrations

At the end of each experiment and after decapitation of the rat, 3 mL of blood sample was taken and put into a test tube containing 30 µL of 10% EDTA-Na₂ (an anticoagulant) and 40 µL of trasyolol, and mixed evenly. The blood sample was refrigerated at 4°C-8°C for 15 min, and then centrifuged at 3500 r/min, 4°C for 5 min to separate the plasma, which was put into a 1 mL tube, stored in the refrigerator at -20°C. The gastric mucosal and bulb tissues were weighed and added to 0.5 mL of 1 mol/L acetic acid and mixed evenly in a homogenizer to obtain a homogenate. The extracted homogenate was added to 0.5 mL of 1 mol/L NaOH and centrifuged at 3000 r/min, 4°C for 30 min. The supernatant fluid was collected and stored at -20°C.

The concentrations of VIP in the plasma and supernatant were determined by radioimmunoassay. The gastric mucosal and bulb tissues were boiled in 2-3 mL of normal saline for 3 min. The NO contents in blood and mucosa of gastric antrum and bulb tissues were assayed according to the method by Green *et al.*^[10]. The test kit was supplied by Beijing Huaying Bio-technique Institute.

Immunocytochemistry and image analysis

The expression of VIP in gastric wall was assayed using avidin-biotin-peroxidase complex^[11]. Rats were anesthetized with intraperitoneal injection of sodium pentobarbital (30 mg/kg). Thoracotomy and aortic cannulation were performed. After flushing of the blood with saline, the rats were perfused iv rapidly with 400 mL of fixative (4% paraformaldehyde and 0.5% glutaraldehyde) and then with slow iv drip infusion for 1 h. Antral tissues were fixed in

Table 1 Effect of EA on gastric electroactivity of antrum under restrained-cold stress in rats (mean ± SD)

Groups	n	Frequency (cpm)	Amplitude (µV)
Control	20	3.07 ± 0.55 (0.18)	363.21 ± 42.41 (0.12)
Model	20	4.26 ± 0.58 ^b (0.14)	428.54 ± 56.23 ^b (0.13)
EA	20	3.41 ± 0.48 ^d (0.14)	378.62 ± 24.38 ^d (0.06)
Non-acupoint	20	4.12 ± 0.36 (0.09)	407.25 ± 65.42 (0.16)

^b*P* < 0.01 vs control group; ^d*P* < 0.01 vs model group. Numerical value in brackets is variation coefficient.

4% paraformaldehyde for 3 h and then immersed into 20% cane sugar fluid for 12 h at 4°C in a refrigerator. The frozen tissue was serially sectioned at 30 µm thickness and mounted onto glass slides. Changes in VIP distributions in antral smooth muscle were observed by immunocytochemistry and image analysis. VIP monoclonal antibody was purchased from Sigma Chemical, USA. SABC kit was purchased from Boshide Biotechnology Co, Wuhan. Detection was carried out according to the instruction of the kit. Five visual fields in three sections of each tissue, were randomly selected and observed under the light microscope and analyzed with LeicaQ500IW image analysis system for the integral optical density (IOD).

Statistical analysis

Data were expressed as mean ± SD, and analysed by SPSS 11.0 software. Analysis of variance and *t* test were used for intergroup comparison. *P* < 0.05 was considered statistically significant. *P* < 0.01 was considered statistically obviously significant.

RESULTS

Gastric myoelectric activity

EGG was regular with frequencies of 3.07 cycle per min (cpm) and amplitudes of 360-370 µV in the control group. In rats with gastric motility disorder induced by cold restraining stress, EGG was disordered and irregular. There was an obvious difference in frequency and amplitude of EGG between the model group and control group (*P* < 0.01). Following EA at “Zusanli” (ST36), the frequency and amplitude of gastric motility were obviously decreased (*P* < 0.01). In the non-acupoint group, the two parameters had no obvious difference compared with those of model group (*P* > 0.05) (Table 1).

Effect of EA on VIP and NO concentrations

In cold restraining stress rats, VIP and NO concentrations in plasma and mucosal and bulb tissues were obviously decreased (*P* < 0.01). Following EA of “Zusanli” (ST36), the concentrations of VIP and NO rose obviously (*P* < 0.01, *P* < 0.05) in comparison with those of the model group. In the non-acupoint group, the levels had no obvious difference compared with those of model group (Table 2).

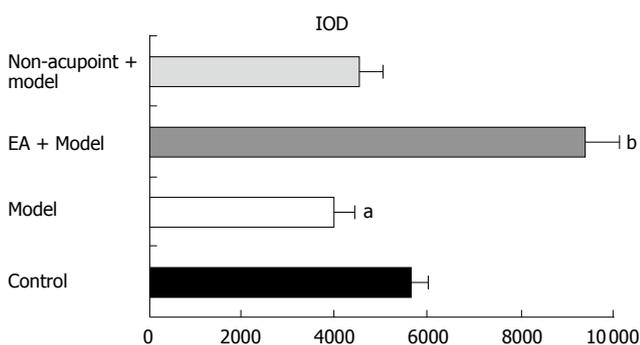

Figure 2 IOD analysis of the effect of EA on VIP immunoreactivity. ^a $P < 0.05$ vs control group; ^b $P < 0.01$ vs model group. Data are mean \pm SD, $n = 10$.

Detection of VIP by immunocytochemistry

Immunocytochemistry results showed that positive immune reaction for VIP in fibers presented as a series of beads or filaments in brown color, with a background showing no staining or stained yellow. The positive reaction was usually located in the muscle layer and submucosa. In the gastric wall muscle layer of model group, positive immune reaction for VIP fibers appeared

as lighter staining and lower density. In gastric wall muscle layer of the EA group, positive immune reaction for VIP fibers appeared as obviously dense staining (Figure 1). In the model group, computer image analysis showed that the expression of VIP in gastric wall declined obviously in comparison with the control group (3979.31 ± 582.10 vs 5646.25 ± 458.79 , $P < 0.05$), while those of VIP in gastric wall in the EA group increased obviously in comparison with model group (9420.50 ± 897.56 vs 3979.31 ± 582.10 , $P < 0.01$). However, no obvious changes of the densities of VIP in gastric wall in the non-acupoint group were found. This indicated that the effect of EA of “zusanli” can enhance the expression of VIP in gastric wall (Figure 2).

DISCUSSION

Brain gut peptides (BGPs) distribute extensively in the brain and the gastrointestinal tract. It has been demonstrated that some BGPs including gastrin (GAS), motilin (MTL), substance P(SP), VIP and somatostatin(SS) participate in gastrointestinal motility, secretion and absorption. Recent data revealed that BGPs are partially responsible for the regulatory effect of EA

on gastrointestinal tract activity, and EA can generate apparent changes in many bioactive substances such as GAS, MTL, SP, VIP, *etc.*, and the effect of EA of “Zusanli” (ST36) is of high specificity^[12,13]. Acupuncture at the stomach channel of foot-Yangming can increase the levels of NO and NOS in gastric mucosa and the NOS-positive nerves in antral myenteric plexus^[14,15]. In recent years, it has been found that decrease in gastric mucosal blood flow (GMBF) and hyperactivity of gastric motility play an important role in inducing gastric mucosal lesions under stress conditions^[16]. During stress, the gastric smooth muscle contracts intensively, resulting in disturbance of the blood circulation, decrease of GMBF and increased permeability of the vascular wall. As a result, gastric ulcer occurs^[17,18]. The results of the present study showed that in cold-restraining stressed rats, the gastric mucosal lesion was obvious. EGG was disordered and irregular. The frequency and amplitude of gastric motility were higher than that in control group ($P < 0.01$). VIP and NO levels in plasma and mucosal and bulb tissues were obviously lowered ($P < 0.01$). Following EA of “Zusanli”(ST36), the frequency and amplitude of gastric motility were lowered ($P < 0.01$), while the concentrations of VIP and NO were increased obviously ($P < 0.01$ or $P < 0.05$) in comparison with those of the model group and the expression of VIP-positive nerve fibers in gastric smooth muscle was elevated significantly ($P < 0.01$ or $P < 0.05$) in comparison with model group. The abnormal gastric motility caused by cold-restraining stress can be improved by EA and the mechanism of EA may be related to the endogenous changes of NO and VIP.

The regulation of gastric motility is a complex process related to neural activity and gastrointestinal hormone. NO and VIP, two main inhibitory neurotransmitters of the nonadrenergic noncholinergic (NANC) nerve of the intrinsic intestinal nerve system, were extensively distributed in the brain and gastrointestinal tract. They play an important role in the modulation of the function of the digestive tract. Immunocytochemistry showed that VIP-positive fibers were closely distributed around the nNOS-positive neurons. The results suggested that nNOS-positive neurons might have close morphological relationship with VIP-positive or AChE-positive neurons. They might be coordinated in the regulation of the function of the digestive tract and nitric oxide might regulate the activity of both myenteric neurons and smooth muscle^[19]. NO is involved in NANC nerve-induced relaxation and the participation of VIP (and related neuropeptides) cannot be excluded in causing relaxation of mouse gastric fundus muscle strips. Experimental findings support the idea that VIP directly stimulates the production of NO by increasing nNOS activity and thereby activating soluble guanosine cyclase in smooth muscle^[20]. It has been found that 65% of NOS containing immune active nerve fibers also have VIP immune activity, and 75% of VIP containing immune active nerve fibers also possess NOS immune activity in alimentary tract smooth muscle neurons, nerve fibers and submucosa in cats^[21]. In the rabbit stomach circular muscle layer, VIP combined with the specific receptor can lead to intracellular Ca^{2+} content increase in stomach muscle cells. Microinjection of VIP

into the dorsal vagal complex(DVC) evokes increases in gastric motor activity^[22]. Extracellular VIP also stimulates stomach muscle cells to produce NO, and increase the content of inner cAMP and cGMP, inducing muscle relaxation. Recent studies in gastric muscle strips of rabbits, rats, and guinea pigs showed that VIP-induced relaxations were inhibited by NOS inhibitors, suggesting the cascade pathway, in which VIP was proposed to be the primary neurotransmitter, inducing relaxation partially via activation of adenylyl cyclase and partially via stimulation of NO production^[23-25].

NANC nerve excitement by electric field stimulation induces muscle relaxation of gastric fundus. The underlying mechanism has been attributed to the low frequency stimulation which acts through NO production and VIP release^[26,27]. Keef *et al.*^[28] proposed that NOS and VIP-like immunoreactivities are co-localized in enteric neurons and varicose fibers in the circular muscle layer, and that NO and VIP are co-transmitters, released in parallel from enteric inhibitory nerves. We conclude that NOS and VIP are extensively distributed in the nerve cells and nerve fibers of the whole alimentary tract from esophagus to anus. In the meantime, coexistence could also be seen. Zhang *et al.* put forward that the mechanism of cooperative effects of VIP and NO may be as follows: NO and VIP act together as NANC nerve inhibitory transmitters. When NANC nerves excite, they induce release of VIP and increase of NO production. NO and VIP through interaction accelerate production of themselves^[29]. NO, besides producing smooth muscle relaxation, may enhance the release of VIP, which in turn may further stimulate NO formation^[30]. In contrast, the ineffectiveness of NOS inhibitors on the relaxations induced by VIP in many gastrointestinal tissues supports the idea that there is no interaction between NO and VIP in the gastrointestinal tract^[31]. Thus there is still controversy about the interaction between NO and VIP and the underlying mechanisms of this interaction remain to be resolved.

The results of this study suggest that gastric motility disorders during restrained-cold stress may be partially mediated by release of BGPs. Changes of NO and VIP levels in plasma and mucosal and bulb tissues may be related with the gastric motility. The regulative effect of EA on gastric motility is closely correlated with the increase or decrease of NO and VIP. EA at “Zusanli” acupoint (ST36) is capable of improving gastric motility function of the animal model by increasing the levels of VIP and NO. These data imply that NO and VIP may have a synergistic modulative effect on gastric mucosal blood flow and gastric motility. The modulative mechanism of acupuncture on gastroenterotract may be through the intricate neuro-endocrine-immune network.

Abstract

AIM: To compare the cleansing quality of polyethylene glycol electrolyte solution and sodium phosphate with different schedules of administration, and to evaluate whether the timing of the administration of bowel preparation affects the detection of polyps.

METHODS: One hundred and seventy-seven consecutive outpatients scheduled for colonoscopy were randomized in one of four groups to receive polyethylene glycol electrolyte solution or oral sodium phosphate with two different timing schedules. Quality of cleansing, polyp detection, and tolerance were evaluated.

RESULTS: Patients receiving polyethylene glycol or sodium phosphate on the same day as the colonoscopy, obtained good to excellent global cleansing scores more frequently than patients who received polyethylene glycol or sodium phosphate on the day prior to the procedure ($P < 0.001$). Flat lesions, but not flat adenomas, were more frequent in patients prepared on the same day ($P = 0.02$).

CONCLUSION: The quality of colonic cleansing and the detection of flat lesions are significantly improved when the preparation is taken on the day of the colonoscopy.

Key words: Colonoscopy; Preparation; Polyp; Flat lesion; Sodium phosphate; Polyethylene glycol

INTRODUCTION

The aim of bowel preparation before colonoscopy is to obtain a clean bowel allowing for examination of the whole mucosal surface. This preparation method should be safe and well tolerated by the patient. However, the ideal colonic lavage solution is not yet available. The two most widely employed cleansing methods are sodium phosphate (NaP) and polyethylene glycol electrolyte solution (PEG-ELS). Available data suggest that NaP achieves excellent cleansing when the first dose is administered the day before the examination and the second one a few hours before the colonoscopy^[1]. On the other hand PEG-ELS administered the same day as the colonoscopy renders a better preparation quality than when given the day before^[2]. For both preparation methods, the cecum and ascending colon seem especially susceptible to a worse preparation when the whole agent is given the day before^[1,2]. To date, no studies have been designed to compare the efficacy of NaP and PEG-ELS at their respective best administration schedules.

In the majority of available studies, the quality of bowel preparation is evaluated according to the endoscopist's impression, using pre-established scales^[1-4]. These scales only take into consideration the features and amount of remaining material. Although the detection of polyps is one of the main aims of colonoscopy, the impact of colonoscopy preparation quality on the detection of polyps has only been investigated in two recently published studies^[5,6]. Flat lesions are hard to detect due to their limited endoscopic expression. However they show a higher rate of high grade dysplasia and cancer than protruding polyps of similar sizes^[7-9], and for that reason they have become a recent field of interest and research. Although it is generally assumed by most experts in the

field that a good preparation is essential for the detection of flat lesions^[10] no prospective studies have addressed that issue. Therefore it is important to determine the influence of bowel preparation quality in the detection of flat lesions and protruding polyps, as it may have important implications in the screening of colorectal neoplasia.

The aim of the present study was to investigate whether the timing of lavage solutions before colonoscopy determines the quality of colonic cleansing and facilitates the endoscopic recognition of polyps.

MATERIALS AND METHODS

Subjects

One hundred and ninety-seven consecutive outpatients, aged between 18 and 85 years, scheduled for elective colonoscopy with morning or afternoon appointments were initially included in the study. Exclusion criteria were: pregnancy, partial or total colectomy, and inflammatory bowel disease (known or suspected). The reason for excluding patients with suspected inflammatory bowel disease was that sodium phosphate can produce mucosal changes similar to those found in Crohn's disease, which may lead to misdiagnosis. Twenty patients were not eligible for the following reasons: impossibility of reaching the cecum due to loop formation ($n = 5$), neoplastic stricture ($n = 2$), abdominal pain during colonoscopy ($n = 2$), bradycardia during colonoscopy ($n = 1$), protocol deviation due to incorrect administration of study medication ($n = 3$), incomplete data ($n = 6$), or breakdown of the endoscope during examination ($n = 1$). Therefore, one hundred and seventy-seven patients were finally included.

Methods

Having provided written informed consent, patients were assigned to one of the following four groups using a computer generated random number list. The numbers were assigned consecutively by the endoscopy assistant when the appointment for endoscopy was given. Group 1: PEG-ELS (Solución Evacuante Bohm, Laboratorios Bohm S.A, Fuenlabrada, Madrid, Spain) 3 Liters starting at 06:00 the same day of colonoscopy ($n = 43$); Group 2: NaP (Fosfosoda, Casen Fleet, Utebo, Zaragoza, Spain) 45 mL the day before (20:00) and 45 mL at 06:00 the same day of colonoscopy ($n = 45$); Group 3: PEG-ELS 3 L starting at 20:00 the day before ($n = 45$); Group 4: NaP 45 mL at 15:00 and 20:00 the day before colonoscopy ($n = 44$). Patients in groups 2 and 4 were encouraged to drink fluids liberally (at least 2 L) during the period of colonic cleansing. PEG-ELS and NaP were supplied by the manufacturers. Every patient in the study received Bysacodyl (Dulcolaxo, Boehringer Ingelheim.S.A., San Cugat del Vallés, Barcelona, Spain), 15 mg. the day before colonoscopy, as it reduces the volume of PEG-ELS required for bowel preparation^[11]. A low-fibre diet (mainly avoidance of fruits and vegetables) was recommended for the day before colonoscopy to all subjects. Having completed bowel preparation, the patients were allowed to drink only clear fluids. Patients with co-morbid conditions (chronic renal failure, symptomatic ischemic heart disease, congestive heart failure, hypertension with poor pharmacological control) allocated to the groups receiving

NaP were given PEG-ELS instead (those allocated to group 2 and 4 were given preparation for groups 1 and 3 respectively), and evaluated on an intention-to-treat analysis. The study was approved by the ethical committee of the University Hospital of the Canary Islands.

Colonoscopic examinations were performed between 09:00 and 15:00 by four experienced endoscopists on staff, one of whom had received additional training in flat polyp detection. Standard colonoscopies (CF140L, Olympus Optical España S.A., Barcelona, Spain) performed the colonoscopic examinations. Indigo carmine (2-5 g/L) was applied with a spraying catheter or a syringe to the polyp at the will of each endoscopist, usually whenever a flat lesion was suspected, or to help clarify the margin or the surface features of any type of polyp. However indigo carmine was not applied in a routine way onto normal appearing mucosa to increase polyp detection yield. Flat elevated lesions were defined according to Sawada *et al*^[12] as those with a height of less than half their diameter. Flat depressed lesions were those with a central distinct depression^[9]. Protruding polyps were resected by cold or hot biopsy when ≤ 3 mm, and those larger were resected by snare polypectomy. Some sessile polyps were resected by saline-assisted polypectomy to enable complete resection. Flat elevated lesions ≤ 5 mm were resected by hot biopsy or mucosectomy, and larger lesions with mucosectomy. Flat depressed lesions amenable to endoscopic treatment were resected by mucosectomy.

The quality of bowel preparation was determined during colonoscopy by two observers (the endoscopist performing the examination, and the attending nurse) both unaware of the preparation method employed, according to the following scale: 5 excellent, (no material or liquid material covering $< 10\%$ of the mucosal surface in each location), 4 good, (liquid material or mucus covering $> 10\%$ of the mucosal surface), 3 acceptable, (small particles easy to suction), 2 fair, (solid material impossible to suction, covering $< 10\%$ of the mucosal surface), 1 poor, (solid material covering $> 10\%$ of the mucosal surface). Global quality was calculated, as the arithmetic mean of the quality in the different locations. Whenever there was a discrepancy in the evaluation, consensus was reached after discussion. The following variables were evaluated: gender, age, chronic constipation (defined as inability to pass stools at least 3 times weekly without laxatives), indication for colonoscopy, nausea, vomiting, abdominal pain, thirst, consideration of the preparation as moderately to very disgusting, procedure time (AM or PM), quality of cleansing (globally and in the different large bowel locations), polyp status (existence or absence), protruding polyp status, flat lesion status, polyp histology, and endoscopist.

Statistical analysis

In advance of the study, a statistical sample size calculation was performed based on previously published data, indicating a good to excellent preparation in 90% of patients receiving PEG-ELS or NaP on the same day of colonoscopy, and in 70% of patients receiving those preparations the day before. To achieve an absolute difference of 20% in the frequency of good to excellent quality of cleansing in the cecum and ascending colon (score ≥ 4) (with a statistical type I error of 5% and a

statistical power of 80%) at least 124 patients (62 patients per group) was calculated as required.

A global chi-square test and singly ordered Kruskal Wallis test were used to compare qualitative data. The comparison of the proportion of patients with good-excellent and those with worse preparation quality in the four groups, was initially analysed with the Chi-square test, and then group to group comparisons were done. For the adjustment of multiple contrasts, the Bonferroni correction was employed.

Continuous variables were compared with the Student's *t* test, and means and standard deviations (SD) were reported. Calculated $P < 0.05$ was considered to indicate statistical significance.

RESULTS

Basal features of the patients are shown in Table 1; there were no differences among the four groups in terms of gender, age, chronic constipation or indication for colonoscopy. Two patients allocated to group 2 and two to group 4 received PEG-ELS due to chronic renal failure ($n = 2$), congestive heart failure ($n = 1$) and hypertension ($n = 1$), and were analyzed on an intention-to-treat fashion. There was no significant difference in the number of examinations performed by each endoscopist on patients prepared the same day or the day before. Endoscopist number 1 performed 84 (47.5%) of the 177 colonoscopies, 42 corresponding to preparation the same day and the remaining 42 to preparation the day before. Colonoscopy was performed in the morning (from 08:30 to 12:00) in 39.5%, 53.3%, 68.9%, 77.3% patients in groups 1 to 4 respectively ($P < 0.01$).

Quality of cleansing

When the four groups were compared, the quality of cleansing was different among all the segments and globally ($P < 0.001$). Per segments, in patients who received the preparation the same day (group 1, 2, Table 2) as the colonoscopy, quality was superior compared to

those prepared the day before (group 3, 4, Table 2). The global score was ≥ 4 in 78.6% ± 0.2%, 80.0% ± 0.2%, 26.7% ± 0.2%, and 6.8% ± 0.1% patients in groups 1 to 4 respectively. Groups receiving preparation the same day had significantly better global scores ($P < 0.001$) than groups prepared the previous day. Fewer patients in group 4, compared to group 3, had global scores ≥ 4 , but the difference was not significant after the application of Bonferroni's correction. In general, in groups 3 and 4 a cleansing score ≥ 4 was more frequent in distal than in proximal colonic locations.

Poor preparation (global quality score < 2), theoretically requiring a repeat colonoscopy, was found in 12.4% (11/89) of the patients prepared the previous day but only in 2.2% (2/88) of those prepared the same day as the colonoscopy ($P = 0.02$). Poor preparation precluded insertion to cecum in two patients in group 4 and one in group 3 respectively.

Polyp detection (Tables 3 and 4)

One-hundred and eighty three polyps were detected in eighty-six (48.6%) patients. Thirty-seven (20.2%) were flat (36 flat elevated, 1 flat depressed); the total number of flat lesions detected in patients who received some preparation the same day as the colonoscopy (groups 1, 2) was significantly higher ($P = 0.002$) than in those prepared the day before (Table 3). However, no significant difference was found between groups prepared the same day or the day before in the total number of polyps, the number of protruding polyps, or the number of small (≤ 3 mm) polyps. Indigo carmine was employed in 39 (44.3%) patients in groups 1 and 2, and in 22 (24.7%) in groups 3 and 4 ($P = 0.005$). There was a histological confirmation for 152/183 (83.1%) polyps, for 79.1% and 86.6% of those detected in patients receiving preparation the day before (group 3, 4) or the same day as the colonoscopy (group 1, 2) respectively. There was one (0.6%) submucosally invasive cancer, 107 (70.4%) adenomas, and 44 (28.9%) non-neoplastic polyps. Among flat lesions, 23/31 (74.2%) were neoplastic, whereas 75/121 (70.2%) protruding polyps were neoplastic. The rate of neoplastic polyps

between patients prepared the same day (61/84: 72.6 %) and those prepared the day before (47/68: 69.1%) was not statistically different. A histological diagnosis was lacking in 31/183 (16.9%) of the lesions; the most frequent reasons being inadequate preparation that precluded polyp sampling, resection or recovery, or patients on whom polypectomy was not performed at that moment, but who required a repeat colonoscopy for that purpose.

Among patients with polyps, fifty-nine (68.6%) had protruding polyps, thirteen (15.2%) had flat lesions, and fourteen (16.2%) had both protruding polyps and flat lesions. Altogether in 27 (31.4%) patients who had any kind of polyp, flat lesions were detected.

For the patient-based analysis, polyp status was evaluated: polyp status positive (patients with polyps), protruding-polyp status positive (patients with protruding polyps irrespective of presence or absence of flat lesions), flat-lesion status positive (patients with flat lesions, irrespective of presence or absence of protruding polyps), multiple-polyps (≥ 3 polyps) status, and minute-polyp (≤ 3mm) status (Table 4). There was no difference in the polyp status, protruding-polyp status, or the minute or multiple polyp status; however flat-lesion status positive was more frequent in groups 1 and 2 compared to groups 3 and 4 (21.6% vs 9.0%, respectively, P = 0.02).

The following factors were significantly associated with the diagnosis of flat lesions in the univariate analysis: male

¹As moderate or severe.

gender, endoscopist number 1, and "same day" preparation.

Tolerance and side effects (Table 5)

There was no difference regarding the occurrence of nausea, vomiting, thirst, abdominal pain or anal pain among patients in the four groups. A similar proportion of the patients in the different groups rated the preparation as moderately to very disgusting. The proportion of patients in the different groups who had bowel activity on their way to the hospital was: 16.3%, 7.7%, 9.1% and 9.5% for groups 1, 2, 3, and 4 respectively (not statistically significant).

DISCUSSION

It has been proven that a superior quality of cleansing is obtained when PEG-ELS is administered wholly or in part on the same day as the colonoscopy^[2,13]. In fact, in many Japanese institutions patients take the PEG-ELS in the endoscopy waiting room and the examination is started when the excretions become liquid and transparent. Similarly, significantly better cleansing scores have been reported when the second dose of NaP is given on the same day as the colonoscopy^[11,3]. Although many studies have compared the efficacy of cleansing between PEG-ELS and NaP, PEG-ELS was given in those studies on the day before the colonoscopy. To the best of our knowledge this is the first study ever to compare oral PEG-ELS and NaP administered at their respective best timing schedules, and our results confirm the importance of timing. In the current study, when the agent was administered the same day as the colonoscopy (the whole agent for PEG-ELS or partial for NaP), the quality of cleansing was significantly better globally and per segment than when the whole preparation was given the day before. In addition, the detection of flat lesions was markedly improved in patients with a better quality of cleansing, given that the number of flat lesions were significantly greater in patients receiving the bowel cleansing agents the same day than in those prepared the day before.

In our study the groups receiving preparation the same day as the colonoscopy reached a good to excellent quality of cleansing for all colonic segments. It is important to note that more than 75% of patients prepared the same day had a global score of ≥ 4 (good-excellent). However in groups prepared the day before, proximal bowel segments were especially poorly prepared. This

would indicate that having obtained a clean colon, material coming later from the small bowel could make the colon become dirty again, starting with the right colon. There are at least two possible explanations for that fact. Firstly, gastric, intestinal and biliary secretions could account for the material staining the colon. Secondly, although bowel preparation methods clean the colon efficiently, their effect on the small bowel might be more modest. In both instances, a longer time interval between the administration of the bowel preparation agent and the colonoscopy could account for a dirty colon. Videocapsule or enteroscopy studies could be useful to determine small and large bowel cleansing quality with different timing of administration of preparation agents.

In Spain both PEG-ELS and NaP are employed for colonoscopy. NaP is usually administered in the same way as in our study; however PEG-ELS is given by most institutions the day before colonoscopy, probably because of concern regarding the duration of diarrhoea after its ingestion. In the current study colonoscopies were scheduled from 09:00 to 14:00, and this is the rule for most public hospitals in our country. Although significant differences were not found among the different groups, we found that 16.3% of those in group 1 (PEG-ELS the same day) had bowel movements on their way to the hospital. Therefore, it might be reasonable to administer PEG-ELS at least one hour earlier than we did in our study. Although such an early administration will interfere with the patient's sleep, we believe that the effort is worthwhile, providing a good quality of cleansing and diagnostic yield, and preventing repeat examinations. Although it could be argued that from the patient's perspective it might be more difficult to ingest a large volume of fluids a few hours before the examination (same day), than the day before, no difference in tolerance variables was found between the groups. Conversely, it could be said that drinking the bowel prep a few hours before the examination, instead of the previous day, would impact on the patient's activities during a shorter period of time. Moreover, in the present study bisacodyl was used in order to reduce the total volume of PEG-ELS, as it has proven to be effective for that purpose^[11]. In our opinion, the remarkably significantly superior preparation quality observed in patients prepared the same day seems to justify that choice. An alternative strategy could be to give the bowel preparation in the endoscopy unit, which is a common practice in many Japanese institutions.

One potential limitation of the present study is the use of a non-validated scale for assessing the adequacy of the bowel preparation. There is no standardized system for describing bowel preparation^[14], and in fact most studies comparing different methods of bowel cleansing have used non-validated scales. We used a scale similar to others employed in previous reports^[4,15], but including a numerical value (90%) to describe the average of the mucosal surface covered by liquid or faecal content. Moreover, quality assessment was done by two examiners. Therefore, although employing a validated scale would have provided more reliable data, we do not believe that this has affected our study significantly.

Colorectal cancer is the second leading cause of cancer

death in most western countries, and the detection and endoscopic removal of colonic polyps has been proven to reduce the incidence of colorectal cancer. The polyp 'miss' rate seems to be especially high for lesions < 10 mm, as determined by tandem colonoscopy studies^[16]. Flat lesions represent about one fourth of all colonic polyps and may be hard to detect at colonoscopy. In the present study, flat lesions were more frequently detected in patients receiving PEG-ELS or oral NaP the same day as the colonoscopy, who reached higher rates of good to excellent bowel cleansing. The impact of colonic cleansing on polyp detection had been assessed only in two previous studies. Harewood *et al*^[5], in a retrospective study including more than 90000 colonoscopic procedures, found that an adequate preparation was associated with the detection of small (≤ 9 mm) polyps, but not of larger polyps. In a prospective multicenter European study, the detection of polyps of any size, but not of cancer, was dependent on cleansing quality^[6]. The present study represents the first evidence that flat lesion detection is associated with quality of cleansing. Although flat lesions were more frequent in patients prepared the same day, no significant difference was detected when flat neoplasia was evaluated; in fact the lack of histological diagnosis in 17% of the polyps is a potential limitation of our study. However, 74% of flat lesions with histological diagnosis available were neoplastic, which is similar to previously reported^[7]. Although an increased detection of small flat hyperplastic lesions can be expected with a high quality of cleansing, it is well known that minute flat adenomas can bear high grade dysplasia and even invasive cancer; an excellent cleansing seems therefore desirable to improve the detection of such lesions.

The more frequent application of indigo carmine in the groups receiving preparation the same day might be interpreted as another limitation of our study, as it has been proven that pancolonial application of indigo carmine with a spraying catheter increases the detection rate of small polyps^[17,18]. However, as explained in the materials and methods section, indigo carmine was applied only when a flat lesion was suspected, and only in a small amount on the suspect area. On the other hand, the more frequent application of indigo carmine in well-prepared patients (those in groups 1 and 2) is not surprising, as chromoendoscopy is used only when the colonic mucosa is sufficiently clean^[19]. Therefore, we believe that the effect of indigo carmine did not play a significant role in the increased detection of flat lesions in groups 1 and 2 in our study.

Nevertheless the outcome of real interest would be the detection of flat adenomas, rather than of flat lesions in general. The impact of the timing of bowel preparation and colonic cleansing quality on flat neoplasia detection should be evaluated in future large-scale randomized studies, adequately powered for that purpose. The importance of other factors presumably involved in flat lesion detection, such as the expertise of the endoscopist and use of chromoendoscopy should be ascertained.

Apart from an excellent bowel preparation, flat lesion detection requires a high suspicion index by the endoscopist including specific training in their detection^[20].

In fact this contention was also proven in our study. Although the four participating endoscopists shared a similar number of explored patients in each study group, endoscopist 1, who had additional training in chromoendoscopy and flat lesion detection, identified significantly more flat lesions than the others. The basic techniques for flat lesion detection, interpretation and treatment should constitute a part of the training in colonoscopy. In the present study, both preparation methods were well tolerated, and we found no difference in this respect, although other studies indicated that NaP is tolerated better due to its smaller volume^[1,3,4,15,21-24]. However in recent studies the amount of oral liquids with NaP has been increased (up to 3.8 liters) in order to prevent hydroelectrolytic disturbances^[25].

In conclusion, the present study demonstrates that the quality of colonic cleansing is significantly improved when the preparation (either PEG-ELS or NaP) is given a few hours before the colonoscopy. Although there was no overall difference in the number of polyps detected, flat lesions were more frequent in patients receiving preparation the same day. Training of the endoscopist in flat lesion detection seems to influence their detection. Larger prospective studies are needed to determine the impact of colonic preparation quality on the detection of flat and protruding neoplasia.

Abstract

AIM: To evaluate the prevalence of abnormalities of the uterine cervix in women with inflammatory bowel disease (IBD) when compared to healthy controls.

METHODS: One hundred and sixteen patients with IBD [64 with Crohn's disease (CD) and 52 with ulcerative colitis (UC)] were matched to 116 healthy controls by age (+/- 2 years) at the time of most recent papanicolaou (Pap) smear. Data collected consisted of age, race, marital status, number of pregnancies, abortions/miscarriages, duration and severity of IBD, Pap smear results within five years of enrollment, and treatment with immunosuppressive drugs. Pap smear results were categorized as normal or abnormal including atypical squamous cells of undetermined significance (ASCUS), low-grade squamous intraepithelial lesion (LGSIL), and high-grade squamous intraepithelial lesion (HGSIL).

RESULTS: The median age at the time of Pap smear was 46 (range: 17-74) years for the IBD group and matched controls (range: 19-72 years). There were more Caucasian subjects than other ethnicities in the IBD patient group ($P = 0.025$), as well as fewer abortions ($P = 0.008$), but there was no significant difference regarding marital status. Eighteen percent of IBD patients had abnormal Pap smears compared to 5% of controls ($P = 0.004$). Subgroup analysis of the IBD patients revealed no significant differences between CD and UC patients in age, ethnicity, marital status, number of abortions, disease severity, family history of IBD, or disease duration. No significant difference was observed

in the number of abnormal Pap smears or the use of immunosuppressive medications between CD and UC patients ($P = 0.793$). No definitive observation could be made regarding HPV status, as this was not routinely investigated during the timeframe of our study.

CONCLUSION: Diagnosis of IBD in women is related to an increased risk of abnormal Pap smear, while type of IBD and exposure to immunosuppressive medications are not. This has significant implications for women with IBD in that Pap smear screening protocols should be conscientiously followed, with appropriate investigation of abnormal results.

INTRODUCTION

Cervical cancer is responsible for almost 4000 deaths annually in the United States^[1]. Due in large part to mass screening protocols with papanicolaou (Pap) smears, mortality from cervical cancer has declined by over 70% in the past 50 years^[2]. The importance of mass cervical cytology screening programs in early detection of pre-cancerous and cancerous lesions has been well established. An increase in Pap smear abnormalities has not been documented in patients with either ulcerative colitis (UC) or Crohn's disease (CD), although anecdotal reports have suggested such an association. A previous study of hospitalized patients at Lenox Hill Hospital has reported a higher rate of Pap smear abnormalities in inflammatory bowel disease (IBD) patients (47%) compared to controls (15%)^[3].

The purpose of the present study was to compare the rate of cervical abnormalities in non-hospitalized patients with IBD *versus* age-matched controls and to evaluate whether

type of IBD (UC *vs* CD) and use of immunosuppressive medications are related to cervical pathology.

MATERIALS AND METHODS

This was a retrospective cohort study approved by the institutional review board. The study was performed at Lenox Hill Hospital as an interdepartmental collaborative effort amongst gastroenterologists, obstetrician-gynecologists and pathologists. Patients with IBD were identified from an IBD database that spans 30 years, which was established by the Director of Gastroenterology (BIK). Patients were contacted by mail, phone or during office visits and asked to complete questionnaires, which required information regarding age, ethnicity, marital status, type and duration of IBD, severity of illness, number of pregnancies/abortions, family history of IBD, and IBD medications [specifically the use of the immunosuppressive drugs 6-mercaptopurine (6-MP) and azathioprine (AZA), and the anti-TNF drug infliximab] used at time of PAP smear. They were 18-80 years of age with confirmed IBD and required at least one Pap smear in the previous five years for inclusion in the study. Exclusion criteria were other immunosuppressed states, such as human immunodeficiency virus (HIV), rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE) positivity. Patients signed IRB-approved release forms in order to collect the Pap smear results from their respective gynecologists. If the IBD cases received treatment with 6-MP, AZA, and/or infliximab, the duration of therapy with these drugs was calculated until the time of the Pap smear result available within the time-frame of our study (retrospective 5 years). Data regarding the use of steroids and 5-ASA products were collected using our internal IBD database, supplemented by personal communication. Severity of IBD was determined by subjective patient opinion of the disease, rated as mild, moderate or severe.

Age-matched controls (± 2 years) were identified utilizing demographic information from participating gynecologists. Controls were asked to complete questionnaires at the time of routine gynecological office visits. Inclusion and exclusion criteria were identical to the cases, except for presence of IBD. Pap smear results were obtained at the time of inclusion for the controls. For the IBD group, we contacted the patients' gynecologists in person or via telephone and requested Pap smear results and, if available, human papillomavirus (HPV) status for five years prior to the study. For the cases diagnosed with IBD within the past 5 years, we included the Pap smear results that were obtained subsequent to the diagnosis. Pap smear results were considered abnormal with any of the following: atypical squamous cells of undetermined significance (ASCUS), low-grade squamous intraepithelial lesion (LGSIL), high-grade squamous intraepithelial lesion (HGSIL), which includes carcinoma *in-situ*. When the Pap smear was abnormal, we requested any subsequent pathology reports from gynecological procedures, including loop electrosurgical excision procedure (LEEP), cone biopsy, and/or hysterectomy.

¹Combined patient-physician assessment; ²Includes at least one other first degree or second degree family member with IBD.

Statistical analysis

Demographic and clinical characteristics were obtained for both cases and controls. The statistical analysis plan included the calculation of descriptive statistics, such as percentage and median (range) for categorical and continuous data. Comparisons on non-parametric (categorical) data between the groups were made with the McNemar test for matched samples (IBD *vs* controls) and with the Pearson chi square test with Yates correction for independent samples (UC *vs* CD). $P < 0.05$ was considered statistically significant. SPSS (version 14.0) statistical software was utilized for all analyses.

RESULTS

A total of 116 cases were enrolled in the study. Of these, 91 were recruited *via* mail and 30 were recruited in person. Five cases were excluded utilizing the exclusion criteria. All the 116 age-matched controls were recruited in person. The demographic information is shown in Table 1 (IBD *vs* healthy controls) and Table 2 (subgroup analysis of IBD, CD *vs* UC). The groups were statistically different in

¹Combined patient-physician assessment; ²Includes at least one other first degree or second degree family member with IBD.

ethnicity, with more Caucasian subjects in the IBD group ($P = 0.025$). There were no significant differences between the two groups with respect to marital status ($P = 0.4$). The control group had a significantly higher number of abortions ($P = 0.008$). More than half of patients within the IBD subgroups had self-reported mild disease (33/52 with UC and 31/64 with CD). One third of the patients with IBD had family clustering of the disease, with at least one other first- or second-degree relative diagnosed with IBD. There were no significant differences between the UC and CD groups with respect to age ($P = 0.94$), ethnicity ($P = 0.66$), marital status ($P = 0.90$), number of abortions ($P = 0.20$), disease severity ($P = 0.14$), family history of IBD ($P = 0.14$), duration of disease ($P = 0.147$) and length of drug therapy, including 6-MP ($P = 0.62$), AZA ($P = 0.43$), infliximab ($P = 0.39$), corticosteroids and 5-aminosalicylate (5-ASA) products.

The main results of the study are presented in Tables 3 and 4. Table 3 shows IBD *versus* controls. Within the IBD group, 18% (21/116) of Pap smears were abnormal compared with 5% (6/116) in healthy controls ($P = 0.004$). The Pap smear abnormalities found in IBD patients were ASCUS: 9.5% (11/116), LGSIL: 5.2% (6/116) and HGSIL: 3.4% (4/116). The control group had 1.7%

Table 3 PAP results in IBD patients *vs* controls

Table 5 HPV Data in IBD patients *vs* controls (for abnormal Pap results)¹

HPV status	IBD total	CD	UC	Controls
Positive (high risk)	5	5	0	2
Positive (low risk)	3	0	3	0
Negative	4	4	0	2
Unknown	9	5	4	2
Total	21	14	7	6

¹HPV data were available in a small subset of abnormal Pap results and in none of the normal Paps.

(2/116), 2.6% (3/116) and 0.9% (1/116) Pap smear abnormalities, respectively. The subgroup analysis of IBD patients shown in Table 4 indicated that 14/50 patients with CD (22%) and 7/45 patients with UC (13%) had abnormal Pap smears. This was not a significant difference ($P = 0.793$).

Table 5 represents the HPV status of abnormal Pap smear results for patients in the IBD and control groups. HPV was positive in 11 of the IBD patients (8 CD and 3 UC) and 2 of the controls, while 4 IBD patients with CD were negative for HPV. There were 9 IBD patients (5 CD and 4 UC) with unknown HPV status. The scarcity of HPV data (more than 50% of abnormal Pap results in both IBD and control groups available and none for the normal Pap outcomes) represents the changing standards of gynecological practice during the last 6 years, the time frame used in this study. Although HPV status could have been extrapolated from the pathology slides, our study

did not include consent for the destruction of Pap smear slides. As a result, no further statistical analysis could be applied and no definitive conclusion could be reached regarding presence of HPV and abnormal Pap results in this study.

Table 6 presents the association between the major medications prescribed for patients with CD and UC and Pap smear outcomes. There was no significant association between the groups with abnormal Pap smears who were on these medications and the groups with abnormal Pap smears who were not on these medications ($P > 0.38$).

DISCUSSION

The obstetrical-gynecological issues related to fertility, pregnancy, influence of drug therapy and fistulae are known entities in patients with IBD^[4], but little is known about the link between IBD and uterine cervical pathology. Other immunosuppressed disease states such as HIV^[5,6], SLE^[7,8], and organ transplantation^[9-11] have been shown to carry increased risk for developing abnormalities of the uterine cervix leading to cervical carcinoma and it is crucial to follow the recommended screening guidelines in these patient populations. In a previous study of hospitalized IBD patients, a much higher rate of cervical abnormalities is found in patients with IBD (47%) compared with non-IBD controls (15%)^[3], for which the severity of IBD symptoms leading to the hospitalization may be responsible. Furthermore, little has been reported regarding immunosuppressive medications and the risk of cervical abnormalities, but a recent study showed that infliximab use does not increase the risk of abnormal Pap smears^[12].

The results obtained through this study of 232 women demonstrate that the presence of inflammatory bowel disease is correlated with abnormal cervical histology. The group with IBD (116) and the healthy control group (116) were well matched demographically and by gynecological history, except for the higher number of Caucasians and the lower number of abortions in the IBD group. This significantly different gynecological history would have theoretically led to an outcome such that the IBD group with a lower rate of abortions should have shown a lower rate of abnormalities on Pap smear. However, the results of our study indicate that despite this significant difference in abortion rate, the IBD group still shows a significantly higher rate of Pap smear abnormalities.

Within the IBD group, the patients with CD and UC were well matched by duration and severity of disease and medication use. Our data indicate that IBD, a group of autoimmune diseases with or without immunosuppression, also carries a higher risk for developing cervical abnormalities, as more than 18% of patients in IBD group had abnormal pap smears compared to 5% in the matched control group ($P = 0.004$) over the 5-year time period. Subgroup analysis between CD and UC revealed no statistically significant difference ($P = 0.793$) in the rate of cervical pathology. Furthermore, there were no significant associations between Pap smear abnormalities and treatments with commonly used medications for IBD patients. Specifically, oral or intravenous steroids

Table 6 Incidence of abnormal pap results in 116 IBD patients after treatment

Pap results	Normal pap n (%)	Abnormal pap n (%)	Total (n)	P

¹5-aminosalicylates (sulfasalazine, mesalamine, olsalazine, etc); ²Monoclonal antibody to Tumor Necrosis Factor α (infliximab); ³6-mp and/or azathioprine.

($P = 0.747$), 5-ASA products ($P = 0.934$), and various combinations of infliximab, azathioprine, and 6-MP ($P = 0.384$) did not significantly contribute to cervical abnormalities in IBD patients. These data provide preliminary support to the conclusion that IBD may be a significant variable for developing an abnormal Pap smear.

Due to the nature of a retrospective design we have identified limitations of our study. We relied on previous Pap smear results obtained from multiple institutions, leading to interobserver variability in the interpretation of the smears. Furthermore, clinical information was obtained from patients' questionnaires, which made the assessment of disease severity and medication use difficult due to recall bias. By relating IBD severity to the timing of Pap smears, we might have been able to determine the causal effect of diarrhea on Pap smear results, but again due to the retrospective nature, this was not possible. In addition, during the time frame of our study, only a small percentage of cases and controls had HPV data available, precluding the ability to make a correlation with this contributing factor.

Despite the limitations of the study design, our data show a significant correlation between IBD and cervical abnormalities, which is not influenced by the use of immunosuppressive medications. The precise mechanism for this correlation is unknown. Other autoimmune diseases, such as rheumatoid arthritis, may also have this correlation and further research into uterine cervical abnormalities with other immunosuppressed disease states is needed. Based on our results, we recommend the standard cervical cancer screening for all IBD female patients with strict follow-up of those with abnormal findings.

INTRODUCTION

Gastroparesis syndrome is a clinical entity characterized by chronic nausea, epigastric discomfort and recurrent vomiting, in the absence of mechanical obstruction^[1]. Gastroparesis may be either primary (idiopathic) or secondary, i.e. associated with illnesses or specific disorders that are the likely cause^[2]. Apart from common secondary causes of gastroparesis, such as diabetes mellitus and gastric surgery, most cases are idiopathic. Although in recent years some previously-labeled "idiopathic" gastroparesis cases have been shown to have a probable causal relationship with prior viral infections^[3] or myoenteric plexus ganglionitis^[4], in most cases a definite cause or even a possible link remains undetected.

Indirect evidence from electrogastrographic^[5-7] and manometric^[8,9] studies suggests that, at least in some patients, gastric hypomotility may be due to alteration of mechanisms controlling the motor activity of the stomach. Interstitial cells of Cajal (ICC), whose importance has been suspected for decades due to their close anatomical relationship with smooth muscle cells and terminal varicosities of enteric nerves^[10-12], are the pacemaker cells in the gastrointestinal tract^[13-16] and can mediate input from the enteric nervous system^[17,18]. It may thus be expected that disruption of ICC networks leads to disordered gastrointestinal motility in the affected segments^[19]. Research into ICC biology has been greatly stimulated by the discovery that they express the proto-oncogene *c-kit*^[20,21], and activation of Kit tyrosine kinase receptor signaling by the natural ligand stem cell factor (SCF or steel)^[22,23] is necessary for development and maintenance of ICC phenotype^[15,24].

Since ICC can express Kit, immunohistochemical analysis using anti-Kit antibodies provides an efficient means of identifying them in a variety of species, including humans^[25-27]. In the last few years several reports have demonstrated that ICC abnormalities are associated with some human upper-gut pathological conditions^[28,29], although few studies in gastroparetic patients to date are available.

An abnormal reduction of pacemaker cells in the stomach has been recently described in a murine model of

Abstract

AIM: To report a case of severe idiopathic gastroparesis in complete absence of Kit-positive gastric interstitial cells of Cajal (ICC).

METHODS: Gastric tissue from a patient with severe idiopathic gastroparesis unresponsive to medical treatment and requiring surgery was analyzed by conventional histology and immunohistochemistry.

RESULTS: Gastric pacemaker cells expressing Kit receptor had completely disappeared while the local level of stem cell factor, the essential ligand for its development and maintenance, was increased. No signs of cell death were observed in the pacemaker region.

CONCLUSION: These results are consistent with the hypothesis that a lack of Kit expression may lead to impaired functioning of ICC. Total gastrectomy proves to be curative.

gastroparesis^[30] and in a case of idiopathic gastroparesis^[31]. Here we report a case of severe idiopathic gastroparesis with complete absence of Kit-positive gastric ICC.

MATERIALS AND METHODS

Case history

A 39-year old woman was investigated for a long-lasting complaint of severe dyspeptic symptoms. Her past history included repeated upper GI series and endoscopic examinations, always unremarkable in 1989-1995. She was treated with antacids, sucralfate, clebopride and ranitidine, with little or no success. In 1996 she received our attention for persisting dyspeptic symptoms associated with gastroesophageal reflux. Physical examination and blood chemistry were unremarkable. An upper panendoscopy showed antral erythema and erosions, and histologic specimens revealed the presence of active gastritis associated with *H pylori* colonization. After eradication therapy, the patient continued to complain of severe post-prandial discomfort and epigastric fullness, sometimes associated with food regurgitation. Esophageal manometry and pH-metry were normal. Scintigraphic gastric emptying of a 300 kcal standard meal (Tc-albumin labeled egg white)^[32] was severely delayed (the $t_{1/2}$ at 120 min was 474, normal values 60-150). Abdominal ultrasound scans, small bowel enema and nuclear magnetic resonance of the brain and brainstem were normal. No autonomic dysfunction was documented. Therapeutic courses of high dose cisapride and domperidone were ineffective, as were oral and intravenous erythromycin.

In 1997, since the symptoms continued to worsen with the appearance of vomiting and weight loss, a percutaneous jejunostomy was thus required for feeding. However, in March 2000, due to a poor quality of life, she was again admitted and an upper gastrointestinal manometry^[33] showed almost no fasting and post-prandial gastric motility, whereas duodenojejunal motor activity was within normal limits. A total gastrectomy with esophagojejunal anastomosis and Roux-en-Y reconstruction was carried out. The post-surgical period was uneventful and she was discharged after 10 d. She subsequently enjoyed a good health, regained body weight, and did not complain of abdominal problems at follow-up.

Histology and immunohistochemistry

Multiple full-thickness samples from the stomach (fundus, corpus, and antrum) were obtained at surgery, and processed for conventional histological examination (H&E, Gomori's trichrome) and immunohistochemistry. The myenteric plexuses were assessed with a rabbit polyclonal anti-S-100 antibody (Dako, Carpinteria, CA, USA, dilution 1:4000), a monoclonal anti-CD56 antibody (clone 1B6, Novocastra Laboratories, Newcastle-upon-Tyne, UK, dilution 1:50), a rabbit polyclonal anti-neuron specific enolase (NSE) antibody (Dako, dilution 1:1000), and a monoclonal anti-neurofilament antibody (clone 2F11, Immunon, Shandon, Pittsburgh, PA, prediluted). Expression of Kit and SCF was assessed using a rabbit polyclonal antibody (Dako, dilution 1:50) and a goat polyclonal antiserum produced against a peptide mapping

at the amino terminus of SCF of human origin (Santa Cruz Biotechnology, Santa Cruz, CA, dilution 1:100), respectively. Briefly, consecutive formalin-fixed and paraffin-embedded sections were dewaxed and rehydrated through alcohol series up to distilled water. Sections were subjected to heat-induced epitope retrieval (CD56, neurofilaments, Kit and SCF) by immersion in a heat-resistant container filled with citrate buffer solution (pH 6.0) placed in a pressure cooker and micro-waved for 20 min. Endogenous peroxidase activity was suppressed by incubation with 3% solution of H₂O₂ for 5 min. Immunostaining for CD56, Kit and SCF was done with a peroxidase-based visualization DAKO EnVision™ kit, following the manufacturer's recommendations. Immunostaining for S100, NSE, and neurofilaments was performed with a peroxidase-based visualization DAKO LSAB® kit, following the manufacturer's recommendations. Diaminobenzidine tetrahydrochloride was used as chromogen. The slides were then counterstained with Mayer hematoxylin for 5 s, dehydrated and mounted in Clarion (Biomed, Foster City, CA, USA).

To determine the non-specific staining, peptides blocking polyclonal antibody binding were used or sections were incubated in the absence of primary antibody. In these cases, no immunostaining was detected. Kit-positive mast cells serving as an internal control, were counted under a light microscope at × 200 magnification within a square micrometer and expressed as mean (SE) per surface area (1 mm²). Quantification of Kit-positive ICC and nervous structures was performed by manual procedures under optical microscope (Carl Zeiss-Axioscop, Germany) and computer-assisted image analysis system (Immagini&Computer, Bareggio, Milano, Italy) using the Image Pro Plus program (Media, Cybernetics, Silver Spring, MD, USA). Five areas (1 mm²) were selected from similar regions in patient and control tissues. The area of immunopositive cells was calculated and expressed as a mean percentage of the total area of the image.

SCF staining patterns were evaluated using the immunoreactive score (IRS) proposed by Remmele^[34] in which IRS = staining intensity (SI) × percentage of positive cells (PP). SI was determined as 0 = negative, 1 = weak, 2 = moderate, 3 = strong. PP was defined as 0 = negative, 1 = 1%-20% positive cells, 2 = 21%-50% positive cells, 3 = 51%-100% positive cells. Ten visual fields from different areas of each specimen were chosen at random for IRS evaluation, and the average (SE) was calculated.

Apoptosis detection

Apoptosis was detected by transferase-mediated digoxigenin-tagged 16-desoxy-uridine-triphosphate nick-end labeling (TUNEL) assay, using the DeathEnd™ colorimetric TUNEL system (Promega, Madison, WI, USA). After deparaffinization and rehydration, sections were digested with 20 mg/L proteinase K (Sigma, St Louis, MO, USA) for 15 min at room temperature, and then incubated with a terminal transferase plus nucleotide mixture for 1.5 h at 37°C. After exposure to antidigoxigenin peroxidase for 45 min, diaminobenzidine (Sigma) was used as chromogen to detect TUNEL-positive cells, and the sections were counterstained with hematoxylin.

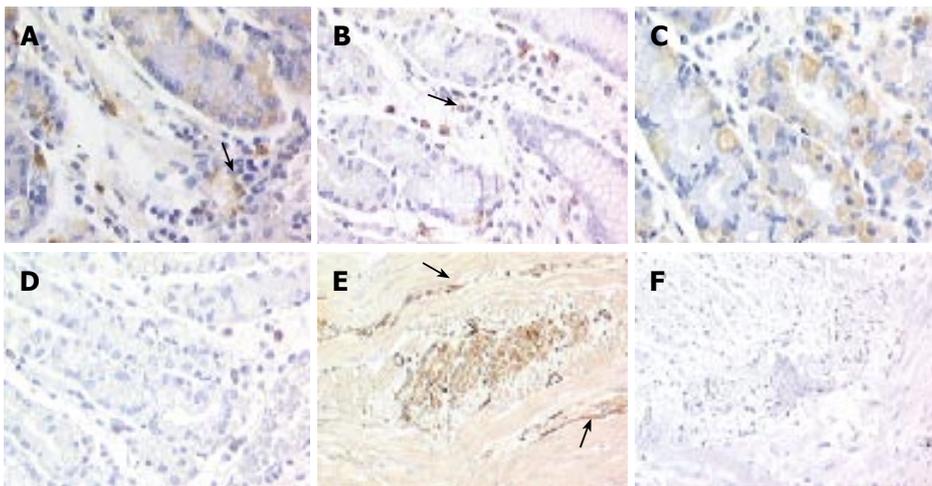

Figure 1 Expression of Kit in normal gastric tissue and gastroparesis (x 200). In both normal (A) and gastroparetic stomach (B), Kit was detected on mast cells (arrows) used as an internal control; In normal gastric samples, positivity is shown on parietal cells (C) and at the intrinsic innervation level (E, arrows), whereas in gastroparesis no staining is present at either levels (D, F).

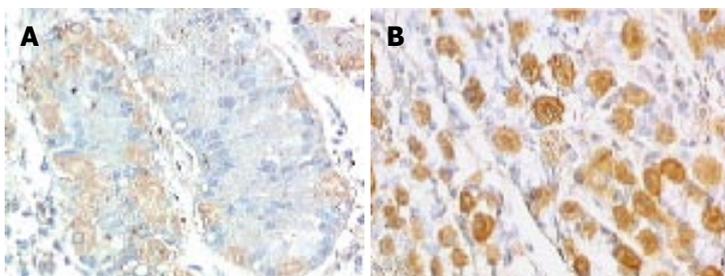

Figure 2 Expression of SCF in normal gastric tissue (A) and gastroparesis (B) (x 200). Intense intracytoplasmic expression of SCF with membrane reinforcement in gastroparesis parietal cells was present.

Controls

Control gastric tissue was obtained from 4 specimens of normal stomach taken during pancreasectomy for tumors of the pancreatic head.

Determination of SCF concentrations in sera

Serum samples collected from the patient prior to surgery and 10 age-matched healthy female volunteers, were assayed for soluble SCF using a commercially-available ELISA kit (R&D Systems, Abingdon, UK), following the manufacturer's instructions. All samples were evaluated in duplicate. The lower threshold of detection of this assay is 9 ng/L.

RESULTS

Histological examination

The mucosal, submucosal, and smooth muscle architecture appeared normal at conventional H&E staining. Trichrome stain revealed mild and scattered fibrosis of the submucosa plus some fibrosis of the external longitudinal mucosal layer as well. Neither intranuclear or viral inclusions nor any acute inflammatory cells were observed.

Immunohistochemistry

The submucous and myenteric plexus cells were abnormal in number and distribution, with ganglion cells reduced in number and size compared to normal counterparts (1.4% vs 3.9%). Kit immunodetection findings showed that scattered Kit-positive cells (identified as mast cells and used as an internal control) were observed in the patient's tissue, numerically distributed as in normal tissue (24.9/

mm² ± 2.6/mm² vs 25.7/mm² ± 3.8 /mm²) (Figures 1A and 1B). By contrast, in both parietal cells and intrinsic innervation locations Kit immunoreactivity was completely absent in the patient's tissue (Figures 1D and 1F), whereas in control tissues Kit was intensely expressed in 10% of mucosal parietal cells and at the level of the intrinsic innervation (1.8%) (Figures 1C and 1E). Since previous studies have shown that functional Kit-positive ICC are disappeared in the murine small bowel when Kit receptors are blocked^[24], we used a TUNEL method to determine whether ICC undergo apoptosis in gastroparesis. No evidence for apoptosis was observed (data not shown).

Intracytoplasmic expression of SCF was intense with membrane reinforcement in 70% of the patient's parietal cells and weaker with no membrane reinforcement in controls (Figures 2A and 2B), while the positivity for SCF, absent at the intrinsic innervation level, was diffuse throughout the tunica muscularis, in both gastroparesis and normal tissues. In order to make quantitative comparisons of SCF staining patterns in normal and diseases tissues, immunoreactive scores were determined as described by Remmele *et al*^[34] and subjected to statistical analysis, which showed significantly elevated levels of SCF in the patient's tissue sample (Figure 3).

Serum levels of soluble SCF

Serum levels of SCF in the patient (332.7 ng/L) were below the range detected in controls (mean: 741 ng/L, range: 558-1441 ng/L).

DISCUSSION

Little is known about the pathogenesis of gastroparesis,

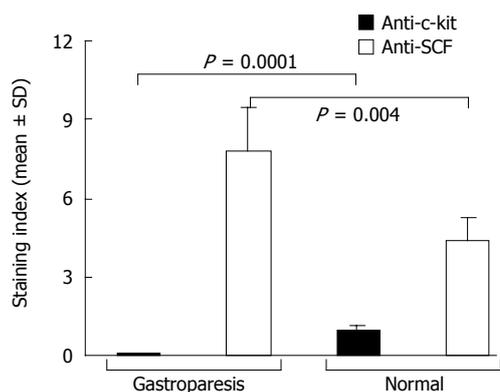

Figure 3 Quantitative evaluation of SCF expression on parietal cells in gastric tissue specimens from control subjects and the patient with gastroparesis. Differences in the immunoreactive score, obtained as described in the text, were assessed by *t*-test.

and apart from causes secondary to well-known conditions (diabetes mellitus, gastric surgery) only sporadic cases of idiopathic myenteric ganglionitis^[4] or infective causes (bacterial, viral) preceding the onset of symptoms have been identified^[35,36]. Unfortunately, pathological studies of idiopathic gastroparesis are rare, and the early ones revealed no abnormalities of the smooth muscle or the myenteric plexus^[37,38]. More recent evidence (with the introduction of Kit immunodetection) points to a reduction of gastric ICC in idiopathic gastroparesis, both in a murine model^[30] and in a single case report^[31], although the potential role in this condition of SCF, the critical factor for Kit signaling in ICC^[39], has not been investigated.

We report a case of severe gastroparesis refractory to diverse therapeutic measures, which eventually required total gastrectomy to relieve the symptoms, and in which there was complete disruption of the Kit-positive ICC network together with a reduction in number and size of ganglion cells in the submucous and myenteric plexus *vs* normal counterparts. No signs of apoptosis in the pacemaker and myenteric regions were observed, suggesting that degenerative injuries are not involved in these abnormalities. To the best of our knowledge, a total lack of detectable ICC has never been described in a “functional” gastrointestinal disorder. Since the gastric ICC network is essential for slow wave generation and plays a key role in neurotransmission of cholinergic excitation and inhibition due to nitric oxide^[17,40], this complete disruption likely explains the significant symptoms, the slow gastric emptying and the lack of response to therapeutic interventions. The lack of detectable Kit-positive ICC may be a primary event or secondary to a loss of connected signaling molecules. Previous studies have shown that ICC can be influenced to abandon the normal course of development, lose pacemaker function, and radically change its morphology if Kit is blocked or if an unsuitable form of SCF is presented^[21,41].

The binding of SCF to Kit receptors is essential to initiate a signaling pathway in ICC, which is essential for their normal development and rhythmic activity in the gastrointestinal tract^[16,42-45]. We also investigated the expression of SCF in the patient’s mucosa, and found that intracytoplasmatic and membrane SCF levels were

particularly high in parietal cells *vs* controls. In addition, as in the normal counterpart, gastroparesis tissue showed diffuse positivity for SCF throughout the tunica muscularis, potentially in close proximity to ICC.

The steel locus encodes two distinct isoforms of SCF, both of which are synthesized as transmembrane proteins expressed at the cell surface^[46]. However, one isoform, known as soluble SCF, is rapidly cleaved by proteolytic processing and released, while the other, known as membrane-bound SCF isoform, lacking the proteolytic cleavage site, releases soluble SCF much more slowly^[47,48]. Soluble and membrane-bound isoforms of SCF are expressed in the gastrointestinal tract, but the role of each isoform in supporting ICC development is unknown. However, since spontaneous Steel-Dickie mutant mice that express soluble SCF exclusively do not display spontaneous, rhythmic electric slow wave activity, and ICC are not present in the myenteric plexus^[21], membrane-bound SCF more likely plays an essential role in development and/or maintenance of ICC. Since membrane-bound SCF expression was not only retained but even increased in gastric parietal cells and supporting cells potentially in close proximity to ICC in the patient’s tissue specimen, we can postulate that in this case of gastroparesis a defective expression of Kit receptor by ICC rather than the absence of these cells leads to accumulation of SCF in this case of gastroparesis. Studies showing that mice harboring inactivating mutations in the *c-kit* gene lack ICC and their gastrointestinal tract fails to display any slow wave-type action potential^[16,24] are in favour of this hypothesis. Since the blocking of Kit receptors in the mouse causes transdifferentiation of ICC to a smooth muscle phenotype^[35], this inherent plasticity between ICC and smooth muscle cells might underlie this clinical condition. If verified, this hypothesis might be exploited, because if ICC do not die in gastroparesis but redifferentiate, it might be possible to create conditions that would shift the phenotype back toward ICC.

Besides the increased local accumulation of SCF in this case of gastroparesis, the soluble circulating form estimated by specific ELISA in the serum, was found to be decreased in our patient compared with healthy subjects. This decreased SCF serum concentration is difficult to explain and correlate with the disease, because several cell types, such as stromal cells, fibroblasts and endothelial cells, present in different tissues as well as in the gastrointestinal tract, express and release SCF and may contribute to the circulating soluble form. Moreover, SCF is thought to act locally, close to the site of production, where the concentration is likely to be much higher^[49].

This patient has undergone numerous treatments with several different prokinetic drugs, but none of them proved to be effective, as is often the case in this condition^[50]. Recently, electrical stimulation of enteric nerves and/or pacing of gastric slow wave activity have been attempted in gastroparesis refractory to medical treatment^[51]. Although reports appear to be encouraging (decreased frequency of vomiting and gastrointestinal symptoms, and improved quality of life)^[52], it must be kept in mind that this is still to be considered an experimental option available only in a few research centers worldwide.

Moreover, it should also take into consideration that, in some cases, pacing the stomach may not be effective in improving emptying when the primary cause of abnormal motility is due to insufficient excitation by the enteric nerves.

The above considerations also leave little room for other therapeutic options, such as injecting botulinum toxin into the pyloric sphincter^[53], and a surgical approach may be necessary, and is possible if small bowel function is intact. Only limited data on surgical treatment of gastroparesis are available, showing that complete gastrectomy may be effective for surgical gastroparesis, whereas a more cautious approach is required for the diabetic or idiopathic forms^[54].

In conclusion, we report a case of severe idiopathic gastroparesis, which was likely due to impaired gastric motility, the absence of ICC, or more likely due to their functional absence (i.e., ICC were present but not expressing Kit receptors, and therefore not functioning). Since this is the first reported abnormality, these findings may be useful for a better understanding of the pathophysiology of "idiopathic" gastroparesis and perhaps, for a more targeted therapeutic approach. Moreover, there is evidence that enteric abnormalities are also found in other so-called "functional" disorders (such as irritable bowel syndrome)^[55], thus leading to a reconsideration of the classification of these entities, in which organic abnormalities are increasingly found.

Abstract

AIM: To investigate the effect of polaprezinc on cellular damage induced by hydrogen peroxide (H₂O₂) in human colon CaCo2 cells.

METHODS: CaCo2 cells were treated with polaprezinc (10-100 μmol/L) for 6 h. After polaprezinc treatment, the cells were incubated with H₂O₂ (20 μmol/L) for 1 h. Cell viability was measured by MTT assay. Western blot analysis for heat shock protein (HSP) 27 and HSP72 in the cells was performed. Moreover, cells were pretreated with quercetin (200 μmol/L), an inhibitor of HSP synthesis, 2 h before polaprezinc treatment, and cell viability and the expression of HSP27 and 72 were assessed in these cells.

RESULTS: Polaprezinc significantly protected CaCo2 cells from cell damage induced by H₂O₂, and up-regulated the expressions of HSP27 and HSP72 in the cells (10, 30 and 100 μmol/L of polaprezinc; 35.0% ± 7.7%, 58.3% ± 14.6% and 64.2% ± 8.2%, respectively. *P* < 0.01 versus polaprezinc-nontreated cells; 6.0% ± 4.4%). Quercetin inhibited the up-regulation of HSP27 and HSP72 by polaprezinc and diminished the protective effect of polaprezinc against H₂O₂-caused injury in the cells.

CONCLUSION: Polaprezinc is a useful therapeutic agent for treatment of colitis and its effects depend on the function of cytoprotective HSP in colon.

INTRODUCTION

Polaprezinc [N-(3-aminopropionyl)-L-histidinato zinc], an antiulcer drug, is a chelate compound consisting of zinc ion, L-carnosine, dipeptide of β-alanine, and L-histidine and has an antioxidant effect and anti-*H. pylori* activity^[1-4]. It has been reported that administration of polaprezinc prevents gastric mucosa from tissue injury in experimental models^[5-9]. Additionally, recent works indicate that polaprezinc has a therapeutic effect in two models of experimental colitis^[10,11]. On the other hand, some studies have shown that polaprezinc up-regulates the expression of heat shock protein (HSP) in stomach and colon^[11,12].

HSP, a highly conserved and ubiquitous protein, is up-regulated to protect against various physiological stress conditions such as infection and ischemia^[13]. Some HSPs are now accepted to be key anti-inflammatory molecules and play an important role in the protection against physiologic and environmental stressors^[14]. Overexpression of these HSPs are thought to prevent apoptosis by regulating intracellular intermediates intimately involved in apoptotic signaling. In intestine, up-regulation of these HSPs by chemicals or non-lethal thermal stress has been shown to protect intestinal epithelial cells and colon tissues against injurious stimulants *in vitro* and *in vivo*^[15-20]. In particular, HSP27 and HSP72 protect cells and tissues from chemical, infectious and ischemic injury^[13]. On the other hand, our previous study demonstrated that polaprezinc up-regulates the expression of HSP27 and HSP72 in the mouse colon^[11], but there are no investigations of the effect of polaprezinc on HSP expression in intestinal epithelial cells *in vitro*. Thus, we herein assessed the effect of polaprezinc on cell damage induced by oxidative stress, which often occurs in intestine

and injured colonic epithelial cells *in vitro*. Moreover, we investigated whether the protective effect of polaprezinc depends on the function of HSPs in human colon cells.

MATERIALS AND METHODS

Materials

Polaprezinc was a gift from Zeria Pharmaceuticals Co. (Saitama, Japan). Antibodies against HSP25 and HSP72 were obtained from Stressgen (Victoria, BC, Canada). Nitrocellulose membrane filters were from Millipore (Bedford, MA). An ECL Western blotting detection system kit was from Amersham Bioscience (Piscataway, NJ, USA). Horseradish peroxidase (HRP)-conjugated goat anti-rabbit IgG antibody and a Micro BCA protein assay kit were from Pierce (Rockford, IL, USA). Quercetin was from Wako Pure Chemical Industries (Osaka, Japan). A CellTiter 96 aqueous one solution cell proliferation assay kit was from Promega (Madison, WI, USA) and an anti-actin antibody was from Sigma-Aldrich Co. (Temecula CA, USA). All other chemicals were of reagent grade.

Cell culture and treatment with polaprezinc

CaCo2 cells (between passages 8 and 14) were grown in high glucose Dulbecco's Vogt modified Eagle's media (DMEM, Sigma, St Louis, MO, USA) supplemented with 100 mL/L fetal calf serum. Cells were incubated at 37°C in 50 mL/L CO₂ and 90% humidity. Each experiment was performed with an 80%-90% confluent monolayer. Polaprezinc was diluted in DMEM and added to the cultured cells at a final concentration of 10-100 µmol/L for 6 h.

Examination of cell viability

To examine the protective effect of polaprezinc on CaCo2 cells against oxidant-induced injury, we assessed cell viability by MTT assay as described previously^[20]. Briefly, cells were grown to an approximate cell concentration of 10⁴ cells/well in 96-well plates. Cells in each well were incubated at 37°C with 150 µL of DMEM and 50 µL of CellTiter 96 aqueous, one solution cell proliferation reagent. Cell viability was determined by the generation of a formazan dye from the substrate. Absorbance (*A*) at 490 nm was measured with a spectrometer 0 and 90 min after addition of CellTiter 96 aqueous, one solution cell proliferation reagent. Difference in *A* between 0 and 90 min after incubation was calculated for evaluation of cell viability. The assay was run on cells without treatment as a negative control. The results were compared to those in a negative control and expressed as percentage of cell viability. All experiments were repeated more than three times to confirm reproducibility.

Western blot analysis

Cells were collected with 1 g/L trypsin and homogenated with a Polytron homogenizer (Kinematica, Lucerne, Switzerland). Equal amounts of homogenates were dissolved in 20 µL of Tris-HCl, 50 mmol/L (pH 6.8), containing 10 g/L 2-mercaptoethanol, 20 g/L SDS, 200 mL/L glycerol and 0.4 g/L bromophenol blue. The samples were heated at 100°C for 5 min, then subjected to SDS-polyacrylamide

gel electrophoresis (SDS-PAGE) and transferred electrophoretically onto a nitrocellulose membrane. The membranes were blocked with 10 mL/L nonfat dry milk in PBS, probed with HSP 27 and 72 Ab, and reacted with goat anti-rabbit IgG Ab coupled with horseradish peroxidase (HRP). The resultant complexes were processed for the ECL detection system according to the manufacturer's protocol. Protein concentration in the homogenate was quantified using a Micro BCA protein assay reagent kit (Pierce, Rockford, IL, USA).

Quercetin treatment

Quercetin is known to strongly inhibit the HSP synthesis^[15,20,21]. To investigate the effect of quercetin, cells were pretreated with quercetin at a final concentration of 200 µmol/L for 2 h before polaprezinc treatment. Cell viability and expression of HSP27 and HSP72 were assessed in the cells treated with quercetin.

Statistical analysis

Data obtained by MTT assay were presented as mean ± SD and statistically analyzed using an analysis of variance (ANOVA), followed by Turkey's comparison test (Stat View, SAS Institute, Cary, NC). *P* < 0.05 was considered statistically significant.

RESULTS

Polaprezinc protected CaCo2 cells against hydrogen peroxide

We assessed the effect of polaprezinc on oxidative injury in the CaCo2 cells. Morphological alteration and growth inhibition were not observed in the CaCo2 cells after exposure to polaprezinc (data not shown). To evaluate the effect of polaprezinc on oxidative stress, cell viability in CaCo2 cells treated with NH₂Cl was analyzed by MTT assay. MTT assay showed that, the difference in *A* at 490 nm, as a parameter of cell viability, was significantly decreased in the cells treated with hydrogen peroxide at a final concentration of 20 mol/L (6.0% ± 4.4%). In contrast, we found that 10, 30 and 100 µmol/L of polaprezinc (35.0% ± 7.7%, 58.3% ± 14.6% and 64.2% ± 8.2%, respectively) significantly improved viability in the cells at 6 h after polaprezinc treatment compared with the cells without polaprezinc treatment (*P* < 0.01).

Enhancement of HSP27 and HSP72 expression in CaCo2 cells treated with polaprezinc

For assessment of the HSP expression in the CaCo2 cells treated with polaprezinc, Western blot analysis for HSPs in the cells was carried out. It was found that HSP27 and HSP72 were constitutively expressed in the CaCo2 cells without treatment. The expressions of HSP25 and HSP72 was greatly up-regulated in the CaCo2 cells treated with 10, 30 and 100 µmol/L of polaprezinc for 6 h compared with those in the non-treated CaCo2 cells (Figure 1).

Quercetin inhibited up-regulation of HSP27 and 72 and diminished the protective effect of polaprezinc on oxidative injury in CaCo2 cells

To clarify the effect of HSPs induced by polaprezinc

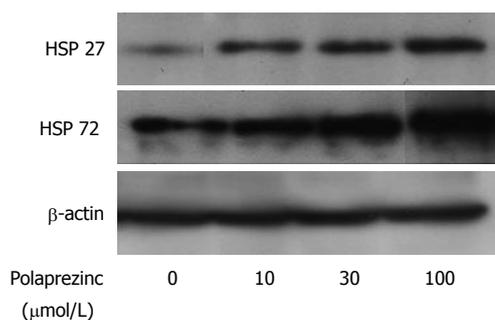

Figure 1 Effect of polaprezinc on up-regulation of heat shock protein HSP27 and HSP70 in CaCo2 cells. The expression of HSP27 and HSP72 was markedly up-regulated in the CaCo2 cells treated with polaprezinc. Representative results of three complete experiments are shown.

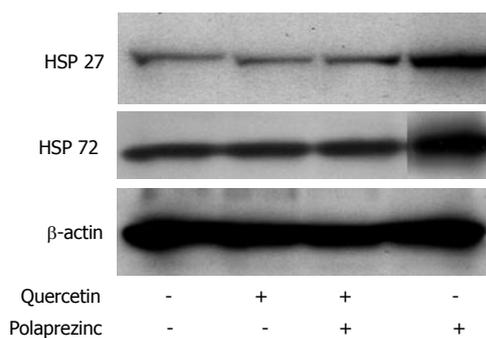

Figure 2 Effect of quercetin on induction of HSP27 and HSP72 in CaCo-2 cells treated with polaprezinc. Quercetin did not up-regulate the expression of HSP27 and HSP72 in the cells. Representative results of three complete experiments are shown.

on cell injury, we investigated the effect of quercetin, an inhibitor of HSP synthesis, and polaprezinc on CaCo2 cells injured by H_2O_2 . Pretreatment with 200 $\mu\text{mol/L}$ of quercetin for 2 h considerably reduced the cell viability in the CaCo2 cells treated with 30 $\mu\text{mol/L}$ of polaprezinc compared with the cells without quercetin treatment when cells were exposed to H_2O_2 ($P < 0.01$; $12.0\% \pm 0.3\%$ and $53.6\% \pm 1.9\%$, respectively), whereas the cell viability in the quercetin-treated CaCo2 cells without H_2O_2 was minimal compared with non-treated cells ($94.3\% \pm 0.1\%$ and $98.8\% \pm 0.1\%$, respectively). In HSP expression, 200 $\mu\text{mol/L}$ of quercetin completely inhibited the up-regulation of HSP27 and HSP72 by polaprezinc in the CaCo2 cells (Figure 2). On the other hand, quercetin did not alter the baseline level of HSP27 and HSP72 in the cells without polaprezinc treatment (Figure 2).

DISCUSSION

In this study, we demonstrated that polaprezinc improved cell viability of CaCo2 cells injured by oxidative chemicals. Moreover, polaprezinc remarkably up-regulated the expression of HSP27 and HSP72, which play an important role in protecting the cells from stresses. Additionally, quercetin, an inhibitor of HSP synthesis diminished the protective effect of polaprezinc on cell injury by H_2O_2 and the up-regulation of HSP27 and HSP72 in CaCo2 cells. These results are consistent with our previous observation that polaprezinc can up-regulate the expressions of HSP27 and HSP70 in murine experimental colitis^[11]. Recent studies have demonstrated that the expression of HSP27 and HSP70 is up-regulated by mild physiological stress and irritants^[13,14]. Furthermore, HSPs have been suggested to be key anti-inflammatory molecules and play a critical role in protective mechanism against severe physiologic and environmental stressors^[13,14]. High expression levels of HSPs are thought to prevent apoptosis by regulating intracellular intermediates intimately involved in apoptotic signaling.

In intestine, induction of HSPs by chemicals or non-lethal thermal stress has been shown to protect intestinal cells and colon tissues against injury and damage^[15-19]. Musch *et al*^[15] reported that induction of HSP72 by

hyperthermia protects rat intestinal epithelial cells from oxidative injury. Hyperthermia rapidly and reproducibly induces HSPs in intestinal epithelial cells. Otani *et al*^[16] demonstrated that preinduction of HSPs by non-lethal hyperthermia protects rats from colitis induced by acetic acid. Hyperthermia elevates the expression of HSPs, including HSP72, and remarkably reduces the severity of acetic acid-induced colitis in the colons of rats, suggesting that HSPs are important for the protection against colon tissue damage such as colitis. Although numerous studies have clarified the protecting effect of polaprezinc, there are a few investigations on the up-regulation of HSP by polaprezinc. Very recently, it has been reported that polaprezinc up-regulates the expression of HSP72 in cultured rat gastric mucosal cells (RGM1) and rat gastric mucosa^[12]. In colon, our previous study demonstrated that polaprezinc enhances the up-regulation of HSP72 in mouse colon during colitis^[11]. However, these studies have not fully clarified the role of HSP induced by polaprezinc. In this study, we demonstrated that quercetin, an inhibitor of HSP synthesis, diminished the protective effect of polaprezinc on cell damage induced by H_2O_2 and up-regulated HSP, suggesting that polaprezinc-induced HSP is essential for protection against oxidative injury in colon cells.

Besides HSP70, HSP27, a member of the small HSP family, have also been found to play an important role in protection of cells against stresses^[13]. Ropeleski *et al*^[18] demonstrated that IL-11-induced HSP27 has a protective effect against oxidative stress induced by monochloramine in cultured rat intestinal epithelial cells, as HSP27 plays a potential role in cytoprotection in intestine. Consistent with these findings and our previous findings, the expression of HSP27 is markedly up-regulated in the CaCo2 cells treated with polaprezinc. However, quercetin did not up-regulate the expression of HSP27 in CaCo2 cells treated with polaprezinc in our study. These findings provide the idea that the protective effect of polaprezinc depends not only on the function of HSP72 but also on HSP27 in colon cells.

The mechanism by which polaprezinc up-regulates the expression of HSPs has not been precisely elucidated. Interestingly, it has been reported that zinc or L-carnosine

cannot up-regulate the expression of HSPs in gastric epithelial cells and rat gastric mucosa^[12]. Our previous study indicates that zinc supplement does not induce HSPs in mouse colon^[11]. Although we did not show the effects of zinc or L-carnosine on induction of HSPs in colon cells, polaprezinc may be a powerful inducer of HSPs compared with zinc or L-carnosine. The reason why polaprezinc but not zinc or L-carnosine markedly up-regulates the expression of HSPs is unclear, thus, further study is needed to clarify this result.

In conclusion, polaprezinc protects colon cells from oxidative injury induced by hydrogen peroxide, and enhances the expression of HSP27 and HSP72 in the CaCo2 cells. The up-regulation of cytoprotective HSPs by polaprezinc is potentially therapeutic for intestinal injuries such as colitis.

Abstract

AIM: To investigate the role of vascular endothelial growth factor (VEGF) and its receptors VEGFR-1 and 2 in the growth and differentiation of gastrointestinal stromal tumors (GISTs).

METHODS: Thirty-three GISTs, 15 leiomyomas and 6 schwannomas were examined by immunohistochemistry in this study.

RESULTS: VEGF protein was expressed in the cytoplasm of tumor cells, and VEGFR-1 and 2 were expressed both in the cytoplasm and on the membrane of all tumors. Immunohistochemical staining revealed that 26 GISTs (78.8%), 9 leiomyomas (60.0%) and 3 schwannomas (50.0%) were positive for VEGF; 24 GISTs (72.7%), 12 leiomyomas (80.0%) and 4 schwannomas (66.7%) were positive for VEGFR-1; 30 GISTs (90.9%), 5 leiomyomas (33.3%) and 4 schwannomas (66.7%) were positive for VEGFR-2. VEGFR-2 expression was statistically different between GISTs and leiomyomas ($P < 0.0001$). However, there was no correlation between the expression of VEGF pathway components and the clinical risk categories.

CONCLUSION: Our results suggest that the VEGF pathway may play an important role in the differentiation of GISTs, leiomyomas and schwannomas.

Key words: Gastrointestinal stromal tumor; Leiomyoma; Schwannoma; Vascular endothelial growth factor; Vascular endothelial growth factor receptors

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are rare mesenchymal tumors of the gastrointestinal (GI) tract that may occur from the oesophagus to the anus, including the omentum^[1,2]. Despite their rarity, GISTs are the most common primary mesenchymal tumors of the GI tract^[1-3]. The mechanisms of tumorigenesis, progression and differentiation of GISTs are unknown. Traditionally, all primary mesenchymal spindle cell tumors of the GI tract are uniformly classified as smooth muscle tumors (e.g., leiomyomas, cellular leiomyomas or leiomyosarcomas). Tumors with epithelioid cytologic features are designated leiomyoblastomas or epithelioid leiomyosarcomas^[4]. Recently, Sircar *et al*^[5] postulated that GISTs originate from Cajal cells in the GI tract and differ from leiomyomas and schwannomas, which are of mesenchymal cell origin. Cajal cells are thought to be gastrointestinal pacemaker cells that regulate intestinal motility^[6]. GISTs are characterized by frequent expression of the bone marrow leukocytic progenitor cell antigen CD34^[7] and the c-kit proto-oncogene^[2,3,5].

Some GISTs have mutations in the genes encoding c-kit and platelet-derived growth factor alpha (PDGFR- α) that cause constitutive tyrosine kinase activation^[3,8-10]. Tumors expressing c-kit or PDGFR- α oncoproteins are indistinguishable with respect to activation of downstream signaling intermediates and cytogenetic changes associated with tumor progression. C-kit and PDGFR- α mutations appear to be alternative and mutually exclusive oncogenic mechanisms in GISTs^[9,10].

Vascular endothelial growth factor (VEGF) has been identified as a key regulator of tumor angiogenesis, and VEGF receptors (VEGFR) are the major mediators of the mitogenic and permeability-enhancing effects of VEGF in endothelial cells^[11,12]. In addition, VEGF is a survival factor for endothelial cells, and a marked dependence on VEGF has been shown in newly formed but not established

tumor vessels^[13]. Although the field of tumor angiogenesis is an area of extensive research, the consequences of enhanced angiogenesis and its reversion on tumor growth and progression are only partially elucidated^[14-16]. Recently, coexpression of VEGF and its receptor, either VEGFR-1 (Flt-1) or VEGFR-2 (Flk-1/KDR), has been reported in tumor cells, suggesting the presence of an autocrine and/or a paracrine VEGF/VEGFR growth pathway in solid tumors^[17-19]. Further, the expression levels of VEGF and its receptors have been shown to correlate with progressive tumor growth and development of metastasis by many carcinomas^[20].

These studies suggest that the VEGF pathway is involved in tumor growth and differentiation. However, there are no data detailing VEGFR expression in GISTs, leiomyomas or schwannomas, or the role of VEGF in the etiology of these tumors. The purpose of this study was to investigate the expression of VEGF and VEGFRs in GISTs.

MATERIALS AND METHODS

Samples

Thirty-three specimens of GISTs (28 from the stomach and 5 from the small intestine), 15 specimens of leiomyomas (4 from the oesophagus, 4 from the stomach and 7 from the large intestine), 6 specimens of schwannomas (5 from the stomach and 1 from the large intestine) were selected from surgical pathology archival tissues at Nagasaki University Hospital between 2001 and 2006. The specimens of GISTs, leiomyomas and schwannomas were 0.8-12.0 cm, 0.1-4.5 cm and 0.6-5.0 cm, respectively. In this study, GISTs were defined as expressing both c-kit and CD34 surface antigens and classified by risk categories, mitosis counts and tumor size^[21]. The number of mitoses was determined by counting 50 high-power fields (HPF, × 400) under a Nikon (Tokyo, Japan) E400 microscope. Leiomyomas were defined both as expressing α -smooth muscle cell actin (SMA) but not c-kit, CD34 or S100-protein and as expressing S100-protein but not c-kit, CD34 or SMA. Two independent pathologists (T. Nakayama and I. Sekine) determined tumor identification/classification.

Immunohistochemical staining

The subcellular localization of VEGF, VEGFR-1 and 2 was determined in GISTs using polyclonal antibodies directed against unique sequences of VEGF, VEGFR-1 and 2. These antibodies were devoid of any cross-reaction with other proteins in the VEGF family. Formalin-fixed and paraffin-embedded specimens were cut into 4 μ m thick sections, deparaffinized and preincubated with normal bovine serum to prevent non-specific binding. The sections were incubated overnight at 4°C with primary polyclonal antibody to human VEGF [(147), 1 mg/L; Santa Cruz Biotechnology Inc., Santa Cruz, CA], VEGFR-1 [Flt-1(C-17), 1 mg/L; Santa Cruz Biotechnology Inc.] or VEGFR-2 [Flk-1(C-20), 1 mg/L; Santa Cruz Biotechnology Inc.], followed by alkaline phosphatase-conjugated goat anti-rabbit IgG antibody (0.4 μ g/mL; Santa Cruz Biotechnology, Inc.). The reaction products

Table 1 Immunohistochemistry of VEGF pathway components in intestinal stromal tumours, *n* (%)

	<i>n</i>	VEGF		VEGFR-1		VEGFR-2	
		-	+	-	+	-	+
GISTs	33	7 (21.2)	26 (78.8)	9 (27.3)	24 (72.7)	3 (9.1)	30 (90.9) ^b
Leiomyoma	15	6 (40.0)	9 (60.0)	3 (20.0)	12 (80.0)	10 (66.7)	5 (33.3)
Schwannoma	6	3 (50.0)	3 (50.0)	2 (33.3)	4 (66.7)	2 (33.3)	4 (66.7)

were visualized using a mixture of 5-bromo-4-chloro-3-indolyl phosphate and nitroblue tetrazolium chloride (BCIP/NBT; Roche Diagnostic Corp., Indianapolis, IN). Negative controls replaced the primary antibody with non-immunized rabbit serum, and human breast cancer tissue served as the positive control^[22]. VEGF, VEGFR-1 and 2 expressions were classified into 3 categories depending upon the percentage of cells stained and/or the intensity of staining (-: 0% to 15% positive tumor cells; +: > 15% positive tumor cells).

Statistical analysis

The Stat View II program (Abacus Concepts, Inc., Berkeley, CA) was used for statistical analysis. Analyses comparing the degree of VEGF, VEGFR-1 or 2 expressions in GISTs, leiomyomas and schwannomas were performed using the Mann-Whitney's test.

RESULTS

The results of immunohistochemical stainings for VEGF, VEGFR-1 or 2 are summarized in Table 1. VEGF, VEGFR-1 and 2 expression was heterogeneous in GISTs, leiomyomas and schwannomas and localized to the cytoplasm and/or membrane of tumor cells (Figure 1). Immunohistochemical staining revealed VEGF expression in the cytoplasm of GIST (Figure 1A), leiomyoma (Figure 1B) and schwannoma (Figure 1C) cells. VEGFR-1 expression was shown in the membrane and cytoplasm of GIST (Figure 1E), leiomyoma (Figure 1F) and schwannoma (Figure 1G) cells. VEGFR-2 was expressed in the membrane and cytoplasm of GIST (Figure 1I), leiomyoma (Figure 1J) and schwannoma (Figure 1K) cells. Immunohistochemical staining was positive for VEGF in 26 (78.8%) of 33 GISTs, 9 (60.0%) of 15 leiomyomas and 3 (50.0%) of 6 schwannomas, respectively. Twenty-four (72.7%) of GISTs, 12 (80.0%) of leiomyomas and 4 (66.7%) of schwannomas showed positive staining for VEGFR-1. There was no statistical difference in VEGF or VEGFR-1 expression between GISTs and leiomyomas or schwannomas. Immunohistochemical staining was positive for VEGFR-2 in 30 (90.9%) of GISTs, 5 (33.3%) of 15 leiomyomas and 4 (66.7%) of schwannomas. There was a statistical difference in VEGFR-2 expression between GISTs and leiomyomas (*P* < 0.0001).

The classification of GISTs by risk category, mitosis counts and tumor size is shown in Table 2. All 4 cases within the high risk category expressed VEGF, VEGFR-1 and 2. All 4 cases with over 10 mitoses per 50 HPFs strongly expressed VEGF, VEGFR-1 and 2. Finally, only one tumor that measured over 10 cm strongly

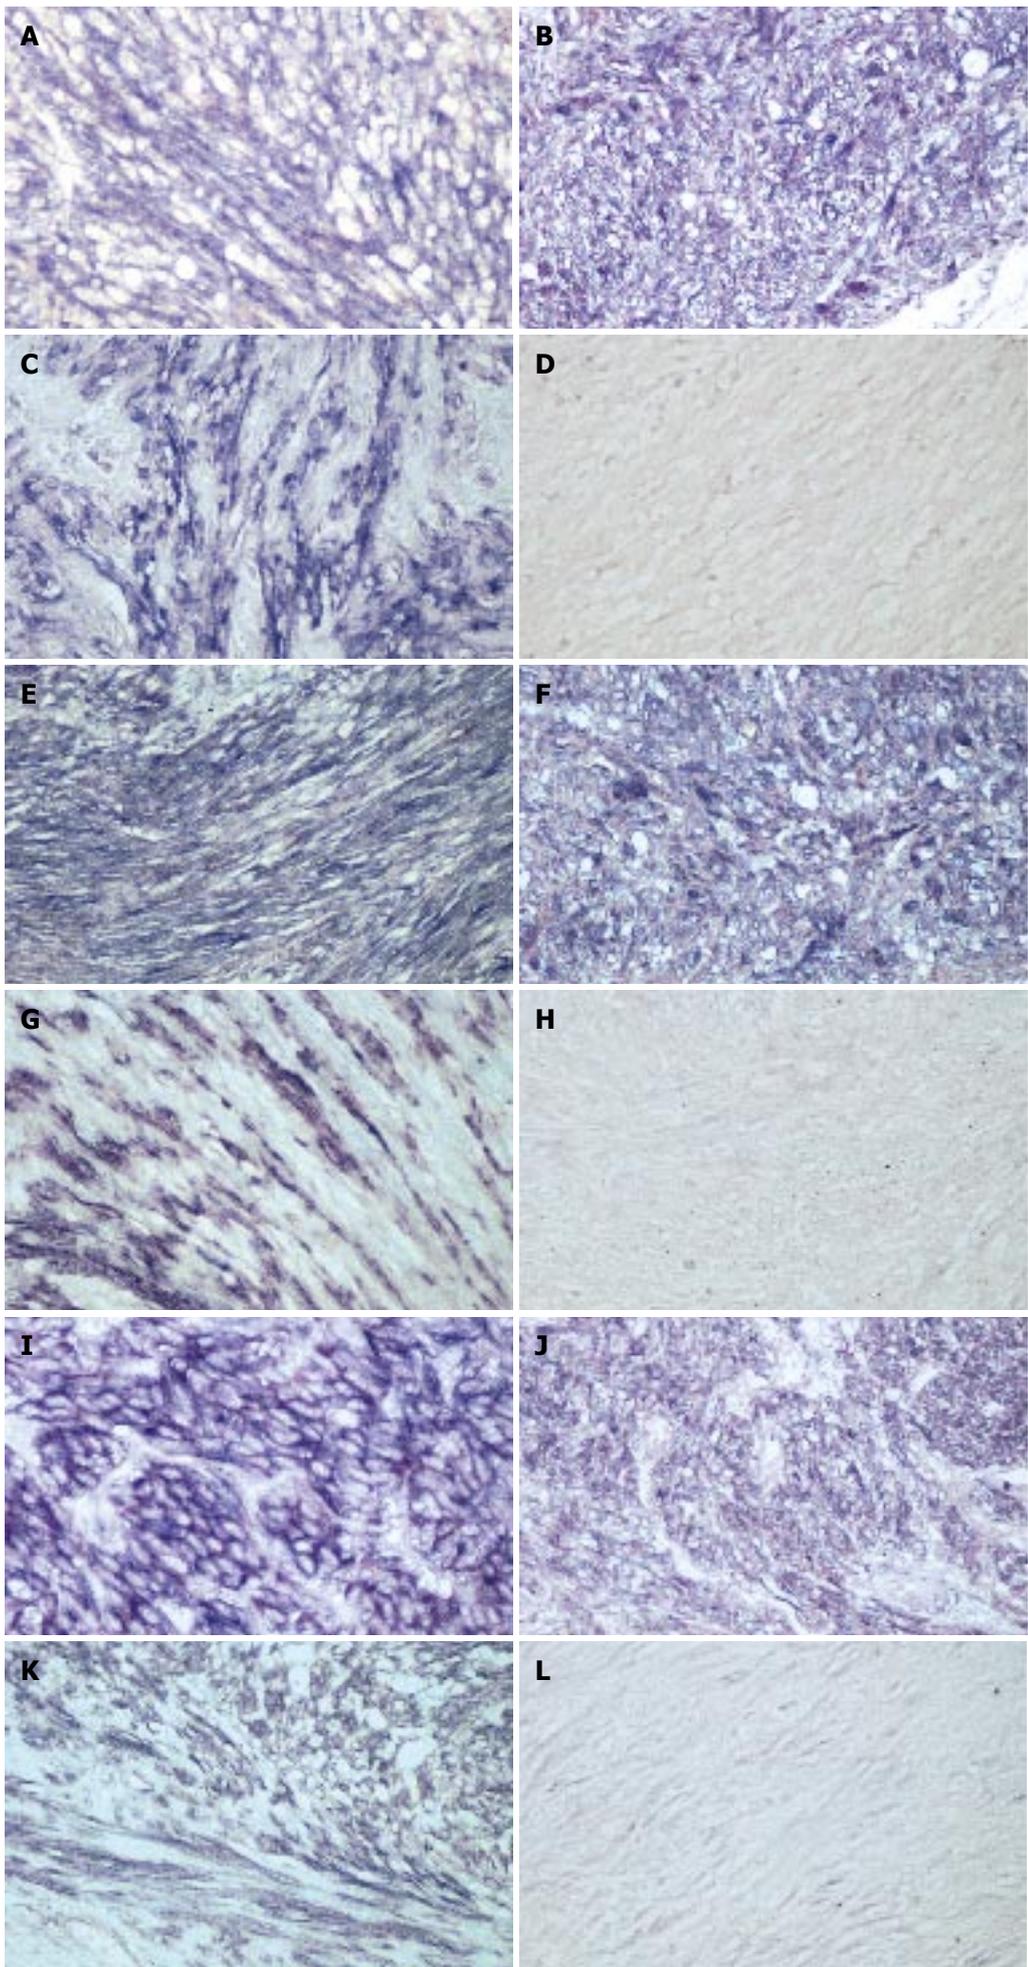

Figure 1 Immunohistochemical staining reveals VEGF expression in the cytoplasm of GIST (A), leiomyoma (B) and schwannoma (C) cells; VEGFR-1 expression in the membrane and cytoplasm of GIST (E), leiomyoma (F) and schwannoma (G) cells; VEGFR-2 expression in the membrane and cytoplasm of GIST (I), leiomyoma (J) and schwannoma (K) cells; negative staining of GIST for VEGF, VEGFR-1 or VEGFR-2 in Figure D, H or L, respectively. BCIP/NBT reaction product demonstrating VEGF, VEGFR-1 and 2 levels. (magnification: x 200).

expressed VEGF, VEGFR-1 and 2. However, there was no correlation between VEGF, VEGFR-1 or VEGFR-2 expression and each classification.

DISCUSSION

The coexpression of VEGF and VEGFR-1 and 2 has been reported in tumor cells, suggesting the presence of an autocrine and/or a paracrine VEGF/VEGFR growth pathway in solid tumors^[17-19]. VEGF also has been shown to play a role in the proliferation and/or differentiation of stromal tumors and normal mesenchymal cells^[23-26]. VEGF expression in GISTs has been already reported^[27,28]. However, there are no studies on VEGF receptor expression in GISTs, leiomyomas and schwannomas, or on the potential roles of VEGF and its receptors in the growth of these tumors. This is the first study to determine the expression of VEGF receptors in GIST and stromal tumors, demonstrating substantial levels of VEGF and its receptors in the cytoplasm of GIST, leiomyoma and schwannoma cells. Therefore, we suggest that VEGF and its receptors may play an important role in the growth and/or differentiation of intestinal stromal tumors via autocrine and/or paracrine pathways.

We did not find any statistical correlation between risk grade and the expression of VEGF or VEGFRs for GISTs. However, all 4 GISTs in the high risk category expressed VEGF and VEGFRs (Table 2). Furthermore, all 4 GISTs that had higher mitosis counts (over ten per 50 HPFs) were positive for VEGF and VEGFRs. Our data suggest that high risk GIST- expressed VEGF and VEGFR level is higher than normal. We thought that the number of high risk GISTs should be less. Further studies are needed to examine the VEGF/VEGFR pathway components in high risk GISTs.

VEGF induces a variety of enzymes and proteins important in the degradation process, including matrix-degrading metalloproteinase, interstitial collagenase, and serine proteases such as urokinase-type plasminogen

activator (u-PA) and tissue-type plasminogen activator (t-PA)^[29,30]. In this study, we did not evaluate the invasive activities of GIST cells, because all the GISTs were solitary and showed clear margins. However, the activation of these factors by VEGFRs provides for the possibility of conduction to a prodegradative environment that facilitates migration and invasion of tumor cells.

Solid tumors develop regions of low oxygen tension because of an imbalance in oxygen supply and consumption. Hypoxia in the tumor microenvironment is sufficient to activate hypoxia-inducible factor (HIF)-dependent gene expression^[31]. HIF-1 alpha (HIF-1 α) is overexpressed in most human malignancies^[32]. HIF-1 binds to HIF responsive elements in the promoter region of certain genes, such as VEGF, to increase transcription^[33]. HIF-1 expression in GIST has been already reported and suggested to contribute to tumor angiogenesis in GIST^[28]. HIF-1 might play a role in the growth of GIST, because VEGF was expressed greater in larger GISTs in this study. However, we do not have any data about hypoxia, angiogenesis or HIF-1 expression in GIST, because the purpose of this study was to clarify the role of VEGF/VEGFR pathway in GIST cells. We hope that the relationship between hypoxia and GIST growth can be clarified in next study.

Joensuu *et al.*^[34] have reported a patient in whom Imatinib (STI-571, Gleevec), a tyrosine kinase inhibitor, is effective against GIST. Imatinib has proven to be remarkably efficacious in heavily pretreated GIST patients with advanced disease in phase III clinical trials^[35]. It was reported that Imatinib down-regulates VEGF expression in the GIST cell line GIST-T1^[24]. Furthermore, anti-VEGF reagents are used in clinical trials for the therapy of colorectal, lung and breast cancer^[36]. Stimulation of VEGFR upregulates the mitogen-activated protein kinase pathway through the activation of tyrosine kinases^[37,38], the same pathway utilized by c-kit activation. These anti-VEGF reagents might be useful for the therapy of GISTs *via* the down-regulation of the VEGF/VEGFR pathway.

ACKNOWLEDGMENTS

We are grateful to Mr. Toshiyuki Kawada (Nagasaki University Graduate School of Biomedical Sciences) for his excellent immunohistochemical assistance.

Abstract

AIM: To examine the presence of human papillomavirus (HPV) in esophageal squamous cell carcinoma (ESCC) specimens collected from Colombia and Chile located in the northern and southern ends of the continent, respectively.

METHODS: We examined 47 and 26 formalin-fixed and paraffin-embedded ESCC specimens from Colombia and Chile, respectively. HPV was detected using GP5+/GP6+ primer pair for PCR, and confirmed by Southern blot analysis. Sequencing analysis of L1 region fragment was used to identify HPV genotype. In addition, P16^{INK4A} protein immunostaining of all the specimens was conducted.

RESULTS: HPV was detected in 21 ESCC specimens (29%). Sequencing analysis of L1 region fragment identified HPV-16 genome in 6 Colombian cases

(13%) and in 5 Chilean cases (19%). HPV-18 was detected in 10 cases (21%) in Colombia but not in any Chilean case. Since Chilean ESCC cases had a higher prevalence of HPV-16 (without statistical significance), but a significantly lower prevalence of HPV-18 than in Colombian cases ($P = 0.011$) even though the two countries have similar ESCC incidence rates, the frequency of HPV-related ESCC may not be strongly affected by risk factors affecting the incidence of ESCC. HPV-16 genome was more frequently detected in p16 positive carcinomas, although the difference was not statistically significant. HPV-18 detection rate did not show any association with p16 expression. Well-differentiated tumors tended to have either HPV-16 or HPV-18 but the association was not statistically significant. HPV genotypes other than HPV-16 or 18 were not detected in either country.

CONCLUSION: HPV-16 and HPV-18 genotypes can be found in ESCC specimens collected from two South American countries. Further studies on the relationship between HPV-16 presence and p16 expression in ESCC would aid understanding of the mechanism underlying the presence of HPV in ESCC.

INTRODUCTION

Human papillomavirus (HPV), a double-stranded DNA virus, is recognized as an etiologic agent of cervical cancer^[1]. In addition, HPV is suspected of causing extragenital cancers, including cancers of the oral cavity, larynx, esophagus, and lung^[2]. However, the role of HPV

infection in the pathogenesis of those malignancies is still controversial. The relationship between HPV and esophageal squamous cell carcinoma (ESCC) has been suspected since the initial reports by Syrjanen *et al* in 1982^[3,4]. An extensive review by Syrjanen published in 2002 reported that HPV is positive in 22.9% of 1485 ESCC cases analyzed by *in situ* hybridization (ISH) and in 15.2% of 2020 ESCC cases analyzed by PCR^[5]. HPV signals were reported to present in normal cells^[6], hyperplastic and dysplastic epithelia surrounding ESCC^[7,8]. Zhou *et al*^[6] reported that HPV expression in normal epithelia rarely accompanies the expression of HPV E6 protein, whereas its expression is frequently observed in carcinoma cells. These findings suggest that the involvement of HPV may take place in very early stages of esophageal carcinomas, which is suspected of being a progressive multistage process^[9]. As postulated in development of head and neck tumors^[10], esophageal cancer may arise from the "condemned mucosa"^[11], and its development is considered to involve various risk factors, including HPV.

More than 99% of cervical cancers are known to be related to HPV^[1]. One of the interesting features of cervical cancer is marked overexpression of p16^{INK4A} (p16), a tumor suppressor which is the cyclin-dependent kinase inhibitor^[12]. P16 binds to the complex of cyclin D1 and cyclin-dependent kinase 4 and represses its ability to phosphorylate the retinoblastoma protein (pRb)^[13,14]. Hyperphosphorylation of pRb promotes unbinding of pRb and E2F while the released E2F, a well-known universal transcriptional activator, stimulates p16 transcription^[15]. At the same time, however, the free pRb negatively regulates p16 expression. In the presence of HPV, this negative feedback loop between pRb and p16 is disrupted by binding of HPV E7 to pRb since E7-bound pRb cannot regulate p16 expression. As a consequence, p16 overexpression is induced by the presence of HPV^[15]. Therefore, the comparison of p16 expression in HPV-positive and -negative ESCC may give some insight into the etiological role of HPV in ESCC development.

Although seroepidemiological evidence is important in evaluating the etiological role of HPV in ESCC, studies have reported inconsistent results. A study in Finland showed that ESCC patients have elevated serum antibody against HPV-16 when compared to blood bank donors^[16]. Whereas a study in Norway has confirmed the Finnish study^[17], a study in Sweden could not confirm it^[18]. On the other hand, a study conducted in Shaanxi Province, China, where esophageal cancer risk is known to be high, ESCC patients have elevated serum antibodies against HPV-16^[19]. However, none of these studies has tried to confirm the presence of HPV in esophageal carcinoma cells.

HPV has been found in variable proportions of ESCC, depending on the methodology and study areas^[5]. Interestingly, studies from Asian countries, especially from China, have reported relatively high percentages of HPV-positive ESCC cases when compared to reports from Western European countries. To our knowledge, there is no study comparing the HPV infection rates in the South American Continent. In the present study, we examined ESCC in Colombia and Chile, located in the northern

and southern ends of the South American Continent, and compared the detection rate of HPV in ESCC in the two countries. In addition, the association of HPV presence with p16 expression was also examined in order to evaluate the possible etiological role of HPV in ESCC development.

MATERIALS AND METHODS

Patients

We examined 47 formalin-fixed and paraffin-embedded ESCC specimens from Hospital Universitario del Valle in Cali, Colombia, from 1996 to 2001, and 26 paraffin-embedded ESCC specimens from Hospital San Camilo, San Felipe, Chile, in 1996-2000. Institutional Review Board of the Faculty of Medicine, Kagoshima University, Japan, approved the present study.

DNA extraction

Each formalin-fixed and paraffin-embedded sample was cut into 10- μ m thick sections. The specimens were treated with 1 mL of xylene and then 1 mL of ethanol. After centrifugation, the pellet was resuspended in digestion buffer (50 mmol/L Tris-Cl pH 8.0, 1 mmol/L EDTA pH 8.0, 0.5% Tween 20) containing 200 μ g of proteinase K (Invitrogen) and incubated at 56°C for 24 h. After incubation, the solution was heated at 100°C for 10 min and centrifuged. An aliquot of the supernatant was directly used for PCR.

PCR, Southern blot hybridization and sequencing

HPV amplification with GP5+/GP6+ primer pair^[20,21] was made in a reaction mix containing 2.5 μ L of template DNA, 200- μ mol/L dNTP, 0.5 μ mol/L of each primer and 1.0 U Taq DNA polymerase (Takara, Japan) in a total volume of 25 μ L reaction buffer (50 mmol/L KCl, 20 mmol/L Tris-Cl, pH 8.3). The conditions of amplification were as follows: an initial denaturation at 95°C for 4 min followed by 45 cycles at 95°C for 1 min, at 40°C for 2 min, at 72°C for 1.5 min, and a final extension at 72°C for 5 min. Beta-globin amplification with PCO3/PCO4 (110 bp) primers was used as the internal positive control. PCR conditions were as follows: an initial denaturation at 95°C for 4 min followed by 40 cycles with the cycling profile at 95°C for 1 min, at 52°C for 1 min, at 72°C for 2 min, and a final extension at 72°C for 5 min. DNA purified from Hela cells containing HPV-18 was used as external positive control.

The amplified products were revealed by electrophoresis with 3.0% agarose gels at 100 volts for 30 min. After electrophoresis, the DNA was transferred onto Hybond N+ nylon transfer membrane (Amersham, UK) by capillary blotting using 0.4 N NaOH. The generic GP5+/GP6+ PCR products amplified from HPV-18, -16, -11 and -6 were purified from agarose gels with QIAEX II extraction kits (Qiagen GmbH and Qiagen Inc., Hilden, Germany) and used as probes. The hybridization was performed at 42°C overnight and then the membranes were washed at 42°C with solution containing 6 mol/L urea, 0.4% SDS and 0.5 \times SSC buffer. For the detection of the HPV band, hybridization was carried out using the

ECL direct labeling and detection kit (Amersham, UK) according to the manufacturers instructions. Amplified PCR products that appeared as a visible band after ethidium bromide staining were purified using QIAGEN PCR purification kit and directly sequenced by fluorescent dye-labeled dideoxynucleotides and cycle sequencing methods using the “Big Dye Terminator cycle sequencing kit” (PE Applied Biosystems, New Jersey, USA). In the samples where positive signal was seen only after Southern blot analysis but not in the agarose-gel electrophoresis, a second round of PCR was conducted. Sequence analysis was performed on the ABI PRISM 310 genetic analyzer (PE Applied Biosystems, New Jersey, USA). The nucleotide sequences were aligned and compared with those of known HPV types available from the GenBank database (NCBI, National Institute of health, Bethesda, MD, USA) by using BLAST 2.2 (<http://www.ncbi.nih.gov/BLAST/>).

P16^{INK4A} protein immunostaining

Sections of paraffin-embedded tissue with a thickness of 2-3 μm were placed on silane-coated glass slides, and deparaffinized by passage through xylene. After the endogenous peroxidase activity was blocked with 0.3% H₂O₂/methanol, the slides were then rehydrated with 0.01 mol/L sodium phosphate/citrate buffer, pH 8.0. For antigen retrieval, the slides were heated in 0.01 mol/L-citrate buffer, pH 6.0, at 95°C for 30 min, and left to cool for 30 min. After rinsed in 0.01 mol/L phosphate-buffered saline (PBS), pH 7.4, nonspecific antibody binding was reduced by incubating the sections with 10% fetal bovine serum in PBS for 30 min. Then, the sections were incubated overnight at 4°C with a mouse monoclonal antibody of p16 protein (1:200 dilution, GST-p16^{INK4A}, PharMingen International). After washing thoroughly with PBS, the slides were incubated with biotinylated horse anti-mouse IgG for 30 min followed by 1:100 dilution of the avidin-biotin-peroxidase complex (Vectastain elite ABC kit, Vector Laboratories, Burlingame, CA) for an additional 30 min. The peroxidase signal was visualized by treatment with DAB substrate-chromogen system (DAKO) for 8 min. Finally the sections were stained lightly with

hematoxylin. In statistical analysis, those having less than 10% cells stained positive were classified as negative cases and the others were regarded as positive cases^[22].

Statistical analysis

Fisher's exact test was used to examine the association between HPV status and each clinico-pathological factor including p16 expression. We used Wilcoxon rank-sum test for the comparison of age distribution. All the P values presented in the present study were two-sided.

RESULTS

We examined 47 Colombian cases and 26 Chilean cases. Their clinico-pathological features are summarized in Table 1. Chilean patients were older than Colombian patients, and Chilean ESCC tended to be more poorly-differentiated than Colombian tumors.

HPV was detected using GP5+/GP6+ primer pair by PCR and its presence was confirmed by Southern blot analysis using HPV-16, -18, -11 and -6 specific probes. In all HPV-negative samples, beta-globin gene was successfully amplified by PCR. Table 2 summarizes the results of HPV detection analysis. HPV-16 and -18 were detected in 11 and 10 cases, respectively. No other HPV genotypes were detected in either country. We confirmed the absence of HPV-6 and -11 by Southern blot analysis using the probes specific for HPV-6 and -11. HPV genotype was determined by sequencing analysis of L1 region fragment.

HPV-16 was detected in 6 Colombian cases (13%) and 5 Chilean cases (19%). The five positive samples from Chile were detected only after Southern blot analysis, and a second round of PCR was necessary for sequence analysis. The difference in HPV detection rate of the two countries was not statistically significant (P = 0.181). HPV-16 detection rate did not show any statistically significant association with sex or age. The presence of

HPV-16 genome was more frequent in well-differentiated carcinoma and p16-positive tumors but their association was not statistically significant.

HPV-18 was detected in 10 Colombia cases (21%) but not in any Chilean cases. The observed difference was statistically significant ($P = 0.011$, Fisher's exact test). HPV-18 detection rate did not show any statistically significant association with sex, age, or with p16 expression. Its detection rate was higher in well-differentiated tumors as was the case for HPV-16 but the association was not statistically significant.

DISCUSSION

In the present study, we detected HPV in 29% of ESCC specimens using PCR and Southern blot analysis. The observed frequency is similar to that obtained from the meta-analysis by Syrjanen^[4]. HPV-16 and -18 were detected in 15% and 14% of ESCC specimens, respectively. HPV-16 positive and negative tumors did not show any differences in demographic and pathological features.

The etiological role of HPV in development of ESCC is as yet unclear. There is, however, evidence that HPV plays an etiological role in development of ESCC. For example, high risk HPV E6/E7 genes have been shown to be capable of inducing immortalization in established cell lines of fetal esophageal epithelial cells and primary culture of human esophageal keratinocytes^[22,23]. HPV E6 proteins are known to bind to p53 *in vivo* and to abrogate p53-mediated repression of transcription^[24]. The mode of p53 activation at a cancer site may differ. It is suggested that the major mode of p53 inactivation may be through interaction with E6 in HPV-infected cervical tissue while both E6-p53 interaction and mutation of the p53 take place in upper aero-digestive tract carcinomas^[11].

The carcinogenic mechanism of HPV involves the binding and inactivation of pRb by HPV E7 products as well, and the expression of HPV-16 E7 protein correlates with reduced pRb levels in cervical biopsies^[25]. However, such a relationship has not been confirmed in esophageal carcinomas. On the other hand, the loss of this protein causes overexpression of p16, which is an inhibitor of cyclin-dependent kinase. This event is very frequent in cervical cancer, where HPV has been demonstrated to play an etiological role^[12]. In the present study, positive HPV-16 was more frequently detected among p16 positive cases, supporting the hypothesis that HPV may have an etiologic role in esophageal carcinogenesis. The observed association was, however, not statistically significant. On the other hand, the frequency of HPV-18 did not differ in p16-positive and -negative carcinomas. Further studies on this association seem warranted.

In the present study, the prevalence of HPV-18 was significantly lower in Chilean ESCC cases than in Colombian cases, whereas HPV-16 detection rate did not show any differences between the two countries. Regarding this observation, the prevalence of HPV in the two countries may give some insights. A study on cervical smears collected from women aged 15-69 years in Santiago, Chile^[26], showed that the most common HPV genotype is HPV-16 followed by HPV-56 and -58, while

HPV-18 is detected in 0.5 % of subjects and HPV-16 in 2.6% of subjects. In Bogota, Colombia, a study on cervical smears^[27] showed that HPV-16 prevalence is 16.1% among women aged 35 or older and HPV genotypes of 18, 39, 45, 59, and 68 are present in 13.6% of women of the same age group. Although comparison of the results obtained from these studies is difficult because of the differences in their study designs, their results suggest that HPV 18 is much less common than HPV-16 in the study areas.

The mortality of esophageal cancer is estimated to be 7.3 per 100 000 men and 3.5 per 100 000 women and the fifth leading cause of cancer death in men and the seventh in women^[28]. Interestingly, its frequency evidently varies worldwide^[29]. The high-risk areas include the so-called Asian esophageal cancer belt from eastern Turkey, Iraq, Iran, and western and northern China^[30]. The wide geographic variations in the risk of esophageal cancer suggest that environmental and genetic factors are involved in development of esophageal carcinomas, and HPV is suspected of a potential factor contributing to the high incidence of ESCC in areas of Iran, China and other countries^[31,32]. Latin America is not known to be a region where esophageal cancer risk is high. In Cali, Colombia, the local cancer registry office reported that esophageal cancer incidence (crude rate) is 6.5 per 100 000 men and 2.0 per 100 000 women, respectively, in 1995-1998^[33]. In Chile, cancer registry data are not available. However, cancer mortality, which is assessable even if cancer registry is not present, is expected to be not much different from cancer incidence because its prognosis is poor as is the case in other countries^[34]. In this country, esophageal cancer is the fifth leading cause of death from neoplastic diseases in men (5.8/100 000) and the twelfth in women (3.5/100 000)^[35]. The Hospital San Camilo, which participated in the present study, is the major medical institution in San Felipe city, Aconcagua Province. In this area, esophageal cancer mortality rate is estimated to be 6.5/100 000 persons, not evidently different from the rate in the entire nation. Thus, we can conclude that the ESCC risk is not much different in the two countries. Since Chilean ESCC cases had a higher prevalence of HPV-16 (without statistical significance), but a significantly lower prevalence of HPV-18 than in Colombian cases in the present study. The frequency of HPV-related ESCC may not be related to factors that play an important role in the incidence of ESCC in the two countries. However, the small number of cases examined makes it difficult to draw any definitive conclusion.

In conclusion, HPV-16 and -18 genotypes can be found in ESCC patients from Colombia and Chile. Further studies on the relationship between HPV-16 and -18 presence and p16 expression are needed for understanding the mechanism underlying the presence of HPV in ESCC.

Abstract

AIM: To analyze $\beta 2$ -integrin expression on blood leukocytes in liver cirrhosis.

METHODS: In 40 patients with liver cirrhosis and 20 healthy individuals, the evaluation of expression of CD11a (LFA-1 α), CD11b (Mac-1 α), CD11c (αX) and CD49d (VLA-4 α) on peripheral blood leukocytes was performed using flow cytometry. The analysis was carried out in groups of patients divided into B and C according to Child-Pugh's classification.

RESULTS: An increased CD11a, CD11b, CD11c and CD49d integrin expression was observed on peripheral blood leukocytes in liver cirrhosis. The integrin levels were elevated as the advancement of liver failure progressed. The highest expression of integrins occurred predominantly on monocytes. A slight expression of VLA-4 was found on lymphocytes and granulocytes and it increased together with liver failure. A positive correlation was noted between median intensity of fluorescence (MIF) expression on polymorphonuclear cells of CD11a and CD11c and CD49d ($r = 0.42$, $P < 0.01$; $r = 0.53$, $P < 0.01$, respectively) in liver cirrhosis stage C. However, no correlation was observed between integrin expression on leukocytes. The concentrations of sICAM-1, sVCAM-1, and TNF α , were significantly elevated in liver cirrhosis.

CONCLUSION: $\beta 2$ -integrin expression on leukocytes increases in liver cirrhosis decompensated as the stage of liver failure increases, which is a result of permanent activation of leukocytes circulating through the inflamed liver environment. $\beta 2$ -integrin expression on circulating leukocytes can intensify liver cirrhosis.

INTRODUCTION

Integrins play a role in organ and tissue damage, by the inflammatory and immunological processes, and in autoimmune diseases^[1-4]. They participate in the regulation of leukocytes in the procoagulant activity and adhesion to infectious factors^[5]. Many integrins mediate transduction of signals that stimulate T cells^[6]. $\beta 2$ integrins participate in the presentation of antigens by antigen-presenting cells (APCs). They mediate the adhesion of T cells to APCs through the formation of immunological synapses with the help of $\beta 2$ /ICAM-1 complexes, known as the supra-molecular activation complex (SMAC). Integrin expression strongly depends on cellular energy metabolism. Activated leukocytes express $\beta 1$ and $\beta 2$ that integrins play a key role in leukocytes mobilization to circulate to inflammatory sites^[7]. Monocytes and granulocytes are important in organic defense against bacterial and viral infections. LFA-1 and Mac-1 are involved in other functions of neutrophils, such as phagocytosis, degranulation, and apoptosis^[2].

Inflammatory and immunological reactions in the liver are accompanied by peripheral blood leukocytes infiltration in the tissue^[8]. Leukocyte recruitment takes its course with the participation of adhesive molecules presented by capillary endothelial cells^[8,9]. The particular stages of recruitment, such as leukocyte rolling, adhesion, and transmigration, depend on signals released by endothelial cells. Activated leukocytes expressed adhesion molecules $\beta 2$ -integrins CD11a (LFA-1a), CD11b (Mac-1a), CD11c (αX), and $\beta 1$ -integrins CD49d (VLA-4a) on their surfaces^[1,3,4]. Integrins mediate in interactions between cells and extracellular matrix (ECM) proteins. ICAM-1 (ligand for LFA-1a and Mac-1a), ICAM-2 (ligand for LFA-1a), VCAM-1 (ligand for VLA-4a), extracellular matrix proteins, such as collagen, laminine, vitronectine as well as blood clotting proteins (fibrinogen, factor X, kininogen) are ligands for integrin receptors on leukocytes. Products released by microorganisms, that can facilitate penetration into cells, can be ligands for integrins^[5]. Cytokines released in inflammatory sites induce the expression of endothelial ligands that activate circulating leukocytes^[10].

Inflammation in liver cirrhotic tissue and in the systemic circulation affects peripheral leukocytes $\beta 2$ -integrin receptors. In this study, the evaluation of $\beta 2$ -integrin expression

on monocytes, lymphocytes, and granulocytes of peripheral blood in liver cirrhosis was carried out. The influence of liver failure stage on the expression of $\beta 2$ -integrin leukocyte receptors was taken into account.

MATERIAL AND METHODS

Forty patients (28 men and 12 women; age 50 ± 13 years) with post-alcoholic liver cirrhosis were enrolled in this study. Liver biopsy of the right lobe established the liver cirrhosis. Clinical characteristics of patients are given in Table 1. According to Child-Pugh's classification^[11], patients were divided into 2 groups: B ($n = 21$) and C ($n = 19$). Those overusing alcohol with immunosuppression therapy, hepatotropic viral infections (HBV, HCV, CMV) or fever were excluded from the study. The control group consisted of 20 healthy individuals (12 women and 8 men; age 40 ± 7 years).

Leukocyte population

Peripheral blood leukocyte population (monocytes, lymphocytes, granulocytes) was determined by flow cytometry (Coulter, USA). Leukocytes were identified by their forward and orthogonal light scatter characteristics on immunological gate. The percentage of leukocyte population and median intensity of fluorescence (MIF) of integrin receptors were determined using mononuclear antibodies CD11a (CD11a PE, DAKO Cytomation, Denmark), CD11b (CD11b PE, DAKO Cytomation, Denmark), CD11c (CD11c PE, DAKO Cytomation, Denmark), CD49D (CD11a PE, DAKO Cytomation, Denmark), and CD14 (CD14 FITC, DAKO Cytomation, Denmark). Two millilitres of blood was collected in plastic tubes containing sodium citrate. Five microlitres of mAb was added to 50 μ L of blood and incubated for 15 min at room temperature in the dark. Erythrocytes were eliminated by adding diluting-lysing fluid (ImmunoPrep-Reagenziensystem ABC, Coulter). A minimum of 10 000 leukocytes was analysed in each sample.

Tumor necrosis factor alpha (TNF α , R&D, England), sICAM-1 (sICAM, R&D, England), sVCAM-1 (sVCAM-1, R&D, England) concentrations were determined in the blood sera using ELISA methodology. Leukocyte counts was carried out in hematological analyzer Sysmex K-1000 (Japan). Ethical approval for research was obtained from the Local Ethics Committee in the Medical University.

Statistical analysis

The results were expressed as median with range values and mean \pm SD. Statistical analysis was performed by non-parametrical Mann-Whitney *U*-test. Result correlation was calculated with the use of Spearman test. A *P* value less than 0.05 was considered statistically significant.

RESULTS

Monocytes

The expression of CD11a (LFA-1a) receptors on peripheral blood monocytes was increased in liver cirrhosis

Table 1 Clinical characteristics of patients with liver cirrhosis

patients as compared with healthy subjects (Table 2). Progressive liver damage resulted in increased population and number of receptors for this integrin on monocytes. The differences in CD11a MIF values between patients in B and C stages were statistically significant (*P* < 0.05). There was a positive correlation between the expression of CD11a and CD11c receptors on monocytes in the control group and in B and C stages of liver cirrhosis ($r = 0.73$, *P* < 0.01; $r = 0.39$, *P* < 0.05; $r = 0.56$, *P* < 0.01, respectively, Table 3). Moreover, a positive correlation was found between monocyte CD11a MIF and CD11a expression on lymphocytes in patients in stage B. However, no other significant relations were observed between CD11a expression and other integrins on other leukocytes.

¹Healthy subjects; ²B stage of liver cirrhosis; ³C stage of liver cirrhosis; ⁴Not significant. Spearman test.

CD11c MIF increased slightly on monocytes in B and C stages of liver cirrhosis ($P > 0.05$). Furthermore, CD 49d expression in subsequent stages of liver cirrhosis was slightly elevated on monocytes ($P > 0.05$). There was no dependence observed between VLA-1a receptor expression and the serum concentration of soluble forms of ICAM-1, VCAM-1, and TNF α .

Granulocytes

The expression of CD11a on granulocytes in healthy subjects and liver cirrhosis (independently the stages B and C) was comparable. CD11b receptor expression on granulocytes in severe liver cirrhosis was significantly elevated ($P < 0.05$, controls *versus* stage B). In contrast, no significant difference was observed in the expression of CD11c on granulocytes between the liver cirrhosis and control groups. CD49d expression on granulocytes was approximately 10 times lower than that on monocytes, although it increased together with the stage of liver damage ($P < 0.01$ *versus* the controls). A positive correlation was observed between CD11a and CD11c MIF on granulocytes ($r = 0.42, P < 0.01$) in liver cirrhosis stage C. Also, a positive correlation between CD11a expression on granulocytes and CD49d in liver disease stage C ($r = 0.53, P < 0.01$) was found.

Lymphocytes

LFA-1, among other $\beta 2$ -integrins, had the highest expression on lymphocytes. In liver cirrhosis, higher values of LFA-1 on leukocytes were observed, and were found to be increased with the advancement of liver insufficiency (stage B: 9.7 ± 1.6 , stage C: 9.9 ± 2.0 , healthy: 8.0 ± 1.2 ; $P < 0.05$ *vs* controls). A significantly lower expression of Mac-1, αX , and VLA-4 was noted on lymphocytes, while increased expression was detected in liver cirrhosis. The elevation of CD11b and CD11c expression was found to be affected by

the stage of liver failure, whereas VLA-4 expression was not influenced by the condition. A positive correlation was noticed between LFA-1 expression and Mac-1 expression (stage C: $r = 0.51, P < 0.02$), as well as VLA-4 expression (stage C, $r = 0.51, P < 0.02$).

We did not observe any correlation between the concentrations of soluble forms of ICAM-1 and VCAM-1 and the expression of integrins in particular stages of liver cirrhosis and in the controls. Stage B of liver cirrhosis was the only stage, in which a negative correlation was observed between sICAM-1 and CD11a expression on lymphocytes ($r = 0.49, P < 0.03$). On contrary, a positive correlation was noted between TNF- α concentration and sICAM-1 level in liver cirrhosis stage B ($r = 0.68, P < 0.01$).

DISCUSSION

Studies showed that the stage of liver failure has a significant impact on $\beta 2$ -integrins by the intensification of their expression on leukocytes. Liver cirrhosis was associated with elevated expression of $\beta 2$ -integrins CD11a, CD11b, CD 11c, and CD49d on leukocytes surfaces. The results indicated leukocyte stimulation in liver cirrhosis, and that a cell population of higher function can potentially appear. It was observed that the expression of $\beta 2$ -integrins on monocytes, granulocytes, and lymphocytes increased in patients with liver cirrhosis. The only exception was LFA-1 on granulocytes, whose expression did not differ as compared to the controls. Monocytes had the highest $\beta 2$ -integrin expression on the surface, indicating that monocytes have an important role in the pathogenesis of liver cirrhosis. The population of monocytes with $\beta 2$ -integrin expression increases with the stage of liver failure. It causes the elevation of their activity in relation between cells and ECM proteins. Circulating monocytes

are precursors of dendritic cells and macrophages of the liver. Activated by a liver inflammatory environment, they expose on their surfaces adhesion molecules that enable active participation in the intensification of inflammatory and immunological processes in the liver. Immunological disorders belong to the main phenomena in the pathogenesis of liver cirrhosis. Moreover, it has been shown that liver cirrhosis is accompanied by high concentrations of TNF- α and soluble adhesive molecules sICAM-1 and sVCAM-1, whose concentrations did not correlate with β 2-integrin expression on leukocytes in our studies.

The activation of endothelial cells has a crucial role in modulation of leukocyte functions in liver cirrhosis. Endothelial soluble adhesive molecules, induced by pro-inflammatory cytokines, are the markers of the functional condition of endothelial cells. The role of adhesive molecules in the pathogenesis of liver cirrhosis and portal hypertension has not been fully explained yet. Integrins participate in adhesion and migration of leukocytes in the microcirculation of highly perfused organs (the liver, lungs)^[12]. Endothelial cell incubation with antibodies against integrin receptors inhibits monocyte adhesion^[7]. The administration of anti-LFA-1 or anti-ICAM-1 antibodies diminishes significantly the stage of hepatocyte damage. It is suggested that T lymphocytes, infiltrating the liver through LFA-1/ICAM-1 interactions, cause the damage of hepatocytes by releasing toxic substances and oxygen radicals^[6]. Damaged endothelial cells present adhesive molecules (selectins, ICAM-1, VCAM-1) on their surfaces and influence flowing leukocytes. Activation signals are transmitted directly cell to cell or by the contact of cells with soluble adhesive molecules. Inflammatory and immunological phenomena have common paths, that are frequently paralleled, and leukocytes are main effector cells.

Integrin expression on leukocytes undergoes regulation by pro-inflammatory cytokines such as TNF- α and IL-8. CD11b expression on leukocytes correlates with IL-6 level and the stage of liver failure^[13]. Increased LFA-1, LFA-3, and ICAM-1 expression on leukocytes and TNF- α production in post-alcoholic liver cirrhosis has been observed^[14]. Peripheral blood monocytes showed activity and elevated expression of TNF- α which correlated with liver disease activity (Child-Pugh stage B and C)^[15]. The concentrations of TNF- α and soluble adhesive molecules are significantly higher in the advanced phase of cirrhosis ($P < 0.05$, Child-Pugh class B and C versus A) and can reflect hemodynamic alterations in the liver^[16]. This is accompanied by the activation of monocytes and increased intracytoplasmic expression of TNF- α ^[17]. Bacterial infections in the alimentary tract play an important role in cellular immunological disorders in patients with liver cirrhosis. A correlation between TNF- α level in blood serum and TNF- α contained in monocytes occurs in decompensated liver cirrhosis with a high concentration of LPS in blood. Antibacterial treatment diminishes monocyte activity and TNF- α -production activity^[17]. Inflammatory mediators, cytokines (TNF- α), and selectins elevate CD11b/CD18 expression on granulocytes. CD11b/CD18 cell population is increased in inflamed tissues. Accumulation of leukocytes with LFA-1, Mac-1,

and VLA-4 expression occurs in liver parenchyma near metastasis focuses^[18].

Patients with liver cirrhosis reveal the immunological system disorders and immunodeficiency, and the activation of certain immunological responses. Luna-Casad *et al*^[19] showed an increase in ICAM-1, LFA-3, and Mac-1 expression on lymphocytes and LFA-3 on monocytes. This correlated with the severity of liver cirrhosis and immunological disorders.

Wong *et al*^[12] showed that most stimulated leukocytes (approximately 80%) adhere to sinusoids and the rest (20%) to post-sinusoidal venules. The adhesion of stimulated leukocytes is independent of P, E, and L-selectin presence in the liver microcirculation. The adhesion of neutrophils to ICAM-1 is possible due to molecules exposed on CD11a and CD11b surfaces^[3]. Bacterial infections are accompanied by activation of peripheral blood leukocytes and their recruitment in the liver. LFA-1 immunoneutralization reduced leukocyte adhesion to a great extent (by 55%), decreased aminotransferase activity by 65%, and reduced apoptosis in the liver by 45%^[20]. It has been shown that LFA-1 plays an important role in the development of liver deficiency through leukocytes. LFA-1 expression in inflammatory infiltrates is elevated in PBC, which points to the role of activated lymphocytes in bile duct damage^[21]. Hepatotropic virus infections (e.g. HHV-6) also induce LFA-1 and VLA-1 expression on lymphocytes infiltrating the liver^[22].

Liver resident macrophages—Kupffer's cells constitutively show high LFA-1, Mac-1, and ICAM-1 expression^[23]. The studies performed on transgenic mice (CD11b-DTR) revealed that activated macrophages participate both in tissue damage and repair in inflammatory processes. Macrophages are capable of diminishing liver fibrosis through ECM protein degradation^[24].

In summary, β 2-integrins play an important role in the development of liver cirrhosis. The stage of disease advancement activates peripheral blood leukocytes, which results in the intensification of liver inflammatory and immunological processes. The activation of leukocytes is a complex phenomenon, influenced by endo- and exogenic factors. The blockade of integrin expression on leukocytes may constitute an important therapeutic aspect of liver cirrhosis.

Abstract

AIM: To analyze the protein expression essential for apoptosis in liver steatosis.

METHODS: The expression of proapoptotic proteins p53, Bax, and antiapoptotic Bcl-2 in hepatocytes with steatosis (SH) and without steatosis (NSH) was evaluated in 84 patients at various stages of non-alcoholic fatty liver disease (NAFLD).

RESULTS: Immunohistochemical staining of liver tissue showed the activation of p53 protein in SH and NSH with increased liver steatosis, diminished Bcl-2 and slightly decreased Bax protein. Positive correlation was found between the stage of liver steatosis with p53 expression in SH ($r = 0.54, P < 0.01$) and NSH ($r = 0.49, P < 0.01$). The antiapoptotic protein Bcl-2 was diminished together with the advancement of liver steatosis, especially in non-steatosed hepatocytes ($r = 0.43, P < 0.01$).

CONCLUSION: Apoptosis is one of the most important mechanisms leading to hepatocyte elimination in NAFLD. The intensification of inflammation in NAFLD induces proapoptotic protein p53 with the inhibition of antiapoptotic Bcl-2.

INTRODUCTION

Liver steatosis results from triglyceride accumulation in hepatocytes in the course of many diseases^[1]. The failure of energetic processes in hepatocytes leads to progressive lipid increase in cytoplasm^[2]. The most common cause of liver steatosis is alcohol abuse (alcoholic liver fatty disease-ALFD)^[3]. The disease accompanies hyperalimentation, obesity, metabolic syndromes, and hyperlipidemia^[4,5]. The phenomenon can be the result of side effects of some contraceptive, NSAID, antimetabolic and other drugs^[1,3]. Non-alcoholic fatty liver disease (NAFLD) is diagnosed by excluding alcohol abuse and other liver diseases and confirmed by histological changes in the liver and increased aminotransferase activity.

A variety of pathological conditions associated with NAFLD could explain the pathogenesis of the disorder. There is a hypothesis concerning multifactorial conditioning of the disease. Different mechanisms are assumed to lead to NAFLD, including imbalanced fatty acid supply, hyperglycemia, upset hormonal balance between hormones responsible for anabolic and catabolic activities in the portal circulation, and endotoxemia in starvation^[2,3]. Oxidative stress that damages lipid peroxidation and mitochondria occurs in chronic liver injury (metabolic disturbances, iron deposition, high fatty acid concentrations). Fatty acid cytotoxic activity is suggested to influence cell survival. Long term accumulation of lipids may lead to hepatocyte necrosis or apoptosis^[6]. The mechanisms underlying cell death have not been explained yet. The significant influence of inflammatory and immunological factors, cytokines, and chemokines is probable^[7]. The stimulation of mechanisms underlying apoptosis, with the contribution of p53 in hepatocytes has been observed in mice in laboratory conditions^[6,8,9].

The aim of our study was to evaluate the expression of proapoptotic p53 and Bax and antiapoptotic Bcl-2 in hepatocytes of patients with liver steatosis. The expression of these proteins, depending on disease advancement and enhancement of steatosis was analyzed in the study.

MATERIALS AND METHODS

Patients

Examinations were performed in 84 patients with liver steatosis (35 women and 49 men, median age 43 years, range 27-62 years). Steatosis was due to obesity, glucose intolerance and chronic use of hepatotoxic drugs. Patients

infected with hepatitis B virus (HBV) and hepatitis C virus (HCV) were excluded from the study. Liver steatosis was confirmed by ultrasonography and biopsy. Liver dysfunction was confirmed by increased aminotransferase values that persisted for longer than 6 mo. The Brunt classification was used to perform the histological analysis of steatosis advancement^[10].

Methods

Right lobule liver oligobiopsies were conducted in all patients. Liver biopsies were performed using the Hepafix System 1.6 (Braun, Melsungen, Germany) before treatment. Liver tissues obtained from biopsies were placed in 4% formaldehyde buffered solution for 24 h, then fixed and paraffin-embedded. Five- μ m thick sections were routinely stained with hematoxylin and eosin as well as picric acid.

Bcl-2: Tissue sections were put into FSG 120 (FSG120-T/T Controlled Antigen Retrieval, Milestone, Italy) at 110°C after paraffin was removed and hydration performed in citric buffer (pH 6.0). The pressure was adjusted to 2 bar for 10 min to obtain antigen retrieval. After cooling, the samples were placed in 3% hydrogen peroxide solution for 5 min, then washed in distilled water and placed in fresh buffered Tris for 5 min. The histological preparation was covered with the primary antibody Bcl-2 at 1:40 dilution (anti-human Bcl-2 coprotein, DakoCytomation, Denmark), incubated at room temperature for 30 min and placed in a fresh Tris bath for 5 min. Then, the secondary antibody was added (biotinylated link universal from the commercial kit LSAB: DakoCytomation, Denmark), incubated at room temperature for 30 min before washing in fresh Tris for 5 min. Another secondary antibody was added (streptavidin-HRP from LSAB kit) for 30 min and the section was placed in fresh Tris for 5 min. The preparation was covered with DAB stain (3, 3-diaminobenzidine tetrahydrochloride, DAB Chromogen, DakoCytomation, Denmark) for 10 min and then bathed in distilled water.

p53: The samples were deprived of paraffin, hydrated and placed in a microwave at 600V for 20 min. The procedures described above using anti p53 antibodies in dilution of 1:50 (anti-human p53 protein, DakoCytomation, Denmark) were repeated.

Bax: Preparations were prepared as above. Bax protein was detected using the commercial kit CSA (CSA, DakoCytomation, Denmark) according to the manufacturer's recommendations. The primary Bax antibody was used at dilution 1:1000 (anti-human Bax protein, Dako, Denmark). Then, the preparation was processed.

Using paraffin at a high melting point (65°C) and antigen retrieval in the microwave, we could not detect Bcl-2 and Bax proteins in hepatocytes. On the other hand, using low-melting point paraffin (55°C) and a FSG 120 machine for routine pressurized high temperature antigen retrieval, positive immunohistochemical reactions for Bcl-2 and Bax in hepatocytes were obtained.

The positive reaction showed as brown color of the cytoplasm for Bcl-2 and Bax, and the nuclei for p53. We calculated hepatocyte percentage (the amount of cells with positive reaction in ratio to 100 cells) containing those

Table 1 Clinical characteristics of patients with liver steatosis

proteins in 5 fields of vision (\times 400) of one slide under a light microscope. Expression of Bcl-2, p53 and Bax was analyzed in steatotic (micro- and macro-droplet steatosis) and non-steatotic hepatocytes. Ethical approval for research was obtained from the Ethics Committee of Medical University.

Statistical analysis

The results were presented as the mean cell number (p53, Bcl-2 or Bax positive hepatocytes) \pm SD. The statistical analysis was carried out using non-parametrical Student's-*t* test and Spearman's correlation test.

RESULTS

Histological analysis of liver biopsies showed mixed micro- and macro-droplet steatosis of hepatocytes occurring mainly in the 2nd and 3rd zones of the lobules. Inflammation and fibrosis were not present in group I (hepatocyte steatosis < 33%), but were present in group II. Moderate periportal and interstitial fibrosis, small necrotic focuses of hepatocytes without necrosis and single lymphocyte clusters were noted in group III (steatohepatitis). Malformation in portal spaces was not observed. Table 1 presents the characteristics of the examined groups. The activity of alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), and gamma-glutamyltransferase (γ -GT) were increased, total protein and albumin concentrations decreased significantly together with the stage of liver steatosis. There was no significant relationship between the activity of aminotransferase (ALT, AST) and the expression of p53, Bax, Bcl-2 in hepatocytes with SH and HNS.

Bax

Bax expression was significantly higher in steatosed hepatocytes with SH (68% \pm 23%) than in non-steatosed hepatocytes (NSH) (59% \pm 21%, *P* < 0.03) in the patients with NAFLD (Table 2). The highest Bax expression was observed in SH in group I with slight liver steatosis. The intensification of inflammation and fibrosis led to an

¹Non-steatosed hepatocytes; ²Steatosed hepatocytes. ^b $P < 0.01$ vs group II, ^d $P < 0.01$ vs group III (non-parametrical Student's-*t* test).

initially insignificant decrease in Bax expression (mainly in NSH). The group of patients with steatohepatitis showed an increased Bax expression mainly in SH. We did not observe any relation between the stage of liver steatosis and the expression of Bax in hepatocytes (Table 3). The expression of p53 in SH ($r = 0.32$, $P < 0.01$) and NSH ($r = 0.33$, $P < 0.01$) was elevated together with the increase in Bax expression. The relationship between Bax expression in NSH and p53 expression in SH and NSH was weak. Together with the increase in alkaline phosphatase in steatohepatitis, Bax expression was enhanced in SH and NSH ($r = 0.57$, $P < 0.01$ and $r = 0.59$, $P < 0.01$ respectively). Gamma-glutamyltransferase elevation was also accompanied by the increase in Bax expression in SH ($r = 0.38$, $P < 0.01$) and NSH ($r = 0.33$, $P < 0.01$).

p53

The expression of p53 was approximately 10% lower in steatosed hepatocytes than in hepatocytes without steatosis (difference was not statistically significant) (Table 2). In the patients with liver steatosis without inflammation (group I), p53 expression in SH and NSH was significantly lower than in the patients with steatohepatitis (group III). There was a positive correlation between p53 expression and the stage of liver steatosis ($r = 0.49$, $P < 0.01$ in NSH; $r = 0.54$, $P < 0.01$ in SH) (Table 3). The level of albumin was negatively correlated with p53 expression in SH ($r = -0.44$, $P < 0.01$) and NSH ($r = -0.69$, $P < 0.01$). The concentrations of ALP and GGT were positively correlated with positive p53 in SH ($r = 0.36$, $P < 0.01$ and $r = 0.32$, $P < 0.01$, respectively) and NSH ($r = 0.25$, $P < 0.03$; $r = 0.34$, $P < 0.01$, respectively).

Bcl-2

Bcl-2 expression diminished in steatosed and non-steatosed hepatocytes in accordance with the stage of liver steatosis. As far as liver steatosis was concerned, there was a statistically significant difference between positive SH, NSH and Bcl-2 (44% \pm 27%, 55% \pm 26% respectively, $P < 0.05$) (Table 2). Group I had the highest expression of Bcl-2 in NSH and a lower expression in SH (77% \pm 21%, 52% \pm 35%, respectively). On the other hand, advanced stage of liver steatosis had a statistically significant decrease in Bcl-2 expression in SH and NSH. A negative correlation was observed between Bcl-2 in NSH and the stage of liver

steatosis ($r = -0.43$, $P < 0.01$) (Table 3). However, such a relationship was not observed between the expression of Bcl-2 in NSH and the stage of the disease. The elevation of Bcl-2 expression in NSH increased Bcl-2 expression in SH ($r = 0.46$, $P < 0.01$), Bax expression in NSH ($r = 0.53$, $P < 0.01$) and SH ($r = 0.57$, $P < 0.01$). We did not observe any relationship between the percentage of positive Bcl-2 in NSH and the expression of p53 in SH and NSH. However, there was a correlation between Bax-2 expression in SH and p53 expression in SH ($r = 0.42$, $P < 0.01$) and NSH ($r = 0.36$, $P < 0.01$). No correlation was observed between Bcl-2 expression, alkaline phosphatase and γ -GT activities.

DISCUSSION

The study revealed that the stage of liver steatosis increased the expression of proapoptotic proteins, mainly p53, in hepatocytes with and without steatosis. Antagonistic protein Bcl-2 was diminished together with the advancement of liver steatosis, especially in normal hepatocytes. Proapoptotic protein Bax seemed to play a minor role in the process of steatosis. Its expression was slightly decreased when steatosis was intensified. There was an apparent difference between hepatocytes with steatosis containing more Bax protein and hepatocytes without steatosis. The pathogenesis of NAFLD is not entirely clear. Triglycerides, localized in the cytoplasm of hepatocytes, are the main component of lipids. Accumulation of lipids can result from insulin resistance, damaged disposal of triglycerides from the cells, β -oxidation damage in mitochondria, or very low density lipoproteins^[11]. It has been suggested that free fatty acids (FFA) can play a crucial role in steatosis intensification and necrotic-inflammatory processes. Damage of lysosome integrity, which results in cathepsin B and TNF-alpha release, is due to the effect of lipotoxicity. The degree of lysosome instability correlates with NAFLD activity^[12].

Cellular free fatty acids show cytotoxic effects, such as

elevation of cytochrome P450 activity^[13]. Steatosed hepatocytes are more sensitive to endotoxin, which can result from intracellular IL-10 mRNA reduction and IFN- γ mRNA concentration elevation^[13]. It is assumed that chronic oxidative stress in NAFLD influences steatosis progression^[14]. Oxidative stress is generated by free fatty acids, pro-inflammatory cytokines, TNF alpha is activated by cytochrome P450 2E1. The disturbances of lipid peroxidation in hepatocytes, which can lead to their extensive accumulation, is the consequence of oxidative stress. Seki *et al*^[15] stated that intracellular increase in markers of lipid peroxidase and oxidative DNA damage correlate with the stage of necroinflammatory changes of steatosis in patients with NASH. Chronic oxidative stress induces overexpression of cytochrome P450 2E1 (CYP2E1) in hepatocytes, causing their damage. The mechanism underlying cell death with the participation of CYP2E1 has not been explained yet. Chronic overexpression of p4502E1 increases epidermal growth factor/c-Raf signaling in hepatocytes. Studies conducted by Schattenberga *et al*^[16] have proved that hepatocytes exposed to chronic oxidative stress have different sensitivity to noxious stimuli. Cellular resistance to proapoptotic factors has observed in hepatocytes with overexpression of p4502E1 after sensitized by polyunsaturated fatty acids.

Incubation of pancreatic beta-cells with FFA results in a significant increase in cell death due to apoptosis^[17]. The cells have a significant drop in Bcl-2 mRNA expression with no change in Bax mRNA expression^[17]. Cell death induced by FFA can be blocked by caspase, serine protease, and ceramide synthesis inhibition, suggesting that FFA is the cause of pancreatic beta-cell reduction and leads to peripheral insulin resistance, which plays a role in obesity and liver steatosis^[18]. It was observed that FFA administration results in proapoptotic p53 increase and anti-proliferative effect in Caco-2 cells. There is also a simultaneous drop in the level of apoptosis suppressor protein Bcl-2 expression^[19].

TNF alpha and CYP2E1, which are more significantly expressed in patients with chronic hepatitis C and steatosis than in those without steatosis, have a role in liver steatosis progression^[20]. Ji *et al*^[21] suggested that incubation of HepG2 cells with palmitic acid could induce cell death via mitochondria-mediated apoptosis. They also stated that Bax expression is significantly increased but Bcl-2 expression is moderately decreased^[21], indicating that liver steatosis influences expression of pro- and anti-apoptotic proteins. Apoptosis is one of the most important mechanisms underlying hepatocyte elimination in non-alcoholic steatohepatitis. The intensification of inflammatory changes in NAFLD induces proapoptotic protein (p53) with the inhibition of antiapoptotic protein (Bcl-2). However, the explanation of mutual relationships between apoptosis and liver steatosis needs further investigation.

Abstract

AIM: To investigate the efficacy of topical application of 0.5% nifedipine ointment in healing acute anal fissure and preventing its progress to chronicity.

METHODS: Thirty-one patients (10 males, 21 females) with acute anal fissure from September 1999 to January 2005 were treated topically with 0.5% nifedipine ointment (t.i.d.) for 8 wk. The patients were encouraged to follow a high-fiber diet and assessed at 2, 4 and 8 wk post-treatment. The healing of fissure and any side effects were recorded. The patients were subsequently followed up in the outpatient clinic for one year and contacted by phone every three months thereafter, while they were encouraged to come back if symptoms recurred.

RESULTS: Twenty-seven of the 31 patients completed the 8-wk treatment course, of them 23 (85.2%) achieved a complete remission indicated by resolution of symptoms and healing of fissure. Of the remaining four unhealed patients (14.8%), 2 opted to undergo lateral sphincterotomy and the other 2 to continue therapy for four additional weeks, resulting in healing of fissure. All the 25 patients with complete remission had a mean follow-up of 22.9 ± 14 (range 6-52) mo. Recurrence of symptoms occurred in four of these 25 patients (16%) who were successfully treated with an additional 4-wk course of 0.5% nifedipine ointment. Two of the 27 (7.4%) patients who completed the 8-wk treatment presented with moderate headache as a side effect of nifedipine.

CONCLUSION: Topical 0.5% nifedipine ointment, used as an agent in chemical sphincterotomy, appears to offer

INTRODUCTION

Anal fissure is a painful condition that affects a sizable majority of the population. The cause is controversial. However, current theories suggest that an initial traumatic tear fails to heal, because of the internal anal sphincter spasm, generating high pressure into the anal canal and leading to secondary local ischemia of the anal mucosa^[1,2]. Treatment aims at improving the blood supply to the ischemic area in order to facilitate healing by reducing, if necessary, the resting anal pressure, a function of the internal anal sphincter. Traditional surgical techniques for treatment include anal dilation and partial division of the internal sphincter, which may be complicated by incontinence^[3,4]. This significant complication has led to a search for alternative therapies for the treatment of anal fissure. The alternative options of "chemical sphincterotomy" include topical glyceryl trinitrate^[5,6], diltiazem^[7,8], botulinum toxin^[9,10], bethanechol^[7], indoramin^[11], and nifedipine^[12-14]. The aim of this study was to investigate the efficacy of local application of a new preparation of nifedipine ointment (0.5%) as an aggressive therapeutic modality in healing acute anal fissure and preventing its evolution to chronicity.

MATERIALS AND METHODS

Subjects

Thirty-one patients (10 males, 21 females, mean age 44.6 ± 11.9 years, range 19-69 years) with acute anal fissure

Table 1 Characteristics of the patients

Characteristic		%
Patients (n)	31	100
Mean age \pm SD (yr) (range)	44.6 \pm 11.9 (19-69)	
Gender ratio (M:F)	10:21	32.3:67.7
Location		
Posterior midline	27	87.1
Anterior midline	4	12.9
Pain	31	100
Bleeding	14	45.2
Mean follow-up \pm SD (mo) (range)	22.9 \pm 14 (6-52)	

participated in the study, from September 1999 to January 2005. The fissures were posterior in 27 patients (87%) and anterior in 4 patients (13%). Symptoms on presentation were anal pain in all patients (100%) and bright red bleeding per rectum in 14 patients (45.2%). The clinical characteristics of the patients are shown in Table 1.

Inclusion criteria included patients with acute anal fissure aged 18 years or older. Exclusion criteria were presumed or confirmed surgery, allergy to nifedipine, associated complications warranting surgery (abscess, fistula and cancer), Crohn's disease, tuberculosis ulcer, leukemic ulcer, HIV-related anal ulcer, cancer, and unwillingness of the patient to participate in the study. Concomitant first- to third-degree hemorrhoids were not considered an exclusion criterion.

Presence of acute anal fissure was considered if the patient presented with a history of anal pain at defecation for less than two months, that failed to resolve with conservative therapy consisting of stool softeners, high fiber diet and topical anesthetic creams prescribed by the general practitioner.

In the same time period we followed up 39 patients with acute anal fissure which was healed in only 8 patients after treatment with stool softeners and topical analgesics alone.

Methods

The study protocol was approved by the Ethics Committee of the Central Hospital of Thessaloniki, and all patients signed an informed consent. Anal manometry was performed in all patients before they entered the study and after two weeks of treatment. Manometric recordings and analysis of the tracings were conducted using a water-perfusion system. The anal canal pressure was recorded in cm of water by the stationary pull-through technique, using a water-filled micro-balloon and external transducer (PVD) perfusion equipment (Medtronic Inc, Bonn, Germany). The recording and analysis of the tracings were both made by a computerized system (8 channels polygraph ID, Medtronic Polygraph with Polygram 98, version 2.2 software, Medtronic, Inc., Minneapolis, MN, USA). Anal resting pressures were recorded, and the mean pressure was determined by the computer.

Topical nifedipine ointment regimen was prepared by a pharmacist diluting 100 mg of nifedipine in 20 g of yellow soft paraffin to produce a preparation of 0.5%. Patients were instructed to apply the ointment circumferentially 1

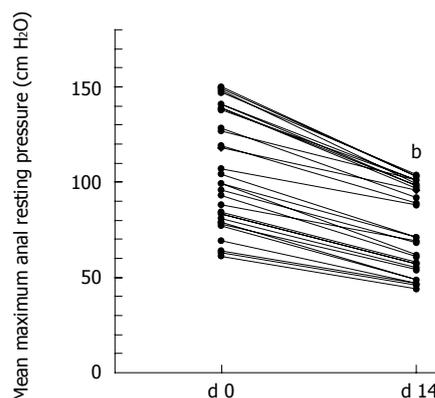

Figure 1 Mean maximal anal resting pressure after the application of nifedipine to the anus (^b $P < 0.0001$ d 14 vs d 0).

cm inside the anus, near the internal anal sphincter, every 8 h for 8 wk. The preparation was kept in a cool place, inside an opaque glass container with a screw top lid, and discarded 3 wk after formulation.

Patients were not prescribed stool softeners or topical analgesic creams during the treatment. A high-fiber diet was encouraged. The patients were followed up at 2, 4, and 8 wk in the outpatient clinic. During each visit, they were asked if they had pain and bleeding on defecation, and if they had headache, dizziness, flush, rash, and incontinence. Healing of acute anal fissure was set as the primary target of our study, and defined as epithelialization achieved on d 57 of therapy. If healing occurred after the initial 8-wk period, the patients were followed up in the outpatient clinic at 3, 6, and 12 mo, or sooner if recurrent symptoms occurred. Thereafter, the patients were contacted by telephone every three mo. If symptoms recurred, the patients were encouraged to call back, and given the option to undergo treatment with 0.5% nifedipine ointment for 4 consecutive wk, and the option of operation. If they selected the last option or if symptoms persisted after the additional 4 wk treatment, the patients were referred for lateral sphincterotomy.

Statistical analysis

The paired *t*-test was used to evaluate the impact of nifedipine application on the mean maximal anal resting pressure (MMRP). $P < 0.05$ was considered statistically significant. The analysis was performed using SPSS (Statistical Package for Social Sciences, version 10.0, Chicago, IL, USA).

RESULTS

The baseline MMRP was 139.6 (range 118-150) cm H₂O (normal range 60-160 cm H₂O) in the 10 male subjects and 90.3 (range 61-141) cm H₂O (normal range 43-142 cm H₂O) in the 21 female subjects. After topical application of 0.5% nifedipine ointment for 14 d, the MMRP was 100 (range 96-104) cm H₂O in males and 63.6 (range 44-102) cm H₂O in females (Figure 1).

The treatment outcomes are summarized in Figure 2. One patient continued to present severe anal pain in the first week of therapy and chose to be operated upon.

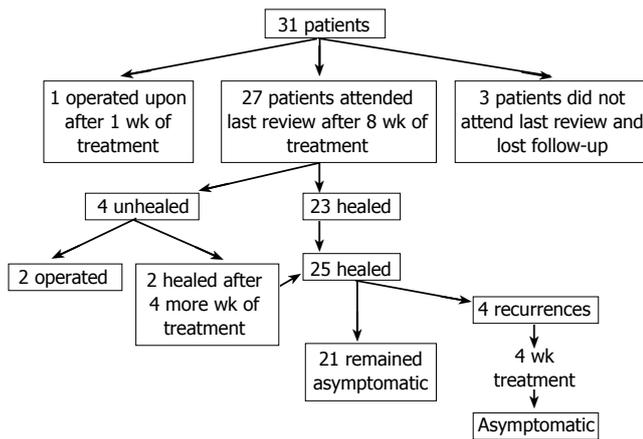

Figure 2 Outcome after aggressive treatment with 0.5% topical nifedipine ointment.

Twenty-seven of the 31 patients attended the last review at 8 wk, of them 23 (85.2%) had complete remission. The remaining 4 (14.8%) did not heal at 8 wk and were given the option of an additional course of nifedipine treatment or the option of lateral internal sphincterotomy. Two of these four patients opted for a further course of nifedipine therapy leading to complete remission, and the other two preferred to be operated.

The 25 patients who were successfully treated with 0.5% nifedipine ointment had a mean follow-up of 22.9 ± 14 (range 6-52) mo, of them 21 (84%) remained asymptomatic and 4 (16%) had recurrences that were successfully treated with an additional 4-wk course of treatment with 0.5% nifedipine ointment. It was not possible to predict healing from the initial manometric response to 0.5% nifedipine ointment.

Two patients with a history of migraine reported moderate headache while being treated with topical nifedipine, which was treated with paracetamol. No other side effects were reported.

DISCUSSION

Oral and topical calcium channel blockers (CCBs) have recently been shown to lower the anal resting pressure by relaxing the internal anal sphincter^[12-16]. The transport of calcium through the L-type calcium channels is important for the maintenance of internal anal sphincter tone^[17]. As opposed to glyceryl trinitrate, which reduces resting anal tone by releasing nitric oxide, nifedipine (a calcium channel blocker) reduces the tone and spontaneous activity of the sphincter by decreasing the intracellular availability of calcium^[17-19]. Oral administration of CCBs is associated with side effects such as hypotension and flushing, which may decrease compliance^[20]. Topical diltiazem and nifedipine are highly effective, achieving a healing rate of 67% for diltiazem and up to 95% for nifedipine^[8,12,13]. A recent randomized study by our group showed that the topical use of 0.5% nifedipine could achieve complete healing in 96.7% of the patients, not significantly different from the group treated with internal sphincterotomy^[21]. However, the problem with temporary "chemical sphincterotomy" is that after treatment the anal pressure

rises to pre-treatment levels, resulting in a high rate of recurrence. Recurrence has been reported in approximately 42% of patients treated with nifedipine^[22]. It should be noted, however, that the above healing and recurrence rates have been reported in patients with chronic anal fissures.

Acute anal fissure in adults is thought to precede chronic fissure and to be more analogous to pediatric anal fissure in its pathologic anatomy^[1]. It is commonly believed that if acute anal fissure is aggressively treated, it can be healed preventing the development of chronic fissure.

To the best of our knowledge, there is only one published work investigating the efficacy of nifedipine ointment in the treatment of acute anal fissure. In the study of Antropoli *et al*^[12], 141 patients were treated topically with 0.2% nifedipine gel, every 12 h for 3 wk. The control group consisting of 142 patients received topical 1% lidocaine and 1% hydrocortisone acetate gel. Complete remission of acute anal fissure was achieved in 95% of the nifedipine-treated patients, as opposed to 50% of the controls. The study does not report the followed up patients. In contrast to the study by Antropoli *et al*^[12], we used 0.5% (instead of 0.2%) nifedipine ointment, the period of treatment was 8 (instead of 3) wk and we included a relatively long-term follow-up of patients of 22.9 ± 14 (range 6-52) mo. The high rate of healing (85.2%) in our study after 8 wk of treatment is possibly related to the long duration of treatment, considering that the usual treatment for acute anal fissure ranges between 3 and 4 wk. This high healing rate may be attributed not only to the reduction of the anal canal pressure (significant in our patients) through the inhibition of the flow of calcium into the sarcoplasm of the internal anal sphincter, but also to the anti-inflammatory action of nifedipine. Experimental studies indicate that nifedipine has a modulating effect on the microcirculation^[23] and a local anti-inflammatory effect^[24], in addition to relaxation of the internal anal sphincter. From a further viewpoint, laser Doppler flowmetry has shown that the posterior area of the anoderm is less well perfused than other areas of the anoderm. It has been speculated that increased tone in the internal sphincter muscle further reduces the blood flow, especially at the posterior midline. Based on these findings, fissures are thought to represent ischemic ulceration^[25]. Since oxidative stress is believed to initiate and aggravate many diseases including peptic-ischemic ulcerations^[26,27], it could be speculated that nifedipine might promote acute fissure healing rate because of its additional free radical-scavenging properties as well as its cytoprotective and peptic ulcer healing-promoting actions^[28]. However, further studies are needed to elucidate these potential therapeutic properties of this drug in healing acute as well as chronic anal fissures.

A high fiber diet by itself or in addition to topical ointments consists of a part of acute anal fissure treatment. Since our study included patients with acute anal fissures, which did not respond to conservative therapy consisting of stool softeners, high fiber diet and topical anesthetic cream, it is impossible to attribute the success of treatment to high fiber diet which we encouraged the patients to continue.

It should be emphasized that the two unhealed patients after 8 wk of treatment and all recurrences during the follow-up were successfully treated with an additional 4-wk course of topical 0.5% nifedipine ointment. The main limitation of this study is the lack of a placebo group. Although CCBs have not been directly compared in any analysis with an arm termed as placebo, there are 2 studies comparing nifedipine with either hydrocortisone^[13] or lidocaine^[12]. A marked advantage of nifedipine over substances currently thought to be the equivalent of placebo has been reported, with a healing rate of approximately 35% in the placebo groups^[13]. Our study has shown a healing rate of 85.2%, significantly higher than the previously reported rate in placebo groups (35%).

Another drawback in our study suggests that treatment of acute anal fissure with 0.5% nifedipine ointment is the length of treatment (8 wk), which is generally considered to be longer than the typical length (usually 3-4 wk). Although this extended length of treatment may increase the percentage of non-compliant patients, only 3 out of the 31 patients (10%) did not complete the 8-wk treatment in our study. This non-compliance percentage is comparable to that of other studies^[7,8,12,13].

An interesting finding of our study is the fact that, despite the applied dosage of nifedipine (0.5%) was at least twice as high as in previous studies^[12,13], there was no increase in adverse effects. Only two patients (7.4%) presented with moderate headache, which was relieved with paracetamol.

In conclusion, topical application of 0.5% nifedipine ointment might be effective both in treating acute anal fissure and in preventing its evolution to chronicity.

Abstract

AIM: To investigate chromosome 8 numerical aberrations, *C-MYC* oncogene alterations and its expression in gastric cancer and to correlate these findings with histopathological characteristics of gastric tumors.

METHODS: Specimens were collected surgically from seven patients with gastric adenocarcinomas. Immunostaining for *C-MYC* and dual-color fluorescence *in situ* hybridization (FISH) for *C-MYC* gene and chromosome 8 centromere were performed.

RESULTS: All the cases showed chromosome 8 aneuploidy and *C-MYC* amplification, in both the diffuse and intestinal histopathological types of Lauren. No significant difference ($P < 0.05$) was observed between the level of

chromosome 8 ploidy and the site, stage or histological type of the adenocarcinomas. *C-MYC* high amplification, like homogeneously stained regions (HSRs) and double minutes (DMs), was observed only in the intestinal-type. Structural rearrangement of *C-MYC*, like translocation, was observed only in the diffuse type. Regarding *C-MYC* gene, a significant difference ($P < 0.05$) was observed between the two histological types. The *C-MYC* protein was expressed in all the studied cases. In the intestinal-type the *C-MYC* immunoreactivity was localized only in the nucleus and in the diffuse type in the nucleus and cytoplasm.

CONCLUSION: Distinct patterns of alterations between intestinal and diffuse types of gastric tumors support the hypothesis that these types follow different genetic pathways.

INTRODUCTION

Gastric cancer is the third most frequent type of cancer in the world^[1]. In Northern Brazil, the State of Pará presents a high incidence of this neoplasia type and its capital, Belém, is ranked eleventh in number of gastric cancers per inhabitant among all cities in the world with cancer records^[2]. Food factors may be related to the high incidence of this neoplasia in Pará, specially high consumption of salt-conserved food, reduced use of refrigerators and little consumption of fresh fruit and

vegetables^[3].

Gastrointestinal tract tumors are notorious for being difficult to analyze by standard cytogenetic techniques^[4-8]. Fluorescence *in situ* hybridization (FISH) technique with specific DNA probes allows rapid detection of chromosome aberrations in tumor interphase nuclei. In FISH studies, numerical aberrations in chromosomes 1, 7, 8, 9, 17, 20, X and Y are common^[9-12]. Chromosome 8 abnormalities are frequent, not only in gastric neoplasias, but also in several types of hematopoietic proliferations and solid tumors^[13-15].

Among the genes found on chromosome 8, *C-MYC*, located at 8q24, has been the most studied. *C-MYC* gene is a regulator of cell cycle and plays a major role in control of cell growth, differentiation, apoptosis and neoplastic transformation^[16]. *C-MYC* gene overexpression is a frequent alteration and has been described in several types of human cancer^[17-19]. An increased *C-MYC* gene expression has been found in gastric neoplasias^[20-23].

The aim of this study was to investigate chromosome 8 numerical aberrations, *C-MYC* oncogene alterations and its expression in gastric cancer samples from the State of Pará, using the FISH technique and immunohistochemistry. Possible correlations between these findings and histopathological characteristics were also evaluated.

MATERIALS AND METHODS

Cases studied

Seven samples of primary tumors submitted to surgical resection were obtained from male patients in Pará State João de Barros Barreto University Hospital (HUJBB). Patients' ages and tumors' anatomical sites were obtained from tumor registries (Table 1). The patients had never been submitted to chemotherapy or radiotherapy prior to surgery, nor had they any other diagnosed cancer. Genetic study of samples was approved by the Ethics Committee of HUJBB. A fraction of each sample was used for routine histopathological diagnosis according to Laurén's classification^[24].

Immunostaining

For antigen retrieval, deparaffinized sections (5 μ m) were pretreated by heating in a microwave oven in citrate buffer 10 mmol/L, pH 6.0 for 20 min. After cooling, sections were immersed in PBS containing 3% hydrogen peroxide for 10 min to block endogenous peroxidase activity. Sections were then incubated in a humid chamber overnight at 4°C with primary antibody C-MYC (clone 9E10.3; dilution 1:100). After rinsing with PBS, slides were incubated with secondary antibody followed by streptavidin-biotin-peroxidase complex, both for 30 min at room temperature with a PBS wash between each step. Slides were visualised with diaminobenzidine-H₂O₂ and counterstained with Harry's hematoxylin.

Fluorescence *in situ* hybridization

Tumor samples from all patients were processed for cytogenetic study as described previously^[25]. FISH assay

was performed on slides with cells fixed in methanol/acetic acid. A directly labeled dual-color probe was used for chromosome 8 alpha-satellite region (8q11) and for *C-MYC* gene region (8q24). Slides were washed in 2 \times saline sodium citrate solution (SSC) and dehydrated in 70%, 80% and 95% ethanol, respectively. Samples were then denatured with 70% formamide/2 \times SSC (pH 7.0) at 70°C for 2 min and transferred to an iced ethanol (-20°C) series at 70%, 80% and 95%. Probes were denatured at 96°C for 5 min. Then, 10 μ L was applied onto the slide under a glass coverslip. *In situ* hybridization occurred at 37°C in a moist chamber overnight. Post-hybridization washings were done, and nuclei were counterstained with DAPI/antifade. Molecular cytogenetic analysis was carried out under an Olympus BX41 fluorescence microscope with triple DAPI/FITC/TRICT filter and an Applied Spectral Imaging image analysis. For each sample, 200 interphase nuclei were analyzed. To avoid misinterpretation due to technical error, normal lymphocyte nuclei and normal gastric tissue were used as a control.

Statistical analysis

For statistical evaluation, chi-square test was used. $P < 0.05$ was taken as significant.

RESULTS

All seven samples studied were histologically classified as gastric adenocarcinomas, 2 of them were diffuse type and 5 were intestinal type, according to Laurén's classification (Table 1).

C-MYC was expressed in all cases. *C-MYC* immunoreactivity was localized in nucleus and cytoplasm of diffuse type samples, but only in nucleus of intestinal type (Figure 1A and 1B).

In peripheral blood lymphocytes, two signals were observed in 98.5% of analyzed nuclei for chromosome 8 probe and 99.5% for *C-MYC* gene probe. Normal stomach tissue showed two signals in 96% of analyzed nuclei for chromosome 8 probe and 98% for *C-MYC* gene probe. All gastric adenocarcinoma cases showed numerical increase of chromosome 8 and *C-MYC* gene (Table 1).

Chromosome 8 trisomy was detected in all cases, varying from 19% (case 3) to 33% (case 1), and chromosome 8 tetrasomy (observed in all cases) varied from 1% (case 4) to 18% (case 3). Five signals for chromosome 8 were observed in 6 cases (85.7%) and the highest frequency was found in case 7 (4%). Six or more signals were observed in 1 case (case 7).

Presence of 6 or more signals for *C-MYC* gene was considered as an intermediary degree of amplification, whereas the cases which presented double minutes (DMs) and/or homogeneously stained regions (HSRs) were classified as presenting a high degree of gene amplification. Cells with more than six signals were found in 5 cases (71.42%). The frequency of cells with high amplification (Figure 1C) of this gene varied from 1% (case 4 and 5) to 6% (case 7) (Table 1). Thus, all intestinal type cases and none diffuse type presented intermediary and high amplification of *C-MYC*.

Table 1 Number of signals by percentage of analyzed nuclei

Case	Age (yr)	Origin	HT	UICC	Immunostaining	Probe	Percentage of nuclei						
							Number of signals

HT: Histological type; UICC: Union Internationale Contre le Cancer; HA: High amplification.

Rearrangements between *C-MYC* gene and chromosome 8 centromere were discriminated by evident separation of the two signals. In tumor samples, translocation was observed between *C-MYC* gene and another chromosome in case 3 (2%) and case 6 (4%), both of them of diffuse type (Figure 1D).

Analyzing the total number of signals for *C-MYC* gene and for chromosome 8 centromere, it was found that the number of signals for the gene was greater than the number of signals for chromosome 8 ploidy in all cases studied.

No significant difference ($P < 0.05$) was observed between chromosome 8 ploidy level and adenocarcinoma site, stage or histological type. Regarding *C-MYC* gene, a significant difference was observed between the two histological types. This difference was due to the presence of HSRs and/or DMs in Laurén’s intestinal type, where multiple (uncountable) signals were found per cell.

DISCUSSION

Gastric cancer is one of the most common neoplasias and both environmental and genetic factors contribute to its occurrence^[26]. The present study used interphase dual-color FISH with direct fluorescent labeling for the chromosome 8 centromere/*C-MYC* gene and compared the copy number observed in 7 gastric adenocarcinoma samples with *C-MYC* expression by immunohistochemistry.

C-MYC amplification has been reported in a small percent of gastric carcinomas^[21,27,28]. *C-MYC* expression was shown to be more frequent in diffuse than in intestinal type gastric cancer cells, and more frequent in gastric adenocarcinoma than in adenoma^[29,30]. In the present study, *C-MYC* was expressed in all cases. *C-MYC* immunoreactivity was localized in the nucleus in intestinal-type and in cytoplasm and nucleus in diffuse type. More samples need to be investigated, in order to clarify if this

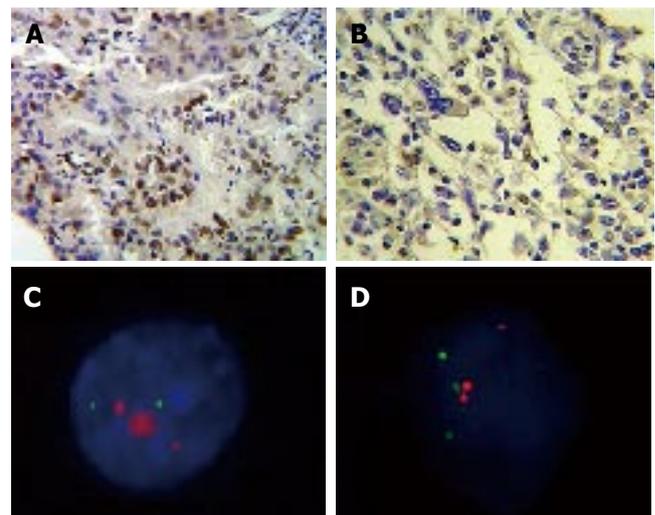

Figure 1 Cells submitted to immunohistochemistry and FISH techniques. **A:** Infiltrating gastric adenocarcinoma of intestinal type shows intense nuclear marcation for C-MYC, × 400; **B:** Gastric adenocarcinoma of diffuse type nuclear marcation and cytoplasmatic light marcation for C-MYC, × 400; **C:** Interphase nuclei presenting *C-MYC* high amplification (red) and chromosome 8 (green); **D:** Interphase nuclei presenting chromosome 8/*C-MYC* rearrangement.

immunostaining differences exist.

Our laboratory has previously observed the presence of chromosome 8 trisomy in all 16 cases studied by direct chromosome analysis and centromeric FISH^[31] and in 60% of analyzed cells of ACP01 gastric adenocarcinoma cell line^[32]. The gain of signals for the two probes analyzed in all samples in the present study corroborates with these data.

Panani *et al*^[9] analyzed 33 gastric tumor samples by FISH, using a chromosome 8 alpha-satellite probe. Numerical aberrations in this chromosome were observed in 62.16% of studied samples, in which trisomy was detected in 43.24%, tetrasomy in 10.81% and monosomy

in 8.10%. Our results confirmed that chromosome 8 trisomy is a common biological phenomenon in adenocarcinoma of stomach and can be used as a gastric mucosa malignancy marker. In our study, 100% of samples presented a gain of chromosome 8 as a clonal alteration.

Chromosome 8 numerical abnormalities, in which *C-MYC* is located, are suggested to be an important mechanism in *C-MYC* copy number increase. Xia *et al*^[5] suggested that chromosome 8 trisomy, associated or not with other chromosomal aberrations, could occur even in less advanced stages of the disease, possibly prior to the occurrence of metastases.

Kitayama *et al*^[12] analyzed interphase nuclei of 51 gastric cancer cases from pathology archives using 18 centromeric probes, including chromosome 8 probe, and a probe for *C-MYC* gene. They observed chromosome 8 numerical abnormalities in 56.9% of samples, which placed them among the most frequent alterations; in 12 cases, a *C-MYC* gain was observed and all of them presented chromosome 8 gain. Amplification of this oncogene was also reported in other FISH studies in gastric neoplasias^[33-35].

C-MYC oncogene seems to be fundamental in the oncogenesis process. Thus, increased *C-MYC* allele number is directly related to the degree of tumor aggressiveness, considering that the greater the gene copy number, the higher its level of expression. This gene was amplified in all samples studied, but without numerically accompanying chromosome 8 ploidy; that is, in all cases there were more *C-MYC* gene alleles than this chromosome copies.

In another study conducted in our laboratory^[36], 90.9% of cases presented intermediary amplification, 60% of which presented DMs and HSRs. It seems that, as our sample presented chromosome 8 gain as a clonal characteristic, *C-MYC* amplification is a later step, a consequence of carcinogenesis clonal expansion.

We have previously demonstrated, by comparative genomic hybridization, gains at region 8q24.1 (38.1%), which were found exclusively, in all intestinal type adenocarcinomas with systemic metastasis (M1). Results from this work also showed the highest amplification level in gastric cancer of intestinal type. *C-MYC* locus amplification may be an aggressiveness predictor in intestinal type gastric cancer, playing an important role in its development and progression. These results should provide useful information for developing more effective strategies in management of gastric cancer^[37].

Stamouli *et al*^[25] studied, by multicolor FISH, two primary gastric adenocarcinoma cases: a well-differentiated intestinal-type and a poorly differentiated diffuse type. The intestinal-type exhibited few structural abnormalities, in contrast to the diffuse type. In our analysis, all diffuse type cases presented at least four cells with translocation. It seems that this histological type is more susceptible to chromosomal rearrangements than intestinal type.

Correa^[38] suggested that the intestinal type fits the multiple-step process. Thus, it is plausible that the intestinal type presents a greater number of DMs and/or HSRs than the diffuse type. Our findings support that these two histological types follow different genetic tumorigenesis mechanisms^[39]. Moreover, it could be observed that translocations were restricted to diffuse

type. This result can be explained by the fact that gene amplification is not necessarily associated or required for its overexpression. Leukemias, lymphomas and sarcomas commonly elicit specific balanced translocations which mediate proto-oncogenes activation, by their juxtaposition with promoter sequences or generating gene fusion^[40].

Enhanced *C-MYC* protein expression contributes to almost every aspect of tumor cell biology. Although the ability of *C-MYC* to drive unrestricted cell proliferation and to inhibit cell differentiation had been well recognized, a recent work showed that deregulated *C-MYC* expression can drive cell growth and vasculogenesis, reduce cell adhesion, and promote metastasis and genomic instability. On the other hand, *C-MYC* loss not only inhibits cell proliferation and cell growth, but can also accelerate differentiation, increase cell adhesion and lead to an excessive response to DNA damage. Studies in animal models suggest that *C-MYC* may be a target for human cancer treatment, but it is still unknown whether such drugs will be useful^[41].

The alterations found in this study have been described in the literature, even though their frequency was higher in our sample. Considering that external factors, such as eating habits and other environmental agents, have a direct influence on the development of this neoplasia, many genetic alterations may be regional characteristics of a given population.

Based on our findings we could also affirm that gastric adenocarcinomas of differing histopathological features are associated with distinct patterns of genetic alterations, suggesting that they evolve through different genetic pathways.

Abstract

AIM: To investigate in children with acute hepatitis A. According to our knowledge, there are no data about the blood levels of malondialdehyde (MDA, an indicator of oxidative stress) and nonenzymic antioxidants in children with acute hepatitis A.

METHODS: Whole blood MDA and reduced glutathione (GSH), serum β -carotene, retinol, vitamin E and vitamin C levels were studied in 19 (10 females, 9 males) children with acute hepatitis A and in 29 (13 females, 16 males) healthy control subjects.

RESULTS: There was a statistically significant difference between patients and controls for all parameters ($P < 0.05$). Lipid peroxidation marker MDA was significantly elevated ($P < 0.001$), while antioxidants β -carotene, retinol and GSH were significantly decreased (all $P < 0.001$) in patients compared to healthy subjects. In addition, α -tocopherol and ascorbic acid levels were significantly lower in patients when compared to age and sex matched controls ($P < 0.05$, $P < 0.01$, respectively).

CONCLUSION: Our study shows that hepatitis A virus induces oxidative stress in children with hepatitis A. This finding could be taken into consideration to improve the therapeutic approach in acute hepatitis A.

INTRODUCTION

Acute viral hepatitis is one of the most common infectious diseases while hepatitis A is the most prevalent form of acute viral hepatitis in many parts of the world. In developing countries located in Africa, Asia, and Latin America, seroprevalence rates approach 100% and most infections occur by 5 years of age. By contrast, seroprevalence rates in the USA, Western Europe, and in several Mediterranean countries, have been falling during the past few decades^[1]. Viral hepatitis is also a major health problem in Turkey. The most important causes of spreading the disease are low levels of socioeconomic status and poor hygiene conditions, particularly in Eastern Turkey^[2,3]. Hepatitis A mostly occurs in the context of community-wide epidemics during which infection is transmitted from person to person by the fecal-oral route^[4]. The highest rates of disease are seen among children and young adults, and asymptomatic infection among young children is common^[5].

Mitochondria and cytochrome P450 enzymes are the main sources of reactive oxygen species (ROS) in hepatocytes acutely and/or chronically exposed to a "toxic" injury (e.g., environmental drugs, alcohol, therapeutic drugs, viruses). ROS also derive from Kupffer and inflammatory cells, in particular neutrophils^[6]. Oxygen-containing free radicals (such as the hydroxyl radical, superoxide anion radical, hydrogen peroxide, oxygen singlet, hypochlorite, nitric oxide radical, and peroxytrite) are highly reactive species, capable in the nucleus and in the membranes of cells of damaging biologically relevant molecules such as DNA, protein, carbohydrates, lipids^[7] and are produced in physiological and pathological conditions in living organisms. Lipid peroxidation (LPO) is an autocatalytic process which is a common consequence of cell death. This process may cause peroxidative tissue damage in inflammation, cancer, toxicity of xenobiotics and aging. Polyunsaturated fatty acids of the membrane are peroxidized by free radical-mediated reactions. Malondialdehyde (MDA) is one of the end-products in

the LPO process^[8,9]. Oxidative stress is a reflection of excess intracellular concentrations of ROS^[10] and one of the important indicators of cellular damage. Antioxidants transform free radicals into less reactive species, thereby limiting their toxic effects. There are several endogenous antioxidant systems to deal with the production of ROS. These systems can be divided into enzymic and nonenzymic groups. The enzymic subgroup includes superoxide dismutase, catalase and glutathione peroxidase. The nonenzymic group includes a variety of biologic molecules, such as vitamins E, A, and C and reduced glutathione (GSH)^[11].

According to our knowledge, there are no data concerning the effects of oxidative stress on blood nonenzymic antioxidant status in children with hepatitis A. Hence, in the present study, we measured lipid peroxidation levels and antioxidant status such as fat-soluble (vitamin A and vitamin E) and water-soluble (vitamin C and GSH) in children with hepatitis A.

MATERIALS AND METHODS

The investigation included 19 children with acute hepatitis A and 29 control subjects who were admitted to Yüzüncü Yıl University, Faculty of Medicine Department of Pediatrics. The definition of the patients was based on clinical, biochemical and serological criteria. The determination of hepatitis A was made by a pediatrician after taking a detailed history and examining the children for signs of infection. The clinical and biochemical criteria are acute illness compatible with hepatitis and serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels greater than 20-50 times the normal upper limit. However, the diagnosis of hepatitis A was confirmed by serologic tests (IgM and total anti-HAV antibodies were detected by enzyme-linked immunosorbent assay). The control group consisted of healthy children with normal physical examination. None of them had a history of recurrent or recent infection.

Parents of the children, who were enrolled in the study, were informed about the purpose of the study and their consent was obtained. In the present study, whole blood MDA and GSH, and serum β -carotene, retinol, α -tocopherol, ascorbic acid, ALT, AST and total bilirubin levels were measured in all of the subjects. Fasting venous blood samples for the biochemical analysis were taken from each person and transferred to heparinized and normal tubes. Whole blood was collected into heparinized tubes and whole blood MDA and GSH levels were studied on the same day of admission. MDA, which is an important indicator of lipid peroxidation, was determined by spectrophotometry of the pink-colored product of the thiobarbituric acid-malondialdehyde complex formation^[12]. Whole blood GSH concentration was measured by a spectrophotometric method^[13]. Serum was obtained by centrifugation at 2000 *g* for 10 min, of blood samples taken without anti-coagulant which was allowed to clot for 30 min at room temperature, and stored at -20°C until analysis date. Hemolysed samples were excluded. To avoid isomerization of vitamin A and vitamin E, blood samples

Table 1 Serum antioxidant vitamins and whole blood MDA and GSH levels in the patient and control groups (mean \pm SD)

	Acute Hepatitis A (n = 19)	Control (n = 29)	P
MDA (nmol/mL)	1.92 \pm 0.14	1.11 \pm 0.11	< 0.001
GSH (mg/dL)	3.89 \pm 1.59	34.38 \pm 1.41	< 0.001
β -carotene (μ g/dL)	10.52 \pm 1.19	17.44 \pm 1.78	< 0.001
Retinol (μ g/dL)	20.87 \pm 1.42	32.81 \pm 2.13	< 0.001
α -tocopherol (mg/dL)	0.56 \pm 0.31	0.71 \pm 0.25	< 0.05
Ascorbic acid (mg/dL)	0.88 \pm 0.17	1.29 \pm 0.18	< 0.01

P values were calculated using the Student's *t*-test. MDA: Malondialdehyde; GSH: Reduced glutathione; Retinol: Vitamin A; α -tocopherol: Vitamin E; Ascorbic acid: Vitamin C.

were protected from light as soon as they were drawn. The levels of β -carotene at 425 nm and vitamin A (retinol) at 325 nm were detected after the reaction of serum: ethanol: hexane at the ratio of 1:1:3, respectively^[14]. Vitamin E (α -tocopherol) was analyzed colorimetrically with 2,4,6-tripridyl-s-triazin and ferric chloride after extraction with absolute ethanol and xylene^[15]. Serum vitamin C (ascorbic acid) level was determined after derivatization with 2,4-dinitrophenylhydrazine^[16]. Serum ALT, AST and total bilirubin levels were measured in an autoanalyzer (Roche). The same parameters were also studied in the control subjects.

The results are expressed as mean \pm SD. Student's *t*-test was used to compare the mean values of different biochemical parameters between hepatitis A and control groups. In all data analysis, a value of *P* < 0.05 was considered statistically significant.

RESULTS

Our study included 19 (53% female, 47% male) children with acute hepatitis A and 29 (45% female, 55% male) healthy control subjects. The age ranged from 2-9 years (4.42 \pm 1.77 years) and 2-12 years (4.89 \pm 2.22 years) in the study and control groups, respectively. The two groups were comparable in terms of age and gender (*P* > 0.05). Serum enzyme markers of hepatic injury (ALT, AST, and total bilirubin) were significantly raised in the study group. The ALT level ranged from 907 to 4051 IU/L (1869.22 \pm 939.3 IU/L, normal values \leq 40 IU/L), the AST level ranged from 352 to 4690 IU/L (1827.11 \pm 1251.5 IU/L, normal values \leq 40 IU/L) and the total bilirubin level ranged from 1.15 to 8.05 mg/dL (4.98 \pm 1.4 mg/dL, 0.2-1.2 mg/dL) in the patients' group.

Whole blood MDA and GSH levels and serum β -carotene, retinol, α -tocopherol and ascorbic acid levels in the patient group and healthy subjects are presented in Table 1. As seen in the Table, there were statistically significant differences between the groups for all parameters (*P* < 0.05). MDA (as indicator of the lipid peroxidation) was markedly increased in the children with acute hepatitis A when compared to the control group (*P* < 0.001). However, nonenzymic antioxidant status such as fat-soluble (vitamin A and vitamin E) and water-soluble (vitamin C and GSH) were found to be decreased in the

study group. Serum β -carotene and retinol, and whole blood GSH levels were significantly lower in children with hepatitis A than in the control group (all $P < 0.001$). Nevertheless, serum α -tocopherol and ascorbic acid levels were also significantly decrease in patient group ($P < 0.05$, $P < 0.01$, respectively).

DISCUSSION

The normal liver is a well equipped organ in terms of either enzymic or nonenzymic antioxidants although most of the hepatic antioxidant defenses are essentially confined to parenchymal cells. Kupffer cells, hepatic stellate cells or endothelial cells are potentially more exposed or sensitive to oxidative stress-related molecules. Published experimental evidence clearly indicates that hepatic as well as plasma antioxidant defenses (in particular, GSH and α -tocopherol) are often significantly decreased in several liver disease^[17,18].

Oxidative stress is a physiologic consequence of aerobic metabolism. The intermediate components formed in aerobic organisms, such as superoxide and hydrogen peroxide, lead to the further production of ROS that can oxidize membrane lipids and disrupt metabolic processes. GSH is essential for protection against these toxic products of oxygen metabolism, especially as a substrate for GSH peroxidases^[19]. Inflammation, oxidative stress and medications that are detoxified through GSH consuming pathways will all result in GSH loss and excessive cysteine catabolism^[20].

GSH depletion in lymphoid cells may interfere with the immunological mechanisms involved in viral clearance, thus facilitating viral replication and enhancing liver damage because of the oxidative stress. Lymphocyte activation *in vitro* can be inhibited completely by decreasing GSH by 10% to 40%^[21] and Barbaro *et al*^[22] reported the depletion of GSH in chronic hepatitis C (CHC) patients was associated with a mean 12.7% reduction of peripheral blood mononuclear cells cytotoxic activity compared to controls^[22].

ROS are well characterized mediators of cell and tissue injury. Generally, cells defend themselves from ROS and other toxic oxygen species by a variety of mechanisms including nonenzymic and enzymic defence systems. An ineffective scavenging capacity of antioxidant systems may play a relevant role in determining the degree of oxidative stress^[23-25].

The increase in serum MDA concentration in CHC patients may very well fit in with the recently reported glutathione depletion observed in hepatic tissue, plasma, and peripheral blood mononuclear cells of CHC patients^[26]. Hepatitis C virus (HCV) infection is associated with reduced GSH levels in both plasma and erythrocytes known to be the main intracellular mechanism against oxidative stress, and this depletion appears to be related to the activity of the liver disease^[26,27]. Likewise, the present study also reports an increased MDA and decreased GSH levels in the acute hepatitis A patients.

The decreased content of cellular and plasma GSH, most likely mediated by HCV, or in the present paper's case by hepatitis A virus, may render biological structures

more susceptible to oxidative attack and this condition may expose circulating lipids and proteins to oxidative modifications with consequent loss of their biological functions. Several authors' findings are consistent with each other, in which it is reported that a reduction of hepatic GSH stores might be partly responsible for the cytopatic effect induced by HCV^[28,29]; it is also conceivable that the observed GSH depletion in lymphoid cells^[26] might interfere with the immunological mechanism involved in viral clearance, thus facilitating viral replication and enhancing, with time, liver damage through a greater oxidative stress^[30].

Free oxygen radicals take part in pathogenesis of chronic hepatitis of B and C type in children as they decrease the antioxidant barrier efficiency diminishing catalase and superoxide dismutase levels^[31]. In the same manner, it is likely that free oxygen radicals can take role in the pathogenesis of the acute hepatitis A since antioxidant vitamin levels were decreased in our study. As mentioned above, the reason might be the altered antioxidant capacity because of the decreased antioxidant vitamins in blood.

As expected from the other hepatitis cases, in acute hepatitis A, nonenzymic antioxidant levels such as GSH and β -carotene, retinol, vitamin E, vitamin C were found to have decreased in this study.

There are several possible explanations for the low serum retinol levels seen in chronic liver disease. Defective synthesis of retinol binding protein prevents the customary mobilization of retinol from the liver to the periphery. This would suggest that retinol exerts its antiproliferative effect in a paracrine or systemic manner rather than by an immediate local effect. Another possibility is that the absorption of dietary retinol is impaired, which may also explain why levels are even lower in patients with cholestatic liver disease. Whilst other groups have suggested that serum retinol levels are a reflection of nutritional status^[32], the other authors did not report any association between decreasing body mass index and lower retinol levels within the cohort of patients studied. In conformity with our results, von Herbay *et al*^[33] showed that vitamin E plasma levels were significantly lower ($P < 0.01$) compared to the control group. They suggest that the decreased vitamin E levels in patients with acute or chronic viral hepatitis with high activity of disease may be due to free radical-mediated liver injury.

Vitamin C, the major water-soluble antioxidant, is beneficial in reducing oxidative stress, but is harmful depending on the sensitive balance of its concentration. Ascorbic acid has been shown to efficiently scavenge superoxide, hydrogen peroxide, hypochloride, hydroxyl radicals, and peroxy radicals^[34] and to restore the antioxidant properties of fat-soluble α -tocopherol, therefore; it interrupts the radical chain reaction of lipid peroxidation^[35]. In this study, vitamin C levels were found to be significantly lower in the hepatitis A group than in the controls (Table 1). To our knowledge, there is no data concerning the levels of serum vitamin C in children with hepatitis A. The reduction in serum concentration of vitamin C might be due to increased rate of ascorbic acid oxidation in oxidative stress.

In conclusion, this study shows that hepatitis A virus

induces oxidative stress in children with hepatitis A. This finding could be taken into consideration to improve the therapeutic approach in acute hepatitis A.

Abstract

AIM: To evaluate Pronto Dry examination in patients with dyspepsia.

METHODS: The study was conducted in patients with dyspepsia who underwent endoscopic examination in several endoscopic centers of several cities in Indonesia from January 2003 until April 2004. Biopsies for histopathologic examination were fixed with formalin and sent to Histopathologic Department to be analyzed and confirm the presence of *H pylori* infection. If *H pylori* was found positive, the density was calculated semi quantitatively. Histopathologic examination from gastric biopsy samples was interpreted based on the updated Sydney system classification.

RESULTS: Of 550 patients, 309 (56%) were male and 241 (44%) were female with ages ranging from 15 to 82 years. Mean age was 44.98 ± 14.46 years. Mean age of male patients was 44.35 ± 13.85 years and mean age of female patients was 45.78 ± 15.19 years. Evaluation of endoscopic results showed gastric ulcer in 36 cases (6.5%) and duodenal ulcer in 20 cases (3.6%). Normal endoscopic finding was found in 45 cases (8.2%) and

minimal disorder of gastritis and duodenitis were found in 246 cases (44.7%). One case of gastric cancer was identified. Of 56 cases which were positive based on the criteria used, 39 patients were positive with Pronto Dry and 17 patients were negative with Pronto Dry. Overall sensitivity and specificity of Pronto Dry were 69.7% and 95.7% respectively. Positive predictive value was 66.1% and negative predictive value was 96.4% and overall accurate rate was 92.9%.

CONCLUSION: Pronto Dry seems promising as a diagnostic tool to detect *H pylori* more rapidly and accurately.

INTRODUCTION

H pylori is a microaerophilic, gram negative, slowly growing, and pathogenic bacterium which produces urease enzyme^[1]. *H pylori* may cause chronic gastritis and predispose to gastric and duodenal ulcer. Recently, *H pylori* has been classified as gastric carcinogen class 1^[2,3].

Diagnosis of *H pylori* may be made by invasive or non invasive methods. During the invasive method patients would undergo endoscopic examination and gastric tissue biopsy. Samples and biopsies are examined to detect the presence of *H pylori* by histopathologic examination, rapid urease test or culture^[4,5]. Culture examination is the gold standard test. Culture examination is not simple because transport media and biopsy samples for observation of the growth of the bacteria need special preparation procedures.

Non invasive methods include the rapid urease test, serologic and *H pylori* examination of the feces (*H pylori* stool antigen)^[6]. Rapid urease test is frequently done in

endoscopic centers in patients with dyspepsia to detect the presence of *H pylori*. This method is rapid and easy to perform in the endoscopic room. Currently, there are various kinds of rapid urease test in the market such as CLO, MIU or Pyloric test and a recent one called Pronto Dry. The advantage of this method is that it is not necessary to keep the sample in the refrigerator, a rapid result may be obtained only in 1 h, and it is easy to read the color changes. Previous studies have shown this test has good sensitivity and specificity^[7,8].

The aim of the present study was to evaluate Pronto Dry examination in patients with dyspepsia in several endoscopic centers in Indonesia including Jakarta, Bandung, Surabaya, Denpasar, Yogyakarta and Medan.

MATERIALS AND METHODS

Research subjects

The study was conducted in patients with dyspepsia who underwent endoscopic examination in the endoscopic centers of several cities in Indonesia which were as follows: RSCM Jakarta, RS Hasan Sadikin Bandung, RS Sardjito Yogyakarta, RS Soetomo Surabaya, RS Adam Malik Medan, and RS Sanglah Denpasar. The study period was from Jan 2003 until Apr 2004.

Inclusion criteria were patients who had been diagnosed dyspepsia and would undergo upper gastrointestinal endoscopic examination, with age more than 15 years old. Patients were not taking antibiotics, H₂ receptor antagonists or proton pump inhibitors during 7 d prior to the examination.

Patients who had fulfilled inclusion criteria had endoscopic examination and biopsy samples were taken two in the antrum and two more in the corpus. Pronto Dry (Medical Instruments Corporation, Solothurn, Switzerland) was performed according to standard procedure and interpretation was read in 1 h after examination.

Biopsies for histopathologic examination were fixed with formalin and sent to Histopathologic Department to be analyzed and confirm the presence of *H pylori* infection. If *H pylori* was found positive, its density would be read semi quantitatively. Histopathologic examination of gastric biopsy samples was interpreted based on the Updated Sydney system classification.

Statistical analysis

The values are expressed as mean \pm SD. Statistical calculation to test sensitivity, specificity, positive predictive value, negative predictive value, and the accuracy was done using statistics software. $P < 0.05$ was taken as significant.

RESULTS

This multicentre study was conducted in 6 endoscopic centers. Each unit collected various numbers of cases and most were obtained from endoscopic room in RSCM, Jakarta. The number of patients included in the study was 550 consisting of 320 (58.2%) patients from RSCM Jakarta, 40 (7.3%) patients from RS Adam Malik Medan, 60 (10.9%) patients from RS Sutomo Surabaya, 37 (6.7%) patients from RS Sardjito Yogyakarta, 43 (7.8%) patients

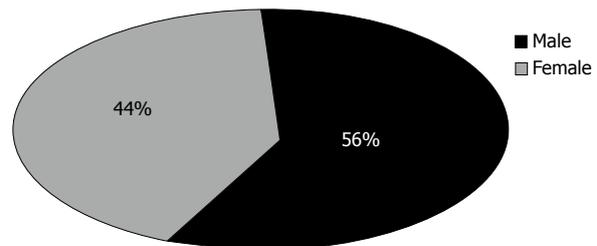

Figure 1 Distribution of patients based on gender.

Table 1 Results of upper gastrointestinal endoscopy of patients with dyspepsia

Endoscopic diagnosis	n	%
Normal	45	8.2
Gastritis and or duodenitis	246	44.7
Gastric ulcer	36	6.5
Duodenal ulcer	20	3.6
Mild erosive gastritis	83	15.1
Esophagitis	85	15.5
Gastric cancer	1	0.2
Mild erosive gastritis/Esophagitis	2	0.4
Severe erosive gastritis	16	2.9
Gr. B Esophagitis/Moderate gastritis	6	1.1
Barrett's esophagus	2	0.4
Esophagitis, gastric ulcer	1	0.2
Esophagitis, pangastritis, duodenal ulcer	1	0.2

from RS Sanglah Denpasar Bali and 50 (9.1%) patients from RS Hasan Sadikin Bandung.

Of 550 patients included in this study, 309 patients (56%) were male and 241 patients (44%) were female (Figure 1) with age ranging from 15 years to 82 years. Mean age was 44.98 ± 14.46 years. Mean age of male patients was 44.35 ± 13.85 years and of female patients was 45.78 ± 15.19 years.

Evaluation of endoscopic results showed gastric ulcer was found in 36 cases (6.5%) and duodenal ulcer in 20 cases (3.6%). Normal endoscopic finding was found in 45 cases (8.2%) and minimal disorders of gastritis and duodenitis were found in 246 cases (44.7%). In addition, one case of gastric cancer was identified (Table 1).

Diagnosis of *H pylori* infection

Based on definition determined at the beginning of the study, *H pylori* infection was considered positive if histopathologic examination showed the presence of *H pylori*. Of 550 cases studied, *H pylori* was found positive in 56 (10.2%). The highest prevalence of *H pylori* was found in patients from Yogyakarta (30.6%) and the lowest was in patients from Jakarta (8%).

Of 550 patients, 25 did not have histopathologic examinations. Furthermore, analysis on sensitivity and specificity was done with only 525 patients because they had complete examination with both histopathology and Pronto Dry. Of 56 cases which were positive based on the criteria used, 39 were positive with Pronto Dry and 17 were negative with Pronto Dry. Overall sensitivity and specificity of Pronto Dry were 69.7% and 95.7%, respectively. Positive predictive value was 66.1% and

negative predictive value was 96.4% and overall accurate rate was 92.9%. If we calculated the sensitivity and specificity of each endoscopic center, results were varied (Table 2).

DISCUSSION

To date, the rapid urease test is still needed to detect the presence of *H pylori*. This test is relatively easy and rapid and thus appropriate therapy is possible if diagnosis of *H pylori* is confirmed. In addition, upper gastrointestinal endoscopic examination is still a reliable procedure to investigate the cause of dyspepsia.

Our result indicated that endoscopic examination of patients with uninvestigated dyspepsia showed various underlying disorders. Almost 45% of endoscopic results showed organic disorders such as esophagitis, peptic ulcer and erosive gastritis. In addition, 1 of 550 cases in this study was found to be gastric carcinoma. This result indicated that endoscopy is very important in evaluating upper gastrointestinal disorder in patients with dyspepsia. Rapid urease test has become indispensable in patients having the indication for endoscopic procedure.

Of all patients with dyspepsia who had undergone endoscopic examination, *H pylori* infection was positive in only 10.2% of cases. This figure was lower than the result of multicentered study in Europe published in 1999. In that study involving 501 patients with dyspepsia, 55.7% were found to have positive result of *H pylori*. Another study conducted in Jakarta found that 9.5% patients with dyspepsia were positive for *H pylori* infection by endoscopic examination^[9].

The sensitivity, specificity, positive and negative predictive values, and overall accurate level were 69.6%, 95.7%, 66.1%, 96.4%, and 92.9%, respectively. A study conducted by Said *et al* in Malaysia to evaluate Pronto Dry found better sensitivity (98.1%) and specificity (100%)^[8]. However, if we compared the result of studies in Jakarta and Bandung, similar results to the study in Malaysia were obtained. The study in Jakarta found a sensitivity of 95.7% and specificity of 98.3%, while the study in Bandung found both sensitivity and specificity of 100%. The difference of the results might be due to different histopathologic evaluation criteria adopted by different centers. This, however, could be overcome by standardization of appropriate biopsy location, standardised type of biopsy instrument and samples size and results read by same pathologists.

Rapid urease test using Pronto Dry which is relatively new is found to have good specificity although the sensitivity is lower than specificity. Studies in several cities

Table 2 Sensitivity, specificity, positive predictive value and negative predictive value by Pronto Dry examination at each endoscopic centre

Endoscopic centre	Sensitivity (%)	Specificity (%)	Negative predictive value (%)	Positive predictive value (%)	Accurate level (%)
Jakarta	95.7	98.3	99.7	81.5	98.2
Bandung	100.0	100.0	100.0	100.0	100.0
Medan	100.0	59.4	100.0	38.1	67.5
Surabaya	33.3	98.1	93.0	66.7	91.6
Yogyakarta	10.0	100.0	75.0	100	75.7
Bali	25.0	94.1	84.2	50.0	81.0

have shown that Pronto Dry has very good sensitivity and specificity level above 95%. If we compare with the other rapid urease test, Pronto Dry can give result in only 1 h. This test seems very promising as a diagnostic tool to detect *H pylori* more rapidly and accurately.

Abstract

Metastatic breast cancer involving the hepatobiliary tract or ascites secondary to peritoneal carcinomatosis has been well described. Luminal gastrointestinal tract involvement is less common and recognition of the range of possible presentations is important for early and accurate diagnosis and treatment. We report 6 patients with a variety of presentations of metastatic breast cancer of the luminal gastrointestinal tract. These include oropharyngeal and esophageal involvement presenting as dysphagia with one case of pseudoachalasia, a linitis plastica-like picture with gastric narrowing and thickened folds, small bowel obstruction and multiple strictures mimicking Crohn's disease, and a colonic neoplasm presenting with obstruction. Lobular carcinoma, representing only 10% of breast cancers is more likely to metastasize to the gastrointestinal tract. These patients presented with gastrointestinal manifestations after an average of 9.5 years and as long as 20 years from initial diagnosis of breast cancer. Given the increased survival of breast cancer patients with current therapeutic regimes, more unusual presentations of metastatic disease, including involvement of the gastrointestinal tract can be anticipated.

INTRODUCTION

Breast cancer is the most common neoplasm in women, accounting for approximately 32% of cancers in women, with a lifetime risk of 1 in 10^[1]. Prognosis is related to the presence of hormonal receptors, the size and grade of the primary tumour, the presence of regional lymphadenopathy, and metastatic disease^[1]. Metastatic breast cancer typically involves the lungs, bones, brain and liver, but occasionally can affect the gastrointestinal tract^[2]. We report 6 patients with a variety of presentations involving the gastrointestinal tract, all of which were eventually found to be due to metastatic breast cancer. These examples highlight the importance of considering metastatic breast cancer as a potential cause of radiological abnormalities affecting any part of the gastrointestinal tract of women, especially those with a previous history of breast cancer.

CASE REPORTS

Case 1

A 51-year old female presented with a 3-mo history of progressive solid food dysphagia. Initial barium swallow and endoscopy were normal. Esophageal manometry showed impaired relaxation of the lower esophageal sphincter, but no other abnormality. A decision was made to follow the patient and re-investigate her in 6 mo. The patient returned after 5 mo with worsening dysphagia and 20-pound weight loss. Barium swallow demonstrated retained secretions, esophageal dilatation and tapered narrowing in the region of the lower esophageal sphincter (Figure 1). Repeat manometry demonstrated changes consistent with achalasia. Repeat endoscopy showed a dilated esophagus and a narrowed gastroesophageal junction with no intrinsic mucosal abnormality. Pneumatic dilatation with a Rigiflex 35 mm balloon was unsuccessful and the patient was referred for thoracoscopic myotomy. At the time of surgery, the left lower lobe of the lung was found to be fixed to the gastroesophageal junction by tumor that extended to involve the distal esophagus and pericardium. Biopsies showed infiltrating lobular breast carcinoma. The patient had a right mastectomy 15 years previously. The patient recovered from surgery and was treated with tamoxifen with gradual normalization of her swallowing function. She declined repeat manometric or radiological assessment.

Case 2

A 58-year old female with a previous history of Paget's disease

Figure 1 Barium swallow demonstrating smooth, symmetric tapering of the esophagus (arrow), suggesting achalasia.

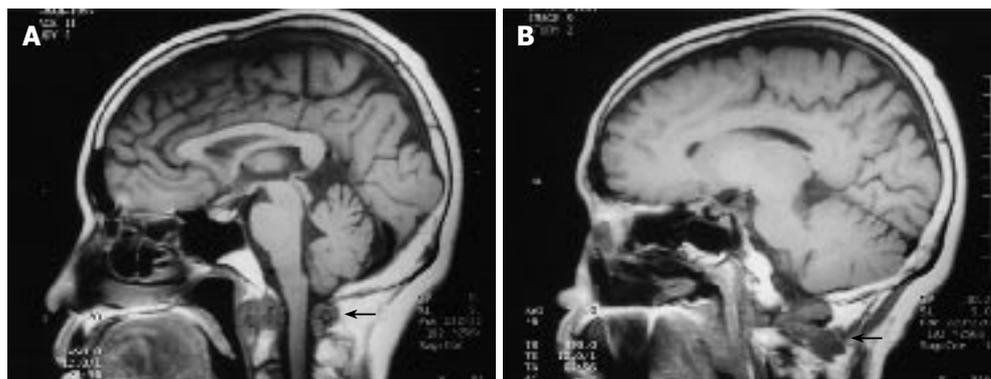

Figure 2 Sagittal T1-weighted MRI demonstrating low-signal consistent with marrow replacement at both C1 and the posterior vertebral body of C3 (arrow) (A), and low-signal soft tissue mass adjacent to the C2 vertebral body (arrow) (B).

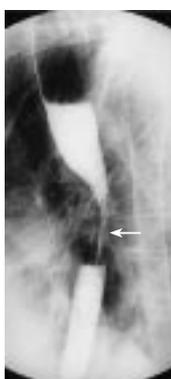

Figure 3 Barium swallow demonstrating irregular stenosis (arrow) involving the middle esophagus.

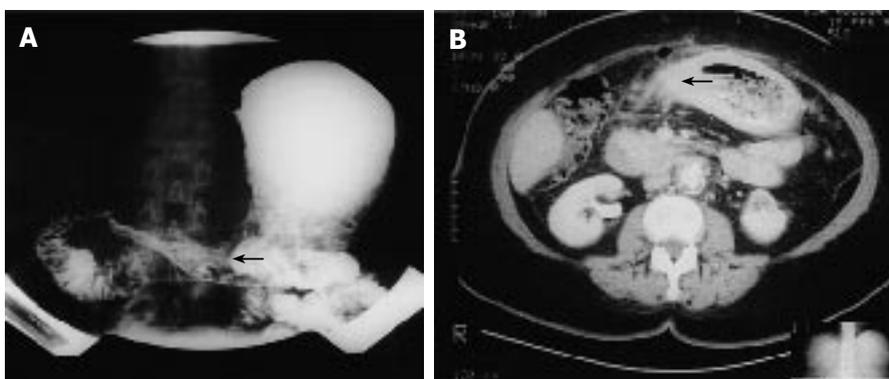

Figure 4 Double-contrast upper GI examination demonstrating irregular narrowing of the gastric antrum (arrow) (A), CT demonstrating gastric mural thickening, perigastric stranding, (arrow) and lymphadenopathy (B).

of the bone involving the cervical spine, multinodular goitre and neck trauma secondary to a motor vehicle accident presented with oropharyngeal dysphagia and mild dysarthria. Barium swallow demonstrated poor bolus formation, decreased laryngeal elevation, incomplete oropharyngeal clearance, and aspiration of barium. Electromyography was suspicious of a motor neuron disease, demonstrating paralysis of the left vocal cord, tongue fasciculations, and denervation of the left sternocleidomastoid. The patient underwent magnetic resonance imaging (MRI) which demonstrated a soft tissue density at the C2 level, as well as marrow replacement in several vertebrae (Figure 2A and 2B). Open biopsy of the soft tissue showed adenocarcinoma consistent with metastatic breast cancer. The patient had a modified left radical mastectomy for ductal adenocarcinoma followed by radiation therapy 20 years previously.

Case 3

A 66-year old female presented with solid food dysphagia for several months. Barium swallow demonstrated a mid-esophageal stricture that was suspicious of neoplastic disease (Figure 3). Endoscopy and biopsy confirmed metastatic infiltration of the esophagus by lobular breast carcinoma. Unfortunately, attempted palliative dilatation resulted in perforation of the esophagus. The subsequent

course of events resulted in prolonged hospitalization with multiple surgical procedures, complications and eventually death. The patient had a modified right mastectomy and radiotherapy 13 years previously for node negative malignancy. The patient had known metastatic disease to the left hilum, proven by biopsy, 6 years prior to the presentation of dysphagia.

Case 4

An 80-year old female presented with a history of early satiety and vomiting. Double contrast upper gastrointestinal barium examination was consistent with linitis plastica (Figure 4A). Endoscopy with biopsy of the gastric body and antrum confirmed metastatic infiltrating lobular carcinoma of breast origin. Subsequent computed tomography (CT) scanning demonstrated changes in the stomach and duodenum (Figure 4B). The patient received palliative care, but her symptoms were progressed after 14 mo. Plain films of the abdomen demonstrated a small bowel obstruction, suspected to be due to intra-abdominal spread of the disease. The patient underwent modified left radical mastectomy 2 years previously and had node positive disease.

Case 5

A 60-year old female presented with a history of diarrhea,

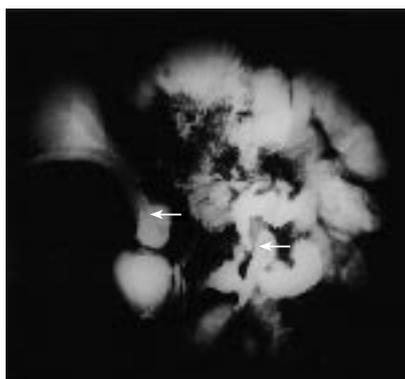

Figure 5 Small bowel enteroclysis showing persistent narrowing of the gastric body and antrum (arrow), prominent irregular gastric rugae with diffuse mucosal serration, and strictures of the ileum.

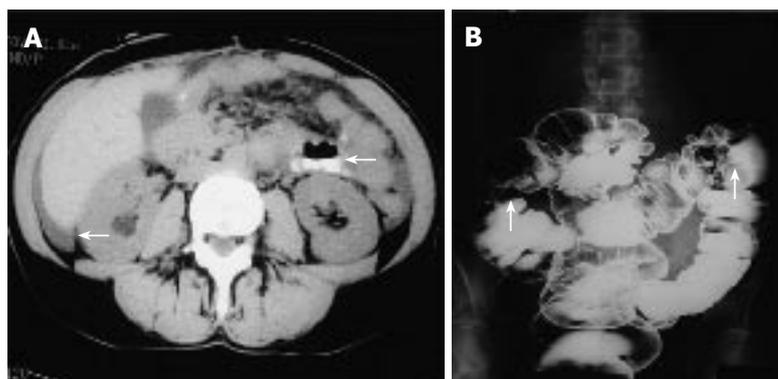

Figure 6 CT demonstrating a dilated loop of small bowel (arrow) and ascites (A), double-contrast barium enema demonstrating fixed eccentric strictures of the ascending colon and splenic flexure (arrows) with a third obscuring lesion seen within the sigmoid colon but not projected in profile on this image (B).

abdominal cramps and vomiting. Crohn's disease was suspected and she was initially treated with prednisone with clinical improvement. Several months later she experienced an exacerbation of her symptoms and presented with a partial small bowel obstruction. Small bowel enteroclysis demonstrated multiple abnormalities, including persistent narrowing of the gastric body and antrum (Figure 5), prominent irregular gastric rugae with diffuse mucosal serration, as well as 3 separate strictures of the ileum. The findings were compatible with the diagnosis of Crohn's disease, but upper gastrointestinal endoscopy showed gross findings suspicious of malignancy. Biopsy demonstrated adenocarcinoma of breast origin. CT examination demonstrated ascites and mesenteric involvement, subsequently confirmed at laparotomy. The patient had a modified radical mastectomy 10 years previously.

Case 6

A 51-year old female had a 3-year history of increasing abdominal pain. CT examination demonstrated a dilated small bowel as well as ascites (Figure 6A). Subsequent laparotomy demonstrated that the patient had a small bowel obstruction secondary to carcinomatosis consistent with metastatic breast cancer. After surgical treatment and hormonal therapy, the patient improved clinically. One year later, she presented with diarrhea. A double contrast barium enema demonstrated lesions in the ascending, distal transverse and sigmoid regions of the colon (Figure 6B). The appearance of the lesions was consistent with synchronous colonic cancers, but proved to be metastatic breast adenocarcinoma on pathology. The patient was diagnosed with breast cancer 4 years prior to the presentation with small bowel obstruction.

DISCUSSION

Breast cancer accounts for 19% of cancer deaths in women^[1]. Current therapies have had a significant impact on the mortality and survival rates of breast cancer^[3]. Prognosis is related to several factors including the presence of metastases with tumor histology being one of

the predictors of metastatic spread. For example, tubular and mucinous carcinomas have a lower incidence of metastases and a better prognosis^[4]. Lobular carcinoma, though less common and by mechanisms that are not clear, is more likely to metastasize to the gastrointestinal tract^[4]. Although the gastrointestinal tract is a less common site for metastatic involvement by breast cancer, recognising the range of possible presentations is important for early and accurate diagnosis and treatment. The cases we described in this report highlight these features. Also, our patients presented with gastrointestinal manifestations after an average of 9.5 years and as long as 20 years of initial diagnosis. A 30-year interval between the original diagnosis and the presentation of metastatic disease has been reported in the literature^[5]. Given the increased survival of breast cancer patients with current therapeutic regimes, more unusual presentations of metastatic disease, including involvement of the gastrointestinal tract can be anticipated^[2,6,7], and hence this diagnosis should be considered in any woman with a previous history of the disease presenting with new gastrointestinal complaints.

Previous case reports and small series that have documented gastrointestinal involvement by metastatic breast cancer, together with the cases presented here, are summarized in Table 1. Any region of the gastrointestinal tract can be involved. However, oropharyngeal and esophageal involvement presenting as dysphagia is unusual^[8]. Our series is unique in that it includes three examples of this: case 1 with pseudoachalasia, case 2 with oropharyngeal dysphagia secondary to nerve involvement, and case 3 with malignant esophageal stricture. In our review of the literature, this is only the third reported case of pseudoachalasia secondary to metastatic breast cancer^[9,10]. As well, this is the first reported case of oropharyngeal dysphagia resembling case 2. There is a previous report of one case of metastases to the tongue^[11]. Esophageal involvement most commonly presents as a short-segment of extrinsic obstruction in the mid-esophagus and has been reported to occur up to 22 years following the initial diagnosis of breast cancer^[8]. Mediastinal and hilar lymphadenopathy may be present^[12], and endoscopic biopsy may not provide the diagnosis

if the obstruction is extrinsic and does not involve the mucosa. Long segment involvement of the esophagus, up to 20 cm, has been described^[13]. Symptoms as well as radiographic findings may mimic radiation-induced or peptic stricture^[12].

The stomach is the most common site of gastrointestinal involvement by metastatic breast cancer with an incidence of up to 15% at autopsy^[12,14]. The usual presentation mimics linitis plastica and is typically due to lobular carcinoma^[6], as illustrated by case 4. Findings include gastric wall thickening, rigidity and decreased peristalsis. Cases in which the linitis plastica-like presentation precedes the diagnosis of breast cancer have been documented^[6]. In one series of 22 patients, endoscopy and biopsy could provide the correct diagnosis in only 13, most likely because tumor infiltration is deep to the mucosa^[15]. Metastatic involvement of the stomach can mimic primary gastric neoplasms and inflammatory conditions such as peptic ulcer or gastritis^[16]. Bleeding and perforation have also been reported^[17-19].

Malignant neoplasms of the small intestine are uncommon and are usually primary adenocarcinomas^[20]. Metastatic involvement of the small bowel can be due to malignant melanoma, or cancer of the colon, cervix, ovary or rarely esophagus^[12,20]. Metastatic involvement of the small intestine is recognized at autopsy^[21,22], but clinical presentation is uncommon. Patients can present with abdominal pain and diarrhea^[20], similar to case 5, intussusception^[12] or even appendicitis^[7]. The terminal ileum is involved more often than the proximal small bowel, possibly due to the tracking of peritoneal fluid along the mesentery into the right lower quadrant. The clinical and radiological presentation can mimic Crohn's disease, as illustrated by case 5. Metastatic disease to the duodenum has also been described^[23].

Colonic involvement is common with some series showing colonic metastases in up to 12% of patients with breast cancer^[22,24]. Carcinoma of the breast is the most frequent source of hematogenous metastases to the large bowel^[2], but involvement via peritoneal and lymphatic spread also occurs^[12]. As in the stomach, the lobular form of breast cancer is more likely to metastasise to the colon^[2,4]. The presentation can be similar to primary neoplasia of the colon or can mimic Crohn's disease, both clinically and radiologically^[2,12,16,15]. Air contrast barium enema or CT may demonstrate diffuse or multifocal involvement^[16]. Mucosal nodularity, stenosis, decreased distensibility, angulation and tethering are also characteristic findings^[12]. Solitary apple-core lesions are less common^[15]. Similar to the upper gastrointestinal tract, endoscopy and biopsy provide only a moderate diagnostic yield: 6 of 10 patients in one series^[15]. Deep biopsy or laparotomy may be required for diagnosis^[18,15]. Rectal involvement has also been described, including rectal stenosis secondary to metastatic breast cancer^[25,26].

Other intra-abdominal sites of metastatic breast cancer that do not involve the gastrointestinal tract per se have been reported. Ascites, secondary to peritoneal carcinomatosis, is a common abnormality demonstrated by abdominal CT^[27]. Metastatic spread to the hepatobiliary tract is well described^[19,28]. Metastases to the diaphragm,

Table 1 Summary of gastrointestinal presentations of metastatic breast cancer

Site	Presentation	Reference
Oropharynx	Oropharyngeal dysphagia	(Case 2)
	Tongue lesion	11
Esophagus	Stricture	(Case 3), 8, 13, 31-44
	Achalasia	(Case 1), 9, 10
	Non-specific dysmotility	30
Stomach	Linitis plastica	(Case 4), 5, 6, 45-52
	Obstruction/Stenosis	(Case 5), 19, 45
	Polyp	45, 53, 54
	Ulcer/Erosion	19, 45, 55, 56
	Perforation	57
Small intestine	Obstruction/Stenosis	(Case 4), (Case 6), 20, 58-61
	Multiple strictures/ Diffuse infiltr	(Case 5)
Colon	Obstruction/Stenosis	25, 59, 62-65
	Asymptomatic abdominal Mass	19
	Multiple strictures/ Diffuse infiltr	(Case 6), 66
	Polyp	67
	Rectum	Obstruction/Stenosis
	Linitis plastica	47

the genitourinary tract, the retroperitoneum, the mesenteric lymph nodes, the abdominal wall and subcutaneous tissues have been reported^[11,12,27]. Spread to the ovaries is identified histologically, but is not usually clinically evident or demonstrated with CT in the absence of other evidence for metastatic disease^[29].

Metastatic breast cancer involving the gastrointestinal tract can produce a wide range of clinical and radiological presentations, often mimicking other gastrointestinal disorders. Given the high prevalence of this disease, breast cancer needs to be considered in any women presenting with new gastrointestinal complaints, especially those with a history of breast cancer, even if the initial diagnosis was made many years previously.

Abstract

Differentiation between autoimmune pancreatitis and pancreatic cancer is sometimes difficult. It has been reported that serum IgG4 concentrations are significantly elevated and particularly high (>135 mg/dL) in autoimmune pancreatitis. Measurement of serum IgG4 has become a useful tool for differentiating between autoimmune pancreatitis and pancreatic cancer. However, we present a 74-year-old female with a markedly elevated serum IgG4 (433 mg/dL) who underwent pancreaticoduodenectomy for pancreatic cancer. Elevated serum IgG4 levels continued after the resection. On histology, adenocarcinoma of the pancreas accompanied with moderate lymphoplasmacytic infiltration infiltrated the lower bile duct and duodenum, but there were no findings of autoimmune pancreatitis. Although a small metastasis was detected in one parapancreatic lymph node, regional lymph nodes were swollen. Abundant IgG4-positive plasma cells infiltrated the cancerous areas of the pancreas, but only a few IgG4-positive plasma cells were detected in the noncancerous areas. Pancreatic cancer cells were not immunoreactive for IgG4. An abundant infiltration of IgG4-positive plasma cells was detected in the swollen regional lymph nodes and in the duodenal mucosa. We believe that the serum IgG4 level was elevated in this patient with pancreatic cancer as the result of an IgG4-related systemic disease that had no clinical manifestations other than lymphadenopathy.

Key words: IgG4; Pancreatic cancer; Autoimmune pancreatitis

INTRODUCTION

Autoimmune pancreatitis is a unique form of pancreatitis, histopathologically characterized by dense lymphoplasmacytic infiltration and fibrosis of the pancreas with obliterative phlebitis^[1,2]. Patients with this disease usually have a swollen pancreas with delayed enhancement on computed tomography (CT), irregular narrowing of the main pancreatic duct on endoscopic retrograde pancreatography, and a favorable response to steroid therapy^[1-4]. Autoimmune pancreatitis has been frequently mistaken for pancreatic cancer for 3 major reasons: most patients are elderly (average age of 59^[4]-61^[5] years); painless obstructive jaundice is present due to the associated sclerosing cholangitis (65%^[4]-86%^[6]); and there is a mass in the pancreas.

In 2001, Hamano *et al*^[7] reported that serum IgG4 concentrations were significantly elevated and particularly high in autoimmune pancreatitis and were closely associated with disease activity. They measured serum IgG4 levels in 20 patients with autoimmune pancreatitis and 70 patients with pancreatic cancer. A cutoff value for the serum IgG4 level of 135 mg per deciliter resulted in a high rate of accuracy (97%), sensitivity (95%), and specificity (97%) for the differentiation of autoimmune pancreatitis from pancreatic cancer. Since this report, IgG4 has become a serological marker of autoimmune pancreatitis^[8,9]. Hirano *et al*^[10] also stated that serum IgG4 concentrations are helpful for differentiating between autoimmune pancreatitis and pancreatic cancer, as none of their 23 patients with pancreatic cancer had a high serum IgG4 level. Here, we present a resected case of pancreatic cancer that had a high serum IgG4 level and discuss the possible mechanisms for the elevated serum IgG4 levels in this patient.

CASE REPORT

A 74-year-old female was admitted to our hospital in May 2005 complaining of jaundice. She had no history of

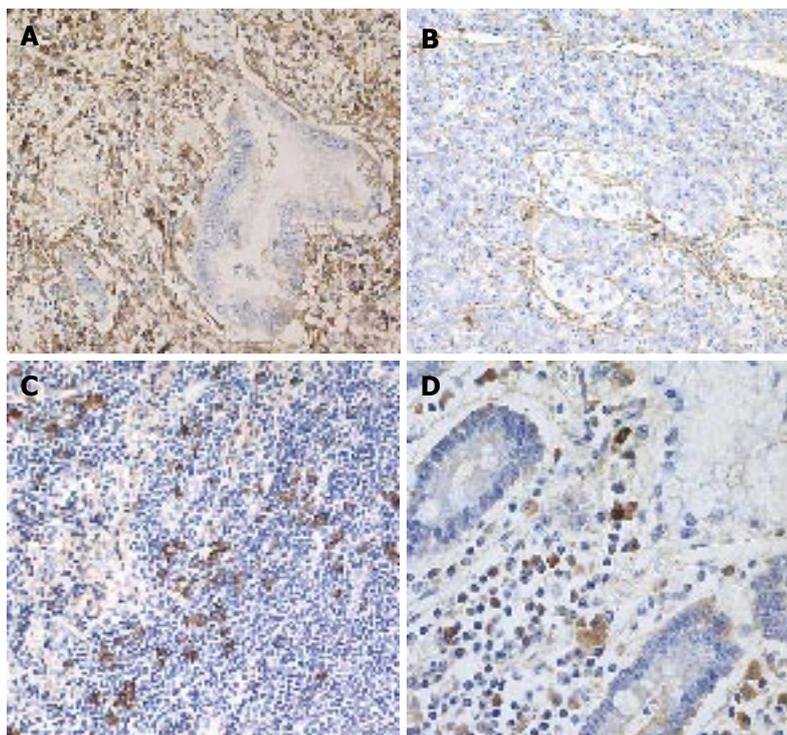

Figure 1 Immunostaining of IgG4 in the resected specimens. Abundant IgG4-positive plasma cells were detected in the cancerous lesion of the pancreas (A) but only a few IgG4-positive plasma cells were seen in the noncancerous areas of the pancreas (B). Infiltration of abundant IgG4-positive plasma cells was detected in regional lymph node (C) and the duodenal mucosa (D).

other illness or alcohol abuse. On admission, there was no swelling of the salivary glands and the cervical lymph nodes were not palpable. Laboratory data included: total bilirubin 7.4 mg/dL (normal: 0.2-1.1 mg/dL), alkaline phosphatase 1466 IU/L (115-359 IU/L), aspartate aminotransferase 236 IU/L (11-25 IU/L), and alanine aminotransferase 431 IU/L (4-27 IU/L). Serum levels of tumor markers DUPAN 2 and Span 1 were elevated to 7526 U/mL (< 150 U/mL) and 101 U/mL (< 30 U/mL), respectively.

Abdominal ultrasonography demonstrated a 4 cm-sized hypoechoic mass in the pancreatic head with dilatation of the intrahepatic and extrahepatic bile ducts and the main pancreatic duct. On helical CT scan, the mass was hypoattenuated to the pancreas in the early phase, but attenuation increased in the delayed phase. Based on the CT finding of delayed enhancement, we examined the serological findings, suspecting autoimmune pancreatitis. Although the serum IgG was 1560 mg/dL (870-1700 mg/dL) and the antinuclear antibody test (ANA) was negative, the serum IgG4 measured by single radial immunodiffusion (The Binding Site, Birmingham, UK) was elevated to 433 mg/dL.

Endoscopic retrograde cholangiopancreatography showed stenosis of the lower portion of the common bile duct and the main pancreatic duct near the major duodenal papilla, and endoscopic nasobiliary drainage was performed. Histological examination of the biopsy specimen from the irregular erosive duodenal mucosa around the major duodenal papilla under duodenoscopy revealed infiltration of adenocarcinoma.

Given the diagnosis of pancreatic head cancer, a pancreaticoduodenectomy was performed. Histological examination revealed that moderately differentiated tubular adenocarcinoma arising in the head of the pancreas

infiltrated to the lower bile duct and duodenum. A small histological metastasis was detected in one parapancreatic lymph node. Although moderate lymphoplasmacytic infiltration was observed in the cancerous areas, no findings of autoimmune pancreatitis were detected in the noncancerous areas of the pancreas.

The specimens resected during pancreaticoduodenectomy were fixed in 10% formaldehyde. Serial sections (4 μ m thick) were cut from paraffin embedded tissue blocks. Sections of the pancreas, including the extrahepatic bile duct, gallbladder, duodenum, stomach and regional lymph nodes were immunostained using anti-CD4-T (Novocastra, Newcastle upon Tyne, UK), CD8-T (DakoCytomation, Glostrup, Denmark), and IgG4 (The Binding Site) with avidin-biotin-peroxidase complex (ABC). The number of immunohistochemically identified IgG4 positive plasma cells was counted per high power field (hpf). Four fields were analyzed per section. Immunohistochemically, abundant IgG4-positive plasma cells (> 20/hpf) and CD4- or CD8-positive T lymphocytes were seen infiltrating the cancerous lesion of the pancreas (Figure 1A), but only a few IgG4-positive plasma cells (< 3/hpf) were detected in the noncancerous areas of the pancreas (Figure 1B). Pancreatic cancer cells were not immunoreactive for IgG4. Regional lymph nodes were swollen up to 1.5 cm in diameter, and infiltration of abundant IgG4-positive plasma cells (> 20/hpf) was detected in almost all regional lymph nodes (Figure 1C). Abundant IgG4-positive plasma cells infiltrated the duodenum (Figure 1D), but there were only a few IgG4-positive plasma cells (< 3/hpf) detected in the extrahepatic bile duct, gallbladder, and gastric mucosa.

The patient was given chemotherapy as an outpatient and was well 6 mo later. Since the operation, her serum IgG4 levels have continued to be elevated (Figure 2).

DISCUSSION

Clinically, patients with autoimmune pancreatitis and pancreatic cancer share many features, including being elderly, having painless jaundice, new-onset diabetes mellitus, and elevation of tumor markers^[1-4]. Radiologically, focal swelling of the pancreas, the “double-duct sign” representing stricture in both the biliary and pancreatic ducts, and angiographic abnormalities seen in pancreatic cancer patients are sometimes also observed in patients with autoimmune pancreatitis^[1-4]. As autoimmune pancreatitis responds dramatically to steroid therapy^[1-4,11], an accurate diagnosis of autoimmune pancreatitis can avoid unnecessary laparotomy or pancreatic resection. Imaging findings, such as a mass showing delayed enhancement and a capsule-like rim on dynamic CT, and a narrowing of the pancreatic duct associated with a less dilated upstream pancreatic duct, are all useful in differentiating pancreatic cancer from autoimmune pancreatitis^[3,4]. Histopathological approach on biopsy is necessary in some cases, but it is sometimes difficult to obtain sufficient pancreatic tissue biopsy. Since Hamano *et al.*^[7] reported that serum IgG4 concentrations were significantly elevated and particularly high in autoimmune pancreatitis, measurement of serum IgG4 has become a useful tool in the differentiation of autoimmune pancreatitis and pancreatic cancer^[8-10].

However, the present case had a histologically proven pancreatic cancer and displayed marked elevation of serum IgG4 concentration. The patient did not have any pathological conditions such as atopic dermatitis, parasitic disease, pemphigus vulgaris and foliaceus, which are sometimes associated with elevated serum IgG4 levels^[7,9]. Interestingly, elevated serum IgG4 levels continued after the resection of the pancreatic cancer. Characteristic histological feature of autoimmune pancreas include dense lymphoplasmacytic infiltration and fibrosis of the pancreas^[1,2]. In our patient, moderate lymphoplasmacytic infiltration was observed in the cancerous lesion, but an inflammatory process was not detected in the noncancerous areas of the pancreas. That is, there were no histological findings that suggested autoimmune pancreatitis in this patient's pancreas. Immunohistochemically, pancreatic cancer cells were not positive for IgG4. Abundant IgG4-positive plasma cells infiltrated the cancerous areas of the pancreas, but only a few IgG4-positive plasma cells were detected in the noncancerous areas of the pancreas. Furthermore, many IgG4-positive plasma cells infiltrated almost all of the swollen regional lymph nodes and the duodenum.

Autoimmune pancreatitis is sometimes associated with sclerosing cholangitis, sclerosing sialadenitis, retroperitoneal fibrosis, and lymphadenopathy^[12,13]. During follow-up of sclerosing sialadenitis, some patients developed autoimmune pancreatitis^[13]. We have reported that lymphoplasmacytic infiltration with fibrosis was observed in the peripancreatic retroperitoneal tissue, biliary tract, and salivary glands, as well as in the pancreas of patients with autoimmune pancreatitis^[13]. Furthermore, an abundant infiltration (> 30/hpf) of IgG4-positive plasma cells together with CD4- or CD8-positive T lymphocytes was observed in the various organs of

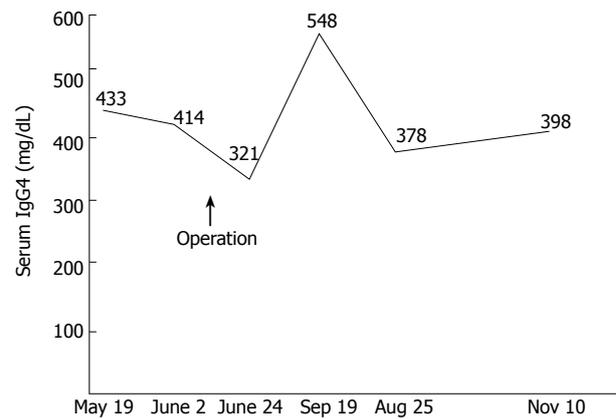

Figure 2 Course of serum IgG4 levels in this patient. Elevated serum IgG4 levels continued after operation.

patients with autoimmune pancreatitis, including the peripancreatic retroperitoneal tissue, biliary tract, salivary glands, gastric mucosa, lymph nodes, and pancreas, but an abundant infiltration of IgG4-positive plasma cells was not detected in the organs of patients with chronic alcoholic pancreatitis^[13-15]. We therefore proposed the existence of a novel clinicopathological entity, an IgG4-related systemic disease incorporating sclerosing pancreatitis, cholangitis, sialadenitis, and retroperitoneal fibrosis with lymphadenopathy, characterized by extensive IgG4-positive plasma cell and CD4- or CD8-positive T lymphocyte infiltration of organs^[14,15]. We also suggested that autoimmune pancreatitis is not simply a pancreatitis but that, in fact, it is a pancreatic lesion reflecting an IgG4-related systemic disease, and that in some cases only organs other than the pancreas might be clinically involved^[14,15].

In our patient, the IgG4-positive plasma cells infiltrating the lymph nodes were as abundant as those in the lymph nodes of patients with autoimmune pancreatitis, and elevation of serum IgG4 levels continued after the resection. We believe that the serum IgG4 level was elevated in this patient with pancreatic cancer as the result of an IgG4-related systemic disease that had no clinical manifestations other than lymphadenopathy. Furthermore, this case calls into question the specificity of elevated IgG4 levels for benign disease, and suggests that serum IgG4 levels should be interpreted with caution in patients with a mass in the pancreas but no histological documentation of either carcinoma or pancreatitis.

Abstract

We report the case of an 84-year-old female who had a partial gastrectomy with Billroth-II anastomosis 24 years ago for a benign peptic ulcer who now presented an acute pancreatitis secondary to an afferent loop syndrome. The syndrome was caused by a gallstone that migrated through a cholecystoenteric fistula. This is the first description in the literature of a biliary stone causing afferent loop syndrome.

INTRODUCTION

The afferent loop syndrome is a mechanical obstruction that impairs the clearance of bile and pancreatic juices from the afferent jejunal loop of a gastrojejunostomy. Entrapment of the afferent loop by postoperative adhesions, internal hernias, loop kinking at the gastrojejunostomy, intestinal volvulus, intussusception, anastomotic cancer, enteroliths and bezoars have all been incriminated as causes. A cholecystoenteric fistula with biliary stone impaction in the anastomosis as a cause has never been reported, as far as we know.

CASE REPORT

An 84-year-old female presented in the emergency room with severe right upper quadrant pain and vomiting in the last 8 h. She referred cholecystolithiasis with infrequent episodes of pain; the last one extended for 6 d and ended

4 d ago, being longer and more severe than usual. She brought a previous abdominal sonography showing a single stone of 1.5 cm in the gallbladder.

Her past history included diabetes mellitus and a partial gastrectomy with a Billroth II reconstruction for benign peptic ulcer 24 years ago. On physical examination the patient reported intense pain in the superior half of the abdomen. Vital signs were stable. Laboratory exams showed mild leukocytosis and acute pancreatitis.

An abdominal sonography was performed and demonstrated air inside the gallbladder associated with a dilatation of the afferent jejunal loop, suggesting a gallstone ileus as a possible cause for the bowel distension.

A computed tomography was then performed and revealed an afferent loop syndrome due to a stone impacted in the gastrojejunal anastomosis. Pancreatitis was also observed (Figure 1, Figure 2, Figure 3, Figure 4).

A few hours after the admission the patient presented hypotension and a decline in her mental status requiring orotracheal intubation and vasopressors. She was then transferred to an intensive care unit.

An upper digestive endoscopy was performed and successfully removed the stone with a basket (Figure 5). During the following two days her white blood cell count increased, her renal and liver functions declined and the vasopressors were progressively augmented. She also presented an abdominal compartment syndrome on the second day being submitted to a decompressive laparotomy. During the laparotomy adhesions were observed between the afferent loop and the gallbladder.

On the third day the patient presented a cardiac arrest and died.

DISCUSSION

The afferent loop syndrome results from the obstruction of the afferent jejunal loop of a gastrojejunostomy. Its acute form usually occurs in the early postoperative period but it can occur decades after the surgery having a devastating course unless promptly treated^[1-4].

There are various causes of the afferent loop syndrome. Adhesions, volvulus, intussusception are some of the most common while enteroliths, cancer and bezoars are some of the rarest^[1-7]. This is the first report in the literature of a biliary stone causing the syndrome (Pubmed, Medscape, Cochrane database and Scielo database were systematically reviewed).

The pain reported by the patient 4 d before the admission might have been an acute cholecystitis that led to the formation of a cholecystoenteric fistula, allowing the biliary stone to ingress the afferent loop and ultimately

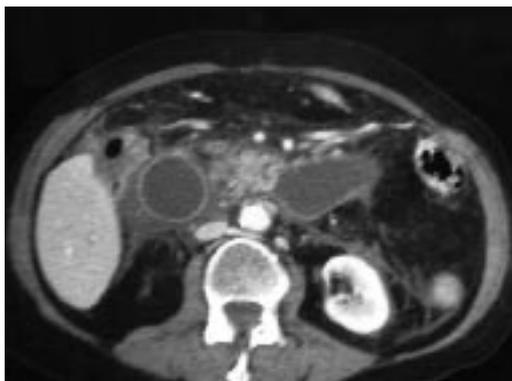

Figure 1 Dilated jejunal loop crossing the midline.

Figure 3 Stone in more detail (arrow).

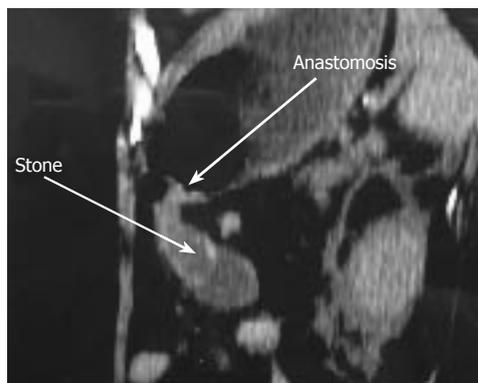

Figure 4 The relation between the gastrojejunal anastomosis (right arrow) and the stone (left arrow) in a tomographic reconstruction.

Figure 5 Biliary stone (with a diameter of 3 centimeters) after endoscopic removal.

stop in the anastomosis causing the obstruction.

Concerning the acute pancreatitis it is an uncommon and aggressive manifestation of the afferent loop syndrome with few cases found in the literature. The transmission of high pressures back to the biliopancreatic ductal system leading to duodenopancreatic reflux seems to play an important role in its pathogenesis. An experimental model of “closed duodenal loop” can simulate this clinical situation^[4,6,8].

Regarding the management of the obstruction, the choice to perform a gastrointestinal endoscopy was based on the patient’s vital signs that were quickly declining. In fact this is a rapid procedure, with low risk of complications, far less aggressive than a laparotomy and it has already been successfully used to remove gallstones

occluding the upper digestive tract^[9,10]. Percutaneous drainage is also a conservative option^[11]. Either way surgical lithotomy can always be performed, even as a last resource when the other options failed^[12].

Although the obstruction was rapidly resolved and the measures for severe pancreatitis were quickly introduced the multiple organ dysfunction was already installed. The patient’s age and the diabetes also contributed to the outcome.

Abstract

Propylthiouracyl (PTU)-related liver toxicity is likely to occur in about 1% of treated patients. In case of acute or subacute hepatitis, liver failure may occur in about one third. We report two further cases of PTU-induced subacute hepatitis, in whom the delay between occurrence of liver damage after the initiation of treatment, the underestimation of its severity and the delayed withdrawal of the drug were all likely responsible for liver failure. The high incidence of liver toxicity related to PTU, its potential severity and delayed occurrence after initiation of treatment are in favor of monthly alanine aminotransferase monitoring, at least during the first six months of therapy.

INTRODUCTION

Propylthiouracyl (PTU)-related severe hepatitis remains a relatively rare occurrence^[1,2] even if a transient increase in liver function tests is observed following the initiation of treatment in 15% to 28% of cases^[2-4]. Before 1998, only 25 cases of PTU-induced severe liver injury were reported^[5] and 83 cases with 28 deaths were included in a recent review of literature^[6]. We here report two additional cases of PTU-induced severe liver injury, one was complicated

by liver failure with hepatic encephalopathy. The late occurrence of liver toxicity and the underestimation of liver damage together with delayed drug withdrawal likely play an important role in their severity.

CASE REPORT

Case 1

A 35-year old woman was referred to our unit on February 4, 2004 for a two-month history of jaundice and pruritus. She was treated for hyperthyroidism with thiamazol, thiamazol and levothyroxin in 1997-1999. In early July 2003 three months following an uneventful delivery, she presented with features of relapsing hyperthyroidism, with her thyroid-stimulating hormone (TSH) unmeasurable (normal range: 0.2-3.5 microU/mL), T4 > 6 ng/dL (normal range: 0.8-2 ng/mL) and a strong positivity of antithyroid antibodies. She was treated with PTU (150 mg per day during the first 2 mo followed by 100 mg per day). In November 2003, she experienced upper abdominal discomfort, nausea and vomiting together with a weight-loss of 4 Kg. Thyroid testing performed on December 16 showed: TSH: 0.04, T4: 0.95, free T3: 9.71. Liver biochemistry showed an increase in aspartate aminotransferase (AST) at 495 IU/L (normal value < 33) and ALT at 1575 IU/mL (normal value < 63). The total serum bilirubin level was 10 mg/dL. Despite this worsening in liver function test (LFT), therapy with PTU was however continued till its delayed withdrawal on January 21, 2004. She was referred to our unit on February 4, 2004 due to jaundice and fatigue together with the persistence of upper gastrointestinal (GI) symptoms.

She was deeply icteric with a hepatomegaly 4 cm under the right costal margin. Liver biochemistry showed alanine aminotransferase (ALT): 458 IU/L, AST: 307 IU/L, alkaline phosphatase (Alk. Phos): 139 IU/L (normal value < 94 IU/L), lactate dehydrogenase (LDH): 239 IU/L (normal value < 192 IU/L), and total s. bilirubin at 22.2 mg/dL. Serology for hepatitis A, B, C, CMV, EBV and herpes was negative. There was a slight positivity of pANCA and cANCA (1/160). At the time of admission, TSH was < 0.01, T4: 3.5 and anti-TPO antibodies: 665 (normal value < 100 U/mL). Upper abdominal ultrasound was unremarkable. Magnetic resonance imaging showed the presence of bands of necrosis scattered throughout the liver parenchyma. At transjugular hepatic vein catheterisation, the hepatic venous pressure was 9 mmHg suggestive of post-sinusoidal portal hypertension. A transvenous liver biopsy specimen showed replacement

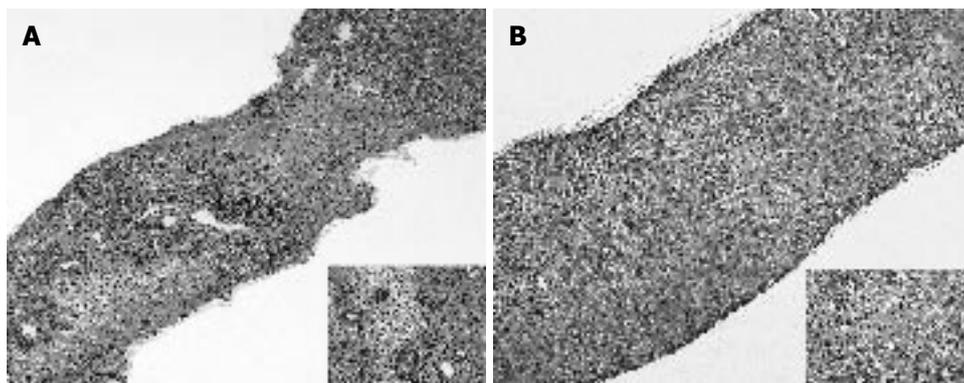

Figure 1 Liver histology of case 1 showing a picture of panlobular necrosis infiltrated with dense inflammatory infiltrates and ductular proliferation at higher magnification (close-up) (A), liver histology of case 2 showing enlarged and infiltrated portal tracts with mild interface hepatitis with prominent lobular necrosis in the centrilobular regions (close-up) (B).

of the normal architecture by areas of multilobular necrosis infiltrated by mononuclear inflammatory cells and regenerating bile ducts (Figure 1A). The few preserved portal structures were enlarged and infiltrated, also showing interface hepatitis. Shortly after admission the patient exhibited features of hepatic encephalopathy with confusion, tremor and agitation which lasted for 8 d. EEG showed features compatible with severe liver encephalopathy (grade 3 of Child's EEG scoring system). The biochemical condition then slowly improved, hyperthyroidism was treated with thiamazol (20 mg per day followed by 10 mg per day). The patient was discharged after 13 d, while her clinical and biochemical resolution occurred within 4 mo.

Case 2

A 43-year old female was referred to our unit on March 6, 2004 for a history of 10-d jaundice, fever and upper GI symptoms. She had no previous medical history except for hyperthyroidism diagnosed in August 2003. The condition was first treated with thiamazol which was however rapidly withdrawn due to the occurrence of skin rash. A treatment with PTU (100 mg per day) was initiated in early October 2003, levothyroxin (75 mg/d) was added shortly thereafter. At clinical examination upon referral, the patient was icteric with no sign of hyperthyroidism. The liver was felt 3 cm under the right costal margin. Liver biochemistry showed: total s. bilirubin: 10.9 mg/dL, AST: 2310 IU/L, ALT: 5040 IU/L. Serology was negative for hepatitis A and B as well as for antinuclear and smooth muscle antibodies. CMV-IgM as well as EBV-IgM antibodies were slightly positive. TSH was 4.09 micro U/mL, T4: 1.2, free T3: 1.9. Anti-TPO and anti-TG antibodies were both negative. Upper abdominal ultrasound showed a normal size hyperechogenic liver parenchyma. A transcutaneous liver biopsy was obtained which showed widely enlarged portal tracts infiltrated with lymphocytes and neutrophils together with ductular proliferation. Interface hepatitis was clearly visible and there were prominent areas of centrilobular necrosis infiltrated with lymphocytes in the lobules (Figure 1B). Acidophilic bodies were scattered into the parenchyma. Immunostaining for both EBV and CMV was negative. Following drug withdrawal the clinical condition of the patient progressively improved together with the normalisation of liver function tests which occurred after 8 wk of follow-up. Thyroid testing remained in the normal range.

DISCUSSION

We reported two cases of severe PTU-induced hepatitis, one appearing 5 mo after the initiation of therapy and the other one after 6 mo. Liver histology of the first case showed multilobular necrosis, the disease ran a subfulminant course complicated by hepatic encephalopathy and liver failure. In the second case characterised by morphological features of centrilobular necrosis, the clinical and biological evolution was less severe, but ran a prolonged disabling course. The diagnosis of PTU-induced hepatitis was based on the occurrence of liver damage within the first few months of therapy, the absence of previous history and/or other causes of liver disease and the recovery following its discontinuation.

Changes in liver function tests occurring in hyperthyroidism have been known for a long time. Abnormal liver function tests can be observed in 15%-76% of the cases. The pathophysiology of these changes remains unknown, likely involving multifactorial factors including liver congestion, increased liver oxygen consumption, reduced bile acid synthesis, and/or glycuronyl-transferase inhibition^[3,7]. In this setting liver histology only shows non-specific changes^[8].

On the contrary, PTU-induced acute hepatitis occurs in 0.1%-1.2% of treated patients^[4,9,10]. This rate is much higher than that observed in the large context of liver immuno-allergic toxicity (1/10000 to 1/100000 or even to 1/1000000 for the majority of drugs)^[11], and much lower than that predicted by an asymptomatic increase in ALT which is observed in about 14%-28% of cases during the first week of therapy^[2,10]. In the presence of acute hepatitis the mortality may be as high as 25%^[12] and so far only 28 lethal cases have been reported in the English literature^[6], with two additional cases successfully transplanted^[12,13]. As in our case reports, histological features liver necrosis of variable severity with or without cholestasis^[10], suggesting the role of an immuno-allergic type of toxicity irrespective of the doses of drug used^[5].

In our cases, the delay between the initiation of therapy and the occurrence of symptoms of hepatitis was 5 and 6 mo, respectively. This is in agreement with previous reports^[3,14,15]. The majority of cases are however observed during the first 6 mo of therapy^[1]. The positivity of antineutrophil cytoplasmic antibody (ANCA) testing is not surprising since PTU is a potential causative agent of ANCA positive vasculitis^[16].

In our first observation thiamazol was substituted with PTU without side effect as in another reported case in which carbimazole was used as a substitute to PTU^[17]. Convincing descriptions of thiamazol and PTU hepatic cross-toxicity are indeed lacking, even if cross-sensitivity may occur^[18] and if the rate of untoward cross-reaction between carbimazole and PTU can reach 15%^[18].

In conclusion, this report reinforces the warning against the potential for PTU to induce severe life-threatening hepatitis. The incidence of transient increase in liver function tests at the initiation of treatment reaches about 28%, while the incidence of severe toxicity is about 1%, a risk being much higher than that observed in the majority of compounds considered as potential hepatotoxins. Due to this high incidence of liver toxicity and the rather short delay between the initiation of treatment and the occurrence of hepatitis as well as its relatively slow "subacute" progression, ALT monitoring may be cost-effective in reducing the severity of the liver side effect. The duration of optimal biochemical follow-up remains to be further evaluated in large prospective trials but should be about six months, during which the highest rate of PTU-induced hepatitis is observed.

Abstract

Infliximab is a potent anti-TNF antibody, which is used with great success in Crohn's disease patients. Since its release in clinical practice, several adverse reactions have been observed. The interest in possible consequences of its administration is still high because of the recent introduction of the drug for the long-term maintenance therapy of refractory luminal and fistulizing Crohn's disease. We present a case of acute coronary syndrome (non-STEMI) in a patient with corticoid resistant Crohn's disease after his first dose of infliximab. By reviewing the scant articles that exist in the literature on this topic we made an effort to delineate the possible mechanisms of this phenomenon.

INTRODUCTION

Serious adverse events (infections, malignancies, serum sickness, lupus syndrome) that need hospitalization have been reported with a divergent frequency of 6%-18.9% for patients with inflammatory bowel disease (IBD) treated with infliximab^[1,2]. We present a case of acute coronary syndrome (non-ST myocardial infarction) that occurred

after infliximab administration in a patient with corticoid-resistant Crohn's disease.

CASE REPORT

The patient was a 40-year-old male Caucasian who visited the emergency department of our hospital because of chronic diarrhea with 10 watery bowel movements per day. After admission, the patient's history, symptoms, physical signs, laboratory, endoscopic and pathological findings during an extensive diagnostic work up, were compatible with the diagnosis of ileocolonic Crohn's disease (CDAI score: 320). The patient was started on mesalamine orally (1 g t.i.d), metronidazole (500 mg t.i.d) and prednisolone (25 mg b.i.d) intravenously along with parenteral fluids. Five days later 15 mg of prednisolone as well as budesonide enemas (2.3 mg b.i.d) were added to the treatment regimen. The unremitting course of his clinical status on the 12th d of hospitalization was the reason to administer infliximab (5 mg/kg) at a total dose of 375 mg. The infusion of infliximab was well tolerated without any acute adverse reactions. On the first day of treatment the patient's laboratory findings were the following: Ht: 31%, leucocyte count: 9900 (normal), platelets: 314000, CRP: 143 mg/l and all biochemicals including basic coagulation tests [prothrombin time (PT), partial thromboplastin time (PTT), international normalized ratio (INR)] were within normal values except serum glucose: 146 mg/dL. Chest X-ray showed only a slightly elevated cardiothoracic ratio. The next day azathioprine 50 mg t.i.d *po* was added to the therapeutic regimen and prednisolone was reduced to 40 mg iv. On the third day after infusion the patient experienced pain in the chest. The electrocardiogram showed T-wave inversion at the V4, V5, V6 precordial leads and at I, II limb leads with sinus rhythm. Cardiac enzymes [creatinine phosphokinase, creatinine phosphokinase isoenzyme MB, aspartate aminotransferase, lactate dehydrogenase, troponine] related to myocardial infarction were measured and troponine I was found increased: 2.2 ng/mL (normal: < 2 ng/mL). The patient was transferred to the emergency coronary care unit where a diagnosis of acute coronary syndrome implying non-STEMI myocardial infarction was made. During his stay he also suffered an episode of atrial fibrillation, which was reset by amiodarone. He received metoprolol, nitrates, low molecular weight heparin and clopidogrel, which permitted him to recover and return to our Unit after 4 d. Fifteen days after the administration of infliximab the patient's clinical and laboratory status has been improved, with 3 bowel movements per day, absence

of abdominal pain, better general state of health, CRP: 106 mg/Lt and CDAI score: 160.

The patient had no family or personal history of heart disease, hypertension, hyperlipidemia, diabetes mellitus, smoking or obesity and was not taking any drugs before his admission. The physical examination of the heart and ECG at the time of presentation was normal. Fifteen days after the coronary episode the patient was subjected to echocardiography, which showed hypokinesia of the interventricular septum and overall impaired systolic function of the heart with an ejection fraction of 45%. A triplex of the carotids and vertebral arteries did not reveal any atherosclerotic lesions. Our patient also had elevated fibrinogen level (6.55 g/L, normal: 2-4.5 g/L), low protein S activity (41.9%, normal: 75%-130%, Protein S Ac test by Dade Behring), abnormal resistance to activated protein C (APCR) (PCAT: 66.6 s, normal: 85-200 s, Pro C Global protocol assay by Dade Behring) and normal antithrombin III and D-dimers levels under mild systemic inflammation with CRP levels of 32.5 mg/Lt. One month later a cardiac exercise stress test was performed and found normal. Protein S activity and APCR were also normal at that time.

DISCUSSION

It is already known that thromboembolic events occur more frequently in IBD patients (up to 8%) than in normal controls (up to 2%)^[3]. Arterial thrombosis is an uncommon feature of IBD in relation to the far more frequent venous thrombosis. One third of IBD patients develop thrombosis while being in remission, weakening the hypothetical association of active inflammation and abnormal coagulopathy. There are a number of acquired risk factors related with IBD that may predispose to thrombosis. These include immobility, surgery, central venous catheters, parenteral feeding, deficits of vitamins B12 and folic acid as well as hyperhomocysteinemia, increased lipoprotein (a) and anticardiolipin antibodies. Inherited thrombophilic factors like V Leiden and G20210A prothrombin gene mutations have also been implicated in the thrombogenesis of IBD patients. Our patient had none of the above-acquired risk factors as specific investigation of the lipid panel, vitamin B12, folic acid, homocysteine and antiphospholipid antibodies (anticardiolipin, lupus) rendered normal results. The patient was also not subjected to any surgical intervention or parenteral nutrition and because of his young age and self-supporting clinical status was relatively active and not totally immobile. Our patient was also examined for inherited thrombophilic mutations with negative results. It is common for IBD patients to demonstrate abnormal laboratory values of thrombophilic factors in as many as 60% of the cases, a proportion far surpasses the prevalence of thromboembolism in IBD estimated at 8%^[4]. In a study of IBD patients and healthy controls, although 21.4% and 9.5% of patients had reduced free protein S and abnormal APCR respectively, only 4.8% (4 patients out of 84) had a history of thromboembolism and furthermore in two of the patients with thrombosis there were none thrombophilic abnormalities detected^[5]. The abnormal APC resistance in our patient is probably due to the low levels of activated protein S as the patient was not carrying the fac-

tor V Leiden mutation. High plasma fibrinogen level has been associated with increased risk of vascular and non-vascular mortality in a recent meta-analysis study including prospective trials with baseline fibrinogen values and subsequent monitoring of adverse events during at least 1 year of follow up^[6]. The association of increased fibrinogen level with nonvascular events (mainly cancer) weakened the specificity of association with vascular diseases.

Among the other drugs administered to the patient, only steroids have been reported to be associated with coronary heart disease, either myocardial infarction or coronary spasm. These adverse events are related to treatment schedules either with long-term high dose steroid administration (120 mg depomethylprednisolone im for 2 years) or to bolus infusion of high dose steroids (as high as 250 mg methylprednisolone). Our patient was given only 40 mg of prednisolone daily divided into two doses. On the other hand, steroids as well as mesalamine are considered to confer an anti-coagulant effect in patients with Crohn's disease^[7]. This protective role derives from the reduction of proinflammatory cytokines, namely the platelet-activating factor (PAF), TNF- α and IL-1.

Our hypothesis is that infliximab administration might be the cause of the myocardial infarction in this patient. There are three case reports that refer to patients with Crohn's disease (CD) who had venous adverse reactions related to infliximab. The first has reported a patient with retinal vein thrombosis^[8], the second an extensive forearm deep venous thrombosis^[9] and the third comes from a cohort study reporting deep venous thrombosis as well^[2]. It has already been noted that infliximab can also aggravate heart failure if given at a dose of 10 mg/kg to patients with moderate or severe chronic heart failure^[10]. Infliximab has also been found responsible for new onset heart failure in patients with rheumatoid arthritis (RA) or CD, some of them aged below 50 years. An acute coronary syndrome has been described in a patient with RA after infliximab therapy by Abedin *et al*^[11]. However, there are substantial differences in the patient's clinical setting in comparison to our report. The patient in the aforementioned report was female and had a long-standing history of refractory RA starting 20 years ago and a 3-year history of hypertension. She needed multiple therapeutic interventions with corticosteroids, methotrexate, and leflunomide which is known to aggravate hypertension and lastly infliximab. The patient was also obese (95 kg) if we can postulate her weight from the infliximab dose (400 mg total dose, 4.2 mg/kg). Finally, the patient had multiple infliximab infusions in the last 2 years and had already received over 5 g of the drug in escalating dosage. It is obvious that an obese patient with hypertension and an active RA for several years, a disease, which by itself confers vascular compromise, is in danger for cardiovascular events even in the absence of infliximab administration, which already had been given in multiple doses without adverse events in the past. Our patient was a young male with newly presented Crohn's disease who suffered a non-ST myocardial infarction three days after his first dose of infliximab and without having any cardiovascular events in his medical history.

Although TNF has procoagulant properties mainly in high circulating concentrations it seems that during a re-

stricted production it may have antithrombotic activity^[12] by reducing the expression of adhesion molecules like P selectin and the aggregation of platelets as well as their binding to fibrinogen. It has been found that TNF assists in the maintenance of myocardial vascular perfusion by producing vasodilation through the induction of nitric oxide (NO), which is also capable of inhibition of apoptosis of myocardiocytes and attenuation of the heart's stimulation by the sympathetic nervous system through the β -receptors^[10]. TNF is also responsible for the release by myocytes of heat shock proteins (HSP 72, HSP 27)^[13] that are considered to confer resistance against hypoxic stress as well as for the production of manganese superoxide dismutase, a scavenger of free radicals^[14]. The administration of a potent anti-TNF antibody like infliximab, which neutralizes both soluble and membrane TNF can abrogate these homeostatic interventions causing deprivation of first line defensive mechanisms. Infliximab has been shown to cause vasoconstriction and increased wall shear stress in arteries of patients with RA after a dose of 3 mg/kg^[15].

On the other hand, there are several reports of unaffected serum TNF- α concentrations despite administration of anti-TNF antibodies in patients with either RA, leucoclastic vasculitis or after myocardial ischemia. High levels of TNF- α in the serum have been associated with higher risk for myocardial infarction (OR: 1.7). It has been found in experimental models that endogenous production of TNF can downregulate its relevant receptors and therefore confer resistance to its continuous action. A counter-regulatory mechanism might upregulate the expression of mTNF and TNF-receptors on the cell membrane of endothelium, monocytes, vascular smooth muscle cells (VSMCs) and myocytes, at the time when anti TNF administration causes a reduction of the serum or tissue TNF levels, with the result of a rupture plaque or myocardial apoptosis. An increase in serum TNF- α levels has been noted in two studies of patients with RA and chronic heart failure respectively after the initial drop in TNF concentration following administration of infliximab^[10,16]. In the former study the increase was noted on the 3rd till the 7th d after infusion. The authors inferred that TNF- α was not bioactive but rather was bound to anti-TNF antibodies. Because of the inability of TNF- α assays to measure free TNF, one can surmise that this paradoxical increase may not be so innocent and could activate monocytes to produce metalloproteinases or stimulate endothelial cells to become thrombogenic by releasing NO, thromboxane and platelet adhesion molecules.

There is therefore a need to study the TNF-receptor expression in Crohn's disease in the myocardium. Furthermore the study of TNF polymorphisms could offer an explanation for the susceptibility of some individuals to the cardiac effects of anti-TNF- α .

In conclusion, we support the notion that anti-TNF therapy is the "probable" cause of acute coronary syndrome in this patient because of the chronological sequence between its administration and the presentation of this adverse reaction (3 d). We also demonstrated that the drug was active for the patient's clinical condition and that the individual completely recovered one month later

when the apparent effect of the drug was completely abolished. We could not find in the English literature an absolutely proven causal relationship between the pathogenesis of Crohn's disease and thromboembolic events. According to published criteria for the estimation of the probability of adverse drug reactions, this reaction could be rated as "probable"^[17].

Abstract

We present ultrasound, computed tomography and magnetic resonance imaging findings in a case with pancreatic solid pseudopapillary tumor and their correlations with histopathology. Ultrasound revealed a hypoechogenic mass, and computed tomography revealed a hypodense mass at the pancreatic head minimally enhanced after intravenous contrast agent administration. Magnetic resonance imaging showed a hypointense mass on unenhanced T1-weighted images including a hyperintense focus representing the hemorrhage. The lesion was hyperintense on T2-weighted images. On the postcontrast images the lesion showed peripheral thin contrast enhancement in arterial phase and enhanced slightly diffusely in venous and equilibrium phases. The patient underwent elective resection of the mass and pancreatoduodenectomy with jejunostomy tube placement. A final diagnosis of solid pseudopapillary tumor was made histopathologically. Solid pseudopapillary tumor is a rare pancreatic tumor. It is important to make the diagnosis preoperatively because with an adequate surgical resection the prognosis is good. A multimodal approach, especially magnetic resonance imaging can suggest the diagnosis without the need for biopsy.

INTRODUCTION

Most pancreatic tumors are malignant and have a bad prognosis. However, solid-pseudopapillary tumor of the pancreas (SPT) is a rare benign or low-grade malignancy. Because of this, it is important to make the diagnosis of this tumor preoperatively so that adequate resection will be undertaken. SPT accounts for less than 1%-2% of the exocrine pancreatic tumors^[1-5]. It affects mostly young females between the 2nd and 3rd decades of life with a male to female ratio of 1:9. The patients with SPT are often clinically asymptomatic or minimally symptomatic^[3,6,7]. Therefore imaging studies should be carefully assessed^[1,2]. Ultrasonography (US), computed tomography (CT) and magnetic resonance (MR) imaging are the useful modalities in the diagnosis of SPT which is not uncommonly diagnosed incidentally at abdominal imaging^[7]. Here we report a case of a 17-year old girl presenting with this rare pancreatic tumor and discuss the differential diagnosis from other pancreatic masses.

CASE REPORT

A 17-year old woman complaining of dyspeptic symptoms and right upper quadrant pain for several months was admitted to our hospital for further evaluation. She had no history of abdominal trauma or surgery, drug usage or smoking. On physical examination tenderness in the right upper quadrant and epigastrium was noted. Laboratory findings showed no abnormalities.

An abdominopelvic US revealed a heterogenous hypoechogenic solid mass lesion at the pancreatic head region (Figure 1). CT scan showed a round shaped, well-marginated, hypodense mass at the pancreatic head with a density of 38.19 HU and no evidence of internal hemorrhage (Figure 2). After intravenous iodine contrast agent administration, the lesion showed minimally heterogenous contrast enhancement markedly less than the normal pancreatic tissue. MR examination included axial fast spoiled gradient-echo (FSPGR) fat saturated T1-weighted images and axial and coronal single-shot fast spin-echo T2-weighted images. Unenhanced and contrast-enhanced arterial, portal venous and equilibrium phase images were obtained. MR showed that the mass lesion was predominantly hypointense on unenhanced T1-weighted images including a hyperintense focus representing the hemorrhagic degeneration (Figure 3). The lesion was predominantly hyperintense (but less

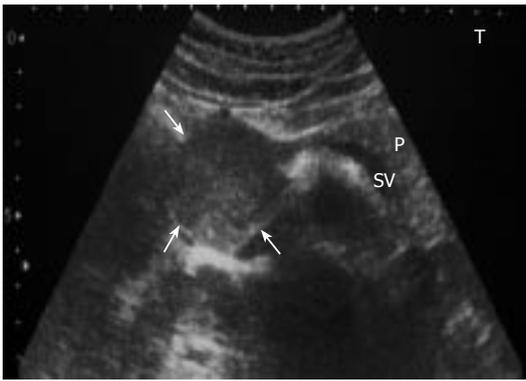

Figure 1 A hypoechoic well-margined solid mass is seen at the pancreatic head region (arrows). Vena cava inferior is slightly compressed by the mass. SV: Splenic vein; P: Pancreatic tail.

Figure 2 Axial precontrast CT image shows that the mass is hypodense with no evidence of calcification. The density of the mass is measured 38.19 HU.

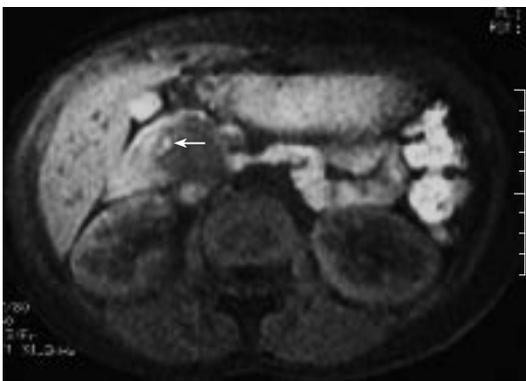

Figure 3 Precontrast T1-weighted axial MR image shows that the mass is predominantly hypointense and the hyperintense focus represents hemorrhage (arrow).

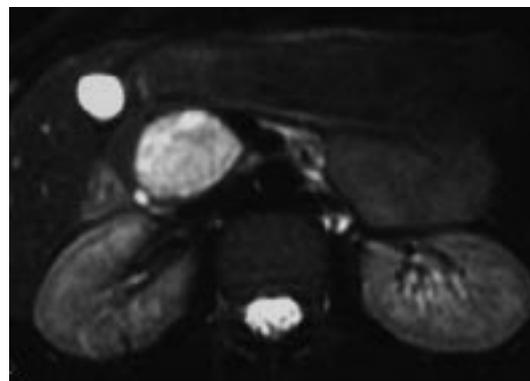

Figure 4 T2-weighted axial MR image shows that the mass is predominantly hyperintense mostly composing of solid compounds and minimal cystic areas.

than cerebrospinal fluid) on T2-weighted images mostly composed of solid and minimally cystic areas (Figure 4). On the initial arterial-phase contrast-enhanced images the lesion was predominantly hypointense with some peripheral thin contrast enhancement (Figure 5A). On the portal venous and equilibrium phase images the lesion seemed to enhance diffusely slightly (Figure 5B and 5C).

The patient underwent elective resection of the mass in the pancreatic head and pancreaticoduodenectomy (Whipple procedure) with jejunostomy tube placement. The resection material was sent to the pathology department. At gross examination, a well-circumscribed, capsulated, round, gray-purple colored tumor was identified in the pancreatic head. By histologic analysis, pseudopapillary aggregates including stromal central vessels were detected. They were separated with partially defective thin fibrous capsule from the pancreatic tissue leading to some pancreatic invasion locally. The tumor was composed of uniform polygonal cells with prominent nucleolus, uniform nucleus and narrow eosinophilic cytoplasm (Figure 6A and 6B). No vascular space or perineural invasion was identified. By immunohistochemical analysis, the tumor cells were positive for vimentin and synaptophysin, and for progesterone receptors (Figure 6C); and negative for cytokeratin, chromogranin and estrogen

receptors. In the evaluation of Ki-67, less than 5% of the tumor cells showed nuclear proliferative activity. These are compatible histopathologic findings for SPTs except for synaptophysin positivity which is unusual.

After the surgery the patient underwent MR imaging examination per 6 mo for the first year and then once a year for the following 2 years until the present and no recurrence, metastases or symptoms occurred.

DISCUSSION

SPT is a rare pancreatic tumor consisting of 1%-2% of exocrine pancreatic tumors^[1,7]. The precise incidence of SPT is not known because it is rare and is frequently misdiagnosed^[1]. This tumor was first described by Frantz in 1959 as a "papillary tumor of the pancreas, benign or malignant"^[8]. Since then, various names have been used to describe this rare lesion, such as solid and cystic tumor of the pancreas, papillary-cystic tumor, solid and papillary epithelial neoplasm and Frantz tumor^[1,2,7]. In 1996, the World Health Organization (WHO) renamed this tumor as SPT for the international histologic classification of tumor of the exocrine pancreas^[7,9].

SPTs are benign lesions but sometimes malignant degeneration may occur especially when the lesion occurs

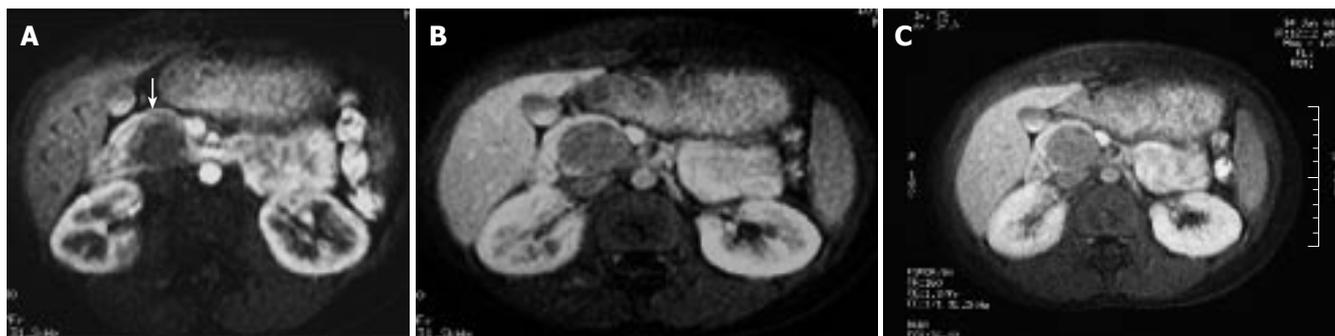

Figure 5 A: Arterial-phase contrast-enhanced T1-weighted image shows minimal peripheral thin contrast enhancement (arrow); B, C: Portal venous and equilibrium-phase contrast-enhanced T1-weighted images show that the mass enhances diffusely slightly.

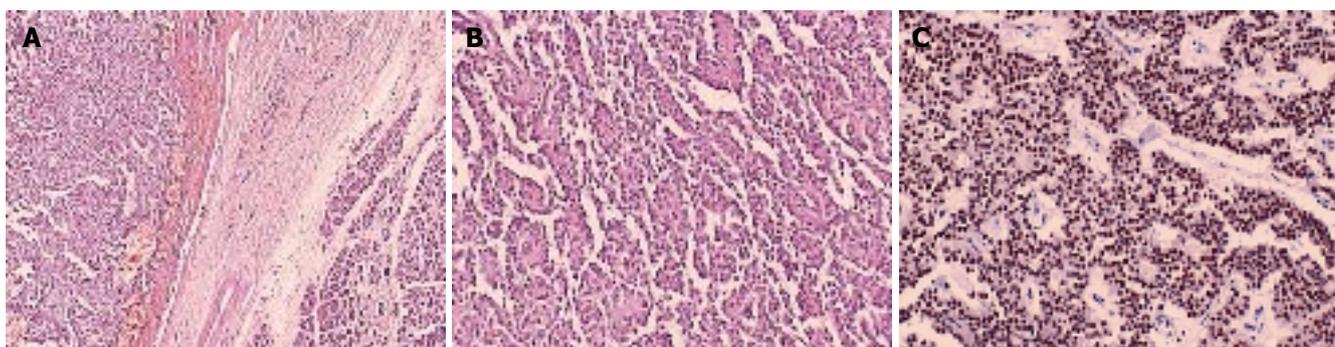

Figure 6 A: Pancreatic tissue is seen around the tumor including papillary structures and hemorrhagic areas (HE $\times 40$); B: Solid pseudopapillary tumor. Pseudopapillary aggregates lined by tumor cells with uniform nucleus and narrow eosinophilic cytoplasm are visible (HE $\times 40$); C: Micrograph shows progesterone receptor positivity in the nucleus of tumor cells ($\times 100$).

in elderly male patients^[2,7].

SPT of the pancreas has distinctive pathologic features. The mass is most frequently found in the head or tail region. On gross examination, the mass is usually large and well encapsulated and contains varying amounts of necrosis, hemorrhage, and cystic change. By microscopic analysis, there are two distinct types of cellular arrangements: solid and papillary^[7]. The pathogenesis of these tumors is still controversial. Whereas some authors postulate an endocrine origin, others claim these tumors arise from ductal cells, acinar cells, or pluripotent stem cells^[1]. Vito *et al*^[1] claimed that, SPT was associated with pregnancy in 3, with polycystic ovary disease in 2, with Sertoli-Leydig cell tumor in 1 of their 19 patients, which supports an endocrine origin for SPT of pancreas^[1]. Also a hormonal influence is also suggested in view of the tumor's high prevalence in women.

SPTs are typically positive for vimentin, neuron-specific enolase (NSE), α -1-antitrypsin, and α -1-antichymotrypsin and negative for chromogranin A, epithelial membrane antigen, and cytokeratin. Differentiation along endocrine cell lines has been postulated for this tumor on the basis of NSE positivity, but the expression of vimentin and α -1-antitrypsin does not support this interpretation^[7]. A study by Kosmahl *et al*^[10] demonstrated that SPTs have a complex immunoprofile that is inconsistent with that of any of the pancreatic cell types and that a pancreatic origin is unlikely. The authors speculated that on the basis of some similarities between SPT and ovarian surface cells

and the proximity between genital ridges and the pancreas anlage during early embryogenesis, SPTs might originate from the genital ridge-related cells that were incorporated into the pancreas during organogenesis. Furthermore, sex hormones may play a role in the pathogenesis or growth of SPTs: Nearly all studies demonstrate no evidence of estrogen receptors; however, progesterone receptors are present in many cases^[7,11] as presented in our case.

The origin of SPTs has not yet been clarified. SPTs cannot be regarded as a purely endocrine neoplasm because the presence of neuroendocrine markers is not significant (chromogranin A is not detected, synaptophysin has a patchy immunoreactivity in 22% and NSE is strongly positive in more than 90% but without a certain significance)^[12-14].

However, SPTs are classified and are generally held to be epithelial neoplasms but immunohistochemical patterns suggest that SPTs cannot be regarded as purely epithelial neoplasms^[12,15]. In fact, cytokeratin expression, usually associated with epithelial differentiation, is rare (less than 30%) or absent in most cases, and markers of acinar differentiation (trypsin/chymotrypsin) and glycoprotein markers of ductal differentiation are often negative^[12,16,17].

Although all these hypotheses of origin are intriguing, they are yet unproved, and further research is necessary.

Another interesting point is the relationship between the synaptophysin positivity and recurrence rates of SPTs. Lai *et al*^[18] analysed 7 patients histopathologically and found that 6 of the patients with no recurrence were negative

for synaptophysin and 1 of the patients who suffered from recurrence was positive. In our case synaptophysin was unusually positive with no recurrence after surgical management in the period of 3 years until now.

Patients with SPT are often clinically asymptomatic^[2,3,6,7]. They may present with palpable abdominal mass, abdominal pain or discomfort^[1-3,6,7] and also acute abdomen can develop due to the rupture of the lesion^[2,3,19]. The abdomen is usually nontender on palpation but obstructive symptoms may occur if the tumor grows large enough to compress adjacent anatomic structures^[7]. However, bile duct or pancreatic duct obstruction is rare, even when it is located in the head of the pancreas because of its softness^[1]. Physical examination is often normal apart from the presence of an upper abdominal mass^[2], and usually no laboratory abnormalities appear associated with pancreatic insufficiency, abnormal liver function, cholestasis, elevated pancreatic enzymes, or an endocrine syndrome. Tumor markers are also expected to be normal^[2,7]. Also an unusual presentation of SPT with acute pancreatitis was reported in the literature^[6].

Given the good prognosis of the disease, it is important to make the diagnosis preoperatively so that adequate resection will be undertaken. Therefore imaging studies should be carefully assessed^[1,2]. US, CT and MR are the useful diagnostic modalities in the diagnosis of SPT which is not uncommonly diagnosed incidentally at abdominal imaging^[7].

On US examination the lesion is well-encapsulated and includes cystic and solid components, but sometimes the mass is pure and solid-looking or has internal septa or calcifications^[7]. Usually the appearance of SPT is variable and lacks correlation with gross pathology^[1].

Contrast-enhanced CT plays a major role in the diagnostic evaluation of cystic neoplasms of the pancreas. However, when compared with MR imaging, CT has inherent limitations in showing certain tissue characteristics, such as hemorrhage, cystic degeneration, or the presence of a capsule. These features may, as shown at pathology, be suggestive of specific lesions such as SPT of the pancreas. Therefore, MR imaging may further aid in showing these characteristics and in the differential diagnosis of complex cystic masses within the pancreas^[1].

CT usually demonstrates a well-encapsulated, heterogeneous lesion with varying solid and cystic components^[7]. After intravenous contrast agent administration, enhanced solid areas are typically noted peripherally, whereas cystic spaces are usually more centrally located^[7].

MR imaging, because of its superior contrast resolution, displays a capsule and intratumoral hemorrhage better than CT. Therefore, MR imaging has the potential to improve our ability to diagnose SPT^[1]. MR images demonstrate a well-defined lesion with heterogeneous signal intensity on T1 and T2-weighted images, which reflects the complex nature of the mass^[7]. In previous reports all SPTs contain some high signal intensity on T1-weighted images representing the blood products^[1,7]. A hyperintense focus was also noted on T1-weighted axial images of our case. Vito *et al*^[1] also defined that 5 of 19 patients did not show high signal on T1-weighted images in their study. Therefore, the absence of high T1 signal should not

exclude the diagnosis.

The T2-weighted appearance was described differently in the literature. Ohtomo *et al*^[20] reported findings for six patients: the masses appeared hyperintense in four patients and mixed-that is, hyper- and hypointense-in two patients. Buetow *et al*^[21] reported areas of high signal intensity on T2-weighted images in nine patients and areas of low signal intensity in three patients. However, they did not report the predominant signal intensity of the masses or whether the lesions appeared homogeneous. Vito *et al*^[1] reported findings for 19 patients: 14 lesions (73.5%) appeared heterogeneous, and all lesions but two (89%) appeared predominantly hyperintense on T2-weighted images. In our case the lesion was also predominantly hyperintense on T2-weighted images.

Angiography usually demonstrates an avascular or hypovascular pancreatic tumor and may help delineate the mass from other involved and adjacent structures^[2]. Vito *et al*^[1] reported that most common enhancement pattern of SPT consists of early, peripheral, and heterogeneous enhancement during the arterial phase with progressive but heterogeneous fill-in of the lesion during the portal venous and equilibrium phases. They also reported that all but one lesion in their series enhanced less than the adjacent normal pancreas during all phases. This feature helps distinguishing SPT from other pancreatic neoplasms, such as islet cell tumors, which typically enhance more than the pancreas. Vito *et al*^[1] reported that all but one of their patients had a peripheral hypointense tumor capsule on both T1- and T2-weighted images. Compared with the lesion, the tumor capsule showed early and more intense enhancement (70%), identical enhancement (20%), or less enhancement (10%). Ohtomo *et al*^[20] reported that four patients (67%) presented with a fibrous capsule detected as a band of low signal intensity on T1- and T2-weighted imaging. Conversely, Buetow *et al*^[21] observed in all their patients a discontinuous low-signal-intensity rim on T2-weighted images. In our case a capsule formation was not detected.

Serous microcystic adenoma, mucinous cystic neoplasm, cystic islet cell tumor, pancreaticoblastoma, and calcified hemorrhagic pseudocyst are differential diagnostic considerations when a pancreatic mass consists of cystic and solid components. The former three tumors occur rarely in patients younger than 30 years^[1,22]. On T1-weighted MR images, serous microcystic adenoma may appear as a heterogeneous hypointense mass with hyperintense foci related to prior hemorrhage and could be confused with SPT. However, on T2-weighted images, serous microcystic adenoma shows hyperintense signal intensity with low-signal-intensity central areas due to scar formation and hypointense septa that may radiate toward an enhanced central scar^[1,22,23]. This radial central scar is not a feature of SPT^[1].

Mucinous cystic neoplasms may be confused with SPT, particularly when the SPT is predominantly cystic^[1,22,23]. Although the mucin-filled cystic spaces are typically hyperintense on T2-weighted images and hypointense on T1-weighted images, mucin occasionally results in high signal intensity on both T1- and T2-weighted images^[1,23]. The signal intensity may vary depending on the

proteinaceous content of the mucin. Also, mucinous cystic neoplasms do not exhibit early peripheral and capsular enhancement^[1].

Islet cell tumors occur in patients who are older and do not have the female predominance. They may appear cystic, contain calcifications, and show areas of internal hemorrhage^[1,21,24]. Islet cell tumors are low in signal intensity on fat-suppressed T1-weighted images, exhibit high signal intensity on T2-weighted images, and show marked ring or diffuse heterogeneous enhancement on immediate gadolinium-enhanced gradient-echo images^[1,21]. The differential diagnosis of SPT from islet cell tumor of the pancreas is the different signal intensity on T1-weighted images and excess contrast enhancement of islet cell tumors after gadolinium injection due to their more vascularity compared with SPTs^[1].

Pancreatoblastoma is more aggressive than SPT and often presents with liver metastases at the time of diagnosis. Intratumoral hemorrhage has not been reported in these tumors using either CT or MR imaging. Although pancreatic adenocarcinoma is the most common primary pancreatic malignancy, it is seen in older patients. Pancreatic pseudocysts may be calcified peripherally as a result of internal hemorrhage and may mimic SPT. However, a history of pancreatitis is almost always present, and pancreatic pseudocysts can be distinguished from SPT by the absence of solid components^[1].

In conclusion, when a young woman presents with a pancreatic mass lesion, SPT must be considered in the differential diagnosis. Multimodal approach, especially MR could suggest the diagnosis of SPT with some imaging features including well-marginated, encapsulated, solid-cystic mass with areas of hemorrhagic degeneration and progressive peripheral or heterogeneous contrast enhancement.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents[®]/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch[®]) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology

Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China

E-mail: wjg@wjgnet.com

<http://www.wjgnet.com>

Telephone: +86-10-85381901

Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5

line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

Key words

Please list 6-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P*<0.05, ^b*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, ^c*P*<0.05 and ^d*P*<0.01 are used. Third series of *P* values can be expressed as ^e*P*<0.05 and ^f*P*<0.01. Other notes in tables or under

illustrations should be expressed as 1F , 2F , 3F ; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (<http://www.wjgnet.com/cgi-bin/index.pl>), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Morse SS. Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1): 24 screens. Available from: URL: <http://www.cdc.gov/ncidod/EID/eid.htm>

Patent (list all authors)

- 16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂ not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please download CAF from <http://www.wjgnet.com/wjg/help/9.doc>.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to *WJG* all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The *WJG* requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1) direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3) supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The *WJG* does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to *WJG* if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Final check list for authors

The format is at: <http://www.wjgnet.com/wjg/help/13.doc>

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: <http://www.wjgnet.com/wjg/help/10.doc>

Abstract

In an era such as the present one in which there is a high demand for health services with the associated pressure of controlling spending, health care organizations are concerned about the cost-effectiveness of quality improvement interventions. On the other hand, the impact of the disease and the treatment on the patient's overall well-being and functioning has become a topic of growing interest not only in clinical research but also in practice. The clinical evaluation of the benefits of specific treatments for chronic, debilitating and incurable diseases should increasingly include formal assessment of patient activity and well-being. Thus, health-related quality of life as subjectively perceived by the patient, is becoming a major issue in the evaluation of any therapeutic intervention, mainly in patients with chronic or difficult diseases where the aim of the intervention is to keep patients either symptom-free and capable of living in the community for a long time or to reduce the discomfort caused by the disease. In this paper, we review the current knowledge on the quality of life assessment in chronic pancreatitis patients.

INTRODUCTION

In the present era, there is a high demand for health services with the associated pressure of controlling

spending, health care organizations are concerned with the cost-effectiveness of quality improvement interventions. On the other hand, the impact of the disease and the treatment on the patient's overall well-being and functioning has become a topic of growing interest not only in clinical research but also in practice. The benefits of the specific treatments as well as the health-care system will be judged more and more on the basis of how the changes in the patient's activity or well-being correspond to his or her expectations. Thus, health-related quality of life as subjectively perceived by the patient, is becoming a major issue in the evaluation of any therapeutic intervention, mainly in patients with chronic or difficult diseases where the aim of the intervention is to keep patients either symptom-free and capable of living in the community for a long time or to reduce the discomfort caused by the disease. Several questionnaires have been developed to measure the health-related quality of life with the number of items ranging from 10 to 100; some of the questionnaires are designed for the assessment of a non-disease group while others were developed for specific disease groups.

CHRONIC PANCREATITIS

Chronic pancreatitis is a disease which is often characterized by recurrent episodes of abdominal pain accompanied by progressive pancreatic exocrine and endocrine insufficiency, and it sometimes requires multiple hospitalizations. The disease is frequently the result of chronic alcohol abuse even if other etiological factors such as genetic alterations, autoimmune disorders and obstructive disease of the biliary tract and the pancreas have recently been postulated. The management of chronic pancreatitis remains a challenging puzzle; for most patients, medical treatment is a good option, especially in those requiring substitutive therapy for either exocrine or endocrine insufficiency; however, controlling the pain remains the main therapeutic challenge. Although the medical management of pain may be one of the therapeutic modalities^[1], in the past as well as in the present, surgical management has been the main option in the case of intractable pain^[2]. In recent years, other therapeutic options, more medical than surgical, have been applied in clinical practice: endoscopic therapy^[3], thoracoscopic splanchnicectomy^[4], and extracorporeal shockwave lithotripsy^[5]. The mechanism of pain in chronic pancreatitis is certainly multifactorial and seems to be mainly based on two mechanisms: ductal hypertension, and

neural and perineural inflammation. The medical option is generally the first which is attempted based on NSAIDs and often on opioids but it is not always satisfactory and, before narcotic dependence develops, endoscopy or surgery should be considered. Endoscopic and surgical treatment is generally the first option when there is any cause of ductal hypertension; however, a surgical approach remains the main option for intractable pain. Other complications in patients with chronic pancreatitis are the formation of pseudocysts, fistulae, bleeding due to rupture of esophageal and/or gastric varices secondary to splenic or portal thrombosis, biliary and duodenal strictures, ascites, and superimposed carcinoma. All these complications require a multi-specialist approach, even if, in most cases, surgery remains the only option.

QUALITY OF LIFE EVALUATION

In the past few years, several self-administered questionnaires for the assessment of the quality of life have been developed. All the questionnaires have been constructed to evaluate two main domains: physical and mental well-being. The items contained in the various questionnaires vary greatly (from 6 to more than 130 questions) and the association of the different items permits the calculation of the various domains. Generally, a high score of the various domains corresponds to a good quality of life whereas a low score indicates a poor quality of life.

In recent years, many studies evaluating the quality of life in chronic pancreatitis patients have been published; these studies involved mixed medical-surgical patients^[6-9]. Three of these studies utilized a questionnaire called Medical Outcome Study 36-Item Short-Form Health Survey (SF-36)^[6-8] made up of 36 items and the most recent study, a questionnaire constituted by two different modules, the European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire-C30 (EORTC QLQ-C30), made up of 30 items, and the Quality of Life Questionnaire pancreatic cancer module (QLQ-PAN26), made up of 26 items, which had previously been tested in pancreatic cancer patients^[9].

All four studies demonstrated that patients with chronic pancreatitis have a substantially impaired quality of life and, most importantly, the impairment of the quality of life in younger patients is higher than in older ones with obvious economic consequences for society.

Regarding gender, in the Italian study^[8], the impairment of various domains was more pronounced in females and this finding differs from that of the German studies^[6,7]. This may be explained, at least in part, by the fact that Italian females affected by chronic pancreatitis have a poor acceptance of the disease.

Among the various clinical variables examined as possible factors related to chronic pancreatitis (pancreatic calcifications, pseudocysts, Wirsung, duct dilatation, pancreatic insufficiency, diabetes), only pain was able to significantly impair all eight domains of the SF-36, thus confirming that pain control is the main therapeutic option to be taken into account in order to improve the quality of life in patients with chronic pancreatitis, thereby suggesting that much effort should be made in order to identify more

efficacious therapies capable of controlling this symptom.

Surprisingly, in the Italian study^[8], neither the type of pancreatic surgery nor endoscopic therapy were able to substantially modify the various physical and mental domains investigated by the SF-36; this is in contrast to previous studies regarding the various surgical and endoscopic options^[4,10-18], and such a difference may be due to the fact that these studies enrolled a highly selected group of patients with a short time interval between intervention and the assessment of the health-related quality of life (3-74 mo); another possible bias present in these surgical/endoscopic studies is that their data were not adjusted for sex and age.

It is worth noting that diabetes and major alterations of the Wirsung duct (which are expressions of long-standing chronic pancreatitis), as well as a decreased BMI (which is an expression of maldigestion) are able to impair some of the physical and mental domains^[6-8].

Co-morbidities were not significantly related to the quality of life of these patients^[6,8]; a possible explanation of this phenomenon is the fact that chronic pancreatitis *per se* determines a high impairment of the quality of life and co-morbidities add little, since these patients already had low values for most of the SF-36 domains.

An important point is that a percentage of patients varying from 4% to 10%^[8,9] missed responses or refused to complete the questionnaires. In the Italian study^[8], this group was better characterized; the patients who refused to complete the questionnaire were male patients, current smokers with a long duration of alcohol consumption, with a long duration of the disease, and free from pain at the time of the study. Patients with the above-mentioned characteristics are probably candidates for an intensive psychological approach in order to counter-balance their unwillingness to improve their relationship with the disease.

The main differences in the four studies exploring the quality of life in chronic pancreatitis patients^[6-9] are that the studies utilizing the SF-36 questionnaire had a control group taken from the general population^[6-8] whereas the study utilizing the EORTC QLQ-C30 and the QLQ-PAN26 did not^[9]; the studies utilizing the SF-36 had a wide number of chronic pancreatitis patients coming from the country where the studies were carried out whereas the study utilizing the EORTC QLQ-C30 and the QLQ-PAN26 enrolled 66 patients coming from four different countries (Germany, Italy, South Africa, and United Kingdom); finally, all the patients utilizing the SF-36 questionnaire were fluent in the native language^[6-8] whereas Afrikaans-speaking patients in South Africa completed the English version of the EORTC QLQ-C30 and the QLQ-PAN26. Since in clinical practice, there is the need to utilize a time-saving questionnaire to assess the quality of life, we have recently carried-out a study utilizing a short version of the SF-36 questionnaire named SF-12 (Medical Outcome Study 12-Item Short-Form Health Survey)^[19]. The aim of this study was to establish the validity of the SF-12 questionnaire in patients with chronic pancreatitis and to identify the predictors capable of modifying the physical (PCS) and mental (MCS) summaries in these patients. The SF-12 and the SF-36 questionnaires were used. One hundred and forty-one patients with proven

chronic pancreatitis were studied. The chronic pancreatitis patients had SF-12 physical (PSC-12) and mental component (MCS-12) summaries significantly related to the PCS-36 and MCS-36 ($P < 0.001$). The presence of pancreatic pain and non-pancreatic surgery accounted for 41.3% in the formation of the PCS-36 score and 37.2% in that of the PCS-12 score, respectively. Gender, BMI, and pancreatic pain accounted for 15.3% of the information in the formation of the MCS-36 and for 14.7% in that of the MCS-12; using these clinical variables, the loss of information in applying the SF-12 instead of the SF-36 was very low (4.6% and 0.6% for the PCS and the MCS, respectively). Thus, the SF-12 seems to be a good alternative to the SF-36 in assessing the quality of life in chronic pancreatitis.

CONCLUSION

The conclusions that can be drawn from studies which have assessed the quality of life in chronic pancreatitis patients are the following: it is necessary to choose a widely accepted questionnaire concerning the quality of life in order to render the various studies in different populations of chronic pancreatitis patients comparable and we need further studies comparing the various questionnaires in order to identify the questionnaire which could be the most useful in routinely evaluating our patients in the office. At present, the SF-12 questionnaire is the instrument of choice to assess the quality of life in the doctor's office. The presence of papers assessing the quality of life in chronic pancreatitis patients leads us to believe that all future studies on the management of chronic pancreatitis should include a validated questionnaire in order to evaluate the point of view of the patient on the various treatments employed^[20].

We recommend the routine use of QoL questionnaires to assess the well-being of patients with chronic pancreatitis in order to select those who need a more intensive medical and psychological approach. However, we could couple the QoL assessment with traditional clinical methods to evaluate the therapeutic effects of the various medical approaches.

Abstract

A very low local recurrence rate of 3%-6% (associated with improved 5 year survival) is possible when proper oncological surgery is performed of mid and distal rectal adenocarcinoma. Restoration of bowel continuity is possible in most cases, without compromise of cancer clearance. Re-anastomosis can be performed with stapled, transabdominal hand-sewn or coloanal pull-through techniques. However after a direct (straight) anastomosis of the colon to the distal rectum/anus, up to 33% of patients have 3 or more bowel movements/d; some can be troubled with up to 14 stools a day. Construction of a 6-cm colonic J-pouch is likely to cause some reversed peristalsis which improves postoperative bowel frequency without causing neo-rectum evacuation problems. Colonic J-pouch-anal anastomosis patients have a median of 3 bowel movements a day compared with a median of 6 a day for straight anastomoses, at 1 year after surgery. In the longer term, bowel adaptation may enable the function after a straight anastomosis to approximate that of a colonic J-pouch-anal anastomosis. This probably depends in the former, upon whether the more rigid sigmoid colon or more distensible descending colon is used. An additional advantage of the colonic J-pouch-anal anastomosis is the lower risk of anastomotic complications. A more vascularized side-to-end (colonic J-pouch-anal) anastomosis is likely to heal better than an end-to-end (straight) anastomosis. Where the pelvis is too narrow for a bulky colonic J-pouch anal anastomosis, a coloplasty-anal-anastomosis is an option. The latter results in postoperative bowel function comparable with the colonic J-pouch. However, the risk of anastomotic complications is higher possibly related to its end-to-end anastomotic configuration. Laparoscopic techniques for accomplishing all the above are being proven to be effective. Restorative surgery for rectal cancer can be safely and effectively performed with

INTRODUCTION

The most important priority in the surgical management of mid and distal rectal cancers is adequate oncologic clearance. It is generally accepted that this is achievable by total mesorectal excision, although in Japan extended pelvic lymphadenectomy is also used in selected cases. Total mesorectal excision involves precise excision of the entire rectum and para-rectal lymph nodes en-block, within an oncologic package termed the 'mesorectal envelope'. A very low local recurrence rate of 3%-6% (associated with improved 5 years survival) has proven to be repeatable, where the surgeon is adequately trained and the technique is correctly practised^[1-3]. Restoration of bowel continuity after total mesorectal excision is possible most of the time, without compromise of oncologic clearance. The reported mortality of 7%-8% is comparable to the 2.2%-8% following the alternative abdominoperineal resection^[4-6]. Furthermore, local recurrence rates following low anterior resection (7%-14.7%) are similar to that of abdominoperineal resection (12%-18.8%)^[4-6].

Confusion in the literature can be minimized by defining clearly the terminology relating to the restoration of bowel continuity after rectal cancer surgery. The type of procedure is defined by the anatomical site of anastomosis rather than the position of the cancer, as commonly described at colonoscopy. The term "high" anterior resection refers to a colorectal anastomosis performed at the level of between the sacral promontory and the anterior peritoneal reflection. The level of the anastomosis is normally measured to be about 8 to 16 cm from the anal verge, depending upon the patient's body build. The term "low" anterior resection refers to a colorectal anastomosis performed at between distal to the anterior peritoneal reflection and proximal to the anorectal junction. This is

normally measured to be about 5 to 8 cm above the anal verge, again depending upon the patient's body build. The term "ultra-low" or "extended" anterior resection refers to a colorectal or more usually, a coloanal anastomosis at the level of the anorectal junction. This is the type of anastomosis that is performed after proper total mesorectal excision and incision of the Waldeyer's fascia posterior to the rectum. The latter technical step allows the rectum to be mobilized/"freed" both anteriorly and proximally from the pelvis, allowing for transection of the rectum safely at the anorectal junction. The level of this anastomosis is normally measured to be about 3-5 cm from the anal verge. Such distal anastomoses have much higher risk of anastomotic dehiscence and consideration should be given to temporary defunctioning by either a colostomy or ileostomy. The term "intersphincteric dissection" refers to the special situation where a very distal rectal cancer is excised with clear oncological resection margins by including an en-block excision of the internal anal sphincter and anal mucosa, to the level of the dentate (pectinate) line. The last part of the procedure is usually performed transanally. Reconstruction is done by a pull-through procedure with hand-sewn anastomosis of the colon to the distal anus, again by the transanal route.

Subsequent discussion will be along (1) methods of anastomosis after resection of the rectal cancer, (2) types of operations i.e. straight colorectal or coloanal anastomosis, colonic J-pouch anal anastomosis, coloplasty anastomosis & colonic side-to-end anastomosis, and (3) anterior resection syndrome & management.

ANASTOMOTIC METHODS

Following successful resection of the rectal cancer with total mesorectal excision, bowel continuity can be restored by coloanal/distal rectal anastomosis performed using various techniques.

Stapled anastomosis

The most common method of performing the coloanal/distal rectal anastomosis is with the use of a circular intraluminal stapling instrument introduced transanally. It is technically challenging to insert a hand-sewn *purse-string suture* to the transected rectal stump and to secure the shoulder of the transanally inserted stapling device, as the transected anorectal junction tends to retract into the pelvic floor. The exposure is often further obscured by a hypertrophied bladder which is commonly found in the older male patients with bladder outlet obstruction problems such as benign prostatic hypertrophy. Hence, the double cross stapled technique is the most commonly employed method particularly in the West where patients are usually of bigger size^[7]. The double cross stapled technique consists of stapling and transecting the anorectal junction distal to the cancer. Prior to this, it is important to irrigate the rectum with tumoricidal agents to reduce the risks of cancer recurrence from exfoliated tumour cell implantation. Then the spike of a transanally introduced intraluminal stapling device is passed through the middle of the transected rectal stump. The anvil of the stapling

instrument is secured around the proximal cut edge of the colon with a purse-string suture. Then the anvil is re-approximated to the spike, followed by closing and firing of the stapling instrument to achieve an anastomosis. A method of enabling the intraluminal circular stapling device to be introduced from the abdomen, rather than from the anus by performing a hand-sewn purse-string suture to the anorectal stump has been reported. This will be discussed in detail later, under "methods to preserve anal sphincter function".

Hand-sewn

Due the technical difficulties in manipulating tissue deep in the pelvis described above, the classical method of hand suturing with 'parachuting' stitches is seldom used in present times. Nonetheless, it is important that the surgeon who performs rectal surgery has the skills to perform a hand-sewn anastomosis on rare occasions when the stapling devices fail.

Pull-through hand-sewn coloanal

The circumstances for performing this type of anastomosis have already been discussed above under "introduction-intersphincteric dissection". In addition, this technique is an option in the obese patient with a narrow pelvis and in circumstances where an anastomosis needs to be salvaged after a stapling instrument mishap.

Stapled instrument malfunctioning

Aspects of salvaging the situation when the stapling instruments malfunction have already been described above, under "hand-sewn" and "pull-through hand-sewn coloanal anastomosis". It is not often possible to re-do the double cross stapled anastomosis, especially when the original rectal transection has been very distal. A very distal anastomosis can usually be accessed more easily for suture repair from the anus. In addition, the transanal route can be used to insert a purse-string for a repeated stapled anastomosis where the defect has been major. An appropriate defunctioning stoma would be essential.

Defunctioning stoma

It is well recognized that after total mesorectal excision, a distal colorectal/anal anastomosis at the level of the anorectal junction has a much higher risk of anastomotic dehiscence than more proximal colorectal anastomoses. Most of the time, these anastomotic problems are subclinical. There is a strong case for a defunctioning stoma to reduce the complications of an anastomotic leak even in routine circumstances. A defunctioning loop ileostomy is technically easier to fashion and to close, with less risk of damaging the marginal vessels than a colostomy. This has become the preferred technique by most surgeons in the West. However, a colostomy is preferable where the bowel preparation has been inadequate because residual faeces distal to a defunctioning stoma will continue to contaminate the anastomosis and hence will not reduce the complications of an anastomotic leak. For the same reasons, a colostomy would be preferable when the anastomosis is compromised or in places where

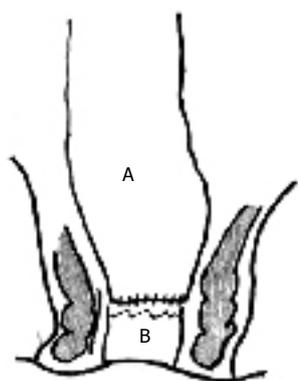

Figure 1 Straight coloanal anastomosis with colon (A) anastomosed directly to anorectum (B).

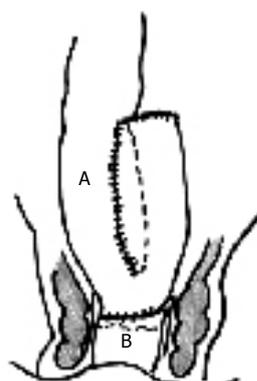

Figure 2 Colonic J-pouch-anal anastomosis with constructed colonic pouch (A) anastomosed to anorectum (B).

hot weather would cause excessive dehydration from an ileostomy. Traditionally, the defunctioning stoma is closed 12 wk later when the intraperitoneal adhesions would be more easily managed. This is provided that a contrast study confirms that the anastomosis is intact. In recent years, a case has been made for barrier agents against adhesions such as hyaluronate carboxymethylcellulose membranes (Seprafilm) to be placed around the stoma to enable earlier closure.

TYPES OF OPERATIONS

Using the above methods to re-anastomose the bowel, 4 types of operations normally result i.e. 'straight' colorectal or coloanal anastomosis, colonic J-pouch anal anastomosis, coloplasty anastomosis & colonic side-to-end anastomosis.

Low anterior resection 'straight' anastomosis (Figure 1)

A straight anastomosis results from a direct end-to-end anastomosis of the colon to the anorectum. After segmental bowel resection (including right hemicolectomy, left hemicolectomy and anterior resection) for colorectal cancer, most patients (58%-78%) have a satisfactory 1 to 2 bowel movements/d^[8]. However after low anterior resection, up to one-third of patients have 3 or more bowel movements/d. At times, patients can be troubled with having up to 14 stools a day^[9,10]. Other patients may have defecation problems after anterior resection; excessive stool frequency or defecation problems under these circumstances has been termed as the "anterior resection syndrome".

Reasons for poor bowel function after 'straight' anastomosis

Multiple regression analysis on factors influencing postoperative bowel function showed that stool frequency at 1 year was independently predicted by the level of anastomosis and less importantly, the rectal sensation^[11]. This suggests that rectal reservoir function is important in controlling stool frequency. After ultra-low anterior resection with a straight colo-rectal/anal anastomosis, it has been shown that stool frequency depends upon the amount of rectum resected^[9,12-14]. When the level of anastomosis is less than 4-4.5 cm from the anal verge (ie. at approximately the anorectal junction), there is an increased risk of poor bowel function^[11,15]. After end-to-end coloanal (straight) anastomosis at the level of the

anorectal junction, the normally compliant rectum that has been removed is replaced by a less compliant segment of descending or sigmoid colon. The replacement colon is physiologically less suitable for storing/regulating feces^[11]. Not surprisingly, the results include excessive stool frequency and possibly fecal incontinence associated with the increased stool frequency. Another cause of post low anterior resection fecal incontinence is anal sphincter injuries, which occurs in up to 28 percent of patients following transanal insertion of a stapling instrument^[16]. This aspect will be discussed later (in "methods to preserve anal sphincter function").

Defecation problems may also occur in about 28% of patients after low anterior resection. This risk is similar to that after sigmoid colectomy (25%), which is substantially higher than the risk after more proximal bowel resections, such as right hemicolectomy (ranging from 4% to 15%)^[8]. This suggests that the sigmoid colon may have a major role in expelling and evacuating stools^[17], which would be consistent with the more muscular nature of this segment of large bowel. Resection causes discontinuity of colonic muscles and intrinsic nerves and, hence, disruption of coordinated colonic mass movement^[18]. In addition, division of the lateral ligaments of the rectum at ultra-low anterior resection may denervate the rectum and lead to significant constipation^[19].

Colonic J-pouch anal anastomosis (Figure 2)

The anterior resection syndrome symptoms have led to various strategies to improve bowel function. To date, most of these strategies have focused on the proximal aspect of the anastomosis. This consists of various methods to better retain stool contents in the neorectum including the colonic J-pouch, coloplasty and colonic side-to-end anastomosis. The evolution of these techniques has been based on physiological considerations, which are hence discussed prior to the technique and results.

Physiology: When colonic J-pouches were first introduced, the aim was to maximize the neo-rectal compliance and volume by constructing a double barreled configuration with limbs sizes measuring up to 15 cm^[10,13,14,20-22]. Randomized controlled trials comparing this 15 cm colonic pouch technique to direct straight colo-rectal/anal anastomoses have confirmed improved stool frequency^[23-27]. Proctometrographic measurements have shown improved rectal volumes (i.e. increased neorectum

reservoir capacity) and rectal compliance (increased ability of the neorectum to retain high pressures)^[20,27]. However, these advantages came at the expense of severe evacuation problems^[27-30].

Meanwhile, a smaller 6 cm colonic J-pouch which is conveniently constructed from a single longitudinal firing of a linear cutting stapling instrument, was found to be effective in improving stool frequency, but with less rectal evacuation problems^[31,32]. This has since been confirmed by studies done in other centres^[26,33], and also in a randomized controlled trial comparing 6 cm with 9 cm colonic J-pouches^[34]. An interesting finding was that although there was improved function, no differences have been found in the rectal physiology (volume of initial sensation, maximum tolerable volume and compliance) measured at 1-year between small colonic J-pouch and straight coloanal anastomosis patients, in a randomized controlled trial^[32].

Compared to stationary anorectal manometric techniques, continuous ambulatory manometric monitoring has the advantage of monitoring pressure changes in the anus and rectum during prolonged periods and in a more physiologically normal environment. Using such techniques, patients with the smaller J-pouch were found to have a better tolerance to higher rectal pressures without increased stool frequencies, compared to straight anastomosis patients in a randomized prospective trial^[35]. The anorectal pressure gradient was also better preserved^[31], which had been described previously to be related to bowel frequency^[24,36]. Defecation in patients with colonic J-pouches may be related to large contraction waves (not corresponding to mass movement complexes) previously detected on ambulatory anorectal manometry, in patients with large colonic J-pouches^[36]. These large contraction waves were not observed after prolonged monitoring in patients with smaller 7 cm pouches, which might well explain the less severe rectal evacuation problems in these patients.

To elicit this further, a scintigraphy study protocol was designed to attempt to follow liquid faeces colonic transit with technetium TC^{99m} tin-colloid and solid faeces colonic transit with I¹³¹ implanted microcapsules ingested at the same time^[37]. More technetium TC^{99m} tin-colloid was distributed into the liquid colonic contents at the distal colon at 24 h in 6 cm colonic J-pouch patients, than in those with straight coloanal anastomosis. This may be related to a backward stacking up effect from factors such as reversed peristalsis in the colonic J-pouch, accounting for the less frequent stools in those patients. The retention of I¹³¹ in the solid stools were not different between colonic J-pouch and straight coloanal anastomosis patients, which may explain the rarity of severe evacuation problems (likely to involve solid stools) in patients with smaller 6 cm colonic J-pouches.

The barostat is a computerized pump that inflates a rectal balloon at controlled and reproducible rates of pressures, and volumes, providing a more accurate technique for assessing rectal physiology. The only study using barostat measurements on colonic J-pouches to date showed that there were no differences at 6 mo between 6 cm colonic J-pouch and straight coloanal anastomosis patients^[38]. At 2 years, there was a trend

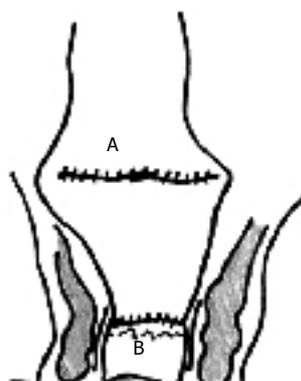

Figure 3 Coloplasty anastomosis with coloplasty in colon (A) anastomosed to anorectum (B).

for improved rectal sensation and maximum tolerable volume (as assessed with the phasic program) in both the types of patients. The phasic program assesses afferent sympathetic nerve function and hence these findings may be related to recovery of function in these nerves. Significant improvements in rectal compliance in straight coloanal anastomosis patients at 2 years had previously been documented in a cohort study, using traditional proctometrographic techniques^[23]. In addition, enlargements of the colonic J-pouch size have been measured radiologically over a 2 years period^[39]. All these changes may be responsible for the long term adaptation seen in patients after straight and colonic J-pouch colorectal/anal anastomoses.

Construction of 6 cm colonic J-pouch: Mobilization of the splenic flexure allows the descending colon to be used for the construction of the J-pouch. Very often this is necessitated by the sigmoid colon being badly affected by diverticulosis. Using a diseased sigmoid colon might compromise the pouch function and the anastomosis integrity. Where the sigmoid colon is healthy and of adequate length, it has been used instead of descending colon with no significant differences in stool frequency, incontinence, urgency, use of pads, need for antidiarrhoeal drugs, sensation of incomplete evacuation and anorectal physiologic results at 1-year follow-up^[40]. However, the descending colon has the advantage of being less muscular and more distensible than the sigmoid colon, which might improve the mid-term functional results^[38]. A comparison of results across studies which use descending and sigmoid colon at 2-year follow-up suggests that the descending colon adapts better^[38].

Coloplasty (Figure 3)

A coloplasty is designed to 'interrupt antegrade colonic peristalsis' and as an option when the pelvis is too narrow to permit a bulky colonic J-pouch anal anastomosis^[41]. It is similar to a pyloroplasty or stricturoplasty, and had initially been tried out in pigs^[42,43] prior to testing out in patients^[44,45].

Construction of coloplasty: A 7 cm longitudinal incision is made between the taenia along the anti-mesenteric side of the descending colon, starting 4 cm above the distal cut end. The incision is closed transversely with a continuous single layer of seromuscular absorbable suture. The coloplasty 'pouch' is then anastomosed to the stapled anorectal stump by a double cross stapling technique with

the coloplasty facing anteriorly.

Side-to-end anastomosis (Figure 4)

The side-to-end anastomosis that was first described by Baker JW in 1950^[45], has been revisited recently as another option to improve postoperative bowel function. There are 2 variations: (1) anastomosis performed by introducing the intraluminal stapler from the anus or (2) anastomosis done entirely from the abdomen alone. Using the former variation, Machado M *et al*^[46] performed a randomized controlled trial which showed that the side-to-end anastomosis was functionally comparable to the 8 cm colonic J-pouch. The only difference was better neorectal evacuation in < 15 min in the colonic J-pouch group, at 6 mo. The second variation of the side-to-end anastomosis hinges upon the concept of preserving anal sphincter function per se (as compared to improving proximal bowel motility or reservoir function), and hence that is discussed in further detail.

Methods to preserve anal sphincter function: After low anterior resection, faecal continence may be compromised in 13%-80% of patients^[5,9,10]. It is known that some damage to the anal sphincters can occur after low anterior resection^[35,47,48]. Anal pressures are significantly impaired and the rectosphincteric inhibitory reflex recovered only in a few patients at 2 years after low anterior resection, regardless of any reservoir construction^[38]. The rectosphincteric inhibitory reflex requires an intact reflex pathway based upon the anal sphincter muscles and intrinsic rectal innervation. Ambulatory anorectal manometric studies have shown that after low anterior resection, patients who complained of soiling while passing flatus had lower minimal anal pressures^[35]. The latter is very likely related to injury to the internal anal sphincter during transanal stapling instrument insertion^[24,35,36].

Horgan *et al*^[49] monitored the anal pressures of patients on the operating table undergoing anterior resections. They found that the anal pressures were maintained at the division of the inferior mesenteric artery, full mobilization of the rectum and mesorectum, and anal transection. The anal pressures only decreased significantly after transanal introduction of the intraluminal circular stapler, suggesting direct injury during anal insertion of the instrument. Molloy *et al*^[50], found that anal resting pressures in dogs was significantly lower after transanal introduction of intraluminal circular stapler than handsewn colorectal anastomoses. However, it was likely that nerve injury during rectal mobilization was also important in dogs, because there was significant impairment of anal pressures after both types of anastomoses. A randomized controlled trial showed that direct injuries to the internal anal sphincter occurred after transanal insertion of the stapler but not with the biofragmentable anastomotic ring (where the anastomosis was performed entirely intra-abdominally) after high anterior resection^[51]. The nature of the injury was documented with endoanal ultrasound in a follow-up randomized controlled clinical study to be the result of anal sphincter injuries^[16]. In order to avoid transanal introduction of the intraluminal stapling device, the second variation of the side-to-end anastomosis was devised to

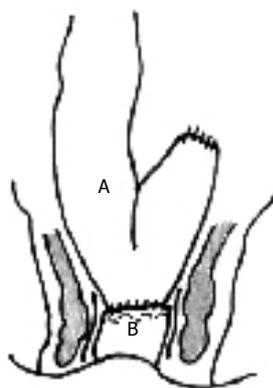

Figure 4 Side-to-end anastomosis with side of colon (A) anastomosed to end of anorectum (B).

enable a stapled anastomosis performed entirely from the abdomen. Huber FT *et al*^[52], reported on a randomized controlled trial which compared this variation of side-to-end anastomosis (with 3-4 cm blind end) with the 6 cm colonic J-pouch.

COLONIC J-POUCH-ANAL ANASTOMOSIS

Complications

The better-vascularized end-to-side anastomosis with a J-pouch has been shown to reduce the risks of anastomotic dehiscence, compared to the straight coloanal/rectal anastomosis^[23]. This will be discussed in detail in the section on 'coloplasty'.

Function

Early function (1 year): Patients with a small 6 cm colonic J-pouch-anal anastomosis have a median of 3 bowel movements a day compared with a median of 6 a day for patients with straight anastomoses, at 1 year after surgery^[31,32]. Urgency to defecate is less troubling in colonic J-pouch patients. However, a frequent sensation of incomplete neorectal evacuation was more common after the small colonic J-pouch-anal anastomosis, but most of these patients do not require suppositories, laxatives or enemas to evacuate.

Late function (2 years): At 2 years of follow-up, patients with 6 cm colonic J-pouch and those with straight coloanal anastomoses have similar bowel frequency at about 1 bowel movement a day^[38]. The need for anti-diarrhoeal medications is minimal in both groups. In the only other randomized controlled trial with long-term follow-up, Lazorthes *et al*^[24] reported no improvements in their straight coloanal anastomosis patients at 2 years. This may well be due to using the sigmoid colon for some of their coloanal anastomoses. As the sigmoid colon is less distensible, it is less likely to adapt successfully in the long-term as a storage reservoir for faeces. This would account for the no difference in bowel function between colonic pouch and straight anastomosis patients, reported in the other available data from cohort studies^[23,53]. Dehni *et al*^[54] reported that stool frequency remained superior in the pouch patients after 5 years but conceded that they had difficulty assessing stool frequency because of significant stool fragmentation in their patients.

Bowel continence has been reported by some to be

better in colonic J-pouch patients than in those with straight coloanal anastomoses^[11,23,25,26]. However, the differences are often minor, like less likelihood of soiling with passing flatus^[38]. At 2 years, studies to date have confirmed no differences in continence with either anastomoses^[23,38,41,43]. At this stage, unless there is excessive stool frequency, it is likely that significant faecal incontinence is related more to anal sphincter injuries than to neorectal reservoir function (see below).

Bowel evacuation is improved at 2 years with straight coloanal anastomosis patients, but major evacuation problems remain minimal with colonic J-pouch patients^[38]. A randomized controlled trial comparing the function of 6 cm and 9 cm colonic J-pouches at 2 years showed that fewer 6 cm pouch patients required laxatives and enemas for severe constipation^[34]. Stool fragmentation/clustering has been defined as multiple evacuations over a 1-2 h period associated with persistent sensation of rectal fullness. More straight anastomosis patients had persistent long-term stool fragmentation^[53,54]. As this phenomenon has not been confirmed in the only other large randomized controlled trial to date, these findings well may be related to cultural and dietary factors^[38]. The results to date suggest that the small 6-7 cm colonic J-pouch-anal/rectal anastomosis is the procedure of choice because of early improved bowel function and less risk of anastomotic complications.

COLOPLASTY ANAL ANASTOMOSIS

Complications

A randomized controlled trial comparing colonic J-pouch with coloplasty 'pouch'-anal anastomosis showed significantly more anastomotic leaks in the latter (15.9%)^[41]. Seven percent were clinical and 9% were radiologic, found at routine barium enema prior to ileostomy closure. All the leaks were at the anterior of the coloanal anastomoses, below the site of the coloplasty. Anastomotic leaks were not significantly associated with postoperative chemotherapy or radiotherapy ($P = 0.417$). A 5% incidence of clinical anastomotic leak had been reported in the only other series on coloplasty pouch patients (*nonrandomized*) to date^[45]. The lower incidence of anastomotic leak after J-pouch may be due to better proximal anastomotic blood supply, as shown by the laser Doppler technique. This better blood supply at the critical anastomotic site was related to the J-pouch being anastomosed side-to-end to the anal canal, compared with the straight coloanal, which is an end-to-end anastomosis. Hence, higher leak rates after coloplasty may be due essentially to the coloanal anastomosis being made end-to-end, as in the straight coloanal anastomoses. The reported coloplasty leak rates were comparable to the straight anastomosis leak rates. An additional possibility to consider would be some compromise of blood supply to the colonic anastomotic end as a result of the coloplasty. This may account for all the clinical and radiologic leaks occurring anteriorly at the coloanal anastomosis, just distal to the coloplasty.

Function

The differences between the early functional results of

the small colonic J-pouch and coloplasty techniques are subtle^[41]. J-pouch patients had significantly less stool fragmentation, which required returning to the toilet at least once within 15 min of evacuation. However, both groups of patients reported increased stool fragmentation at 1 year. It is known that patients may have difficulty in differentiating stool fragmentation from increased bowel frequency. No differences were found with other stool evacuation problems. However, coloplasty patients had significantly better stool deferment time and less nocturnal liquid stool leakage. No differences were found with other stool incontinence symptoms and with continence scoring. The only other published study on the coloplasty technique compared 20 patients with historical controls consisting of 16 J-pouch and 17 straight coloanal anastomoses^[45]. It confirmed no significant differences between coloplasty and colonic J-pouch patients when stool frequency, use of antidiarrheal medication, and continence were compared. Patients' perceptions as measured by the Fecal Incontinence Quality of Life scale also showed no difference between the small colonic J-pouch and coloplasty techniques^[41].

Physiology

Anorectal manometric findings did not show any significant differences in the function of small colonic J-pouch and coloplasty patients^[41]. Colonic pouch reservoir function, as measured by the rectal volume of initial sensation, maximum tolerable volume, and compliance, was not different between the groups. This was consistent with the findings of Mantyh *et al*^[45], mentioned above. Z'graggen *et al*^[42] also found no differences in maximum tolerable volume and compliance between J-pouch and coloplasty in their experimental surgery on 15 pigs. Although experimental surgery construction of a coloplasty may provide a 40% increase in volume^[42], it is more than likely that in the clinical situation motility factors such as disruption of colonic propulsion as a result of the coloplasty on the antimesenteric surface may be more important^[44].

At this time because of higher risks of anastomotic complications, coloplasty cannot be recommended except for special circumstances when a bulky J-pouch cannot be brought through a narrow pelvis for anastomosis to the anorectal junction. Nonetheless, further studies with variations in coloplasty design and longer follow-up may reveal other advantages in the technique. However, due caution, including the use of defunctioning stoma and careful postoperative observation, should be exercised.

SIDE-TO-END COLOANAL ANASTOMOSIS

Complications

As both the colonic J-pouch and the side-to-end anastomoses are essentially side-to-end anastomoses, the vascularity and the related complications would be expected to be similar. This has proven to be the case in studies. A unique complication of the side-to-end anastomosis technique is bowel obstruction related to inadvertent inclusion of the side-wall of the opposite limb into the anastomosis. Unlike the colonic J-pouch, the side-

to-end anastomosis has a narrow lumen which makes inclusion of the side-wall a potential risk.

Function

The colonic J-pouch group was reported to have better stool frequency at 3 mo, but the functional results equalized in both groups at 6 mo^[52]. It was interesting that despite the different methods of introducing the intraluminal stapling instrument, there were no differences in postoperative continence and anal manometric findings. It is conceivable that a similar mechanism to 'reverse peristalsis' in the small colonic J-pouch would occur with a 3 to 5 cm blind limb side-to-end anastomosis. With some distension over time, the final anatomic configuration of the latter may well conform to that of the 5 cm colonic-J-pouch. However with regard to incontinence related to anal sphincter injuries, there were no differences between the transabdominal and transanal introduction of the stapling device^[52]. When total mesorectal excision has been properly performed, the distal mesorectum would have been lifted off the pelvic floor. The rectum and the mesorectum would be transected at the level of the anorectal junction. Application of a purse-string suture from the abdomen would be a difficult exercise, particularly in Western patients who are usually more heavily built. In particular, balancing the conical or narrow disc shaped stapler anvil in the anal canal without having it squeezed out by the anal muscles whilst securing the purse-string suture at the anorectal junction at the same time is no mean feat.

MANAGEMENT OF 'ANTERIOR RESECTION' SYNDROME

Conservative

Traditionally, management of poor bowel function has been managed expectantly having excluded other causes particularly tumour recurrence and pelvic sepsis. It is now known the colonic adaptation can take up to 18 mo to occur after ultra-low anterior resection with total mesorectal excision^[38]. The patient is advised to take adequate soluble fibre in the diet and to avoid foods which aggravate the bowel dysfunction. Those with increased stool frequency may be prescribed diphenoxylate, codeine and/or bile salt binding agents to help control the symptoms. Patients with rectal evacuation problems may be prescribed regular laxatives and enemas. On rare occasions, patients fail to respond to conservative treatment with persisting debilitating bowel function lasting beyond 18 mo. Under such circumstances, anorectal biofeedback therapy and/or postanal sphincter repair may need to be considered. Resort to a stoma would be only needed in very exceptional circumstances only, where patients are managed in a specialist colorectal surgical centre.

Anorectal biofeedback

Biofeedback has been shown to be effective in treating certain types of faecal incontinence^[55]. This is a specific form of behaviour modification that aims to control

bodily function. Biofeedback has been reported to be successful in managing patients who have stool frequency and/or incontinent problems after anterior resection^[56]. At a mean follow-up of 10.6 mo, 90% success with no regressions or complications was found. Anorectal physiologic tests done before and after biofeedback show minimal increase in anal pressures. It is possible that biofeedback works by improving the anal sphincteric coordination, rectal sensation, rectal liquid retention and/or anal canal sensation. Although patient-biofeedback therapist relationship may be vital, none of the patients received any formal psychiatric counseling. Biofeedback has also been reported to be 90% successful in managing intractable constipation following low anterior resection^[57]. Intractable constipation after low anterior resection is likely to result from resection of the sigmoid colon, which is the main propulsive organ of the large intestine^[17]. Again, the results of pre and post-biofeedback anorectal physiologic tests are inconclusive, suggesting that similar factors outlined previously may play an important role in bringing about the positive changes in bowel function.

Postanal sphincter repair

Treatment options are limited for persistent intractable excessive stool frequency and incontinence after low anterior resection for rectal cancer. Fortunately, this is quite rare, but such patients treated successfully by postanal sphincter repair have been reported^[58]. In such cases, it is essential that anorectal physiologic tests and endoanal ultrasound findings are consistent with internal anal sphincter injuries, which are known to occur with transanal insertion of stapling instruments. After postanal sphincter repair, stool frequency was reported reduced from a mean 5.7 to 1.7 stools per day^[58]. Fecal incontinence requiring pads in all patients was improved to full continence in 67% and minor incontinence for flatus in 33%. Continence score improved from a mean 13.7 to 1.3. Mean follow-up was 3.2 years. With the recent advent of bulking agents implanted intersphincterically by injection, another option for managing internal sphincter injuries in patients after low anterior resection is now available. Clinical studies are awaited.

LAPAROSCOPIC ULTRA-LOW ANTERIOR RESECTION

Laparoscopic colonic cancer surgery has been proven to be at least as safe and effective as traditional open surgery. However, data is still sparse with regard to the laparoscopic management of rectal cancer. It is now technically possible to perform the mobilization of the left colon and total mesorectal excision by a laparoscopic technique. The anorectal junction can be stapled and transected with an endoscopic linear cutter stapler. The specimen can then be extracted through a plastic drape protected 4-5 cm muscle splitting transverse incision, which can be used eventually for the temporary defunctioning stoma. A colonic J-pouch or coloplasty can be performed extracorporeally and pneumoperitoneum reconstituted to perform an intracorporeal end-to-end double cross

stapled anastomosis, with the intraluminal stapling device introduced transanally. Further data and refinement of the technique is awaited.

In conclusion, at present, the small colonic J-pouch-anal anastomosis is the most widely accepted method of restoring colonic anal continuity after a total mesorectal excision. A straight colorectal anastomosis is preferred where the anastomosis is more than 4-6 cm above the anal verge. In these circumstances, there is adequate residual rectum to provide the necessary rectal reservoir capacity. Besides, performing a colonic J-pouch-rectal anastomosis at this proximal level is likely to result in rectal evacuation problems. Where a coloanal anastomosis at the anorectal junction needs to be considered in a heavily built patient with a narrow pelvis, a coloplasty can be considered. The other methods of restoring bowel continuity are best kept for special circumstances such as stapling gun misfiring, where their unique technical features will help salvage the operation, where others are not possible. A laparoscopic technique is likely to be the method of choice in the near future.

Abstract

In recent years, the results of several studies suggest that human liver tumors can be derived from hepatic progenitor cells rather than from mature cell types. The available data indeed strongly suggest that most combined hepatocellular-cholangiocarcinomas arise from hepatic progenitor cells that retained their potential to differentiate into the hepatocytic and biliary lineages. Hepatic progenitor cells could also be the basis for some hepatocellular carcinomas and hepatocellular adenomas, although it is very difficult to determine the origin of an individual hepatocellular carcinoma. There is currently not enough data to make statements regarding a hepatic progenitor cell origin of cholangiocarcinoma. The presence of hepatic progenitor cell markers and the presence and extent of the cholangiocellular component are factors that are related to the prognosis of hepatocellular carcinomas and combined hepatocellular-cholangiocarcinomas, respectively.

INTRODUCTION

The traditional view that adult human liver tumors arise from mature cell types has been challenged in recent decades. The results of several studies suggest that some types of human liver tumors can be derived from hepatic progenitor cells (HPCs). In this review, the evidence for a HPC origin of several types of liver tumors and the pos-

sible clinical implications are discussed.

DEFINITION OF HEPATIC PROGENITOR CELLS IN HUMAN LIVER

HPCs are small epithelial cells with an oval nucleus, scant cytoplasm and location in the bile ductules and canals of Hering^[1]. HPCs can differentiate towards the biliary and hepatocytic lineages. Differentiation towards the biliary lineage occurs *via* formation of reactive bile ductules, which are anastomosing ductules lined by immature biliary cells with a relatively large and oval nucleus surrounded by a small rim of cytoplasm. Hepatocytic differentiation leads to the formation of intermediate hepatocyte-like cells, which are defined as polygonal cells with a size intermediate between that of HPCs and hepatocytes^[1]. In most liver diseases, hepatic progenitor cells are “activated”, which means that they proliferate and differentiate towards the hepatocytic and/or biliary lineages. The extent of activation is correlated with disease severity^[2-4].

HPCs and their immediate biliary and hepatocytic progeny not only have a distinct morphology, but they also express several markers, with many also present in bile duct epithelial cells^[1,5]. Immunohistochemistry using antibodies against these markers facilitates the detection of HPCs. The most commonly used markers are cytokeratin (CK) 19 and CK7^[1,6].

HEPATOCELLULAR CARCINOMA AND HEPATOCELLULAR ADENOMA

Evidence for a hepatic progenitor cell origin of hepatocellular carcinoma and adenoma

The proposal that a human hepatocellular carcinoma (HCC) does not necessarily arise from a mature hepatocyte, but could have a HPC origin, has classically been based on three different types of observations. Each of them, however, gives only indirect evidence that can be disputed.

Firstly, it has been shown that HPCs are the cells of origin of HCC in some animal models of hepatocarcinogenesis^[7,8], which has led to the suggestion that this might also be the case in humans. However, in other animal models, the HCCs arise from mature hepatocytes and not from HPCs or reactive bile ductular cells^[9,10]. Since it is currently insufficiently clear which of these animal models accurately mimics human hepatocarcinogenesis^[11,12], one should be careful about extrapolating data regarding the HPC origin of HCC in animal models to the human situation.

Secondly, liver diseases that are characterized by the

presence of carcinogens and development of dysplastic lesions also show HPC activation^[1]. Therefore, the suggestion has been made that HPCs form a “target population” for carcinogens^[3,13], but this is only a theoretical possibility not supported by experimental data.

Thirdly, several studies have shown that a considerable proportion of HCCs express one or more HPC markers that are not present in normal, mature hepatocytes^[14-18]. Due to the fact that most HPC markers are also expressed in the biliary lineage, the term “biliary marker” has been used in some of these studies^[16,17]. The “maturation arrest” hypothesis^[19] states that genetic alterations occurring in a HPC, or its immediate progeny, cause aberrant proliferation and prevent its normal differentiation (Figure 1). Further accumulation of genetic alterations eventually leads to malignant transformation of these incompletely differentiated cells. The resulting HCC expresses HPC markers as evidence of its origin. However, expression of HPC markers can also be interpreted in the setting of the “dedifferentiation” hypothesis^[19], which suggests that the expression of HPC markers is acquired during tumor progression as a consequence of accumulating mutations (Figure 1). For example, experiments in which human HCC cell lines were transplanted into nude mice have nicely shown that the expression of the HPC marker, CK19, steadily increased when the tumors became increasingly aggressive and metastasized to the lungs^[20]. Thus, the expression of CK19 in a HCC does not necessarily mean that the tumor has a HPC origin, but it can also be a mutation-induced, acquired expression associated with tumor progression. Both possibilities are not mutually exclusive.

To further address this issue, precursor lesions of HCCs have been investigated for the presence of HPCs and their immediate hepatocytic progeny. It was found that HPCs and intermediate hepatocyte-like cells were present in 50% of small cell dysplastic foci and hepatocellular adenomas^[21,22]. Since both types of these lesions are precursors of HCC^[12], this supports the idea that at least some HCCs are HPC-derived. Indeed, if the expression of HPC markers in HCCs would always be acquired during tumoral progression, these precursor lesions would not contain HPCs and their immediate hepatocytic progeny (Figure 1). Furthermore, HPCs and intermediate hepatocyte-like cells in hepatocellular adenomas were present in a “starry sky” pattern on a background of mature hepatocytes (Figure 2)^[22]. This picture is in agreement with the “cancer stem cell” theory: stem cells that have undergone transformation retain their renewal properties and nourish the tumor by their continuous proliferation and differentiation^[23]. Hepatocellular adenomas with HPCs and intermediate hepatocyte-like cells did not form a specific clinicopathological subtype^[22].

Although these findings further support a HPC origin for some human HCCs, they certainly do not give definite proof. Moreover, these are findings and hypotheses that apply to HCC in general. For an individual HCC that expresses a HPC marker, it remains impossible to determine whether this marker reflects the cellular origin and/or is caused by tumor progression. This can only be elucidated by determining whether the HCC contains cells that are ultrastructurally identical to HPCs in non-tumoral liver. Until now, this type of investigation has only been done for

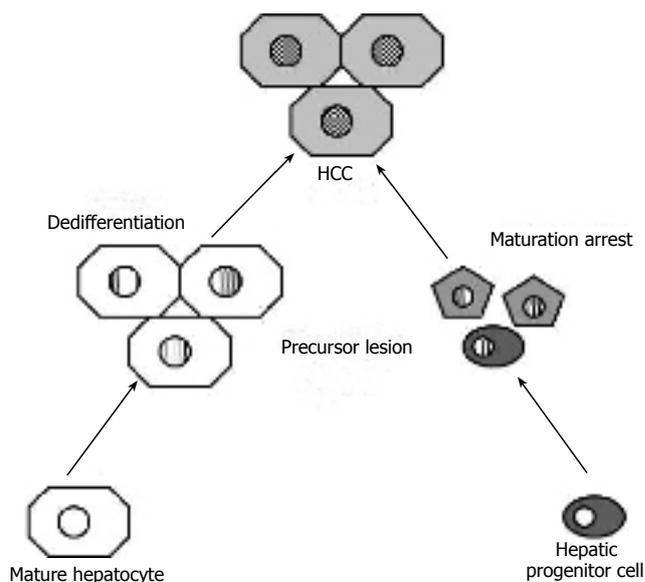

Figure 1 Schematic representation of the “maturation arrest” hypothesis and the “dedifferentiation” hypothesis applied to hepatocellular carcinoma and its precursor lesions. According to the “maturation arrest” hypothesis, genetic alterations (grid in nuclei) occurring in hepatic progenitor cells causes proliferation and incomplete differentiation of these cells, eventually leading to hepatocellular carcinomas that express hepatic progenitor cell markers (grayscale) as an evidence of their cellular origin. In this scenario, precursor lesions contain hepatic progenitor cells and intermediate cells (the small polygonal cells). The “dedifferentiation” hypothesis states that the expression of hepatic progenitor cell markers in hepatocellular carcinoma is merely a result of tumor progression and consequently the precursor lesions should only consist of mature hepatocytes.

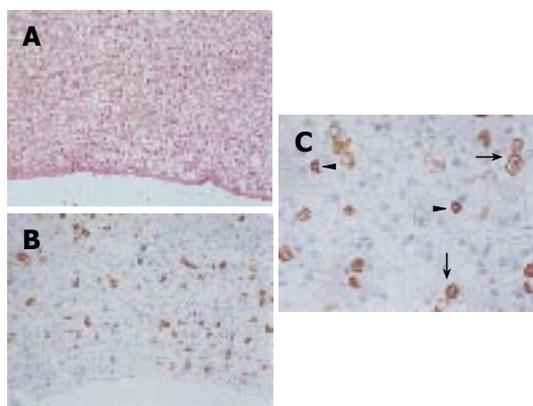

Figure 2 Hematoxylin-eosin stained section of a hepatocellular carcinoma, which suggests that the tumor consists of mature hepatocytes (A). However, the staining for the hepatic progenitor cell marker cytokeratin 7 (B and C) shows the presence of hepatocellular adenomas (arrowheads) and intermediate hepatocyte-like cells (arrows) distributed in a “starry sky” pattern against a background of mature hepatocytes. Original magnification: x 100 (A and B) and x 200 (C).

some hepatocellular adenomas and a very small number of HCCs^[22,24].

Prognostic value of the expression of hepatic progenitor cell markers in hepatocellular carcinoma

From a purely clinical viewpoint, the reason why some HCCs express HPC markers is not important. However, the fact that several studies have shown that HCCs expressing HPC markers have a worse prognosis than HPC

marker-negative HCCs might be potentially clinically relevant^[14-17]. All but one^[14] of these studies also reported that HPC marker-positive HCCs were less differentiated than marker-negative HCCs. Multivariate analysis was performed in only one of these studies and expression of the HPC marker CK19 was an independent predictor of postoperative recurrence^[15]. This finding needs to be confirmed before one can consider using CK19-expression for prognostication instead of more strongly established independent prognostic markers, such as the immunohistochemical expression of the cell proliferation marker Ki-67^[25-27].

In a recent study, unsupervised clustering of microarray data from human HCCs and rat hepatoblasts led to the identification of a subgroup of HCCs that resembled rat hepatoblasts, designated “hepatoblast (HB) subtype” of HCC^[11]. This HB subtype of HCCs was characterized by the high expression of several HPC markers, such as CK7 and CK19. However, the expression of other known HPC markers, such as alpha-fetoprotein and ABCB1^[28,29], was not different and was even lower, respectively, in HB subtype HCCs when compared to the “hepatocyte subtype” of HCCs. Therefore, the exact relationship between HPCs and this HB subtype of HCCs remains unclear. Remarkably, HB subtype HCCs consisted of tumors associated with a very poor prognosis and the HB signature had a very strong and independent prognostic power. Unfortunately, direct application in clinical practice will not be possible because microarrays can not be performed in every hospital and, more importantly, the method relies on unsupervised clustering. This means that adding new HCCs to the group most likely will alter the dendrogram and hence also the subtype of several of the already included HCCs. This effect has already been observed in breast cancer^[30].

COMBINED HEPATOCELLULAR-CHOLANGIOCARCINOMA

Three subtypes of combined hepatocellular-cholangiocarcinoma (CHC) can be distinguished. The first type consists of the so-called “collision tumors” and “double cancers” in which the HCC and the cholangiocarcinoma components are either completely separated or sharply demarcated from each other, indicating that these tumors arise from the coincidental occurrence (and collision) of a HCC and a cholangiocarcinoma^[31,32]. The possible HPC origin of the independent components are discussed in the sections on HCC and cholangiocarcinoma.

The second type of CHC represents tumors containing unequivocal (i.e. recognizable on a hematoxylin-eosin-stained section) hepatocellular and cholangiocellular components that are intimately admixed^[33,34]. In almost all cases, these tumors also show a variable amount of so-called “transitional areas” that consist of immature-appearing cells that have morphological and immunohistochemical features of both hepatocytes and cholangiocytes^[32,33,35]. The cells in the transitional area sometimes resemble HPCs and reactive bile ductules in the non-tumoral liver^[33,35-37]. Overall, this picture strongly suggests that the origin of these

tumors lies in a HPC that has undergone malignant transformation while differentiating in both the hepatocytic and biliary lineages. It is not completely excludable that the cholangiocellular components are directly derived from the hepatocellular components or *vice versa*, but this can not account for the presence of tumor cells with morphological, immunohistochemical and architectural features reminiscent of HPCs and reactive bile ductules.

CHCs that consist (almost) completely of such transitional areas and contain only very limited or no unequivocal hepatocellular and cholangiocellular components have been designated as “primary liver carcinoma of intermediate (hepatocyte-cholangiocyte) phenotype” and they are thus also likely to have a HPC origin^[37,38]. However, only a few cases of this type of tumor have been described, so it is currently not clear whether this third CHC subtype has clinical and prognostic features that are distinct from the second subtype of CHCs.

In contrast, there exist several rather large studies (i.e. at least 20 patients) on the clinicopathological features of the second type of CHCs, including a comparison with HCC and cholangiocarcinoma^[35,39-42]. Although the results of these studies are conflicting regarding the associations with cirrhosis and hepatitis B or C infection, there is a general consensus that these CHCs are almost always invasive and have a prognosis that lies in between that of HCC and cholangiocarcinoma. A recent study has nicely revealed that CHCs with an extensive cholangiocellular component are more frequently invasive and metastatic to lymph nodes and have a worse prognosis than those with a limited cholangiocellular component^[35]. So, it is the extent of differentiation towards the biliary lineage rather than the HPC origin as such that determines the specific prognostic features of this type of tumor.

CHOLANGIOCARCINOMA

The issue of whether some cholangiocarcinomas could arise from HPCs rather than from mature cholangiocytes has not yet been investigated in detail. It has been shown that cholangiocarcinoma can originate from HPCs in some animal models^[43,44] and a considerable proportion of human cholangiocarcinomas express the neural cell adhesion molecule, which is a marker for reactive bile ductules not present in mature cholangiocytes^[45]. However, more studies are needed before statements regarding the HPC origin of cholangiocarcinoma can be made.

CONCLUSION

The available data strongly suggest that most CHCs arise from HPCs. Furthermore, HPCs could also be the basis of some HCCs and hepatocellular adenomas, although it is very difficult to determine the origin of a specific, individual HCC. There is currently not enough data to make statements regarding a HPC origin of cholangiocarcinoma. The presence of HPC markers and the presence and extent of the cholangiocellular component are factors that are related to the prognosis of HCCs and CHCs, respectively.

Abstract

This review focuses on current aspects of the novel technology of combined impedance manometry for esophageal motility testing. It presents methodological features, summarizes current results and discusses implications for further research. The combined technique assesses simultaneously bolus transport and associated peristalsis, thus allowing detailed analysis of the relationships between bolus transit and esophageal motility. Recent studies demonstrate that combined impedance manometry provides important additional information about esophageal motility as compared to conventional manometry: (1) monitoring of bolus transport patterns, (2) calculation of bolus transit parameters, (3) evaluation of bolus clearance, (4) monitoring of swallow associated events such as air movement and reflux, and (5) investigation of the relationships between bolus transit and LES relaxation. Studies with healthy subjects have identified several useful parameters for comprehensive assessment of esophageal function. These parameters were found to be pathological in patients with classical achalasia, mild GERD, and ineffective esophageal motility. The technology of combined impedance manometry provides an important new tool for esophageal function testing, advancing both clinical and basic research. However, several important issues remain to be standardized to make the technique suitable for widely clinical use.

INTRODUCTION

The basic function of the esophagus is the transport of the bolus from the pharynx into the stomach. Esophageal peristalsis is based on propulsive mechanisms along the axis of the organ, generated by a latency gradient that is modulated by the inhibitory neurotransmitter nitric oxide^[1-3]. Much is known about the physiological and pathological phenomena of peristalsis based on intraluminal manometry^[4], and up to now, this technique is the standard method to study esophageal motility^[5-7]. But until recently, the relationships between peristalsis, intrabolus forces and bolus transport could be assessed by radiological contrast studies only^[8-10]. For this purpose, other technologies have emerged, such as ultrafast computed tomography^[11,12], intraluminal high frequency esophageal ultrasonography^[13], and topographical esophageal manometric methods^[14]. However, these techniques are expensive, require specific technical support and personal expertise, and do not clarify some details of bolus transport along the esophagus.

In 1991, Silny described a new catheter-related procedure for high-resolution measurements of gastrointestinal motility and bolus transport based on intraluminal measurements of electrical impedance^[15]. Subsequently, this technique was validated by means of manometry and videofluoroscopy studies^[16-18] and it was applied for studying of intestinal chyme transport^[19,20], for monitoring of reflux^[21-23], and for evaluation of esophageal bolus transport^[24].

However, the impedance technique alone also has some limitations. The contraction amplitude, an important parameter in predicting organ function, cannot be determined^[25]. Impedance measurements without manometry can underestimate some aspects of the relationships between esophageal wall movement and bolus motion, especially in patients with dysphagia or chest pain. In order to cope with these difficulties, a second generation of impedance catheters was developed^[26]. The catheter integrates impedance monitoring and manometry

in a single device. Thus, both tests can be performed simultaneously and the relationships between the dynamics of bolus transport and wall motion can be analysed well, while the quality of recording is maintained.

Recently combined impedance manometry has been increasingly applied for esophageal motility testing^[27-36]. This report summarizes current results and discusses future prospects of this novel technique.

SCIENTIFIC BASICS

The method is based on the esophageal intraluminal measurement of electrical impedance and pressure between a number of arranged impedance electrodes and pressure sensors during a bolus passage using an intraluminal probe (Figure 1).

The intraluminal electrical impedance is inversely proportional to the electrical conductivity of the luminal contents and the cross-sectional area (Figure 1). Compared to the muscular wall, air has a lower electrical conductivity and yields increased impedance. In contrast, saliva or nutrients show a higher conductivity and therefore cause an impedance drop at the corresponding measurement segments. On the other hand, luminal dilatation results in an impedance drop, whereas luminal narrowing causes an increase in impedance^[15].

The bolus passage along each measured segment allows the delineation of the typical tracing of impedance, which includes a maximum of five phases (Figure 2, upper panel): (1) phase 1 is the resting stage of the organ; (2) phase 2 represents the facultative arrival and passage of an air volume ahead of the bolus; (3) phase 3 is associated with the arrival and the passage of a bolus. The initial rapid fall of impedance is associated with the arrival of the bolus front as bolus entry (F-Point). During the subsequent nearly plateau phase the bolus is mainly located within the measuring segment; the minimum impedance during this phase represents the bolus body (B-Point); (4) during phase 4 the bolus leaves the measuring segment as bolus exit due to wall contraction with facultative lumen occlusion, which can be represented by the maximum impedance (C-Point); (5) phase 5 is the transitory stage to resting stage. This characteristic impedance wave form may change in the case of absence of air in front of the bolus or absence of a lumen-occluding contraction wave (Figure 2, upper panel). For visualization of the maximum and minimum impedance values an individual scaling (Figure 2, lower panel, left side) can be used instead of the standard scaling (Figure 2, lower panel, right side).

The F-Point, B-Point and C-Point can be determined by computer assistance according to the presumed definitions, as shown in Figure 3, left panel. Alternatively, bolus entry and exit have been defined as follows^[33,34]: Bolus entry is considered to occur at the 50% point between impedance baseline and impedance nadir during bolus passage, and bolus exit is determined as 50% point on the impedance recovery curve, as shown in Figure 3, right panel.

EQUIPMENT AND TECHNOLOGY

There are two prototypes of combined impedance

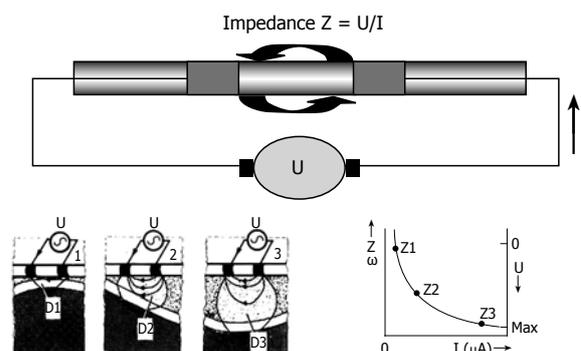

Figure 1 Upper panel: Principles of intraluminal impedance manometry: the electrical impedance (Z) of a electric field between 2 electrodes is the ratio between applied voltage (U) and resulting current (I). Lower panel: Impedance is non-linearly inversely dependent on bolus diameter and electrical conductivity of luminal content.

manometry catheters available (Figure 4)

(1) 15-channel esophageal function testing catheter^[26-30]: the impedance-manometry catheter is a polyvinyl catheter with an external diameter of 2.5 mm. The catheter consists of 11 impedance segments (each 2 cm long) and 4 semiconductor solid-state pressure transducers to register the manometry tracings. The solid-state pressure transducers are located at the junction between the impedance channels 1-2, 4-5, 7-8, and 10-11, with an intertransducer distance of 6 cm (Figure 4, left panel). (2) 9-channel esophageal function testing catheter^[31-35]: it incorporates five pressure (two circumferential and three unidirectional) sensors and four impedance-measuring segments. The two circumferential solid-state pressure sensors are located at 5 cm and 10 cm from the tip and three unidirectional pressure sensors at 15, 20, and 25 cm. Impedance measuring-segments consist of pairs of metal rings placed 2 cm apart, centered at 10, 15, 20 and 25 cm from the tip, thus spanning the four proximal pressures transducers (Figure 4, right panel).

The first system^[26-30] displays a cascade configuration of the impedance measuring segments similar to the systems used in previous impedance studies for the study of bolus transport^[19,20,24] and for monitoring of reflux^[21,22]. The pressure transducers also serve as impedance electrodes and are located exactly at the junction between 2 adjacent impedance segments (the end of one segment and beginning of the adjacent segment). In contrast, in the other system^[31-35] the impedance segments are arranged at an intersegmental distance of approximate 2 cm. Furthermore, the pressure transducers are located inside the impedance segment.

STUDY PROTOCOLS

The procedure is very similarly to standard manometry. The patients are asked to fast for at least 8 h before recording. In the sitting position, the recording assembly is passed nasally and positioned with all sensors in the stomach. The intragastric pressure is set as baseline pressure. With the subject lying in the supine position and after a 10-min accommodation period, a station pull-through is performed to accurately locate the LES

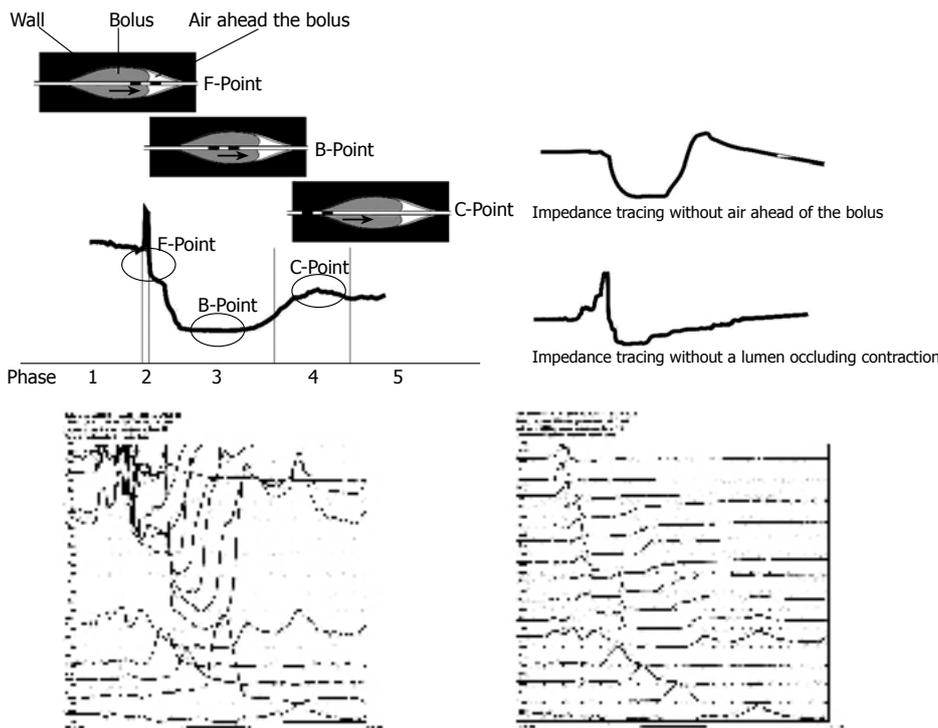

Figure 2 Upper panel: Characteristics of the impedance tracing during bolus passage in the esophagus of healthy persons. The black electrodes indicate a measuring segment. From baseline, the initial sudden impedance increase represents the arrival of ingested air ahead of the bolus. During the rapid impedance fall due to the arrival of the bolus, the bolus head (F-Point) can be determined as the return of impedance closely to baseline. The bolus passage is represented by a further decrease of impedance followed by a plateau phase. During the plateau phase (phase 3) the bolus is located within the measuring segment. The minimum impedance value during this phase is related to the maximum bolus volume located within the segment, which represents the bolus body (B-Point). Subsequently impedance increases due to wall contraction and the bolus is leaving the segment. The maximum value during impedance increase back to baseline is associated with the moment of lumen occlusion (C-Point). Dependent on bolus volumen and bolus viscosity the exact position of the points of interest is variable as indicated by the oval circle. The impedance tracing may be variable as shown at the right side without air ahead of the bolus or without a rapid lumen occluding contraction. Lower panel: For visualisation of the minimum and maximum impedance an individual scaling (left side) can be used instead of a normal scaling (right side).

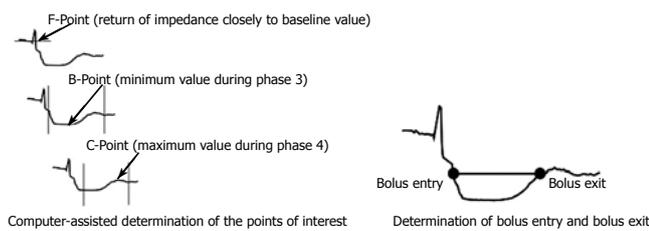

Figure 3 Upper panel: computer assisted determination of the points of interest according to presumed definitions as suggested by Nguyen *et al*^[24,27,29]. Lower panel: bolus entry and bolus exit can be considered to be 50% of the basal impedance as compared to nadir impedance as suggested by Tutuian *et al*^[32,33,34].

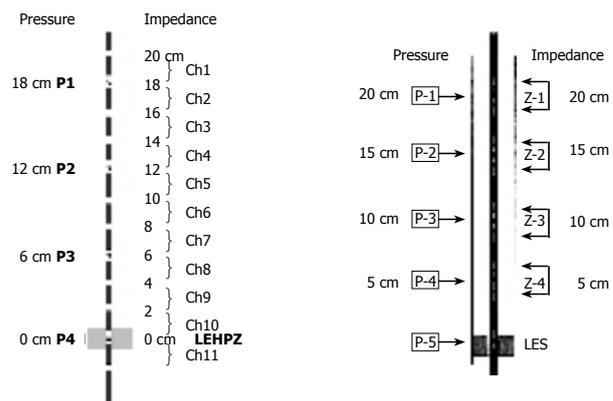

Figure 4 The 2 recently available systems of combined impedance manometry. During esophageal motility testing the most distally located pressure transducer was positioned at the lower esophageal high pressure zone. Left panel: 15 channel catheter for combined impedance-manometry procedure. The 4 semiconductor solid-state pressure transducers (P1-P4) serve also as impedance electrodes and are placed at 6 cm distance each. There are 11 impedance segments, each 2 cm long (Ch1-Ch11) with a cascade configuration. The solid-state pressure transducers (P1-P4) are located exactly between the impedance channels 1-2, 4-5, 7-8 and 10-11, respectively. Right panel: 9-channel esophageal function testing catheter with five pressure sensors and four impedance-measuring segment. The impedance measuring-segments consist of pairs of metal rings placed 2 cm apart, centered at 10, 15, 20 and 25 cm from the tip (Z1-Z4). Four of five the pressure sensors are located within the impedance segments (P1-P4). The 5th pressure sensors (P5) is located 5 cm from the tip.

position. The most distal pressure sensor is placed at the level of the LES at the point at which the highest sphincter pressure is obtained during the pull-through procedure, the so-called lower esophageal high-pressure zone (LEHPZ).

To evaluate esophageal peristalsis and its associated bolus transport, liquid boluses (5 mL or 10 mL physiological saline) and semisolid boluses (5 mL standard viscous material provided by Sandhill Scientific Inc. or 10 mL of a commercially available plain yogurt, Morbo, Borken, Germany) are administered. The boluses are dispensed into the mouth with a syringe and the swallows are performed on command. All swallows are separated by at least 30 s during which no esophageal peristaltic occurs. An event marker is used to denote each swallow event. When a second swallow is incidentally initiated within 20 s of the primary event, both swallows are excluded from analysis. For each investigation, the baseline impedance is determined as the first predeglutitive impedance. After each yogurt bolus, at least 2 swallows of water are administered to clear small amounts of bolus material attached to the probe, until the impedance returns closely to baseline ($\leq 5\%$ deviation).

PHYSIOLOGICAL OBSERVATIONS

With combined impedance manometry 3 different features of bolus transport can be obtained during swallowing (Figure 5): (1) monitoring of bolus transport patterns, (2) calculation of bolus transport parameters, and (3) monitoring of swallow associated events. These features can not be obtained by conventional techniques such as manometry or fluoroscopy.

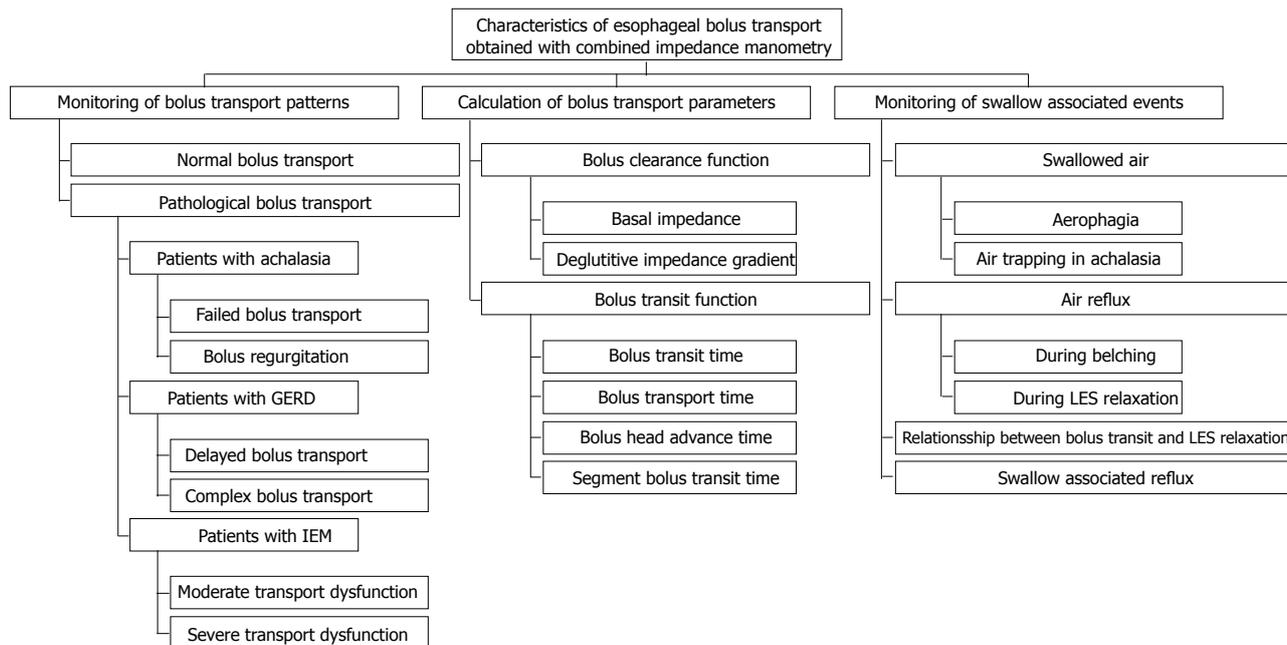

Figure 5 Characteristics of bolus transport as obtained by combined impedance manometry.

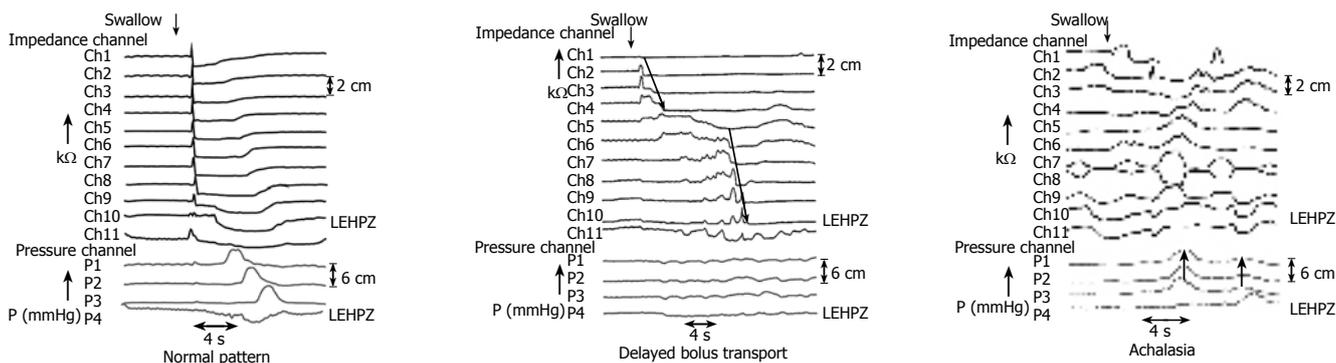

Figure 6 Bolus transport patterns as obtained by combined impedance manometry normal pattern (left panel), delayed bolus transport (middle panel) in some patients with GERD, failed transport (right panel) in patients with achalasia.

Monitoring of esophageal bolus transport patterns (Figure 6)

Recent results indicate that monitoring of bolus transport patterns may be helpful for the characterization of pathological esophageal bolus transport. (1) Healthy subjects show characteristic impedance patterns of continuous bolus transit through the esophagus into the stomach; (2) In patients with achalasia the manometry patterns are unique, while the impedance patterns are very variable^[28]. Different pathological patterns of bolus transport have been observed in patients with achalasia. They are (a) failed swallow-induced bolus transport through the esophagus in all cases, and (b) impedance evidence of luminal content regurgitation together with excessive air trapping. The results may explain some symptoms in achalasia, including chest pain and regurgitation; (3) In patients with GERD several pathological bolus transport patterns types have been described^[29], including failed bolus transport, delayed bolus transport, and complex bolus transport. The contribution of these phenomena and the clinical significance regarding to dysphagia symptoms remains to be determined.

Calculation of bolus transport parameters (Figure 7)

(1) Baseline impedance: It has been shown that there is a significant difference between gastric and esophageal baseline impedance in healthy subjects^[27] and a significant difference of esophageal baseline impedance between healthy subjects and achalasia patients^[28]. The results indicate that this parameter may be used to describe the esophageal resting state, including lumen width and filling state, particularly in minimal disease states. (2) Deglutitive impedance gradient: It has been shown that the postdeglutitive impedance is significantly lower in GERD patients as compared to healthy subjects, indicating that the deglutitive impedance gradient can be used to assess the propulsive esophageal clearance function^[29]. For correct calculation of this parameter, repetitive clearing swallows between test swallows are necessary^[29]. This parameter should be evaluated and standardized in further studies to determine its clinical significance for the definition of complete bolus transit. (3) Parameters of bolus transport: Several parameters can be calculated during impedance studies, i.e. propulsion velocity or transit time of bolus,

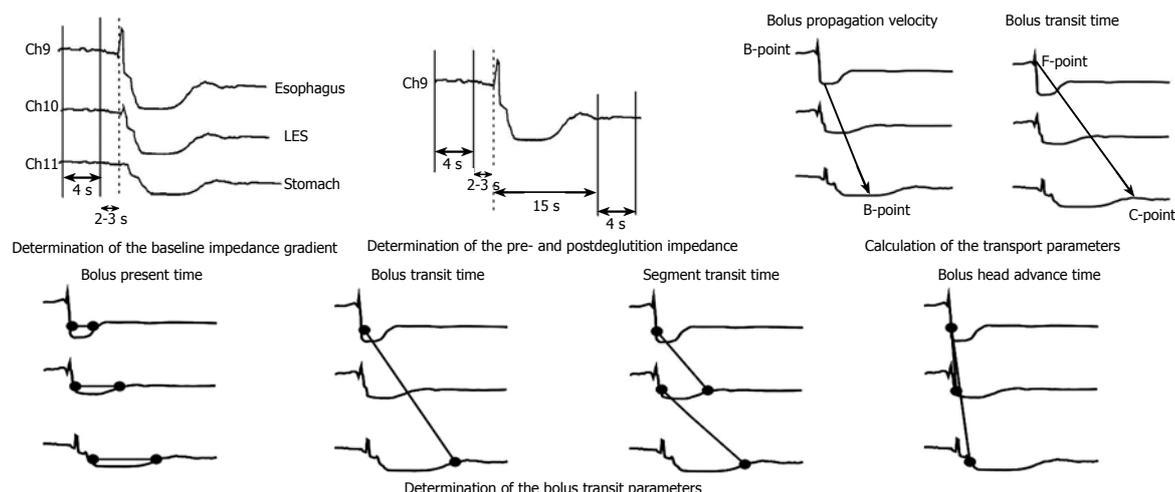

Figure 7 Bolus transport parameters, which can be obtained by combined impedance manometry according to presume definitions of the points of interest.

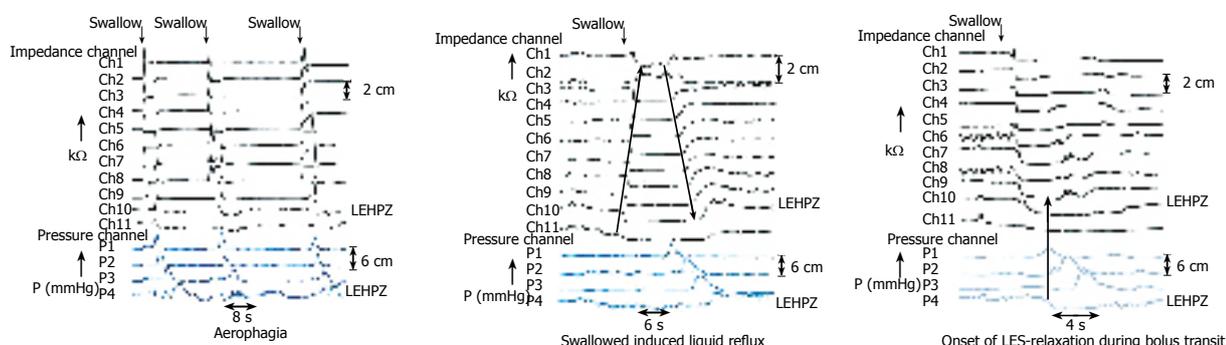

Figure 8 Swallow associated events as obtained by combined impedance manometry are aerophagia (left panel), swallow induced reflux (middle panel), relationship between bolus transit and LES-Relaxation (right panel).

bolus head and bolus tail^[24,27,29] or total bolus passage time, bolus head advance time, bolus presence time, and bolus transit time^[32-34]. The dynamics of the bolus transport along the esophagus has been described in detail^[24]. These parameters clearly discriminate liquid from semisolid boluses and show that bolus transport depends on both test substance and body position^[24,31,32]. (4) Quantitative data in healthy subjects indicate that impedance and manometry provide independent parameters of esophageal motor function^[27,33]. There is no clear correlation between contraction amplitude and bolus propagation velocity^[27]. As normal esophageal volume clearance may occur within a wide range of peristaltic amplitudes^[8], it is possible that after a critical pressure, excess amplitude does not appear to be needed to move the bolus. (5) Quantitative data in patients with mild GERD demonstrate delayed bolus transit in patients with non-erosive GERD and GERD grade I, indicating that combined impedance-manometry may increase the sensitivity for detection of minor motility abnormalities^[29]. (6) Quantitative data in patients with ineffective esophageal motility^[34] indicate that presumed "ineffective" low-amplitude esophageal peristaltic contractions of < 30 mmHg^[37] may be associated with a substantial number of complete transit: 23 patients (3.9%) had normal bolus transit for both liquid and viscous swallows, 12 patients (17.1%) had normal bolus transit

for liquid swallows and abnormal bolus transit for viscous swallows, and 10 patients (14.3%) had normal bolus transit for viscous swallows and abnormal bolus transit for liquid, whereas 25 patients (35.7%) had abnormal bolus transit for both liquid and viscous. The results indicate that combined impedance manometry better describes and classifies patients with ineffective esophageal motility according to severity: no functional abnormalities with normal transit, moderate functional abnormalities with abnormal transit either for liquid or viscous boluses, and severe functional abnormalities with abnormal bolus transit for both liquid and viscous boluses.

Monitoring of swallow-associated events (Figure 8)

(1) Movement of air during swallowing: In early studies it was shown that one advantage of the impedance technique is the monitoring of air movement during swallow and LES-relaxation^[24]. Recent studies have expanded the finding of esophageal air movement in patients with achalasia, so-called air trapping^[28], as well as during aerophagia^[36]. The clinical significance of this phenomenon as a cause of dysphagia remains to be determined. (2) Swallow-associated reflux: Different types of reflux have been observed in patients with GERD during swallowing^[29]: (a) liquid reflux initiated by a swallow and preceding the regular bolus transport, (b) liquid reflux

following a swallow-induced regular bolus transport, and (c) spontaneous liquid reflux initiating a clearing swallow. Since conventional 24-h pH-monitoring does not differentiate between fasting and deglutition associated reflux, the prevalence of these impedance phenomena and their relevance for mucosal damage have yet to be defined. (3) Relationships between bolus transit and LES relaxation: Our recent study^[30] revealed close relationships between bolus transit and LES relaxation. In 76% of the cases LES relaxation occurs during bolus transit, when the position of the bolus is very close to the LES. The results indicated that LES-relaxation may be partially initiated by bolus transit. The clinical significance of this finding for characterization of patients with LES-dysfunction other than achalasia - such as hypertensive LES or poorly relaxing LES - should be evaluated. Using high-resolution impedance monitoring, the opening patterns of the esophageal gastric junction during deglutition and transient lower sphincter relaxation have been studied recently^[37].

CLINICAL RELEVANCE

Clinical studies showed that combined impedance manometry is particularly suitable for comprehensive esophageal motility testing and monitoring of bolus transport patterns. With impedance different aspects of bolus transport can be obtained: (1) normal and pathological bolus transport patterns including bolus escape and retrograde bolus transport can be monitored, (2) several parameters of bolus transit can be calculated allowing differentiation between normal and abnormal bolus transport, (3) parameters related to bolus propulsive clearance and bolus transit completion can be determined, (4) swallow-associated events such as normal and pathological air movement as well as pathological reflux can be monitored, and (5) the relationship between bolus transit and LES relaxation can be investigated. Thus, using combined impedance manometry complete data about esophageal motor function and associated bolus transport can be obtained during a single investigation. In patients with achalasia the technique provides additional information about the functional status and may explain some symptoms in these patients. However, the gold standard for diagnosis of achalasia remains manometry due the clear definitions and the unique manometry patterns. In patients with GERD combined impedance manometry provides additional information about mechanisms related to disturbed bolus transit and bolus clearance. In patients with ineffective esophageal motility it helps clarifying the associated functional abnormalities. Thus, combined impedance manometry is on the way to be an important tool for obtaining detailed information about the physiology and pathophysiology of esophageal motility. The potential clinical implications of this technique include (1) the functional classification of esophageal motor disturbances in patients with non-obstructive dysphagia; (2) the perioperative management of laparoscopic fundoplication and other (endoscopic) antireflux procedures and (3) the evaluation of pharmacological approaches to esophageal motility and bolus transport.

FUTURE PROSPECTS

However, the studies also indicate that standardization of experimental set-up including equipment, study protocols, and particularly analysis algorithms with definition of the events of interest are important to make the data reproducible and the interpretation of the results more concise. There are important issues to be solved in order to make the technique more reliable and suitable for routine clinical use.

The equipment, particularly the spatial arrangement of impedance segments and pressure transducers should be clarified, because this is the most important determinant for the analysis of the relationship between manometric and impedance events during simultaneous monitoring. Since bipolar impedance measurements are performed between two electrodes, the impedance values obtained are the results of an integrative change of intraluminal electrical conductivity and cross-sectional area in the whole 2 cm segment. This should be kept in mind as an important aspect that differs from point manometry. At each corresponding impedance segment there is a 2 cm distance between the bolus entry point (first electrode) and the bolus exit point (second electrode). In case that the pressure transducer is located at the end of an impedance segment^[27,29,30], the impedance and manometric timing of bolus exit are approximately identical. If the pressure transducer is located inside the impedance segments^[33-35], the manometry bolus tail is not identical with the impedance bolus tail, as the bolus has not yet left the segment. The appropriate number of impedance segments is another issue. With both available systems several parameters of bolus transport can be obtained. The 15-channel system allows a detailed monitoring of bolus transport patterns and associated events^[24,27-30]. It remains to be determined, if these features are clinically significant. In contrast, the 9-channel system allows a significant reduction of data acquisition and reduces production costs, thus it is now available for routine clinical use^[31-34].

The analysis algorithm including the definition of bolus entry and bolus exit points should be refined. Since impedance is non-linearly dependent on different parameters around the electrodes such as lumen width and electrical conductivity of luminal contents, the interpretation of impedance tracings is based on impedance changes from variable levels and not from fixed calibrated points: (1) relative impedance changes as compared to baseline or extreme values (maximum and minimum) should be used in favour of absolute values as normally seen in manometry; (2) a small amount of a highly conductive substance may yield the same impedance change as a great amount of a low conductive substance, particularly if the conductivity of luminal contents is highly variable, i.e. gastric contents during reflux or duodenal contents during gastric emptying^[38,39], or when different test substances are employed^[27,29,33,34].

In the early studies^[24,27,29] the points of interests were determined visually with computer assistance according to a presumed definition of these points based on theoretical considerations and small validation studies^[15,16]. The analysis is time consuming and therefore not appropriate

for large routine studies. In later studies^[33,34], bolus entry is considered to occur at the 50% point between impedance baseline and impedance nadir during bolus passage, and bolus exit is determined as 50% point on the impedance recovery curve. This analysis algorithm is simplified and computerized calculation is possible. However, these conventions may have to be refined. Since the same level of impedance was used both for the bolus head (bolus entry) and the bolus tail (bolus exit), and both for liquid and viscous boluses, this definition implied that bolus geometry remains constant independent from bolus characteristics and that the forms of bolus head and tail are identical, or that the bolus is symmetric, respectively. However, fluoroscopic studies^[8] have demonstrated that both conditions are not relevant to real life. Considering the impedance tracing during a bolus passage, bolus entry is associated with a very rapid drop of impedance. In this setting, 5%-10% variation in impedance will not yield significant differences regarding the determination of the bolus head. Therefore, this convention appears to be suitable for determination of the bolus entry. In contrast during bolus exit, impedance increases slowly, and 5%-10% variation will result in significant differences regarding the determination of the bolus tail. Therefore, constant impedance levels may not be appropriate to describe bolus transport under various conditions, particularly for the definition of bolus exit as a parameter for completion of bolus transit^[33,34]. Further studies are needed to reach consent on this critical issue.

The study protocols should be standardized and include characteristics of the test substances (viscosity and volume) and information on body position, all of which have been identified as determinants of impedance in several studies^[24,27,31,32]. Considering the bolus viscosity, a commercially available test substance with constant viscosity and electrical conductivity should be used as standard^[33,34]. Considering the test volume, both 5 mL or 10 mL are used^[24,27,33,34]. Traditionally, the 5-mL test volume is used to induce an appropriate manometric esophageal response to a swallow. It has been shown that during deglutition different amounts of air are swallowed together with the bolus^[12], which may interfere with impedance recording. According to our personal experience, 10 mL seems to be an appropriate volume^[15,16], because the larger volume reduces air swallows that might interfere with impedance recording. Since body position affects the impedance of bolus transport^[24,32]-which seems to depend on the degree of inclination as a result of the addition of gravity to bolus propulsion-studies may be performed with subjects at supine or recumbent position to eliminate this gravity affect.

More clinical studies are required to prove if combined impedance manometry effectively helps to improve our management of patients with esophageal symptoms, as did manometry in patients with achalasia several decades ago.

Abstract

Several clinical reports confirmed that gastric atrophy is a pathology not only limited to adult patients. In pediatrics, it is most often described in association with a *H pylori* infection but this bacteria does not seem to be the only etiological factor of this preneoplastic state in children. The frequency of gastric atrophy and intestinal metaplasia in children are unknown because they are not systematically sought during upper gastrointestinal endoscopy. The lack of specific histological classification of children's gastropathies makes their diagnosis difficult for pathologists. Based on our knowledge to date, we think that it is necessary to describe, in detail, the natural course of this lesion during childhood. A close and prolonged clinical and endoscopic follow-up is important for children with gastric atrophy.

INTRODUCTION

The discovery of *H pylori* in adult patients by Warren and Marshall^[1] was a major event in modern gastroenterology, rewarded with the Nobel Prize in 2005, and strongly stimulated paediatric studies focused on gastroduodenal pathology. The presence of this microorganism in children's stomachs was described several years after it was found in adults. In fact, up to that time, gastric biopsy had never been a priority for paediatricians because of the

low frequency of gastroduodenal pathologies in children and the non existence of gastric cancer at this age of life. On the contrary, gastric atrophy is systematically sought for in adult stomach biopsies because of cancer pathology. Its histological diagnosis is based on the updated Sydney System^[2]. During the last few years, several publications reported the presence of this preneoplastic state in children and the search for *H pylori* during endoscopy contributed to the improved knowledge of histological lesions of gastric mucosa in pediatrics. However, uncertainty persists regarding histological criteria of chronic gastritis in children, its long term course, its relationship with intestinal metaplasia in adults^[3,4] as well as the responsibility of other etiological agents other than *H pylori*.

GASTRIC ATROPHY IN PEDIATRICS

Several clinical reports confirmed that gastric atrophy is a pathology not only limited to adult patients^[5-9]. However, because of the non-systematic search during pediatric gastroscopy for this histological state considered as preneoplastic in adults^[3,4,10,11], its prevalence is not well evaluated in pediatrics, varying from 0 to 72% according to different studies (Table 1). Moreover, published clinical data refer mainly to *H pylori*-infected children and therefore, the prevalence of gastric atrophy due to other etiologies is unknown at this time. Finally, the reported prevalence of gastric atrophy and intestinal metaplasia (IM) in pediatric studies includes all histological grades, whereas in the majority of adults' studies only medium and severe grades are considered; this could be a possible source of overestimation.

A recent Turkish study reported prevalence of 72% of gastric atrophy in a small series of 18 *H pylori*-infected patients^[6]. This study was performed in a country with a very high *H pylori* prevalence ranging from 43.9% to 53% and a relatively high age of the recruited patients (median age of 12.2 years) which incites one to think that such a severe mucosal alteration could be related to a prolonged disease duration, in predisposed individuals^[6,16], as it has been suggested in adults^[17,18]. However, a selection bias cannot be excluded because another Turkish group, which examined gastric biopsies of 175 *H pylori* positive children, found only five cases of gastric atrophy and/or IM corresponding to a lower prevalence of 2.8%^[8]. Authors of studies carried out in other countries, who focused on *H pylori*-positive children, reported gastric atrophy in a very limited number of cases varying from 0 to 4%^[13,14,19,20].

Gastric atrophy of young children was only described in five cases^[5,7]; two were one year-old infants and two others were two year-old patients. Those observations do

¹IM: Intestinal metaplasia. Hp: *H. pylori*

not call into question the hypothesis of Correa *et al.*^[4] about the progressive, stepwise installation of precancerous lesions but they incite one to think that individual susceptibility to those premalignant lesions probably exists. In fact, it is probable that genetic and environmental factors do not only participate in the pathogenesis of gastric atrophy in adults^[21] but also in children. This was shown in the study by Campbell *et al.*^[14], which was carried out within the West African population where the infection rate with *H. pylori* is one of the highest in the world (70% to 90%), yet did not describe any cases of gastric atrophy. This phenomenon was called “the African enigma”. To our knowledge, there is no pediatric study, comparing by using the same methodology, the prevalence of gastric atrophy in a population according to its geographic/genetic origins or environmental factors.

Cases of intestinal metaplasia in stomach, which is also considered as a precancerous lesion in adults^[3,4,10,11], were more rarely reported in pediatric patients^[6,8,15] (Table 1). According to some authors, intestinal metaplasia is never associated to *H. pylori* infection^[5,13,14,19], whereas others point out its frequency to be lower than 5% among infected patients^[8,15,20,22]. In contrast with this very low rate, Guarner *et al.*^[7] reported a prevalence of 21% which brings one to think that an obvious relationship exists between *H. pylori* gastritis and intestinal metaplasia.

ARE SPECIFIC HISTOLOGICAL CRITERIA FOR PAEDIATRIC ATROPHIC GASTRITIS AVAILABLE?

Up until now, no specific histological classification of children’s gastropathies has been validated^[23]. By extension with adult gastropathies, in clinical practice, the Updated Sydney System is widely used^[2]. Its main

purpose is to allow for pathologists to establish a severity classification by visual comparison between the sampling and the published diagrams by Dixon *et al.*^[2]. This essential publication defines gastric atrophy as glandular loss of mucosa which is replaced either by fibrous tissue or by intestinal metaplastic cells. However, the interposition of inflammatory cells between the stomach’s glandular cells may inappropriately orientate the pathologist to the diagnosis of atrophy, where one is not present. Sampling interpretation is observer-dependent and this was emphasized by several studies^[1,3,24,25]. Without strict validated criteria, the severity assessment of gastric atrophy remains subjective and not easily reproducible^[26].

The authors of the same study recommend to perform five gastric biopsies in adults (2 antral, 2 corporeal and one from the angulus) for histological analysis but no consensus is available about the optimal number of biopsies needed in children. Clinical practices in this domain are very heterogeneous, which may be responsible for the underestimation of the prevalence of atrophic gastritis in children. To this end, Bedoya *et al.*^[26] performed only two gastric biopsies in the diagnosis of 175 cases of *H. pylori* gastritis, whereas Guarner *et al.*^[7] as well as Derambure-Wizla *et al.*^[27] carried out 3 or 4 biopsies for series of 64 and 436 children, respectively. In light of these studies and the Dixon’s recommendations^[2], it is probable that the multiplication of gastric biopsies is an essential factor for a positive diagnosis and severity assessment of gastric atrophy in children.

Regarding intestinal metaplasia with a patchy distribution throughout the gastric mucosa^[2,7], the situation is similar and it may be easily missed if not enough gastric biopsies are taken. In contrast to gastric atrophy, metaplastic epithelium is easily detected by the pathologist, owing to the very characteristic goblet cells^[2].

However, endoscopy for younger children cannot be

as frequently performed as in adult patients. Less invasive procedures for detecting histological modifications of gastric mucosa could be valuable in the clinical practice. In adult patients, it has been shown that gastric atrophy was responsible for loss of production of hydrochloric acid, decreased serum levels of pepsinogen I and increased gastrin serum levels^[28]. Probably, hypergastrinemia could be a valuable marker for gastric atrophy in pediatrics, in order to select patients for further investigation by gastroscopy^[29]. It was also hypothesized that low levels of gastric acid secretion were a factor in the development of gastric atrophy in adults^[30] but no evidence for this hypothesis was published regarding pediatric patients. Due to the low prevalence of gastric atrophy during childhood, it would be difficult to validate these potential screening tests for children.

ARE THERE SPECIFIC FEATURES FOR CHILDREN'S GASTRIC ATROPHY?

Even though reported frequencies of gastric atrophy and intestinal metaplasia in children are extremely variable depending on authors (Table 1), they are definitely lower than those in adults^[31-35], thus some authors do not confirm their existence^[22,36,37]. It seems that in the series where the median age is higher, the prevalence of gastric atrophy is also increased. It is plausible that the duration of *H pylori* infection in childhood may explain this phenomenon^[38].

No specific clinical symptoms are noted in adults and children. In most pediatric cases, its diagnosis is established in relationship with upper gastrointestinal symptoms^[39], but the prevalence of asymptomatic cases is unknown.

The main histological differences between atrophic gastritis of children and adults seem to be related to the characteristics of inflammatory response accompanying mucosal atrophy. In most series comparing children and adults, the degree of gastric mucosa colonisation by *H pylori* seems to be significantly more important in children. However, the severity of the inflammatory response remains controversial depending on the authors' findings. Whitney *et al*^[5] reported a higher gastritis activity in adults compared to children, whereas Meining *et al*^[22] concluded that gastric inflammation is very severe in the pediatric age group. The absence of standards to measure inflammation could explain those differences. This highlights the importance of generalising the use of the Updated Sydney Classification for the assessment of gastric inflammation (not used by Meining). Finally, the study by Campbell *et al*^[14] carried out in Western Africa, using the Updated Sydney System, confirms some of the conclusions by Whitney: severity of gastric inflammation is more important in adults than in children, while differences in the degree of mucosal colonization by *H pylori*, between children and adults, was not found.

IS *H PYLORI* THE ONLY RESPONSIBLE AGENT FOR GASTRIC ATROPHY IN CHILDREN?

The role of *H pylori* as a main etiological agent in atrophic gastritis is indisputable. However, several observations of

Table 2 Studies reporting observations of atrophic gastritis in children without *H pylori* infection

Authors	Total of cases		atrophic gastritis Hp- (n)	Clinical symptoms (average age)

Hp: *H pylori*.

gastric atrophy in children without infection are reported^[6,7,9] and Table 2). It seems logical to suspect the existence of other etiological factors responsible for gastric atrophy. In adults, Kuipers *et al* reported that patients receiving omeprazole for long periods of time presented with a higher risk to develop gastric atrophy, yet in their series, all patients were *H pylori*-positive^[40,41]. Those data were not confirmed in more recent studies^[42-44] and to date, proton pump inhibitors (PPI) are not considered as responsible for gastric atrophy in adults. To our knowledge, no cases of gastric atrophy attributable to PPI in pediatrics have been reported.

The hypothesis of an autoimmune disorder responsible for the appearance of antigastric antibodies was confirmed in adults. The frequency of those antibodies in patients with gastric atrophy may be as high as 50%^[45,46]. It has been reported that in some cases of severe gastric atrophy in adults, previously infected by *H pylori*, any infection stigmata may disappear when anti-gastric-parietal cell antibodies appear^[47,48]. The authors of those observations suggested that anti-gastric-parietal cells antibodies could be a biological marker for the severity of gastric atrophy. In contrast, very few pediatric data are available. The only clinical situation where anti-gastric-parietal cell antibodies were discovered was type I diabetes with a frequency of 6% but no cases of atrophic gastritis have been reported^[49-51]. Celiac disease is another cause of chronic gastritis with positive findings of anti-gastric-parietal cell antibodies in 10% of cases in adults^[52], but similarly, no pediatric data are available. The study by Kolho *et al*^[12] included sixty children with celiac disease but no cases of anti-gastric-parietal cell antibodies have been pointed out. Nevertheless, several anecdotic cases of autoimmune thyroiditis and juvenile hypothyroidism, some of which with achlorhydria and gastric antibodies have been reported^[53].

LONG TERM COURSE OF GASTRIC ATROPHY IN CHILDREN

The long term course of gastric atrophy in children is unknown. To our knowledge, no longitudinal study of this course, through to adulthood, has been published.

In adults, Correa *et al* suggested that chronic gastritis, gastric atrophy, intestinal metaplasia, dysplasia and gastric cancer develop stepwise over decades, in predisposed individuals infected by *H pylori*^[2,3]. However, observations of atrophic gastritis have been reported in very young children (Table 1), including the presence of intestinal metaplasia in pediatric patients. Therefore, the chronological sequence of appearance of those lesions is not respected in all the cases. The association of intestinal metaplasia with *H pylori* infection is variable and it is impossible to prove that intestinal metaplasia is preceded by gastric atrophy in all cases. The risk of cancer in adults grows proportionately with the histological progression of metaplasia (evaluated from I: mild to III: according Dixon *et al*^[54]). Gastric cancer is exceptional in pediatric population and only one case has been reported, involving a 15 years old boy who was not infected by *H pylori*^[55].

It is actually well established that only 1% of *H pylori*-positive patients will develop gastric cancer^[56], whereas infection starts almost all the time during childhood^[57-60]. The rarity of intestinal metaplasia and gastric cancer in the pediatric age group could probably be explained by the long time period necessary for those complications to appear as well as the absence of other cumulative factors for gastric cancer, during childhood.

Probably insufficient ingestion of vitamin C could contribute to the development of *H pylori* infection in children^[61] and in adults^[62-64] but its role in the genesis of gastric precancerous lesions is not clearly established^[63,65]. Moreover, the question of the spontaneous reversibility of gastric atrophy after *H pylori* eradication is frequently discussed.

It seems difficult or even impossible, because of evident ethical barriers, to investigate whether the eradication of *H pylori* during childhood would decrease the risk of gastric cancer during adulthood^[66].

CONCLUSION

Gastric atrophy exists in children and it is sometimes found in very young children. It is necessary to describe, in detail, the natural course of this lesion during childhood. A close and prolonged clinical and endoscopic follow-up is necessary for children with gastric atrophy. The efficiency of preventive strategy^[66] or screening of *H pylori* infection in evaluating the risk of gastric atrophy and cancer in adult age should be evaluated. Finally, it is necessary to identify, by means of multicentric studies, the other circumstances (excluding *H pylori*) predisposing to gastric atrophy and its evolutionary potential over decades.

Abstract

AIM: To investigate the expression of cyclin-dependent kinase inhibitors p21 and p27 in gastric well differentiated endocrine tumors (GWDET) (ECL-cell carcinoids).

METHODS: The expressions of p21 and p27 were examined immunohistochemically in endoscopic biopsy specimens from 16 patients matching the diagnostic criteria of GWDET. Percentage of positive nuclear staining either weak or strong was noted. The association of immunexpressions with age, gender, tumor localization, multifocality and accompanying chronic atrophic gastritis, neuroendocrine cell hyperplasia (NEH), neuroendocrine dysplasia (NED), intestinal metaplasia (IM), Ki-67 proliferation index and clinical outcome were also evaluated.

RESULTS: All cases expressed p27 with a mean expression score of 43.6%, while 31.3% of the cases showed any p21 expression. p21 and p27 immunexpressions were significantly correlated with each other ($P < 0.01$), and the p21-expressing group had higher p27 expression scores (68% vs 22%). p21 and p27 expressions were lower in women, in non-atrophic mucosa and cases whose tumors were located somewhere other than fundus without submucosal extension. On contrary, p21 and p27 expressions were higher in males and the patients with submucosal extension and atrophic gastritis. Cases presenting lower p27 scores had solitary tumors showing neither NEH-NED nor IM. Despite, cases with lower p21 expression presented multifocal tumors accompanied by NEH-NED. However, no correlation of p21 and p27 expressions was found with age and Ki-67 expression.

CONCLUSION: p27 is widely expressed in GWDETs, while p21 expression is sparse and observed in two thirds of the cases. Loss of p21 and p27 expressions may be correlated with different carcinoid tumor subtypes; however,

INTRODUCTION

Carcinoid tumors arise from proliferating enterochromaffin-like cells (ECL) of fundus. Elevated plasma gastrin levels are responsible of the neoplastic changes in these cells, but neoplastic transformation can also be observed in absence of hypergastrinemia as well. The overall incidence rates for carcinoid tumors have increased significantly over the past 25 years^[1]. Recent studies also suggest an apparent increase in incidence of gastric carcinoids which accounted about 2% of the total gastrointestinal (GI) carcinoids in the past but increased to a frequency of 7.2% to 30% in recent years^[2-5]. Increased awareness of the existence of these lesions as well as the improvements in upper GI endoscopy and more frequent application of immunohistochemical methods to biopsies are probably related to this trend. The causes of this inclination need further investigations, but the conclusion is clear that we have to cope with more endoscopic biopsies with neuroendocrine cell hyperplasia and tumors. The role of the pathologist is not only to diagnose the lesion but also provide the histopathologic data that will help to determine the management strategies.

Well differentiated endocrine tumor (WDET) is proposed as synonymous with the time-honoured term "carcinoid" according to the last WHO classification of the endocrine tumors of the GI tract (Table 1) and defined as "an epithelial tumor of usually monomorphous endocrine cells showing mild or no atypia and growing in the solid nests and trabeculae or pseudoglandulae, restricted to the mucosa or submucosa"^[6]. Further WDET's of stomach are ECL-cell carcinoid, EC-cell, serotonin-

producing carcinoid, G-cell gastrin-producing tumors and others^[6]. ECL-cell carcinoids clinically has three distinctive types: Type 1 which is associated with chronic atrophic gastritis with or without hypergastrinemia; Type 2 with hypertrophic gastropathy with high gastrin levels; and Type 3, sporadic form, associated with neither atrophy nor hypergastrinemia^[7]. Gastric well differentiated endocrine tumors (GWDET) are benign, non-angioinvasive tumors, measuring ≤ 1 cm in size and showing ≤ 2 mitoses per 10 high power field (HPF). The preferred therapy is endoscopic removal, followed by regular endoscopic surveillance and antrectomy in hypergastrinemic cases^[8].

In daily practice, type 1 ECL-cell carcinoids are more frequently observed than other subtypes. Despite their benign nature, recurrence is one of the leading problems in management of these tumors^[9]. Besides, lymph node metastases, although rare, are reported even in minute lesions^[10]. Furthermore, the frequent recurrences lead to more aggressive surgical approaches. So the prediction of tumor behavior from endoscopic biopsies is very critical, but it is quite difficult, if not impossible. In most of the cases, biopsy specimens are very small and submucosa is rarely visualized. Even when the submucosa is present, it is generally not deep enough to rule out submucosal invasion. Cytomorphologic features are helpless since the tumors do not show nuclear pleomorphism, anaplasia and frequent mitosis. Ki-67 proliferation index (PI) and p53 has clinical implications to some extent but new markers are needed to understand the mechanisms of tumor development and differences in clinical behavior even in benign lesions.

p21^{waf1} (p21) and p27^{kip1} (p27) are nuclear proteins reported to have a role in development and progression of several organ tumors. They are members of the KIP subgroup of cyclin-dependent kinase inhibitory (CDKI) family, which prevents cell entry to S phase in response to DNA damage, thus act as tumor suppressors. Loss of p27 has a role in carcinogenesis of several organ tumors, including breast, prostate and colon, and is related with poor prognosis^[11]. p27 expression has been reported to be valuable in differentiating parathyroid adenomas and carcinomas^[12,13]. Altered patterns of p21 expression seem to have an association with clinical outcome in certain tumors but there are conflicting results whether low or high levels of p21 serve as a prognostic marker^[13,14]. Although there are previous studies on the role of CDKIs in several types of endocrine carcinomas, the expression of these proteins in GI endocrine tumors, particularly GWDETs, is less well investigated^[15,16].

In this study, we first investigated expressions of p21 and p27 in GWDETs, and then evaluated the association of p21 and p27 expressions with age, gender, tumor localization, multifocality and accompanying chronic atrophic gastritis, as well as neuroendocrine cell hyperplasia (NEH), neuroendocrine dysplasia (NED), intestinal metaplasia (IM), Ki-67 PI and clinical outcome.

MATERIALS AND METHODS

Subjects

Formalin-fixed, paraffin-embedded endoscopic biopsy

Table 1 Gastric endocrine tumor classification, WHO^[6]

Classification	Diameter	Ki-67 PI ¹	Mitosis	Extension
Well differentiated endocrine tumor (carcinoid tumor)	≤ 1 cm	$\leq 2\%$	$\leq 2/10$ HPF ²	Mucosa-submucosa
Well differentiated endocrine carcinoma (malignant carcinoid)	> 1 cm	$> 2\%$	$> 2/10$ HPF ²	Muscularis propria and beyond
Poorly differentiated endocrine carcinoma (small cell carcinoma)	Any diameter	$> 15\%$	$> 10/10$ HPF ²	Vascular and neural invasion

¹Proliferation index; ²High power field.

specimens from 16 patients, whose archival materials were available for immunohistochemistry and matching the diagnostic criteria of GWDET^[6], were included in the study. The biopsy samples were fixed in 100 mL/L neutral buffered formalin. Following routine tissue process, tissues were cut into 4- μ m thickness and stained with hematoxylin & eosin and chromogranin A. Age, gender, tumor localization, multifocality (defined as tumors seen in more than one samples taken from different parts of stomach or same part of the stomach but described as separate nodules in endoscopy report) and accompanying chronic atrophic gastritis, NEH, NED and IM were recorded. Size of the tumors (although smaller than 1 cm) could not be measured properly because of the fragmented nature of the biopsies.

Immunohistochemistry

Mouse monoclonal antibodies (mAb) anti-p21 (Neomarkers, MS 230-P, 200 mg/L, 1:40 dilution), anti-p27 (Neomarkers, MS 256-P, 200 mg/L, 1:50 dilution) and Ki-67 (Dako, M 7240, 1:150 dilution) were used for immunohistochemistry by streptavidin-biotin peroxidase method. Briefly, sections were incubated at 50°C overnight, deparaffinized in xylol and rehydrated through graded alcohol rinses. To enhance antigen retrieval, slides prepared for p21 staining were heated in 0.1 mmol/L EDTA buffer (pH 8) in a microwave oven (650 W for 5 min plus 450 W for 20 min) and those for p27 were immersed in citrate buffer (10 mmol/L, pH 6) and heated in a vacuum-pan for 2.5 min and cooled for 20 min. Endogenous peroxidase activity was blocked with 30 mL/L H₂O₂ for 5 min. The incubation time with monoclonal antibodies p27 and p21 was optimized as 30 min. Immunostaining of p27 and p21 was performed with the streptavidin-peroxidase method (Labvision, TM-125-HL), and alkaline phosphate-based visualization system. 3, 3'-diaminobenzidine (Dako, TA-125 HD) was used as a chromogen. Carcinomatous breast and colon tissue served as a positive control, whereas primary mAb was omitted for negative control sections. Stained lymphocytes were used as an internal control. Scoring was performed separately by two pathologists (BD, BS) who were blinded to the patient characteristics as well as each others scores. In each case, a total of 200 cells were counted in two randomly selected representative HPF areas. Percentage of positive nuclear staining either weak or strong was noted. The mean of the scores counted by each observer was accepted as expression score.

Gene	Mean \pm SD	Range
p21	1.09 \pm 1.44	0-4
p27	43.58 \pm 31.27	10-95
Ki-67	0.7 \pm 0.94	0-3

Statistical analysis

Statistical analysis was carried on a PC-based analysis program, SPSS 10.0. Pearson correlation analysis was carried out for univariate associations between p21 and p27 scores and age. Mann-Whitney *U* test was performed to investigate the relationship of p21 and p27 scores with gender, localization (fundus), multifocality, NEH, neuroendocrine dysplasia and presence of atrophy and IM as well as clinical outcome. Submucosal invasion, although enclosed in the definition of GWDET, was also noted when present and evaluated for its statistical significance by using Mann-Whitney *U* test. Chi-square test and Fisher's exact test were applied for dichotomized data. Student's *t*-test was used for associations with age. $P < 0.05$ was considered statistically significant.

RESULTS

Patient and tumor characteristics

Mean age of the patients was 52.4 ± 7.0 (range: 41-66) years, and 56.3% of them were female. All cases were classified as type 1 ECL-cell tumors clinically. Nine (56.3%) of the tumors were located in corpus and 2 (12.6%) of them were in fundus. Most of them showed more than

one histologic pattern (Figure 1A). Chromogranin A was identified in all tumors (Figure 1B). None of the cases showed mitosis in 10 HPF except one case (1/10 HPF). Multifocality was observed in 5 (31.4%) cases. Accompanying histopathologic features are shown in Table 2. Eleven (68.8%) of the cases were cured by endoscopic excision, followed by regular endoscopic surveillance and endoscopic ultrasound when necessary and did not show recurrences during the follow-up. Among the rest of 5 (31.4%) cases, 3 cases needed re-excision and 2 were conveyed to surgery because of multiple recurrences. No additional histopathologic features were found in the operation materials of these 2 cases. None of the cases showed distant organ or lymph node metastasis at the time of diagnosis nor developed any during a mean follow-up period of 34.12 ± 25.63 (range: 9-69) mo.

p21 and p27 expressions

Descriptive statistics of p21, p27 and Ki-67 nuclear immunoreactivity are shown in Table 3, and Figure 1C, 1D. We observed a significant correlation between p21 and p27 expressions ($P < 0.01$, Pearson correlation analysis). All cases expressed p27, while 5 (31.3%) of the cases showed no expression for p21 in tumor areas. The p21-expressing group had higher p27 scores of 68% vs 22%, although statistically insignificant ($P = 0.07$) (Table 4). High p27-

expressing tumors (over the cut-off level of mean p27 expression of 43.6%) had higher p21 scores as well ($P = 0.022$, Mann Whitney *U*-test).

p21 and p27 expressions were higher in 3 tumors located in fundus either as a single focus ($n = 2$) or part of a multifocal spread ($n = 1$) ($P < 0.05$, Mann Whitney *U*-test) (Table 4). In addition, p21 and p27 expressions were higher in males and the patients with submucosal extension and atrophic gastritis. The patients with multifocal tumors, NEH and NED showed higher p27 and lower p21 immunoexpression. But no correlation of p21 and p27 expressions was found with the age and Ki-67 PI. Also, the p21-expressing tumors did not show any particular difference in respect to presence of atrophy, NEH, NED, IM, multifocality, submucosal extension, Ki-67 PI and age. Cases, who needed surgery or re-excision because of recurrence had lower p27 expression scores ($26.7\% \pm 4.2\%$ vs $50\% \pm 34.6\%$ in recurrent cases) and p21 immunoexpression ($0\% \pm 1.5\% \pm 0.53\%$ in recurrent cases), however, data did not research statistically significant. These cases did not differ in respect to presence of NEH, NED, atrophy, submucosal extension, IM, multifocality, gender and age.

DISCUSSION

The overall incidence rates of gastric carcinoids and related endoscopic biopsies have increased significantly over the last few years. Although a better prognosis can be predicted for most cases, the clinical outcome and management of these tumors vary widely^[2,4,17]. Determination of the most appropriate treatment modality and follow-up strategy depends on the associated or underlying disease process as well as the histologic findings in endoscopic biopsies.

Among the histologic parameters, Ki-67 PI is of diagnostic and prognostic value but it can be quite low in either benign or malignant neoplasms^[6,15]. In this study, the expression of two prospective prognostic markers, CDK1's p21 and p27, and their relationship with clinicopathologic features were investigated.

Cell cycle regulation is influenced by nuclear proteins that enhance cell division, cyclin-dependent kinases (CDK) or disrupt cell division, CDKIs. The induction of CDKI inhibits the activities of CDK2 and completely arrests cells at G1 phase of the cell cycle, thus acts as tumor suppressors^[18]. Loss of CDKIs has a role in carcinogenesis of several organ tumors as well as endocrine tumors. Canavese *et al.*^[15] performed study on 109 endocrine tumors of the pancreas and GI tract, and found that p27 was highly expressed especially in differentiated tumors, while expression of p21 was very sparse in midgut (ileum-right colon) carcinoids but significantly higher in insulinomas^[16]. Zirbes *et al.*^[19] stated that primary pulmonary carcinoid tumors failed to show a staining for p21 and p27.

We found that all cases expressed p27 with a mean expression score of 43.6%, while 31.3% of the cases showed p21 expression. p21 and p27 expressions were significantly correlated with each other and the p21-expressing group had a higher p27 expression score as 68% versus 22%. p27 has a 42% amino acid homology with p21, at the region that mediates inhibition of CDK^[12],

Table 4 p21 and p27 expressions and clinicopathologic features (%)

Clinicopathologic feature		p21	P ³	p27	P ³
Gender	Male	1.5	0.60	58.0	0.34
	Female	0.85		36.4	
Localization	Fundus	3.0	< 0.05	90.5	< 0.05

	Non-recurrent	1.5		49.9	

¹Neuroendocrine cell hyperplasia-dysplasia; ²Intestinal metaplasia; ³Mann-Whitney *U* test; ⁴Result is omitted since p21 value was constant in IM (-) cases.

but recently it was suggested that p21, supposed to be functionally similar to p27, plays a lesser role in tumor suppression^[20]. But some studies suggest a co-regulation between p27 and p21 in some tumors like colorectal carcinoma and renal cell carcinoma^[21,22], but it is not yet clear how these two CDKIs relate to each other in carcinogenesis sequences.

In the present study, cases presenting clinical progression had lower p21 and p27 immunoexpression. But no particular difference was found in respect to presence of atrophy, NEH, NED, IM, multifocality, submucosal extension, and age. Ki-67 PI was very low in most of the cases and no correlation was found between p21, p27 expressions and the other clinicopathologic features. When we examined the general features of all cases, we found that both p21 and p27 expressions were lower in women, in non-atrophic mucosa and cases whose tumors were located somewhere other than fundus without submucosal extension. Cases presenting lower p27 scores were generally solitary tumors showing neither NEH-NED nor atrophy and intestinal metaplasia. Despite, in cases with lower p21 expression, tumors were multifocal and accompanied by neuroendocrin cell hyperplasia and dysplasia. These observations may suggest a probable association of p27 loss with sporadic form of the disease (Type III) and p21 loss with hypergastrinemic cases (Type I or II) although do not cover the whole picture.

Loss of p27 expression is reported to be correlated with aggressive behaviour of various organ tumors^[12,14]. But although Lloyd *et al.*^[23] reported a marked decrease of 27 expression in benign and malignant endocrine tumors when compared with normal tissue and Erickson *et al.*^[12] suggested the use of p27 in the differential diagnosis between parathyroid hyperplasia and adenoma, Canavese *et al.*^[15] objected the use of high p27 expression as a marker of benign behaviour since it can be observed in differentiated

malignant tumors. Observation on p21 is more limited and needs further studies. To our best of knowledge, there is no previous study dedicated only to p21 and p27 immunexpressions in gastric well differentiated endocrine tumors. Although we appreciate that our study has limitations, the observations presented above can help to enlighten the pathogenesis of gastric carcinoid tumors. Larger series with long-term results are needed to assess the role of p21 and p27 in gastrointestinal endocrine tumors.

Abstract

AIM: To investigate the expression of insulin-like growth factor binding protein-2 (IGFBP-2) in gastric carcinoma and its clinical significance and to explore its relationship with cell proliferation.

METHODS: Expressions of IGFBP-2 and Ki-67 in 118 cases of gastric carcinoma and 40 cases of normal gastric mucosa were detected by EnVision immunohistochemical technique.

RESULTS: Expression of IGFBP-2 in gastric carcinoma was higher than that in normal gastric mucosa ($P < 0.01$). There was no difference between high- and low-grade gastric carcinoma ($P > 0.05$). Expression of IGFBP-2 in advanced gastric carcinoma was higher than that in early gastric carcinoma ($P < 0.05$). Expression of IGFBP-2 in gastric carcinoma with lymph node metastasis was higher than that without lymph node metastasis ($P < 0.01$). IGFBP-2 expression was a positively related to the clinical stage of gastric carcinoma ($P < 0.01$). There was a positive correlation between IGFBP-2 and Ki-67 ($P < 0.05$).

CONCLUSION: IGFBP-2 may be involved in carcinogenesis and progression of gastric carcinoma by promoting cell proliferation.

Shi LH, Zhu XQ, Zhao GH, Xia YB, Zhang YS. Expression of insulin-like growth factor binding protein-2 in gastric carcinoma and its relationship with cell proliferation. *World J Gastroenterol* 2006; 12(39): 6285-6289

INTRODUCTION

The insulin-like growth factor (IGF) system plays a crucial role in normal cell proliferation and malignant transformation^[1,2]. It comprises IGF- I and IGF- II, the type I and II receptors^[3], and a family of IGF binding proteins (IGFBPs) that specifically bind to IGFs^[4]. The IGFBPs are a family of binding proteins involved in the regulation of tissue development through their interactions with IGFs. By sequestering free IGFs and reducing their bioavailability for interaction with IGFs, IGFBPs are able to modulate cellular growth and differentiation at a local level^[5]. IGFBP-2 is the second most abundant IGFBP in the circulation and can be found in a variety of mammalian fluids and tissues. IGFBP-2 was initially thought to mainly bind to IGFs (IGF- I and IGF- II) through its IGF-binding motif, and thereby inhibits IGF-mediated mitogenic activities^[6]. However, recent studies have shown that IGFBP-2 also increases the tumorigenic potential and mitogenesis in some cancer cells^[7-9], suggesting that IGFBP-2 possesses multifaceted functions.

So far, only one study focusing on the expression of IGFBPs in gastric cancer cells^[10] is available. In this study, we used immunohistochemical method to clarify the expression and localization of IGFBP2 in malignant and normal gastric tissues. The aim was to determine whether IGFBP-2 plays a role during gastric carcinogenesis and to clarify the correlation of IGFBP2 expression with cell proliferation.

MATERIALS AND METHODS

Tissue samples and histopathological study

Paraffin blocks from gastrectomy specimens were obtained from the archives of Department of Pathology, Affiliated Yijishan Hospital of Wannan Medical College, between May 2004 and June 2005. Selected cases were classified as cardia carcinoma, fundus/body and antrum carcinomas according to their location, following the criteria described in a previous study^[11]. Mean age and gender were also recorded. Carcinomas were divided into two types, namely early and advanced carcinoma. The depth of wall penetration and nodal status were also recorded. The 1997 version of the International Union Against Cancer (UICC) pTNM system was employed to stage the carcinomas^[12].

Immunohistochemistry

Monoclonal antibody against IGFBP2 diluted 1:150 (c-18; Santa Cruz Biotechnology, Inc., Santa Cruz, UK) was used in immunohistochemistry studies. This antibody is specific and does not crossreact with other isoforms of IGFBP. For each procedure, the samples were chosen randomly from each group. The 4- μ m thick sections of phosphate buffered saline (PBS)/formalin-fixed and paraffin wax-embedded specimens were routinely dewaxed in xylene, rehydrated in a graded series of ethanol, and washed in distilled water. Antigen retrieval was achieved by placing the specimens in 0.01 mol/L citrate buffer at pH 6.0 and exposing them to repeated microwave heating for 10 min at 450 W. The buffer was replenished after each interval because of evaporation. The specimens were cooled at room temperature for 15 min and washed in sterile water for 5 min and then in PBS at pH 7.6 for 5 min. Endogenous peroxidase or phosphatase activities were quenched in 0.3% H₂O₂ for 30 min, followed by blocking non-specific antibody binding in 10% goat serum for 30 min at room temperature. Tissue sections were incubated overnight at 4°C in a humidifier with primary goat anti-IGFBP2. Mayer's hematoxylin nuclear stain was used as a counter stain. Negative controls were performed using conjugate alone.

Assessment of immunohistochemical staining

Immunohistochemical staining results were assessed semi-quantitatively using the Busund score system^[13]. Expression of IGFBP2 was then graded semi-quantitatively and classified into one of the four grades. The staining was scored as: 0: no staining; 1: weak staining; 2: strong staining of 25% tumor cells or moderate staining of < 80%; 3: strong staining of 25%-50% or moderate staining of > 80%; 4: strong staining of > 50% tumor cells. In each case, 10 high power fields of representative areas were counted. The maximal staining intensity was typically higher in those cases where more cells were positive. Most positive cells showed cytoplasmic staining. Slides were examined and scored independently by two of the authors, blinded to other pathological information. The Ki-67 labeling index (KI) was calculated as the percentage of positive tumor nuclei divided by the total number of tumor cells examined. At least 1000 tumor cells per specimen were examined in 5 randomly selected fields by light microscopy ($\times 400$).

Statistical analysis

Data are presented as mean \pm SD. Individual groups were compared using the parametric Student's *t* test. Association between IGFBP2 expression and different clinical parameters in malignant tissue was tested by nonparametric *t* test. The relation between IGFBP2 expression and Ki-67 was tested by Spearman's correlation coefficient. For all these statistical analyses, $P < 0.05$ was considered statistically significant.

RESULTS

Clinicopathological features

The clinical and pathological characteristics of 118 patients are summarized in Table 1.

Table 1 Clinical and pathological characteristics of patients with early gastric carcinoma ($n = 118$)

Characteristic	<i>n</i>

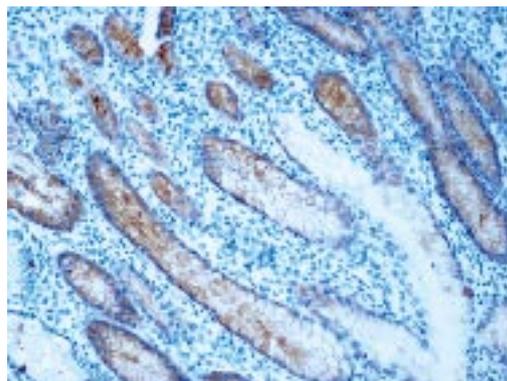

Figure 1 IGFBP2 expression showing a weak pancytoplasmic staining in normal gastric mucosa ($\times 200$).

Immunohistochemical expression of IGFBP2 in normal gastric mucosa and carcinoma

Among the 118 tumor samples, 40 specimens of normal mucosa (≥ 10 cm distant from cancer) showed a weak pancytoplasmic expression of IGFBP2 (Figure 1). The immunohistochemical staining score of IGFBP2 was judged as 0, 1 or 2. There was an over-expression of IGFBP2 in carcinoma. Pancytoplasmic staining or more diffuse granular staining was observed in cytoplasm of neoplastic cells (Figures 2 and 3). IGFBP2 expression score was 2.61 ± 0.94 in gastric carcinoma and 1.06 ± 0.64 in normal human gastric mucosa respectively. There was a significant difference between carcinoma and normal mucosa ($t = 5.223$, $P < 0.01$) as shown in Table 2.

Correlation between IGFBP2 expression and clinicopathological parameters of gastric carcinoma patients

A significant difference was observed in IGFBP2 expression and tumor depth of wall penetration ($P = 0.019$).

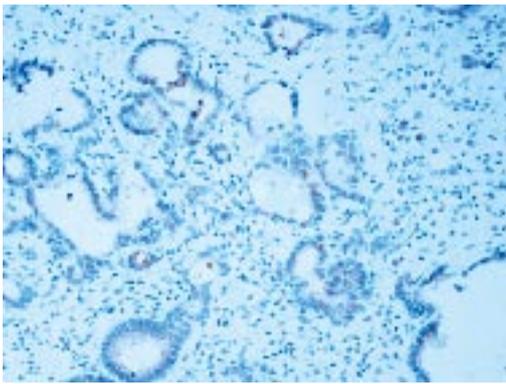

Figure 2 IGFBP2 expression showing a weak cytoplasmic staining in the tumor cells ($\times 200$).

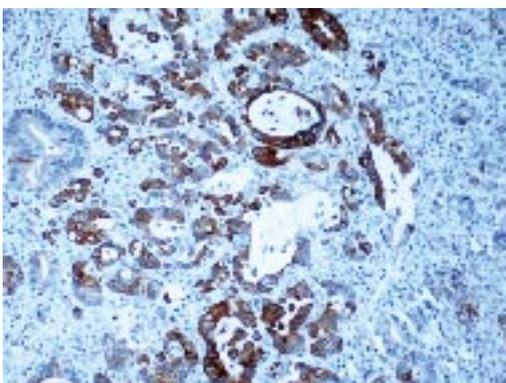

Figure 3 IGFBP2 expression showing a more diffuse granular cytoplasmic staining in the tumor cells ($\times 200$).

Table 2 Quantitative score of IGFBP2 expression in normal gastric mucosa and gastric carcinoma

Group	Quantitative score of IGFBP2 expression (mean \pm SD)	<i>P</i>
Normal mucosa	1.06 \pm 0.64	< 0.01
Carcinoma	2.61 \pm 0.94	

Although immunohistochemical staining score of IGFBP2 expression in undifferentiated carcinoma (2.72 \pm 0.88) was higher than that in differentiated carcinoma (2.31 \pm 0.82), the difference was not significant ($P = 0.336$).

A significant difference was also observed in IGFBP2 expression and nodal metastasis ($P = 0.0048$). The immunohistochemical staining score of IGFBP2 expression in stages I and II (2.02 \pm 0.93) was lower than that in stages III and IV (2.98 \pm 0.87) ($P = 0.0027$) (Table 3).

No significant difference was observed in the distribution of immunohistochemical staining scores of IGFBP2 expression, gender of patients and location of the tumor ($P = 0.235$) (Table 3).

Correlation between expressions of IGFBP2 and Ki-67

The expression of Ki-67 was localized to the nuclei of neoplastic cells (Figure 4). As shown in Figure 5, a significant positive correlation was observed between the

immunohistochemical staining score of IGFBP2 and the proliferating index of Ki-67 ($P = 0.005$).

DISCUSSION

In this study, we determined the expression of IGFBP2 in 118 specimens of gastric carcinoma. To our knowledge, the expression of IGFBP2 in gastric carcinoma has not been evaluated by immunohistochemistry. Normal gastric epithelial tissue was negative or weakly positive and localized to the cytoplasm of gastric mucosa. Weak, moderate to strong expression of IGFBP2 was observed in gastric carcinoma with diffuse granular staining or strong pancytoplasmic staining. This finding is in accordance with previous reports showing that IGFBP2 can augment IGF1-induced mitogenicity of cancer cells^[14].

Serum IGFBP-2 concentrations in combination with carcinoembryonic antigen determinations are highly

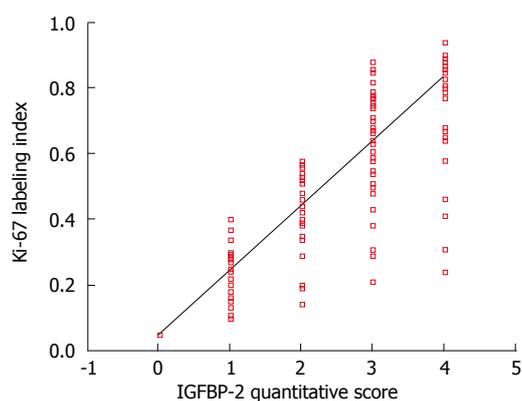

Figure 5 The positive correlation between IGFBP2 expression and Ki-67 in gastric cancer (Spearman's correlation coefficient, $P = 0.005$).

prognostic for metastasis and recurrence of colon cancers, and their use in cancer surveillance is suggested^[15,16]. In ovarian cancer patients, serum IGFBP-2 levels are positively correlated with the ovarian tumor marker CA 125^[17]. Some studies showed that serum IGFBP-2 levels in patients with prostate carcinoma are elevated and significantly correlated with PSA levels, suggesting that serum IGFBP-2 measurement in patients with low serum PSA levels can be used to monitor prostate tumor burden^[18-20]. IGFBP-2 is consistently elevated in cerebrospinal fluid (CSF) of patients with malignant tumors of the central nervous system (CNS), whereas in patients with peripheral tumors, normal IGFBP-2 levels have been found in CSF^[21], suggesting that IGFBP-2 in CSF can be considered a specific marker for CNS tumors. Busund *et al*^[13] reported that IGFBP-2 is not significantly expressed in normal and hyperplasia glandular cells of breast. Atypical hyperplasia slightly increases cytoplasmic expression of IGFBP-2, and carcinoma *in situ* shows a distinctive membrane and cytoplasmic expression. Infiltrating carcinomas strongly express cytoplasmic IGFBP-2, suggesting that IGFBP-2 might be an independent indicator of malignancy. Richardsen *et al*^[22] have found a significant over-expression of IGFBP-2 in prostatic intraepithelial neoplasia (PIN) and in more than 90% of cancers regardless of their grade. All cases of benign prostatic hyperplasia (BPH) are almost negatively or very weakly stained. In the present study, the immunohistochemical staining score of IGFBP-2 in gastric carcinomas was higher than that in normal mucosa, suggesting that over-expression of IGFBP-2 may have a stimulatory role in the pathogenesis of gastric cancer.

IGFBP-2, the second most abundant IGFBP in circulation, has traditionally been thought as a growth inhibitor. In transgenic mouse models, for example, IGFBP-2 over-expression through the CMV-promoter results in significantly reduced weight gain, presumably through IGFBP-2 sequestering of IGFs by reducing the bioavailability of these growth factors for their receptors^[23,24]. Over-expression of IGFBP-2 in human embryonic kidney fibroblasts inhibits cell proliferation, which can be reversed by the addition of exogenous IGFs, suggesting that IGFBP-2 has an inhibitory effect on IGF action^[25]. Conversely, expression of IGFBP-2 has also

been found to be positively correlated with tumor grade, including hepatoblastoma, mammary and ovarian cancer, Wilm's and adrenal tumors as well as prostate cancer^[26], indicating that IGFBP-2 might have cancer-promoting properties^[8]. Recently, Song *et al*^[27] used a yeast two-hybrid system to identify a binding partner of IGFBP-2, which was named invasion inhibitory protein 45 (Iip45), and found that IGFBP-2 could stimulate glioblastoma multiform (GBM) cell invasion, but Iip45 inhibits GBM cell invasion. Because IGFBP-2 carries the Tg domain and the RGD motif, IGFBP-2 may stimulate cell invasion via the integrin-mediated signaling pathway and Iip45 may inhibit IGFBP-2-stimulated invasion by interacting with the Tg-RGD region of IGFBP-2. Indeed, IGFBP2 has been recently found to interact with the alpha v beta 3 and alpha 5 beta 1 integrins^[28,29]. In addition, IGFBP2 can stimulate the growth of prostate cancer cells, an effect that can be blocked by MAP kinase and PI3-kinase inhibitors^[26]. IGFBP2 is co-expressed with the vascular endothelial growth factor in pseudopalisading glioma cells surrounding tumor necrosis^[30]. These findings suggest that IGFBP2 plays a key role in human cancer development.

We examined the correlation between the immunohistochemical staining score of IGFBP-2 and several clinicopathological factors. The immunostaining score of IGFBP-2 in carcinoma with T3-T4 penetration was higher than that with T1-T2 penetration. Higher immunohistochemical staining score of IGFBP-2 significantly correlated with lymph node metastasis and clinical stage. These findings suggest that IGFBP-2 might be a marker of invasive gastric carcinoma. However, in contrast to other tumors, no relationship was found between the immunohistochemical staining score of IGFBP-2 in gastric carcinoma and tumor grade. This discrepancy might be possibly attributed to the different materials studied.

Hormone status as measured by estrogen receptor (ER) and progesterone receptor (PR) correlates with IGFBP-2 in breast carcinoma^[13]. However, the relationship between proliferation and IGFBP-2 expression in various tumors including gastric carcinoma has not been analyzed. Therefore, we carried out the present study to investigate the association of proliferative activity with IGFBP-2 expression in gastric carcinoma. Cell proliferative activity is important for evaluating tumor growth. Monoclonal antibodies that recognize Ki-67 can label all proliferating cells in G1, S, G2 and M phases of the cell cycle and have been widely used to estimate the proliferative fraction of neoplasms^[31]. Our results reveal that the immunohistochemical staining score of IGFBP-2 is positively correlated with KI. These findings suggest that IGFBP-2 might play an important role in the progression of gastric carcinoma by promoting cell proliferative activity.

In conclusion, increased IGFBP-2 expression is related to malignant transformation of gastric carcinoma and plays an important role in the progression of gastric carcinoma. Although our data provide evidence for a role of IGFBP-2 in predicting biologic behavior in a relatively large series of gastric carcinoma, further studies are needed to establish the relationship between IGFBP-2 expression in this tumor and survival of patients with this tumor.

Abstract

AIM: To prospectively evaluate the usefulness of a pattern-based classification of contrast-enhanced sonographic findings for differential diagnosis of hepatic tumors.

METHODS: We evaluated the enhancement pattern of the contrast-enhanced sonography images in 586 patients with 586 hepatic lesions, consisting of 383 hepatocellular carcinomas, 89 metastases, and 114 hemangiomas. After injecting a galactose-palmitic acid contrast agent, lesions were scanned by contrast-enhanced harmonic gray-scale sonography in three phases: arterial, portal, and late. The enhancement patterns of the initial 303 lesions were classified retrospectively, and multiple logistic regression analysis was used to identify enhancement patterns that allowed differentiation between hepatic tumors. We then used the pattern-based classification of enhancement we had retrospectively devised to prospectively diagnose 283 liver tumors.

RESULTS: Seven enhancement patterns were found to be significant predictors of different hepatic tumors. The presence of homogeneous or heterogeneous enhancement both in the arterial and portal phase was the typical enhancement pattern for hepatocellular carcinoma, while the presence of peritumoral vessels in the arterial phase and ring enhancement or a perfusion defect in the portal phase was the typical enhancement pattern for metastases, and the presence of peripheral nodular enhancement both in the arterial and portal phase was the typical enhancement pattern for

hemangioma. The sensitivity, specificity, and accuracy of prospective diagnosis based on the combinations of enhancement patterns, respectively, were 93.2%, 96.2%, and 94.0% for hepatocellular carcinoma, 87.9%, 99.6%, and 98.2% for metastasis, and 95.6%, 94.1%, and 94.3% for hemangioma.

CONCLUSION: The pattern-based classification of the contrast-enhanced sonographic findings is useful for differentiating among hepatic tumors.

INTRODUCTION

Contrast-enhanced harmonic gray-scale sonography is a useful tool for evaluating the vascularity of liver tumors^[1-11], because it allows visualization of the blood perfusion of liver tumors without motion artifacts^[12] and it is simple, easy, and sufficiently non-invasive to be performed on an out-patient basis. In addition, it can be used in renal failure patients and patients who are allergic to iodine contrast agents.

Several investigators have reported that contrast-enhanced harmonic gray-scale sonography is a useful modality for differentiating among the types of hepatic tumors. However, no statistical evidence was presented, because they did not use multivariate logistic regression analysis for differential diagnosis of liver tumors^[13-22]. We previously classified the contrast-enhanced harmonic gray-scale sonographic findings in hepatic tumors into combinations of enhancement patterns^[23]. The results of a multiple logistic regression analysis and positive

predictive values calculated from the results of pattern combinations for each hepatic lesion demonstrated that the enhancement pattern-based classification of contrast-enhanced harmonic gray-scale sonographic findings is useful for making the differential diagnosis of hepatic tumors. However, this classification was not applied to diagnosis prospectively, and a prospective study of the enhancement pattern-based classification was needed to confirm its accuracy for the differential diagnosis for hepatic tumors. Moreover, the perfusion images in our previous study could only be obtained at a slow frame rate, because sufficient time is needed to allow the contrast agent to perfuse the tumor.

In November 2001, we began to use the newly developed contrast-enhanced harmonic gray-scale sonography mode to evaluate tumor vessels and tumor enhancement of hepatic mass lesions. Improvements in spatial and contrast resolution have now made it possible to evaluate the viability of hepatocellular carcinoma at a higher frame rate (7 frames per second) than with the previous mode^[23]. Although both the new and previous modes are based on phase inversion technology, by deliberately adjusting the time interval between the transmit pulses, the new contrast mode detects flow motion as well as bubble disruption. This allows the new mode to detect a sufficient flow signal even when there is little contrast agent left in the blood stream. As a result, the new contrast mode enabled identification of hypervascular liver tumors, e.g., advanced hepatocellular carcinoma (HCC) lesions, as hypervascular enhancement in the arterial phase at a high frame rate^[11].

In the present study, we first retrospectively classified enhancement pattern combinations for each hepatic lesion obtained with the new contrast mode described above and then prospectively diagnosed each hepatic tumor according to the pattern-based classification of enhancement we had retrospectively devised.

MATERIALS AND METHODS

Patients and tumors in the retrospective evaluation

Between November 2001 and August 2003, we examined 315 consecutive patients with hepatic tumors by conventional sonography. All patients were examined by both dual-phase helical CT and contrast-enhanced harmonic gray-scale sonography, and the patients who were suspected of having HCC were examined by arteriography. Twelve patients with 12 lesions located 12 cm or more beneath the skin surface were excluded, because the increase in attenuation of the ultrasound beam with depth made it difficult to destroy the Levovist bubbles in such lesions^[23]. Thus, the remaining 303 patients (238 with solitary focal lesions and 65 with multiple focal lesions) were enrolled in this study, and 303 hepatic lesions were evaluated the largest lesion in patients with more than one focal lesion. Since no significant difference in sensitivity calculated from the results of pattern combinations for each hepatic lesion according to the contrast-enhanced harmonic gray-scale sonographic findings was observed between solitary lesions and multiple lesions in the previous study^[23], we enrolled the

patients with both solitary and multiple lesions. There were 173 men (104 HCC, 38 metastases, 31 hemangiomas) and 130 women (74 HCC, 18 metastases, 38 hemangiomas), without significant difference in age between the men (65.2 ± 9.6 years) and women (64.4 ± 11.2 years). We classified cholangiocellular carcinoma as hepatic metastasis because pathologically the tumors are adenocarcinomas originating from the intrahepatic bile duct.

The final diagnosis of the lesions studied was HCC in 178 patients, liver metastasis in 56 patients (14 from colon carcinoma, 11 from pancreatic carcinoma, 7 from rectal carcinoma, 6 from cholangiocellular carcinoma, 3 from gastric carcinoma, 3 from gallbladder carcinoma, 2 from malignant melanoma, 2 from lung carcinoma, and 1 each from malignant lymphoma, nasopharyngeal carcinoma, esophageal carcinoma, laryngeal carcinoma, thyroid carcinoma, and hemangiopericytoma), and hemangioma in 69 patients. All HCCs were histologically diagnosed after surgical resection (12 lesions), sonography-guided biopsy (162 lesions), or autopsy (4 lesions). All liver metastases were histologically diagnosed after surgical resection (6 lesions), sonography-guided biopsy (48 lesions), and autopsy (2 lesions). The diagnosis of hemangioma was confirmed by contrast-enhanced CT and MR and the absence of any changes on follow-up images more than 1 year later. Of the 178 patients with HCC lesions, 155 had cirrhosis, and the diagnosis was made histologically and/or clinically.

The hepatic tumors were measured on conventional US images by one of the two operators who performed the contrast-enhanced harmonic imaging. The mean maximal diameters were: 26 ± 16 mm for HCCs, 33 ± 21 mm for metastases, and 28 ± 19 mm for hemangiomas. The numbers of HCC lesions, classified according to maximal tumor diameter, were 2 lesions < 10 mm, 87 lesions between 10 mm and 20 mm, and 89 lesions > 20 mm.

Patients and tumors in the prospective evaluation

Between September 2003 and April 2005, we examined 283 consecutive patients (195 men with age 67.1 ± 9.2 years, and 88 women with age 68.0 ± 8.8 years) with hepatic tumors by conventional US, and using the pattern-based classification of enhancement, we retrospectively devised to prospectively diagnose their liver tumors. Solitary focal lesions were detected in 207 patients and multiple focal lesions in 76 patients.

The final diagnosis of the lesions was HCC in 205 patients, liver metastasis in 33 patients (8 from colon carcinoma, 8 cholangiocellular carcinoma, 4 from pancreatic carcinoma, 4 from gastric carcinoma, 2 from gallbladder carcinoma and 1 each from esophageal carcinoma, lung carcinoma, rectal carcinoma, prostate carcinoma, malignant lymphoma, adenoid cystic carcinoma, and leiomyosarcoma), and hemangioma in 45. All liver metastases were histologically diagnosed after surgical resection (5 lesions), sonography-guided biopsy (27 lesions), and autopsy (1 lesion). Of the 205 HCC lesions, 12 were histologically diagnosed after resection, 194 after sonography-guided biopsy, and the remaining 3 after autopsy. Of the 205 patients with HCC lesions, 177 had cirrhosis which was diagnosed histologically and/or

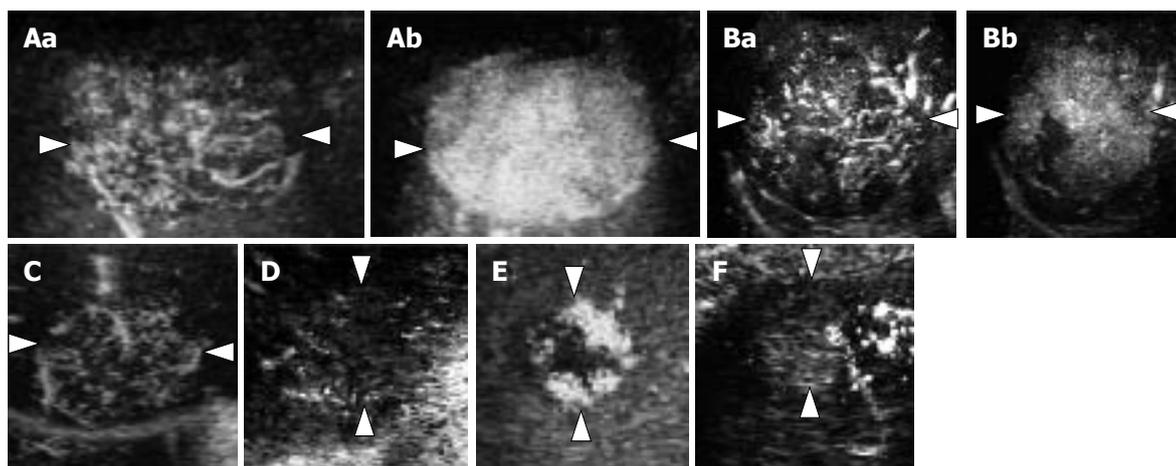

Figure 1 Diagram showing enhancement patterns of hepatic tumors in the arterial phase. **A:** Intratumoral vessels in the early arterial phase (a) with homogeneous enhancement in the late arterial phase (b) (pattern A1); **B:** Intratumoral vessels in the early arterial phase (a) with heterogeneous enhancement in the late arterial phase (b) (pattern A1); **C:** Intratumoral vessels without homogeneous or heterogeneous enhancement (pattern A2); **D:** Peritumoral vessels alone (pattern A3); **E:** Peripheral nodular enhancement without tumor vessels (pattern A4); **F:** No enhancement and no tumor vessels (pattern A5).

clinically.

The hepatic tumors were measured by conventional US by one of the two operators who performed the contrast-enhanced harmonic imaging. The mean maximal diameter of the HCCs was 26 ± 15 mm, of the metastases was 33 ± 17 mm, and of the hemangiomas was 30 ± 22 mm.

Informed consent was obtained from all patients before the study, and the study was approved by Institutional Ethics Committee.

We defined "early HCC lesions" as well-differentiated cancers with no substantial destruction of the preexisting hepatic framework^[24].

Procedures

To minimize variations between operators, the contrast-enhanced harmonic gray-scale imaging studies were performed by either one of two operators (K. N., T. I.) using the same examination protocol. Neither operator was aware of the results of the helical CT and angiography examinations or the histological diagnosis. Contrast-enhanced harmonic gray-scale sonography was performed with a SONOLINE Elegra machine (Siemens Medical Systems, Issaquah, WA), a 3.5-MHz convex probe, and Sie flow mode imaging software until the end of September 2004, and with a LOGIQ 7 machine (GE Healthcare, Milwaukee, WI), a 3.5-MHz convex probe, and Coded harmonic angio mode imaging software from October 2004 onward.

After intravenous bolus injection of a half vial of the 300 mg/mL concentration of galactose-palmitic acid mixture contrast medium (Levovist; Schering AG, Berlin, Germany), the liver was scanned by real-time contrast-enhanced harmonic gray-scale sonography at 5-13 frames per second, usually at 7 frames per second. The transmission power was 100%, and the mechanical index values were between 1.0 and 1.6. The focus position was just below the bottom of the tumor. Levovist is a suspension of galactose (99.9%) stabilized with 0.1% palmitic acid. A 3.5-mL dose of this agent was injected at

0.5 mL/s via a 22-gauge cannula placed in an antecubital vein. After the bolus injection of Levovist, 50 g/L glucose was continuously infused at 5 mL/min. The patients gently inspired and then held their breath for about 30 s (10-40 s after the contrast medium injection) while the tumor vessels and tumor enhancement were examined (arterial phase).

After observation of the arterial phase, we froze the image. In the cases scanned with the Elegra machine, we reviewed the images frame by frame from cine loop memories and stored them on magneto-optical disks. In the cases scanned with the LOGIQ 7 machine, we stored the images as a cine clip with GE exclusive raw-data format files in the LOGIQ 7 computer. This procedure took approximately 15-35 s (mean, 25 s), and we used the time to allow the contrast agent to pool in the hepatic parenchyma. We then scanned the whole tumor and examined the tumor for enhancement 60-120 s after injection of the contrast agent while the patients held their breath for a few seconds (portal phase). We froze the images and stored them by the same method as mentioned above. Finally, 5 min after injection of the contrast agent, we examined the lesion in a sweep scan to determine if it was iso-echoic or hypo-echoic (late phase). We stored these images by the same method as described above. The complete examinations were recorded on S-VHS videotape.

Image evaluation

We evaluated the images for the presence and shape of tumor vessels and the enhancement patterns during the arterial phase and classified the patterns into five categories (Figure 1) as follows: pattern A1, intratumoral vessels with homogeneous (Figure 1A) or heterogeneous enhancement (Figure 1B); pattern A2, intratumoral vessels without homogeneous or heterogeneous enhancement (Figure 1C); pattern A3, peritumoral vessels alone (Figure 1D); pattern A4, peripheral nodular enhancement without tumor vessels (Figure 1E); and pattern A5, no enhancement

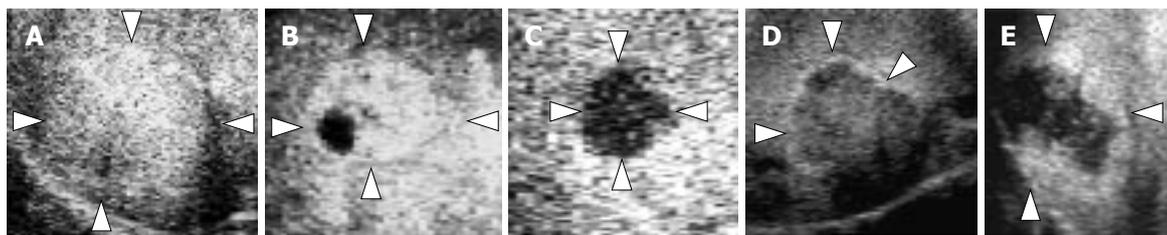

Figure 2 Diagram showing enhancement patterns of hepatic tumors in the portal phase. **A:** Homogeneous enhancement (pattern P1); **B:** Heterogeneous enhancement (pattern P1); **C:** Perfusion defect (pattern P2); **D:** Ring enhancement (pattern P3); **E:** Peripheral nodular enhancement (pattern P4).

and no tumor vessels (Figure 1F). In the portal phase, the enhancement patterns of the lesions were classified into four categories (Figure 2) as follows: pattern P1, homogeneous (Figure 2A) or heterogeneous enhancement (Figure 2B); pattern P2, perfusion defect (Figure 2C); pattern P3, ring enhancement (Figure 2D); and pattern P4, peripheral nodular enhancement (Figure 2E). The enhancement patterns of the lesion in the late phase were classified into two categories relative to the enhancement pattern in the surrounding liver parenchyma (Figure 3): pattern L1, iso-echoic (Figure 3A); and pattern L2, hypo-echoic (Figure 3B).

The image evaluation was performed independently by two readers (K.T., M.M.), both of whom reviewed all of the sonographic images recorded on video-tape, cine clips, and magneto-optical disks, and they were asked to classify each lesion into one of the patterns shown in Figures 1-3. The readers had no knowledge of the results of the helical CT or angiography, or of the histological diagnosis. Since 16 of the 586 hepatic lesions were classified differently by the two readers, the two readers and the two operators had a consensus meeting to arrive at a consensus for the final classification.

Statistical analysis

A multiple logistic regression analysis was performed to select independent variables of imaging features associated with the dependent variable, i.e., tumor type, as described previously^[23]. Since only dichotomous variables can be used as the dependent variable in multiple logistic regression analyses, we used one of the three tumor types *versus* the other two tumor types as the dependent variables in our analysis. The independent variables were different imaging features observed in the three different phases after contrast enhancement, and each variable had a dichotomous value (not observed = 0, observed = 1). We selected independent variables with a *P* value less than 0.05 in the multiple logistic regression analysis and used these significant independent variables to construct a multivariable model. All tumors exhibited one of the defined combinations of statistically significant independent variables, and statistically significant independent variables were used to make the defined combinations. The diagnostic performance of our multivariable model was evaluated by calculating the positive predictive values according to Bayes theorem^[25], based on sensitivity, specificity, and prior probability (positive predictive values = prior probability × sensitivity/

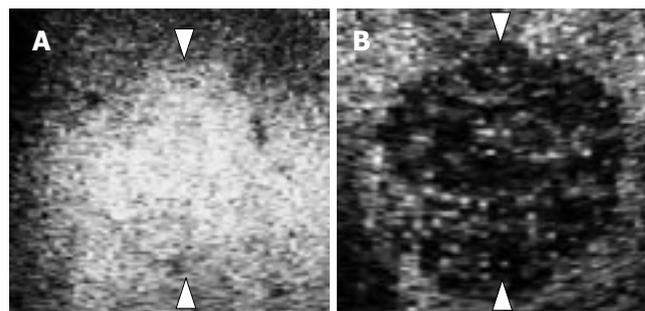

Figure 3 Diagram showing enhancement patterns of hepatic tumors in the late phase. **A:** Iso-echoic (pattern L1); **B:** Hypo-echoic (pattern L2).

{sensitivity × prior probability + (1-specificity) × (1- prior probability)}). Prior probability was calculated by dividing the numbers of HCCs, metastases, and hemangiomas by the total number of tumors (303 tumors). The diagnosis of each hepatic tumor was made on the basis of the largest positive predictive value of each combined enhancement pattern based on the results of the retrospective study, and the enhancement patterns of the prospective study were used to make the diagnosis based on the results of the retrospective study. Finally, we calculated the sensitivity, specificity, and accuracy of each tumor diagnosis based on the results of the enhancement pattern-based classification system as described above. The SPSS computer program (SPSS Japan, Tokyo, Japan) was used to perform the data analysis.

RESULTS

Retrospective study

Arterial phase: Table 1 shows the enhancement patterns of hepatic tumors observed by contrast-enhanced harmonic gray-scale sonography. In the arterial phase, 169 (95%) of the 178 HCC lesions showed intratumoral vessels with homogeneous or heterogeneous enhancement (pattern A1), and among the other 9 HCC lesions, 1 (1%) showed intratumoral vessels without homogeneous or heterogeneous enhancement (pattern A2), 2 (1%) showed a peripheral nodular enhancement without tumor vessels (pattern A4), and 6 (3%) showed no enhancement and no tumor vessels (pattern A5). Five (9%) of the 56 liver metastases showed intratumoral vessels with homogeneous or heterogeneous enhancement (pattern A1), 15 (27%) showed intratumoral vessels without

A1: Intratumoral vessels with homogeneous or heterogeneous enhancement; A2: Intratumoral vessels without homogeneous or heterogeneous enhancement; A3: Peritumoral vessels; A4: Peripheral nodular enhancement without tumor vessels; A5: No enhancement and no tumor vessels; P1: Homogeneous or heterogeneous enhancement; P2: Perfusion defect; P3: Ring enhancement; P4: Peripheral nodular enhancement; L1: Iso-echoic; L2: Hypo-echoic.

homogeneous or heterogeneous enhancement (pattern A2), 31 (55%) showed peritumoral vessels (pattern A3), and 5 (9%) showed no enhancement and no tumor vessels (pattern A5). One (1%) of the 69 hemangiomas showed intratumoral vessels without homogeneous or heterogeneous enhancement (pattern A2), 42 showed peripheral nodular enhancement without tumor vessels in the arterial phase (pattern A4), and 26 (38%) showed no enhancement and no tumor vessels (pattern A5).

Portal phase: In the portal phase, 166 (93%) of the 178 HCC lesions showed a homogeneous or heterogeneous pattern of enhancement (pattern P1): a homogeneous pattern in 148 (83%), and a heterogeneous pattern in 18 (10%). Since Levovist did not enhance the necrotic areas of the tumors, tumors that contained necrotic areas showed a heterogeneous pattern^[23]. Eight (4%) of the 178 lesions showed a perfusion defect in the portal phase (pattern P2): two exhibited arteriportal shunting on arteriography and intratumoral vessels with homogeneous enhancement in the arterial phase, and the remaining 6 lesions were early HCCs. Two (1%) of the remaining 4 (2%) HCC lesions showed ring enhancement (pattern P3) and 2 (1%) showed a peripheral nodular enhancement (pattern P4). Nine (16%) of the 56 liver metastases showed homogeneous or heterogeneous enhancement (pattern P1), 8 (14%) showed a perfusion defect (pattern P2), 37 (66%) showed ring enhancement (pattern P3), and 2 (4%) showed peripheral nodular enhancement (pattern P4). Of the 69 hemangiomas, 32 (46%) showed homogeneous enhancement (pattern P1), 1 (1%) showed ring enhancement (pattern P3), and 36 (52%) showed peripheral nodular enhancement (pattern P4).

Late phase: In the late phase, 164 (92%) of the

A1: Intratumoral vessels with homogeneous or heterogeneous enhancement; A3: Peritumoral vessels; A4: Peripheral nodular enhancement without tumor vessels; P1: Homogeneous or heterogeneous enhancement; P2: Perfusion defect; P3: Ring enhancement; P4: Peripheral nodular enhancement.

HCC lesions were visualized as hypo-echoic with the surrounding liver parenchyma (pattern L1), and 14 (8%) as iso-echoic (pattern L2). Histological examination revealed that all iso-echoic HCCs lesions in the late phase were well differentiated HCCs. All metastases were hypo-echoic (pattern L1). Of the 69 hemangiomas, 55 (80%) were hypo-echoic (pattern L1), and the remaining 14 (20%) were iso-echoic (pattern L2).

Factors predicting the diagnosis of hepatic tumors:

To identify predictors of the diagnosis of hepatic tumors, multiple logistic regression analysis was performed on 11 parameters based on the results of contrast-enhanced harmonic gray-scale sonography with contrast agents. Only 7 parameters were selected as independent variables associated with a type of hepatic tumor (Table 2). Intratumoral vessels with homogeneous or heterogeneous enhancement in the arterial phase (pattern A1) (odds ratio: 189.665; *P* < 0.01) and homogeneous or heterogeneous enhancement in the portal phase (pattern P1) (odds ratio: 38.993; *P* < 0.01) were selected as statistically significant variables to differentiate HCC from the other two types of hepatic lesions combined, i.e., metastases and hemangiomas. Peritumoral vessels in the arterial phase (pattern A3) (odds ratio: 73.139; *P* < 0.01), perfusion defect in the portal phase (pattern P2) (odds ratio: 17.92; *P* < 0.01), and ring enhancement in the portal phase (pattern P3) (odds ratio: 137.385; *P* < 0.01) were selected as statistically significant variables to differentiate metastases from the other two types of lesions combined, i.e., HCCs and hemangiomas. Peripheral nodular enhancement without tumor vessels in the arterial phase (pattern A4) (odds ratio: 102.175; *P* < 0.01) and peripheral nodular enhancement in the portal phase (pattern P4) (odds ratio: 695.141; *P* < 0.01) were selected as statistically significant variables to differentiate hemangiomas from the other two types of lesions combined, i.e., HCCs and metastases. Two parameters of the late phase were not statistically significant variables.

Enhancement pattern-based classification: Combinations of patterns of enhancement in the arterial phase (A1, A3, A4, and others) and portal phase (P1, P2, P3, and

A1: Intratumoral vessels with homogeneous or heterogeneous enhancement; A3: Peritumoral vessels; A4: Peripheral nodular enhancement without tumor vessels; P1: homogeneous or heterogeneous enhancement; P2: Perfusion defect; P3: Ring enhancement; P4: Peripheral nodular enhancement. ¹Diagnosis was made on the basis of the largest positive predictive value for each of the three kinds of tumors in each combination of enhancement patterns. ²Others mean A2 or A5 as shown in Table 1.

P4) were then analyzed, and 16 different combinations of statistically significant predictors in the arterial phase and portal phase were identified. Since two combinations of patterns were not observed in any of the cases in this study, only 14 patterns were analyzed (Table 3).

Enhancement pattern combinations 1, 2, 4, 9, and 12 showed high positive predictive value for HCC, and “pattern combination 1” was the most predominant pattern among them. According to the greatest tumor diameter, the numbers of all lesions that were “pattern combination 1” lesions were: 2 (100%) of 2 lesions less than 10 mm; 82 (94%) of 87 lesions between 10 and 20 mm; and 81 (91%) of 89 lesions greater than 20 mm. Both “pattern combination 2” lesions were HCCs with arteriportal shunting. Five of the six “pattern combination 12” lesions were early HCCs.

The enhancement pattern combinations 3, 5, 6, 7, and 13 showed high positive predictive value for metastasis, and “pattern combination 7” was the predominant pattern. “Pattern combinations 3 and 13” were observed in hypervascular metastases.

Enhancement “pattern combinations 8, 10, 11, and 14” showed high positive predictive value for hemangioma, and “pattern combination 8” was the most predominant pattern among them. The hemangiomas that showed “pattern combination 8” were relatively high-flow type hemangiomas. All 8 lesions that showed “pattern combination 11” exhibited no enhancement and no tumor vessels in the arterial phase, and homogeneous enhancement in the portal phase.

Prospective study

Table 4 shows the results of a prospective study of hepatic tumors diagnosed by using the pattern combination-based classification of the contrast-enhanced harmonic gray-scale sonography findings. Three combination patterns were not found in any of the cases in the prospective study.

Of the 205 HCCs, 183 lesions corresponded to “pattern combination 1”, and 8 corresponded to “pattern combination 12”; these lesions were correctly diagnosed as HCC. According to greatest tumor diameter, the numbers of all lesions that were “pattern combination 1” were: 1 (50%) of 2 lesions less than 10 mm; 80 (83%) of 96 lesions between 10 mm and 20 mm; and 102 (95%) of 107 lesions greater than 20 mm. Fourteen HCC lesions were not diagnosed as HCC. These lesions were corresponded to “pattern combination 11” and were diagnosed as hemangioma. Eleven of the 14 “pattern combination 11” lesions showed intratumoral vessels without homogeneous or heterogeneous enhancement in the arterial phase (pattern A2), and the remaining three showed no enhancement and no tumor vessels in the arterial phase (pattern A5). These lesions were histologically diagnosed as well differentiated HCC.

Of the 33 metastases, 14 corresponded to “pattern combination 7”, 8 to “pattern combination 13”, 5 to “pattern combination 3”, and one each to “pattern combinations 5 and 6”. These 29 lesions were correctly diagnosed as metastases. Four metastases were not diagnosed as metastases; three corresponding to “pattern

combination 1” were diagnosed as HCC, and one corresponding to “pattern combination 11” was diagnosed as hemangioma.

Of the 45 hemangiomas, 16 corresponded to “pattern combination 8”, 7 to “pattern combination 10”, 18 to “pattern combination 14”, and 2 to “pattern combination 11”. These hemangioma lesions were not correctly diagnosed as hemangiomas. One hemangioma was not diagnosed as hemangioma; it corresponded to “pattern combination 5” and was diagnosed as a metastasis. The remaining one case of hemangioma was not diagnosed because the pattern combination did not exist in the retrospective study.

The sensitivity, specificity, and accuracy of prospective diagnosis based on the combinations of enhancement patterns, respectively, were 93.2%, 96.2%, and 94.0% for hepatocellular carcinoma, 87.9%, 99.6%, and 98.2% for metastasis, and 95.6%, 94.1%, and 94.3% for hemangioma.

DISCUSSION

In the present study, we first retrospectively classified the contrast-enhanced harmonic gray-scale sonography findings in hepatic tumors into combinations of enhancement patterns. The results of a multiple logistic regression analysis and the positive predictive values calculated from the results of the pattern combinations for each hepatic lesion demonstrated that the enhancement pattern-based classification of contrast-enhanced harmonic gray-scale sonography findings was useful for making the differential diagnosis of hepatic tumors in the subsequent prospective study. Hence, we concluded that contrast-enhanced harmonic gray-scale sonography is a useful modality for differentiating among the types of hepatic tumors we studied.

To visualize tumor perfusion in our previous mode of contrast-enhanced harmonic gray-scale sonography, we reduced bubble destruction and used a frame rate of 2 frames per second, and at that rate intratumoral vessels were observed in the arterial phase in 98 (84%) of the 116 lesions^[23]. We used the novel mode in the present study and 169 (95%) of the 178 hepatocellular carcinoma lesions showed homogeneous or heterogeneous enhancement with intratumoral vessels in the arterial phase. Clearer and more frequent visualizations of homogeneous or heterogeneous enhancement with intratumoral vessels were achieved when the frame rate was 7 frames per second. This real-time observation of the arterial phase made the diagnosis of hepatocellular carcinoma easier when the lesion showed hypervascular enhancement with intratumoral vessels. This novel mode of real-time contrast-enhanced harmonic gray-scale sonography also enabled detection of viable hepatocellular carcinoma lesions which were not detected by conventional sonography^[11], and we were able to treat these lesions in real time by percutaneous therapy under guidance by this modality. Improved sensitivity also permitted us to perform this examination after injection of a smaller volume of contrast agent than with the previous mode^[11].

The arteries feeding hepatic tumors are directly supplied by branches of the hepatic artery. Hemangiomas

are hypervascular tumors in which normal-caliber arteries taper normally and subdivide normally into small vessels^[26]. The typical finding of hemangiomas in previous mode was absence of enhancement in the arterial phase^[23]. However, the typical findings of hemangioma in the present study were peripheral nodular enhancement without tumor vessels in the arterial phase of contrast-enhanced harmonic gray-scale sonography. The novel contrast mode improved both spatial resolution and contrast resolution, and this development made it possible to observe peripheral nodular enhancement in the arterial phase. The arterial branches supplying HCCs tend to show irregularly tortuous extension, whereas the arterial branches supplying hepatic metastases are scanty or fine, and are located in the periphery of the tumors, distinguishing them from HCCs^[27]. The typical arterial phase finding in metastases is peritumoral vessels without early enhancement, whereas the typical finding in HCCs is intratumoral vessels with homogeneous or heterogeneous enhancement. These different findings in the arterial phase may be of use in differentiating between hypervascular metastasis and typical HCC. Moreover, more than 80% of metastases show ring enhancement or a perfusion defect in the portal phase, whereas more than 95% of HCCs show homogeneous or heterogeneous enhancement in the portal phase. However, the tumor vessels of hepatic metastases exhibit many variations. Hypervascular metastases sometimes show intratumoral vessels with homogeneous or heterogeneous enhancement in the arterial phase, and this enhancement pattern mimics that of HCC. In the portal phase, however, almost all hypervascular metastases showed ring enhancement. Thus, the combinations of pattern enhancement in the arterial and the portal phase are useful for making the differential diagnosis of hepatic tumors.

The multivariate analysis in the present study showed that the parameters in the late phase were not significant predictors of the diagnosis, suggesting that observation of the vascular phase (arterial and portal phase) is important in making the differential diagnosis of hepatic tumors. This finding is the same as with the previous mode^[23]. We think that the late phase may be useful for detecting metastases, because all metastases were visualized as a hypo-echoic lesion in the late phase. All HCC lesions that exhibited “pattern combination 1” in the vascular phase and that were iso-echoic in the late phase were well differentiated HCC, whereas almost all HCC lesions with “pattern combination 1” in the vascular phase and hypo-echoic in the late phase were moderately to poorly differentiated HCC. These results are similar to those reported by Nicolau *et al*^[28] in a study using SonoVue, a second generation ultrasound contrast agent. We think that the late phase finding may be useful for evaluating the grade of malignancy of HCC. However, they are not of value for differentiating hepatic tumors, because whether a lesion is iso-echoic or hypo-echoic with the surrounding liver parenchyma is not a significant predictor of the diagnoses of hepatic tumors.

In this prospective study, the pattern-based classification failed to correctly diagnose 14 HCC lesions that were histologically well differentiated HCCs. These lesions

did not show early homogeneous or heterogeneous enhancement in the arterial phase, but showed homogeneous or heterogeneous enhancement in the portal phase. These misdiagnoses are attributable to the fact that there were only a small number of well differentiated HCC lesions in the retrospective study compared to the prospective study, because 1 HCC lesion, 3 metastatic lesions, and 8 hemangioma lesions exhibited this pattern of enhancement in the retrospective study and it had high positive predictive value for hemangioma.

The European Association for the Study of the Liver (EASL) conference has stated that HCC can be diagnosed without biopsy in patients with cirrhosis who have a lesion greater than 2 cm in diameter that shows characteristic arterial vascularization on two different imaging modalities, i.e., triphasic CT scan and MRI^[29,30]. Such lesions should be treated as HCC, since the positive predictive value of the clinical and radiological findings exceeds 95%^[29,30]. In this study, 348 (93%) of the 379 HCC lesions equal to or greater than 10 mm exhibited the most predominant pattern of HCC lesions on contrast-enhanced sonography. Because contrast-enhanced sonography has highly accuracy for the diagnosis of HCC, we hope that this modality will be included in imaging modalities like triphasic CT scan and MRI.

We prospectively diagnosed hepatic tumors correctly according to the results of the enhancement pattern based on the retrospective study using Levovist, a first-generation contrast agent, suggesting that this enhancement pattern-based classification will be useful for differentiating among the hepatic tumors in future trials using second-generation contrast agents.

Abstract

AIM: To evaluate the prognostic significance of p27^{kip1} in colorectal cancer patients.

METHODS: Cytoplasmic and nuclear p27^{kip1} expression was evaluated in 418 colorectal cancers using tissue microarrays. Data were associated with known patient and tumor variables and long-term patient outcomes, providing further insight into the mechanisms by which p27^{kip1} may influence tumor development.

RESULTS: Nuclear and cytoplasmic p27^{kip1} expressions were detected in 59% and 19% of tumors respectively. Cytoplasmic p27^{kip1} was almost invariably associated with positive nuclear p27^{kip1} expression. Neither case correlated with known clinical or pathological variables, including tumor stage, grade or extramural vascular invasion. Furthermore, nuclear p27^{kip1} expression had no impact on survival. However, we identified a significant correlation between expression of cytoplasmic p27^{kip1} and longer disease-specific survival times. On multivariate analysis, TNM stage and extramural vascular invasion were highly significant independent prognostic factors, with positive cytoplasmic p27 expression showing a trend towards improved patient survival ($P = 0.059$).

CONCLUSION: These findings support the recent evidence that cytoplasmic p27^{kip1} has a distinct and important biological role that can influence tumor outcome.

INTRODUCTION

p27, also known as Kip1, is expressed in most cells and its role is to bind and inhibit cyclin/cyclin-dependent kinase (cyclin-CDK) complexes, thereby inhibiting cell cycle progression^[1]. This role in the cell cycle makes p27^{kip1} a key player in multiple cell fate decisions including proliferation, motility, differentiation and apoptosis. Numerous studies have shown that p27^{kip1} is a tumor suppressor gene whose loss co-operates with mutations in several oncogenes and tumor suppressor genes in order to facilitate tumor growth. p27^{kip1} is rarely mutated, and is predominantly regulated at the post-transcriptional level by degradation in the ubiquitin-proteasome pathway^[2]. However, in contrast to most tumor suppressor genes, which are recessive, tumor suppression by p27^{kip1} appears critically dependent upon on the absolute level of p27^{kip1}^[3]. Several clinical studies have correlated absent or low p27^{kip1} expression with a poor prognosis in a range of malignancies, including breast, colorectal, gastric, ovary, prostate, bladder and oesophageal tumors^[4-11]. Other investigators have failed to reproduce, or have only partially confirmed, the previously published results^[12-14]. Some controversy also exists over the importance of cytoplasmic expression of p27^{kip1}, which was originally thought to represent a mechanism for inactivating p27^{kip1} by sequestering it away from its site of action within the nucleus^[15]. Cytoplasmic expression of p27^{kip1} has been identified in colorectal cancer, ovarian cancer and Barrett's oesophagus^[6,16-18], and recent evidence

suggests that it may have an active role, as it has been shown to bind to RhoA and inhibit its activity^[19]. Members of the Rho family include Cdc42, Rac and RhoA. These act as molecular switches in signalling pathways affecting gene transcription and cytoskeletal rearrangements. In particular, the Rho proteins regulate and co-ordinate the cytoskeletal remodelling that underlies changes in cell adhesion and migration^[20]. Consistent with these studies, p27's ability to regulate motility is distinct from its ability to inhibit cellular proliferation. Indeed, the region of p27^{kip1} that binds to RhoA and is required for migration is different from the region that binds cyclin-CDKs^[21].

Using high-throughput Tissue Microarray (TMA) technology^[22] we have investigated the expression of both cytoplasmic and nuclear p27^{kip1} in a series of over 400 paraffin wax-embedded colorectal tumor specimens. Data derived from this analysis was then associated with known patient and tumor variables, and with long-term patient outcome data, in order to gain further insight into the mechanisms by which p27 may influence tumor development.

MATERIALS AND METHODS

Patients

Four hundred and sixty-two patients were included in this study. A detailed description of these cases has been provided previously^[23,24]. Briefly, all patients included in the TMA underwent elective resection of a histologically proven primary colorectal cancer between 1st January 1993 and 31st December 2000 at the University Hospital Nottingham, with prospective collection of associated clinical and pathological data including tumor site, TNM stage, histological tumor type and grade, and the presence of extramural vascular invasion. Histological factors more recently identified as having potential prognostic value in colorectal cancer, such as tumor budding and the tumor border configuration, were not recorded routinely at our institution and hence were not considered in the data analysis. Patients with lymph node positive disease were characteristically treated with adjuvant chemotherapy, consisting of 5-fluorouracil and folinic acid. The UK Office for National Statistics has provided comprehensive follow-up regarding the date and cause of death for this cohort of patients. The length of follow-up was determined from the date of primary tumor resection, with surviving cases censored for analysis on the 31st December 2003. Disease specific survival was used as the primary end-point of the study.

Immunohistochemical procedures

Arrayed tumors were analysed for the expression of p27^{kip1} using a murine monoclonal anti-human p27^{kip1} antibody (clone SX53G8; Dako Ltd, Ely, UK) and standard immunohistochemistry with an avidin-biotin/horseradish peroxidase development system. Five microns formalin-fixed, wax-embedded tissue array sections were dewaxed in an incubator for 20 min at 60°C, deparaffinised with xylene, rehydrated through graded alcohol and immersed in 0.3% hydrogen peroxide-methanol solution to block endogenous peroxidase activity. Antigen retrieval was

achieved by microwaving slides for 20 min in pH 9.0 EDTA buffer. Endogenous avidin/biotin activity was blocked using an avidin/biotin blocking kit (Vector Labs, USA). One hundred microliters of normal swine serum (NSS) was added to the sections for 10 min to block non-specific binding of the primary antibody. 100 μ L of anti-p27^{kip1} antibody diluted 1:25 (v/v) in NSS/TBS was then applied to the test sections for 1hr at room temperature. Positive controls consisted of multi-tissue sections containing human kidney and tonsil, with omission of the primary antibody from negative control sections. After washing with TBS, sections were incubated with 100 μ L of biotinylated goat anti-mouse/rabbit immunoglobulin (Dako Ltd, Ely, UK) diluted 1:100 in NSS for 30 min. One hundred microliters of pre-formed streptavidin-biotin/horseradish peroxidase (HRP) complex (Dako Ltd, Ely, UK) was then applied for 60 min at room temperature. Finally, bound antibody visualisation was accomplished using 3, 3'-Diaminobenzidine tetrahydrochloride (Dab, Dako Ltd, Ely, UK).

Evaluation of immunohistochemical staining

Immunohistochemical staining patterns were interpreted by two observers (DSGS and NFSW) blinded to the associated clinicopathological data. Nuclear p27^{kip1} expression was scored as follows: cases with < 10% tumor cell nuclei stained = 0, 10%-20% tumor cell nuclei stained = 1 and > 20% tumor cell nuclei stained = 2, irrespective of the staining intensity. Cytoplasmic staining was scored: complete absence of cytoplasmic staining or cytoplasmic staining of any intensity in < 10% tumor cells = 0, weak/moderate intensity cytoplasmic staining in > 10% tumor cells = 1, and intense cytoplasmic staining in > 10% tumor cells = 2. These cutoffs were based on previously published reports investigating the prognostic significance of p27^{kip1} expression in colorectal tumors^[16,25]. For the purposes of statistical analysis, these scores were re-categorized, with tumors considered either positive (score 1 or 2) or negative (score 0) for both nuclear and cytoplasmic p27^{kip1} expression. It has previously been established that in colorectal cancers, no significant differences in p27 immunoreactivity are usually seen between the centre and the invasive edge of the tumors^[26].

Statistical analysis

All calculations were performed using SPSS software (version 11.5 for Windows, SPSS Inc., Chicago, IL). Associations between categorical variables were examined using crosstabulation and the Pearson chi-square test. Kaplan-Meier curves were plotted in order to assess correlations with disease-specific survival and the significance of differences in disease-specific survival between groups was calculated using the log-rank test. Patients whose deaths related to their colorectal cancer, including early deaths from post-operative complications, were considered in the disease-specific survival calculations. Deaths resulting from non-colorectal cancer related causes were censored at the time of death. Multivariate analysis was conducted using the Cox proportional-hazards model to determine hazard ratios, and to identify variables with independent prognostic significance in this cohort. In

RESULTS

Clinicopathological data

The characteristics of the 462 patients included in this study are summarized in Table 1. Male patients comprised 58% of the cohort, and the median patient age at the time of surgery was 72 years. At the time of censoring for data analysis 49% of patients had died from their colorectal cancer, with a further 14% deceased from non-colorectal cancer causes. The remaining 37% were still alive. The majority of tumors were of a moderately differentiated histological grade (77%). Similarly, 85% of tumors were adenocarcinomas, with a further 11% showing mucinous differentiation. Surviving patients had a median length follow-up of 75 (range 36-116) mo. Of the conventional clinicopathological variables, strong correlations were observed between tumor stage and disease specific survival (DSS) (Log rank = 207.33, *P* < 0.001) and between the presence of extramural vascular invasion and DSS (Log rank = 44.30, *P* < 0.001).

Of the 462 tumor specimens analyzed, 44 (9.5%) were subsequently uninterpretable due to loss of tissue from the TMA during the Immunohistochemical procedure. Among the remaining 418 tumors, three distinct patterns

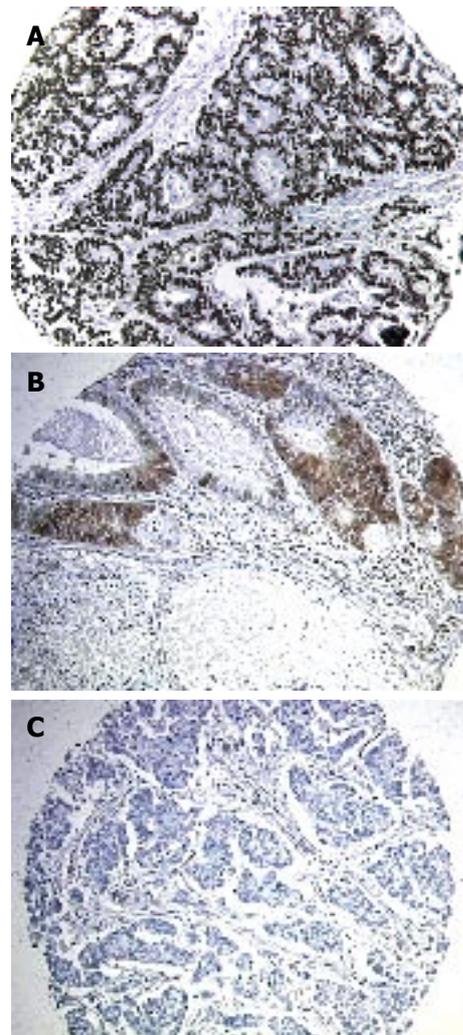

Figure 1 p27^{Kip1} expression in representative tumor samples. Tumors displayed either nuclear p27^{Kip1} alone (A), both nuclear and cytoplasmic p27^{Kip1} (B), or absent p27^{Kip1} expression (C).

of p27^{Kip1} expression were observed (Figure 1A-1C). These comprised staining of the tumor cell nuclei alone, staining of both tumor cell nuclei and cytoplasm, and absent staining of tumor elements. In contrast, no tumor cell membrane or stromal expression of p27^{Kip1} was detected in any specimen.

Nuclear p27^{Kip1} expression

Variable expression of nuclear p27^{Kip1} was observed in 217/418 (51.9%) tumors (Table 2). In 29 of these cases nuclear p27^{Kip1} was present in 10%-20% of tumor cells within the core, and in the remainder, nuclear p27^{Kip1} was present in > 20% of tumor cells. There were no significant associations detected between any level of nuclear p27^{Kip1} expression and known clinicopathological variables, including tumor grade, stage and the presence of extramural vascular invasion. Furthermore, on Kaplan-Meier analysis, no association was found between nuclear p27^{Kip1} expression and DSS (Figure 2A, Log rank = 1.701, *P* = 0.1815).

Cytoplasmic p27^{Kip1} expression

Expression of cytoplasmic p27^{Kip1} was detected in 79/418

Table 2 p27^{kip1} localisation within 418 colorectal tumor specimens

p27 localisation	Positive n (%)	Negative n (%)	Missing n (%)
Nuclear	217 (51.9)	201 (48.1)	44 (9.5)
Cytoplasmic	79 (18.9)	339 (81.1)	44 (9.5)

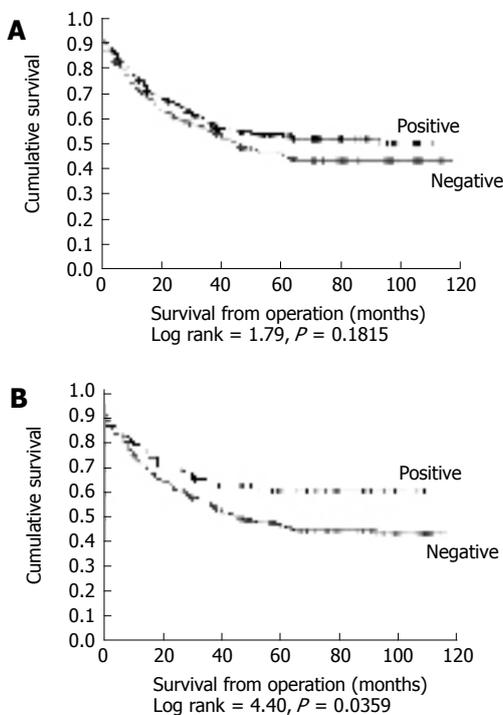

Figure 2 Kaplan-Meier plots for disease specific survival in relation to expression of nuclear (A) and cytoplasmic (B) p27^{kip1}.

(18.9%) tumors (Table 2). These tumors appeared to form a distinct subset of the nuclear p27^{kip1} positive tumors, as co-expression of nuclear and cytoplasmic p27^{kip1} was noted in 74/79 cases (93.6%). In 55 of the cytoplasmic p27^{kip1} positive tumors, expression was of weak or moderate intensity and in the remaining 24 cases strong expression was noted. As with nuclear p27^{kip1}, no statistically significant associations were found between the presence of cytoplasmic p27^{kip1} within the tumor and clinicopathological variables for the patient cohort. However, a significant relationship was identified between the presence of cytoplasmic p27^{kip1} and DSS. Kaplan-Meier analysis revealed that patients with cytoplasmic p27(+), tumors, had a significantly longer mean DSS of 72 (95% CI 62-83) mo, compared with a mean DSS of 62 (95% CI 57-68) mo in patients with cytoplasmic p27^{kip1}(-) tumors (Figure 2B, Log rank = 4.40, $P = 0.0359$).

Multivariate analysis

A multivariate analysis of factors influencing survival in 418 available cases was performed using the Cox proportional hazards model (Table 3). Of the conventional clinicopathological variables analysed, tumor stage ($P < 0.001$) and extramural vascular invasion status ($P = 0.001$) were demonstrated to confer independently significant

Table 3 Multivariate analysis of Cytoplasmic p27^{kip1} expression in relation to known clinical and pathological variables ($n = 418$)

Variable	Category	Hazard ratio (HR)	95% CI for HR	P
Gender	Female	1		
	Male	1.055	0.787-1.415	0.719

	Positive	0.681	0.458-1.015	0.059

prognostic information. In this model expression of cytoplasmic p27^{kip1} within the tumor samples was associated with a strong trend towards improved DSS (HR for death in cytoplasmic p27^{kip1} positive tumors = 0.681, 95% CI 0.458-1.015), which approached statistical significance ($P = 0.059$).

DISCUSSION

p27^{kip1} is a universal CDK inhibitor that acts in G₀ and early G₁ to inhibit cyclin E/CDK2 and thereby prevents entry into the S phase of the cell cycle. It can also bind other cyclin-CDK complexes, including those involving the D-cyclins, and complexes of cyclin A/cdk2. Mitogenic growth factor signalling causes a decrease of p27^{kip1} levels and/or activity and, conversely, p27^{kip1} levels and/or activity increase in response to differentiation signals, loss of adhesion to extracellular matrix, or signalling by growth-regulatory factors such as TGF- β , c-AMP and IFN- γ . Studies in animals have shown that loss of p27^{kip1} increases the formation of tumors and also increases tumor associated deaths rates. Several studies have shown that loss of nuclear p27^{kip1} is an independent predictor of poor prognosis in colorectal cancer^[6,27,28], although other studies have failed to confirm this observation^[29,30]. Loss of nuclear

p27^{Kip1} was observed in 48% of tumors in our study. However, this showed no significant associations with known clinical or pathological variables. Additionally, on Kaplan-Meier analysis, no association was found between nuclear p27^{Kip1} expression and survival.

Several clinical studies have detected cytoplasmic expression of p27^{Kip1}, and found an inverse correlation with disease free survival^[17,28,31]. In contrast, in this large study of 418 colorectal tumors, cytoplasmic expression of p27^{Kip1} was significantly associated with a good prognosis. This may be related to the findings from recent studies showing that p27^{Kip1} can bind and inactivate Rho proteins. For tumors to metastasise, cells must alter their connections to both their neighbours and their substrate, and then migrate. Efficient migration requires a tightly balanced activation and deactivation of Cdc42, Rac and RhoA in both time and space. Indeed, two modes of tumor cell motility have been described in 3D matrices. Rho signalling through ROCK promotes a rounded bleb-associated mode of motility that does not require pericellular proteolysis. In contrast, elongated cell motility is associated with Rac-dependent F-actin-rich protrusions and does not require Rho or ROCK^[32]. Consistent with this observation are other studies that have shown inhibition of ROCK reduces the invasive behaviour of tumor cells *in vivo*^[33,34]. Sequestrations of RhoA by cytoplasmic p27^{Kip1} may inhibit RhoA, resulting in inhibition of ROCK and less aggressive tumors. In the current study, cytoplasmic expression of p27^{Kip1} was almost invariably associated with nuclear expression. These tumors may therefore have relatively controlled cell proliferation together with a reduced capacity for migration, resulting in a less aggressive tumor and a good prognosis. In contrast, loss of both cytoplasmic and nuclear p27^{Kip1} may result in uncontrolled proliferation and increased invasion, leading to an aggressive tumor and poor prognosis. Tumor cells expressing only nuclear p27^{Kip1} would have reduced proliferation but may still be invasive, resulting in an intermediate prognosis. This may explain the inconsistency of previous studies linking p27^{Kip1} expression with prognosis, as studies considering nuclear p27^{Kip1} expression alone have not identified the subgroup of tumors with additional cytoplasmic p27^{Kip1} expression. It is anticipated that the role of cytoplasmic p27^{Kip1} in promoting tumor progression may also depend upon the site and mechanism of invasion, as in a study of 61 patients with pancreatic cancer in which those with exclusively nuclear p27^{Kip1} expression were shown to have a better prognosis than those with both nuclear and cytoplasmic p27^{Kip1} expression^[31].

Recently, it has been suggested that the presence of high numbers of detached clusters of tumor cells in adjacent stroma (termed tumor budding) may serve as an adverse histopathological prognostic feature in colorectal cancer^[35]. As this tumor budding is the morphological counterpart of epithelial-mesenchymal transition, micro-invasion, and acquisition of individual cell motility, it would be of interest to correlate p27 immun-expression patterns with colorectal tumor budding activity. However, this would be best performed using conventional whole tissue section analysis rather than TMA's. Similarly, as the size of this array does not provide us with the statistical power to co-analyze two rare events, we have not

performed analysis of DNA mismatch repair gene status and therefore cannot comment on whether cytoplasmic p27 expression may have a diverse role in colorectal tumors of differing microsatellite instability status. Finally, although out of the scope of this manuscript, it would be of interest to compare disease specific survival between p27^{Kip1} and wild-type mouse in a colorectal cancer mouse model.

The identification of novel molecular and genetic markers of prognosis will eventually allow us to provide a cancer patient with individually tailored therapy based upon the specific molecular fingerprint of his or her tumor. Our findings in a large cohort of unselected patients with colorectal cancer suggest that cytoplasmic p27^{Kip1} expression deserves further consideration as a marker of prognosis, as patients with colorectal tumors showing cytoplasmic expression of p27^{Kip1} appear to have a more favourable disease specific survival.

Abstract

AIM: To select accurately good candidates of hepatic resection for colorectal liver metastasis.

METHODS: Thirteen clinicopathological features, which were recognized only before or during surgery, were selected retrospectively in 81 consecutive patients in one hospital (Group I). These features were entered into a multivariate analysis to determine independent and significant variables affecting long-term prognosis after hepatectomy. Using selected variables, we created a scoring formula to classify patients with colorectal liver metastases to select good candidates for hepatic resection. The usefulness of the new scoring system was examined in a series of 92 patients from another hospital (Group II), comparing the number of selected variables.

RESULTS: Among 81 patients of Group I, multivariate analysis, i.e. Cox regression analysis, showed that multiple tumors, the largest tumor greater than 5 cm in diameter, and resectable extrahepatic metastases were significant and independent prognostic factors for poor survival after hepatectomy ($P < 0.05$). In addition, these three factors: serosa invasion, local lymph node metastases of primary cancers, and post-operative disease free interval less than 1 year including synchronous hepatic metastasis, were not significant, however, they were selected by a stepwise method of Cox regression analysis ($0.05 < P < 0.20$). Using these six variables, we created a new scoring formula to classify patients with colorectal liver metastases. Finally, our new scoring system not only classified patients in Group I very well, but also that in Group II, according to long-term outcomes after hepatic resection. The positive number of these six variables also classified them well.

CONCLUSION: Both, our new scoring system and the positive number of significant prognostic factors are useful to classify patients with colorectal liver metastases in the preoperative selection of good candidates for hepatic resection.

INTRODUCTION

It is well accepted that hepatic resection for colorectal liver metastases is beneficial; it has been reported survival rates improve to as high as almost 30% to 50% at 5 years after curative hepatic resection recently^[1-10]. However, the feasible criteria for surgery are still controversial. The purpose of the present study is to implement a useful classification system to select optimal candidates for hepatic resection among patients with colorectal liver metastases.

MATERIALS AND METHODS

Patients

Group I: Between January 1, 1981 and March 31, 1997, 83 consecutive patients underwent partial hepatectomy for colorectal liver metastases at the First Department of Surgery, presently the Department of Surgical Oncology, Tokyo University Hospital. Every hepatectomy was considered curative because of complete macroscopic resection of hepatic tumors. Even though extrahepatic metastases were excised, hepatectomy was performed if extrahepatic metastatic tumors could be completely resected as well macroscopically. During the post-operative period, two patients died in the hospital. One died secondary to aspiration pneumonia and the other by

developing severe intra-abdominal sepsis (mortality rate: 3.1%). Therefore, the remaining 81 patients were followed until death or their last outpatient visit up to December 31, 2004. The follow-up period ranged from 4 to 197 mo. with a median of 53.0 mo. After discharge from the hospital, patients were closely monitored at the outpatient clinic or affiliated institutions. During visits, measurement of serum carcinoembryonic antigen (CEA) levels and ultrasonography were performed at least once every two months for early detection of recurrence. In addition, computed tomography was performed approximately twice a year. Almost all cases of cancer recurrence were diagnosed by these investigative tests. When the diagnosis was unclear, angiography and/or needle biopsy under ultrasonic guidance was performed to establish a firm diagnosis.

Group II: Between January 1, 1981 and December 31, 2003, 92 consecutive patients underwent partial hepatectomy for colorectal liver metastases at the Department of Surgery, Teikyo University Hospital. During the post-operative period, two patients died in the hospital from post-operative hepatic failure (mortality rate: 5.6%). The remaining 92 patients were followed up until death or their last outpatient visit up to December 31, 2004. The follow-up period ranged from 4 to 110 mo. with a median of 39.0 mo. After discharge from the hospital, each patient was closely monitored at the outpatient clinic or affiliated institutions in a manner similar to the patients at University of Tokyo hospital.

Prognostic factors

We examined the statistical significance of thirteen factors that were expected to influence long-term prognosis in patients in Group I. Each factor could only be determined preoperatively or during surgery. These included gender; male or female, age at hepatectomy; < 60 or \geq 60 years, chronology of hepatic metastases; synchronous or metachronous, and post-operative disease free interval, \leq 1 year including synchronous metastasis or > 1 year; number of hepatic metastases; solitary or multiple, maximum diameter of the hepatic metastases; \leq 5 cm or > 5 cm, unilobar or bilobar hepatic involvement, resectable extrahepatic distant metastasis, which included pulmonary metastases, localized peritoneal metastases, or hepatoduodenal lymph node metastases, serum carcinoembryonic antigen level (CEA) at hepatectomy; less or higher than 10 times of the upper normal level, serosa invasion, and regional lymph node metastases of the primary colorectal carcinoma, type of hepatic resection; lobectomy or limited resection less than lobectomy, and macroscopical surgical resection margin; < 1 cm or \geq 1 cm. The demographic characteristics and tumor-related features, which are statistically analyzed later, are summarized in Table 1.

Statistical analysis

Survival rates after hepatectomy were calculated using data obtained from patients in Group I and Group II by the Kaplan-Meier method. Only deaths attributable to recurrent cancer were treated as events. Patients who died secondary to other causes without recurrence were treated

Table 1 Prognostic factors entered into multivariate analysis based on proposed clinical and histopathological features

Variable	n
Gender (male/female)	61/20
Age at hepatectomy (< 60/ \geq 60 yr)	32/49
Chronology of hepatic metastasis (synchronous/metachronous)	41/40
Disease free interval after colectomy (synchronous or \leq 1 yr/> 1 yr)	56/25
Extrahepatic distant metastases (no/yes)	9/72
CEA (\leq 10 times of normal value/> 10 times of normal value)	57/24
Primary lesion	
Depth of invasion (up to subserosa/more)	57/24
Lymph node metastasis (no/yes)	39/42
Hepatic metastasis	
Number (single / multiple)	45/36
Maximum diameter (\leq 5 cm/> 5 cm)	59/22
Lobe involved (unilobar/bilobar)	64/17
Therapeutic factor	
Type of hepatectomy (limited/lobectomy)	56/25
Surgical margin (< 1 cm / \geq 1 cm)	61/20

as censored. Selection of independent and significant prognostic variables was performed by multivariate analysis in patients of Group I with the stepwise analysis of Cox proportional hazard regression model. The stepwise variable selection was performed at a 0.20 significant level in this study. The creation of a scoring formula was based on the results of the multivariate analysis as above. Each selected independent and significant prognostic factor was respectively given a coefficient. The total score of each patient ($y1$) was calculated according to a formula that consisted of these selected prognostic factors.

The scoring formula was applied to patients in Group II as well as Group I. Patients were divided into sub-groups depending on their total scores ($y1$) as follows; $y1 = 0$, $0 < y1 \leq 1$, $1 < y1 \leq 2$, $2 < y1 \leq 3$, $3 < y1 \leq 4$, $4 < y1 \leq 5$, $5 < y1 \leq 6$, $6 < y1$. Survival rates according to the sub-groups were calculated using the Kaplan-Meier method. On the other hand, survival rates according to the positive number of selected significant prognostic factors ($y2$) were also calculated, and compared to the results of the scoring formula ($y1$). They were analyzed using the log-rank test.

RESULTS

The overall cancer-related survival rates after surgical resection in the 81 patients in Group I were 88.2% at 1 year, 67.7% at 2 years, 56.0% at 3 years, 51.6% at 4 years, and 49.1% at 5 years, respectively (Figure 1). The results from the multivariate analysis of those variables expected to influence cancer-related survival after surgical resection in Group I are provided in Table 2. Only variables selected by the stepwise analysis of the Cox proportional hazard regression model are shown in the table ($P < 0.20$). Multiple hepatic metastatic tumors, hepatic metastatic tumors that were greater than 5 cm in maximum diameter, and resectable extrahepatic distant metastases were significant and independent variables that influenced cancer-related survival ($P < 0.05$). In addition, serosa

invasion and regional lymph nodes metastases of primary colorectal cancer, and recurrent hepatic metastases within one year after resection of primary colorectal cancer including synchronous hepatic metastases were considered close to significant (0.05 < *P* < 0.20).

As described above, multivariate analysis indicated six variables that more independently influenced cancer-related survival after hepatic resection. In the next step of creating a scoring formula, we use these six variables to classify patients as shown in Table 3. In this formula, each variable had a coefficient, which was indicated as a parameter estimate by Cox regression analysis, as shown in Table 2. If the factor was positive, it was given a score of one point. If it was negative, it was given a score of 0 points. Thereafter the total score of each patient (*y1*) could be calculated. On the other hand, the positive number of

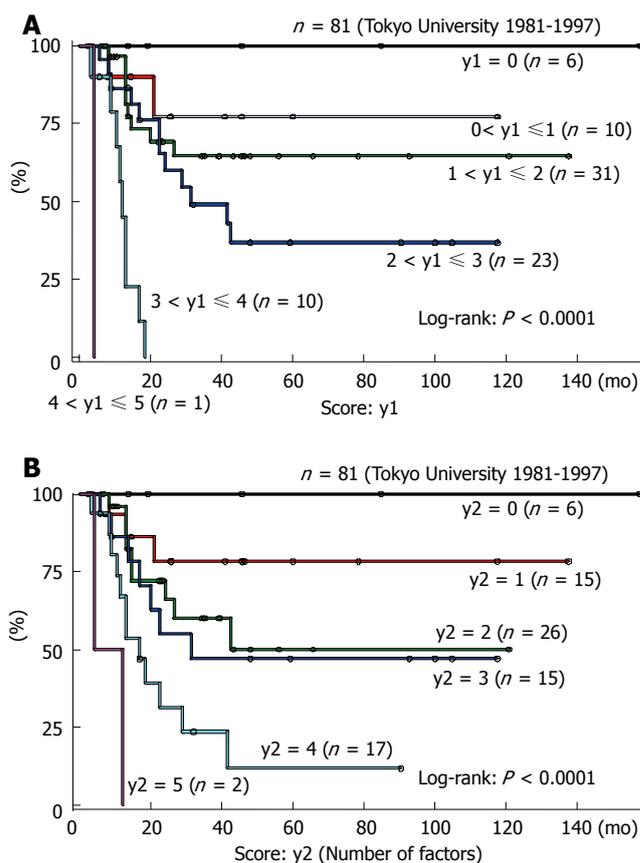

Figure 2 Kaplan-Meier cancer-related survival curves after hepatic resection for colorectal liver metastases. **A:** According to the total score (*y1*) in patients of Group I ; **B:** According to the positive number of risk factors (*y2*) in patients of Group I .

these six variables (*y2*) of each patient was also calculated

Classification of patients and survival

The total scores of patients (*y1*) in Group I were distributed between 0 and 5.2324. The survival curves of patients based on the total score (*y1*) are shown in Figure 2A. Which were accurately and significantly classified (*P* < 0.0001). We clearly found that the prognosis of patients with a total score of (*y1*) >3 were very poor. On the other hand, the survival curves of patients based on the positive number (*y2*) are shown in Figure 2B. They were well and significantly classified as well (*P* < 0.0001). We clearly found that the prognosis of patients with positive number ≥ 5 were very poor.

The survival curves of all patients in Group II are shown in Figure 3. The overall cancer-related survival rates of the 92 patients in Group II after surgical resection were 83.2% at 1 year, 62.6% at 2 years, 49.4% at 3 years, 41.0% at 4 years, and 36.4% at 5 years, respectively. We applied our scoring system to 92 patients in Group II. The total scores of these patients (*y1*) were distributed between 0 and 5.2324. The survival curves of patients based on the total score (*y1*) are shown in Figure 4A. They were also significantly classified (*P* < 0.0001). We clearly found that the prognosis of patients with total score (*y1*) > 3 were very poor. On the other hand, the survival curves of patients based on the positive number (*y2*) are shown in Figure 4B. They were significantly classified as well (*P* < 0.0001).

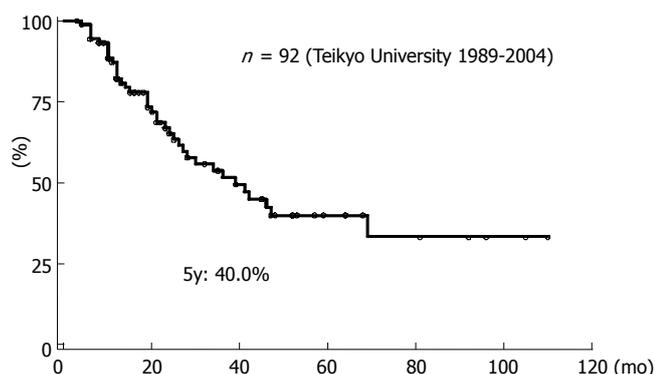

Figure 3 Kaplan-Meier cancer-related survival curve after hepatic resection for colorectal liver metastases in patients of Group II.

clearly found that the prognosis of patients with positive number ≥ 5 were very poor.

DISCUSSION

Clinical and pathological factors have been identified as important prognostic determinants of survival after surgical resection for colorectal liver metastases. These include sex^[11], age at hepatectomy^[1,12], stage of the primary tumor^[1,3,4,11-15] (including local lymph node metastases and depth of invasion), synchronous or metachronous hepatic metastases^[1-3,6,8,10,12,13,16] (including disease free interval between resection primary tumor and presence of hepatic metastasis), number^[1-4,6,7,11,12,15,17-19], size^[1,2,8,9,11,13,17,20], and distribution^[6,12,14] of hepatic metastases; serum carcinoembryonic antigen (CEA) level^[1,3,4,7,20,21], extrahepatic distant metastases^[4-6,8,10,11,15,20] (including lymph node metastasis of hepatic hilum), type of hepatectomy^[14], surgical margin^[5,7,9,11-13,15,17,18,20], and adjuvant chemotherapy^[8,22,23].

In the present study, we aimed to create a new classification system of patients with colorectal liver metastases to distinguish patients who would be good candidates for hepatic resection. There have been some classification systems for these patients so far^[1-3,12], however, they are not accepted world wide yet. We selected clinicopathological features that could be recognized as prognostic factors only before or during surgery, because we had to decide how to treat those patients pre- or intraoperatively. We included some therapeutic factors as well in this study because we intended to determine whether those therapeutic factors were significant or not. We believed that any therapeutic factors that may be significant should also be included in the classification scoring system. However, we excluded adjuvant chemotherapy because it has been arbitrarily performed in past years and we could not evaluate its efficacy. We considered positive surgical margins to be a very important factor^[5], however, we excluded it because it was an incidental factor and could only be recognized after surgery.

Among the thirteen clinicopathological factors we proposed, we found and selected the following to be more significant and independent prognostic factors for poor survival after hepatectomy: multiple hepatic metastatic tumors; hepatic metastatic tumor greater than 5 cm in

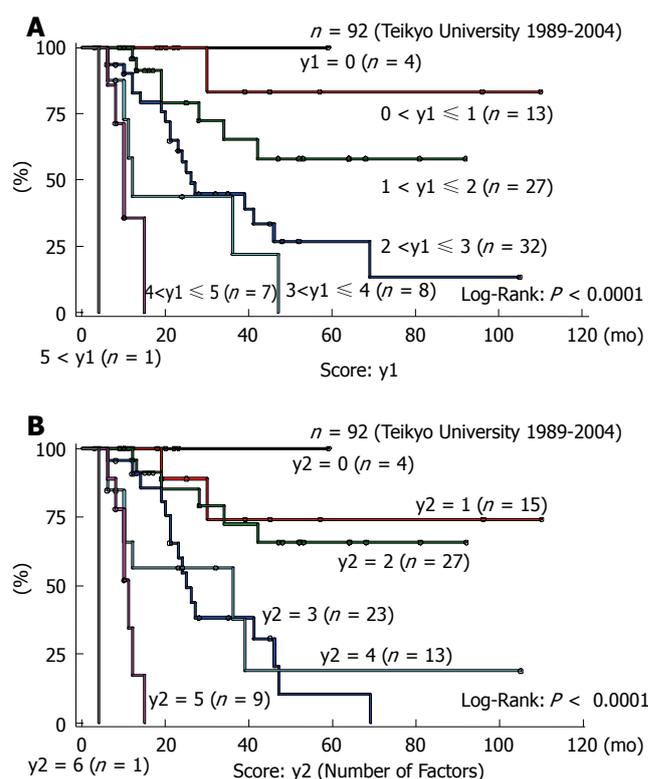

Figure 4 Kaplan-Meier cancer-related survival curves after hepatic resection for colorectal liver metastases. **A:** According to the total score ($y1$) in patients of Group II. **B:** According to the positive number of risk factors ($y2$) in patients of Group II.

diameter; resectable extrahepatic distant metastases; recurrent hepatic metastases within one year after resection of primary colorectal cancer including synchronous hepatic metastases; regional lymph node metastases and serosa invasion of primary colorectal cancers. On the other hand, none of the therapeutic factors we proposed were selected as significant prognostic factors. We found that a 1 cm negative surgical margin and type of hepatectomy were not important as long as the tumor was resected completely for colorectal liver metastases. The goal of the present study was to establish a new scoring system to classify patients with colorectal liver metastases. Hence, this would allow an accurate prediction of long-term prognosis after surgical resection in these patients. Such a system would enable better selection of candidates for surgical resection. At last, our new scoring system, which includes six prognostic factors described above, significantly classified not only a group of patients in one hospital but also a group of patients in another hospital. We are not aware of a similar scale system for predicting the long-term outcome of surgical resection for colorectal liver metastases. According to our scoring system, patients with a total score of $0 \leq y1 \leq 3$ were suitable candidates for hepatectomy. On the other hand, patients with a total score of $y1 > 5$ should not undergo hepatectomy. We believe that patients with a total score of $3 < y1 \leq 5$ should undergo hepatectomy first, since there is no other treatment superior to hepatectomy at present.

In addition, we realized that the positive number of significant prognostic factors also classified patients well with colorectal liver metastases. The prognosis of pa-

tients with positive number ≥ 5 was very poor. It seemed that our scoring formula and the positive number of risk factors had almost equal usefulness to select good candidates for hepatic resection at present. The former is more accurate, but complicated to calculate, while the latter is less accurate, but simple. Further investigation should be necessary to prove their superiority.

In conclusion, we identified six important and independent prognostic factors that were recognized before or during surgery. We used multivariate analyses from a retrospective review of patients who underwent hepatic resection for colorectal liver metastases in one hospital. We proposed a new scoring system to classify those patients according to the long-term outcome after hepatectomy. Our scoring system accurately classified a different group of patients from another hospital as well. In addition, the positive number of significant prognostic factors also classified with those patients with good accuracy. Further investigation is necessary in the future.

RESULTS: Thirty patients were excluded. Per-protocol analysis showed successful eradication in 53% in group 1, 56% in group 2, 58% in group 3, 33.3% in group 4, 28% in group 5, and 53% in group 6. Eradication rate, patient compliance and satisfaction were not significantly different between the groups.

CONCLUSION: It seems that adding sugar or levodopa or both to anti *H pylori* eradication regimens may lead to shorter duration of treatment.

Abstract

AIM: To evaluate the gastric emptying inhibitory effects of sugar and levodopa on *H pylori* eradication period.

METHODS: A total of 139 consecutive patients were randomized into 6 groups. The participants with peptic ulcer disease or non-ulcer dyspepsia non-responding to other medications who were also *H pylori*-positive patients either with positive rapid urease test (RUT) or positive histology were included. All groups were pretreated with omeprazole for 2 d and then treated with quadruple therapy regimen (omeprazole, bismuth, tetracycline and metronidazole); all drugs were given twice daily. Groups 1 and 2 were treated for 3 d, groups 3, 4 and 5 for 7 d, and group 6 for 14 d. Groups 1 to 4 received sugar in the form of 10% sucrose syrup. Levodopa was prescribed for groups 1 and 3. Patients in groups 2 and 4 were given placebo for levodopa and groups 5 and 6 received placebos for both sugar and levodopa. Upper endoscopy and biopsies were carried out before treatment and two months after treatment. Eradication of *H pylori* was assessed by RUT and histology 8 wk later.

INTRODUCTION

H pylori has been implicated as a predisposing factor in gastric cancer, chronic active gastritis, duodenal ulcer, gastric ulcer and gastric lymphoma^[1]. The incidence rate of stomach cancer in Iran is high, well above the world average; it is the most common cancer in males and the third one in females^[2]. Also, the reinfection rate in our country is high enough (20%, 3 years after successful eradication)^[1] to justify wide investigations to find safe and short *Helicobacter* treatments. However, *H pylori* eradication is a multifactor problem and depends on histological findings and ulcer depth, kind of medication and duration of treatment, age, patient compliance, genetic predisposition, geographical area of living, *H pylori* resistance, non-steroid anti-inflammatory drugs (NSAIDs) exposure and finally stomach dynamicity (gastric emptying)^[3-16].

The current approach to the patient with suspected *H pylori* infection consists of an adequate indication to test for the presence of the infection, choice of an appropriate antimicrobial regimen, and education about its use and

side effects, followed by post-therapy testing to confirm cure^[17]. In order to achieve the best results from this approach, patient compliance is of outmost importance and the favored regimen should have the least side effects; otherwise, treatment failure may ensue^[3,18].

H pylori infection plays a role in gastric emptying in type 1 diabetic patients; a delay in gastric emptying is observed with the disappearance of gastritis associated with *H pylori* infection after eradication treatment in those patients^[19]. In contrary, others have shown that *H pylori* infection is not associated with delayed gastric emptying in diabetes^[20,21]. Barnett *et al*^[22] revealed that not only gastroparesis does not predispose to *H pylori* infection or chronic gastritis, but also there is a significantly lower incidence of *H pylori* in individuals with delayed gastric emptying compared to those with normal emptying (5% *vs* 31%, respectively). Moreover, there is no link between anxiety and gastric emptying in chronic duodenal ulcer whether in “fast” emptiers ($t_{1/2}$ less than 90 min) or “normal” emptiers ($t_{1/2}$ more than 90 min)^[23]. Thus, inhibition of gastric emptying by physiologic and pharmacological methods may enhance local delivery of therapeutic agents to the stomach which is a useful strategy in the treatment of *H pylori* infection^[24-27] especially given that *H pylori* is found both attached to mucous cells of the human stomach and under the mucous layer; there is no evidence that attachment of *H pylori* to eukaryotic cells increases their resistance to antibiotics compared with free-floating bacteria^[28] and that omeprazole may displace *H pylori* from the antrum to the stomach body which could interfere with colonization studies in patients receiving the drug^[17]. However, omeprazole has shown no significant effect on solid or liquid gastric emptying in duodenal ulcer^[29]. Also, various alterations of gastric emptying in duodenal ulcer have been demonstrated by different studies^[30-33].

Sugar^[34-39] and levodopa^[40] are among the safest agents that prolong gastric emptying. Glucose in the pylorus has an inhibitory effect on gastric emptying which will be even slower with progressive increases in glucose concentration^[36,37]. Dopamine receptor antagonists (metoclopramide, domperidone) also play an important role in the treatment of gastric emptying disorders^[41].

One of the problems of the currently used anti-*H pylori* drug regimens is their long period of treatment which will be accompanied by more frequent side effects and lower compliance. In this study, we aimed to evaluate the gastric emptying inhibitory effects of sugar and levodopa on *H pylori* eradication period.

MATERIALS AND METHODS

Design

This is a double blind randomized placebo-controlled mono-center trial with 6 parallel groups which was conducted at a university hospital.

Participants

Patients with peptic ulcer disease or non-ulcer dyspepsia non-responding to other medications who were also *H pylori*-positive either with positive rapid urease test (RUT)

or positive histology were included in the study. Written informed consent was obtained from all patients. Since administration of glucose in diabetic patients is not ethical and both gastroparesis and accelerated gastric emptying are seen in these patients^[20,42], those with diabetes mellitus or abnormal fasting blood sugar were not included in the study. The same was applied to those who received NSAIDs or those with other systemic diseases in which quadruple therapy was harmful, such as epilepsy. Exclusion criteria were refusal to undergo re-endoscopy, medication side effects and non-compliance.

Interventions

A total of 139 consecutive patients, who were eligible to undergo *H pylori* eradication based on endoscopic findings, were randomized into 6 groups (Table 1). The subjects' gastrointestinal signs and symptoms were recorded. They were then referred to the clinical pharmacist responsible for prescriptions and completion of the questionnaires on medication side effects and compliance. All groups were pretreated with omeprazole (20 mg bid administered at 6 AM and 6 PM) for 2 d and then, treated with quadruple therapy; i.e. omeprazole (20 mg bid administered at 6 AM and 6 PM), bismuth (240 mg bid administered at 6:35 AM and 6:35 PM), tetracycline (750 mg bid administered at 6:35 AM and 6:35 PM) and metronidazole (500 mg bid administered at 6:35 AM and 6:35 PM); groups 1 and 2 were treated for 3 d, groups 3, 4 and 5 for 7 d, and group 6 for 14 d. Groups 1 to 4 received sugar in the form of 10% sucrose syrup. Since glucose solutions empty biphasically, rapidly for the first minutes, then slowly and proportionately to glucose concentration to deliver glucose calories through the pylorus at a regulated rate (0.4 kcal/min)^[38], we administered 125 cc of solution, 5 min before taking medications (6:30 AM and 6:30 PM) and then, 375 cc with medications. For groups 1 and 3 sinemet (levodopa 125 mg plus 62.5 mg carbidopa) was administered twice daily at 6 AM and 6 PM. Patients in groups 2 and 4 were given placebo for levodopa and groups 5 and 6 received two placebos for sugar and levodopa. All patients were repositioned to prone, supine, left and right lateral decubitus positions and remained in each position for 5 min twice daily at 7 AM and 7 PM. Each of the *H pylori* eradication regimens was followed by famotidine administration for 4 wk (40 mg/d at bedtime).

Outcome measures

Upper endoscopy was carried out before treatment and two months after initiation of treatment. This was to allow for a 6-wk antibiotic-free period and also a 2-wk antisecretory-free period before re-evaluating *H pylori* positivity. Four antral (two for RUT and two for histology) and four corpus (two for RUT and two for histology) biopsy specimens were taken. Eradication of *H pylori* was considered as the main outcome measure which was assessed by RUT and histology 8 wk after initiation of intervention^[43]. Also, peptic ulcer symptoms and signs as well as endoscopic findings were recorded by gastroenterologist before, and 8 wk after initiation of treatment. Medication side effects were asked and recorded before starting and after ending

Table 1 Summary of drug regimens administered double-blindly for 6 groups

Group	Quadruple therapy	Pretreatment with omeprazole for 2 d	Sugar (10% sucrose)	Levodopa (Sinemet)	Placebo for sugar	Placebo for levodopa	Duration of treatment

Group 1: Quadruple Therapy + Sugar (S) + Levodopa (L) for 3 d; Group 2: Quadruple Therapy + Sugar + Placebo (P) for 3 d; Group 3: Quadruple Therapy + Sugar + Levodopa for 7 d; Group 4: Quadruple Therapy + Sugar + Placebo for 7 d; Group 5: Quadruple Therapy + Placebo + Placebo for 7 d; Group 6: Quadruple Therapy + Placebo + Placebo for 14 d.

the period of each regimen by the clinical pharmacist who was also responsible for inquiring about patient compliance.

Statistical analysis

Kruskal-Wallis test was used to assess differences in eradication rates, rates of medication side effects, frequencies of symptoms and endoscopic signs, patient compliance and satisfaction rates among 6 groups. Wilcoxon test was applied to evaluate the above-mentioned factors within the groups before and after intervention. ANOVA and paired *t*-test were used to find the differences in size and number of ulcers between, and within the groups, respectively. *P* value of less than 0.05 was taken as significant.

RESULTS

Thirty patients were excluded from the study either due to refusal to undergo re-endoscopy (18 patients) or because of medication side effects (11 patients) or non-compliance (interruption of therapy, 1 patient).

The frequencies of symptoms before and after intervention were not significantly different between the groups but were all significant within the groups except for severe weight loss (Table 2). The only side effect showing

significant difference between the groups was nausea ($P < 0.05$), which was least frequent in groups 2 and 1 (56% and 59% respectively) and most frequent in group 6 (79%), 5 (73%) and 3 (70%). This comparison shows that the duration of treatment has a direct relationship with nausea. Other reported side effects included vomiting, anorexia, dry mouth, metal taste, diarrhea, tinnitus, headache, dyskinesia, vertigo, paresthesia and insomnia.

The frequencies of endoscopic results including fundal erythema and ulcer, antral erythema and ulcer, body erythema and ulcer, duodenal erythema and ulcer, ulcer hemorrhage and number and size of ulcers before and after intervention did not show any significant difference between the groups. On the other hand, treatment was significantly effective in all groups because eradication rates, ulcer numbers and ulcer sizes were significantly different within the groups. Index of successful *H. pylori* eradication was defined as negative RUT plus negative pathology report; both were evaluated 8 wk after the first day of intervention. Per-protocol analysis showed successful eradication in 10/19 (53%) patients in group 1, 10/18 (56%) in group 2, 11/19 (58%) in group 3, 6/18 (33.3%) in group 4, 5/18 (28%) in group 5, and 9/17 (53%) in group 6. Intention-to-treat analysis resulted in successful eradication in 10/20 (50%) patients in group 1, 10/20 (50%) in group 2, 11/21 (52.5%) in group 3, 6/20 (30%) in

group 4, 5/20 (25%) in group 5, and 9/20 (45%) in group 6. Eradication rate, patient compliance and satisfaction rates were not significantly different between the groups.

DISCUSSION

Multiple therapeutic regimens involving different combinations of omeprazole, lansoprazole, ranitidine, famotidine, amoxicillin, bismuth, clarithromycin, furazolidone and metronidazole have been tested during various periods of time to determine the optimal regimen(s) for *H pylori* eradication, leading to very different results depending on the geographical area.

A group of gastroenterologists at Jichi Medical School, Japan, instilled triple antibiotics (bismuth subnitrate, amoxicillin and metronidazole) plus pronase into the stomach through a nasally introduced intestinal tube. They showed that 1 to 2 h of topical therapy was a safe, effective, and well-tolerated procedure for the treatment of *H pylori* infection^[25-27]. In another study, by contrast, the 1-h topical method with the same antibiotics and pronase did show low eradication rates in patients with duodenal ulcer. In addition, the topical treatment was characterized by a high rate of side effects and poor tolerance^[44]. On the other hand, Atherton *et al*^[24] demonstrated that dosing after food profoundly prolongs gastric residence of the drug label and also improves intragastric distribution by increasing delivery to the body and fundus. Omeprazole enhanced the effect of food, but had no effect in fasted subjects. Post-prandial dosing may, therefore, be useful for improving delivery of some anti-*H pylori* agents.

Currently, successful cure of *H pylori* infection requires 2 or more antibiotics and the ideal duration of therapy is unknown, but in general, some believe that therapy for one-week or less is not as effective as therapies of longer durations^[3,17,45-51]. Meanwhile, others have shown one-week treatment or even shorter could be curative^[52-65]. Our findings revealed that both 7 d and 14 d of metronidazole-based quadruple therapy with no sugar or levodopa resulted in suboptimal (< 75%)^[66] eradication of *H pylori* infection which can be explained by the high rate of metronidazole resistance in Iran (50%-60%)^[66-68]. Clarithromycin is expensive and has low availability in Iran^[67,69] and there is a nearly 20%-25% rate of resistance to this macrolide^[68,70] despite the fact that clarithromycin has not yet been introduced to the Iranian formulary as a generic drug. Furazolidone may also interfere with levodopa^[71]. In countries with a high prevalence of metronidazole resistance, higher doses of metronidazole^[72] and increased drug concentration in situ^[73] augment the eradication rate of *H pylori*. All of these factors and the 0% dual resistance of *H pylori* to metronidazole and tetracycline^[68] led us to use metronidazole-based quadruple therapy combined with delayed gastric emptying in the current study. We found only one study in the literature using levodopa to delay gastric emptying in the presence of *H pylori* which showed pretreatment with levodopa would not modify either the sensitivity or the specificity of the urease breath test in identifying *H pylori* infection^[74].

In conclusion, shorter duration of *H pylori* eradication in groups 1, 2 and 3 (which included sugar, levodopa or

both) combined with the eradication rate seen with the 14-d regimen (with no sugar or levodopa) indicates that adding sugar or levodopa to anti-*H pylori* regimens through increasing gastric emptying time may lead to short-term treatments. Nonetheless, there were less than 30 subjects in each group which is the minimum requirement for normal distribution. Further evaluation with larger sample size is warranted.

Abstract

AIM: To elucidate the biological effects of transforming growth factor- β 1 (TGF- β 1) on intrahepatic cholangiocarcinoma (ICC).

METHODS: We investigated the effects of TGF- β 1 on human ICC cell lines (HuCCT1, MEC, and HuH-28) by monitoring the influence of TGF- β 1 on tumor growth and interleukin-6 (IL-6) expression in ICC cells.

RESULTS: All three human ICC cell lines produced TGF- β 1 and demonstrated accelerated growth in the presence of TGF- β 1 with no apoptotic effect. Studies on HuCCT1 revealed a TGF- β 1-induced stimulation of the expression of TGF- β 1, as well as a decrease in TGF- β 1 mRNA expression induced by neutralizing anti-TGF- β 1 antibody. These results indicate that TGF- β 1 stimulates the production and function of TGF- β 1 in an autocrine fashion. Further, IL-6 secretion was observed in all three cell lines and exhibited an inhibitory response to neutralizing anti-TGF- β 1 antibody. Experiments using HuCCT1 revealed a TGF- β 1-induced acceleration of IL-6 protein expression and mRNA levels. These findings demonstrate a functional interaction between TGF- β 1 and IL-6. All three cell lines proliferated in the presence of IL-6. In contrast, TGF- β 1 induced no growth effect in HuCCT1 in the presence of small interfering RNA against a specific cell surface receptor of IL-6 and signal transducer and activator of transcription-3.

CONCLUSION: ICC cells produce TGF- β 1 and confer a TGF- β 1-induced growth effect in an autocrine fashion.

INTRODUCTION

Intrahepatic cholangiocarcinoma (ICC) is the second most common form of primary liver cancer after hepatocellular carcinoma. Despite advances in diagnosis and treatment, the prognosis of ICC has not yet been resolved^[1-3]. When compared with other malignancies, ICC is generally characterized by strong proliferation, invasion, and early metastasis. To improve the prognosis, we require a fuller understanding of the molecular mechanisms behind its proliferation and progression.

Transforming growth factor- β 1 (TGF- β 1) is a multifunctional polypeptide with potent effects as a growth inhibitor for most epithelial cells^[4]. TGF- β 1 has been shown to induce cell arrest and fibrosis in hepatocytes^[5-8]. While TGF- β 1 expression is normally low in normal intrahepatic biliary cells, it has been found to markedly increase in inflammatory and obstructive lesions of the bile duct^[9,10]. There are also reports suggesting that the TGF- β 1 signaling system plays a role in carcinogenesis and cancer progression^[11,12]. Patients with breast cancer^[13,14] and hepatocellular carcinoma^[15] have shown elevated concentrations of TGF- β 1 in serum. TGF- β 1 and its receptor mRNA were confirmed to be expressed at elevated levels in an animal model of ICC^[15,16], and the former has also been found to be elevated in human ICC^[17,18]. These data seem to conflict with the well-known mitoinhibitory effect of TGF- β 1, and the mechanism and function of TGF- β 1 in carcinogenesis remain poorly

understood. In this study we investigated the biological effects of TGF- β 1 on ICC by monitoring the influences of TGF- β 1 on tumor growth and interleukin-6 (IL-6) expression in human ICC cells.

MATERIALS AND METHODS

Cells and culture conditions

Three human intrahepatic cholangiocarcinoma cell lines, HuCCT1, MEC, and HuH-28, and a mink lung epithelial cell line, Mv1Lu, were kindly provided by the Cell Resource Center for Biomedical Research, Tohoku University, and used for the various experiments in this study. HuCCT1 and MEC were cultured in RPMI1640 (Sigma-Aldrich Co., St. Louis, MO), HuH-28 was cultured in MEM (GIBCO, Rockville, MD), and Mv1Lu was cultured in EMEM-NEAA (GIBCO). All medium was supplemented with 100 units/mL penicillin, 100 μ g/mL streptomycin (GIBCO), and 10% fetal calf serum (PAA Laboratories GmbH, Pasching, Austria). Cells were grown as subconfluent mono-layers in a humidified atmosphere containing 5% CO₂ at 37°C and passaged using a treatment with 0.25% trypsin every 7 d.

Immunofluorescence study

HuCCT1 cells grown to 70% confluency on slide glass were fixed in Zamboni solution at room temperature for 30 min. After a specific antibody against TGF- β 1 (rabbit polyclonal, Santa Cruz Biotechnology, Santa Cruz, CA), TGF- β receptor II (rabbit polyclonal, Santa Cruz Biotechnology), and IL-6 (mouse monoclonal, Genzyme, Cambridge, MA) were added for 45 min at 37°C, Alexa Fluor 488-conjugated anti-rabbit antibody (Invitrogen Corp., Carlsbad, CA) was used as a second antibody for 30 min at 37°C. Finally, cells were stained for 30 min at room temperature with 4, 6-diamidino-2-phenylindole (DAPI). Pictures were taken using a cooled CCD camera and MetaMorph Imaging Software (Universal Imaging Corporation, Downingtown, PA) with equal exposure times.

ELISA for TGF- β 1 and IL-6 in cell culture supernatants

Conditioned media were generated by plating approximately 3.0×10^5 ICC cells in 6-well dishes in growth medium overnight. The cells were washed 3 times with PBS, switched to serum-free medium (SFM). After incubation for indicated times, the supernatants were collected, and stored frozen at -80°C. TGF- β 1 and IL-6 concentrations were assessed by ELISA (DuoSet; R&D systems, Minneapolis, MN) according to the manufacturer's instructions. The plates were read on an ELN96 microplate reader (SCETI Co., Ltd., Tokyo, Japan) at 450 nm.

Experiments were also performed to assess the effects of recombinant human TGF- β 1 (rhTGF- β 1, R&D systems) and neutralizing anti-TGF- β 1 antibody on IL-6 production by the cell lines. Cells were cultured as describe above. SFM supplemented with rhTGF- β 1 (0, 1, 10 ng/mL, R&D systems), 5 μ g/mL neutralizing anti-TGF- β 1 antibody (mouse monoclonal, R&D systems), or nonimmune control IgG (mouse monoclonal IgG_{2b}, R&D systems) was collected after indicated times. IL-6 concentrations were

measured by ELISA by the method described above.

Western blotting

Approximately 3.0×10^5 HuCCT1 cells were cultured in growth medium overnight to determine the expression of the Smad2 phosphorylation (phospho-Smad2), p15^{Ink4B}, and plasminogen activator inhibitor-I (PAI-1). After 3 washes with PBS, the cells were switched to SFM with additional rhTGF- β 1, stimulated for indicated times, and lysed by M-PER protein extraction reagent (PIERCE Biotechnology, Rockford, IL) with Halt protease inhibitor cocktail (PIERCE Biotechnology) for protein extraction. Total cell lysates were electrophoresed by SDS-PAGE and transferred to membranes. Anti-Phospho-Smad2 (1:400; rabbit polyclonal, CHEMICON International, Temecula, CA), anti-p15^{Ink4B} antibody (1:200; rabbit polyclonal, Santa Cruz Biotechnology) and anti-PAI-1 antibody (1:500; rabbit polyclonal, Santa Cruz Biotechnology) was used together with a secondary horseradish peroxidase-conjugated polyclonal goat anti-rabbit antibody (1:1000; Medical & Biological Laboratories Co., Nagoya, Japan). Immunodetection was performed using an enhanced chemiluminescence kit for Western blotting detection (Amersham Biosciences, Buckinghamshire, UK). X-ray film was exposed for about 1 min for visualization. Autoradiograms of the immunoblots were scanned using Adobe Photoshop (Adobe System, Inc., San Jose, CA). The blots were adjusted for brightness and contrast for minimum background, and the mean density for each band was analyzed.

Real-time semi-quantitative PCR

Studies with cell lines were conducted to investigate the effects of rhTGF- β 1 and anti-TGF- β 1 antibodies on the expression of TGF- β 1, IL-6, p15^{Ink4B}, and PAI-1 mRNA. Conditioned media were generated by plating 3.0×10^5 ICC cells in 6-well dishes in growth medium overnight. The cells were washed 3 times with PBS, switched to SFM supplemented with rhTGF- β 1 (0, 0.1, 1, 10 ng/mL, 5 μ g/mL neutralizing anti-TGF- β 1 antibody, or 5 μ g/mL nonimmune control IgG, and incubated for indicated times. RNA was isolated using ISOGEN reagent (Nippon Gene Co., Toyama, Japan) according to the manufacturer's instructions. Total RNA (1 μ g per sample) was reverse transcribed in a final volume of 20 μ L using a High Capacity cDNA Archive kit (Applied Biosystems, Foster City, CA). TaqMan probes for human TGF- β 1, IL-6, p15^{Ink4B}, and PAI-1 RNA gene (TaqMan Gene Expression Assays; Applied Biosystems) were obtained. The samples were amplified in a total volume of 20 μ L containing 1 μ L of each specific probe and 10 μ L of the TaqMan PCR Core Reagent Kit (Universal PCR Master Mix; Applied Biosystems). The amplifications were performed in 40 cycles using a GeneAmp 5700 Sequence Detection system (Applied Biosystems), and the expression levels were calculated using the comparable cycle number method as recommended by the manufacturer. Semi-quantitative mRNA levels were evaluated based on the ratios of the mRNA levels of the target to those of the mRNA levels of GAPDH.

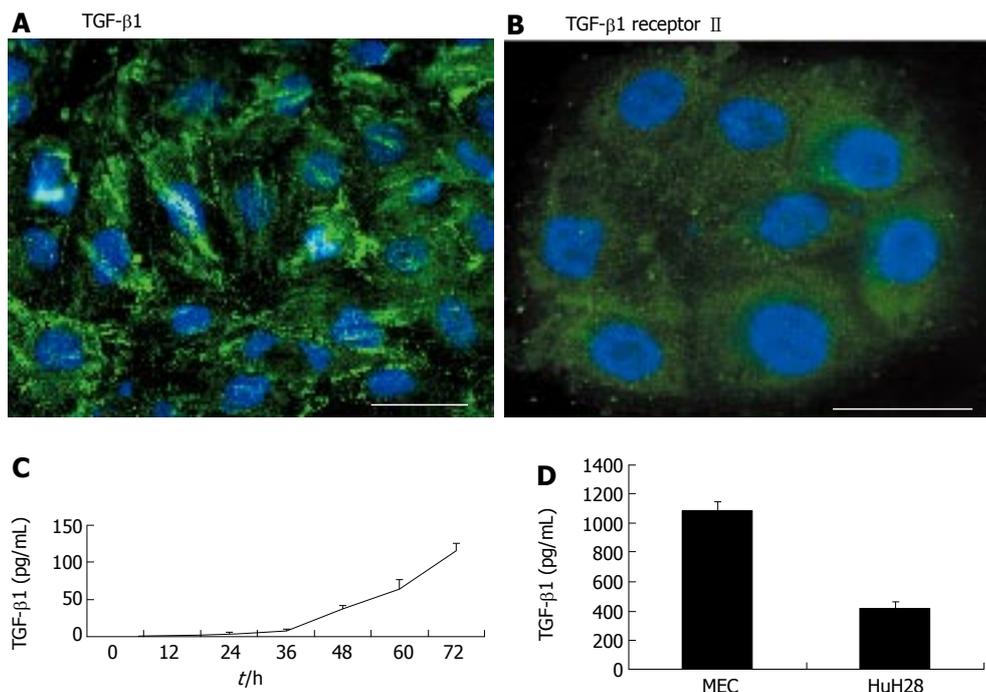

Figure 1 Expression of TGF-β1 and TGF-β receptor II in intrahepatic cholangiocarcinoma cell lines. Immunofluorescence showed staining of TGF-β1 (A) and TGF-β receptor II (B) in HuCCT1 cells. Scale bar = 20 μm. C: Detection of TGF-β1 in supernatant of HuCCT1 by ELISA. TGF-β1 levels in the supernatant of HuCCT1 showed a time-dependent increase; D: The other ICC cell lines were incubated for 48 h and assayed by ELISA to determine the levels of TGF-β1 in the supernatants. MEC and HuH-28 cells also secreted TGF-β1 into the supernatants.

³H-thymidine incorporation

1×10^4 cells were plated in a 96-well flat-bottomed plate in growth medium and changed to SFM 24 h later. The indicated concentrations of rhTGF-β1 and rhIL-6 (R&D systems) were added the following day for 12 h. For the measurement of DNA synthesis, 1 μCi/mL of ³H-thymidine (Perkin Elmer, Boston, MA) was added for 3 h. The ³H-thymidine incorporation was determined using a liquid scintillation counter (LSC-3000, Aloca, Tokyo, Japan) after detaching the cells from the plates with 0.25% trypsin.

Apoptosis assay

HuCCT1 and Mv1Lu cells were seeded on slide glass, and incubated in SFM in the absence or presence of rhTGF-β1 for 48 h. Apoptotic cells were identified by a terminal deoxynucleotidyl transferase (TdT)-mediated dUTP nick-end labeling (TUNEL) method. TUNEL assay was performed using an in situ Apoptosis Detection Kit (TAKARA BIO INC., Shiga, Japan) according to the manufacturer's instruction. Positive staining was detected by diaminobenzidine. Finally, slides were restained slightly with 1.0% methyl green. The apoptotic effect was determined by counting the number of positively labeled nuclei per 300 cells. The apoptotic index was calculated as follows: (number of apoptotic cells/total number counted) $\times 100\%$ ^[9].

RNA interference to IL-6Rα and STAT3

The mRNA expressions of interleukin-6 receptor (IL-6Rα or gp80) and the signal transducer and activator of transcription-3 (STAT3) were silenced by small interfering RNA (siRNA) using the SureSilencing siRNA kit (SuperArray Bioscience Co., Frederick, MD). One day before transfection, 5.0×10^4 cells were seeded in each well of a 24-well plate. The cells were transfected for 24 h at 37°C in a CO₂ incubator using transfection reagents

(Lipofectamine2000; Invitrogen Corp., Carlsbad, CA) and Opti-MEM Reduced-Serum Medium (GIBCO) according to the manufacturer's instructions. After transfection, the cells were incubated in SFM with or without 1 ng/mL TGF-β1 for 12 h, detached from the plates with 0.25% trypsin, and tested to determine DNA synthesis based on the method of ³H-thymidine incorporation described above. Reverse transcription-PCR (RT-PCR) was used to check the silencing effects of gene expression. The RT² real-time gene expression assay kit (SuperArray Bioscience Co.) and TaqMan probe (Applied Biosystems) were used for human IL-6Rα and STAT3, respectively.

Statistical analysis

The data were expressed as mean \pm SD ($n = 4$, independent experiments) and analyzed for significance using the Mann-Whitney *U*-test. A *P* value of less than .05 was considered statistically significant.

RESULTS

Expressions of TGF-β1 and TGF-β receptor II in human ICC

We began our study by confirming the expression of TGF-β1 and its receptors in the HuCCT1 cell line. Immunofluorescent staining with specific antibody confirmed the expression of TGF-β1 and TGF-β receptor II in HuCCT1 (Figure 1A and 1B). Next, we used the ELISA technique to examine the secretion of TGF-β1 from HuCCT1 into the medium. As shown in Figure 1C, HuCCT1 secreted TGF-β1 in a time-dependent fashion. The mean concentration of TGF-β1 in the supernatants after 72 h of incubation was 115.1 pg/mL. We also measured TGF-β1 production in two other ICC cell lines, MEC and HuH-28. TGF-β1 was secreted into the supernatants of the MEC and HuH-28 cell lines at mean concentrations of 1094.4 and 419.9 pg/mL at 48 h, respectively (Figure 1D).

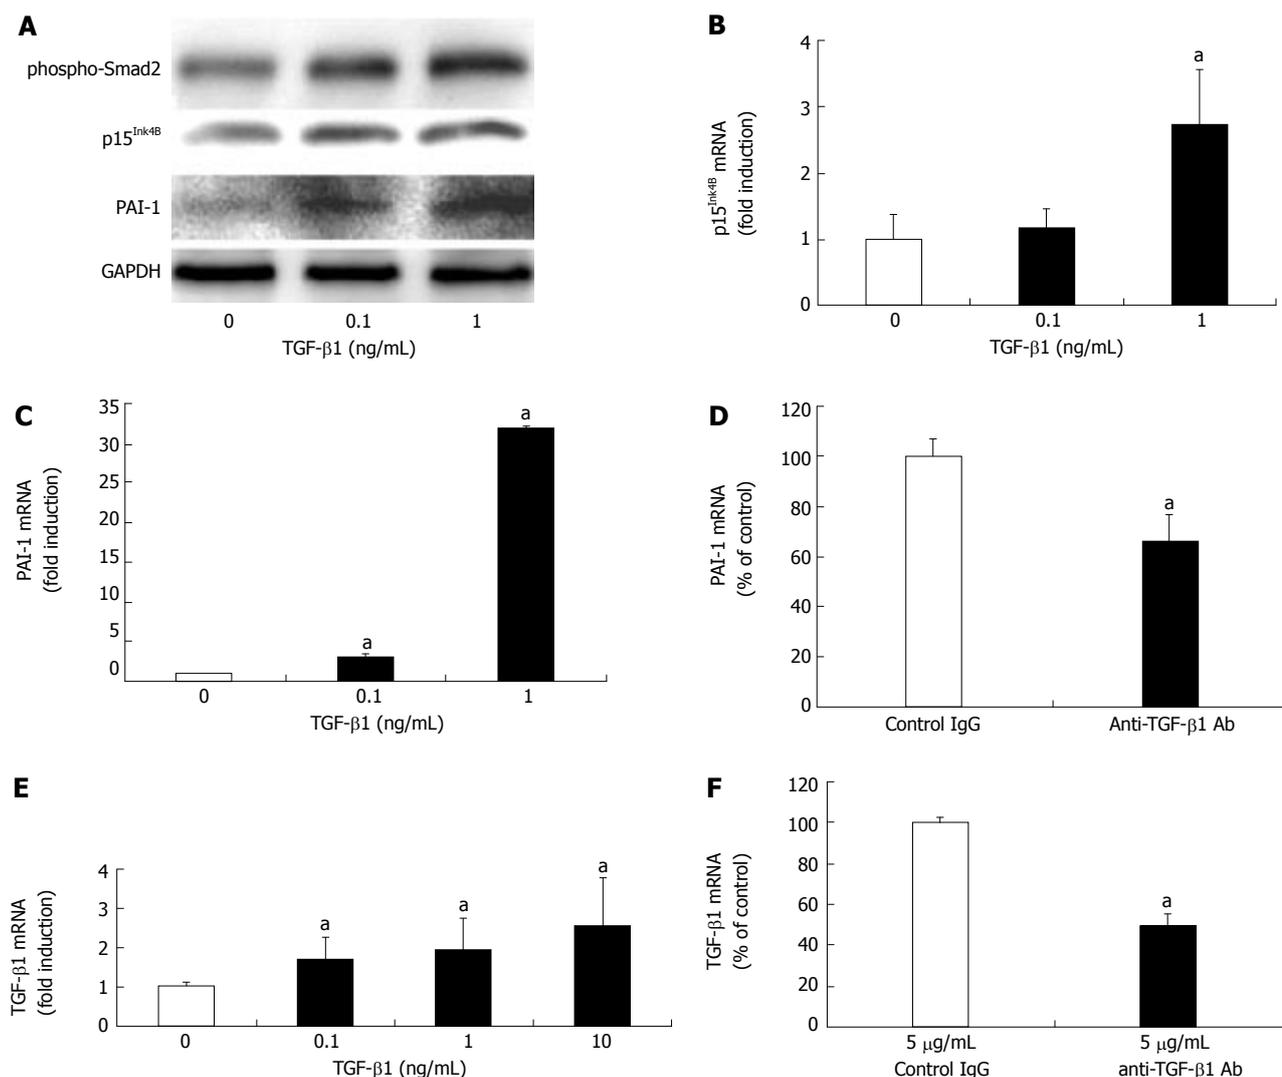

Figure 2 TGF- β 1 stimulates the TGF- β signaling pathway. **A:** The addition of 0.1 and 1 ng/mL TGF- β 1 augmented Smad2 phosphorylation (phospho-Smad2), p15^{Ink4B}, and PAI-1 proteins in Western blotting of HuCCT1 cells; **B:** TGF- β 1 stimulation for 48 h enhanced p15^{Ink4B} mRNA expression in HuCCT1 cells in RT-PCR: ^a $P < 0.05$ vs absence of TGF- β 1; **C:** TGF- β 1 stimulation for 48 h also augmented PAI-1 mRNA expression in HuCCT1 cells in RT-PCR: ^a $P < 0.05$ vs absence of TGF- β 1; **D:** PAI-1 mRNA was determined by RT-PCR after incubating the HuCCT1 cells with 5 ng/mL neutralizing anti-TGF- β 1 antibody or nonimmune control IgG for 96 h. The addition of anti-TGF- β 1 antibody attenuated the level of PAI-1 mRNA: ^a $P < 0.05$ vs control IgG; **E:** The addition of TGF- β 1 to HuCCT1 for 6 h led to a concentration-dependent increase in TGF- β 1 mRNA expression by RT-PCR: ^a $P < 0.05$ vs absence of TGF- β 1; **F:** TGF- β 1 mRNA in HuCCT1 was determined by RT-PCR after incubating the cells with 5 ng/mL neutralizing anti-TGF- β 1 antibody or nonimmune control IgG for 96 h. The addition of anti-TGF- β 1 antibody attenuated the level of TGF- β 1 mRNA: ^a $P < 0.05$ vs control IgG.

TGF- β 1 stimulates the TGF- β signaling pathway

TGF- β 1 has been reported to induce the expressions of p15^{Ink4B} and PAI-1 in a variety of different cells^[12,20]. Accordingly, we confirmed Smad2 phosphorylation (phospho-Smad2) and expression of the target genes p15^{Ink4B} and PAI-1 as markers of TGF- β 1 and the status of Smad-dependent signaling. Figure 2A demonstrates the effects of rhTGF- β 1 on endogenous expression of the phospho-Smad2, p15^{Ink4B}, and PAI-1 proteins in the HuCCT1 cell line. Western blotting of HuCCT1 cells after 48 h of stimulation by 0, 0.1, and 1 ng/mL rhTGF- β 1 revealed induction of phospho-Smad2, p15^{Ink4B}, and PAI-1 proteins. Similar results were obtained by measurements of the mRNA levels of p15^{Ink4B} and PAI-1. The expression of p15^{Ink4B} mRNA induced by 48 h of incubation with 1 ng/mL rhTGF- β 1 (Figure 2B) was significantly greater than that measured in the absence of rhTGF- β 1 stimulation. Forty-eight hours of incubation with rhTGF- β 1 at

concentrations of 0.1 and 1 ng/mL also induced significant increases in PAI-1 mRNA (3.0- and 32.0-fold increases, respectively) (Figure 2C). Furthermore, the addition of a neutralizing anti-TGF- β 1 antibody reduced the PAI-1 mRNA level. The addition of neutralizing TGF- β 1 antibody for 96 h significantly reduced PAI-1 mRNA to 66.1% of the level measured in the presence of nonimmune control IgG (Figure 2D). These findings demonstrate that secreted TGF- β 1 can stimulate the TGF- β signaling pathway mediated by Smads in an autocrine fashion without disrupting TGF- β signaling.

TGF- β 1 stimulates endogenous TGF- β 1 mRNA expression in an autocrine fashion

Next, we studied the effect of TGF- β 1 on endogenous TGF- β 1 mRNA expression in HuCCT1 with RT-PCR. Additional rhTGF- β 1 stimulation for 6 h resulted in a significant dose-dependent increase of TGF- β 1 mRNA

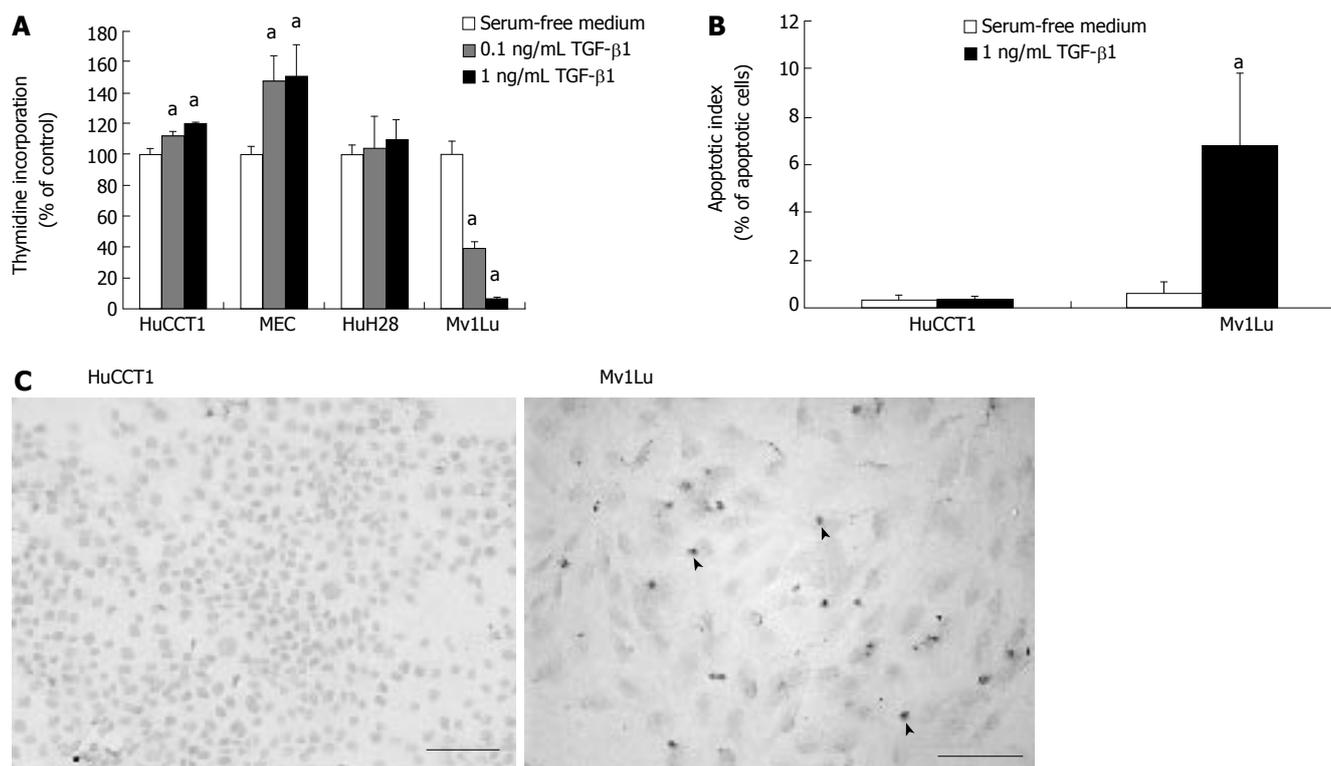

Figure 3 Effect of TGF- β 1 on the cell growth and apoptosis of ICC cell lines. **A:** The cells were subjected to a ^3H -thymidine incorporation assay in the absence or presence of TGF- β 1. No mitoinhibitory effect of TGF- β 1 was observed in the ICC cells. TGF- β 1 stimulation augmented the DNA synthesis of TGF- β 1 in the HuCCT1 and MEC cells. In contrast, TGF- β 1 treatment elicited a strong mitoinhibitory effect in Mv1Lu; **B:** Stimulation with 1 ng/mL TGF- β 1 for 48 h did not induce apoptosis of HuCCT1 cells in a TUNEL assay. In the experiment using Mv1Lu, however, stimulation with TGF- β 1 at the same concentration for the same duration did elicit an apoptotic effect: $^3P < 0.05$ vs absence of TGF- β 1; **C:** HuCCT1 and Mv1Lu cells were treated with 1 ng/mL TGF- β 1 for 48 h. The arrows denote apoptotic cells identified by the TUNEL method. Scale bar = 100 μm .

expression in HuCCT1 cells (Figure 2E). Moreover, the addition of neutralizing TGF- β 1 antibody for 96 h resulted in a significant decrease of TGF- β 1 mRNA to 49.1% of the level measured in the presence of nonimmune control IgG (Figure 2F).

TGF- β 1 accelerates ICC cell proliferation

To further confirm the effect of TGF- β 1 on ICC cells, we investigated whether TGF- β 1 influenced the proliferation and apoptosis of ICC cells. The HuCCT1 and MEC cell lines showed significant increases in ^3H -thymidine incorporation in response to 0.1 and 1 ng/mL rhTGF- β 1 stimulation for 12 h (Figure 3A). No mitoinhibitory effect of TGF- β 1 was observed in any of the ICC cell lines in this study. In contrast, the additions of 0.1 and 1 ng/mL rhTGF- β 1 to Mv1Lu resulted in 61.1% and 95.8% reductions in DNA synthesis, respectively.

Next, we applied the TUNEL method to determine whether we could observe apoptosis of the ICC cells. In an experiment using HuCCT1 cells, no significant differences in the levels of apoptosis were observed between cells incubated in SFM for 48 h and cells incubated with 1 ng/mL rhTGF- β 1 for 48 h. However, the TUNEL assay demonstrated that 1 ng/mL rhTGF- β 1 induced evident apoptosis of Mv1Lu cells, and the apoptotic index at 48 h after rhTGF- β 1 treatment was significantly higher than that of the control group (Figure 3B). Almost no apoptotic cells were observed in the HuCCT1 cells stimulated with 1 ng/mL rhTGF- β 1 for 48

h (Figure 3C). However, the TUNEL assay using Mv1Lu indicated an increase of apoptotic cells in response to 1 ng/mL rhTGF- β 1 for 48 h. On the basis of these results, we can conclude that TGF- β 1 inhibits cell proliferation and induces apoptosis in normal epithelial cells, whereas ICC cells are equipped with a mechanism to resist the growth-inhibitory response and apoptotic effect induced by TGF- β 1.

TGF- β 1 stimulates the secretion of IL-6

Previous studies have shown that IL-6 can induce the proliferation of ICC cells^[21,22]. To elucidate the mechanism further, we measured the level of IL-6 production by ICC cells and explored the relationship between TGF- β 1 and IL-6. A time-dependent increase of IL-6 was observed in the HuCCT1 supernatants unexposed to TGF- β 1. To investigate the potential interaction between TGF- β 1 and IL-6, we evaluated the levels of IL-6 in the HuCCT1 supernatants stimulated with rhTGF- β 1. As a result, we found a time-dependent increase of IL-6 concentrations in response to rhTGF- β 1 throughout the 72-h observation period (Figure 4A). The increases in IL-6 induced by 1 and 10 ng/mL rhTGF- β 1 after 72 h of incubation (2.2- and 5.7-fold increases, respectively) were significantly greater than the increases observed in the supernatants from cells untreated by rhTGF- β 1. Similar results were obtained in IL-6 mRNA quantification after 6 h of stimulation by rhTGF- β 1. A significant 2.7-fold increase of IL-6 mRNA was observed in the HuCCT1 cells stimulated with 10

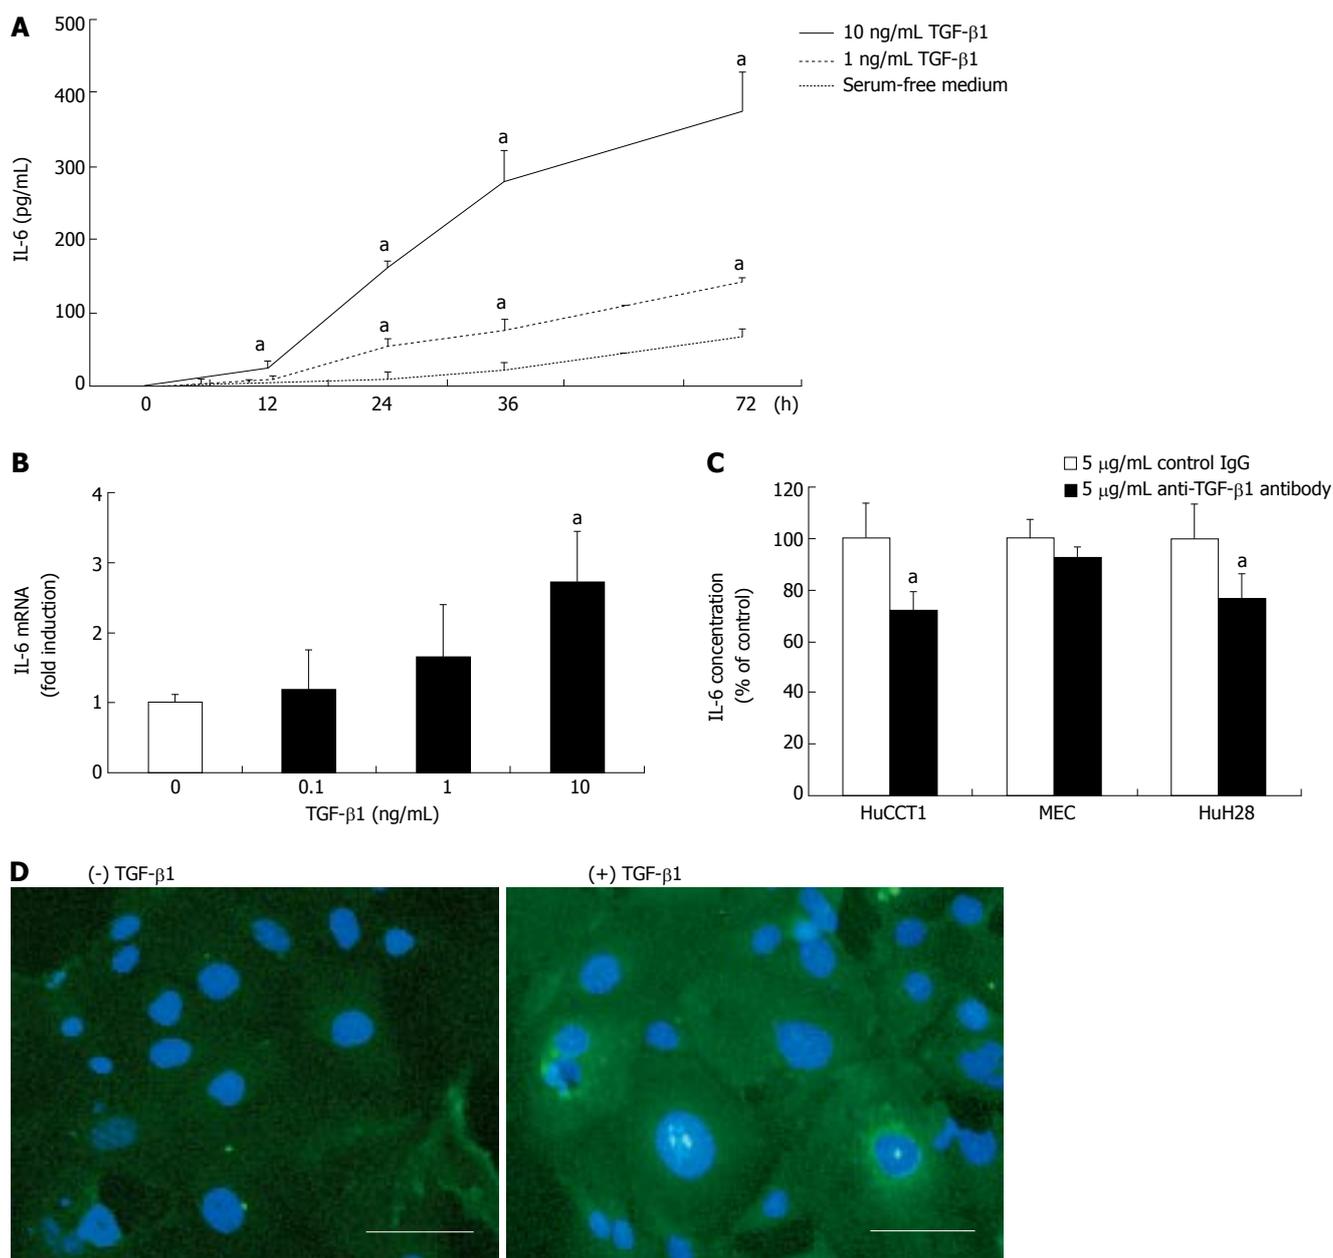

Figure 4 Effect of TGF- β 1 on the IL-6 expression of ICC cells. **A:** ELISA revealed the secretion of IL-6 by HuCCT1 into the serum-free medium. HuCCT1 also showed a time-dependent increase of IL-6 concentrations in response to 1 and 10 ng/mL TGF- β 1 stimulation: $^{\ast}P < 0.05$ vs absence of TGF- β 1; **B:** The addition of TGF- β 1 to HuCCT1 for 6 h resulted in a dose-dependent increase of IL-6 mRNA expression by RT-PCR: $^{\ast}P < 0.05$ vs absence of TGF- β 1; **C:** IL-6 levels in the supernatants were determined by ELISA after incubating ICC cells with 5 ng/mL neutralizing anti-TGF- β 1 antibody or nonimmune control IgG for 96 h. The addition of neutralizing anti-TGF- β 1 antibody resulted in a decrease of IL-6 production in HuCCT1 and HuH28: $^{\ast}P < 0.05$ vs control IgG; **D:** An immunofluorescence study using HuCCT1 cells demonstrated an increase in IL-6 production in response to TGF- β 1. Immunoreactivity with a specific anti-IL6 antibody was weak, with no stimulation of TGF- β 1, whereas 10 ng/mL TGF- β 1 induced IL-6 expression in the cytoplasm of the HuCCT1 cells. Scale bar = 20 μ m.

ng/mL TGF- β 1 (Figure 4B). IL-6 production was also confirmed in the MEC and HuH-28 ICC cell lines. After 72 h of incubation in SFM, the mean IL-6 concentrations in the supernatants of MEC and HuH-28 cells were 307.4 and 6.93 ng/mL, respectively. We next investigated the effects of a neutralizing anti-TGF- β 1 antibody on IL-6 production in ICC cell supernatants. Compared with nonimmune control IgG, the addition of anti-TGF- β 1 antibody resulted in a significant inhibition of IL-6 concentrations in the HuCCT1 and HuH28 supernatants (Figure 4C). Next, we investigated the IL-6 localization in response to rhTGF- β 1 by immunofluorescence. As shown

in Figure 4D, the cytoplasm of HuCCT1 cells untreated by rhTGF- β 1 was only weakly immunoreactive to the anti-IL-6 antibody. In contrast, we identified a dominant localization of IL-6 in the cytoplasm of the HuCCT1 cells stimulated with 10 ng/mL rhTGF- β 1 for 48 h.

Effects of TGF- β 1 on ICC cell growth under inhibition of IL-6 functions via RNA interference with IL-6R α (gp80) and STAT3

We measured thymidine incorporation in the ICC cells after the addition of 0.1 and 1 ng/mL rhIL-6 to clarify whether IL-6 accelerates the cell growth of ICC cells.

As seen in Figure 5A, rhIL-6 brought about significant increases in thymidine incorporation in all of the ICC cells studied. This, taken together with the results of the other experiments described in this study, indicates that TGF- β 1 and IL-6 act as ICC growth factors with interrelated functions.

To further elucidate the mechanism of TGF- β 1-induced proliferation of ICC, we examined whether TGF- β 1 functioned as a growth factor while IL-6 functions were inhibited with the use of small interfering RNA (siRNA) in order to silence the expression of IL-6R α and STAT3 mRNA. As shown in Figure 5B, siRNA treatment suppressed IL-6R α and STAT3 mRNA expressions in the HuCCT1 cells to 10.6% and 41.9% of the control siRNA level, respectively. Figure 5C shows the effects of rhTGF- β 1 on DNA synthesis in HuCCT1 cells with siRNA against IL-6R α and STAT3. HuCCT1 stimulated by 1 ng/mL rhTGF- β 1 exhibited a 37.4% increase of DNA synthesis under the control siRNA condition, whereas HuCCT1 stimulated by rhTGF- β 1 during siRNA silencing of IL-6R α brought about no increase after TGF- β 1 stimulation. Furthermore, HuCCT1 stimulated by TGF- β 1 during siRNA silencing of STAT3 exhibited a 19.4% decrease of DNA synthesis. These findings indicate that the TGF- β 1-induced production of IL-6 confers resistance to the growth inhibition by TGF- β 1 and plays a role in the mechanism of TGF- β 1-induced ICC proliferation.

DISCUSSION

In previous studies, ICC cells were found to resist the growth inhibitory effect of TGF- β 1^[18,22]. Our current study, in contrast, demonstrated that TGF- β 1 stimulation in ICC resulted in cellular proliferation rather than resistance to the innate mitoinhibition. The molecular mechanism by which some malignant cells evade the mitoinhibitory effect of TGF- β 1 remains obscure. Recent studies on malignancies have demonstrated the disruption of TGF- β signaling, including lack or mutations of the TGF- β receptor^[23-26] and the Smad family^[26-29]. This study, in contrast, revealed no disruption of TGF- β signaling. In fact, TGF- β 1 was found to activate the expression of PAI-1 as a target gene via Smad2 phosphorylation. These results suggest that ICC cells are equipped with a mechanism to resist the innate mitoinhibitory response and encourage cell activation by TGF- β 1. Given that TGF- β 1 upregulation has been identified in both pancreatic cancer and hepatocellular carcinoma, we know that it may also contribute to disease progression in patients with some malignancies^[12,30,31].

The results from our current study demonstrate that the growth effect of TGF- β 1 in ICC cells is closely associated with IL-6 production and function. IL-6 plays a key role in the hepatic response to inflammation, as well as in the regulation of bile duct growth^[32-35]. ICC is generally characterized by strong cellular proliferation and inflammation around the tumor. From these points of view, we decided to perform several studies on IL-6, a reported inducer of ICC growth^[21,22,36,37]. IL-6 is elevated in the serum of patients with ICC^[38] and expressed in

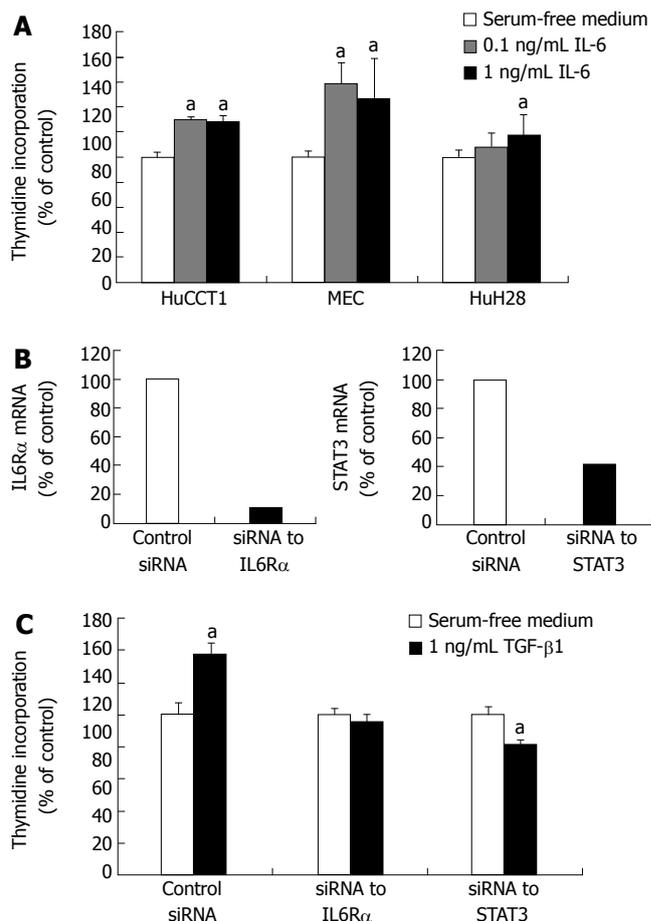

Figure 5 Effects of TGF- β 1 on DNA synthesis during inhibition of IL-6 functions. **A:** All of the ICC cells demonstrated enhanced DNA synthesis in response to IL-6: $^aP < 0.05$ vs absence of IL-6. We next investigated whether TGF- β 1 promoted ICC cell growth during the inhibition of IL-6 functions by small interfering RNA (siRNA); **B:** RT-PCR was conducted to assess the effects of siRNA in suppressing the mRNA expressions of IL-6R α and STAT3. IL-6R α and STAT3 mRNA expression was suppressed by 10.6% and 41.9%, relative to control siRNA; **C:** The silencing of IL-6R α and STAT3 mRNA expressions by siRNA in HuCCT1 cells led to a suppression in the TGF- β 1-induced DNA synthesis relative to that observed under the control siRNA condition. $^aP < 0.05$ vs absence of rhTGF- β 1.

ICC surgical specimens and cell lines^[21,36,39]. All of the ICC cell lines used in our study expressed IL-6. This IL-6 expression was augmented by TGF- β 1 and attenuated by the neutralizing anti-TGF- β 1 antibody. A similar mechanism of TGF- β 1-induced IL-6 expression was also reported in prostate cancer cells^[40]. Stimulation by IL-6 augmented DNA synthesis in all cell lines. In contrast, TGF- β 1 stimulation during siRNA silencing of IL-6R α and STAT3 mRNA expression led decreased levels of DNA synthesis in HuCCT1 cells. On this basis, we know that the two cytokines share a functional relation, and further, that IL-6 function is very important for the TGF- β 1-based growth effect in ICC. Recent studies on ICC cells have also demonstrated effects of TGF- β 1 on the induction of prostaglandin E₂^[41] and vascular epithelial growth factor (VEGF)^[17], two factors closely related to tumor proliferation and angiogenesis. This may shed light on the oncogenic switch to resist the innate growth inhibitory effect of TGF- β 1. As one step in this switch, the malignant cells might acquire a mechanism to produce

cell growth inducers via the stimulation of TGF- β 1.

IL-6 has also been reported to participate in the chemoresistance of IL-6-induced inhibitors of apoptosis protein against conventional chemotherapeutic agents^[42]. In addition to facilitating ICC cell growth, IL-6 aggravates the difficulties in treating malignancy. Effective regulators of these cytokines might be attractive therapeutic targets to encourage tumor cell apoptosis and cell growth inhibition.

In summary, we have provided evidence in support of the autocrine growth effect of TGF- β 1 in human ICC. We also demonstrated that the TGF- β 1-induced growth effect is closely associated with IL-6 function. ICC has acquired these mechanisms to resist the well-known growth inhibitory response of TGF- β 1. Further elucidation of the TGF- β 1 and IL-6 function in cholangiocarcinogenesis may afford an important opportunity to define a novel molecular target for ICC prevention and treatment.

Abstract

AIM: To examine the influence of lipoprotein lipase (LPL) gene polymorphism in ulcerative colitis (UC) patients.

METHODS: Peripheral blood was obtained from 131 patients with UC and 106 healthy controls for DNA extraction. We determined LPL gene polymorphisms affecting the enzyme at Ser447stop, as well as *Hind*III and *Pvu* II polymorphisms using PCR techniques. PCR products were characterized by PCR-RFLP and direct sequencing. Polymorphisms were examined for association with clinical features in UC patients. Genotype frequencies for LPL polymorphisms were also compared between UC patients and controls.

RESULTS: In patients with onset at age 20 years or younger, C/G and G/G genotypes for Ser447stop polymorphism were more prevalent than C/C genotype (OR = 3.13, 95% CI = 0.95-10.33). Patients with H^{+/+} or H^{-/-}

genotype for *Hind*III polymorphism also were more numerous than those with H^{+/+} genotype (OR = 2.51, 95% CI = 0.85-7.45). In the group with H^{+/+} genotype for *Hind*III polymorphism, more patients had serum triglyceride concentrations over 150 mg/dL than patients with H^{+/+} or H^{-/-} genotype ($P < 0.01$, OR = 6.46, 95% CI = 1.39-30.12). Hypertriglyceremia was also more prevalent in patients with P^{+/+} genotypes for *Pvu* II polymorphism ($P < 0.05$, OR = 3.0, 95% CI = 1.06-8.50). Genotype frequency for LPL polymorphism did not differ significantly between UC patients and controls.

CONCLUSION: Ser447stop and *Hind*III LPL polymorphisms may influence age of onset of UC, while *Hind*III and *Pvu* II polymorphisms influence serum triglyceride in UC patients.

INTRODUCTION

Inflammatory bowel disease (IBD), characterized by chronic recurrent inflammation of the intestinal tract, includes two common forms: Crohn's disease (CD) and ulcerative colitis (UC). For both forms, the etiology is unclear, but likely to be multifactorial. Factors that may affect IBD include diet, infantile environment and immune defense abnormalities limited to the intestinal tract. Recently, genetic factors have been examined in IBD, but many studies seeking susceptibility genes for IBD have not produced a consensus. We presently investigated possible influence of the lipoprotein lipase (LPL) gene in UC. LPL plays a critical role in lipid metabolism. Dietary triacylglycerol (TAG) exists in the human circulation as macromol-

ecules (TAG-rich lipoprotein) that are too large to pass through the endothelium of most capillaries. LPL catalyses conversion of TAG-rich lipoprotein to triglyceride (TG), very low-density lipoprotein (VLDL), and chylomicrons (CM), all of which circulate and can enter tissues more readily to serve energy source^[1,2]. Our interest in LPL in IBD was provoked by identifying high lipid intake as a risk factor for IBD. Shoda *et al*^[3] reported associated intake of n-6 polyunsaturated fat and animal fat with development of CD in Japanese patients, while Geering *et al*^[4] reported high intake of mono- and polyunsaturated fats to be a risk factor for the UC. Furthermore, the LPL gene has been localized to chromosome 8p22 near N-acetyltransferase2 (NAT2) gene, while Machida *et al*^[5] reported an association between NAT2 gene haplotype NAT2*7B and CD. Considering these various findings, we suspected that LPL gene polymorphisms could influence characteristics and incidence of UC. These issues were examined in the present molecular genetic investigation.

MATERIALS AND METHODS

Subjects

We studied 131 patients with UC (75 males and 56 females) and 106 healthy controls (53 males and 53 females). Diagnosis of UC was based on conventional clinical, radiologic, endoscopic, and pathologic criteria. Characteristics of UC patients are shown in Table 1. We investigated the effect of LPL polymorphism on clinical features as shown in this table. To examine LPL polymorphisms in terms of influence on UC incidence, we compared LPL genotype frequencies in UC patients with those in controls.

DNA extraction

Blood samples were obtained from patients and controls after they had given informed consent to sampling and analyses. This study was approved by the Fujita Health University Ethics Committee. DNA was extracted from blood samples using a PUREGENE DNA isolation kit (Gentra Systems, Inc, Minneapolis, USA).

Genotype

LPL polymorphisms were typed using polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) methods to detect Ser447stop, *Hind*III and *Pvu*II polymorphisms^[6]. The primer sets were as follows: for Ser447stop, 5'-GATGTGGCCTGAGTGTGACAG-3' (forward) and 5'-TCCCTTAGGGTGCAAGCTCAG-3' (reverse); for *Hind*III, 5'-GATGTCTACCTGGATAATCAAAG-3' (forward) and 5'-CTTCAGCTAGACATTGCTAGTGT-3' (reverse); and for *Pvu*II, 5'-GAGACACAGATCTCTCTTAAGAC-3' (forward) and 5'-ATCAGGCAATGCGTATGAGGTAA-3' (reverse). PCR was carried out in a 30- μ L aliquot containing 50 ng of genomic DNA, 12 pmol of each primer, 3.0 μ L of 10 \times buffer solution, 20 nmol/ μ L of dNTP, and 1U of Taq polymerase. PCR conditions for Ser447stop included initial denaturation at 95°C for 5 min, followed by 35 amplifica-

Table 1 Characteristics of patients with ulcerative colitis

Characteristic	UC (n = 131)
Age of onset (yr)	36.8 \pm 15.3
Colitis duration (yr)	8.8 \pm 7.7
Extension	
Proctitis	22 (16.8%)
Left-sided	59 (45.0%)
Pancolitis	50 (38.2%)
Type of clinical course	
First episode	14 (10.7%)
Chronic relapse	79 (60.3%)
Chronic persistent	38 (29.0%)
Severity	
Mild	40 (30.5%)
Moderate	61 (46.6%)
Severe	30 (22.9%)

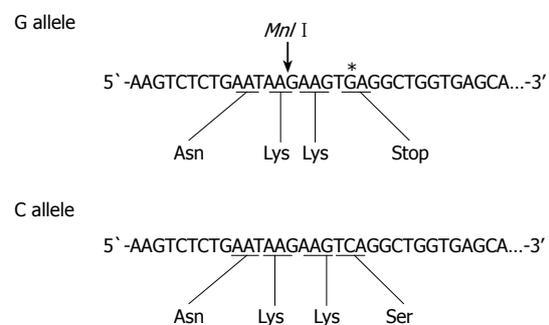

Figure 1 Strategy for detection of the C/G allele (Ser/stop) in exon 9 of the lipoprotein lipase by PCR-RFLP analysis. Introduction of G (*) is in place of C creates a new *Mnl* I site.

tion cycles, each cycle containing denaturation at 95°C for 30 s, primer annealing at 62°C for 30 s, and extension at 72°C for 30 s. PCR conditions for *Hind*III and *Pvu*II included initial denaturation at 95°C for 5min, followed by 35 amplification cycles, each cycle containing denaturation at 95°C for 30 s, primer annealing at 61°C for 30 s, and extension at 72°C for 30 s. PCR products subjected to overnight digestion with *Mnl*I, *Hind*III, and *Pvu*II were examined by electrophoresis on 20 g/L agarose gels. The strategy for the detection of the G allele (Ser447stop) is shown in Figure 1. A 315-bp segment of exon 9 of the lipoprotein lipase gene was amplified by the PCR. In the presence of the G allele, the amplified DNA contains a new site for *Mnl*I, but does not contain a site in the presence of the C allele. However, there is a restriction site for *Mnl*I in the forward primer sequence regardless of G/C mutation. After digestion, the PCR product yielded 248- and 67-bp fragments. The PCR product containing a *Hind*III restriction site yielded 210- and 140-bp fragments, while the product containing a *Pvu*II restriction site yielded 222- and 209-bp fragments. Some products after digestion were examined on polyacrylamide gels (GeneGel Excel 12.5/24 kit from GE Healthcare Bio-sciences, Tokyo) and stained with DNA silver staining kit (GE Healthcare Bio-sciences,

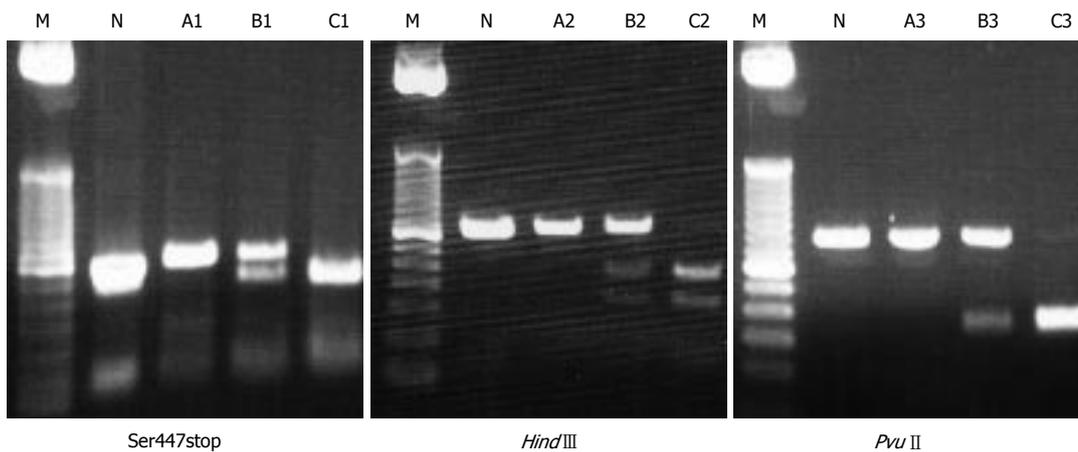

Figure 2 Electrophoresed pattern of LPL polymorphism. M: Marker, N: No digestion. In Ser447stop, A1: C/C genotype (315 bp); B1: C/G genotype; C1: G/G genotype. In *Hind*III, A2: H^{+/+} genotype; B2: H^{+/-} genotype (350 bp); C2: H^{-/-} genotype. In *Pvu*II, A3: P^{+/+} genotype (431 bp); B3: P^{+/-} genotype; C3: P^{-/-} genotype.

Table 2 Allele frequency and genotype distribution of LPL polymorphism in UC patients and controls

	Allele frequency		Genotype (%)		OR (95% CI)
	C	G	CC	CG+GG	
Ser447stop					
UC (n = 131)	0.92	0.08	111 (84.7)	19 + 1 (15.3)	1.49

Tokyo), e.g. *Pvu*II digestion-cases. Electrophoresed patterns of LPL polymorphisms are shown in Figure 2.

Results of PCR-RFLP were confirmed by direct sequencing. DNA was extracted from agarose gels using an extraction kit (QIAGEN, Hilden, Germany). Then genotype was confirmed by sequence analysis using an auto sequencer (data not shown).

Statistical analysis

All data were analyzed by Excel 2000 and STATISCA software. Clinical features of UC, allele frequency, and genotype distribution were evaluated by using χ^2 test. A *P* value less than 0.05 was considered statistically significant.

Allelic and genotype frequencies were determined from observed genotype counts, and the extensions of Hardy-Weinberg equilibrium were evaluated by using χ^2 test.

RESULTS

LPL polymorphisms and risk of UC

The allele frequency of LPL polymorphism and the genotype distribution are shown in Table 2. The observed genotype data were consistent with Hardy-Weinberg equilibrium (Ser447stop: $\chi^2 = 0.48$, *P* = 0.49; *Hind*III: $\chi^2 = 1.73$, *P* = 0.19; *Pvu*II: $\chi^2 = 0.88$, *P* = 0.35). In the patient group, one patient was not able to identify with genotype of *Hind*III polymorphism. In the control group, two patients

were not able to identify with genotype of Ser447stop polymorphism. The allele frequency of Ser447stop polymorphism showed no difference between UC patients and controls. Frequencies of C/C, C/G and G/G genotypes of Ser447stop polymorphism in the control group were 78.8%, 18.3% and 2.9%, respectively, while these were not significantly different in patients. In the control group, frequencies of H^{+/+}, H^{+/-} and H^{-/-} genotypes for *Hind*III polymorphism were 60.4%, 26.4% and 13.2%, respectively, while frequencies of P^{+/+}, P^{+/-} and P^{-/-} genotype for *Pvu*II polymorphism were 40.6%, 47.1% and 12.3%, respectively. In UC patients, neither *Hind*III nor *Pvu*II polymorphisms differed significantly from genotype and allele frequencies in controls.

LPL polymorphism and characteristics of UC patients

We sought to identify associations between characteristics of UC patients (age at onset, gender, nature of the clinical course, extent of lesions, severity of colitis) and LPL polymorphisms. The relationship between age of onset of UC patients and their LPL polymorphisms are summarized in Table 3. In patients with onset at age 20 years or younger, more patients had either C/G or G/G genotype for Ser447stop than a C/C genotype (OR = 3.13, 95% CI = 0.95-10.33). In this early-onset group, more patients had either an H^{+/-} or H^{-/-} genotype for *Hind*III polymorphism than an H^{+/+} genotype (OR = 2.51, 95% CI = 0.85-7.45). Other characteristics (gender, nature of

the clinical course, extent of lesions, severity of colitis) showed no significant differences between polymorphism-defined groups. Details of treatment among UC patients contained 5-aminosalicylic acid agents only (35 cases), steroid therapy (65 cases), operation (20 cases), other therapy (plasma exchange in 31 cases, immunosuppressant in 4 cases). We classified UC patients into a steroid-effective group (remission with a conventional steroid dose) and a steroid-resistant group (lack of such a remission, requiring surgery or other therapy, such as plasma exchange). We did not find an effect of LPL polymorphism on steroid effectiveness of UC patients.

We also investigated serum total cholesterol in terms of LPL polymorphism in UC patients. First, 108 UC patients were classified into groups with total cholesterol below or above 220 mg/dL. LPL polymorphisms did not differ between these groups. Next, triglyceride concentration in 88 UC patients was divided into those below or above 150 mg/dL (Table 4). Patients with an H^{+/+} genotype for *Hind*III polymorphism were more likely to have triglyceride concentrations over 150 mg/dL than those with an H^{+/-} or H^{-/-} genotype (P < 0.01, OR = 6.46, 95% CI = 1.39-30.12). This was also true for patients with a P^{+/+} genotype for *Pvu* II polymorphism compared with those with P^{+/-} or P^{-/-} genotype (P < 0.05, OR = 3.0, 95% CI = 1.06-8.50).

DISCUSSION

The LPL gene, located on chromosome 8p22^[7], consists of 10 exons. As for the LPL polymorphisms investigated in this study, the Ser447stop polymorphism is within exon 9^[8], involving substitution of G for C at nucleotide 1595. The *Hind*III polymorphism is located in intron 8^[9,10], and *Pvu* II in intron 6^[9,11]. Abnormalities in LPL function have been associated with various diseases, those linked with LPL polymorphisms are cardiovascular disease^[12], cerebrovascular disease^[13], chylomycronemia^[14], insulin resistance^[15], Alzheimer's disease^[16] and various infections^[17]. Life styles and habits also can influence many diseases, possibly including UC. We presently sought out the relationship between UC and the LPL gene.

This study is probably the first to report an association

between characteristic of UC and LPL polymorphism, representing two important findings. The first finding was that *Hind*III and *Pvu* II polymorphisms affected serum triglyceride concentrations in UC patients. Some studies reported that Ser447stop polymorphism activated LPL, decreasing triglycerides and increasing HDL cholesterol. As opposed to Ser447stop, *Hind*III polymorphism lowered LPL activity, and elevated triglycerides, and decreased HDL cholesterol. *Pvu* II polymorphism has similar function^[12,18]. Using a cutoff triglyceride value of 150 mg/dL, the above relationship for *Hind*III and *Pvu* II polymorphisms held true in our UC patients. Patients homozygous for *Hind*III polymorphism were even more likely to have triglyceride above 150 mg/dL than those homozygous for *Pvu* II polymorphism. *Hind*III polymorphism, therefore, would appear to suppress LPL activity more strongly than *Pvu* II polymorphism. Among studies of associations between triglyceride in healthy individuals and LPL polymorphism, Ann *et al*^[19] reported that *Hind*III polymorphism elevated triglycerides, while Chamberlain *et al*^[18] pointed out some subjects with *Hind*III polymorphism showed normal concentrations. Since associations between elevated triglyceride in healthy individuals and *Hind*III polymorphism thus are a matter of some disagreement, our finding that UC patients with H^{+/+} genotype for LPL polymorphism were particularly likely to have elevated triglycerides, some part of the difference seen in our UC patients might be specific to UC.

Previous studies have reported that serum triglyceride concentrations did not differ between UC patients and controls^[20,21]. In this study, however, patients with H^{+/+} genotype had serum triglyceride concentrations over 150 mg/dL compared to patients with H^{+/-} or H^{-/-}, thereby suggesting that *Hind*III polymorphism may contribute to elevate triglyceride levels directly or may influence other gene-elevated triglyceride concentrations. Although few studies have examined associations between UC and LPL, lipid intake has been reported to influence risk of IBD. Many studies have reported relationship between lipid metabolism and inflammation. During various human inflammatory states, serum triglyceride concentrations increase because some cytokines responsible for inflammatory responses, including tumor necrosis factor (TNF)- α , interferon (IFN)- γ , inhibit LPL activity^[22]. Other studies reported that lipopolysaccharides derived from Gram-negative bacteria reduced LPL activity in macrophages^[23]. LPL also directly induces the expression of the TNF- α gene^[24], which synergizes with IFN- γ in stimulating nitric oxide synthetase expression in macrophages^[25]. Since LPL is strongly associated with cytokines, it may contribute to development of inflammation. In addition, De Sanctis *et al*^[26] reported an association between natural killer (NK) cells and LPL polymorphism. Some studies have suggested that UC is associated with changes in humoral immunity^[27,28] and cellular immunity^[29], while UC may be associated with loss of immune tolerance in the intestine. Association between LPL and characteristic of UC may shed some light on mechanisms of onset of UC.

The second finding was that Ser447stop polymorphism

and *Hind*III polymorphism might be associated with age of onset of UC patients. In patients with onset at 20 years or younger, more patients had either C/G or G/G genotype at Ser447stop than a C/C genotype, while more patients had either H^{+/-} or H^{-/-} genotype for *Hind*III polymorphism than H^{+/+} genotype. As for the significance of relatively early onset, the LPL gene might influence onset of disease directly or by acting upon another gene or factor. In addition to genotype, age may affect LPL activity, while lipid metabolism might influence onset of IBD. Hamilton *et al.*^[30] reported that older individuals had inefficient triglyceride metabolism and elevated serum triglycerides because of reduction of LPL activity in postural skeletal muscle during aging. Among UC patients in our study, 10% (2/20) of those aged 20 to 29 years and 15% (4/26) of those aged 30 to 39 years showed triglycerides over 150 mg/dL, while Arai *et al.*^[31] reported that, in a Japanese population sample, the mean triglyceride concentration was 83 mg/dL in the third, and 118 mg/dL in the fourth decade of life. Our finding that younger UC patients appeared more likely to have high triglyceride concentration requires further investigation.

In conclusion, our study indicates that LPL polymorphism influences lipid metabolism in UC patients and age of onset of UC, and might contribute to onset and biologic behavior of UC.

Many studies have considered gene polymorphisms in UC, but few have suggested an influence of polymorphism on metabolism in UC patients. Further study on LPL and other gene polymorphisms in UC remains an important line of investigation.

Abstract

AIM: To compare endoscopic sclerotherapy (ES) with distal spleno-renal shunt (DSRS) in the prevention of recurrent variceal bleeding in cirrhotic patients during a long-term follow-up period.

METHODS: In 1984 we started a prospective, controlled study of patients with liver cirrhosis. Long-term follow-up presents a natural history of liver cirrhosis complicated by advanced portal hypertension. In this study the effects of 2 types of treatment, DSRS or ES, were evaluated. The study population included 80 patients with cirrhosis and portal hypertension referred to our department from October 1984 to March 1991. These patients were drawn from a pool of 282 patients who underwent either elective surgery or ES during the same period of time. Patients were assigned to one of the 2 groups according to a random number table: 40 to DSRS and 40 to ES using polidocanol.

RESULTS: During the postoperative period, no DSRS patient died, while one ES patient died of uncontrolled hemorrhage. One DSRS patient had mild recurrent variceal hemorrhage despite an angiographically patent DSRS and another patient suffered duodenal ulcer rebleeding. Eight ES patients suffered at least one episode of gastrointestinal bleeding: 4 from varices and 4 from esophageal ulcerations. Eight ES patients developed transitory dysphagia. Long-term follow-up was completed in all patients except for 5 cases (2 DSRS and 3 ES patients). Five-year survival rates for shunt (73%) and ES (56%) groups were statistically different: in this follow-up period and in subsequent follow-ups this difference decreased and ceased to be of statistical relevance. The primary cause of death

became hepatocellular carcinoma (HCC). Four DSRS patients rebled due to duodenal ulcer, while eleven ES patients had recurrent bleeding from esophago-gastric sources (seven from varices, three from hypertensive gastropathy, one from esophageal ulcerations) and two from unknown sources. Nine DSRS and 2 ES patients developed a chronic encephalopathy; 13 DSRS and 5 ES patients suffered at least one episode of acute encephalopathy. Five ES patients had esophageal stenoses, which were successfully dilated.

CONCLUSION: In a subgroup of patients with good liver function, DSRS with a correct portal-azygos disconnection more effectively prevents variceal rebleeding than ES. However, this positive effect did not influence the long-term survival because other factors (e.g. HCC) were more important in deciding the fate of the cirrhotic patients with portal hypertension.

INTRODUCTION

The selective distal spleno-renal shunt (DSRS) proposed by Warren^[1] in 1967 has been considered to be the best procedure available for surgical decompression of patients with portal hypertension^[2-4]. DSRS has been compared with sclerotherapy in four trials^[5-8]. Meta-analysis of these studies^[9] showed that DSRS significantly reduces the incidence of rebleeding and only slightly increases the occurrence of chronic encephalopathy, but does not improve survival. We began a prospective, randomized clinical trial to study the prevention of recurrent variceal bleeding in cirrhotic patients during long-term follow-up in 1984^[8]. We continued recruitment until 1991 and

continued to study the patients in the following years. In this interval of time, new procedures and new randomized trials were carried out, but as regards to survival, no treatment seems to be superior to another in patients with good or moderate liver function^[10]. As regards to other surgical options, use of a small-diameter prosthetic H-graft portacaval shunt has been compared with the transjugular intra-hepatic porto-systemic shunt (TIPSS), showing a favorable trend in survival in the surgical group^[11]. On the other hand, TIPSS has been compared with endoscopic sclerotherapy (ES) in 11 randomized trials and TIPSS seems, as confirmed by two meta-analyses^[12,13], to reduce rebleeding, but significantly increases encephalopathy without differences in survival. Furthermore, a number of trials comparing endoscopic band ligation with ES have been performed in the past few years and a meta-analysis of these studies^[14] showed that it is more effective than ES in preventing rebleeding, with no differences in survival.

Based on these analyses, it seems reasonable to choose as first-line therapy (i.e. beta-blockers, endoscopic band ligation, *etc.*) the least aggressive therapy^[15]. TIPSS or shunt surgery can be performed as a salvage treatment in patients who continue to rebleed and maintain good liver function. The purpose of this report is to describe the follow-up of patients in this study, which now extends beyond 20 years for surviving patients. Long-term follow-up presents the natural history of a subgroup of patients with portal hypertension in whom an active treatment (DSRS or ES) reduced the risk of rebleeding without causing irreversible damage to liver function.

MATERIALS AND METHODS

Patients

The study population comprised 80 patients with cirrhosis and portal hypertension referred to our department from October 1984 to March 1991. These patients were drawn from a pool of 282 patients who underwent either elective surgery or endoscopic sclerotherapy because of portal hypertension during this period of time.

Criteria for inclusion in the study were as follows: (1) liver cirrhosis confirmed by biopsy in all patients; (2) endoscopic documentation of variceal hemorrhage (actively bleeding varix or non-bleeding varices without other lesions) requiring at least one unit of blood transfusion; (3) arrest of acute variceal hemorrhage either spontaneously or by use of intravenous vasopressin and/or somatostatin and/or balloon tamponade and/or haemostatic sessions of ES; (4) less than 70 years old; (5) good or moderate liver function (Child's A and B class)^[16]; (6) patency of the splanchnic venous system and hepatopetal portal flow (according to Nordlinger's classification)^[17]; (7) eligible for either shunt or ES; (8) absence of life-threatening diseases (e.g. tumors); (9) willing to return for regular follow-up. Patients bleeding from gastric varices were excluded. Figure 1 shows the reasons for the exclusion of 202 patients.

Randomization for assignment into groups was carried out when the patient was stabilized, which occurred no more than 24 h before treatment. Patients were assigned to one of the 2 groups according to a random numbers table.

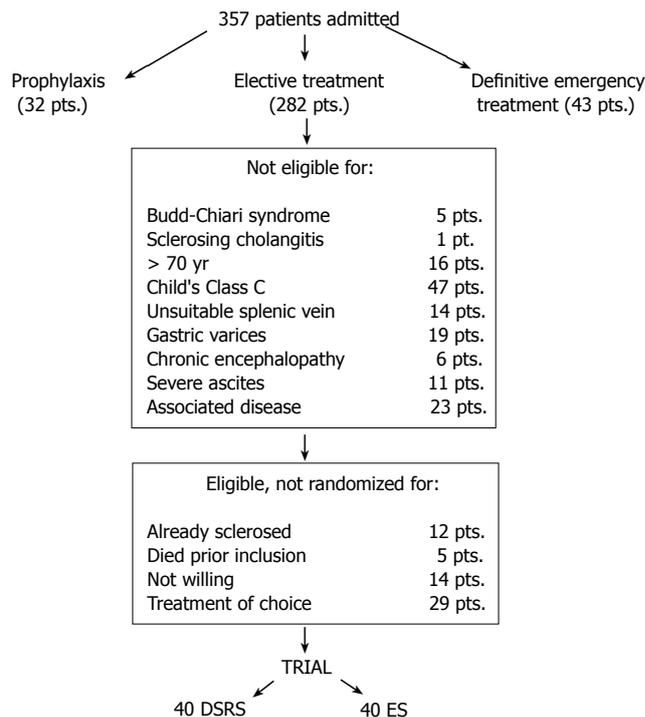

Figure 1 Reasons for exclusion. pts: patients.

Informed written consent was obtained from all patients prior to their inclusion in the study. No patient refused the assigned treatment.

Variceal rebleeding within 2 years of first treatment was considered as the primary measure of patient outcome. The sample size needed to show a decrease in variceal rebleeding from 43% to 7% is about 20 patients for each group, applying standard power (90%), type I error ($P < 0.05$) and a two-tailed t -test^[18].

Preoperative evaluation

A complete medical history was obtained for each patient, and particular notice was taken of previous episodes of gastrointestinal bleeding and evidence of either primary or post hemorrhagic hepatic failure (jaundice, ascites or edema). Routine laboratory tests were performed to evaluate liver function (Table 1). Overall assessment of the severity of liver disease was graded according to the Child-Pugh classification system^[16] and a personal hepatic score was obtained as previously described^[4,19]. Serum alpha-fetoprotein assessment and ultrasonography were routinely performed in order to screen for the presence of hepatocellular carcinoma. The presence of esophageal varices was assessed through endoscopic examination. Criteria used for classifying the endoscopic findings were based on the General Rules for Recording Endoscopic Findings on Esophageal Varices compiled by the Japanese Research Society for Portal Hypertension^[20].

Cerebral function was assessed through a complete neurological examination, taking into account mental state, asterixis, electroencephalographic findings (EEG), the trail making test^[21] and the "Cancelling A's" test^[22]. Our grading of hepatic encephalopathy (HE) has been previously described^[4,8,23]. We called HE "acute" if it was

precipitated by gastrointestinal bleeding, heavy drinking, pharmacological or dietary imbalances, of brief duration and easily controlled with elimination of the precipitating cause. We called HE "chronic" if it was spontaneous, of long duration and more difficult to manage. Naturally, preoperative HE was excluded in all patients.

A visceral angiogram was obtained by selective catheterization of the celiac axis and superior mesenteric artery. The degree of hepatic perfusion was evaluated according to Nordlinger's criteria^[17]. The rate of contrast infusion (sodium and meglumine ioxaglate, Hexabrix 320-Byk Gulden, Milan, Italy) infusion was 6 mL/s × 10 s.

Operative management

All shunt procedures were performed by a single experienced surgical team^[24]. DSRS was constructed according to the technique described by Warren^[25] (20 cases). In 18 cases a spleno-pancreatic disconnection^[26] was performed as a technical addition to DSRS, offering the optimum surgical therapy for each patient. In 2 patients a total shunt was performed for technical reasons; they were included in the statistical analysis on an intention-to-treat basis.

Endoscopic variceal sclerosis was conducted by 2 endoscopists with extensive experience in the field^[27]. All patients were given 5-10 mg diazepam premedication. ES was performed using an Olympus GIF IT flexible endoscope or an electronic Welch Allyn videoendoscope. At each session 10 to 50 mL of polidocanol (5-10 g/L) (Athoxysclerol, Creusller) and 5 g/L methylene blue were injected using a flexible injection needle in the area 5-7 cm above the esophago-gastric junction. Methylene blue allowed visual confirmation of intravariceal and paravariceal injections.

Postoperative evaluation

In the evaluation of hospital mortality and early complications, we defined the first 30 d after the initial treatment as the postoperative period. In the ES group, the events that occurred during the interval between the first session and eradication were also recorded and evaluated.

In the postoperative period, esophageal endoscopy was performed on each patient. A visceral angiography was performed on the 10th average postoperative day only in patients having DSRS. Shunt patency was verified in the venous phase of angiograms in the DSRS group. In the ES group, the number of further sessions depended on the findings obtained at endoscopy performed one week after the first sclerosis session. As soon as the eradication was achieved, the patient was included in the follow-up program. The remaining ES patients underwent further sclerosis sessions if they were free of complications, such as mucosal ulcerations, symptomatic stricture, severe esophagitis, fever and pneumonia. In the presence of complications, an upper endoscopy was performed at intervals of seven to ten days and further ES sessions were considered only when complications were resolved.

During the follow-up period, DSRS patients were checked at 1, 3 and 6 mo after discharge and then at least twice yearly, on an outpatient basis. Follow-up endoscopy was scheduled 4-6 wk after the last session and then at

Table 1 Characteristics of patients enrolled in the RCT

Characteristic	DSRS (n = 40)	ES (n = 40)	P
Age (yr)	49.4 ± 9.9	53.8 ± 8.4	0.027
Sex: M/F	27/13	33/7	0.121

Easily controlled preoperative ascites	5	11	0.09

6-mo intervals, unless recurrent hemorrhage occurred.

At each visit, liver function was evaluated following a complete medical examination and laboratory tests. Assessment of the neurological status was performed using the above-mentioned criteria. An EEG was performed at least once a year. A return to drinking was ascertained based on patients' statements, our own assessment and information from relatives. Continued drinking was defined as daily consumption in excess of 1 liter wine and/or spirits. All patients were on a 10-meq sodium and protein-balanced diet (1 g protein/kg body wt) and undergoing lactulose prophylactic treatment: the initial dose was 60 g/d in 3 separate doses and adjusted thereafter to induce at least 1 bowel movement per day.

Definitions

Eradication was defined as the absence of varices or the presence of F1 white varices.

Rebleeding was defined as hemorrhage due to esophago-gastric varices and/or congestive gastropathy, requiring at least 1 unit blood transfusion and was designated as being from varices if this was supported by endoscopic findings. The treatment of choice for variceal rebleeding was emergency sclerotherapy. Chronic rebleeding from congestive gastropathy was treated with beta-blocking therapy^[28]. Rebleeding due to peptic ulcer was recorded separately. The risk of hospitalization for HE was defined by taking the number of late hospital admissions due to episodes of HE, and dividing it by the total number of patients evaluated in the follow-up period.

Data management and statistical analysis

Initial and subsequent data for the patients were collected on a dedicated spreadsheet (Excel, Microsoft Corp., Delaware, USA) for personal computer input (Macintosh G4, Apple Computer Inc.) and subsequent analysis

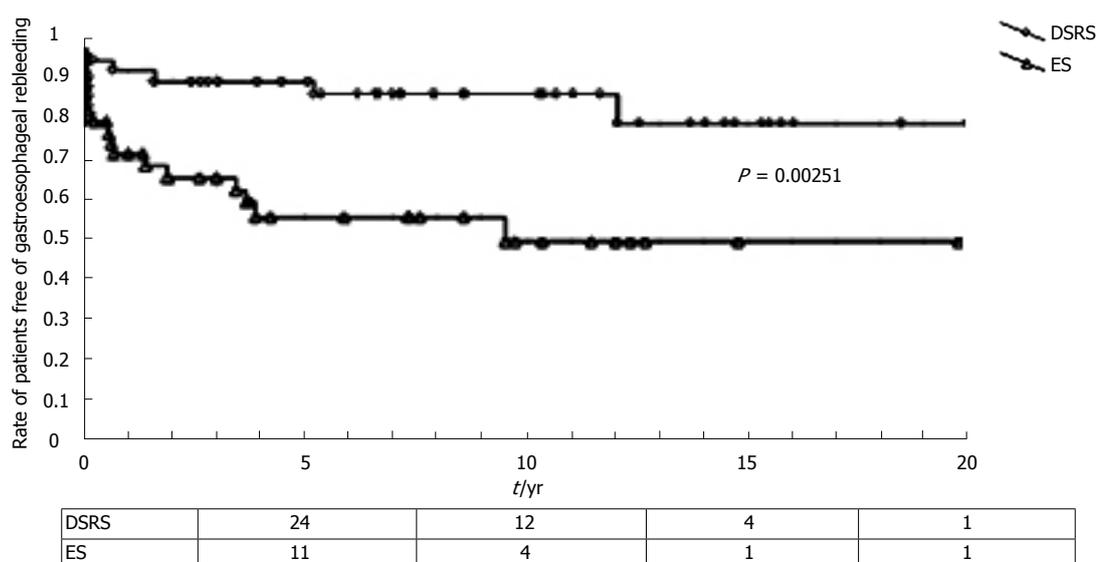

Figure 2 Actuarial curves of patients free from gastroesophageal rebleeding after distal spleno-renal shunt (DSRS) and endoscopic sclerotherapy (ES). $P < 0.05$ vs ES using the log-rank test.

(Statistica-Mac, Statsoft, Tulsa OK, USA). Survival and therapy failures were analyzed by the Kaplan-Meier method and were compared by Breslow and log-rank test^[29]. Comparison between groups was made by Chi-square test for proportions and Student's *t*-test for the means. In all patients, some preoperative variables were recorded and their influence upon survival in each treatment group was assessed by means of univariate analysis and Cox's proportional hazards regression model^[30]. The association of each parameter with survival was univariately estimated by comparing actuarial curves (Kaplan-Meier product-limit method and log-rank test) after categorization of the continuous variables in a multivariate setting^[31]. Only those parameters showing a statistical value of $P < 0.2$ were included in the multivariate analysis. The results of the univariate analysis helped to substantially reduce the number of prognostic factors. For each parameter analyzed in the multivariate analysis, the regression coefficient (beta), the T-values (Hazard ratio) and the 95% confidence intervals (CI) are given.

RESULTS

In the ES group, varices were completely eradicated in 36 patients (90%): 1 patient died before eradication and 3 patients abandoned the sclerotherapy program. The number of injection sessions was 3.7 ± 1.4 occurring over 5.1 ± 3.4 mo and the mean amount of polydocanol required for eradication was 84.7 ± 38.7 mL.

During the postoperative period, no DSRS patient died, while 1 ES patient died of uncontrolled hemorrhage after the first sclerosis session. One DSRS patient had mild recurrent variceal hemorrhage controlled by conservative therapy, despite an angiographically patent shunt and another patient rebled due to duodenal ulcer. Eight ES patients suffered at least one episode of gastrointestinal bleeding. Four were from varices requiring emergency variceal sclerotherapy and 4 from esophageal ulcerations, which were managed conservatively. No patient had episodes of hepatic encephalopathy during the immediate postoperative period. Eight ES patients developed

transitory dysphagia due to esophageal ulcerations. One ES patient suffered pleural effusion.

The mean follow-up in the DSRS group was 109 ± 58 (median 99.5) mo; ranging from 3 to 240 mo and the mean follow-up in the ES group was 87 ± 61 (median 71) mo; ranging from 1 to 237 mo. Long-term follow-up was complete in all patients, except for 5 cases (2 DSRS and 3 ES patients). No DSRS patient had shunt thrombosis, while 3 ES patients changed treatment: in 1 case a liver transplantation was successfully performed for liver failure and in 2 other cases a porto-caval H-graft shunting was performed for recurrent digestive bleeding. In the ES group, varices reformed in 14 of 36 eradicated patients (39%) after 20.4 ± 16.4 mo. They were successfully reeradicated. No DSRS patient had variceal rebleeding (four DSRS patients had duodenal ulcer rebleeding), while 7 ES patients had recurrent hemorrhage from varices, 3 from hypertensive gastropathy, 1 from esophageal ulcerations and 2 from unknown sources. The global percentage of patients who rebled was 10% and 33%, respectively ($P = 0.0194$). Figure 2 shows the actuarial curves of patients at risk of rebleeding. This risk was significantly higher in the ES group than in the DSRS group ($P = 0.00251$), above all for the first four years of follow-up. In the subsequent intervals of time, the two curves showed similar behavior.

There was no difference between patients with DSRS and ES in terms of preoperative results for the Trail making test, canceling A's test and EEG (Table 2). Postoperatively, the Trail making test showed no modifications in either group, while the canceling A's test showed an improved performance in both groups (probably due to a better comprehension of the test). EEG was unchanged after ES but worsened after DSRS. Thirteen DSRS (32.5%) and 5 ES patients (13%) suffered at least one episode of acute encephalopathy ($P = 0.0189$): three (2 DSRS and 1 ES) due to pharmacologic imbalance, three (2 DSRS and 1 ES) due to heavy drinking, three (1 DSRS and 2 ES) due to liver failure, seven (6 DSRS and 1 ES) due to constipation, one DSRS patient due to dietary abuse and one DSRS patient due to severe hyperglycemia. HE disappeared in all patients after medical therapy and dietary control in

Table 2 Comparison of the results of TMT, cancelling A's test and EEG. A's test refers to the number of A's the patients has omitted to cancel in the test

	Preoperative	Long-term follow-up	P
TMT (s)			
DSRS	55.3 ± 24.9	55.4 ± 27.9	NS
ES	60.1 ± 19.7	66.1 ± 40.1	NS
A's test			
DSRS	4.9 ± 3.8	2.6 ± 2.5	< 0.05
ES	5.5 ± 4.3	3.7 ± 3.4	< 0.05
EEG (% abnormal)			
DSRS	20%	36%	< 0.05
ES	16%	21%	NS

NS: Not significant.

Table 3 Causes of death of patients submitted to DSRS (*n* = 26) or ES (*n* = 31)

Causes of death	DSRS	ES
Digestive bleeding	1 (4%)	5 (16%)
Liver failure	6 (23%)	11 (36%)
Hepatocellular carcinoma	13 (50%)	10 (32%)
Other causes	6 (23%)	5 (16%)

all patients. Nine DSRS (22.5%) and 2 ES patients (5%) developed a mild chronic encephalopathy: the difference in the incidence of chronic HE between DSRS and ES was statistically significant ($P = 0.0263$). However, the risk of hospitalization for HE was not different: 0.38 ± 0.4 and 0.28 ± 0.3 after DSRS and ES, respectively ($P = \text{NS}$). In summary, HE was more frequent in the DSRS group than in the ES group, but not more severe. Seven DSRS patients (17.5%) and 9 ES patients (23%) returned to drinking ($P = \text{NS}$). Five ES patients had esophageal stenosis that was successfully dilated. Ascites developed in 11 DSRS patients (27.5%) and in 19 ES patients (49%; $P = 0.0521$).

Long-term survival rates for shunt and ES groups were not statistically different according to the log-rank test (Figure 3); however, a statistical difference was found by the Breslow test which better reflects the initial results. Causes of death are shown in Table 3: hepatocellular carcinoma became the primary cause of death with an increase in follow-up time (Figure 3). In the first five-year follow-up, the primary cause of death was liver failure (38%). No differences were found with respect to the etiology of liver cirrhosis: HCC developed in 35% of patients with non-alcoholic cirrhosis and in 32.5% of patients with alcoholic cirrhosis. Table 4 shows the results (actuarial survival curves and log-rank test) of the univariate analysis of some variables calculated at different follow-up intervals. By multivariate analysis according to Cox's model, age over or below 53 years old was the only independent predictor of global survival rate.

DISCUSSION

The design of a randomized, controlled trial (RCT)

Table 4 Results (actuarial survival curves and log-rank test) of the univariate analysis of some variables calculated during different interval of follow-up

Variables	P (at 5 yr)	P (at 10 yr)	P (total follow-up)
Type of treatment (DSRS vs ES)	0.0385	0.1415	0.1168

Preop: Preoperative; Postop: Postoperative.

comparing surgical treatment with a conservative therapy like ES, is often a complicated process requiring a choice of end-point, patient selection criteria, treatment schedules and methods of patient evaluation. In addition to our study^[8], three other RCTs comparing DSRS to ES^[5-7] have been published. They took different approaches to study these issues. It is true that survival is the primary end-point in prospective studies. In 2 studies^[5,6] the definition of major end-point was not specified (survival, prevention of recurrent bleeding and maintenance of hepatic function) and no statistical method for determining trial size was used. The study of Terés^[7] was designed to observe an increase in survival. However, the expected increase in survival appears to be too optimistic. On the basis of the available data^[2,24,32-35], the sample requirements needed to show a realistic 10% increase in survival at 5 years is about 470 patients per group, applying standard power (80%), type I error ($P < 0.05$) and a two-tailed *t*-test^[56].

Since gastro-esophageal rebleeding is considered the most life-threatening complication in ES, we wanted to verify whether DSRS was more effective in the prevention of rebleeding than ES and evaluate if this improvement affected survival. We limited the necessary recruitment to 20 patients per group, so the trial needed only one surgical team. This consideration is a general problem in surgical multicenter trials, as the surgeon's skill is a major factor in the surgical outcome, especially in the case of a technically complex operation such as DSRS^[37]. Our trial was undertaken after the team had acquired experience over 80 selective shunt procedures, to ensure a fairly good standardization of the surgical approach and intra- and post-operative treatment^[24]. We then decided to increase the number of patients to be recruited to 40 patients per group (P in order to either eliminate the difference observed for the preoperative variables or carry out a subgroup analysis. The results of these trials^[5-7] confirm

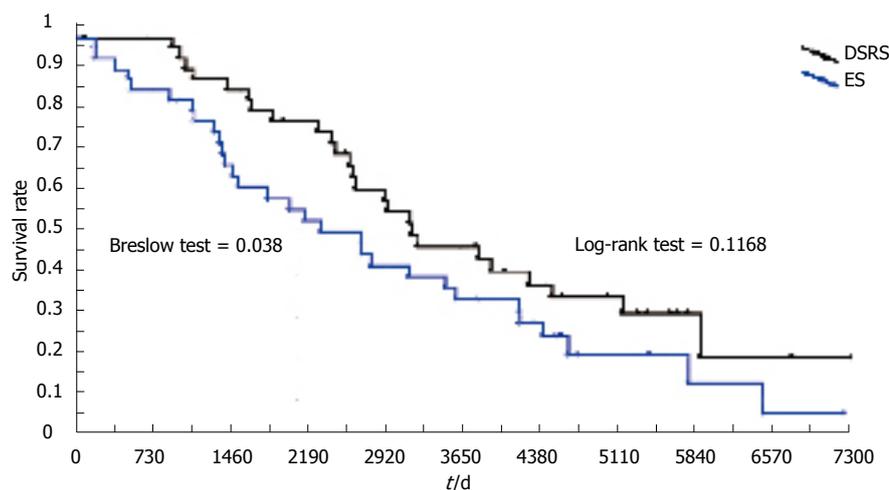

Figure 3 Actuarial survival curves for distal spleno-renal shunt (DSRS) and endoscopic sclerotherapy (ES). DSRS vs ES for the first 5 years (breslow test $P = 0.038$) while no differences were found in the final outcome (log rank test $P = 0.1168$)

DSRS	39	33	28	20	16	11	6	3	2	1
ES	33	25	20	16	12	8	4	2	1	1

previous results showing that DSRS is more effective in preventing variceal rebleeding than ES (Table 5). Either gastroduodenal lesions or esophageal varices can cause gastro-esophageal rebleeding after DSRS. The most common cause of variceal rebleeding is shunt thrombosis, but hemorrhage can also occur when the shunt is patent, because of renal vein hypertension^[38].

The problem of rebleeding in the ES group is complex and is connected with a number of factors, such as the number of patients with eradicated varices, the time interval required for eradication, the incidence of sclerosis-induced mucosal ulcerations of the esophageal wall, the variceal relapses after eradication and the incidence of hypertensive gastropathy^[39]. Our incidence of rebleeding (35%) is similar to that reported by Terés^[7] but lower compared to other studies^[5,6]. The relevance of the difference in techniques in explaining these differences is not clear^[40,41]. Different treatment intervals have been shown to affect the incidence of variceal rebleeding^[42]. Finally, it is a common experience that early rebleeding occurs frequently in Child's C patients^[5] and the number of Child's patients differed in all these RCTs.

The main complication in shunted patients was chronic HE that little affected ES patients. In the 4 RCTs the incidence of HE was higher in the DSRS group than in the ES group. This trend became significant in Terés's study^[7], probably due to the modified technique employed, which did not associate portal-azygos disconnection with the spleno-renal shunt. In fact, the entity of collaterals after DSRS seems to be an important factor influencing the incidence of HE^[43,44]. In Rikkers's^[6] and Warren's^[5] studies chronic HE was probably attributed to the hepatic failure, and that was due to the fact that both Child's C patients^[5,6] and total shunts^[6] were taken into consideration. In our preliminary study^[8], the low rate of chronic HE in the DSRS group could be due to the recruitment of patients with good liver function and a shorter follow-up period than in other studies. In fact, the lengthening of the follow-up led to an increased risk of developing HE, above all in patients who underwent surgical shunt, but the quality of life was only slightly affected, as confirmed

Table 5 2-yr survival and rebleeding rate in randomized controlled trials comparing DSRS with ES

	Warren ^[5]	Terés ^[7]	Rikkers ^[6]	Our data
2-yr survival rate after DSRS	59% ^a	71%	65%	95%
2-yr survival rate after ES	84% ^a	68%	61%	85%
Child's C patients	43%	0	33%	0
Interval between bleeding and treatment (d)	> 3-5	10-15	NR	901
Rebleeding rate after DSRS	3% ^a	14% ^a	19% ^a	2.5% ^a
Rebleeding rate after ES	53% ^a	37% ^a	57% ^a	35% ^a
Variceal eradication rate	NR	46%	63%	90%
Failure to salvage rebleeders	17%	33%	47%	14%
Shunt for ES failure	31%	6%	7%	5%
Global mortality rate due to rebleeding	3%	14%	27%	16%
Global mortality rate due to other causes	13%	16%	13%	17%

NR = Not reported; ¹mean value; ^a $P < 0.05$ vs ES.

by the same incidence of hospitalization rate. In fact, the selective effect of DSRS prevented the onset of the severe form of chronic HE.

Two-year survival rate ranged from 59% to 95% in DSRS and from 61% to 90% in the ES group (Table 5). Where do these great differences stem from? The different incidence in these studies for two prognostic factors (Child's class C patients and the interval between hemorrhage and treatment) can explain these results^[45]. However, a more important factor is present in the ES group: the fate of the patient after variceal rebleeding (Table 5). The fact that some studies^[6,7] do not have available a good therapeutic option available in case of ES failure can influence these results. The better survival rate reported in Warren's

study^[5] seems to be due to the large number of ES patients who underwent shunt surgery (10 out of 36 patients) with low operative mortality (10%). This advantage was not shown in the other studies^[6,7].

The lack of statistical difference observed in our study was also confirmed by meta-analysis of the four RCTs: the overall risk of death following DSRS was only marginally lower in comparison to that following ES (0.78 odds ratio; 95% CI: 0.47-1.29). In this study, we found a statistically improved survival following DSRS with the Breslow test; it gives more emphasis to early deaths occurring in the ES group. When lengthening the follow-up period, the survival curves become more similar and the risk of rebleeding does not increase with increasing follow-up time, while the appearance of HCC heavily influenced long-term survival in both groups, becoming the primary cause of death. The Breslow test better reflects initial results while the log-rank test more accurately characterizes final outcome.

In contrast with a recent study^[46], our analysis did not find any significant differences regarding the development of HCC (44% in DSRS group *vs* 42% in ES group even though there was a higher proportion of patients' deaths due to HCC (50% of all the causes of death in the DSRS group *vs* 32% in the ES group). This finding should be interpreted cautiously since this trial was not specifically designed to evaluate the effect of DSRS or ES on the development of HCC. In any case, it is possible that the surgical access of the DSRS could promote an HCC diagnosis at a more advanced stage and prevent the use of specific therapies for HCC, such as radiofrequency (through a percutaneous or a laparoscopic approach) or surgical resections. Another study^[47] concluded that DSRS was not a problem preventing safe performance of therapies for the HCC that developed during the follow-up period. On the other hand, it has been shown that patients with esophageal variceal bleeding who underwent ES had a high risk of developing HCC with an adverse impact on survival^[48]. Further studies are necessary to evaluate the correlations between the therapies for portal hypertension and the appearance of HCC. Furthermore, in our analysis, no differences were found regarding the etiology of liver cirrhosis, although it is not possible to know how many patients had an HCV-related cirrhosis because the test has only been used in our Department since 1991. Hepatitis C disease has assumed increasing importance over the past years and undoubtedly contributed to cirrhosis and HCC in patients with cryptogenic or alcoholic liver disease before serologic markers became routinely available.

Multivariate analysis by Cox's model found that the only factor contributing independently to the estimation of prognosis was the age of patients at the time of inclusion in the study (Hazard risk: 2.339; coefficient beta: 0.849; T-value: 2.729). That age was a prognostic variable is not surprising, since it reflects a longer duration of follow-up.

Meanwhile, in 2006, what is the lesson provided by the analysis of such a long-term follow-up study? First of all, although it is clear that all patients who survive a variceal bleeding should be treated with beta-blockers or endoscopic band ligation, which appears to be better than ES in preventing rebleeding, it is also clear that all patients in whom bleeding cannot be controlled or who continue to

rebleed can be treated with salvage TIPSS or shunt surgery, even though some studies seem to show the superiority of surgical over angiographic shunt in good-risk patients^[11,49]. Secondly, although the number of patients who have uncontrolled rebleeding following beta-blockers or endoscopic band ligation are very few, it is important that there be centers with qualified surgeons who can offer DSRS to selected patients to guarantee long-term survival comparable to that obtained by liver transplantation. Finally, it is important to underline that, in the evaluation of chronic disease with multiple complications such as liver cirrhosis, the time factor should be considered and the effect of each therapy should also be analyzed over a long-term follow-up period. This work confirms that it is possible to perform a shunt procedure without impairing liver function or the prognosis of the cirrhotic patient.

Abstract

AIM: To evaluate sample adequacy, safety, and needle passes of a new biopsy needle device compared to the Quick-Core biopsy needle for transjugular liver biopsy in patients affected by liver disease.

METHODS: Thirty consecutive liver-disease patients who had major coagulation abnormalities and/or relevant ascites underwent transjugular liver biopsy using either a new needle device (18 patients) or the Quick-Core biopsy needle (12 patients). The length of the specimens was measured before fixation. A pathologist reviewed the histological slides for sample adequacy and pathologic diagnoses. The two methods' specimen adequacy and complication rates were assessed.

RESULTS: Liver biopsies were technically successful in all 30 (100%) patients, with diagnostic histological core specimens obtained in 30 of 30 (100%) patients, for an overall success rate of 100%. With the new device, 18 specimens were obtained, with an average of 1.1 passes per patient. Using the Quick-Core biopsy needle, 12 specimens were obtained, with an average of 1.8 passes per patient. Specimen length was significantly longer with the new needle device than with the Quick-Core biopsy needle ($P < 0.05$). The biopsy tissue was not fragmented in any of the specimens with the new aspiration needle device, but tissue was fragmented in 3 of 12 (25.0%) specimens obtained using the Quick-Core biopsy needle. Complications included cardiac arrhythmia in 3 (10.0%) patients, and transient abdominal pain in 4 (13.3%) patients. There were no cases of subcapsular hematoma, hemoperitoneum, or sepsis, and there was no death secondary to the procedure. In particular, no early or delayed major procedure-related complications were observed in any patient.

CONCLUSION: Transjugular liver biopsy is a safe and effective procedure, and there was significant difference in the adequacy of the specimens obtained using the new needle device compared to the Quick-Core biopsy needle. Using the new biopsy needle device, the specimens showed no tissue fragmentation and no increment in major procedure-related complications was observed.

INTRODUCTION

To diagnose the cause and stage of liver disease, transjugular liver biopsy is an effective way to obtain a liver specimen in patients with a contraindication to percutaneous biopsy, such as coagulopathy or ascites^[1-3]. Several different kinds of biopsy needles have been designed, including the modified Ross needle (Cook, Bloomington, Indiana) placed through a 9-F curved sheath^[4], and a side-cutting needle, such as the Quick-Core needle (Cook Medical, Bloomington, IN, USA) placed through a 7-F curved sheath with a guiding metal cannula inside the sheath^[5]. A widely used, single-use biopsy needle, the Quick-Core system uses an 18-, 19-, or 20-gauge cutting needle with an automated spring-fired mechanism to obtain tissue. The popularity of the Quick-Core system is its relative ease of use and high diagnostic yield. The success rate for transjugular liver biopsy is high, but sometimes tissue samples inadequate to secure a diagnosis are obtained by this device. The present report describes the results obtained by a new biopsy device of our own design for transjugular liver biopsy.

In our hospital, we use two types of needle: a new aspiration needle device of our own design (supplied by Hakko Co Ltd, Nagano, Japan) and the Quick-Core biopsy

needle (Cook Medical). To our knowledge, there have been only a few reports comparing the safety and adequacy of the different types of needles. The purpose of this study was to evaluate and compare the safety, complications, and tissue sample adequacy, including the diagnostic yield, of transjugular liver biopsy using the two different needles.

MATERIALS AND METHODS

Between April 2002 and April 2006, 30 patients had a transjugular liver biopsy at Saiseikai Niigata Second Hospital. There were 15 men and 15 women, aged 22-75 years, with an average age of 46.57 years. All cases had a contraindication for percutaneous liver biopsy due to coagulation abnormalities and/or massive ascites. Coagulation abnormalities were defined as an INR of 1.4 or greater, and a platelet count less than 30 000/cm³. After sedation and local anesthesia, a transjugular liver biopsy was performed in 18 patients using an 18-gauge new aspiration needle device (Figure 1A), and in 12 patients using the 18-gauge Quick-Core Biopsy Needle (Figure 1B) System. With the new device, histological core liver specimens were obtained by manually aspirating through the inner cannula. All patients gave their informed consent after being fully informed of the nature of the study. The study was approved by the Ethical Committee of our hospital and was conducted in accordance with the principles of the Declaration of Helsinki. Patients were randomly allocated using a computer generated randomization code to undergo transjugular liver biopsy with the new device or with the automated Quick-Core device. The randomization results were securely kept in sealed opaque envelopes.

Technique

A 9-F, 45-cm vascular sheath (Cook Medical), was placed over a 0.035-inch guide wire into the right internal jugular vein according to the Seldinger technique, and then a 7-F multipurpose catheter was advanced under fluoroscopic control into the right, middle, or left hepatic vein. Subsequently, contrast venography was done to determine the actual position of the catheter before biopsy. With the new device, the aspiration biopsy needle was advanced within the catheter to its tip, and then the specimen was obtained by aspiration while further pushing it into the parenchyma in an antero-inferior direction. With the 18-gauge, 60-cm-long, side-cutting automated biopsy device (Quick-Core needle) the needle was positioned in the same direction, and one or several passes were done to obtain an adequate sample. Fluoroscopy and ECG monitoring were used throughout the procedure in both groups.

After the biopsy procedure, contrast medium was injected through the catheter to rule out capsular perforation. The retrieved specimens were mounted longitudinally on dry paper, and their lengths were measured before formalin fixation. An adequate amount of liver tissue was obtained and placed in formalin for pathologic evaluation. The samples were considered fragmented if the largest core sample was less than 6 mm in length. The procedure was considered to be

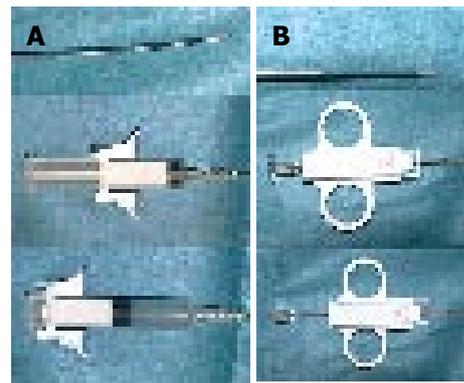

Figure 1 A: Top: Edge of new needle device; Middle: The plunger of the new needle device in the puncture position; Bottom: The plunger of the new needle device in the aspiration position, obtained by pulling back until a firm click is felt; B: Top: A 20-mm specimen notch of the Quick-Core biopsy needle; Middle: The plunger of the Quick-Core biopsy needle; Bottom: The Quick-Core biopsy needle is prepared by pulling back on the plunger until a firm click is felt, which indicates that the needle spring is locked in the ready position.

Table 1 Indications for transjugular approach to liver biopsy

(1) Increased risk of liver bleeding: 16 cases (53.3%) Severe coagulation disorders (14 cases) including: -Thrombocytopenia: 1 cases (due to hypersplenism or hematological disorders) -Fulminant hepatitis (Severe acute hepatitis): 13 cases Miscellaneous disorders (2 cases) including: -Hematological diseases (DIC): 2 cases
(2) Measurement of hepatic pressure gradient: 4 cases (13.3%)
(3) Massive ascites: 5 cases (16.6%)
(4) Miscellaneous: suspicion of amyloidosis or peliosis, obesity, failure of percutaneous liver biopsy: 5 cases (16.6%)

technically successful if a liver tissue sample was obtained. If the pathologist was able to determine the histological diagnosis based on the sample provided, the procedure was considered diagnostic. One experienced hepatobiliary pathologist was not informed about the technique. She evaluated the histological slides to obtain a pathologic diagnosis and to determine the adequacy of the submitted specimens. Complications during the procedure were recorded, and patients' clinical records were reviewed for any delayed complications. The Mann-Whitney *U*-test was used to statistically analyze any differences between the two groups.

RESULTS

Indication

Table 1 presents the indications for transjugular biopsy in our hospital (Table 1). In 70.0% of the patients in this study, coagulation disorders, thrombocytopenia, or ascites were the indications for transjugular biopsy.

Clinical Features

The clinical features of the patients included in the study and the indications for biopsy were similar between the two groups (Table 2).

Table 2 Clinical features of patients

Clinical feature	New device (<i>n</i> = 18)	Quick-core biopsy needle (<i>n</i> = 12)
Sex (M/F)	9/9	6/6
Mean age ± SD (range) (yr)	46.6 ± 15.4 (22-72)	49.4 ± 16.3 (27-75)
Indications		
Increased risk of bleeding:	9	7
Measurement of hepatic pressure gradient:	3	1
Massive ascites:	3	2
Miscellaneous:	3	2

Table 3 Final diagnosis of successful biopsies (*n* = 30)

(1) Liver cirrhosis: 9 cases (30.0%) Alcohol: 5 cases AIH: 3 cases IPH: 1 case
(2) Viral hepatitis: 14 cases (46.6%) Fulminant: Massive necrosis: 4 cases, Submassive necrosis: 9 cases, Chronic: 1 case
(3) Unknown Origin: 2 cases (6.6%) Focal necrosis: 2 cases
(4) Tumoral diseases: 2 cases (6.6%) Metastasis: 1 case, Lymphoma: 1 case
(5) Others: 3 cases (9.9%) Intrahepatic cholestasis: 1 case, NASH s/o: 1 case, Amyloidosis s/o: 1 case

Histological Findings (Table 3)

The histological diagnoses included: cirrhosis (9 patients, 30.0%), viral hepatitis (14 patients, 46.6%), focal necrosis (2 patients, 6.6%), tumoral diseases (2 patients, 6.6%), and others (3 patients, 9.9%).

Biopsy Specimens obtained from successful attempts (Table 4)

Transjugular biopsy was technically successful in 30 of 30 (100%) cases. A total of 30 specimens (18 for the new needle device and 12 for the Quick-Core biopsy needle) were obtained, with an average of 1.4 needle passes per patient (1.1 for the new needle device and 1.8 for the Quick-Core biopsy needle). However, the tissue was fragmented in 3 (25%) of 12 specimens obtained using the Quick-Core biopsy needle. In contrast, there was no tissue fragmentation in any of the 18 specimens obtained using the new aspiration needle device. Furthermore, all 12 specimens obtained using the Quick-Core biopsy needle were shorter than 10 mm, probably because of insufficient parenchymal puncture. Although sample fragmentation was present in 3 (25%) cases, all 12 procedures were diagnostic (100%).

The lengths of the specimens obtained using the Quick-Core biopsy needle were significantly shorter (3-10 mm, mean = 6.8 mm) than the lengths of the specimens obtained using the new needle device (10-21 mm, mean = 15.3 mm, $P < 0.05$). All of the specimens obtained using the new biopsy needle device were adequate for making a diagnosis (100%). Transjugular liver biopsy with the new aspiration device was more effective than with

Table 4 Biopsy specimens obtained in successful attempts

	New device (<i>n</i> = 18)	Quick-core biopsy needle (<i>n</i> = 12)
Tissue Length (mm)	15.3 ± 5.1 (10-21)	6.8 ± 2.1 (3-10)
Number of portal triads	6.5 ± 1.2	3.5 ± 0.6
Number of fragments	0/18 (0%)	3/12 (25%)
Number of passes	1.1 ± 0.2	1.8 ± 0.8
Minutes (min)	28.5 ± 7.9	45.1 ± 9.9

Table 5 Complications of transjugular liver biopsy

	New device (<i>n</i> = 18)	Quick-core biopsy needle (<i>n</i> = 12)
Cardiac arrhythmia (Supraventricular tachycardia)	1	2
Transient fever	0	1
Transient abdominal pain	1	3

the Quick-Core biopsy needle with respect to obtaining an accurate diagnosis. The mean procedure time was statically significant shorter using the new needle device (28.5 ± 7.9 min) than with the Quick-Core biopsy needle (45.1 ± 9.9 min).

Complications (Table 5)

There were no early or late complications, such as capsular perforation, hemoperitoneum, or puncture site hematoma with either device.

Three minor complications were reported in 8 (26.6%) patients; there were no major complications. Three patients developed supraventricular tachycardia during the procedure, which was believed to have been a pre-existing condition. The patients' supraventricular tachycardia responded to medical therapy with conversion to normal sinus rhythm within 24 h. Other minor complications included transient abdominal pain ($n = 4$) and transient fever ($n = 1$) that spontaneously resolved before the procedure was completed. The complication rate with the new device was significantly lower than with the Quick-Core needle.

DISCUSSION

Percutaneous liver biopsy allows one to obtain adequate tissue samples with minimal injury to the liver. However, the procedure is contraindicated in patients with an increased risk of hemorrhage, such as those with marked coagulopathy, thrombocytopenia, or ascites^[6,7]. In 1964, Dotter reported successfully biopsying the livers of several dogs using a transvenous catheter^[8]. Subsequently, Hanafee and Weiner first described the technique of transjugular catheterization of the hepatic veins in human subjects^[9]. Three years later, the first human transjugular liver biopsies were performed in a few patients by the same authors^[10].

In 1973, Rosch and colleagues reported the first major clinical series of transjugular liver biopsy with a description of 44 biopsies^[11].

Today, transjugular liver biopsy is an established alter-

native procedure for patients who have a contraindication for percutaneous biopsy. The factors that affect the quality of the specimen obtained are: type of needle, operator skill, and texture of the liver parenchyma. The selection of a needle for doing liver biopsy is based on needle safety, ease of manipulation, and reliability in retrieving specimens of an adequate length that are not fragmented. The new needle device and the Quick-Core biopsy needle use different mechanisms to obtain tissue samples. The new device uses an aspiration (suction) mechanism, while the Quick-Core device uses a swift side-cutting motion (Figure 1). The Quick-Core biopsy needle is part of a semi-automated 18-gauge Trucut needle biopsy gun device, composed of a cutting cannula and an inner stylet with a 20-mm specimen notch. Papatheodoridis *et al*^[12] found no difference in the adequacy of the specimens obtained by the Quick-Core system and the Colapinto needle, but they did not specify the core size.

We report our experience of 18 transjugular liver biopsy procedures using the 18-gauge new needle device system. The technical success rate of the biopsy was 100%. In our study, there were no cases of intraperitoneal or subcapsular bleeding; this may have been due to the use of routine venography after the biopsy passes.

DeHoyos *et al*^[13] reported a mean of 2.4 ± 1.0 passes, Papatheodoridis *et al*^[12] reported a mean of 1.8 ± 1.0 passes, Choh *et al*^[14] reported a mean of 2.8 passes, and Gonzalez-Tutor *et al*^[15] reported a mean of 3.1 passes. A larger number of needle passes contributes to a higher incidence of complications, most notably perforation of the liver capsule. In our study, 30 specimens (18 with the new needle device and 12 with the Quick-Core biopsy needle) were obtained, with an average of 1.4 needle passes per patient (1.1 for the new needle device and 1.8 for the Quick-Core biopsy needle). The number of passes was significantly lower with the new needle device than with the Quick-Core system.

The specimens obtained were significantly longer with the new needle device (10-21 mm, mean = 15.3 mm) than with the Quick-Core biopsy needle (3-10 mm, mean = 6.8 mm, $P < 0.05$).

The transjugular liver biopsy specimens obtained using the new needle device had a high diagnostic yield comparable to those obtained using the Quick-Core biopsy system. A critical disadvantage of the Quick-Core system needle is frequent tissue fragmentation. Previously, transjugular liver biopsy done using conventional aspiration techniques has been shown to yield insufficient tissue samples. It is known that a suction or aspiration biopsy of a cirrhotic liver is likely to result in tissue fragmentation. Using the Quick-Core biopsy needle, the tissue was fragmented in 3 (25%) of 12 specimens, while there was no tissue fragmentation in any of the 18 specimens obtained using the new aspiration needle device.

Therefore, the new needle device system would appear

to be superior to the Quick-Core system transseptal needle for obtaining pathologically adequate specimens. The length of all specimens obtained with the Quick-Core needle was less than 10 mm, due primarily to insufficient puncture of liver parenchyma. In our study, no procedure-related problems occurred with our new needle device system. There were no cases of intraperitoneal hemorrhage, even without the insertion of plugging material into the biopsy tract.

In conclusion, transjugular liver biopsy is a safe and effective procedure in high-risk liver-disease patients for whom percutaneous biopsy is contra-indicated. With the new biopsy needle device, larger specimens are usually obtained without tissue fragmentation. In summary, transjugular liver biopsy using the new needle device is safe and has a high diagnostic yield in patients with advanced liver disease.

Abstract

AIM: To investigate simultaneously *UGT1A7*, *UGT1A9*, *ARP*, *SPINK1* and *CFTR* genes to verify whether genetic polymorphisms predispose to the development of pancreatic cancer (PC).

METHODS: Genomic DNA of 61 pancreatic cancer patients and 105 healthy controls (HC) were analyzed. *UGT1A7* genotyping was determined by PCR-RFLP analysis. Specific PCR and sequencing were used to analyze genetic variants of *UGT1A9*, *ARP*, *SPINK1* and *CFTR* genes.

RESULTS: Four different alleles (*1: WT; *2: N129K and R131K; *3: N129K, R131K, and W208R; and *4: W208R) in *UGT1A7* and three different alleles (*1: WT; *4: Y242X; and *5: D256N) in *UGT1A9* were detected. All *UGT1A* polymorphisms were observed at similar frequency in PC patients and HC. Seven different alleles in *ARP* were found in PC patients and HC at similar frequency. The *SPINK1* mutations N34S and P55S occurred in five PC patients with a prevalence (4.1%) not significantly different from that observed (2.0%) in HC. The only *CFTR* Δ F508 mutation was recognized in three PC patients with a prevalence (4.9%) similar to HC.

CONCLUSION: *UGT1A7*, *UGT1A9*, *ARP*, *SPINK1* and *CFTR* gene polymorphisms are not associated with PC in Italian patients.

INTRODUCTION

Pancreatic cancer (PC) is still a major cause of morbidity and mortality worldwide. Despite extensive research, its etiology remains elusive. Recent data suggest that both genetic and environmental factors play a role in the development and progression of PC.

In 5%-10% of cases, PCs are inherited either as part of a known familial cancer syndrome or in association with familial forms of chronic pancreatitis^[1]; in contrast, in 90%-95% of PC cases, the relationship between possible genetic predisposition and environmental risk factors is less clear. Tobacco smoking is actually recognized as the only environmental risk factor in at least 30% of all sporadic PC^[2], while the role of alcohol and other xenobiotics is still controversial.

Polymorphisms in low penetrance genes involved in carcinogen metabolism and oxidative stress, such as *CYP1A1*, *CYP2D6*, *GSTM1*, *GSTT1*, *NAT1*, *UGT1A7* and *UGT1A9*, could increase susceptibility to PC through exposure to endogenous metabolites or environmental xenobiotics^[3]. Interestingly, among all these detoxifying activities, the *UGT1A7* and *UGT1A9* seem to be the only enzymes capable of tobacco-borne toxicant inactivation^[4-6]. Only few studies have investigated the polymorphism of *UGT1A7* and *UGT1A9* genes in PC patients with controversial findings^[7,8].

The known pancreatic cancer susceptibility genes include germline mutations of high penetrance tumor suppressor genes or oncogenes involved in cell cycle control and DNA repair such as *CDKN2A* (also known as *p16*), *p53*, *DPC4* (also known as *SMAD4*), *STK11*, *BRC42*,

K-ras, *hMLH1* and arginine-rich protein (*ARP*). The effect of these gene mutations in inducing PC seems to be poorly influenced by environmental factors^[2]. In particular, *ARP* gene has been described as oncogene. Although the functional role of the encoded protein is still unknown, the gene has been found in all species and is highly conserved at the DNA and RNA level^[9]. The presence of multiple AGG repeats around codon 50 of the mRNA and the gene has been reported in a variety of solid tumors^[10,11]. Thus, variations in the ARP trinucleotide repeat region correspond to polymorphisms of the gene^[12].

The known familial chronic pancreatitis susceptibility genes include germline mutations of moderate penetrance genes, such as cationic trypsinogen (*PRSS1*)^[13], serine protease inhibitor Kazal type 1 (*SPINK1*)^[14-16] or cystic fibrosis transmembrane conductance regulator (*CFTR*)^[17] which determine hereditary pancreatitis (HP)^[13], idiopathic chronic pancreatitis (ICP)^[15] and cystic fibrosis (CF)^[17], respectively. These genes are involved in trypsinogen activation and chloride transport, cause long-standing chronic pancreatitis and, in combination with other environmental factors such as smoking, may induce PC. However, when the polymorphisms of these genes were investigated in patients with PC, data have been inconclusive^[18,19].

We hypothesize that patients with PC could have an asymptomatic chronic pancreatitis due to the interaction of environmental factors (smoking and other xenobiotics) and genetic variations of genes involved in chronic pancreatitis susceptibility or detoxifying activities (i.e. *UGT1A7*). Moreover is conceivable that these genes may interact with each other and with other known risk factors (i.e. smoking) thus increasing the risk for PC. A possible explanation of the inconclusive results of the previous studies could be the evaluation of polymorphisms of single gene. This study focused on the simultaneous investigation of the genetic variations in *UGT1A7*, *UGT1A9*, *ARP*, *SPINK1* and *CFTR* genes as potential risk factor for sporadic PC in an Italian population cohort. A possible gene-gene interaction and correlation with age at diagnosis and smoking habit was also evaluated.

MATERIALS AND METHODS

Subjects

We investigated the prevalence of *UGT1A7*, *UGT1A9*, *ARP*, *SPINK1* and *CFTR* gene polymorphisms in 61 consecutive unrelated patients with sporadic pancreatic adenocarcinoma (PC) (mean age: 63 ± 10 years; range: 44-81 years; male/female: 31/30) and in 105 healthy blood donors (HC) (mean age: 39 ± 9 years; range: 19-60 years). Information on histological diagnosis and tumor location were available for all patients with pancreatic cancer (Table 1). DNA from patients and controls was obtained from peripheral blood samples after written informed consent was given. The study was approved by the Ethics Committee of our hospital.

Genotyping of *UGT1A7* (MIM: 606432)

UGT1A7 exon 1 polymorphic variants were identified by PCR-RFLP methods, as described by van der Logt *et al*^[20].

Table 1 Clinical features of pancreatic cancer patients

Characteristic	Pancreatic cancer patients n = 61
Mean age ± SD (range) (yr)	63 ± 10 (44-81)
Male/Female	31 (50.8%)/30 (49.2%)
Primary tumor location	
Head	38 (62.3%)
Body	15 (24.6%)
Tail	8 (13.1%)
Smoking	
Yes/No	18 (29.5%)/43 (70.5%)

Briefly, to detect variations at *UGT1A7* codons 129/131, we used the forward primers F1 and F2 and the reverse primer R1 (Table 2). F1 only detects the N129K/R131K polymorphism, whereas F2 detects both the N129K/R131K and N129R/R131K polymorphisms. To detect the W208R alteration, we used the forward primer F3 and the reverse primer R2 (Table 2). To determine whether the N129K/R131K or N129R/R131K and W208R occur cis or trans, we used the primers F4 and R1 (Table 2). PCR conditions were 5 min at 95°C, then 37 cycles of 45 s at 95°C, 45 s at 55°C (codons 129/131)/65°C (codon 208)/56°C (allele specific), and 45 s at 72°C, and finally an elongation step at 72°C for 5 min. Aliquots of 10 µL of the PCR product were digested with the restriction enzyme *VspI* (codons 129/131) or *RsaI* (codon 208/allele specific) for at least 1 h at 37°C.

Genotyping of *UGT1A9* (MIM: 606434)

The strategy used to identify polymorphisms in the *UGT1A9* was PCR amplification of the exon 1, followed by direct DNA sequencing. *UGT1A9* exon 1 sequences were amplified using a 5' primer that specifically anneals to sequence upstream of the *UGT1A9* (GenBank accession number S55985) first exon, which is unique to the *UGT1A9* gene. Specific primers (Table 2) were used to amplify a PCR product of 939 bp^[21]. The PCR conditions were 3 min at 94°C, then 30 cycles of 94°C for 30 s, 57°C for 30 s, and 72°C for 60 s. The *UGT1A9* was sequenced on both strands for all subjects. The sequence of the PCR products was determined by automated sequencing and analysed by using Sequencing Analysis 3.4.1 (Applied Biosystems, Applera, Foster City, CA).

Genotyping of *ARP* (MIM: 601916)

PCR amplification of the (AGG) repeats around codon 50 of the *ARP* gene was performed using two primers, G and I (Table 2)^[9], and analyzed by both sequencing and genotyping assay. For genotyping assay, forward primer was labelled with fluorescent 6-FAM dye (provided by MWG-Biotech AG). Enzymatic amplification of DNA was performed using AmpliTaq Gold[®] DNA Polymerase (Applied Biosystems, Applera) and amplification cycles consisted of 10 min at 94°C, followed by 35 cycles run at 94°C for 45 s, 62°C for 75 s and 72°C for 45 s, and a final extension step of 72°C for 10 min. The PCR products were analyzed for sequence by using Sequencing Analysis 3.4.1, and for genotyping by using Genescan (Applied

Biosystems, Applied, Foster City, CA).

Genotyping of *SPINK1* (MIM: 167790)

The *SPINK1* polymorphisms in exon 3 were determined by automatic sequencing. PCR-RFLP (restriction endonuclease: *TaaI*, MBI Fermentas, Germany)^[22] or PCR-CTPP (PCR with confronting two pair primers)^[23] assays were used to confirm the N34S and P55S variants.

Genotyping of *CFTR* (MIM: 602421)

The 31 most frequent mutations were examined by an oligonucleotide ligation assay (OLA kit, Applied Biosystems, Applied, Foster City, CA), whereas other seven mutations, frequently observed in Italian cystic fibrosis patients were examined by sequencing as previously described^[24].

Statistical analysis

The Hardy-Weinberg equilibrium was tested by using the Arlequin software^[25]. Comparison of allele and genotype frequencies of *UGT1A7*, *UGT1A9*, *ARP*, *SPINK1* and *CFTR* polymorphism was evaluated using the Monte Carlo approach with CLUMP program^[26] for the presence of multiple allele variants.

Univariate analysis was performed for tumor location, age at diagnosis and smoking habits by sorting patients according to their genotype distribution using the SPSS statistical package (SPSS v13 Inc. Chicago, IL, US). Continuous variable was expressed as means and standard deviations. Comparison of variables was performed with ANOVA method. Categorical variables were reported as percentage and comparison of them was performed by χ^2 -test or Fisher exact test when appropriate.

Sample size calculation to detect a significant difference between two allelic frequencies was carried out based on data reported by Ockenga *et al.*^[7]. The software package available as shareware on the World Wide Web at <http://statpages.org/proppowr.html> was used to determine the sample size. We hypothesized an allelic frequency of 20% and 35% (difference proportion rate: 15%) in controls and pancreatic cancer patients. Setting the power of the test at 80% with a significance level of 5% and assuming a relative sample size proportion of 0.6 between pancreatic

cancer patients and controls, we calculated a sample size of 198 alleles for controls and 119 alleles for patients. Consequently, we decided to recruit at least 100 controls and 60 pancreatic cancers into our study.

RESULTS

A summary of the demographic characteristics of the study population is shown in Table 1. In five subjects the diagnosis was made on clinical ground; the remaining 56 cases were confirmed histologically as ductal adenocarcinoma. In 62.3% of patients the tumor was located in the head of the pancreas, in 24.6% in the body, and in 13.1% in the tail at the time of diagnosis.

For each of the five genes, the distribution of the allele frequencies among the control population was found to fit with the assumption of the Hardy-Weinberg equilibrium ($P > 0.05$).

Three mutations (N129K, R131K, and W208R) combined into four different alleles (*1: wild type; *2: carrying N129K and R131K; *3: carrying N129K, R131K and W208R; and *4: carrying only W208R) were detected in the *UGT1A7* gene. *UGT1A7* genotyping did not show a significantly different distribution of previous alleles among patients compared to healthy controls except for the genotype *2*3 more commonly observed in healthy controls [21.0% *vs* 6.6%; CLUMP (T3): $\chi^2 = 6.05$, $P = 0.01$]. Nevertheless, after 1000 simulations with CLUMP this difference became insignificant ($P_c = 0.07$) (Table 3). Most notably, the frequency of the *UGT1A7**3 risk allele was comparable between patients (42.6%) and controls (42.0%) ($P = NS$).

Two variations (Y242X and D256N) combined into three different alleles (*1: wild type; *4: Y242X; *5: D256N) were detected in the *UGT1A9* gene. The distribution of the *UGT1A9**1, *UGT1A9**4 and *UGT1A9**5 alleles did not differ in PC patients and controls (Table 3). The variations were observed only in heterozygous state in both patients and controls.

In *ARP* gene a high frequency of genetic changes in the multiple arginine-coding-area such as M50R substitution (14.9% *vs* 11.1%), insertion of (AGG)_n (1.4% *vs* 1.1%), deletion of (AGG)_n (2.7% *vs* 4.4%) was observed in both

PC and HC, respectively. Thus, we genotyped this variable site as a simple tandem repeat (STR) polymorphism. Seven different alleles (*1: 143 bp; *2: 146 bp; *3: 149 bp; *4: 152 bp; *5: 155 bp; *6: 158 bp; *7: 176 bp) were detected with wild type sequence corresponding to allele *3 and the other allele to either deletion or insertion of trinucleotide repeats. We did not observe significant difference in both allele and genotype frequencies of *ARP* between PC patients and HC (Table 4).

Direct sequencing of the coding exonic and flanking intronic sequence of the exon 3 of *SPINK1* detected mutations in 5 (4.1%) out of 61 patients. Four of them carried a heterozygous N34S mutation, and one patient had a heterozygous P55S mutation (Table 4). In 4 (2.0%) out of 105 controls two heterozygous mutations in both N34S and P55S (*P* = NS) were detected.

For the *CFTR*, only the $\Delta F508$ mutation was found in a heterozygous state in 3 patients with PC (prevalence rate 2.5%) and in 4 controls (3.8%) (*P* = NS) (Table 4).

The statistical analysis was also performed after sorting pancreatic cancer patients out according to the histological type of the tumor, age at diagnosis and smoking habit. No statistically significant difference in genotype distribution of gene polymorphisms was observed (data not shown).

Moreover, no evidence of interaction between investigated genes was found.

DISCUSSION

The link between genetic polymorphisms of *UGT1A*, *UGT1A9*, *ARP*, *SPINK1* and *CFTR* genes and PC represent an attractive model combining genetic predisposition with environmental exposure. In the present study, we performed a simultaneous analysis of all these five genes in patients with sporadic pancreatic carcinoma. Our working hypothesis was that the predisposition to pancreatic cancer could be due to a gene-gene interaction.

Oxidative cellular injury is a prominent mechanism that could induce pancreatic inflammation and lead to genotoxicity and cancer. A major family of proteins that

play a role in cellular detoxification and defense are the UDP-glucuronosyltransferase, which are expressed in different tissues with xenobiotic contact and have been implicated in chemical carcinogenesis^[7,27]. Moreover, recent findings indicate that the presence of UGT polymorphisms may modify the risk of cancer development and reinforce the critical role of this pathway in the regulation of the biological activity of endogenous molecules and in determining the response to toxic chemicals^[7]. In the present study we found that the frequency of genetic polymorphisms in *UGT1A7* in PC patients was not different from those of healthy controls. In particular, the frequency of the *UGT1A7**3 allele encoding less active enzymes was 42.6% in pancreatic cancer compared to 42% in healthy controls, a figure comparable to that reported by Verlaan *et al.*^[8] in patients with pancreatic disease (35%-48%) and healthy controls (41%), thus suggesting that individuals bearing this allele are not at a higher risk of developing PC. Two polymorphisms of the *UGT1A9* gene (*UGT1A9**4 and *UGT1A9**5), described only in Japanese population^[28-30], were found at a similar frequency in PC and healthy controls (0%-1%).

ARP gene has been described as a possible oncogene responsible for PC. Although the functional role of the encoded protein is still unknown, the gene was found evolutionarily conserved^[9]. To examine the involvement of the *ARP* gene in exocrine PC, we screened genetic variations around multiple AGG repeats and STR polymorphism present in exon 1. We did not find a difference in mutation frequency between PC patients and controls, well in keeping with Tanaka *et al.*^[31], who found that the frequency for wild-type, M50R substitution, (AGG)₂ insertion, and AGG deletion amounted to 82%, 14%, 3% and 1%, respectively^[31]. No significant difference in allele and genotype frequencies between PC and controls for STR polymorphism were observed.

Recently, *SPINK1* polymorphisms and *CFTR* mutations have been associated with long standing chronic pancreatitis^[32,33]. *SPINK1* is a potent protease inhibitor that is thought to specifically inactivate intrapancreatic trypsin^[34]. Evidence suggests that *SPINK1* may act as a protective mechanism by preventing the activation of the pancreatic digestive enzyme cascade. Mutations in *CFTR* may disturb the subtle balance between proteases and their inhibitors by intrapancreatic acidification or by a defective apical trafficking of zymogen granules that might facilitate the intrapancreatic activation of digestive enzymes and result in pancreatitis^[35,36]. In the current study, we observed that the prevalence of the *SPINK1* N34S and P55S polymorphisms was similar between PC patients and healthy controls as previously reported in Caucasian sporadic pancreatic cancer groups^[37]. Regarding the frequency of the most common *CFTR* mutations, we found a similar prevalence of the Δ F508 mutation in PC patients and HC, consistent with similar results reported by Malats *et al.*^[19].

To the best of our knowledge, this is the first study to evaluate the prevalence of all five gene polymorphisms potentially involved in patients with exocrine pancreatic cancer. The findings of this study suggest that these polymorphisms are possibly not implicated in pancreatic cancer risk, although this study was powered to detect

a difference proportion rate of at least 15% in allelic frequencies between controls and pancreatic cancer patients. Moreover, no gene-gene interaction or correlation with tumor location, age at diagnosis and smoking habit could be demonstrated. Further studies are needed to explore other polymorphisms involved in the metabolism of carcinogens and/or endogenous factors.

Abstract

AIM: To evaluate the functional aspect of esophageal motility in healthy subjects and in patients who were referred for esophageal function testing using multichannel intraluminal impedance-esophageal manometry (MII-EM), and to assess the clinical utility of MII-EM.

METHODS: From September 2003 to January 2004, we performed the MII-EM on healthy volunteers and all the patients who were referred for esophageal function testing. Each patient received 10 liquid and 10 viscous swallows. We analyzed the results, the impedance and the manometric findings. Some of the subjects had additional ambulatory 24-h pH study performed to diagnose gastroesophageal reflux disease (GERD).

RESULTS: Among 89 studied subjects, the MII-EM findings showed normal esophageal motility in 50 (56.17%), ineffective esophageal motility (IEM) in 17 (19.10%), nutcracker esophagus in 7 (7.86%), achalasia in 4 (4.49%), and scleroderma esophagus in 11 (12.35%) cases. The completeness and the speed of bolus transit were in the order of nutcracker esophagus, normal manometry and IEM. Some of the swallows showing normal manometry and IEM had incomplete transit. In the achalasia and scleroderma esophagus, almost all the swallows had incomplete transit. The body amplitudes were higher for the swallows with complete transit than for the swallows with incomplete transit. There was not a significant difference in the manometric and impedance findings between the subjects with and without GERD.

CONCLUSION: MII-EM is a useful tool in assessing the

esophageal function in the patients having esophageal motility abnormality. The primary factors influencing the bolus transit are the amplitude of the esophageal body and normal peristalsis.

INTRODUCTION

Esophageal manometry has been considered the "gold standard" test for the evaluation of esophageal motility. Esophageal manometry allows physicians to assess peristalsis by using informations about the shape, amplitude and duration of the esophageal contraction, but it does not offer direct information about bolus transit, while barium study and single photon emission computed tomography visualize the bolus transit and offer anatomical information, but these techniques have the disadvantage of radiation exposure^[1].

The principles of impedance testing are based on measuring the differences in resistance to an alternating current that passes through the intraluminal contents. Impedance testing can detect and quantify bolus movement^[2-4]. The ability of impedance testing to detect bolus transit was validated with video-fluoroscopy in normal subjects^[5,6]. Combined multichannel intraluminal impedance-esophageal manometry (MII-EM) evaluates the functional aspects of esophageal contractions by simultaneously measuring bolus transit and esophageal contraction. Generally, the findings of esophageal manometry correlate with the symptoms or clinical progress in achalasia and diffuse esophageal spasm, but their findings do not always correlate in nutcracker esophagus and ineffective esophageal motility (IEM). The assessment of bolus transit and

esophageal function may help the physician to understand the clinical progress of a patient with esophageal disease. The aim of this study was to evaluate the functional aspects of esophageal contraction in patients having diverse esophageal motility abnormalities by using MII-EM, and to investigate its clinical utility.

MATERIALS AND METHODS

Impedance manometry

From September 2003 to January 2004, all the subjects who were referred for esophageal function testing and the healthy volunteers had esophageal function testing performed using MII-EM technology at Kangnam St. Mary's hospital, the Catholic university. The volunteers did not have any esophageal symptoms, as was investigated by an esophageal symptoms questionnaire, and they also did not have any gastrointestinal motility disorders that would influence esophageal motility, as was ascertained by physical examination and history taking. The MII-EM catheter (Sandhill EFT catheter; Sandhill Scientific Inc. Highland Ranch, CO.) was inserted transnasally into the esophagus. The 4.5-mm diameter catheter design had two circumferential solid-state pressure sensors at 5 cm and 10 cm from the tip, and it had two unidirectional pressure sensors at 15 cm and 20 cm from the tip. The impedance measuring segments consisted of pairs of metal rings placed 2 cm apart and they were centered at 10, 15, 20 and 25 cm from the tip. Intraesophageal pressure sensors and impedance measuring segments were thus located at 5, 10, 15 and 20 cm above the lower esophageal sphincter (LES), respectively (Figure 1). The LES was identified using the stationary pull-through method. The esophageal function test was performed after the subjects had rested for 10 min. With the patients in a sitting position, they were given 10 swallows of 5 cm³ normal saline and 10 swallows of 5 cm³ viscous material at 20-30 s apart. Normal saline was used instead of water since it has a standardized ionic concentration and provides for better impedance changes. The viscous material was manufactured as a food substance, and its known, standardized impedance value was provided by Sandhill Scientific Co.

Analysis

Manometry: The swallows were manometrically classified as (1) normal if the contraction amplitudes at 5 and 10 cm above the LES were each greater than or equal to 30 mmHg, and the distal onset velocity was less than 8 cm/s, (2) ineffective if either of the contraction amplitudes at 5 and 10 cm above the LES was less than 30 mmHg, (3) simultaneous if the contraction amplitudes at 5 and 10 cm above LES were each greater than or equal to 30 mmHg at the site, and the distal onset velocity was greater than 8 cm/s.

The manometric parameters used to characterize the swallows included (1) the contraction amplitude at 5 and 10 cm above the LES, (2) the distal esophageal amplitude as the average of the contraction amplitudes at 5 and 10 cm above the LES, and (3) the onset velocity of the esophageal contractions in the distal part of the esophagus. The mid-respiratory resting pressure and the LES residual pressure during swallows were used to assess the LES

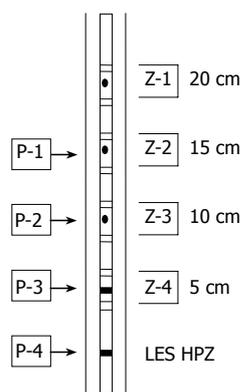

Figure 1 The 8-channel MII-EM catheter. Pressure sensors are located in LES high pressure zone (HPZ) (P-4), 5 cm (P-3), 10 cm (P-2) and 15 cm (P-1) above LES. Impedance measuring segments are centered on 5 cm (Z-4), 10 cm (Z-3), 15 cm (Z-2) and 20 cm (Z-1) above LES.

function.

Impedance: In the impedance curve, the bolus entry at each level was determined as the 50% point between the 3-s pre-swallow impedance baseline and the impedance nadir during the presence of the bolus, and the bolus exit was determined as the return to this 50% bolus point on the impedance recovery curve.

The swallows were classified by MII as showing (1) complete bolus transit, if the bolus entry occurred at the most proximal site (20 cm above LES) and the bolus exit points were recorded at all three distal impedance measuring sites (15, 10 and 5 cm above LES), (2) incomplete bolus transit, if the bolus exit points were not identified at any one of the three distal impedance measuring sites. We calculated the complete bolus transit rate for the liquid and viscous swallows.

Impedance parameters included (1) the total bolus transit time (TBTT) as the time that elapsed between bolus entry at 20 cm above the LES and bolus exit at 5 cm above the LES, (2) the complete bolus transit rate, and (3) the baseline impedance during the resting state. To assess the baseline impedance value, a pair of cursors (the time difference between the cursors was about 4 s) were placed on one channel about 2-3 s before the onset of the impedance changes related to the arrival of a bolus front. The maximal and minimal values between the cursors were subsequently determined by computer analysis. The baseline impedance was defined as the mean of these values.

Evaluation of esophageal motility and function: The diagnoses of manometric motility abnormalities were established from 10 liquid swallows with using the criteria published by Spechler and Castell^[7]. Achalasia was defined by the absence of esophageal body peristalsis and, if present, a poorly relaxing LES. Scleroderma esophagus was defined based on an appropriate clinical diagnosis and confirmed by the presence of low amplitude contractions in the distal esophagus with or without a low LES pressure. Diffuse esophageal spasm was defined as 20% or more simultaneous contractions. IEM was defined as 30% or more swallows with a contraction amplitude less than 30 mmHg in either of the two distal sites located at 5 and 10 cm above the LES. Nutcracker esophagus was defined as normal peristalsis of the esophageal body with the average distal esophageal amplitude exceeding 180 mmHg. Poorly relaxing LES was defined as the average LES residual pressure exceeding 8 mmHg and this was associated with nor-

mal esophageal body contractions. Hypertensive LES was defined as the LES resting pressure exceeding 45 mmHg with normal esophageal body contractions. Hypotensive LES was defined as the LES resting pressure below 10 mmHg with normal esophageal body contractions. Normal esophageal manometry was defined as not more than 20% ineffective swallows and not more than 10% simultaneous swallows with a distal esophageal amplitude < 180 mmHg and with normal LES resting and residual pressures. For the patients having both esophageal body and LES abnormalities, the final diagnosis was based on the esophageal body findings.

The overall diagnosis of esophageal transit abnormalities was defined as abnormal liquid transit if more than 20% of the liquid swallows had incomplete bolus transit and there was abnormal viscous transit if more than 30% of the viscous swallows had incomplete bolus transit.

Statistical analysis

Descriptive statistics were used to describe the manometric and impedance findings. Analysis of variance (ANOVA) was used to evaluate the differences of impedance parameters by the manometric diagnosis. Unpaired *t*-test was used to compare the differences of the distal esophageal amplitudes between swallows with and without complete transit. Unpaired *t*-test was also used in the comparison of the manometric and impedance parameters between the patients with and without gastroesophageal reflux. A *P* value less than 0.05 was considered statistically significant.

RESULTS

Subjects

Using combined MII-EM, 89 subjects including 26 healthy volunteers (27 males and 62 females, mean age: 41.4 years), underwent esophageal function testing. While all the subjects received liquid swallows, 10 subjects did not receive the viscous swallows. The primary symptoms for which the subjects received esophageal function testing were: ENT symptoms, such as throat discomfort or a globus sense in 26 subjects, chronic cough in 5 subjects, heartburn in 16 subjects (including 6 scleroderma patients), dysphagia in 4 subjects, other symptoms in 4 subjects and there were asymptomatic 8 scleroderma patients in order to evaluate the esophageal involvement of scleroderma. In 37 subjects, esophageal function testing was performed prior to ambulatory 24-h pH monitoring, which was done to diagnose gastroesophageal reflux disease (GERD).

Based on the aforementioned manometric criteria of liquid swallows, 50 (56.17%) patients had normal esophageal manometry, 17 (19.10%) patients had IEM, 7 (7.86%) patients had nutcracker esophagus, 11 (12.35%) patients had scleroderma esophagus and 4 (4.49%) patients had achalasia. Two patients with nutcracker esophagus had hypertensive LES simultaneously. There was no patient who had an isolated LES abnormality (hypertensive LES, hypotensive LES and poorly relaxing LES). The additional viscous swallows did not change the diagnosis of achalasia, scleroderma esophagus and nutcracker esophagus. However, the manometric diagnoses of 8

Table 1 Impedance parameters of the liquid and viscous swallows by the manometric diagnosis (mean ± SD)

Impedance parameter	Bolus transit rate (%)		TBTT (s)	
	Liquid	Viscous	Liquid	Viscous
Normal	88 ± 18	72 ± 28 ^d	6.5 ± 1.3	7.6 ± 1.5 ^d
IEM	59 ± 16 ^b	61 ± 27 ^{b,d}	7.4 ± 1.6 ^b	8.3 ± 1.4 ^{b,d}
Nutcracker esophagus	98 ± 8 ^b	98 ± 5 ^{b,d}	6.0 ± 1.2 ^b	6.9 ± 1.4 ^{b,d}
Scleroderma	9 ± 14 ^b	3 ± 5 ^b	-	-
Achalasia	5 ± 10 ^b	0 ^b	-	-

among the 50 subjects who had normal manometry upon the liquid swallows were changed to IEM, and 4 among the 17 patients who had IEM upon the liquid swallows had their diagnosis changed to normal manometry upon the viscous swallows when we applied the same manometric criteria to the patients receiving viscous swallows. The final manometric diagnosis for each patient was based on the liquid swallows so as to remain consistent with the current tradition.

Evaluation of overall bolus transit using liquid and viscous swallows

The bolus transit rate was high and the TBTT was short in the order of nutcracker esophagus, normal manometry and IEM, upon both liquid and viscous swallows (^b*P* < 0.01). The liquid bolus moved faster than the viscous bolus (^d*P* < 0.01, Table 1).

All patients with nutcracker esophagus had normal transit for the liquid and viscous swallows. For the subjects with normal manometry, 20% had abnormal liquid transit and 34% had abnormal viscous transit, and 46% of the patients with IEM had abnormal viscous transit. None of the patients with achalasia and scleroderma esophagus had normal transit for the liquid and viscous swallows.

In the analysis of individual swallows, the liquid bolus transit rates were 90% for the manometric normal swallows, 24% for the manometric ineffective swallows and 5% for the manometric simultaneous swallows. The viscous bolus transit rates were 83% for the manometric normal swallows, 9% for the manometric ineffective swallows, and 0% for the manometric simultaneous swallows (Table 2).

The distal esophageal amplitudes of the swallows with complete transit were significantly higher than those of the swallows with incomplete transit for both the liquid and viscous swallows, except for the manometric simultaneous swallows (*P* < 0.01, Figure 2).

Baseline impedance

The baseline impedance values for the patients with achalasia and scleroderma esophagus were lower than those of the subjects with normal manometry, IEM and nutcracker esophagus at all impedance measuring sites (*P* < 0.05, Table 3). There was no difference in the baseline impedance among all of the impedance-measuring sites for the patients with achalasia, but for the scleroderma patients, the impedance of the most proximal site was

markedly higher than those of the other sites ($P < 0.01$).

MII-EM in the patients with pathologic gastroesophageal reflux

Among the 37 subjects who had a 24-h pH study performed, 26 (70.27%) had normal results and the 11 (29.72%) subjects were diagnosed with GERD. The manometric diagnoses for the subject without pathologic gastroesophageal reflux were normal in 62%, IEM in 23% and nutcracker esophagus in 15%. The manometric diagnoses for the subjects with pathologic gastroesophageal reflux were normal in 73%, IEM in 18% and nutcracker esophagus in 9% cases. The distal esophageal amplitudes of the patients without pathologic reflux were higher than those of the subjects with pathologic gastroesophageal reflux ($P < 0.05$). The LES pressure, the pattern of esophageal contraction, bolus transit rate and the TBTT were not obviously different between them (Table 4).

Table 4 The manometry and impedance evaluation based on pathologic gastroesophageal reflux (mean \pm SD)

DISCUSSION

We evaluated the peristalsis and bolus transit in the subjects having abnormal and normal esophageal motility by using combined MII-EM. All the patients with achalasia and scleroderma esophagus, and some of the patients with IEM had abnormal bolus transit. Yet the patients with nutcracker esophagus had much better bolus transit than did the subjects having normal manometry.

The subjects having diverse esophageal motility abnormalities as well as the asymptomatic volunteers were included. Especially, the eleven patients with typical scleroderma esophagus were included. Most of the manometric ineffective swallows belonged to the scleroderma esophagus group and the IEM group. The bolus transit rate was markedly different between the IEM and scleroderma esophagus: 59% vs 9% on the liquid swallows and 61% vs 3% on the viscous swallows, respectively. Almost all the manometric simultaneous swallows belonged to the achalasia group. The bolus transit rate of the manometric simultaneous swallows was very low, less than 5%. We propose that the manometric ineffective or simultaneous swallows of patients with severe esophageal dysmotility and those of patients with the mild motility abnormality or normal motility should be classified and analyzed separately because their bolus transits were markedly different, as was

seen by the results.

The esophageal body pressure, the LES pressure and the peristaltic movement can be considered as factors that have an influence on the bolus transit. This study showed that the major determinants of complete bolus transit were the esophageal body pressure and normal peristalsis. The bolus transit rate and the TBTT were better in the order of nutcracker esophagus, normal manometry and IEM. The higher the distal esophageal amplitude was, the better was the bolus transit. The contraction amplitudes of the swallows with complete transit were higher than those of the swallows with incomplete transit. So, it can be concluded that the esophageal body pressure is important to determine the complete bolus transit. Because there were no subjects with a poorly relaxing LES or hypotensive LES and only two patients with hypertensive LES in this study, we could not evaluate the effect of LES pressure on bolus transit. As the bolus transit rate and the TBTT of the two subjects with hypertensive LES who were classified as nutcracker esophagus were not different from those of the other subjects with nutcracker esophagus and normal LES pressure, we can guess that the high esophageal body amplitude overcomes the interference with bolus transit by the hypertensive LES. Almost all the swallows of the patients with achalasia and scleroderma esophagus had functional aperistalsis and incomplete bolus transit, so normal peristalsis is very important for bolus transit. If the subjects with diffuse esophageal spasm were included in this study, we could then know the role of isolated peristaltic abnormality on bolus transit. Our conclusion somewhat coincides with Tutuian *et al.*^[8] that the major determinant of bolus transit is the esophageal body pressure and any isolated LES pressure abnormality has a minor role. They suggested the new functional classification of esophageal motility abnormality: defects of bolus transit and isolated pressure abnormalities. The defects of bolus transit include achalasia, scleroderma esophagus, IEM and diffuse esophageal spasm. The isolated pressure defects include nutcracker esophagus, hypertensive LES, hypotensive LES and poor relaxation of the LES.

We suggest that the nutcracker esophagus should be classified as functionally normal as it had a better bolus transit than the manometrically normal esophagus. Up to now, esophageal hypercontraction abnormalities, such as hypertensive LES and nutcracker esophagus, have been the most controversial of the dysmotility patterns because it is not clear that esophageal hypercontraction has any physiological importance. Achalasia clearly showed low baseline impedance and failure of bolus transit. Retrograde esophageal contraction, intermittent reflux of the luminal contents and pathologic movement of luminal air during swallows seen in a previous study^[9] were not clearly observed. Almost all the swallows of the patients with a scleroderma esophagus, in which the peristalsis was present faintly but very hypotensive, had incomplete transit like the achalasia patients. Because impedance testing has not yet been validated with radiographic studies in these patients, we should consider that impedance testing might overestimate incomplete transit. For example, the low pre-swallow impedance caused by the residual luminal content may influence the analysis of impedance of the following

swallow.

There was no difference of baseline impedances among the patients with normal manometry, IEM and nutcracker esophagus. Compared to those, the baseline impedances of swallows with achalasia and scleroderma esophagus were significantly lower. Impedance correlates negatively with the cross sectional area of the esophagus and the conductivity of the luminal contents^[10]. Low baseline impedance means the dilatation of lumen or the existence of luminal content. So, we could expect that the baseline impedance of the achalasia patients was significantly lower^[11-13]. We had expected that impedance of the distal esophagus in the patients with achalasia would be higher than the impedance at the more proximal sites, but it was not. In the scleroderma esophagus, the impedance of the proximal esophagus was higher than that of the distal esophageal body. It means that the bolus transit of the upper esophagus and around the UES is preserved compared to the other sites. The low impedance of the distal esophagus adjacent to LES seemed to be associated with the decreased resistance of the gastroesophageal junction, which consists of smooth muscle^[14]. The baseline impedance is considered to be the reflection of the dilatation of the esophageal body or the residual bolus produced by aperistalsis rather than it being a factor influencing bolus transit.

The bolus transit rate in the subjects with normal manometry was lower and had wider variation, as compared to previous studies. For example, one patient with normal manometry had a 20% transit rate for both liquid and viscous transit. Another patient with normal manometry had 100% liquid transit, but 0% viscous transit. The only 85% of the asymptomatic subjects with normal manometry had normal liquid transit and 78% had normal viscous transit. This showed that the precise evaluation of esophageal function was impossible via the indirect information from manometry only.

The viscous material may be a more sensitive material for the detection of minor motility abnormalities because generally, the viscous transit rate and transit time were worse than the liquid transit rate and transit time in the manometric normal and ineffective swallows. We should also consider the results of viscous swallows for the evaluation of esophageal dysmotility in that the manometric diagnoses of some patients with minor IEM or normal manometry were changed after applying the result of viscous swallows.

Some of the manometric ineffective and simultaneous swallows had complete transit, and there is the possibility of overestimation of the functional defect when using only the parameters of the manometry. The functional information from MII-EM will be useful for understanding the symptoms or pathophysiology of esophageal dysmotility which is minor or of unclear clinical significance such as nutcracker esophagus. However, the use of MII-EM is not always needed in daily clinical situation in that its result does not change the treatment option.

Impedance did not offer any additional information for the diagnosis of GERD. The differences of the distal esophageal amplitudes may be due to the fact that the group of patients without reflux included more number of

patients with nutcracker esophagus. We had expected that the bolus transit of patients with pathologic gastroesophageal reflux would be worse because they had the abnormal acid clearance, but their parameters of impedance were not significantly different from those of the patients who were without gastroesophageal reflux.

In conclusion, the combined MII-EM provides delicate and functional informations about the bolus transit of normal subjects and the patients with minor esophageal dysmotility as well as severe esophageal dysmotility. The major factors to determine the complete bolus transit are the esophageal body pressure and normal peristalsis. The validation of measuring impedance along with performing radiographic study will be needed for the patients with esophageal motility abnormality, and its clinical and prognostic value should be clarified by an outcome study^[15].

Abstract

AIM: To evaluate the 5-lipoxygenases (Loxs) expression level in human colorectal cancer specimens in order to determine its clinicopathologic significance in human tumorigenesis.

METHODS: The relative quantity of 5-Lox mRNA in paired 91 colorectal tumor and adjacent normal mucosa samples was determined by real time quantitative PCR. Additionally, the expression of 5-Lox and cyclooxygenase (Cox)-2 proteins was also examined using immunohistochemical staining methods.

RESULTS: There was a marked increase in 5-Lox mRNA levels in the tumor compared with paired normal mucosa samples ($P < 0.0001$). Sixty six (72.5%) tumors showed high 5-Lox mRNA levels. The positivity rate of 5-Lox and Cox-2 protein expression was 68.7% and 79.1% respectively. There was a significant association between tumoral 5-Lox mRNA level and tumor size (Rho = 0.392, $P = 0.0002$), depth or vessel invasion.

CONCLUSION: These results suggest that 5-Lox is up-regulated in colorectal cancer and that inhibition of its expression might be valuable in the prevention and treatment of colorectal cancer.

INTRODUCTION

Evidence from epidemiological and animal studies suggests that a high-fat consumption is associated with an increased incidence and growth of tumors at several specific organ sites, including breast, pancreas, colon, and prostate^[1]. In this respect, it has been demonstrated that the metabolism of arachidonic acid, a polyunsaturated fatty acid by either the Cyclooxygenase (Cox) pathway or the Lipoxygenase (Lox) pathway, generates a host of pro-inflammatory substances called eicosanoids including prostaglandins, thromboxanes, leukotrienes, *etc.*, that act as potent autocrine and paracrine regulators of cell biology^[2]. These substances are known to modulate diverse physiological and pathological responses, including growth and invasiveness of tumor cells as well as suppression of immune surveillance^[2].

To date, two Cox isozymes have been identified, the constitutive Cox-1, and the inducible Cox-2^[3-5]. For Lox, three major isoforms have been characterized in human tissue, according to the oxygenation sites in the substrate arachidonic acid. These enzymes are named, 5-, 12-, and 15-Lox^[4,7]. Over the last two decades, a large body of evidence from experimental and clinical studies has shown that Cox-1/-2 play an important role in the promotion and progression of many types of human neoplasms^[3,8-11]. And most importantly, specific inhibition of these enzymes is reported to exhibit a dramatic anti-neoplastic activity^[12-15]. Although most attention has focused on prostaglandins (PGs) and other Cox-derived metabolites, emerging evidence now suggests that Lox-catalyzed products, Leukotrienes (LTs) and Hydroxyeicosatetraenoic acids (HETEs) also exert profound biological effects on the development and progression of human cancers^[7]. An increase in expression of Lox and their metabolites has been detected in a variety of human cancer cell lines and tissues including those of the prostate^[16], bladder^[17], breast^[18], lung^[18], colon^[5,19], pancreas^[1,20], oral^[21] and esophagus^[22]; and this over-expression was reported to be significantly associated with tumor cell proliferation, resistance to apoptosis, and angiogenesis^[23-25]. Moreover, the direct inhibition of 5-Lox or 12-Lox, was found to markedly suppress the tumor cell growth^[2,17,18,26]. Nonetheless, some investigators also have demonstrated a

down-regulation of 15-Lox-1/-2 in human colorectal^[27,28] and prostate tumors^[29] compared with adjacent normal tissues. The clinicopathologic significance of Lox expression is less clearly defined in human colorectal cancer. This observation prompted us to evaluate the expression level of 5-Lox and, determine its correlation with clinical and pathological features of colorectal cancer.

MATERIALS AND METHODS

Patients and tissue samples

Ninety one patients who underwent surgical resection for colorectal cancer in our institution between January and December 2004 were included in this study. These consisted of 53 men and 38 women with a mean age of 64 ± 11 years; 49 colon cancers and 42 rectal cancers. The clinicopathologic parameters were determined according to the International Union Against Cancer Tumor-Node-Metastasis (TNM) classification of malignant tumors^[30] and, the tumor size represents the greatest dimension measured after formalin fixation. Immediately after surgery, a small piece of colorectal tumor samples and matched adjacent normal mucosa (taken from the borders of the surgical specimen), were separately placed directly in RNA stabilization reagent (RNAlater, Qiagen) and stored frozen at -80°C until further analysis. Additionally, 67 formalin-fixed, paraffin-embedded tumor tissue blocks obtained from the same patients were also available for immunohistochemical studies.

This study was approved by the Institutional Review Board of the Tokyo Medical and Dental University, and written informed consent was obtained from all patients.

RNA extraction and cDNA synthesis

Total RNA for each sample was extracted using the RNeasy mini kit (Qiagen) according to the manufacturers' instructions. RNA was quantified by measurement of A_{260} and A_{280} using a UV spectrophotometer (Beckman, Life Science); and, its quality was determined by electrophoresis through agarose gels and visualization of the 18S and 28S RNA bands under UV light. For cDNA synthesis, 10 μg of total RNA was reverse-transcribed into cDNA samples using Superscript II RNase H-Reverse transcriptase (Invitrogen) according to the manufacturer's protocol.

Real time PCR

Real time quantitative Polymerase Chain Reaction (RTQ-PCR) analysis was done by using the 7300 Real Time PCR System (Applied Biosystems). Primers and probe sequences were designed using the Primer Express software (Applied Biosystems) as follows: 5-Lox primers: GGGCATGGAGAGCAAAGAAG and ACCTCGGCCGTGAACGT, probe: TACTTCTACCGGGACGACGGGCTCCT; ACTB-1 primers: TGAGCGCGGCTACAGCTT and TCCTTAATGTCACGCACGATTT; probe: ACCACCACGGCCGAGCGG.

The PCR reaction was carried out with the TaqMan Universal PCR Master Mix (Applied Biosystems) using 1 μL of cDNA in a 24 μL final reaction volume. The thermal cycling conditions were as follows: 50°C for 2 min,

95°C for 10 min and 45 cycles of 15 seconds denaturation at 95°C and 1 min annealing at 60°C . Each sample was run in duplicate for both target gene and endogenous gene.

The amount of 5-Lox (target) normalized to ACTB-1 (endogenous control) and relative to HCT15 (calibrator), was determined by the comparative C_T method^[31] using the Relative Quantification (ddCt) Study Software (7300 Sequence Detection System version 1.2.1, Applied Biosystems).

The human colon adenocarcinoma cell line HCT15 used as a calibrator in this study, was kindly provided by Cell Resource Center for Biomedical Research Institute (Tohoku University, Miyagi, Japan).

Immunohistochemical evaluation of 5-Lox expression

A Universal Immuno-enzyme Polymer method (Nichirei simple staining) was performed for immunohistochemical staining as we previously described^[32]. Anti-5-Lox polyclonal antibody (Cayman Chemical, Ann Arbor, MI; dilution: 1:250) and anti-Cox-2 monoclonal antibody (Cayman Chemical, Ann Arbor, MI; dilution: 1:250) were used as the primary antibody for 2 h incubation at room temperature.

The immunoreactivity of 5-Lox/Cox-2 protein in the tumor cells was determined according to the procedure previously described^[32]. Briefly, staining intensity was scored as 0 (negative), 1 (weak), 2 (medium), 3 (strong). Extent of staining was scored as 0 (0%), 1 (1%-25%), 2 (26%-50%), 3 (51%-75%), and 4 (76%-100%) according to the percentage of positive staining area in relation to the whole carcinoma area. Then, the sum of intensity and extent score was regarded as the final staining score for 5-Lox or Cox-2; and, tumors having a final score of ≥ 3 were considered to be positive^[32].

Statistical analysis

Median value of normal samples was used as the cut-off point to distinguish between low and high levels of mRNA expression. Nonparametric Wilcoxon and Mann-Whitney U tests were used to evaluate differences in 5-Lox mRNA expression levels between groups. The correlations with clinicopathologic parameters were assessed with a Chi-square test for categorical variables and a Spearman rank test for continuous variables. The strength of association between 5-Lox and Cox-2 staining scores was determined by the Spearman rank test. The difference was considered significant at $P < 0.05$. All analyses were performed with the statistical software package Stat View (version 5.0).

RESULTS

5-Lox mRNA expression and its association with clinicopathologic parameters

The median value of 5-Lox mRNA expression (relative quantity, RQ) in normal and tumor samples was 36.094 (minimum: 5.966, maximum: 131.859) and 61.113 (minimum: 6.228, maximum: 224.773), respectively. Both Wilcoxon and Mann-Whitney U tests, showed a significant difference in mRNA levels between the two groups of samples ($P < 0.0001$; Figure 1). Using the median RQ of normal samples as the cut off point, we found that 66 of

¹Spearman rank test P value; NS: Not Significant ($P > 0.05$).

91 tumor specimens (72.5%) showed high 5-Lox mRNA level. In Table 1, the associations between 5-Lox mRNA expression status and various clinicopathologic parameters are shown. 5-Lox expression was significantly correlated

with tumor size (Rho = 0.392, $P = 0.0002$; Figure 2), depth of invasion ($P = 0.0208$), lymphatic invasion ($P = 0.0297$), and venous invasion ($P = 0.0057$). There was no significant correlation with patient age and gender, tumor site, histological type, lymph node metastasis and TNM stage.

5-Lox and Cox-2 protein expression

Immunoreactivity of 5-Lox protein was found in the tumor epithelial cells within the cytoplasm, nucleus and nuclear membrane. In contrast, Cox-2 expression was mainly cytoplasmic. Occasionally, little staining was found in the stromal cells or tissue and the adjacent normal mucosa particularly for 5-Lox. Representatives of the staining patterns are shown in Figure 3.

The positivity rate (staining score of 3-7) for 5-Lox and Cox-2 expression was 68.7% and 79.1%, respectively. The Spearman rank test, showed a significant correlation between 5-Lox and Cox-2 staining scores (Rho = 0.277, $P = 0.0246$); and, 5-Lox mRNA levels versus protein staining scores (Rho = 0.380, $P = 0.0025$). Forty four samples stained concurrently positive for both proteins, and had a greater mean tumor size when compared with the group of other samples (58.273 ± 19.966 vs 46.391 ± 20.221 , $P = 0.0476$; Figure 4).

DISCUSSION

In the current study, we demonstrated that 5-Lox expression is significantly up-regulated in human colorectal tumor compared with the adjacent normal mucosa. Similar results have been reported for various tumors including those of the colon and rectum^[19], esophagus^[22], pancreas^[11], oral^[21], bladder^[17], and prostate^[16]. However, according to a PubMed search using the keywords 5-Lipoxygenase, and cancer, this is the first study to examine the expression levels and clinicopathologic significance of this gene in a large series of surgical specimens.

Our most important finding was the positive correlation found between 5-Lox expression level with tumor size, depth and vessels invasion. This observation is similar to our previous data indicating that gastric^[33] or colorectal^[32] tumors with higher Cox-2 level, grow

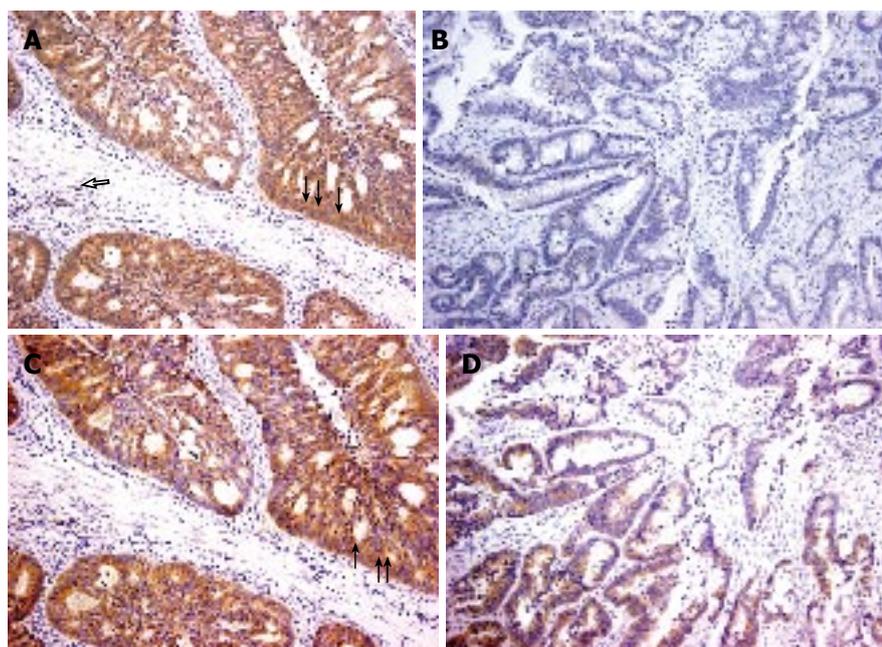

Figure 3 Representative cases of 5-Lox/Cox-2 immunostaining in colorectal cancer (x 200). **A:** Positive, diffuse, strong cytoplasmic and focal nuclear membrane 5-Lox staining in epithelial tumor cells (black arrow) and stromal cells (white arrow); **B:** Negative, weak 5-Lox staining. The same samples are shown with strong (**C**) and moderate (**D**) Cox-2 staining.

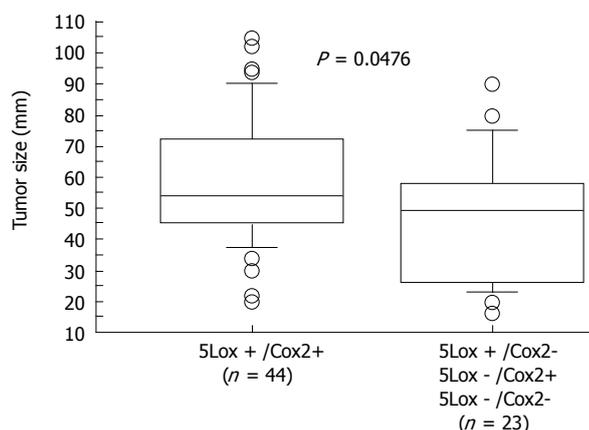

Figure 4 Differential tumor size between a group of concurrent 5-Lox/Cox-2 positive samples and a group of others (5Lox+/Cox2-, 5Lox-/Cox2+, 5Lox-/Cox2-).

more larger and deeper. It also provides further support to the concept that 5-Lox and Cox-2 display similarities in expression and function in human cancer such as proangiogenic and anti-apoptotic properties^[3] and a substrate preference. In our series, the fact that concurrent 5-Lox and Cox-2 positive tumors had the largest mean size, may be considered as the consequence of a combined effect of the two metabolic pathways that remove a proapoptotic substrate, arachidonic acid^[9], and generate more proangiogenic, anti-apoptotic products, eicosanoids; leading to an increase tumor cells growth. The absence of a statistically significant correlation between 5-Lox overexpression and more aggressive tumor behavior such as lymph node metastasis, confirmed the observation by Ohd *et al*^[19] that positive 5-Lox expression was not a strong predictor of survival in a study of 61 colorectal cancer patients^[19].

In contrast to Cox-2, little is known about the mechanisms by which lipoxygenases contribute to tumor growth and progression; but, emerging evidence from

several experimental studies suggest that these enzymes and their products, similarly to Cox-2 and PGs, may act on tumor cells through inhibition of apoptosis, increase of cell proliferation and stimulation of angiogenesis^[23-25]. Recently, Hoque *et al*^[25] using esophageal cancer cell lines, demonstrated that 5-Lox inhibitors caused a dose- and time-dependant reduction in cell viability and induced apoptosis, which was associated with the level of 5-Lox expression and LTB4 production in these cell lines^[25]. According to Romano *et al*^[24], the regulation of vascular endothelial growth factor (VEGF) release and mRNA levels by 5-Lox activity in malignant mesothelial cells was a crucial mechanism of 5-Lox actions on proliferation and apoptosis^[24]. Similarly, Ye *et al*^[34] in a mice inflammation-associated colon cancer formation model study, found that 5-Lox expression was accompanied by an up-regulation of matrix metalloproteinase (MMP)-2 activity and VEGF expression, both of which are key angiogenic factors for tumorigenesis^[34].

Regarding other Lox family enzymes, little is known about 12-Lox and, a great controversy exists in the literature as to the involvement of 15-Lox in human carcinogenesis. Ikawa *et al*^[5] reported that 15-Lox-1 was highly expressed in human colorectal tumor compared with adjacent normal mucosa^[5]. On the contrary, other investigators have extensively demonstrated not only a down-regulation, but also potential tumor-suppressor functions of 15-Lox-1/-2 in colorectal^[27,28] and prostate^[29] tumors.

Nevertheless, many questions still remain unanswered, including the exact contribution of individual enzymes as well as their interactions. Further studies are warranted. Finally, it is worthy to notice that several studies have consistently indicated that pharmacologic agents that specifically inhibit the Lox and/or Cox metabolic pathways, exhibit a dramatic anti-neoplastic activity in addition to their classic anti-inflammatory effect^[7,12-15,35]. And, despite the recent withdrawal of Vioxx (rofecoxib) from the

market and warning about other Cox-2 inhibitors over risk of cardiovascular side effects^[36], these pathways still remain an exciting and promising research area for cancer chemoprevention and treatment. Particularly the class of dual 5-Lox/Cox inhibitors such as licofelone (previously named ML3000) has emerged as an effective and well-tolerated therapy that could offer safety advantages over Cox inhibition alone^[4,37,38].

In conclusion, our data suggest that 5-Lox overexpression may influence the development of colorectal cancer. Therefore, inhibition of this metabolic pathway might provide an effective therapeutic option for colorectal cancer prevention and treatment.

Abstract

AIM: To examine the association of inducible nitric oxide synthase (iNOS) C150T polymorphism with gastric cancer, as well as with gastric atrophy and *H pylori* seropositivity.

METHODS: A single nucleotide polymorphism of iNOS C150T was examined for 454 Japanese health checkup examinees (126 males and 328 females) aged 35 to 85 years without a history of cancer and 202 gastric cancer patients (134 males and 68 females) aged 33 to 94 years with pathologically confirmed diagnosis of gastric adenocarcinoma.

RESULTS: The iNOS C150T polymorphism was not associated with gastric atrophy or with *H pylori* seropositivity. The odds ratio (OR) of the C/T + T/T for gastric cancer was increased without statistical significance (OR=1.19, 95% confidence interval (CI): 0.68-2.08). In the differentiated subgroup ($n = 113$), however, the OR of the C/T genotype for gastric cancer was significant (OR = 2.02, 95% CI: 1.04-3.92) relative to the C/C genotype. In addition, considering the location of gastric cancer ($n = 105$), there were significant differences between the controls and non-cardia group with the OR of 2.13 (95% CI: 1.08-4.18) for C/T and 1.94 (95% CI: 1.00-3.78) for C/T + T/T.

CONCLUSION: The iNOS C150T polymorphism is associated with the risk of *H pylori*-related gastric cancer

INTRODUCTION

Gastric cancer is the second most frequent cancer in the world, accounting for a large proportion of cancer cases in Asia, Latin America, and some countries in Europe^[1]. *H pylori* strains carrying the cytotoxin-associated gene A (*cagA*) are strongly associated with increased risk of gastric adenocarcinoma^[2]. However, only some of those infected with *H pylori* developed *H pylori*-related gastric cancer, even in Asian countries including Japan with high prevalence of *cagA*-positive *H pylori* infection. Therefore, it is important to examine any host genetic predisposition to *H pylori*-related gastric cancers.

Nitric oxide (NO) produced by activated phagocytes has been reported to play a role in the processing of carcinogenesis^[3-5]. NO is synthesized enzymatically from L-arginine by a family of three distinct nitric oxide synthase (NOS) isoforms^[5,6]. Two NOS isoforms, eNOS (expressed in vascular endothelial cells) and nNOS (expressed in neurons of the central and peripheral nervous system), are constitutively expressed and are calcium dependent. The third isoform, inducible NOS (iNOS), is calcium independent, and expressed in response to bacterial endotoxins and cytokines to cause sustained NO release. iNOS is one of the most important enzymes involved in the pathway of reactive oxygen and nitrogen species metabolism in the presence of *H pylori* infection. iNOS can produce larger amounts of NO than either eNOS or nNOS. iNOS expression in the gastric mucosa is higher in *H pylori* positive gastric cancer patients than in

H. pylori negative patients^[7].

Several types of polymorphisms have been identified in the promoter region of the iNOS gene: G to C at -954, C to T at -1173, and tandem repeat number polymorphism of (TAAA)_n and (CCTT)_n^[8-11]. iNOS production is mainly regulated at the transcriptional level^[12]. The human iNOS gene comprises 27 exons, with the transcription start site in exon 2 (E2) and the stop codon in E27^[13]. Johannesen *et al*^[14] have detected 10 polymorphisms in 8 exons of the iNOS gene, of which one polymorphism (C150T) in exon 16 resulting in an amino acid substitute, Ser608Leu, showed the only distorted transmission in the transmission disequilibrium test. This polymorphism is associated with cigarette- and alcohol- induced gastric cancer in Chinese population^[15], indicating that iNOS Ser608Leu allele may have a dramatic effect on the enzyme activity.

Accordingly, we have investigated the associations of iNOS C150T polymorphism with *H. pylori* seropositivity, gastric atrophy and gastric cancer in Japanese population.

MATERIALS AND METHODS

Study subjects

Detailed information of the characteristics of healthy controls and gastric cancer patients in this study has been published in our previous paper^[16]. Briefly, the control group included 454 health checkup examinees (126 males and 328 females) aged 35 to 85 years with no history of cancer who attended a health checkup program supported by the Nagoya Municipal Government in August and September, 2000. The case group consisted of 202 patients (134 males and 68 females) aged 33 to 94 years with a pathologically confirmed diagnosis of gastric adenocarcinoma undergone tumor resection in different hospitals affiliated to Nagoya University. Informed consent was obtained from all subjects. Approval for the study was given by the relevant ethical committees.

Tests for *H. pylori* antibody and pepsinogens

Anti-*H. pylori* IgG antibody tests, high molecular weight campylobacter-associated protein (HM-CAP) ELISA (Enteric Products Inc., Westbury, NY) and HM-CAP with antigens extracted from clinically isolated Japanese *H. pylori* strain (J-HM-CAP) ELISA (Kyowa Medex, Tokyo, Japan), were used for the identification of *H. pylori*-infected participants. An ELISA value of 2.3 or over was regarded as positive for both tests. The infection was confirmed in all gastric cancer cases by culture and bacteriological tests (Gram-negative, oxidase, catalase, and urease test-positive spiral, curved rods) using biopsy specimens before gastric resection. Pepsinogens I and II (PG I and PG II) in serum were measured by radioimmunoassay using a commercially available kit (DINABOT, Tokyo, Japan). Gastric atrophy was defined as PG I < 70 ng/mL and PG I/PG II ratio < 3. These parameters for atrophy are widely used in Japan and have been validated against histological confirmatory studies.

Genotyping

DNA was extracted from the buffy coat fraction by Qiagen QIAamp DNA blood mini kit (QIAGEN

Inc., Valencia, CA). We carried out PCR-RFLP to identify iNOS C150T gene genotype as previously described by Shen *et al*^[15]. However, the way to do PCR was somewhat different. Genomic DNA was used per 25 μ L of reaction with 0.12 mmol/L dNTPs, 25 pmol of each primer, 0.5 units of "AmpliTaq Gold", and 2.5 μ L GeneAmp 10 \times PCR buffer including 15 mmol/L MgCl₂ (Perkin-Elmer Corp., Foster City, CA). Amplification conditions were 10 min of initial denaturation at 95°C, followed by 30 cycles of 1 min at 95°C, 1 min at 58°C and 1 min at 72°C, then a final extension at 72°C for 5 min. The PCR product was digested with a restriction enzyme (*Tsp* 509 I) by the same way as previously described by Shen *et al*^[15].

Statistical analysis

The strength of associations of *H. pylori* seropositivity, gastric atrophy and gastric cancer with the iNOS C150T polymorphisms was measured as odds ratios (ORs). ORs adjusted for sex and age with 95% confidence intervals (CIs) were calculated using logistic regression analysis. Hardy-Weinberg equilibrium was tested for iNOS C150T polymorphism. We used two-sided *P* values. *P* < 0.05 was considered statistically significant. These calculations were performed by computer program STATA Version 8 (STATA Corp., College Station, TX).

RESULTS

The characteristics of study subjects have been described elsewhere^[16]. Only one case could not be genotyped. The distributions of the iNOS C150T gene was in the Hardy-Weinberg equilibrium ($\chi^2 = 1.37$ and *P* = 0.24). The iNOS C150T polymorphism had no significant effect on *H. pylori* seropositivity. Table 1 shows the sex-age-adjusted ORs and 95% CIs of the iNOS C150T genotypes for gastric atrophy among *H. pylori* seropositive controls. The iNOS C150T polymorphism was not associated with gastric

^aP < 0.05 vs control group. ¹Information on gastric cancer phenotype was not available for 16 cases; ²One case subject with undifferentiated type could not be genotyped.

atrophy. Table 2 shows the sex-age-adjusted ORs and 95% CIs of the *iNOS* genotypes for gastric cancer. The OR of the C/T+T/T genotype for gastric cancer was increased without significance.

In the same way as our previous report^[17], we divided case subjects into differentiated and undifferentiated type according to their tumor phenotypes, referring to Nakamura *et al.*^[18] (Table 3). We could not get information on the phenotypes for 16 cases. In the differentiated type subgroup, the OR of the C/T genotype for gastric cancer was significant (OR = 2.02, 95% CI: 1.04-3.92). Considering the location of gastric cancer, there were significant differences between the controls and non-cardia group with the OR of 2.13 (95% CI: 1.08-4.18) for C/T genotype and 1.94 (95% CI: 1.00-3.78) for C/T+T/T genotype. The prevalence of *H. pylori* seropositivity in the cases and healthy controls was 100% and 55.1%, respectively. All non-cardia subgroups with differentiated phenotype had gastric atrophy. On the other hand, atrophy was present in 34.8% of 454 controls, 21 of which were seronegative.

Especially compared with *H. pylori* seropositive controls or gastric atrophy positive controls, the corresponding ORs were 2.20 (95% CI: 1.08-4.49) for C/T genotype and 1.94 (95% CI: 0.97-3.89) for C/T+T/T genotype.

DISCUSSION

This study showed that the *iNOS* C150T polymorphism was associated with gastric cancer where the cell type was differentiated type and located in non-cardia, namely *H. pylori*-related gastric cancer. Our control *iNOS* gene frequency is coincident with the results presented by Shen *et al.*^[15], which represents the genotype frequency in China.

We could not evaluate the interaction between *iNOS* C150T polymorphism and smoking-induced risk of gastric cancer as the study of Shen *et al.*^[15], because we have no information on smoking habit in case group. *iNOS* is expressed in response to bacterial endotoxins and cytokines to cause sustained NO release. This excess NO would contribute to the development of gastric atrophy, reacting with superoxide produced by *H. pylori* infection^[19] to form

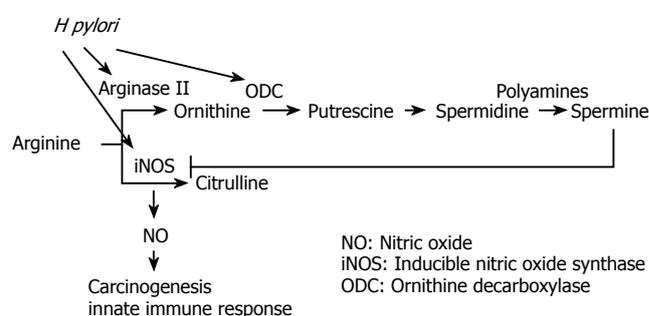

Figure 1 Regulation of Nitric oxide (NO) and polyamine pathways. *H. pylori* induces inducible nitric oxide synthase (*iNOS*) expression, arginase II and ornithine decarboxylase (ODC). *iNOS* competes with arginase for arginine. Gastric cancer relates to the high expression of *iNOS*. *H. pylori*-induced *iNOS* is inhibited by spermine produced by the arginase-ODC pathway.

peroxynitrite which has strong oxidizing properties. We chose the seropositive controls as the comparison group. The *iNOS* C150T polymorphism, however, was not associated with gastric atrophy as the precursor lesion of gastric cancer in this study.

It was reported that immune dysregulation induced by *H. pylori* in which stimulated spermine synthesis by the arginase-ornithine decarboxylase (ODC) pathway inhibits *iNOS* translation and NO production, can lead to persistence of the bacterium^[20] (Figure 1). We hypothesized that the *iNOS* C150T polymorphism might affect *H. pylori* infection. But, this gene polymorphism was not associated with *H. pylori* seropositivity in this study, confirming the finding that there is no correlation between *H. pylori* infection and *iNOS* expression^[21]. On the contrary, it has been reported that *iNOS* detection is significantly associated with *H. pylori* infection^[22,23].

There are many reports concerning the high expression of *iNOS* in gastric cancer, which increases with the stage of cancer and lymph node metastasis^[24-26]. It was reported that the long forms of *iNOS* promoter region are associated with intestinal gastric cancer in Japanese women^[27]. Nam *et al.*^[28] reported that *iNOS* contributes to *H. pylori*-associated gastric carcinogenesis, and that *H. pylori* is associated with non-cardiac tumor but not with cardiac tumor^[29]. The

high incidence of *H pylori* infection in patients with gastric cancer including both intestinal type and diffuse type, particularly in those with intestinal type has been confirmed^[30]. Our study has confirmed that iNOS C150T polymorphism is related to the risk of *H pylori*-related gastric cancer, by stratification of iNOS genotype frequency among cases according to the location of gastric cancer and histologic phenotype. It may take decades for superficial gastritis to progress to atrophic gastritis. *H pylori* infection is highly associated with each stage of this progression^[31]. Loss of serological markers of *H pylori* infection following onset of severe atrophy and intestinal metaplasia is a well described phenomenon, including in Japan^[32]. Considering these facts, the comparison with the controls with *H pylori* seropositivity and/or gastric atrophy might be adequate to evaluate the effect of the genotype on *H pylori*-related gastric cancer risk. In fact, the corresponding OR was significantly stable (OR = 2.20 for C/T, 95% CI: 1.08-4.49) in our study.

iNOS differs independently of Ca²⁺ from the constitutive forms of NOS (eNOS and nNOS). One major divergence in the close sequence similarity is a 40-50-amino acid insert in the middle of the FMN-binding domain of eNOS and nNOS. When this insert is removed from nNOS, the deleted mutant retains maximal NO synthesis activity at a lower concentration of free Ca²⁺ than the wild type enzyme^[33]. The iNOS C150T polymorphism is located at the position near to this deletion. The amino acid change in E16 may be of functional interest. As in the study of Shen *et al*^[15], our study indicated that those with T allele might increase iNOS expression and the level of NO in gastric mucosa. But specific functional tests of this polymorphism remain to be elucidated.

It is important to discuss our finding that iNOS C150T polymorphism is associated with *H pylori*-related gastric cancer but not with *H pylori* infection or with gastric atrophy (especially the association with the latter two is controversial). iNOS-derived NO is a central effector molecule in the innate immune response to pathogens, with essential antimicrobial functions in host defense. *H pylori* induces both arginase II and ODC in macrophages^[34] (Figure 1). Arginase converts L-arginine to L-ornithine, which is metabolized by ODC to produce putrescine that is converted to polyamines (spermidine and spermine). Spermine inhibits *H pylori*-stimulated NO production in macrophages by a post-transcriptional effect on iNOS translation^[20]. The temporal switch of arginine as a substrate for the cytostatic iNOS/NO axis to the pro-growth arginase/ornithine/polyamine and proline axis is regulated by inflammatory cytokines as well as interregulated by the arginine metabolites themselves. Satriano^[35] has proposed that agmatine, converted from arginine by arginine decarboxylase, coordinates the early and repair phase pathways of arginine in the inflammatory response as a gating mechanism at the transition from the iNOS/NO axis to the arginase/ODC/polyamine axis. Therefore the stage of *H pylori* infection and gastric atrophy might follow the arginase/ODC/polyamine axis. On the other hand, the stage of gastric cancer might follow the iNOS/NO axis. In addition, there is

no significant association between cagA positive *H pylori* strains and iNOS expression^[20]. CagA might affect the mechanisms that regulate this temporal switch, resulting in the arginase/ODC/polyamine axis.

In conclusion, iNOS C150T polymorphism is associated with the risk of *H pylori*-related gastric cancer in Japanese and Chinese population. This polymorphism may play an important role in increasing the risk of gastric cancer in Asian countries with the highest rates of gastric cancer. The confirmation of this finding requires much larger studies of different ethnic groups to stimulate the interest in the molecular mechanisms of this polymorphism function.

Abstract

AIM: To compare the efficacy and safety of five days apostrophe therapy of mebendazole (MBZ) versus quinacrine (QC) on human giardiasis in children.

METHODS: A clinical trial was carried out in paediatric patients (aged 5-15 years) with confirmed symptomatic *G. duodenalis* mono-infection. Patients were randomly assigned to receive either MBZ [200 mg taken three times per day (TID) ($n = 61$)] or QC [2 mg/kg bodyweight tid ($n = 61$)], both for five days. Follow-up faecal samples were obtained at 3, 5 and 7 d after the end of the treatment.

RESULTS: Although the frequency of cure was higher for QC (83.6%) than for MBZ (78.7%), the difference was not statistically significant ($P > 0.05$). Adverse events were reported more in the QC group ($P < 0.05$), all of them transient and self-limiting.

CONCLUSION: Despite final cure rates occurring lower than expected, the overall results of this study reconfirmed the efficacy of MBZ in giardiasis and also indicate that, although comparable to QC, at least in this setting the 5 d course of MBZ did not appear to improve the cure rates in this intestinal parasitic infection.

INTRODUCTION

Giardiasis is one of the commonest intestinal parasitic diseases diagnosed worldwide. Its clinical presentation is highly variable, most of the time it is characterized by mild and self-limiting signs and symptoms. However, it is not unusual that in some cases, this disease can become a significant cause of morbidity, resulting in malabsorption of fats, vitamins and lactose with serious consequences, particularly in children, causing failure-to-thrive syndrome^[1,2].

Classically, 5-nitroimidazole compounds have been accepted for decades the world over as the "gold standard" for treatment of patients with giardiasis. However, there is an increasing number of treatment failures reported in the literature, requiring repeated courses of the same drug, change to other compounds or make a combination of two anti-*Giardia* drugs for therapy^[3,4]. Consequently, newer and older drugs, such as nitazoxanide^[5,6] and chloroquine^[7] respectively, have been proposed as alternatives for the treatment of this intestinal infection.

In recent years, chemotherapy with mebendazole (MBZ), the benzimidazole-carbamate compound that has been extensively used in the treatment of helminthic infections, has also demonstrated *in vitro* activity against *Giardia duodenalis* (*G. duodenalis*)^[8-14], the causative agent of human giardiasis. Clinical experience has also shown therapeutic benefits for the use of MBZ in this infection^[15-17], although it is usually accepted, the optimal dosage and duration of the treatment remain to be determined. For this reason, in the present study it was decided to evaluate the efficacy and safety of a five-day regimen of MBZ versus quinacrine (QC) in the treatment of giardiasis in a group of Cuban paediatric patients.

MATERIALS AND METHODS

Patient selection

This study was carried out at the Gastroenterology in-

stitute in Havana, Cuba. In order to recruit a sufficient number of patients for this trial, all the specialists of the institution were invited to refer their paediatric patients (aged 5-15 years) who were received seeking treatment for symptomatic acute *G. duodenalis* infection with or without diarrhoea from May to December, 2003. To be eligible for the study a child had to have mono-infection with *G. duodenalis* (proven by microscopic examination of faecal samples, as wet mounts and/or after Ritchie concentration^[18]). Patients were excluded from the study if any of the following conditions were present: (1) known history of sensitivity to any of benzimidazole compounds or QC, (2) had received any antiparasitic chemotherapy in the preceding 4 wk, (3) diseases other than giardiasis. Also were excluded those who were unlikely to attend follow-up examinations.

The protocol was approved by the Research and Ethics committee of the institute. Parents or legal guardians of each child were fully informed about the aim of the study, the characteristics of the drugs under investigation and they were told that his/her child's participation was optional. Written informed consent was obtained from them prior to trial enrollment.

The sample size for each treatment group (n) needed to ensure sufficient statistical power (80%) to reject the null hypothesis that MBZ and QC are not equally effective (in terms of a parasitological cure) with a significant level of 5%, was calculated according to Armitage and Berry^[19]. The following equation was used:

$$n = \left(\frac{Z_{2\alpha} \sqrt{2p(1-p)} + Z_{2\beta} \sqrt{p(1-p_1) + p_2(1-p_2)}}{p_1 - p_2} \right)^2$$

where:

π_1 : denotes the proportion of population cured with standard treatment.

π_2 : denotes the proportion of population cured with the assayed treatment.

$$Z_{2\alpha} = 1.96$$

$$Z_{2\beta} = 0.842$$

One hundred and twenty two children were required (i.e. 61 in each treatment arm).

Experimental design

Patients who (a) were eligible, (b) met none of the exclusion criteria, and (c) one of their parents or legal guardians had given written informed consent for the trial, were included in the study. A random-number table was used to allocate each of these 122 children to receive either MBZ (Reynaldo Gutierrez Pharmaceutical, Havana) 200 mg thrice a day or QC (Reynaldo Gutierrez Pharmaceutical, Havana) at 2 mg/kg bodyweight thrice daily, both for 5 d. The drugs were provided at no charge.

A detailed history was taken from the accompanying parent or legal guardian; a standardized questionnaire was used to record clinical signs and symptoms before starting treatment and at the end. Also, a physical examination was carried out, and each child was weighed.

Comprehensive oral instructions were given to all children and parents or legal guardians accompanying them

Table 1 Demographic characteristics of the study patients randomized to MBZ and QC at admission

	MBZ group <i>n</i> = 61	QC group <i>n</i> = 61
Sex		
Male: <i>n</i> (%)	28 (45.9)	26 (42.6)
Female: <i>n</i> (%)	33 (54.1)	35 (57.3)
Age (yr)		
Mean (range)	8.2 (5-15)	9.7 (5-15)

in an attempt to maintain a high level of compliance with the study plan, including the administration of the drug and the importance of good hygiene and of measures they could take to reduce the risk of giardial infection in the future.

Follow-up

The evaluation of efficacy of the chemotherapy was based on parasitological response to therapy assessed by the same laboratory tests that were done initially. Parents or legal guardians of each child were asked to provide three faecal samples on d 3, 5, and 7 after treatment completion in order to avoid including the possibility of re-infection, considering it is a very frequent phenomenon in children, mainly in developing countries. Also, they were encouraged to return to the clinic at any time, if they considered that his or her child was ill. A child was only considered to be cured, if no *Giardia* trophozoites or cysts could be found in any of the three post-treatment faecal specimens.

Evaluation of adverse events

Irrespective of their causal relationship to study treatment, details of all clinical adverse events reported spontaneously at any time during the trial, regardless of their relationship to the study drugs and those elicited by the investigators with no leading questions in each of the clinic visits scheduled, were taken into account. Adverse event was defined as the development of any sign or symptoms that did not exist before or which became more serious following the commencement of the treatment. Serious adverse events were defined as death, any life-threatening, disabling or incapacitating events, or those requiring hospitalization.

Statistical analysis

The data on the parasitological response and adverse events were taken on pre-designed record forms and subsequently analysed to determine the frequency of each response/effect. The statistical significance of differences between mean values was determined using the Student's *t*-test. Where appropriate Fisher exact test (χ^2 test) was used to establish the significance of differences in proportions.

RESULTS

All 122 paediatric patients who began treatment completed this study and were included in the statistical analysis. Characteristics of the treatment groups at the entry with

Table 2 Cure rates and drug-related adverse events reported by treatment groups

	MBZ group <i>n</i> = 61	QC group <i>n</i> = 61
Cure rate	48 (78.7%)	51 (83.6%)
Any adverse event	14 (22.9%)	36 (59%)
Abdominal pain	11 (18 %)	10 (16.3%)
Vomiting	3 (4.9%)	14 (22.9%)
Nausea	3 (4.9%)	14 (22.9%)
Headache	1 (1.6%)	11 (18%)
Yellowish coloration of the skin	-	15 (24.6%)

regard to sex and age are presented (Table 1). There were no significant-between the groups- differences in demographics ($P > 0.05$).

The efficacy did not differ significantly between the two groups ($P > 0.05$), although it was slightly lower in the MBZ group [48 out of 61 (78.7%)] than that seen in the group treated with QC (83.6%) (Table 2).

Adverse events recorded with any treatment are also shown in Table 2. The therapy with the drugs was well tolerated and did not produce adverse events that warranted discontinuation of the study medication; in fact, no patients had to stop treatment because of potentially drug-related adverse events. Of the 122 patients studied, 72 (59%) had no adverse events, but 50 [14 in the MBZ group (22.9%) and 36 (59%) in the group treated with QC] reported at least one such event, none of them unexpected. Nausea, vomiting, headache and yellow discoloration were reported statistically significant by the QC group ($P < 0.05$). All adverse events were graded as mild, transient in nature, and did not require administration of drugs for relief or hospitalization. Except for yellow discoloration which lasted longer, the rest of the clinical adverse events usually resolved within 1-2 d and any of them were severe enough to interfere with activities of daily living.

DISCUSSION

Treatment failures with the currently available drugs used to treat giardiasis have provided a continuous stimulus to search for other therapeutic alternatives. MBZ has been one of the drugs proposed in the treatment of this infection due to the observations of Hutchison *et al*^[20] who during their investigation of the activity of this drug against intestinal nematodes realized that some cases of *Giardia* infection could also be cured. Lately, although *in vitro* studies not only confirmed the effect of MBZ on *Giardia* trophozoites, but have also served to clarify its activity against this protozoan, a number of clinical studies have been performed in adults and children comparing this drug with the currently available anti-giardial drugs. This could be, in part, because giardiasis as a new indication of MBZ is still a topic of discussion due to the contradictory clinical reports concerning its efficacy. Thus, while most of the published clinical data documented the effect of this drug in *Giardia* infections, in contrast there are some reports that show the failure of this drug to clear their

patients' symptoms or stop the patients from excreting *Giardia* cysts using MBZ for 1 and 5 d, respectively^[21,22]; and interestingly, Rousham^[23] noticed that during a deworming study in northern Bangladesh, the prevalence of *G. duodenalis* increased significantly among children receiving periodic treatment with MBZ; for this reason there is a continuous necessity to evaluate treatment dosage and regimens with this drug.

The present study again confirms previous findings that MBZ is an attractive and efficacious agent against *Giardia* infections because it can be easily administered and has not been associated with serious adverse events. In a previous trial of MBZ, Bulut *et al*^[24] used this drug at 100 mg thrice for 1 d and for 7 d and obtained responses of 41.7% and 58.3%, respectively. Other studies have reported higher parasitological response rates e.g., Rodriguez-Garcia *et al*^[5], found that treatment with administered 100 mg of MBZ every 12 h, for 3 d achieved a cure rate of 80.4% that was comparable to 100 mg of nitazoxanide administered in the same way. In a closely related trial, similar outcomes were obtained by Sadjjadi *et al*^[6], who used 200 mg of MBZ thrice daily for 5 d -which resulted in somewhat higher cure rates [43 out of 50 (86%)] than that seen in the present study- and found a frequency comparable to that obtained by using a 7-d course of metronidazole.

Based on the experience of Sadjjadi *et al*^[6] and on a previous study carried out in Cuba in paediatric patients for 3 d where the cure rates obtained were 78.1%^[17], we decided to treat patients in this current study with a 5-d course of MBZ at 200 mg thrice a day in order to see if the response rate could be improved after this prolonged course; however, no additional benefit in the efficacy rate could be demonstrated.

Contrary to what was expected, it was noted that QC resulted in considerably lower cure rates than that which have been previously reported by other authors. This drug was widely used for the chemosuppression of malaria and used to be the front line drug for the treatment of adult giardiasis, but it was superseded for these purposes by chloroquine and metronidazole, respectively. QC has been regarded the most efficacious drug of any of the anti-*Giardia* therapeutics by some researchers^[25] because its clinical efficacy in giardiasis has been found over 90%. This drug also has the benefits that even in patients with severe diarrhoea its intestinal absorption is not interfered^[26] with and it has the additional epidemiological advantage that it could also kill cysts^[27]. However, this drug has the potential of adverse events, including yellow discoloration of the skin, bitter taste, nausea and vomiting, and it has also been reported in toxic psychosis^[28]. For these reasons, at this moment this old drug might experience a revival in the clinical management of patients where other drugs have failed (to whom it has almost wholly been reserved). Nevertheless, clinical reports in which *Giardia* has not been eliminated despite one or more appropriate courses with QC have been published^[3,29]. Additionally, in one study resistance against QC could be induced in *Giardia* laboratory stocks^[30].

In the present study, no new or previously undescribed adverse events occurred. Both drugs were well tolerated,

resulting in good patient compliance. In no case, adverse events observed lead to discontinuation of the drugs. The adverse events observed were all mild, transient in nature and self-limiting; all generally occurred at similar frequencies to those observed in previous trials with the same drugs. In general, MBZ is very well tolerated which could be due, in part, to the advantage of being hardly absorbed from the gut (no more than 20% of the dose, even after a fat rich meal)^[31].

One possible weakness in the current study was that for practical reasons it was conducted in an open fashion. As the two drug treatments look very different and the number of tablets to take daily varied it was impossible to make the study blind. Certainly, in the market it would have had been possible to obtain placebos for the two drugs but this would have been costly for the study. This could be a limitation and consequently, despite well-defined pre-study criteria for evaluating efficacy and safety, evaluation of the treatment response and possible cause of adverse events could have been somewhat biased; but it could not have influenced the major result (eradication of *Giardia* infection) because the efficacy analysis was done by the laboratory department where those checking post-treatment faecal samples were unaware of the treatment allocation and had no clinical involvement with the paediatric patients or their parents.

For us, this study has the strength that in many countries MBZ is not considered even a major alternative treatment for giardiasis; therefore, it is useful information that there is a therapeutically effective high dose used daily at least three times the usual dose for helminthic infections caused by hookworms and six times that used for enterobiasis. Additionally, there have been several studies of MBZ for giardiasis, but it is the first to compare with QC which has permitted evaluation and update of the current efficacy of QC in Cuban children with giardiasis.

Where does the present data lead us with the use of MBZ in giardiasis? That is the question that could have been asked to answer given the current context. We shall approach the problem by offering a series of related conclusions: clearly, our study adds support to the observation that this drug has a place as an alternative treatment of giardiasis in children when (a) other first-line drugs have failed, (b) in areas where this infection and other sensitive organisms, e.g., intestinal nematodes, are prevalent, (c) in patients with a history of known sensitivity to any of the currently anti-giardial compounds, and (d) possibly, as adjunctive therapy in combination with other available anti-giardial drugs in order to offer potentially higher cure rates.

Taking into account that the ideal antiparasitic agents would be efficacious, easily dosed and administered, inexpensive, and with few adverse effects, in view of the above-given data for MBZ and QC, neither would be first line drugs, but this paper may help to inform about choices for those people where other currently recommended drugs have failed. MBZ belongs to a chemical family that differs from 5-nitroimidazoles, acts against *Giardia duodenalis* by a different mechanism, and has a different safety profile. In the present study it was at least as effective as, and better tolerated than QC. All of these advantages

should not be forgotten when we are treating giardiasis, but the benefits of extending treatment from three to five consecutive days were not apparent, at least in this setting.

Abstract

AIM: To assess the clinical features, yield of the diagnostic tests and outcome of abdominal tuberculosis in non-HIV patients.

METHODS: Adult patients with discharge diagnosis of abdominal tuberculosis (based upon; positive microbiology, histo-pathology, imaging or response to trial of anti TB drugs) during the period 1999 to 2004 were analyzed. Patient's characteristics, laboratory investigations, radiological, endoscopic and surgical findings were evaluated. Abdominal site involved (intestinal, peritoneal, visceral, and nodal) and response to treatment was also noted.

RESULTS: There were 209 patients enrolled. One hundred and twenty-three (59%) were females. Symptoms were abdominal pain 194 (93%), fever 134 (64%), night sweats 99 (48%), weight loss 98 (47%), vomiting 75 (36%), ascites 74 (35%), constipation 64 (31%), and diarrhea 25 (12%). Sub-acute and acute intestinal obstruction was seen in 28 (13%) and 12 (11%) respectively. Radiological evidence of pulmonary tuberculosis was found in 134 (64%) patients. Basis of diagnosis of abdominal tuberculosis were radiology (Chest and barium X-Rays, Ultrasound and CT scan abdomen) in 111 (53%) and histo-pathology (tissue obtained during surgery, colonoscopy, CT or ultrasound guided biopsy, laparoscopy and upper gastro intestinal endoscopy) in 87 (42%) patients. Mycobacterium culture was positive in 6/87 (7%) patients and response to therapeutic trial of anti tubercular drugs was the basis of diagnosis in 5 (2.3%) patients. Predominant site of involvement by abdominal TB was intestinal in 103 (49%) patients, peritoneal in 87 (42%) patients, solid viscera in 10 (5%) and nodal in 9 (4%) patients. Response to medical treatment was found in 158 (76%) patients and

additionally 35 (17%) patients also underwent surgery. In a 425 ± 120 d follow-up period 12 patients died (eight post operative) and no case of relapse was noted.

CONCLUSION: Abdominal TB has diverse and non-specific symptomatology. No single test is adequate for diagnosis of abdominal tuberculosis in all patients. Abdominal TB in non-HIV patients remains an ongoing diagnostic dilemma requiring a high index of clinical suspicion.

INTRODUCTION

In developing countries, tuberculosis is associated with poverty, deprivation, overcrowding, illiteracy, and limited access to health care facilities. While in developed worlds, tuberculosis is commonly accompanied with HIV infection, ageing population or due to trans-global migration^[1,2]. Approximately one eighth of total TB cases are extra pulmonary^[3,4], of these abdominal tuberculosis (ATB) accounts for 11%-16%^[5,6]. In HIV positive patients the incidence of extra pulmonary TB is up to 50%^[1,6].

TB involves the abdomen as the primary disease from the reactivation of a dormant focus acquired somewhere in the past or as a secondary disease when infections spread to the abdomen via swallowed sputum, hematogenous or spread from an infected neighboring organ or ingestion of unpasteurized milk^[2,5]. Abdominal TB may be, enteric (intestine involved itself), peritoneal, nodal (lymph nodes involvement) and solid visceral TB like liver, spleen, kidney and pancreas or in any combination of these four varieties. Intestinal lesions may be ulcerating, hyperplastic or combined^[7,8].

Diagnosis of abdominal tuberculosis is difficult because of (1) vague and non-specific clinical features or (2) low yield of mycobacterium culture or smear. Moreover,

costly and invasive procedures are required for obtaining tissue for histo-pahtological examination or culture and these are not easily available in developing countries^[6,9]. Investigations like Imaging (ultrasound, barium X-Rays, and CT scan) and Mantoux test have only supportive value. In some cases, response to therapeutic trials of anti-tuberculous drugs is the basis of diagnosis that may cause a delay in the diagnosis of other diseases which mimic abdominal tuberculosis e.g. Crohn's disease, abdominal lymphoma and malignancy of abdominal organs^[5]. Therefore, diagnosis of abdominal tuberculosis is an ongoing challenge to the physicians, especially with limited resources.

The aims of this study were to examine the clinical features and distribution of the disease, diagnostic yield of various tests and outcomes of abdominal tuberculosis in non-HIV patients.

MATERIALS AND METHODS

Patients above 15 years of age with a diagnosis of abdominal TB on discharge during the study period January 1999 to December 2004 were retrieved using the International classification of diseases 9th revision with clinical modification (ICD-9-CM- USA). Diagnosis of abdominal TB was based upon (1) a positive Acid Fast Bacilli (AFB) smear or culture, (2) histo-pathology showing tubercular granuloma (with or without caseation), (3) radiological features compatible with tuberculosis on barium x-rays of the abdomen, ultrasound or CT scan of the abdomen, and (4) patients with a high index of clinical suspicion and negative diagnostic workup but showed a good response to therapeutic trial of anti TB medicines^[10].

Patient's demographic, clinical features associated with medical illnesses, family and past history of TB were evaluated. Laboratory tests, mantoux skin test, chest and abdominal imaging results, histo-pathology findings, Acid Fast Bacilli (AFB) staining and culture reports, ascetic fluid analysis, HIV screening, findings of upper gastrointestinal endoscopy, colonoscopy, laparoscopy or laparotomy were noted. Response to anti-tubercular treatment surgical procedure performed, clinical course and complications were also evaluated.

Statistical analysis

The Statistical package for social science (SPSS 11.5) IL-Chicago- USA standard version was used for data analyses. Descriptive analysis was done for demographic, clinical and radiographic features and results are presented as mean \pm SD and percentages for continuous variable and number and percentage for categorical variable. All *P*-values were two sided and considered as statistically significant if *P* < 0.05.

RESULTS

Demographics and clinical characteristics

A total of 209 patients were analyzed and 123 (59%) were female. Mean age was 33 ± 15 years. The most frequent symptoms were abdominal pain (194, 93%), fever (134, 64%), night sweats (99, 48%), weight loss (98, 47%), vomiting (75, 36%), ascites (74, 35%), constipation

Table 1 Characteristics of non-HIV patients with abdominal tuberculosis (*n* = 209) mean age 33 ± 15 years

Patients characteristic	<i>n</i>	%
Male	86	41
Female	123	59
Past History of TB	13	6
Family History of TB	6	3
Associated Pulmonary TB	10	5
Abdominal pain	194	93
Fever	134	64
Night sweats	99	48
Weight loss	98	47
Vomiting	75	36
Ascites	74	35
Constipation	64	31
Diarrhea	25	12
Sub acute intestinal Obstruction	28	13
Acute intestinal Obstruction	22	11

Results are presented as number (percentage).

Table 2 Diagnostic yield of various investigations in patients with abdominal tuberculosis

Investigation	<i>n</i> (Patients in which investigations performed)	Yield of diagnostic test <i>n</i> /%
Barium meal and follow through	70	58/83
Barium enema	34	15/44
Ultra sound	93	82/88
CT Scan Abdomen	35	28/80
Histopathology of surgical specimen	35	35/100
Histopathology of Colonoscopic biopsy	35	29/83
Histopathology of ultrasound and CT guided biopsy	28	14/50
Histopathology of Laparoscopic biopsy	5	5/100
Histopathology of upper GI endoscopic biopsy	10	4/40
AFB culture	87	6/7

Results are presented as number (percentage).

(64, 31%), and diarrhea (25, 12%). Sub acute and acute intestinal obstruction was present in 28 patients (13%) and 22 (11%) patients, respectively (Table 1). Average duration of symptoms before first presentation was 265 ± 150 d. Past history of treatment for tuberculosis was present in 13 (6.2%) patients and a family history of tuberculosis was found in 6 patients (2.9%). Important systemic diseases associated with abdominal TB were diabetes mellitus in 22 (10.5%) patients and cirrhosis of liver 15 (7.7%).

Basis of diagnosis and yield of various investigations in abdominal tuberculosis

Radiology: Out of 209 patients, 130 were subjected to abdominal radiological investigations and presumptive diagnosis of abdominal tuberculosis was made in 110 patients (53%) (Table 2) that included barium meal and follow through in 58/70 (83%), barium enema in

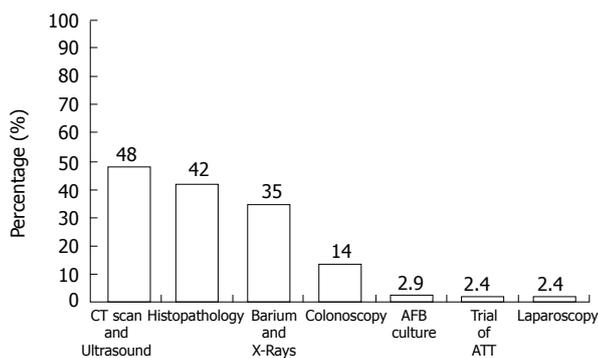

Figure 1 Basis of diagnosis in abdominal tuberculosis (n = 209).

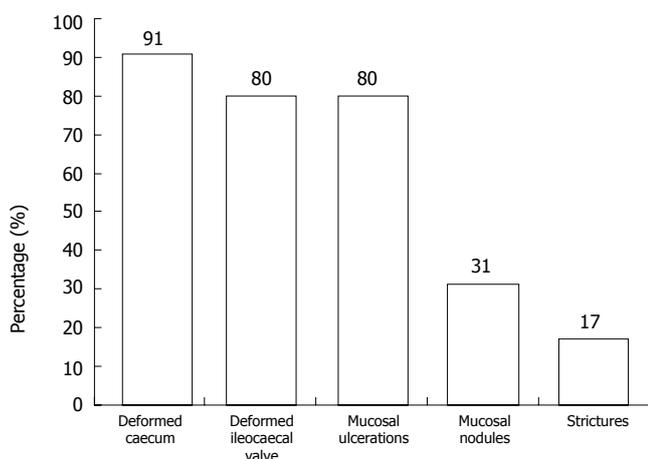

Figure 2 Colonoscopic findings in abdominal TB (n = 35).

15/34 (44%), ultrasound in 72/93 (77%) and CT scan abdomen in 28/35 (80%). Common features suggestive of abdominal tuberculosis on barium X-Rays were luminal narrowing with proximal dilation of bowel loops in 52/58 (90%) patients. Whereas on abdominal ultrasound and CT scan, findings suggestive of abdominal tuberculosis were; ascites 87/110 (79%), enlarged lymph nodes in 39/110 (35%), omental thickening 32/110 (29%) and bowel wall thickness in 28/110 (25%) patients. Features suggestive of pulmonary tuberculosis on x-rays chest were found in 134 (64%) patients and 10 (4.8%) patients had radiological features of active pulmonary TB (Figure1).

Histopathology: Histopathology was the basis of diagnosis in 87/113 patients. Diagnostic yield of histopathology on biopsy in abdominal TB was variable depending upon the method used to take the biopsy. Diagnostic yield of tuberculosis on surgical specimen were found in 35/35 (100%) patients. Biopsies obtained by colonoscopy had a yield of 29/35 (83%) and Ultrasound or CT guided biopsy of the viscera, omentum or LN suggestive of tuberculosis in 14/28 (50%) of patients. Diagnostic laparoscopic peritoneal biopsy was positive for abdominal tuberculosis in all (100%) patients. On the other hand biopsies taken during upper GI endoscopy favored diagnosis in 4/10 (40%) patients.

Common histological features on biopsy specimen was the presence of non caseating granuloma in 59/87

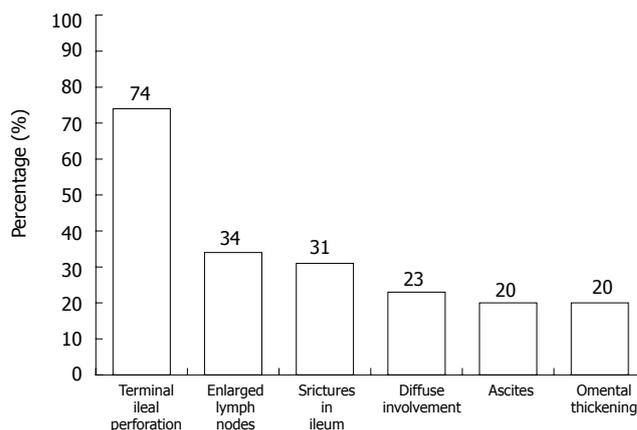

Figure 3 Laparotomy findings in abdominal TB (n = 35).

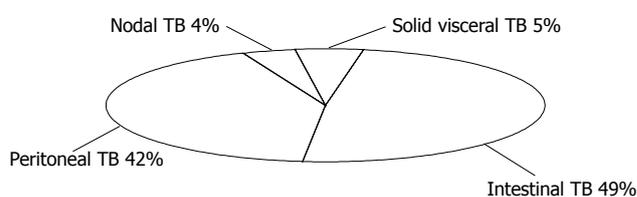

Figure 4 Predominant sites of involvement in abdominal TB (n = 209).

(68%) patients; however a central caseation was noted only in 22/87 (25%) cases and in 6/87 (7%) patients, chronic inflammatory cells infiltration but no definite granuloma was seen.

Samples (ascetic fluid, omental or intestinal biopsy tissues) were sent for acid-fast bacilli culture. The positive yield for acid-fast culture was only in 6/87 (7%) patients, all were on ascetic fluid.

In five (2.3%) patients with suggestive clinical history and negative diagnostic workup, response to therapeutic trial of anti TB drugs was the basis of diagnosis.

Colonoscopy and laparotomy findings in intestinal TB

Colonoscopic findings in 35 patients revealed deformed caecum in 32 (91%), irregular ileocaecal valve in 28 (80%), colonic mucosal ulcerations in 28 (80%), mucosal nodules in 11 (31%), and colonic strictures in 6 (17%) patients (Figure 2).

Laparotomy was performed in 35/209 (17%) of patients and notable findings were terminal ileal perforation in 26 patients, enlarged lymph nodes in 12, strictures in ileum in 11, diffuse involvement of the visceral and parietal peritoneum in 8, ascites in 7 and omental thickening in 7 patients (Figure 3).

Types of abdominal tuberculosis

Based upon predominant clinical features and investigations, site of abdominal TB involvement was intestinal in 103 (49%), peritoneal in 87 (42%), solid viscera in 10 (5%) and nodal in 9 (4%) patients (Figure 4).

Treatment and outcome

Antituberculous treatment was given to all patients.

158/209 (76%) patients responded to medical treatment alone and 35 (17%) patients with complications at admission required additional surgical intervention. Antituberculous treatment was comprised of isoniazid, rifampicin, ethambutol or streptomycin and pyrazinamide in various combination for a period of 9 to 12 mo. A follow-up of 425 ± 120 d was available in 197 (94%) patients. No patient showed a relapse of disease during this follow-up period. However three patients developed drug induced hepatitis. Two of them recovered with modification of drug therapy and one 42 year old female patient developed hepatic encephalopathy and died. In total 12 (6%) patients died due to various complications; eight of them were those who underwent surgery for the complications of abdominal tuberculosis.

DISCUSSION

Current series of abdominal tuberculosis patients without HIV have highlighted several important considerations. Female predominance was shown as one characteristic feature of abdominal tuberculosis in several studies in the past and also evident in our current series with females contributing to 59% of all patients. Possible reasons for female predominance apart from malnutrition, illiteracy, and poor access to health care facility may be contiguous spread from tuberculous salpingitis^[6,11,12]. In contrast, a study from India showed 69.4% patients with ATB were male^[3,13].

The most frequent symptom at presentation was abdominal pain, which was present in 93% of patients in our study. Mid abdominal colicky pain represented intermittent small bowel obstruction and was seen in 90%-100% of patients in other studies as well^[14]. This highlight the non-specific nature of abdominal pain and common feature that is present in abdominal malignancy and Crohn's disease^[6,12].

Radiological investigation is the mainstay in making presumptive diagnosis of abdominal TB^[12,15], this include chest x-rays, ultrasound or CT scan abdomen and barium studies. In this review, half of the patients (53%) had suggestive radiological findings on barium study, CT scan and or ultrasound abdomen. In another review, barium study was supportive of diagnosis of ATB in 60% of patients^[1]. However CT scan of the abdomen, which is a costly investigation, gives a better view of intestinal and extra intestinal structures^[16]. In our series 28 (13.4%) patients had CT scan of the abdomen with supportive features. Another interesting feature in the present series is the evidence of concomitant pulmonary tuberculosis on chest x-rays in 134 (64%) patients out of these 10 (4.8%) patients had features suggestive of active pulmonary TB. In the literature, associated active pulmonary TB is highly variable and is reported up to 29%^[3,17]. Diagnosis made on the basis of radiology is rapid, easy and less expensive but it is presumptive and cannot exclude completely other diseases like Crohn's disease and malignancies of solid abdominal viscera^[18].

Colon and terminal ileum are the most common site of involvement in intestinal variety of tuberculosis and in this regard colonoscopic images and biopsies are considered

to be a quick and good diagnostic tool. In the present series, colonoscopy was helpful in making diagnosis in 35 patients, out of them in 29/35 patients, colonoscopic biopsies were positive for presence of granuloma. Colonoscopy also helps in differentiating the colonic tuberculosis from Crohn's disease^[19]. In patients with intestinal TB on colonoscopy, ulcers, strictures, nodules, pseudo polyps, fibrous bands, fistulas, and deformed ileocaecal valve are seen. Mucosal ulcers in intestinal TB tend to be circumferential and are usually surrounded by inflamed mucosa. The ileocaecal valve is either patulous or destroyed in ATB and in few cases it is like fish mouth opening. On the other hand colonoscopic features that favor Crohn's disease such as aphthous ulcers with normal surrounding mucosa skipped lesions or the presence of cobble stoning^[19].

Laparoscopy and biopsy is safe and may help in diagnosing peritoneal TB because of increased peritoneal involvement. In different studies, laparoscopy was found helpful in the diagnosis up to 87%-92% of peritoneal tuberculosis^[20,21]. Peritoneal biopsy *via* mini-laparotomy should be considered if laparoscopy is non-diagnostic^[21,22].

Demonstrating tuberculous granuloma is probably the most important investigation for a definitive diagnosis of ATB. In our series of patients, histo-pathology was the basis of diagnosis in 87/209 patients; however a typical granuloma with caseation was found only in 22/87 of patients in our series. Moreover in our patients the yield of demonstrating tuberculous granuloma was high when the specimen was taken surgically or through laparoscopy but it is invasive, expensive and not easily available. On colonoscopic biopsies, if granuloma is non-caseating, interpretation is difficult because Crohn's disease cannot be excluded^[16].

Many authors advocated therapeutic trial with anti tubercular therapy but it should not be encouraged routinely as it may delay the diagnosis of malignancy, lymphoma and Crohn's disease^[1,23]. In the present series, 5 (2%) patients with suggestive history but negative workup, therapeutic trial of anti TB drugs therapy (ATT) was the basis of diagnosis. In the literature up to 40% patients were given therapeutic trial of anti TB drugs^[1].

Types of Abdominal TB

Intestinal TB was the predominant form in this cohort of patients and accounted for 103 (49%) of patients. The majority of patients in this review have ileocaecal involvement. This is in agreement with other reviews on abdominal tuberculosis in which intestinal type of abdominal tuberculosis was ranged from 50%-78%^[14]. In one study, jejunocolic and ileocaecal involvement was more than 75% of all gastrointestinal TB^[2]. Relatively common involvement of terminal ileum in intestinal tuberculosis is due to either physiological stasis, large surface area of this part of the intestine, complete digestion of food and abundant lymph nodes in the region^[9].

The other, commoner type of abdominal tuberculosis in our patients was peritoneal TB, seen in 87 (42%) patients. In the literature, peritoneal TB involvement is around 43%^[9]. Typically exudative fluid with predominant

lymphocytes is seen in ascetic fluid but efforts should be made to establish tissue diagnosis by peritoneal biopsy^[21].

Prognosis and outcome

Response to anti tubercular drugs is generally very good. In our series 158 (76%) patients responded to medical treatment alone and 35 (17%) patients who presented with complications at the time of admission required additional surgery. Other studies have also shown the similar frequency of surgical intervention in patients with abdominal tuberculosis that is around 20%-40%^[24].

None of our patients showed signs of relapse after 14 mo follow-up. Twelve patients in this series died; eight of them post operatively. A possible reason for increased mortality in operated patients may be due to late presentation and previous complications like malnutrition, perforation and sepsis.

Mortality due to abdominal tuberculosis ranged from 8 to 50 percent in various series. Advanced age, delay in initiating therapy, and underlying cirrhosis have been associated with higher mortality rates^[13,22].

Limitations of the study

One of the limitations in this study is the retrospective nature of the data set but it doesn't interfere with the objective of the study. Secondly, all tests were not done in every patient because each test is not indicated in every case. The other limitation was the inability to confirm diagnosis of abdominal tuberculosis either by culture of Acid Fast Bacilli or by PCR in all cases. Yield of AFB culture on biopsy specimen and ascetic fluid is low^[1]. Polymerase Chain Reaction is not yet standardized in diagnosis of tuberculosis^[25].

In conclusion, abdominal TB is a complex disease and has diverse symptomatology that is non-specific. Tissue diagnosis is mandatory for appropriate management but it is invasive, expensive and unfortunately not always conclusive either. A high index of clinical suspicion is required along with the help of multiple adjuvant diagnostic tools for diagnosis of ATB. Until the time when we have a specific test for diagnosis of abdominal tuberculosis, this remains a challenge for physician.

Abstract

AIM: To investigate whether extracellular signal-regulated kinase 1 (ERK₁) is activated and associated with hepatic stellate cell (HSC) proliferation in fibrotic rat liver tissue.

METHODS: Rat hepatic fibrosis was induced by bile duct ligation (BDL). Histopathological changes were evaluated by hematoxylin and eosin staining, and Masson's trichrome method. ERK₁ mRNA in rat liver tissue was determined by reverse transcription-polymerase chain reaction, while the distribution of ERK₁ was assessed by immunohistochemistry. ERK₁ protein was detected by Western blotting analysis. The number of activated HSCs was quantified after alpha smooth muscle actin (α -SMA) staining.

RESULTS: With the development of hepatic fibrosis, the positive staining cells of α -SMA increased obviously, and mainly resided in the portal ducts. Fiber septa and perisinuses were accompanied with proliferating bile ducts. The positive staining areas of the rat livers in model groups 1-4 wk after ligation of common bile duct (12.88% \pm 2.63%, 22.65% \pm 2.16%, 27.45% \pm 1.86%, 35.25% \pm 2.34%, respectively) were significantly larger than those in the control group (5.88% \pm 1.46%, $P < 0.01$). With the development of hepatic fibrosis, the positive cells of ERK₁ increased a lot, and were mainly distributed in portal ducts, fiber septa around the bile ducts, vascular endothelial cells and perisinusoidal cells. Western blotting analysis displayed that the expression of ERK₁ and ERK₂ protein was up-regulated during the model course, and its level was the highest 4 wk after operation, being 3.9-fold and 7.2-fold higher in fibrotic rat liver than in controls. ERK₁ mRNA was expressed in normal rat livers as well, which was up-regulated two days after BDL and reached the highest 4 wk after BDL. The expression of ERK₁ was positively correlated with α -SMA

expression ($r = 0.958$, $P < 0.05$).

CONCLUSION: The expression of ERK₁ protein and mRNA is greatly increased in fibrotic rat liver tissues, which may play a key role in HSC proliferation and hepatic fibrogenesis.

INTRODUCTION

Mitogen-activated protein kinase (MAPK) pathway is an important intracellular signal transduction system^[1], and extracellular signal-regulated kinase 1 (ERK₁) is the critical and classical pathway of MAPK and plays an important role in several physiological phenomena, including cell local adhesion, migration, proliferation, differentiation, apoptosis and cell cycle^[2]. Hepatic stellate cells (HSCs) play a pivotal role in hepatic fibrogenesis^[3-6]. In normal liver, HSCs are perisinusoidal mesenchymal elements characterized by intracytoplasmic lipid droplets rich in retinyl esters. On the contrary, in chronic liver injury, HSCs undergo a response known as "activation", which is the transition of quiescent cells into proliferative, fibrogenic and contractile myofibroblasts^[7-9].

Up till now, many studies have focused on the role of MAPK in various cultured cells^[10,11], little is known about its regulation *in vivo*^[12]. No report on dynamic expression of ERK₁ mRNA in fibrotic liver tissue is available. To probe into the molecule mechanism of fibrogenesis by ERK₁, the changes in distribution and contents of ERK₁ protein and mRNA in rat hepatic fibrogenesis were observed by immunohistochemistry, Western blotting and reverse transcription-polymerase chain reaction (RT-PCR). The dynamic expression of α -smooth muscle (α -SMA) as a marker of activated HSCs was also examined by immunohistochemistry in this study.

MATERIALS AND METHODS

Reagents

The monoclonal antibodies against ERK₁ and α -SMA were products of Santa Cruz Biotech Inc. Streptavidin-peroxidase immunohistochemical kit was purchased from Zhongshan Biological Technology Co (Beijing). Trizol reagent was obtained from Life Technologies Inc (USA). One tube RT-PCR kit was from Promega Co (USA). Primers for rat ERK₁ and β -actin were designed by ourselves in accordance with gene sequence in Genbank, synthesized and purified by Bao Biological Engineering Co (Dalian). All other reagents were analytically pure.

Animal model and experimental protocol

A total of 80 adult male Sprague-Dawley rats weighing 350-400 g were purchased from the Experimental Animal Center of Hebei Medical University (Clearing Grade, Certificate No. 04057). All rats were housed in plastic cages with free access to food and water. The rats were randomly divided into 8 groups (10 rats in each group). The rats were subjected to laparotomy with complete ligation of the common bile duct and received ketamine hydrochloride at a dose of 100 mg/kg by intraperitoneal injection^[13]. Under deep anaesthesia, the peritoneal cavity was opened and the common bile duct was double-ligated with 3-0 silk and cut between the ligatures. Control animals underwent a sham operation that consisted of exposure but not ligation of the common bile duct. At various intervals post-operatively, the animals were anaesthetised and the livers were harvested. Liver tissue specimens were routinely fixed in 10% phosphate-buffered formaldehyde and embedded in paraffin. Some liver tissue specimens were used for light microscopy and immunohistochemistry by using anti- α -SMA and ERK₁, while others were snap-frozen in liquid nitrogen and stored at -80°C for RNA analysis. In addition, control livers were harvested 4 wk after sham operation.

Histopathology

Liver specimens were routinely fixed overnight in 10% phosphate-buffered formaldehyde, embedded in paraffin for light microscopic examination. Tissue sections (5- μ m thick) were stained with haematoxylin and eosin (H&E) for morphological evaluation and Masson's trichrome for assessment of fibrosis.

Immunohistochemical detection of α -SMA and ERK₁

All immunohistochemical studies using the streptavidin-peroxidase technique were performed on 5- μ m thick paraformaldehyde-fixed and paraffin-embedded liver tissue sections mounted on APES-coated slides. Slides were deparaffined in xylene and rehydrated in graded ethanol. Endogenous peroxidase activity was quenched with a 3% hydrogen peroxide solution in methanol at room temperature for 30 min, followed by rinsing in pH 6.0 phosphate-buffered saline (PBS). After antigen retrieval in a water bath set in a 10 mmol/L citrate buffer (pH 6.0) at 94°C for 8 and 10 min, respectively, the slides were immediately cooled for 20 min at room temperature. Non-specific binding sites were blocked by incubation with wash buffer containing 10% normal goat serum at 37°C for 30 min.

The sections were then incubated overnight at 4°C with a mouse monoclonal antibody directed against α -SMA or a rabbit monoclonal antibody directed against ERK₁ at a dilution of 1:100. The secondary antibody bindings were localized using a biotin-conjugated rabbit anti-mouse IgG for α -SMA and goat anti-rabbit IgG for ERK₁ (1:100 dilution), followed by incubation with streptavidin-peroxidase complex (1:200 dilution). Peroxidase conjugates were subsequently visualised by utilizing diaminobenzidine (DAB) solution in hydrogen peroxide as a chromogen yielding a brown reaction product. The sections were then counterstained with Mayer's hematoxylin and mounted on a cover slip. All incubations were performed in a moist chamber. Furthermore, between each incubation step, the slides were washed 3 times with PBS for 5 min. To ensure the specificity of antibody, negative control samples were processed in parallel under the same conditions but with omission of the first antibody, which was replaced by an equal volume of PBS. The α -SMA and ERK₁ positive parenchymas were measured by a video-image analysis system and expressed as a percentage of area occupied by the signal.

Preparation of cell lysates and Western blotting analysis

Liver tissues from control and bile duct ligation (BDL) animals were quickly removed and washed twice with ice-cold PBS, and then homogenized in modified radioimmunoprecipitation assay (RIPA) buffer (50 mmol/L Tris-HCl, pH 7.5; 150 mmol/L NaCl; 1% Nonident P-40; 0.5% sodium deoxycholate; 0.1% sodium dodecyl sulfate; 1 mmol/L EDTA; 1 mmol/L PMSF; 2 μ g/mL 1 \times leupeptin) for 30 min at 4°C, followed by rotating the tubes at 12000 \times g at 4°C for 10 min. After centrifugation, cleared tissue lysates were collected and stored at -80°C and protein concentration of each sample was determined by Coomassie brilliant blue protein assay. Each sample was adjusted up to a desired protein content of 150 μ g, an equal volume of 5 \times SDS loading buffer was added and the sample was incubated at 100°C for 3 min. Lysate containing 150 μ g of protein was separated by electrophoresis on 10% acrylamide sodium dodecyl sulfate (SDS) gels and transferred onto nitrocellulose membranes. After blocked in a buffer (pH 7.2) containing 1% bovine serum albumin and 5% skim milk powder, the membranes were incubated with rabbit anti-ERK₁ antibodies diluted at 1:600 overnight at 4°C, then incubated for 2 h at 37°C with horseradish peroxidase-conjugated goat anti-rabbit secondary antibody diluted 1:5000 in a blocking buffer. After washed 3 times with PBS containing 0.1% Tween 20, immunoreactive proteins were visualized with an enhanced chemiluminescence detection system on radiograph film. The intensity of the bands was determined by scanning video densitometry. Experiments were performed at least 3 times with similar results.

RNA extraction and RT-PCR assay

Expression of ERK₁ mRNA was evaluated by RT-PCR. Total RNA from liver specimens (100 mg) was isolated using a monophasic solution of phenol and guanidine thiocyanate (Trizol), precipitated in ethanol and resuspended in sterile RNAase-free water for storage at -80°C until use, as recommended by the suppliers. Total

RNA was quantified spectrometrically at 260 nm, and the quality of isolated RNA was analysed on agarose gels under standard conditions. One-step RT-PCR was performed according to the manufacturer's instructions. Two-microgram RNA was added to each reaction and RT-PCR was routinely performed utilizing 5 units of AMV reverse transcriptase, 5 units of *T7* DNA polymerase, 10 pmol of each oligonucleotide primer, 10 pmol of dNTP mix and 25 mmol/L MgSO₄ in a final reaction volume of 50 μ L. Primer sequences were as follows: ERK₁: forward 5'-GCT GAC CCT GAG CAC GAC CA -3' and reverse 5'-CTG GTT CAT CTG TCG GAT CA -3', fragment length 451 bp; β -actin: forward 5'-AGC TGA GAG GGA AAT CGT GCG -3' and reverse 5'-GTG CCA CCA GAC AGC ACT GTG -3', fragment length 300 bp. RT-PCR was performed in the following steps: reverse transcription at 41°C for 45 min, pre-denaturation at 94°C for 2 min. Then amplification was performed in a thermal controller for 35 cycles (denaturation at 94°C for 40 s, annealing at 52°C for 1 min, extension at 72°C for 1.5 min, and a final extension at 72°C for 10 min). Ten μ L of the PCR products was analyzed by 1.5% agarose gel electrophoresis with TAE buffer at 80 V for 40 min, visualized with ethidium bromide staining and photographed under UV illumination. The band intensities were quantified by densitometry. ERK₁/ β -actin quotient was the indication of ERK₁. Experiments were performed at least 3 times with similar results.

Statistical analysis

The data were expressed as mean \pm SD. Group means were compared by using analysis of variance followed by the Student-Newman-Keuls test if the former was significant. The correlation between the expressions of ERK₁ and α -SMA was analyzed for statistical significance by the simple linear regression analysis. $P < 0.05$ was considered statistically significant.

RESULTS

Histology of progressive fibrotic liver injury

In the present study, spotted (or scattered) perivenular degeneration of hepatocytes, increased inflammatory infiltrate in the necrotic areas and bile ductular proliferation in the portal triads were observed after 1 wk of BDL. After 2 wk of BDL, all rats showed expanded portal tracts with fibrous tissue, portal-to-portal fibrous bridging, nodular transformation and widespread proliferating bile ductules which extended into the parenchyma in places, without clear-cut cirrhosis. After 3-4 wk of BDL, the animals developed severe fibrosis associated with proliferating bile ducts which formed a continuous meshwork of connective tissue with complete distortion of lobular architecture, whereas there was no histological abnormality or evidence of stainable collagen in any of the sham-operated control livers.

Identification of proliferating and activated HSCs

Immunostaining for α -SMA was used to detect and quantify the number of activated HSCs in this study. The α -SMA positive cells in the sham-operated control

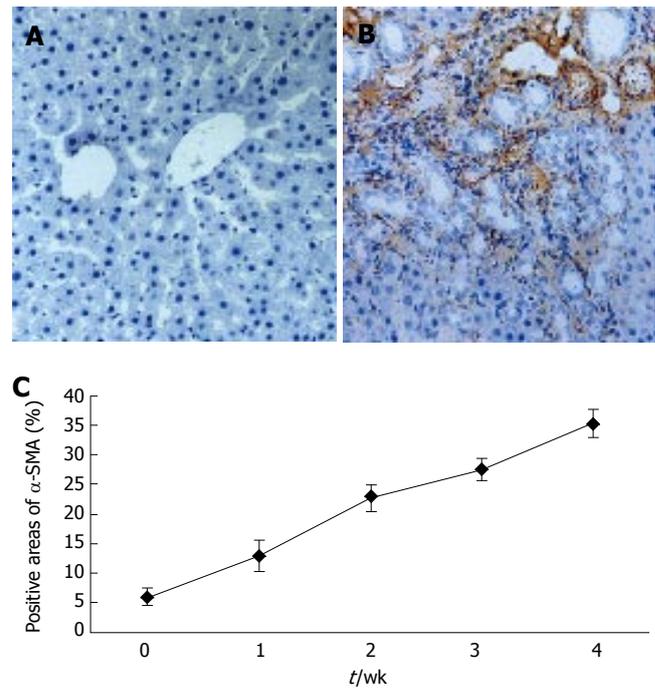

Figure 1 α -SMA protein expression in immunohistochemically-stained liver tissue (SP \times 200). **A:** Few α -SMA expressions in sham operation group; **B:** Positive α -SMA cells residing in the cells of portal ducts, fiber septa, perisinuses and around the proliferated bile ducts 2 wk after BDL; **C:** Positive areas of α -SMA expression in model groups at wk 1 to 4 after common bile duct ligation.

livers were observed in vascular smooth muscle cells and sinusoids with a weak staining. With the development of hepatic fibrosis, the number of positive α -SMA cells was greatly elevated and mainly resided in the cells of portal ducts, fiber septa, and perisinuses accompanied with proliferating bile ducts. The positive areas of the rat livers were larger in model groups at 1 to 4 wk (12.88% \pm 2.63%, 22.65% \pm 2.16%, 27.45% \pm 1.86%, 35.25% \pm 2.34%) than in control group (5.88% \pm 1.46%) ($P < 0.01$, Figure 1A-1C).

Distribution of ERK₁ protein in bile duct-ligated rat liver tissues

To explore the distribution of ERK₁, the normal and fibrotic rat liver tissue sections were immunostained using specific monoclonal anti-ERK₁ antibody. ERK₁ was found in vascular endothelial and perisinusoidal cells of normal rat liver tissue sections. With the development of hepatic fibrosis, the positive ERK₁ cells increased a lot and were mainly distributed in portal ducts, fiber septa, around the bile ducts, as well as in vascular endothelial and perisinusoidal cells and hepatocytes. ERK₁ protein was expressed not only in cytoplasm mentioned above, but also in nuclear membrane, indicating its activation. The positive areas of rat livers in model groups at 1 to 4 wk (9.58% \pm 1.01%, 17.43% \pm 1.78%, 23.88% \pm 2.97%, 28.63% \pm 2.72%) were larger than those in control group (5.03% \pm 1.10%) ($P < 0.01$, Figure 2A-2C).

Expression of ERK₁ protein in common bile duct-ligated rat livers

Western blot analysis showed that ERK₁ was expressed in normal rats with a prolonged model-making period.

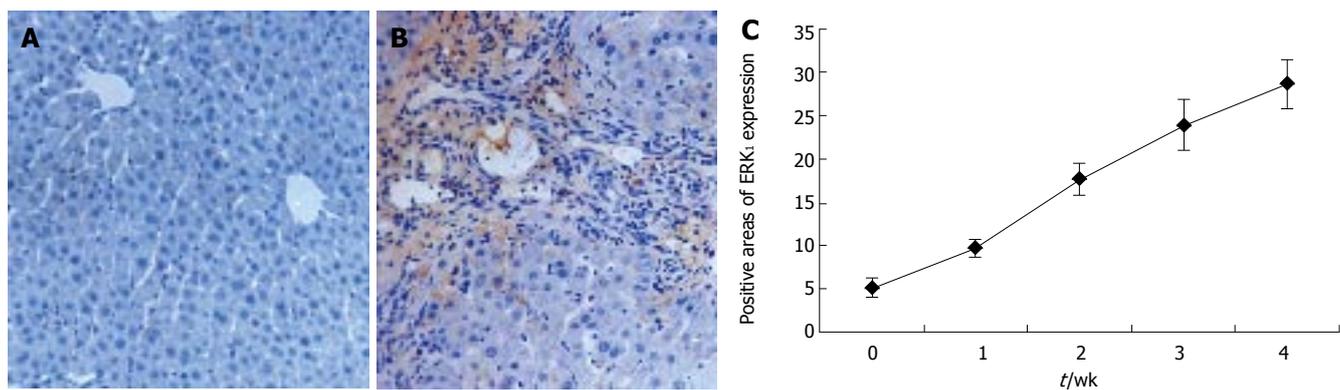

Figure 2 ERK₁ distribution in immunohistochemically-stained liver tissue (SP × 200). **A**: ERK₁ distribution in sham operation group; **B**: ERK₁ distribution 2 wk after BDL; **C**: The time course of ERK₁ distribution in hepatic fibrogenesis.

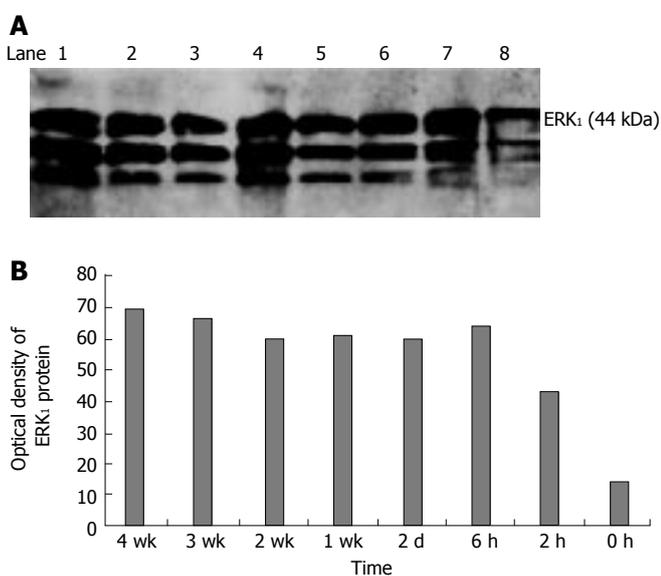

Figure 3 Time course of ERK₁ protein expression (**A**) and quantitative results (**B**) in fibrotic and normal rat liver tissues by Western blotting analysis. 1: 4 wk after BDL; 2: 3 wk after BDL; 3: 2 wk after BDL; 4: 1 wk after BDL; 5: 2 d after BDL; 6: 6 h after BDL; 7: 2 h after BDL; 8: Sham operation group.

The expression of ERK₁ increased 3.07-, 4.51-, 4.36-, 4.36-, 4.36- and 4.71-fold at 2, 6 h; 2 d; 1, 2 and 3 wk; respectively, and reached the peak at 4 wk, which was 4.93 times of the expression in sham-operated group ($P < 0.01$, Figure 3A and 3B).

Increased ERK₁ mRNA expression in bile duct-ligated rat livers

Although ERK₁ protein is produced by liver tissue *in vivo*, it is not clear whether the ERK₁ mRNA level under fibrogenic response is increased *in vivo*. Therefore, we investigated the production of ERK₁ mRNA in liver. Total liver RNA was analyzed by RT-PCR. The results revealed faint transcript of ERK₁ mRNA in sham-operated rat livers. However, specific banding to ERK₁ mRNA was detected in fibrotic liver sections. Moreover, ERK₁ mRNA expression was initially up-regulated at 6 h and reached its peak level 4 wk after BDL, which increased 2.4-fold. Levels of the housekeeping gene, β -actin, did not show

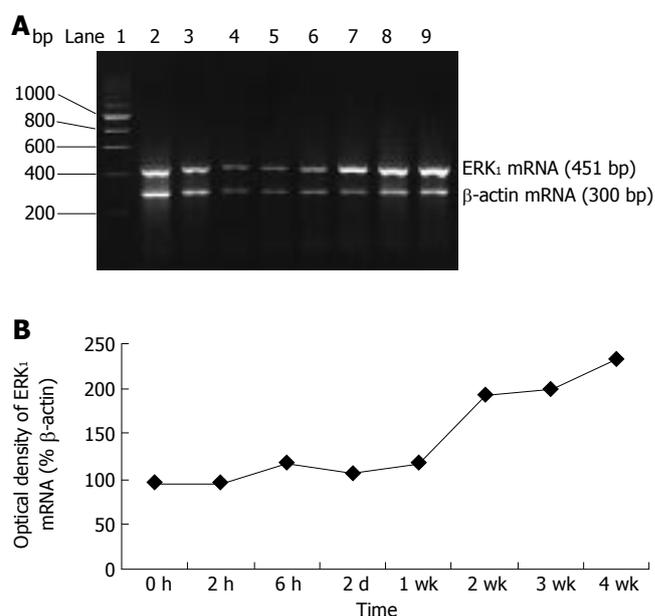

Figure 4 Electrophoresis of RT-PCR for ERK₁ mRNA expression in hepatic fibrogenesis at different time points (**A**) and percentage of optical density of ERK₁ mRNA electrophoretic strip (**B**). 1: marker; 2: sham operation group; 3: 2 h after BDL; 4: 6 h after BDL; 5: 2 d after BDL; 6: 1 wk after BDL; 7: 2 wk after BDL; 8: 3 wk after BDL; 9: 4 wk after BDL.

any significant differences between control and BDL rat liver tissue (Figure 4A and 4B).

Analysis of relation between ERK₁ and α -SMA

Immunohistochemistry experiments were performed to analyze whether the above described ERK₁ protein distribution was correlated with α -SMA in sham operated livers compared with BDL rats. The results indicated that ERK₁ was positively correlated with α -SMA ($r = 0.958$, $P < 0.05$).

DISCUSSION

HSCs, the principal cellular source of extracellular matrix during chronic liver injury, undergo a transition into α -SMA-expressing myofibroblastlike cells in

response to various liver injuries such as ECM, cytokine, inflammation mediator, ethanal, oxygen radical and lactic acid. Furthermore, HSC activation is associated with stellate cell proliferation, increased contractility and enhanced matrix production. HSCs express a number of fibrogenic and proliferative cytokines and their cognate receptors. Therefore, HSCs play a crucial role in cellular and molecular events that lead to hepatic fibrosis^[4]. Cassiman *et al*^[13] and Ramm *et al*^[14] have demonstrated that positive α -SMA cells mainly reside in the portal ducts and fiber septa, accompanied with proliferating tubercle, corresponding to the distribution of collagen. This study displayed that with the development of hepatic fibrosis, the positive α -SMA cells were greatly elevated and mainly situated in cells of the portal ducts, fiber septa, perisinuses accompanied with proliferating bile ducts. The positive areas of α -SMA in rat livers of model groups at 1 to 4 wk increased in turn and were larger than those in control group ($P < 0.01$). The result is in accordance with the above reports and indicates that the level of liver fibrosis can respond to α -SMA.

The activation and proliferation of HSCs may be regulated by various factors and signal transduction pathways^[7,15]. MAPK is a group of cytoplasmic serine/threonine kinases distributed extensively in cytoplasm, as a point of convergence of extracellular signal causing nuclear reaction^[1]. It becomes activated after threonine and tyrosine are phosphorylated altogether. In the MAPK family, ERK has been identified. ERK subset includes 2 subtypes: ERK₁ (P44^{MAPK}) and ERK₂ (P42^{MAPK}). The activation pathway is RAS-RAF-MEK-ERK. The combination of extracellular stimulation signal and receptors in cell membrane provokes dimerization of receptors and then phosphorylates self residue-Tyr. Some adapter proteins such as (growth factor receptor bound₂ (Grb₂) are recruited. Grb₂ is composed of one SH₂ region and two SH₃ regions. The SH₃ region of Grb₂ can combine with son of sevenless, which provokes the change of Ras's GDP and GTP. RAS activates RAF kinases further and phosphorylated RAF activates mitogen-activated protein kinase kinase (MEK), which can phosphorylate Thr and Tyr residues of ERK_{1/2}. At last, activated ERK enters nuclear membrane to regulate gene transcription and provokes cell biologic effects.

The role of ERK in promoting HSC proliferation *in vitro* has been increasingly acquainted in recent years. As mentioned earlier, it has been suggested that many cytokines, such as platelet derived growth factor (PDGF), endothelin (ET), epidermal growth factor (EGF), insulin, insulin-like growth factor-1 (IGF-1) and tumor necrosis factor (TNF), as well as endotoxin, ethanol, acetaldehyde, ROS and ECM, can all activate HSCs and promote the production of ERK^[10,16-19]. PD98059, an inhibitor of MEK kinase which is a upstream signal molecule of ERK, can restrain the transformation of HSCs into myofibroblasts, HSC proliferation and collagen synthesis^[14, 20-22]. The study on HSC-deleting MAPK gene *in vitro* discovered that the collagen gene expression of HSCs decreases to one third of the primary^[23]. On the contrary, little is known about the role and regulation mechanism of ERK *in vivo*. In addition, the mechanism of ERK mRNA is unknown. Nguyen *et al*^[24] have demonstrated that the expression of ERK₁ and

ERK₂ in patients with alcoholic liver disease increases 3.9- and 3.2-fold respectively, compared with that in normal people. By using immunohistochemistry, Alvaro *et al*^[25] have confirmed that the activated ERK_{1/2} in rat liver enters nuclear membrane from cytoplasm, and the expression coincides with liver pathology, suggesting that ERK₁ protein and ERK₁ mRNA are scarcely expressed in normal rat livers. In addition, ERK₁ protein and ERK₁ mRNA expressions are elevated with the progression of hepatic fibrosis. The position distribution demonstrates that ERK₁ protein is scarcely expressed in vascular endothelial and perisinusoidal cells in normal rat liver. With the development of hepatic fibrosis, the positive ERK₁ cells are mainly resided along with HSCs, in portal ducts, fibrotic septa, and epithelium of bile ducts. ERK₁ protein is expressed not only in plasma of cells, but also in nuclearmembrane, indicating its activation. Based on these results, we presume that hepatocytes, vascular endothelial cells, epithelium of bile ducts and HSCs are all cellular sources of ERK₁. However, the major cellular source is HSCs during hepatic fibrosis. ERK₁ in the MAPK family probably participates in the development of hepatic fibrogenesis.

In conclusion, ERK₁ protein distribution is positively correlated with α -SMA. ERK₁ is associated with HSC proliferation. Activation of ERK₁ in rat liver tissue can activate the downstream signal molecule which modulates gene expression of HSCs and gives rise to hepatic fibrosis.

INTRODUCTION

Pylorus-preserving pancreaticoduodenectomy (PPPD) was first reported by Watson in 1944^[1] and reintroduced by Traverso and Longmire in 1978^[2]. For the sake of functional preservation of the stomach and improvement of life quality, it has been accepted and adopted by more and more surgeons. With the wide use of PPPD, delayed gastric emptying (DGE) becomes the most common complication in the early postoperative course. Although there is no generally accepted definition of DGE, it may be described as the need for gastric suction during postoperative 7-10 d. Despite the self-limited characteristics of DGE, it prolongs the hospitalization days and increases the sufferings of patients. Meanwhile, it also affects the confidence of surgeons in further use of PPPD. In order to reduce the risk of DGE, we have adopted some effective approaches during operative process, as well as some postoperative managements and gained satisfactory results.

MATERIALS AND METHODS

Patients

From March 1992 to December 2003, 186 consecutive patients from the Department of Hepatobiliary Pancreatic Surgery of our hospital underwent PPPD performed by the same surgical group. Of these patients, 110 were male (59.1%) and 76 were female (40.9%), with a median age of 55.3 years (range, 32 to 83). The most frequent indication was peri-ampullary carcinomas (184 patients) (Table 1).

Operative techniques

Blood supply of duodenal residue should be well preserved: When the hepatogastric ligament and right part of gastrocolic ligament were resected, the vessel arch around the stomach should be preserved. The right gastric artery and gastroduodenal artery were divided and ligated at their origins to keep the distal arcade. The duodenum was transected 2 to 3 cm below the pylorus. The stomach was packed with wet gauze to protect it from loss of fluid. If the blood supply of residual duodenum was poor, PPPDs were substituted by standard pancreaticoduodenectomy (PD).

Abstract

AIM: To explore some operative techniques to prevent the occurrence of delayed gastric emptying (DGE) after pylorus-preserving pancreaticoduodenectomy (PPPD).

METHODS: One hundred and eighty-six patients in a single medical center who accepted PPPD were retrospectively studied. The incidence of DGE was investigated and the influence of some operative techniques on the prevention of DGE was analyzed.

RESULTS: During the operative process of PPPD, the methods of detached drainage of pancreatic fluid and bile and gastric fistulization were used. Postoperatively, six patients suffered DGE among the 186 cases; the incidence was 3.23% (6/186). One of them was complicated with intraabdominal infection at the same time, and two with pancreatic leakage.

CONCLUSION: Appropriate maneuvers during operation are essential to avoid postoperative DGE in PPPD. The occurrence of DGE is avoidable. It should not be used as an argument to advocate hemigastrectomy in PPPD.

Key words: Delayed gastric emptying; Pylorus-preserving pancreaticoduodenectomy; Gastric fistulization

Bu XM, Xu J, Dai XW, Ma K, Yang FQ, Hu J, Wang NF. Is delayed gastric emptying so terrible after pylorus-preserving pancreaticoduodenectomy? Prevention and management. *World J Gastroenterol* 2006; 12(39): 6382-6385

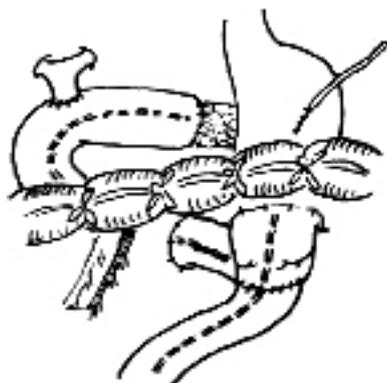

Figure 1 Intubation in pancreatic duct and gastric fistulization.

The detached drainage of pancreatic fluid and bile was performed: After the neck of pancreas was transected, a thin drainage tube (about 3 mm in diameter and 40 cm in length) was inserted into the distal pancreatic duct (Figure 1). The tube could drain the pancreatic fluid out of peritoneal cavity before pancreaticojejunostomy. When the posterior wall of pancreaticojejunostomy was completed, the thin tube was put into the jejunum to drain the pancreatic fluid away from the pancreaticojejunostomy and cholangiojejunostomy. Several small steel balls were put into the distal end of the tube, and their gravity may keep the tube from bending in the jejunum. We named the drain method detached drainage of pancreatic fluid and bile. Regarding the alimentary reconstructive procedures, Child's method was adopted.

Gastric fistulization tube was put into the intestine through the duodejejunal anastomosis: After the posterior wall of duodejejunojejunostomy was sutured, gastric fistulization was made routinely. A small hole was made in the anterior wall of the stomach, and a thin tube (about 40 cm in length and 4 mm in diameter) was inserted through the hole and pylorus to the proximal jejunum. The other end of the tube passed through the abdominal wall and was fixed to the skin. Two abdominal drainage tubes were essential for the operation, one was placed behind the pancreaticojejunostomy and choledochojejunostomy, and the other was placed in front of the pancreaticojejunostomy.

Peri-operative managements

In order to help the patients recover well, relatively stable internal environment and good nutritional condition of the patients should be maintained. In the preoperative and early postoperative stages, correction of imbalance of water and electrolytes and appropriate nutritional support should be undertaken. In most cases, total parenteral nutrition was needed.

The drainage tubes must be carefully watched to keep fluent in postoperative stage, because sometimes blood clots and necrotic tissues may obstruct them. If postoperative abdominal infection was suspected or proved, effective therapies such as drainage of the infectious focus and prescription of antibiotics should be taken promptly. Gastric suction may be stopped within postoperative 2 to 3 d; meanwhile, gastrointestinal motility

drugs may be taken orally. After the recovery of alimentary function, the patients may have liquid diet, and the amount of the intravenous fluid may be reduced. The use of antacid drugs was routine.

If the DGE was suspected, some examinations were helpful. The first was X-ray examination of the stomach; 76% of meglucamine diatrizoate was injected into the stomach by gastric suction tube. The typical manifestation of DGE was the decrease or diminish of gastric peristalsis; the contrast media retained in the stomach and could not go into the jejunum. A further choice was gastroscopic examination; the obstruction of gastrojejunostomy might be excluded. To improve the DGE, nutritional support was essential. Because of the thin tube in the stomach and jejunum; enteral nutrition was available and convenient. Small doses of erythromycin (0.6-0.9 g/d) might be administered intravenously. Some other drugs might also be used to stimulate the peristalsis of gastrointestinal tract, such as cisapride. For some patients, the change of body position was helpful, such as lying on the right side.

Therapeutic results

The complications of PPPD are listed in Table 2. Six patients suffered DGE among the 186 cases; the incidence was 3.23% (6/186). Among them, one was also complicated with intraabdominal infection simultaneously, and two with pancreatic leakage. The median recovery time was 36 (range: 15-81) d. One patient recovered after the gastroscopic examination. Three patients became normal after the use of small doses of erythromycin and cisapride. One patient did not show remission though all of the above methods were tried. However, at the 81st day postoperation, the uncomfortable symptoms of the patient disappeared spontaneously.

DISCUSSION

As the main complication of PPPD, DGE may occur

in 20%-60% of patients^[3-8]. The pathogenesis of DGE is still unknown. Thor and his coworkers^[9] found that the operation might damage the enteric nervous system, which induced the profound changes in gastric motility and emptying. Some authors^[9,10] stressed that the ischemic injury of antrum and pylorus plays an important role in the occurrence of DGE. Others emphasized the central role of the change of motilin concentration in plasma in DGE occurrence. All these above factors may partially participate in occurrence of DGE. In clinics, DGE is characterized with gastric dysfunction. The gastrointestinal radiography indicates the stomach is dilated; the gastric peristalsis is decreased or diminished. By the examination of gastroscopy, we may see the duodenojejunostomy anastomosis and gastric mucosa is congested and edematous, but the anastomosis is unobstructed, and the top end of gastroscopy may go through the anastomosis smoothly.

In our series, gastric fistulization was a routine maneuver. We assumed that the thin tube played an important role in prevention of DGE. In the early postoperative period, even if the existence of gastric atony, the gastric juice and liquid food may flow into jejunum along the wall of the tube, similar to the situation of flow of the bile into the duodenum in the patient with endoscopic nasobiliary drainage. Therefore, the gastric retention can be decreased. The corresponding symptoms such as nausea and vomiting may be avoided. Because the tube had many orifices in the walls at its forepart, if the gastric retention was very serious, negative pressure suction was convenient through the tube. If the abnormal gastric function lasted for a period of time and led to delayed food ingestion, enteral nutrition was available through the jejunal tube, thus avoiding some complications arising from long-term parenteral nutrition.

Besides the above-mentioned factors that may lead to DGE, postoperative intra-abdominal complications are also an important cause. Riediger^[11] studied 204 patients undergoing PPPD. By multivariate analysis, it was revealed that the postoperative complications were the most important factor associated with the occurrence of DGE. Park^[12] studied 150 consecutive patients who underwent PPPD performed by one surgeon. The incidence of DGE was 41.7% (15 of 36) in the group with complications, yet only 8.8% (10 of 114) in the other group ($P = 0.0001$). Among the postoperative intraabdominal complications, pancreatic leakage was most often seen. In our series, two of the six patients with DGE were complicated with pancreatic leakage. Therefore, it is important to prevent the pancreatic leakage during postoperative period.

Pancreatic leakage is also a primary complication after PPPD. It is far more disastrous than DGE. It is not only related to delayed gastric emptying, but can lead to some fatal consequences such as intra-abdominal bleeding and infection. How to prevent its occurrence is always a compelling problem for surgeons. In our experience, detached drainage of pancreatic fluid and bile is an effective method^[13] for the prevention of pancreatic leakage. The tube in pancreatic duct can drain pancreatic fluid into the jejunum away from the pancreaticojejunostomy. No pancreatic fluid detains in the intestinal lumen near the

pancreaticojejunostomy, the enteral pressure is decreased and pancreaticojejunostomy is free of the soaking and corrosion resulting from pancreatic fluid. Along the outer wall of the tube, the bile is also drained to the distal jejunum away from cholangiojejunostomy where it mixes with pancreatic fluid and activates the digestive proenzyme in pancreatic fluid. Due to adoption of these methods, the incidence of pancreatic leakage was rather low in our series. We believe that it is helpful for the prevention of the DGE. Compared with the traditional method, in which the pancreatic fluid is drained outside body, our technique may decrease the loss of body fluid, thus helpful for maintaining stable internal environment and balancing the water and electrolytes of the patients.

As a postoperative complication characterized by gastrointestinal dysfunction, DGE is not specific for PPPD. It may occur after other abdominal operations, including the standard pancreaticoduodenectomy. Tran studied^[14] a nonselected series of 170 consecutive patients and found DGE occurred equally in the 2 groups. Horstmann^[15] also proposed that pylorus preservation did not increase the frequency of DGE. DGE almost exclusively occurs as a consequence of other postoperative complications. As we know, the best way to avoid postoperative complications is appropriate maneuvers during operation. In our series, besides elaborate surgical techniques, we used the thin tube twice, and the small tubes really play big roles in preventing DGE. Since the occurrence of DGE is avoidable in most cases, DGE should not be used as an argument to advocate hemigastrectomy in PPPD.

Abstract

AIM: To evaluate the role of microcirculatory disorder (MCD) and the therapeutic effectiveness of tetramethylpyrazine (TMP) on intestinal mucosa injury in rats with acute necrotizing pancreatitis (ANP).

METHODS: A total of 192 Sprague-Dawley rats were randomly divided into three groups: normal control group (C group), ANP group not treated with TMP (P group), ANP group treated with TMP (T group). An ANP model was induced by injection of 50 g/L sodium taurocholate under the pancreatic membrane (4 mL/kg). C group received isovolumetric injection of 9 g/L physiological saline solution using the same method. T group received injection of TMP (10 mL/kg) *via* portal vein. Radioactive biomicrosphere technique was used to measure the blood flow at 0.5, 2, 6 and 12 h after the induction of ANP. Samples of pancreas, distal ileum were collected to observe pathological changes using a validated histology score. Intestinal tissues were also used for examination of myeloperoxidase (MPO) expressed intracellularly in azurophilic granules of neutrophils.

RESULTS: The blood flow was significantly lower in P group than in C group ($P < 0.01$). The pathological changes were aggravated significantly in P group. The longer the time, the severer the pathological changes. The intestinal MPO activities were significantly higher in P group than in C group ($P < 0.01$). The blood flow of intestine was significantly higher in T group than in P group after 2 h ($P < 0.01$). The pathological changes were alleviated significantly in T group. MPO activities were significantly lower in T group than in P group ($P < 0.01$ or $P < 0.05$). There was a negative correlation between intestinal blood flow and MPO activity ($r = -0.981$, $P < 0.01$) as well as between intestinal blood flow and pathologic scores ($r = -0.922$, $P < 0.05$).

CONCLUSION: MCD is an important factor for intestinal injury in ANP. TMP can ameliorate the condition of MCD and the damage to pancreas and intestine.

INTRODUCTION

Acute pancreatitis (AP) is often complicated by intestinal injury. However, its pathogenesis remains unclear. As we know, AP involves a complex array of mediators initiating and amplifying the systemic inflammatory response and therefore leads to failure of the distant organ systems, such as the lungs, intestine and kidneys^[1-3]. Failure of intestinal barrier function often occurs in acute necrotic pancreatitis (ANP), resulting in the increased intestinal permeability and subsequent translocation of bacteria or/and endotoxin from gut^[4]. Recent studies indicate that during the pathogenesis of ANP, changes in microcirculation play an important role in the worsening of pancreatitis^[5]. A number of agents have been tried for preventing or ameliorating this destructive effect on intestine in experiment conditions. Pharmacologic studies have demonstrated that tetramethylpyrazine (TMP), an intravenous drug made from traditional Chinese herbs, is able to inhibit release of intracellular calcium and to scavenge oxygen free radicals^[6,7]. The significant efficacy of TMP in cerebral ischemia and reperfusion injury has been confirmed. This study was to evaluate the role of microcirculatory disorder (MCD) in ANP of rats and the therapeutic effectiveness of TMP on intestinal injury in ANP.

MATERIALS AND METHODS

Animals

Adult Sprague-Dawley rats of both sexes weighing

250-300 g were provided by the Laboratory Animal Center of Jiangsu University. The animals were fed with standard rat chow and water *ad libitum*. The rats were allowed to acclimatize to our laboratory conditions for 1 wk and then subjected to mesh stainless-steel cages at a constant temperature ($21 \pm 1^\circ\text{C}$) in a 12 h day/night cycle. Prior to experiment, the rats were fasted overnight with free access to water.

Experimental design

The animals were randomly divided into control group (C group), ANP group not treated with TMP (P group), ANP group treated with TMP (T group) with 64 rats in each group. Each group was further divided into 0.5, 2, 6 and 12 h subgroups, respectively. The rats were anaesthetized with sodium pentobarbital (50 mg/kg, ip) and operated under aseptic conditions. The rats were infused with sodium taurocholate (50 g/L, 4 mL/kg, Ward Blen Kinsop CO) through the pancreatic membrane to induce ANP model as previously described^[8]. After 5-10 min, pancreatic edema and dotted bleeding occurred. The rats in T group were infused with sodium taurocholate. Then 6 g/L TMP (Wuxi No. 7 Pharmaceutical Factory, China; batch number: 0008241) was infused *via* femoral vein (10 mL/kg). The rats in C group received isovolumetric injection of 9 g/L physiological saline solution. The abdominal wounds were closed and all the rats were returned to their cages. Thirty-four animals in each group were sacrificed at 0.5, 2, 6 and 12 h after infusion for further examination. Part of distal ileum was removed immediately and fixed in paraformaldehyde solution for 12-24 h and paraffin-embedded for routine histopathologic analysis and measurement of myeloperoxidase (MPO) activity. The histopathologists were blinded to routine histopathologic analysis. The other rats in each group were used for intestinal blood flow determination by intravenous injection of radioactive microsphere technique (RMT).

Blood flow measurements

At 0.5, 2, 6 and 12 h after infusion, intestinal blood perfusion values were determined using RMT as previously described^[9] and modified by Chen and Dai^[10]. $^{99}\text{Tc}^{\text{m}}$ -labeled microspheres (^{99}Mo - $^{99}\text{Tc}^{\text{m}}$ generator preparation provided by Chinese Institute of Nuclear Power) with a specific activity of 74 MBq/mL were used for measurement of blood flow. The right carotid artery was catheterized with the tip of the catheter placed in the left ventricle for infusion of $^{99}\text{Tc}^{\text{m}}$ -labeled microspheres. One mL $^{99}\text{Tc}^{\text{m}}$ radioactive microspheres (approximately 500 000 microspheres) was injected for 10 s *via* the catheter with its tip in the aortic ventricle of heart. A reference blood sample was obtained from the femoral artery catheter for 60 s at a constant rate of 1 mL/min with a continuous-withdrawal pump. The microsphere animals were killed by intra-arterial injection of 2 mL 100 g/L KCL. The distal ileum was removed, weighed and cut into small pieces and placed in a γ counter (GC-1200 gamma radioimmunoassay counter was from USTC Chuangxin CO.Ltd) to determine the radioactivity. Samples from each animal were counted and expressed as counts per minute (CPM). The blood

flow values were calculated according to the following formula:

$$Q_{\text{org}} [\text{mL}/(\text{min} \cdot \text{g})] = \frac{Q_{\text{ref}} (\text{mL}/\text{min}) \times N_{\text{org}} (\text{cpm})}{N_{\text{ref}} (\text{cpm}) \times \text{Weighing} (\text{g})}$$

Where Q_{org} denotes the organ blood flow (mL/min* g), Q_{ref} is the withdrawal rate of the reference sample (mL/min), N_{org} is the number of microspheres in the organ (cpm) and N_{ref} is the number of microspheres in the reference sample (cpm).

Myeloperoxidase activity

Sequestrations of neutrophils within the intestinal mucosa were evaluated by quantifying tissue MPO activity as previously described^[11]. Intestinal tissue was removed and immediately frozen and stored at -80°C until MPO assay with a 753 UV-Vis spectrophotometer (Shanghai Optical Instrument Factory). The results were expressed as nKat/g of tissue.

Pathological examination

The rats were killed by intra-arterial injection of 2 mL 100 g/L KCl. The whole pancreas and parts of distal ileum were obtained and promptly fixed in 40 g/L phosphate-buffered formaldehyde for further studies. Paraffin-embedded tissue sections (5-7 μm thick) were stained with hematoxylin and eosin. Histological evaluation was performed under light microscope by two blinded observers on two separate occasions. Mucosal damage was assessed according to the standard scale of Chiu *et al.*^[12]. Grading was performed and classified as: 0 = normal mucosa; 1 = development of subepithelial space at the tip of the villus; 2 = extension of the space with epithelial lifting; 3 = massive epithelial lifting; 4 = denuded villi; 5 = disintegration of the lamina propria (Figure 1).

Statistical analysis

Results were expressed as mean \pm SD except for data of the grading of intestinal mucosal injury. The results were analyzed using the postHoc test. Differences in grading of intestinal mucosal injury were analyzed with the Mann-Whitney *U* test. The correlation of intestinal blood flow with MPO activity was analyzed using Pearson's correlation. The correlation of pathologic score with the intestinal blood flow was analyzed using Spearman's rank correlation. $P < 0.05$ was considered statistically significant.

RESULTS

Intestinal mucosal blood flow

As shown in Table 1, the blood flow was significantly lower in P group than in C group ($P < 0.01$). It began to decrease at 0.5 h and reached the lowest at 12 h. However, the blood flow in T group was significantly higher than that in P group after 2 h ($P < 0.05$), and significantly different from that in C group ($P < 0.01$).

Myeloperoxidase activity

MPO activity in P group greatly increased compared to that in C group ($P < 0.01$). For T group, Although its MPO

activity was also higher in T group than in control group, it increased less than in P group (*P* < 0.01 or *P* < 0.05, Table 2).

Pathologic examination of intestinal mucosa and pancreas

After induction of ANP model, pancreas showed mild edema and congestion. Two hours after introduction of

the model, typical pathologic changes were found in ANP, such as a large number of inflammatory cells, necrosis of adjacent fat tissues, interstitial edema, parenchyma hemorrhage and necrosis, large amount of ascites. The results had a concordance of 100% of the readings by 2 pathologists. The degree of intestinal pathological injury is shown in Table 3. The grades of P group were

significantly higher than those of control group ($P < 0.01$). The histopathological grades of T group were significantly lower than those of P group ($P < 0.05$) (Figure 1).

Correlation analysis

Correlation analysis showed that there was a negative correlation between intestinal blood flow and MPO activity ($r = -0.981$, $P < 0.01$) as well as between intestinal blood flow and pathologic score ($r = -0.922$, $P < 0.05$).

DISCUSSION

Microcirculatory mechanisms are involved in the development of acute pancreatitis^[13,14]. Changes in microcirculation is an important factor for the development of ANP. It can damage the pancreas and extra pancreatic vital organs^[15,16], leading to a series of changes including vasoconstriction, ischemia, increased vascular permeability, impairment of nutrient tissue perfusion, ischemia/reperfusion injury, leukocyte adherence. RMT provides an efficient method for estimating blood flow to various organs in the body. Our results revealed that, at the early stage of ANP, intestinal mucosal blood flow decreased significantly 0.5 h after injection of 50 g/L sodium taurocholate as compared with control group ($P < 0.01$). Intestinal mucosal injury occurred at the same time which might result from ANP and release of inflammatory mediators. Changes in the nerve endocrine system bring about redistribution of viscera blood flow, producing a sharp decrease in intestinal blood flow. Intestinal mucosa is sensitive to the shortage of blood and oxygen. Due to the further decrease in circulatory blood and over activation of inflammatory mediators, much lower intestinal blood flow further damages the mucosa, suggesting that microcirculation disturbances may contribute to intestinal mucosal damage.

The second prominent feature in this experimental model is the development of granulocytosis and accumulation of neutrophils in intestinal tissue. Because neutrophils are known to be required for the development of intestinal injury in ANP, interventional studies were undertaken to assess whether intravenous administration of TMP would result in decreased neutrophil accumulation in intestinal tissues. The MPO activities in intestinal tissue were assayed to assess the number of recruited neutrophils to the intestinal tissue in C, P and T groups. Our results showed that the MPO activity was markedly elevated after induction of pancreatitis and TMP significantly reduced neutrophil accumulation in intestinal tissue, suggesting that TMP attenuates the increase in MPO activity and improves the histological findings in both pancreas and intestine.

TMP is widely used in traditional Chinese medicine, often in combination with other herbal medicines. It is traditionally used to treat a diversity of ailments, particularly cardiovascular disorders such as atherosclerosis or blood clotting abnormalities. TMP can intervene in hemorheological events in the organs, such as blood flow, erythrocyte deformation, leukocyte adhesion, platelet aggregation and thrombolysis^[17]. TMP protects against vascular endothelial cell injuries induced by hydrogen peroxide^[18] and tissue injuries caused by activated

neutrophils by scavenging oxygen radicals^[19], as well as enhances the action against free radicals and inhibits ca function, which may be one of the mechanisms underlying the protection of cells against intestinal ischemic reperfusion injury^[20].

In conclusion, TMP attenuates MPO activity and improves intestinal microcirculation. Its protective effects against intestinal injury may be attributed to improving microcirculation and further preventing accumulation of neutrophils. MCD plays an important role in the development of intestinal injury. Early use of TMP seems to be effective in ameliorating intestinal injury.

Abstract

AIM: To study the correlation between the patterns of subcellular expression of p16 and CDK4 in colorectal epithelia in the normal-adenoma-carcinoma sequence.

METHODS: Paraffin sections of 43 cases of normal colorectal epithelia and corresponding adenomas as well as carcinomas were analysed immunocytochemically for subcellular expression of p16 and CDK4 proteins.

RESULTS: Most carcinomas showed more cytoplasmic overexpression for p16 and CDK4 than the adenomas from which they arised or the adjacent normal mucosa. Most normal or non-neoplastic epithelia showed more p16 and CDK4 expression in the nucleus than their adjacent adenomas and carcinomas. There was a significant difference between the subcellular expression pattern of p16 and CDK4 in normal-adenoma-carcinoma sequence epithelia ($P < 0.001$). Neither p16 nor CDK4 subcellular patterns correlated with histological grade or Dukes' stage.

CONCLUSION: Interaction of expression of p16 and CDK4 plays an important role in the Rb/p16 pathway. Overexpression of p16 and CDK4 in the cytoplasm, as well as loss expression of p16 in the nucleus might be important in the evolution of colorectal carcinoma from adenoma and, of adenoma from normal epithelia.

INTRODUCTION

p16, as a cyclin-dependent kinase-4 inhibitor is expressed in a limited range of normal tissues and tumors. The Rb/p16 tumor-suppressor pathway is frequently abrogated in many types of human tumors, either through inactivation of Rb or p16 tumor-suppressor proteins, or through alteration or overexpression of cyclin D1 or cyclin-dependent kinase 4/6 (CDK4/6) oncogenes^[1-4]. However, no deletion and only quite a low frequency of mutation of p16 gene have been found in colorectal cancer and adenoma-carcinoma-sequence since this gene was identified in 1994^[1,5]. CpG islands are areas rich in CpG dinucleotides, which are found within the promoters of about 60% of human genes. These CpG islands normally lack DNA methylation, regardless of the expression status of the gene^[6]. Methylation of promoter usually leads to irreversible inhibition of gene transcription^[7]. It has become apparent that *de novo* methylation is an important alternate mechanism underlying coding region mutation which inactivates tumor suppressor genes during neoplasia^[8-12]. Methylation of the 5' CpG island in p16 gene was previously reported not only in colorectal cancer but also in normal colonic tissue by the more sensitive PCR-based assay, in which all p16 genes were inactivated^[9,10]. Furthermore, it has been found that the aberrant cytoplasmic expression of the p16 protein without gene alteration is associated with accelerated tumor proliferation in breast cancer^[13], and p16 protein plays an important role in the regulation of glioma angiogenesis, suggesting a novel function of the p16 gene^[14]. It was also reported that overexpression of p16 was observed in a majority of colorectal cancer^[15-17] and a low p16 expression due to methylation^[18] or not^[15,19,20] may contribute to tumor enlargement, expansion and metastasis and even prognosis of colorectal cancer. Immunohistochemistry with p16 antibody has been used as a diagnostic adjunct in premalignant and malignant lesions of gynecologic pathology^[21], oral cavity^[22,23], head and neck^[24-26] and skin^[27,28] in recent years. Diffuse positivity but not focal one with p16 staining in the cervix can be regarded as a surrogate marker of the presence of

high-risk human papillomavirus (HPV)^[29-31]. Most high-grade cervical intraepithelial neoplasia (CIN) and some cases of low-grade CIN, are usually associated with high-risk HPV. In cervical squamous lesions, the expression of p16 is found almost diffusely positive. And also p16 expression may be helpful to identify small focal high-grade CIN lesions, to distinguish CIN involving immature metaplastic squamous epithelium from immature metaplastic squamous epithelium not involved by CIN and to distinguish high-grade CIN from benign mimics. p16INK4A stain is also found to be a valuable ancillary test in making the diagnosis of squamous dysplasia. Combined with the conventional hematoxylin and eosin stain, the p16INK4A staining may help to identify truly dysplastic foci in tissues which is particularly challenging, because of poor orientation or small biopsies, tissues that show severe inflammation or ulceration or keratinizing dysplasia. Other series indicated that p16 overexpression within malignant epithelium in the female genital tract should not be interpreted as synonymous with HPV-induced carcinogenesis. Data also indicated that p16 overexpression could occur in non-HPV-related cancers of the gynecological tract and that p16 overexpression suggested generic functional RB1 pathway abnormalities in cancer evolution. These preliminary results are promising; however, there is no corresponding report on colorectal carcinogenesis from normal-adenoma-carcinoma sequence. Therefore additional studies are needed to identify whether the p16INK4A as well as its binding protein, CDK4 has the similar prognostic value in predicting lesions that are likely to progress in colorectal neoplasm. We used the p16INK4A and CDK4 antibodies to stain reactive and dysplastic lesions in this series of colorectal normal-adenoma-carcinoma sequence and to investigate the possible role of p16 or CDK expression in the evolution of colorectal neoplasia.

MATERIALS AND METHODS

Samples

Forty-three cases of colorectal carcinoma with residual adenoma, in which adjacent normal mucosa was available in 42 of the cases, were randomly and retrospectively selected from the pathology files of St. Mark's Hospital, London and 31 cases of colorectal carcinoma were from the Department of Pathology, Chinese People's Liberation Army (PLA) General Hospital. Specimens obtained at surgery were routinely fixed in 10% neutral formalin and embedded in paraffin. The clinical stage was classified according to Dukes: 22 in Dukes' A, 22 in Dukes' B and 30 in Dukes' C, respectively. The histological grade of the tumors was determined according to WHO criteria as follows: 24 in grade I, well differentiated; 41 in grade II, moderately differentiated; and 9 in grade III, poorly differentiated.

Immunocytochemical analysis

Immunocytochemical staining for p16 and CDK4 was performed with a standard ABC method except that the pressure cooking procedure was used for antigen retrieval pretreatment^[15]. Serial sections were cut 4 μ m thick and

dewaxed in xylene and rehydrated in a graded ethanol series. The sections were immersed in 3% hydrogen peroxide in methanol for 15 min to block endogenous peroxidase activity and rinsed in running water. Sections were then immersed in boiling 1 mmol/L EDTA-NaOH (pH 8.0) buffer in a pressure cooker. The pressure cooker was then sealed and brought to full pressure. The heating time was 2 min, beginning only when full pressure was reached. At 2 min the cooker was depressured and cooled under running water. The lid was then removed, and the hot buffer was flushed out with cold water from a running tap. The cooled sections were washed twice in PBS before immunohistochemical staining, then immersed in 0.05% avidin for 30 min to block any possible endogenous biotin exposed by heating. Prior to application of antibodies, the sections were incubated with 10% horse serum, for monoclonal antibodies and 10% goat serum, for polyclonal antibodies, respectively for 15 min to block non-specific binding. The primary monoclonal mouse antibody against human p16 protein (Pierce, USA) was produced, using a full-length recombinant bacterially produced GST-p16INK4 fusion protein as the immunogen, and could only be reactive to human tissue. The polyclonal rabbit antibody against human CDK4 protein (Santa Cruz Biotechnology, USA), was raised against the epitope corresponding to amino acids 282-303 mapping at the carboxy terminus of mouse CDK4 and is specific for CDK4 with no cross-reactivity with other cyclin dependent kinases in mouse, rat and human tissue. The antibodies were diluted 1:200 with 0.01 mol/L PBS (pH 7.2). After exposure to primary antibody the sections were allowed to react with the standard ABC method with VECTASTAIN Elite PK-6100 kit (Vector Laboratories, Inc. USA) as directed by the manufacturer. A previously known positive glioma was used as a positive control. The primary antibody was replaced by 0.01 mol/L PBS as a negative control. Normal colon mucosa tissue was used as a normal control.

Interpretation of p16 and CDK4 immunocytochemical staining

Immunostained sections were evaluated according to the localization of staining of positive tumor cells as follows: tumors were classified as cytoplasmic/nuclear (C/N) and cytoplasmic (C) pattern, respectively, when immunoreactivity was present in a large proportion of epithelial cells. When immunoreactivity was not visible, the result was classified as negative.

Statistical analysis

The correlation between variables was determined using the nonparametric test with SPSS10.0. A value of *P* less than 0.05 was accepted as statistically significant. The results are summarized in Table 1, Table 2, Table 3.

RESULTS

p16 subcellular expression in normal-adenoma-carcinoma sequence

Of the 42 normal epithelia examined, cytoplasmic/nuclear expression pattern was found in 40 (95.2%) and

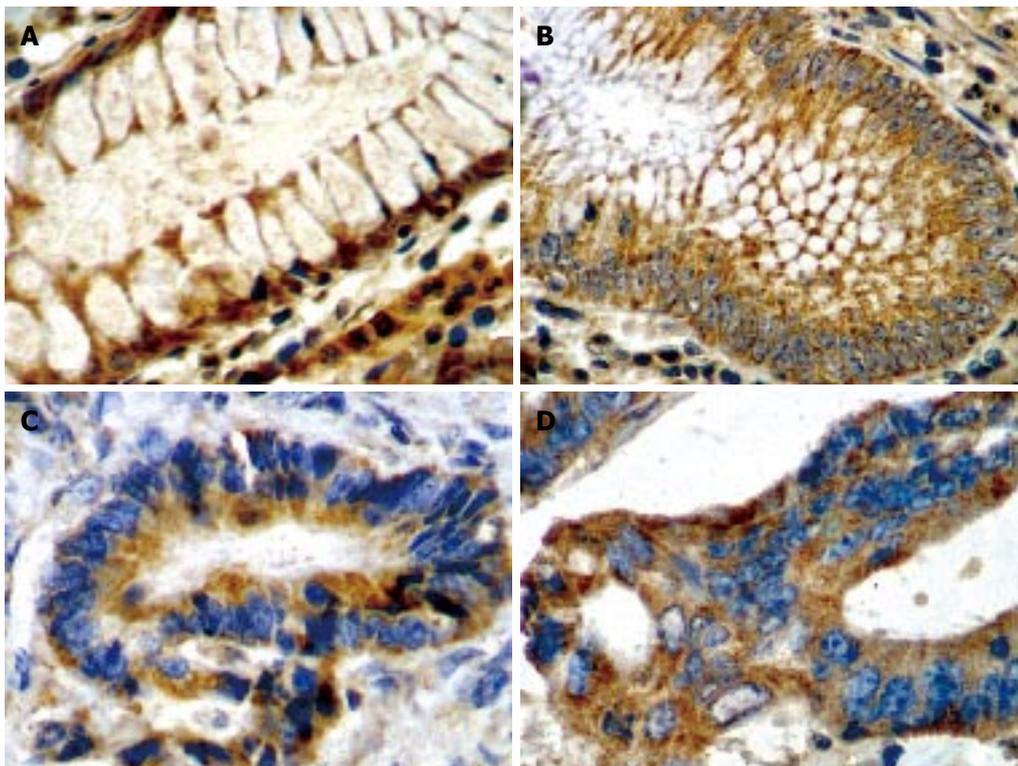

Figure 1 Subcellular expression of p16 and CDK4. **A:** Cytoplasmic/nuclear pattern of p16 in normal epithelia of colon mucosa ($\times 200$); **B:** Cytoplasmic pattern of p16 in adenomatous epithelia of adenoma ($\times 200$); **C:** Cytoplasmic pattern of p16 in colonic adenocarcinoma ($\times 400$); **D:** Cytoplasmic pattern of CDK4 in colonic adenocarcinoma. Original magnifications ($\times 400$).

Table 1 Relationship between the subcellular expression pattern of p16 or CDK4 and the histology of epithelia of normal-adenoma-carcinoma sequence

Histology	Subcellular expression pattern		
	Total	C/N	C
p16			
Normal	42	40	2
Adenoma	43	32	11
Carcinoma	73	27	46
$P < 0.001$			
CDK4			
Normal	38	29	9
Adenoma	43	10	33
Carcinoma	74	15	59
$P < 0.001$			

C/N: Cytoplasm/nucleus.

cytoplasmic only in 2 (4.8%) (Figure 1A). Of the 43 adenomas, 32 (74.4%) showed cytoplasmic/nuclear and 11 (25.6%) cytoplasmic only for p16 (Figure 1B). Of the 74 carcinomas arising from the adenomas, 27 (36.5%) showed cytoplasmic/nuclear and 46 (62.1%) cytoplasmic expressing pattern for p16 (Figure 1C). Only in one additional advanced carcinoma was the poorly differentiated signet cells negative. There was a significant difference between the patterns of p16 expression in any two positive types of epithelia of the normal-adenoma-carcinoma sequence ($P < 0.001$) (Table 1). In non-neoplastic mucosa adjacent to carcinoma, p16 expression was present weakly in the nucleus and moderately only in the cytoplasm around the nucleus. Most of the cytoplasm of goblet cells filled with mucus was negative. Expression for p16 was almost always observed strongly in the cytoplasm and sporadically weakly in the nuclei of cancer cells.

Table 2 Relationship between p16 subcellular expression pattern and clinicopathological features

Clinicopathological feature	n	p16 subcellular pattern	
		C/N	C
Dukes' stage			
A	22	8	14
B	22	6	16
C	29	13	16
Histological grade			
I	24	8	16
II	40	16	24
III	9	3	6
Total	73	27	46

C/N: Cytoplasm/nucleus. There was no significant correlation between p16 subcellular expression pattern and the Dukes' stage ($P = 0.441$) or histological grade ($P = 0.865$) of the carcinoma.

CDK4 subcellular expression in normal adenoma-carcinoma sequence

In non-neoplastic mucosa adjacent to carcinoma, CDK4 nuclear and cytoplasmic expression was slightly weaker than the p16 expression, but was otherwise identical. Of the 42 normal epithelia examined, CDK4 expression was cytoplasmic/nuclear in 29 (69.0%), cytoplasmic in 9 (21.4%), and negative in 4 (9.5%). Of the 43 adenomas, CDK4 expression was cytoplasmic/nuclear in 10 (23.3%) and cytoplasmic positive in 33 (76.7%). In 74 carcinomas, CDK4 staining was cytoplasmic/nuclear in 15 (20.3%) and cytoplasmic alone in 59 (79.7%) and like p16, almost always observed strongly in the cytoplasm (Figure 1D). There was a significant difference between the subcellular patterns of CDK4 expression in any two positive types of epithelia in the normal-adenoma-carcinoma sequence ($P < 0.001$) (Table 1).

Table 3 Relationship between CDK4 subcellular expression pattern and clinicopathological features

Clinicopathological feature	n	CDK4 subcellular pattern	
		C/N	C
Dukes' stage			
A	22	4	18
B	22	4	18

II	41	10	31
III	9	1	8
Total	74	15	59

C/N: cytoplasm/nucleus. There was no significant correlation between CDK4 subcellular expression pattern and the Dukes' stage ($P = 0.844$) or histological grade ($P = 0.584$) of the carcinoma.

Correlation between p16 or CDK4 subcellular expression and Dukes' stage or histological grade in carcinomas

There was no significant correlation between p16 or CDK4 subcellular expression pattern and the Dukes' stage ($P = 0.441$; $P = 0.844$) or the histological grade ($P = 0.865$; $P = 0.584$) of the carcinoma (Tables 2 and 3).

DISCUSSION

Research on expression of p16 has made much progress in gynecologic pathology in recent years^[21,29-31]. p16 is found diffusely positive in most cervical carcinomas including squamous, glandular, and small cell type. In cervical glandular lesions, p16 is also useful to diagnose the lesions between adenocarcinoma *in situ*, which shows diffusely positive pattern and benign mimics, including tuboendometrial metaplasia and endometriosis, which usually shows p16-negative or focally positive pattern. Combined with other markers, p16 may be used to distinguish between a cervical adenocarcinoma (diffuse positivity) and an endometrioid-type endometrial adenocarcinoma (negative or focally positive). In some uterine serous carcinomas the staining is diffusely positive. In the vulva, p16 is positive in HPV-associated vulval intraepithelial neoplasia (VIN) but negative in VIN not associated with HPV. Similarly, HPV-associated invasive squamous carcinomas are p16-positive, whereas the more common non-HPV-associated neoplasms are largely negative or focally positive. In the uterus, p16 positivity is more common and widespread in leiomyosarcomas than in leiomyomas, and it may be a useful marker to diagnose problematic uterine smooth muscle neoplasms. Metastatic cervical adenocarcinomas in the ovary are usually diffusely p16-positive, and because these may closely mimic a primary ovarian endometrioid or mucinous adenocarcinoma, it may be a valuable diagnostic aid, although p16 expression in primary ovarian adenocarcinomas of these morphologic subtypes has not been widely investigated. Some ovarian serous carcinomas, similar to their uterine counterparts, are p16-positive. Darvishian *et al*^[32] reported that the sensitivity and specificity of p16 immunoreactivity in the detection of anal intraepithelial neoplasia or squamous cell carcinoma

were 72% and 71%, respectively. The presence of p16 immunoreactivity is a good predictor of dysplasia in anal specimens. Nilsson *et al*^[28] found that the expression of p16INK4a varied between the skin lesions including actinic keratosis, squamous cell carcinoma *in situ* and invasive squamous cell carcinoma, with weak and cytoplasmic p16INK4a expression and functional Rb in actinic keratosis. Strong nuclear and cytoplasmic p16INK4a expression was observed in all carcinomas *in situ* in parallel with a lack of Rb-phosphorylation but high proliferation, indicating a nonfunctional Rb. More interestingly, despite this disability of p16INK4a to inhibit proliferation there is an upregulation of cytoplasmic p16INK4a in infiltrative cells compared to tumor cells towards the tumor center, suggesting a potentially proliferation independent function for p16INK4a in infiltrative behavior. It has been reported that p16 overexpression is a potential early indicator of transformation^[30] and associated with poor clinical outcome in ovarian carcinoma^[31]. In addition, it was also reported that intensity of p16 expression may play an important role in clinicopathological features and prognosis of colorectal adenocarcinoma^[15-19]; However, there has been no subcellular localization analysis on colorectal epithelia of adenoma-carcinoma sequence compared with their normal counterpart.

In the current study, we aimed to clarify if p16 overexpression, with its binding protein, CDK4 overexpression has any role in colorectal neoplasia. Our result showed that p16 overexpression was almost always observed strongly in the cytoplasm and sporadically weakly in the nuclei of colorectal cancer cells and most carcinomas showed more cytoplasmic overexpression for p16 and CDK4 than the adenomas from which they were arising or the adjacent normal mucosa. Most normal or non-neoplastic epithelia showed more p16 and CDK4 expression in the cell nucleus than their adjacent adenomas and carcinomas. There was a significant difference between the subcellular expression pattern of p16 and CDK4 in normal-adenoma-carcinoma sequence epithelia ($P < 0.001$). The findings suggest that CDK4 may be activated as one of the initial events, which is followed by activation of the p16 gene, possibly as a feedback mechanism, with the effect of preventing G1/S transition through pRB phosphorylation by CDK4 overexpression. In normal colorectal epithelia there was much mucin in the cytoplasm. In the tumorigenesis, from normal epithelia to adenoma, and then to carcinoma, the mucin loss was observed gradually with the increase of p16 and CDK4 expression in the cytoplasm of epithelia. It is further suggested that cytoplasmic overexpressions for p16 and CDK4 may be involved in the mechanism for the loss of mucin and the transformation from normal mucosa to adenoma, and from adenoma to carcinoma. Cytoplasmic localization of p16 might be due to its binding with CDK4, forming a larger molecule, difficult to pass through the nuclear membrane. Loss of expression of p16 in the nucleus might suggest that there is a loss of function of p16 besides binding with CDK4, which negatively regulates the transcription of some important genes in tumorigenesis. p16 overexpression is known to occur in neoplastic cells as an indirect phenomenon of an aberrant

RB1 functional pathway, as is well known in carcinomas of the lower genital tract, in which high-risk types of HPV have caused inactivation of RB1. Some data^[33] also indicate that p16 overexpression may occur in non-HPV-related cancers of the gynecological tract and possibly indicate generic functional RB1 pathway abnormalities in cancer evolution in which p16 overexpression may not be caused by mutational silencing of the *Rb1* gene directly in the majority of cases, but rather the retinoblastoma pathway is rendered dysfunctional by some other mechanism. Unlike our previous report in intensity analysis^[15], there were no differences in p16 or CDK4 subcellular expression between Dukes' stages and histological grades in this research, indirectly suggesting that the subcellular expression of the two proteins may be significant in the evolution, but not in the progression, of colorectal carcinomas. Extensive research is needed to further clarify the mechanism.

In summary, our results support experimental evidence that interaction of expression of p16 and CDK4 plays an important role in the Rb/p16 pathway, and cytoplasmic overexpression of CDK4 and p16 as well as loss expression of p16 in nucleus might be important in the evolution of colorectal carcinoma from adenoma and, of adenoma from normal epithelia. Thus cytoplasmic overexpression of CDK4 and p16 may be a potentially early marker of transformation in colorectal carcinoma.

Abstract

A 68-year-old man underwent cholecystectomy and choledochoduodenostomy for biliary obstruction and nephrectomy for a renal tumor. Based on clinical and histopathologic findings, autoimmune pancreatitis (AIP) was diagnosed. The renal tumor was diagnosed as a renal cell cancer. Steroid therapy was started and thereafter pancreatic inflammation improved. Five years after surgery, the patient was readmitted because of pyrexia in a preshock state. A *Klebsiella pneumoniae* liver abscess complicated by sepsis was diagnosed. The patient recovered with percutaneous abscess drainage and administration of intravenous antibiotics. Liver abscess recurred 1 mo later but was successfully treated with antibiotics. There has been little information on long-term outcomes of patients with AIP treated with surgery. To our knowledge, this is the second case of liver abscess after surgical treatment of AIP.

INTRODUCTION

The differentiation of autoimmune pancreatitis (AIP) from pancreatic cancer is sometimes difficult because these diseases share many clinical features^[1]. When pancreatic cancer cannot be ruled out, laparotomy or pancreatic resection may be performed for patients with AIP. To date, there has been little information on long-term outcomes of patients with AIP treated with surgery. Some reports have described recurrences of AIP and pancreatic insufficiency after surgery^[2-4]. However, there have been only two reports describing infections^[4,5]. To our knowledge, this is the second reported case of liver abscess after surgical treatment of AIP.

CASE REPORT

A 68-year-old man with bronchial asthma visited a neighborhood clinic. The patient began to feel abdominal fullness and decreased appetite in January 2000. After laboratory studies showed liver dysfunction and hyperglycemia, he was referred to our hospital in February 2000. He had no history of malignancy or autoimmune diseases. He was not a drinker. Physical examination showed no abnormal findings. Laboratory studies showed elevated liver enzymes and hyperbilirubinemia: total bilirubin was 34 mg/L (normal, 3-11) and direct bilirubin was 24 mg/L (normal, 0-6). Serum levels of pancreatic enzymes were as follows: amylase, 75 IU/L (normal, 50-200); lipase, 52 IU/L (normal, 8-46); and elastase I, 3900 ng/L (normal, 810-2960). A fasting plasma glucose test and an oral glucose tolerance test indicated diabetes mellitus. Serum levels of gammaglobulin (13.4 g/L) and IgG (14550 mg/L) were not elevated. Serum IgG4 was not examined. Antinuclear antibodies were negative. Serum levels of tumor markers, such as carcinoembryonic antigen and carbohydrate antigen 19-9, were normal. A dynamic computed tomography scan showed swelling of the gallbladder, dilatation of the common bile duct, and slight swelling of the pancreas head (3.5 cm × 3.0 cm) (Figure 1A and 1B). Furthermore, a 2.8-cm-diameter tumor was detected incidentally in the right kidney (Figure 1C). Endoscopic retrograde cholangiopancreatography showed that the main pancreatic duct in the head was irregularly narrowed and that the upstream duct was slightly

Figure 1 Dynamic computed tomography scan showing swelling of the gallbladder and slight swelling of the pancreas head (white arrow) (A). The pancreas body and tail are not swollen (B). A tumor is detected in the right kidney (C).

Figure 2 Endoscopic retrograde cholangiopancreatography showing short irregular narrowing of the main pancreatic duct in the head. The narrowing is less than one third of the length of the main pancreatic duct (white arrowheads).

Figure 3 Percutaneous transhepatic gallbladder drainage. Fluorography through the biliary drainage catheter shows obstruction of the distal common bile duct.

dilated (Figure 2). Contrast agent could not be injected into the common bile duct. Percutaneous transhepatic gallbladder drainage was performed for obstructive jaundice. Fluorography through the biliary drainage catheter showed obstruction in the distal common bile duct (Figure 3). After biliary drainage, the patient underwent laparotomy in March 2000, because pancreatic cancer could not be ruled out and because a malignant renal tumor was suspected. Because wedge biopsy of the pancreas head showed no malignancy, cholecystectomy and choledochoduodenostomy were performed for biliary obstruction. Simultaneously, nephrectomy was performed

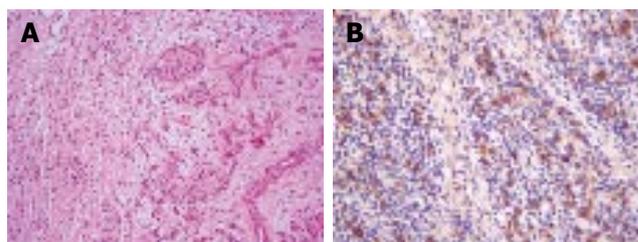

Figure 4 Wedge biopsy of the pancreas head reveals lymphoplasmacytic infiltration and interstitial fibrosis with acinar atrophy (HE x 100) (A). Immunohistologic study shows dense IgG4-positive plasma cell infiltration in peripancreatic lymph nodes (HE x 200) (B).

for the renal tumor. Further histopathologic examination of the pancreas specimen revealed lymphoplasmacytic infiltration and interstitial fibrosis with acinar atrophy (Figure 4A). An immunohistologic study performed 5 years after surgery showed dense IgG4-positive plasma cell infiltration in peripancreatic lymph nodes (Figure 4B). The renal tumor was diagnosed as a renal cell cancer (clear cell carcinoma, stage I).

Seven months after surgery, the patient complained of abdominal discomfort. Serum levels of pancreatic enzymes were markedly elevated: amylase, 621 IU/L; and lipase, 1082 IU/L. A serum level of carbohydrate antigen 19-9 was also elevated to 159.9 IU/mL (normal, 0-37). Dynamic computed tomography showed that swelling of the pancreas progressed from the head to the entire pancreas (Figure 5A and 5B). On the basis of clinical and histopathologic findings, AIP was diagnosed. Treatment with prednisolone of 5 mg per day was started. Thereafter, the symptom disappeared and serum levels of pancreatic enzymes were normalized. The swelling of the pancreas and irregular narrowing of the main pancreatic duct improved (Figure 6). Diabetes also improved.

In February 2005, 5 years after surgery, laboratory studies showed slightly elevated biliary enzymes, but the patient had no symptoms. In April 2005, the patient was admitted because of acute pyrexia in a preshock state. At that time, he had been continuing to take oral prednisolone, 5 mg per day. Laboratory studies showed elevated liver enzymes and an inflammatory response: white blood cell count, $18.9 \times 10^9/L$ (normal, $3.1-9.2 \times 10^9/L$) and C-reactive protein, 288 mg/L (normal, < 5). Blood culture was positive for *Klebsiella pneumoniae*. Ultrasonography and

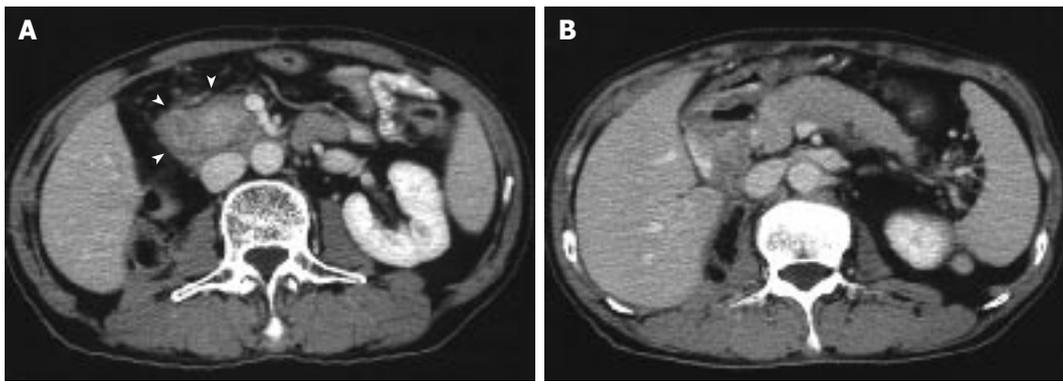

Figure 5 Dynamic computed tomography scan showing swelling of the pancreas head. A capsule-like low-density rim can be seen around the pancreas head (white arrowheads) (A). The pancreas body and tail are swollen (B).

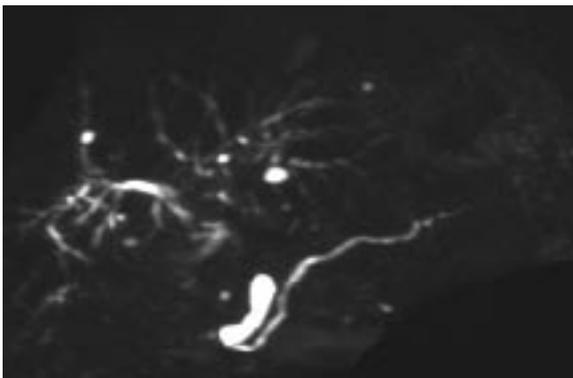

Figure 6 Magnetic resonance cholangiopancreatography performed 4 years after steroid therapy. The narrowing site is resolved in the main pancreatic duct.

computed tomography scan showed a multilocular liver abscess, 5.6 cm × 5.3 cm in size, in the right anteroinferior segment (Figure 7A and 7B). Vasopressor was administered for the preshock state, and percutaneous abscess drainage was performed for the abscess in combination with intravenous administration of cefoperazone/sulbactam at a dosage of 2 g per day. Prednisolone was stopped. A pus culture also showed *Klebsiella pneumoniae*. The patient was discharged after 2 wk of treatment; however, a liver abscess occurred in the left medial segment 1 mo later (Figure 7C), but was successfully treated with antibiotics. Hepatobiliary scintigraphy suggested no decrease of bile flow. The patient has been in good health since the second liver abscess was treated. AIP has not recurred irrespective of cessation of steroid therapy.

DISCUSSION

The clinical entity of AIP was established when Yoshida *et al*^[6] proposed the concept in 1995; however, a worldwide consensus on diagnostic criteria for AIP has not been achieved^[7]. Retrospectively, the present case did not satisfy the diagnostic criteria proposed by the Japan Pancreas Society^[8] at the onset of AIP. However, the results of histopathologic examinations^[9] and the clinical findings after surgery were compatible with AIP. Recent reports have described various AIP cases, such as the present one, in which pathologic changes are not found throughout the pancreas^[5,10-12]. These “focal” and “segmental” types

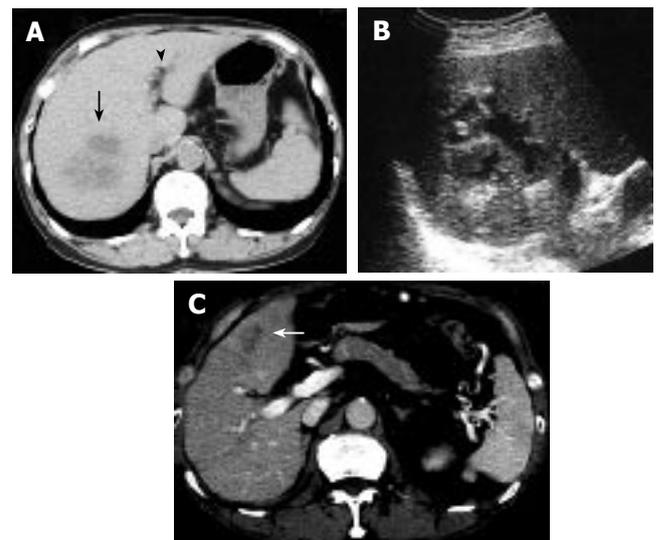

Figure 7 Computed tomography scan showing an abscess in the right anteroinferior segment of the liver (black arrow). Pneumobilia is detected (black arrowhead) (A). Ultrasonography shows partial liquefaction in the abscess (B). Computed tomography scan showing an abscess in the left medial segment of the liver (white arrow) (C). Note that the pancreas is not swollen.

of AIP have been considered to correspond to an early stage of AIP^[10-12]. To avoid unnecessary laparotomy or pancreatic resection, the establishment of definitive diagnostic criteria for AIP is urgent. If AIP is suspected but pancreatic cancer cannot be ruled out by imaging and laboratory studies, endoscopic ultrasonography-guided trucut biopsy may help establish a diagnosis of AIP^[13]. A short course of steroids can also be used to guide diagnosis^[7].

Horiuchi *et al*^[5] reported the first case of AIP associated with liver abscess. This is the second one. It should be noted that liver abscess developed several years after surgical treatment of AIP in both cases. The pathogenesis of liver abscess in the present case remains unclear. The route of infection seemed to be the biliary tract because other routes, such as the portal tract, were unlikely. AIP is often associated with sclerosing cholangitis^[14-16]. Biliary stenosis caused by sclerosing cholangitis or anastomotic stenosis can induce cholestasis, which may cause biliary infection and liver abscess. However, cholestasis was not observed in the present case, suggesting that cholestasis is not a prerequisite for liver abscess formation after surgery.

Furthermore, there have been few reports describing cases of liver abscess after choledochoduodenostomy. The sump syndrome, a complication of side-to-side choledochoduodenostomy, can cause secondary liver abscess^[17]; however, the present patient had undergone end-to-side choledochoduodenostomy before the development of liver abscess. There may be other factors contributing to the development of the patient's liver abscess in addition to duodeno-biliary reflux due to biliary reconstruction.

Putative predisposing factors for infection in patients with AIP are as follows. First, diabetes mellitus, which is often associated with AIP^[18], can compromise patients' defenses against infection. Recent reports have shown that diabetes is present in many patients with pyogenic liver abscess^[19,20]. Second, steroid therapy for AIP can impair immunity. In most patients with AIP and diabetes, steroid therapy improves diabetes; however, in some cases, steroid therapy induces or exacerbates diabetes^[18]. The present patient had been receiving long-term steroid therapy, which improved the diabetes but might have induced an immunocompromised state.

In conclusion, pyogenic liver abscess can occur as a late complication of biliary reconstruction in patients with AIP. Careful follow-up should be performed to allow early detection of such a serious complication in patients with AIP treated with surgery.

Abstract

A 55-year old male patient was diagnosed with strongyloides hyper-infection with stool analysis and intestinal biopsy shortly after his chemotherapy for myeloma. He was commenced on albendazole anthelmintic therapy. After initiation of the treatment he suffered life-threatening gastrointestinal (GI) bleeding. Repeated endoscopies showed diffuse multi-focal intestinal bleeding. The patient required huge amounts of red blood cells and plasma transfusions and correction of haemostasis with recombinant activated factor VII. Abdominal aorto-angiography showed numerous micro-aneurysms ('berry aneurysms') in the superior and inferior mesenteric arteries' territories. While the biopsy taken prior to the treatment with albendazole did not show evidence of vasculitis, the biopsy taken after initiation of therapy revealed leukoclastic aggregations around the vessels. These findings suggest that, in addition to direct destruction of the mucosa, vasculitis could be an important additive factor causing the massive GI bleeding during the anthelmintic treatment. This might result from substances released by the worms that have been killed with anthelmintic therapy. Current guidelines advise steroids to be tapered and stopped in case of systematic parasitic infections as they might reduce immunity and precipitate parasitic hyper-infection. In our opinion, steroid therapy might be of value in the management of strongyloides hyper-infection related vasculitis, in addition to the anthelmintic treatment. Indeed, steroid therapy of vasculitis with other means of supportive care resulted in cessation of the bleeding and recovery of the patient.

INTRODUCTION

Chemotherapy of malignancies as well as immunosuppression of immunological disorders is frequently complicated with severe infections, including bacterial, viral, fungal or parasitic infections. We present here a case of life-threatening gastrointestinal bleeding related to strongyloides hyper-infection as a consequence of chemotherapy for myeloma.

CASE REPORT

A 55-year-old male patient was diagnosed with kappa light chain myeloma stage III-B based on the Salmon-Durei staging system. The patient started chemotherapy according to the VAD protocol^[1,2], consisting of vincristine, doxorubicin and high dose dexamethasone along with zoledronic acid every 4 wk. After he received three full courses of chemotherapy the patient was admitted to the hospital for generalized fatigue, and fever with signs and symptoms of chest infection. Laboratory investigations showed haemoglobin of 105 g/L, white blood cell count of $5.5 \times 10^9/L$ (neutrophils 0.84, lymphocytes 0.11, monocytes 0.02, eosinophils 0.00, basophils 0.00, bands 0.03), and platelet counts of $1.91 \times 10^{11}/L$. His blood chemistry and coagulation profile were within normal limits except a low albumin level of 29 g/L (normal: 35-48 g/L). Chest X-ray showed no obvious abnormality. After obtaining blood and urine cultures ceftazidime therapy was started with an assumption of respiratory tract infection. For the following two days the patient kept a spiking fever which was associated with progressive pulmonary symptoms (dry cough and dyspnea). His oxygen saturation dropped to 90% in room air, and a moderate eosinophilia was observed: neutrophils 0.76, lymphocytes 0.12, monocytes 0.02, eosinophils 0.08, basophils 0.00, bands 0.02. On physical examination he had bilateral wheezes and basal crackles.

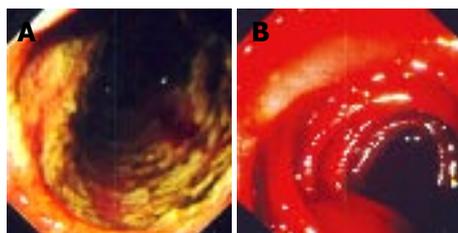

Figure 1 Endoscopic findings. **A:** Extensive confluent necrotic ulcerations of the duodenal mucosa due to chemotherapy related *S. stercoralis* helminthic hyper-infection. **B:** Enteroscopic presentation of diffuse mucosal bleeding during anthelmintic therapy of *S. stercoralis* hyper-infection, aggravated potentially by toxic/inflammatory compounds from destroyed parasites.

The chest X-ray was suspicious of hilar infiltrates at that time. A full cardiac assessment was done, and both ECG and echocardiography were within normal limits.

Subsequent spiral CT scan was not confirmatory for potential opportunistic chest infection, and the antibiotics however were changed to high dose septrin and levofloxacin intravenously. Serology tests for *Legionella*, *Mycoplasma*, hepatitis A, B, C, cytomegalovirus and Epstein-Barr virus were all negative. The blood culture grew staphylococcus and for that reason the portacath of the patient was removed and vancomycin was given. In spite of these managements, the patient's general condition did not improve. He presented soon new symptoms of dysphagia, odynophagia and vomitus, associated with major metabolic disturbances (sodium 117 mmol/L [N: 136-145 mmol/L], albumin corrected calcium 1.84 mmol/L [N: 2.2-2.6 mmol/L], and albumin 21 g/L [N: 35-48 g/L]), all quite resistant to treatment. Many options in the differential diagnosis were considered including inappropriate anti-diuretic hormone secretion (urine and plasma osmolality test and CT of the brain requested) and other endocrine dysfunction (PTH, TSH, free T₄, T₃, cortisol levels investigated). All of these investigations showed no hormonal abnormality.

Possibilities of gastrointestinal (GI) losses were also considered (exudative enteropathies, motility disorders, etc.). Plain abdominal X-ray, barium swallow and esophago-gastro-duodenoscopy (OGD) were completed. OGD showed diffuse confluent necrotic ulcerations in the stomach and the duodenum (Figure 1A). Biopsies were taken and intravenous omeprazole was started. A few days later the patient complained of epigastric pain accompanied with bilious and feculent vomitus. On examination, his abdomen was distended with decreased bowel sounds. A decubitus abdominal X-ray showed multiple fluid levels consistent with paralytic ileus. By this time, stool parasitology (Figure 2) as well as histopathology from both the duodenum (Figure 3A) and the stomach confirmed *Strongyloides stercoralis* helminthic infection with heavily infiltrated intestinal mucosa, but without histology criteria of vasculitis (Figure 3B). The patient received albendazole therapy (400 mg twice daily). Two days later, the patient developed massive GI bleeding with hypovolemic shock and major drop in the haemoglobin (40 g/L) requiring intensive care unit monitoring. His platelet count and coagulation profile were both normal at the first presentation of GI bleeding. Repeat OGD, magnetic resonance imaging study of the

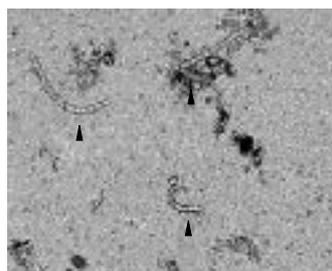

Figure 2 *S. stercoralis* larvae in the stool.

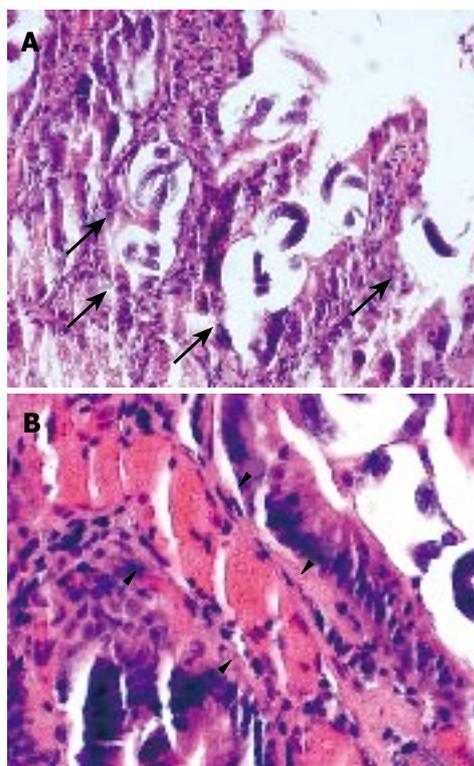

Figure 3 **A:** Intraluminal and intramucosal *S. stercoralis* larvae in the duodenum during the exudative enteropathy hyper-infection phase (arrows). Scale: 200 μ m. **B:** No intramural or peri-vascular inflammatory cell clusters are recognised during this early period of infection. Scale: 50 μ m.

abdomen and pelvis, radio-labelled red blood cell (RBC) nuclear investigations failed to localize a specific site of the bleeding. Colonoscopy was inconclusive due to heavy continuous flow of feculent content mixed with fresh blood from the small intestine. Abdominal aorta angiography showed numerous micro-aneurysms in the superior and inferior mesenteric arteries' territories with segmental strictures on the small intestine, consistent with vasculitis (Figure 4).

With repeated episodes of massive blood loss, during an overnight call an explorative laparotomy was decided on to localize a potentially resectable particular region of the intestine-as a desperate, life-saving procedure. During the procedure an intra-operative intestinoscopy was performed showing diffuse small intestinal bleeding (Figure 1B). No intestinal resection was done. However, as an additional proof of vasculitis at this point, intestinal biopsy revealed leukoclastic aggregations around the vessels of the mucosa (Figure 5). Screening for connective tissue diseases including immunoglobulin levels, rheumatoid factor, anti-

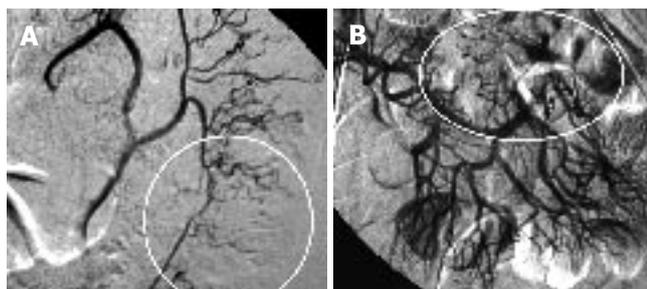

Figure 4 A: Segmental vasospasms (circled area). B: "berry-type" microaneurysms (circled area) in the mesenteric superior and inferior arteries' territory are both suggestive of active vasculitis during the anthelmintic therapy of *S. stercoralis* hyper-infection.

nuclear, anti-smooth muscle, and anti double-strand DNA antibodies was not suggestive of systemic autoimmune disorder. The patient was managed with huge amounts of blood transfusion, fresh frozen plasma, tranexamic acid (Cyklokaprone[®]), somatostatin, and, to correct secondary coagulopathy, with recombinant factor VIIa (Novoseven[®]). In addition, he was given antibiotics, anthelmintic drugs (albendazole and ivermectin) and steroids (dexamethasone). He required more than 120 units of RBC transfusion and 16 doses of Novoseven[®]. After 10 d of intensive support the bleeding gradually subsided. Stool analysis became repeatedly negative for strongyloides. An endoscopy was carried out 20 d later and showed complete recovery of the mucosa on review as well as on histopathology.

DISCUSSION

Strongyloidiasis is a worldwide infection, caused by the nematode *Strongyloides stercoralis* helminth^[3]. This thread-worm spreads in poorly sanitized areas from moist soil. It is endemic in the tropical Asia, Africa, Latin America, Southern US and Eastern Europe. In Southeast US its prevalence is as high as 4%^[4,5]. Chronic infection with *S. stercoralis* is usually asymptomatic, but it may manifest with symptoms such as episodic creeping urticaria, epigastric crampy abdominal pain, or diarrhea. Myeloma, as well as its chemotherapy can interfere with the immune competence of the patients. In addition to more frequent bacterial, viral and fungal infections, disseminated parasitosis may develop in such situations. There is remarkable absence of cellular immune response to these invaders specifically eosinophilia^[4]. In case of *Strongyloides stercoralis*, steroids may not only affect the host's cellular immunity, but also mimic an endogenous parasitic-derived regulatory hormone^[5,6]. *Strongyloides* were noticed to produce more eggs in the presence of exogenous steroids. Due to immunosuppressant therapy, there is a larger proportion of the rhabditiform larvae which mature into the filariform larvae within the host. This leads to a greater larval load and disseminated hyper-infection^[5,7]. Secondary bacterial infections are also frequent complications of dissemination phase. Pulmonary symptoms of our patient at his post-chemotherapy admission to the hospital are likely to be related to pulmonary migration of the larvae during the dissemination phase.

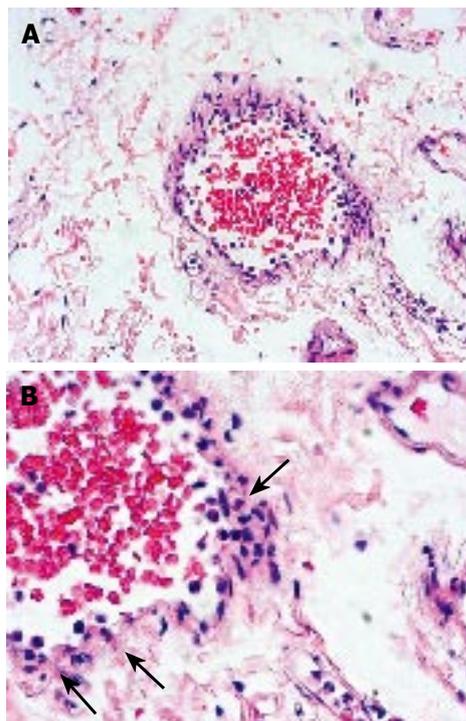

Figure 5 Perivascular granulocytic infiltration in the mucosa during the anthelmintic therapy of *S. stercoralis* hyper-infection is also suggestive of active vasculitis. Scale: A: 200 µm; B: 50 µm.

In hyper-infection syndrome, complete disruption of the GI mucosa, ulcerations, paralytic ileus with exudative enteropathy as well as massive GI bleeding may also occur due to the direct invasion of the larvae. Profound diarrhea, malabsorption with consequent hypo-albuminemia and electrolyte disturbances were all consistent with hyper-infection related enteropathy in our patient. On the other hand, effective anthelmintic treatment in hyper-infected patients can lead to mass-destruction of intraluminal and intramural larvae and to release of huge amounts of different toxic inflammatory and vaso-active compounds^[7,8]. Angiography and histopathology findings after initiation of albendazole therapy were consistent with active vasculitis in our patient, caused potentially by such compounds. For that reason we decided to maintain steroid therapy instead of rapid tapering and discontinuation of it, as advised by some experts. In our opinion, vasculitis due to helminth-derived inflammatory factors might contribute to mucosal disruption and massive GI bleeding. Steroids might reduce inflammation in such situation. Anthelmintic treatment and supportive management with transfusions of blood products and parenteral nutrition were also maintained until no more larvae could be detected in the stool. Finally, we have to emphasize the heroic multi-disciplinary efforts that led to a complete recovery of this 55 year old patient with strongyloides hyper-infection related life-threatening gastrointestinal bleeding.

Abstract

Cavernous hemangiomas of the colon and liver in a 38-year-old woman presenting with a history of cramp like abdominal pain and a mass in the right iliac fossa are presented. Abdominal ultrasonography and computed tomography demonstrated multiple liver hemangiomas as well as a noncystic lesion in the right iliac fossa. Operative findings were suggestive of diffuse hemangiomas of the right colon and an extensive right hemicolectomy was performed. A review of the literature is presented, considering current diagnostic and therapeutic methods.

INTRODUCTION

Hemangiomas constitute 7% of all benign vascular tumors and are characterized by increased numbers of normal or abnormal vessels filled with blood and are usually localized; however, when they involve a large number of organs in the body the situation is called angiomatosis or hemangiomas^[1]. Although a variety of histological and clinical types of hemangiomas exist, capillary and cavernous subtypes are most frequently encountered. Cavernous hemangiomas of the colon is uncommon. However, the case reported in this study presents the hemangiomas of

the colon and the liver, a situation rarely reported.

CASE REPORT

A 38-year-old female patient presented with a 2-mo history of cramp like abdominal pain and radiating ipsilateral lumbar pain, without any rectal passage of blood. The physical examination did not reveal any specific signs. The abdominal ultrasound revealed multiple liver lesions measuring 10 mm × 23 mm each and the computed tomography demonstrated a large non-cystic lesion in the right iliac fossa, as well as multiple small liver lesions with heterogeneous enhancement (Figure 1). Operative findings were suggestive of right colon diffuse hemangiomas, innumerable mesenteric and multiple small liver hemangiomas. An extensive right hemicolectomy and end-to-end ileo-transverse anastomosis was carried out.

A specimen of a right hemicolectomy was sent to the Pathology Department, presenting grossly as a reddish-hemorrhagic tumor at the ileo-colic valve level, measuring 4 cm × 5 cm (Figure 2). The tumor had a sponge-like consistency and infiltrated the entire wall thickness extending in to the surrounding fatty tissue. The mesocolic and mesenteric fat, as well as the greater omentum, presented multiple hemorrhagic nodules measuring 0.6-1 cm in greater diameter. The specimen was subjected to routine procedures and multiple histological sections, stained with hematoxylin-eosin, were studied microscopically (Figures 3 and 4). The diagnosis of diffuse cavernous hemangiomas of the colonic and enteric wall with concomitant lymphangiectatic lesions of the submucosa and infiltration of the mesocolic and mesenteric fat and the greater omentum was decided.

DISCUSSION

Hemangiomas of the colon is a rare benign disease arising from the submucosal vascular network. According to the literature these lesions originate from embryonic sequestrations of mesodermal tissue^[2]. Histologically, hemangiomas are distinct from telangiectasias and angiodysplasias and approximately 80% of colonic hemangiomas are of the cavernous subtype. Capillary hemangiomas are usually solitary and produce no symptoms, while cavernous hemangiomas composed of large thin-walled vascular channels, have no capsule, involve the rectosigmoid region in up to 70% of the cases and present with rectal bleeding (60%-90%), anemia (43%), obstruction (17%) and rarely with platelet sequestration, although approximately 10%

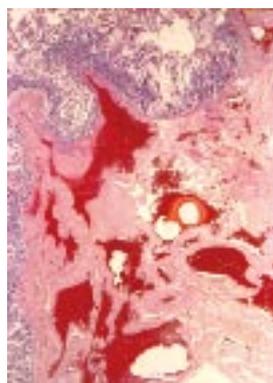

Figure 4 Histological section of colonic wall showing multiple hyperemic angiomatous spaces in the muscular layer (HE x 25).

of patients remain asymptomatic^[3]. A rare case of intussusception in a 39-year old male due to a capillary hemangioma of the right colon has been reported in the literature as a rare complication of colon hemangiomas^[4]. The average age of the patient at presentation is 12 years, equally affecting males and females^[2]. A case report of a 3-mo old infant presenting with ascites, anemia, minimal rectal bleeding and thrombocytopenia due to several hundred small cavernous hemangiomas of the colon and peritoneal surfaces who underwent subtotal colectomy^[5] and a 9-mo old child with an isolated colonic cavernous hemangioma of the hepatic flexure^[6], as well as a 3-wk old boy with diffuse hemangiomatosis of the small bowel^[7] are some of the youngest cases reported from the review of the literature. Up to 80% of patients undergo an unnecessary surgical procedure before diagnosis is made^[8], with an average delay time of 19 years elapsed between initial symptoms and diagnosis. Hemangiomatosis affecting the right colon is rather a rare case and from the review of the English literature fewer than 10 cases have been reported since 1950^[4,6,9-12]. Liver and bladder involvement seems to be unusual as well^[13,14]. The presence of phleboliths on plain abdominal radiographs is an important diagnostic clue, seen in 26%-50% of adult patients, indicating a sequential process of thrombosis in the tumor caused by perivascular inflammation and stasis of blood flow^[15]. In our patient no phleboliths were demonstrated on plain abdominal radiographs. Barium enema reveals non specific polypoid or multilobular masses that collapse with air insufflation. Endoscopically, a bluish, soft, submucosal polypoid mass consistent with widened varices usually indicates the pres-

ence of a hemangioma. Mesenteric angiography shows hypervascularity and delayed venous pooling associated with cavernous hemangiomas. Abdominal CT scans can give useful information about the size of the lesion and the extension to adjacent organs. Recently, three dimensional CT colonography was used to gain a more complete knowledge of the characteristics and distribution of lesions throughout the colon^[9]. Complete surgical resection is the definitive therapy, although (1) a pedunculated polypoid hemangioma (2) less or equal to 2.5 cm, with (3) an endoscopic ultrasonography demonstrating that the depth is limited in the submucosal layer are the three major criteria for endoscopic polypectomy^[16]. In conclusion, a high suspicion index is required when a young patient presents with abdominal pain, painless rectal bleeding, phleboliths in plain radiographs or heterogeneous masses in CT, in order to approach a definite diagnosis before planning any therapeutic intervention.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents[®]/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch[®]) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology

Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China

E-mail: wjg@wjgnet.com

<http://www.wjgnet.com>

Telephone: +86-10-85381901

Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5

line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

Key words

Please list 6-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P*<0.05, ^b*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, ^c*P*<0.05 and ^d*P*<0.01 are used. Third series of *P* values can be expressed as ^e*P*<0.05 and ^f*P*<0.01. Other notes in tables or under

illustrations should be expressed as ¹F, ²F, ³F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (<http://www.wjgnet.com/cgi-bin/index.pl>), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 µg/L; CO₂ volume fraction, 50 mL/L CO₂ not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please download CAF from <http://www.wjgnet.com/wjg/help/9.doc>.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to *WJG* all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The *WJG* requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1) direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3) supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The *WJG* does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to *WJG* if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Final check list for authors

The format is at: <http://www.wjgnet.com/wjg/help/13.doc>

Responses to reviewers

Abstract

AIM: To identify genes differentially expressed in mouse hepatocarcinoma ascites cell line with low potential of lymphogenous metastasis.

METHODS: A subtracted cDNA library of mouse hepatocarcinoma cell line with low potential of lymphogenous metastasis Hca-P and its syngeneic cell line Hca-F with high metastatic potential was constructed by suppression subtracted hybridization (SSH) method. The screened clones of the subtracted library were sequenced and GenBank homology search was performed.

RESULTS: Fifteen differentially expressed cDNA fragments of Hca-P were obtained with 3 novels.

CONCLUSION: Tumor metastasis is an incident involving multiple genes. SSH is a useful technique to detect differentially expressed genes and an effective method to clone novel genes.

Cui XN, Tang JW, Hou L, Song B, Ban LY. Identification of differentially expressed genes in mouse hepatocarcinoma ascites cell line with low potential of lymphogenous metastasis. *World J Gastroenterol* 2006; 12(42): 6893-6897

<http://www.wjgnet.com/1007-9327/12/6893.asp>

INTRODUCTION

Tumor metastasis is an incident involving multiple genes. However, the number of metastasis related genes available nowadays is very limited to elucidate the puzzling process of metastasis. Therefore, more attentions have been paid to screen candidate genes responsible for metastasis by high throughput technique. Hca-P and Hca-F are a pair of syngeneic mouse hepatocarcinoma ascites cell lines, possessing a specific potential of lymphogenous metastasis when inoculated subcutaneously into 615 mice, Hca-P showing a low metastatic potential (< 30%), while Hca-F showing a high potential (> 80%)^[1]. In the current study, we employed suppressive subtracted hybridization (SSH) technique to identify differentially expressed genes specific for Hca-P in an effort to obtain candidate genes related to lymphogenous metastasis of hepatocarcinoma in mice.

MATERIALS AND METHODS

Hca-F and Hca-P have been established and maintained by our laboratory^[1]; inbred 615-mice were provided by the experimental animal center of our university.

Determination of lymph node metastatic rates of Hca-P and Hca-F

Sixty inbred 615-mice were randomly divided into 2 groups. The Hca-P and Hca-F tumor cell lines were inoculated at 2×10^6 tumor cells of approximately 0.1 mL cell suspension into each mouse subcutaneously in each group. The mice were decapitated on the 28th day post-inoculation. The implanted tumor and the regional lymph nodes were removed and paraffin sections of tissues were HE stained and examined under microscope. The lymph node metastatic rates of Hca-F and Hca-P tumor cells were calculated.

Construction of a subtracted cDNA library by SSH

Preparation of total RNA and mRNA: Isolation of total RNA was performed by TRIZOLTM(GIBCOBRL) and that of mRNA was carried out according to the protocol of oligotex mRNA spin column purification kit (Qiagen). The quantity and integrity of mRNA were detected by ultraviolet spectrometer and by electrophoresis on a denaturing formaldehyde agarose stained by EB. mRNA of Hca-P served as tester and mRNA of Hca-F

as driver. SSH was performed between tester and driver by a PCR selectTM cDNA subtraction kit and 50 × PCR enzyme kit (Clontech, Heidelberg, Germany) following the instructions of the manufacturer.

dscDNA synthesis and digestion with *Rsa* I: Briefly, 2 μg aliquots of each of poly (A⁺) mRNA from the tester and the pooled driver were subjected to dscDNA synthesis. Thereafter, they were purified by passing through Chroma spin-400 columns (Clontech, USA). Each purified dscDNA was digested with *Rsa* I.

ligation to adaptor 1 and 2R: The tester cDNAs were subdivided into 2 equal groups and then ligated to adaptor 1 and 2R in separate ligation reactions. Ligation efficiency analysis was performed by amplifying ligation products with G3PDH 3' primer/PCR primer 1 and G3PDH 3' primer/G3PDH 5' primer, respectively, and their intensity was compared.

Subtractive hybridization: Subtractive hybridization was performed by annealing an excess of driver cDNAs with each sample of adaptor-ligated tester cDNAs. The cDNAs were heat-denatured and incubated at 68°C for 8 h. After the first hybridization, the 2 samples were mixed together and hybridized again with freshly heat-denatured driver cDNAs for 20 h at 68°C. Two rounds of hybridization would generate a normalized population of tester-specific cDNAs with different adaptors at each end. After filling in the ends, 2 rounds of PCR amplification were performed to enrich desired cDNAs containing both adaptors by exponential amplification of these products^[2]. The optimized cycles for the first and second PCRs were 27 and 13 respectively to increase representation and reduce redundancy of subtracted cDNA libraries.

Analysis of subtractive efficiency: Secondary PCR products were used as templates for PCR amplification of human G3PDH for 18, 23, 28 and 33 cycles respectively to assure subtraction efficiency. PCR products were run on 1.8% agarose gel.

Ligation of the subtracted library into a TA vector

Products of the secondary PCR reactions were cloned into a pT Adv vector (Clontech) and the resultant ligation products were then transformed into DH5α *E. coli* competent cells. The bacteria were subsequently grown in 800 μL of liquid Luria-Bertani medium and allowed to incubate for 45 min at 37°C with shaking at 150 rpm. Thereafter, the cells were plated onto agar plates containing ampicillin (50 μg/mL), 5-bromo-4-chloro-3-indoly-b-D-galactoside (x-gal; 20 μg/cm²) and iso-plopr-b-D-thiogalactoside (IPTG; 12.1 μg/cm²) and incubated overnight at 37°C. Individual recombinant white clones were picked and grown in single line pattern onto Luria-Bertani agar solid medium containing ampicillin and allowed to incubate at 37°C for 6-7 h before single clone was picked from single-line pattern agar medium and allowed to grow in Luria-Bertani liquid medium containing ampicillin overnight at 37°C with shaking at 150 rpm.

Identification of the subtracted clones

Plasmids of candidate positive clones from subtracted cDNA library were isolated and amplified by PCR with

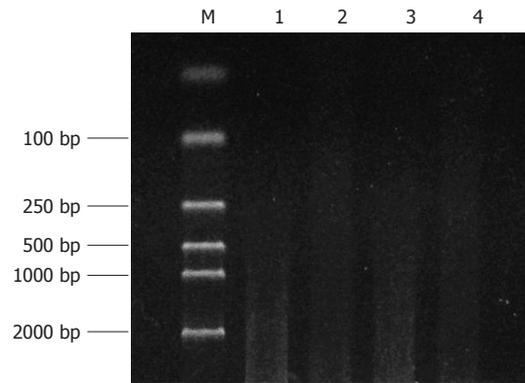

Figure 1 The effect of *Rsa* I digestion. Lane 1, 3: cDNA of Hca-F and Hca-P cells; Lane 2, 4: cDNA of Hca-F and Hca-P cells after *Rsa* I digestion; M: DNA Marker DL2000.

nested primer 1 and primer 2. Meanwhile the product of PCR was detected by agarose gel electrophoresis.

Sequencing and BLAST homology search

Randomly screened 14 positive clones from the subtracted cDNA library were sequenced by T7/SP6 chain termination reaction in TaKaRa (DaLian, China). Nucleic acid homology searches were subsequently performed at the National Center of Biotechnology Information (National Institutes of Health, Bethesda, Md., NCBI).

RESULTS

Determination of lymph node metastatic rates of Hca-P and Hca-F

Implanted tumors of both Hca-P tumor-bearing mice and Hca-F tumor-bearing mice were palpable on 7th day post-inoculation. On the 28th day post-inoculation, 10% Hca-P cells bearing mice developed metastatic regional lymph nodes (3/30), while 80% Hca-F cells bearing mice developed metastatic regional lymph nodes (24/30).

Total RNA and mRNA analysis

The RNA samples electrophoresed on 1% agarose/EB gel exhibited 2 typical bands, corresponding to ribosomal 28s and 18s RNA, respectively, with a ratio of intensities > 2:1 and 1.9, ideal A260/A28 ratios of both samples obtained, indicating high integrity and purification of the total RNA we obtained. mRNA samples appeared as a smear with weak ribosomal RNA band: a high-quality mRNA was purified.

Rsa I digestion

Both the digested cDNA and undigested cDNA usually presented as smears. However, their patterns were different. The digested cDNA fragments became shorter after *Rsa* I digestion (Figure 1).

Ligation efficiency analysis

Intensity of the PCR product amplified using one gene-specific primer (G3PDH 3' primer) and PCR primer 1 was 25% more than that of PCR product amplified using two

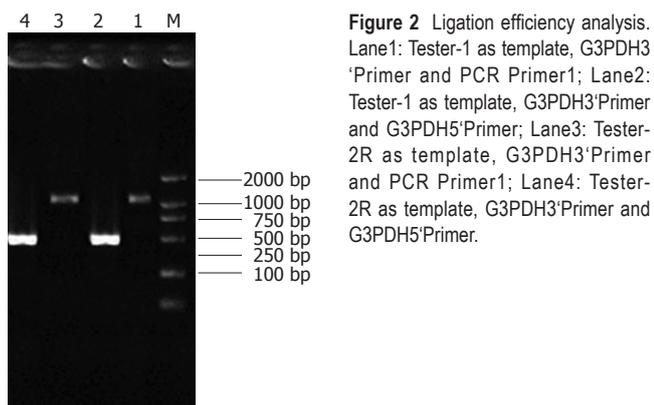

Figure 2 Ligation efficiency analysis. Lane1: Tester-1 as template, G3PDH3'Primer and PCR Primer1; Lane2: Tester-1 as template, G3PDH3'Primer and G3PDH5'Primer; Lane3: Tester-2R as template, G3PDH3'Primer and PCR Primer1; Lane4: Tester-2R as template, G3PDH3'Primer and G3PDH5'Primer.

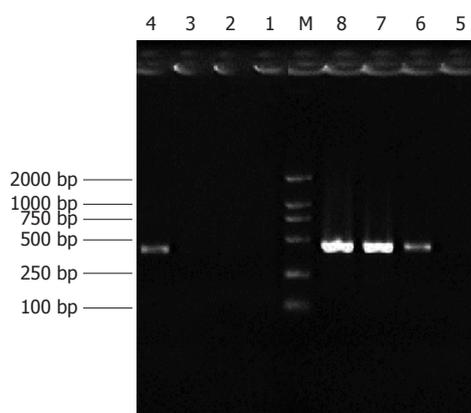

Figure 4 Analysis of subtraction effect. PCR was performed on subtracted(Lane1-4) or unsubtracted(Lane5-8) secondary PCR product with G3PDH 5'Primer and 3' primer. Lane1, 5: 20 cycles, Lane 2, 6: 25 cycles, Lane 3, 7: 30 cycles, Lane 4, 8: 35 cycles. M: DNA Marker DL2000.

gene-specific primers (G3PDH 3' primer and 5' primer). Ligation efficiency was > 25%, ensuring enough tester cDNA in the following hybridization (Figure 2).

Construction of subtracted cDNA library by SSH

PCR products of the subtracted and unsubtracted usually looked like smears with or without discrete bands. However, the patterns between them were different (Figure 3).

Analysis of subtractive efficiency

Subtraction efficiency analysis showed the effectively reduced amount of non-differentially expressed genes. In unsubtracted cDNA libraries, housekeeping gene G3PDH PCR products were visible after 23 cycles of amplification and became saturated after 23-28 cycles. However, subtracted libraries required 33 cycles for G3PDH to be detected (Figure 4).

Differential screening of subtracted cDNA libraries

The subtracted cDNA libraries were composed of 995 positive clones, of which 200 clones were randomly picked up and plasmids of the candidate positive clones were isolated and amplified by PCR with nested primer 1 and primer 2. As a result, 189 positive clones showed PCR products of a size of 300-1000 bp (Figure 5).

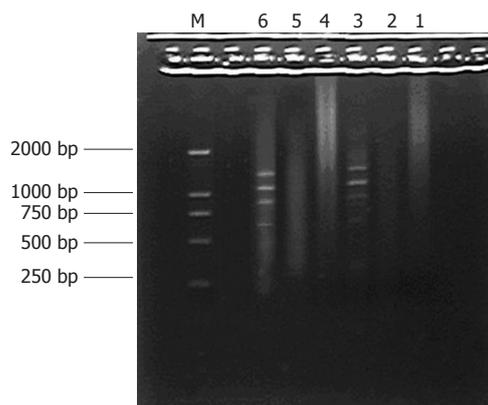

Figure 3 The results of secondary PCR amplification. Lane 1-3: Product of primary PCR amplification, Lane 4: secondary PCR amplification product of PCR control cDNA, Lane5: secondary PCR amplification product of unsubtracted cDNA, Lane6: secondary PCR amplification product of subtracted cDNA, M: DNA Marker DL2000.

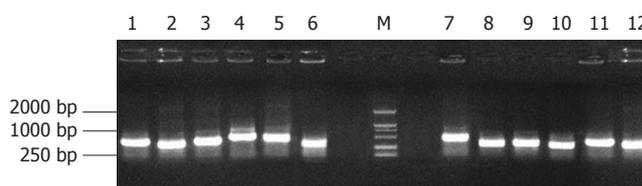

Figure 5 The results of clone PCR amplification, There was a average insert size of 300-1000 bp.

Sequencing and homology search

Fifteen screened clones randomly selected were sequenced and homology search (<http://www.ncbi.nlm.nih.gov/BLAST/>) revealed 8 known genes and 4 expressed sequence tags (ESTs). Three cDNAs showed no homology and presumably represented novel genes (Table 1).

DISCUSSION

Tumor metastasis, as the leading cause of tumor related death, is a process involving multiple genes and their products. Elucidation of the gene expression profiles specific for tumor cells with different potential of metastasis might help in the understanding of the molecular mechanisms of metastasis. As one of the high throughput screening techniques, SSH technique has two distinct advantages: (1) it boasts a high subtraction efficiency; (2) it harbors an equalized representation of differentially expressed sequences which can separate effectively both high and low copy expressed genes mainly because of normalization^[2]. von Stein *et al.*^[3] found about 94% positive rate in their research. Thus they considered confirmation of differentially expressed genes by Northern blot analysis for each clone obtained was probably unnecessary.

For a long time, studies have focused on the angiogenesis of tumors, but the roles of lymphatic vessels in tumor growth and metastasis were neglected. However, it is well known that lymphatic metastasis is mainly responsible for the spread of epithelial malignant tumors,

Table 1 Homologue searching of the sequenced cDNA fragments from SSH library

Clone serial number	Size (bp)	Sequence identity
1-3	508	Mus musculus Telomere repeat binding factors TRF1
3-5	543	Mus musculus Telomere repeat binding factors TRF2,
9-6	489	Mus musculus maspin
15-4	335	mouse chromosome 3 clone RP 6-126M1
11-7	386	mouse 7 d embryo whole body cDNA RIKEN full-length enrich library, clone 2210102k3
16-3	503	mouse 5 d liver cells cDNA RIKENfull -length library enriched library, clone E330462F4
10-1	549	mouse chromosome 17 clone RP 26-122M3
13-7	502	mouse chromosome 4 clone RP13-110N10
9-8	340	EST-mouse
6-6	411	EST-mouse
11-2	390	EST-mouse
20-9	399	EST-mouse
23-3	470	unknown
17-6	486	unknown
12-3	344	unknown

and is closely related to the prognosis of patients.

Hca-P and Hca-F are a pair of synogenetic mouse hepatocarcinoma ascites cell lines presenting a specific potential of lymphogenous metastasis with a significant difference in their potential of metastasis^[1]. Candidate genes involved in lymphogenous metastasis are supposed to be among the differentially expressed genes.

Using Hca-P as tester, Hca-F as driver, we employed SSH technique to identify differentially expressed genes specific for Hca-P (low metastatic potential) so as to obtain candidate suppressor genes of lymphogenous metastasis. Fifteen screened clones randomly selected were sequenced and homology search revealed 8 known genes as TRF₁, TRF₂ (telomere repeat binding factor 1, 2); maspin; mouse 7 days embryo whole body cDNA, RIKEN full-length enriched library clone 2210102k3; mouse 5 days liver cells cDNA, RIKEN full-length enriched library, clone E330462F4; mouse chromosome 3 clone RP 6-126M1; mouse chromosome 17 clone RP 26-122M3 and mouse chromosome 4 clone RP13-110N10. Studies showed TRF₁, and TRF₂ play important roles in genome stabilization^[4-11] and are down-regulated in some malignant cell lines and tumor tissues^[12-18]. In hematopoietic carcinogenesis, gene expression of telomerase suppressors such as TRF and TIN2, is decreased. mRNA encoding TRF₁ and TRF₂ when gastric cancer becomes more deeply invaded, is significantly decreased, indicating a negative association with tumor progression. Of the 8 known fragments, one showed high homology to mouse Maspin gene. Serving as one of the few p53-targeted genes involved in tumor invasion and metastasis, Maspin, a member of the serpin family, has been reported to suppress metastasis and angiogenesis in breast and prostate cancers, and is closely correlated with their clinical manifestations^[19-31]. It indicates that SSH in our study is capable of enriching metastasis related genes.

Another 5 known fragments were attributed to embryo

genes. Embryo genes AFP and CEA are overexpressed in hepatocarcinoma and other malignant tumors, indicating a possible association between embryo development and tumor. Embryo genes were also found in our previously established SSH library which contains candidate tumor metastasis genes^[32]. These data showed that up-regulated expression of embryo genes during metastasis is not a casual event. Their roles in tumor metastasis need to be clarified. Moreover, 4 cDNA fragments demonstrated homology with 4 ESTs-mouse and 3 cDNA fragments showed no homology and presumably represented novel genes^[33].

In summary, the findings of our study suggest that the lymphatic invasiveness of tumor cells is determined by multiple genes and co-factors with complex cellular signal pathways. Further functional study of the candidate novel genes might provide clues to molecular mechanism of tumor metastasis.

Abstract

The facts that *H pylori* infection is commoner in duodenal ulcer (DU) patients than in the normal population, and that eradication results in most cases being cured, have led to the belief that it causes DU. However, early cases of DU are less likely than established ones to be infected. *H pylori*-negative cases are usually ascribed to specific associated factors such as non-steroidal anti-inflammatory drugs (NSAIDs), Crohn's disease, and hypergastrinaemia, but even after excluding these, several *H pylori*-negative cases remain and are particularly common in areas of low prevalence of *H pylori* infection. Moreover, this incidence of *H pylori* negative DU is not associated with a fall in overall DU prevalence when compared with countries with a higher *H pylori* prevalence. In countries with a high *H pylori* prevalence there are regional differences in DU prevalence, but no evidence of an overall higher prevalence of DU than in countries with a low *H pylori* prevalence. There is no evidence that virulence factors are predictive of clinical outcome. After healing following eradication of *H pylori* infection DU can still recur. Medical or surgical measures to reduce acid output can lead to long-term healing despite persistence of *H pylori* infection. Up to half of cases of acute DU perforation are *H pylori* negative. These findings lead to the conclusion that *H pylori* infection does not itself cause DU, but leads to resistance to healing, i.e., chronicity. This conclusion is shown not to be incompatible with the universally high prevalence of DU compared with controls.

Hobsley M, Tovey FI, Holton J. Precise role of *H pylori* in duodenal ulceration. *World J Gastroenterol* 2006; 12(40): 6413-6419

INTRODUCTION

The award of the Nobel Prize to Warren and Marshall for the discovery of *H pylori*^[1] was rightly acclaimed by the medical profession, because the eradication of the organism turns a chronic, relapsing disease into one that in most (but not all) cases can be readily cured. The prevalence of infection with the organism is greater in patients with, than in subjects free of, duodenal ulcer; the organism is present in most (but not all) cases of the disease; and its removal results in most (though not all) cases being cured without relapse. The inference usually drawn from this combination of events is that *H pylori* actually causes duodenal ulcer.

In that case, why do most individuals infected with the organism not develop the disease? There has been considerable work done exploring the concept that the presence or absence of virulence factors explains this anomaly, but in a recent publication^[2] we explain why we do not find this hypothesis convincing.

This unsatisfactory situation, the facts that most patients with infection do not have a duodenal ulcer, that, geographically, duodenal ulcer prevalence is not related to the prevalence of *H pylori*, and many other anomalies, has been highlighted in several review articles, such as *H pylori*: the African Enigma^[3]. The enigma is two-fold: firstly, that DU prevalence is not higher in countries with a higher prevalence of *H pylori* infection, secondly, that within these countries, despite an uniformly high *H pylori* prevalence, regional differences in DU prevalence are found, that as described later, are related to diet but not to smoking, genetic or other factors.

Our continuing search for an explanation of the anomalies led us to review all the papers that provide evidence about the following: (1) Is *H pylori* infection present at the onset of DU? (2) Is there a dose-response relationship between *H pylori* and DU? (3) Does recurrence or non-recurrence of DU after successful treatment correlate with *H pylori*-status? (4) Can we deduce anything of importance from the prevalence and distribution of *H pylori*-negative DU?

The present paper analyses the evidence of the literature on these subjects and we show how the higher prevalence of *H pylori* in DU than in the normal population and some of the other anomalies can be explained by a self-consistent theory, but only by relinquishing the belief

that *H pylori* causes DU.

To the best of our knowledge, no paper has been published that contradicts statements in this review. We shall be obliged to readers for letting us know about any exceptions that we have missed.

Is *H pylori* infection present at the onset of DU?

One is entitled to expect that the cause always precedes its effect. The problem with duodenal ulceration is that the patient usually presents to the physician some time after the symptoms start: it is unlikely that evidence of infection has been sought before the symptoms began. It occurred to us to examine the *H pylori*-status of patients with duodenal ulcer in relation to the length of history before the initial biopsy that established the diagnosis of DU. Assuming the organism was the cause of the ulcer, we expected the infection to be manifest at least as often in the first six months as it was more than six months after symptoms started. We studied 37 patients: to our surprise, 5 whose history was of less than six months were *H pylori*-negative, the remaining 32, all with a length of history greater than six months, were *H pylori*-positive. The odds against this happening by chance were (Fisher's exact test) greater than 1000 to 1^[4]. It looked as though the DU was causing the infection, rather than the other way about.

Searching the literature at that time (2001), we could find only one paper that gave figures for infection status, distinguished by different lengths of history^[5]. Repeating the search in 2005, we were only able to find one further paper with the appropriate data^[6]. Both these papers showed a higher infection rate later compared with earlier in the ulcer disease.

There are two reports^[7,8] which suggest that pre-existing *H pylori* infection predisposes to DU based on seropositivity. The first paper refers to young inductees into the Israeli army and the second to an older population in Hawaii. In the first paper it is noteworthy that 7 of the 29 reported DU cases were *H pylori*-negative at the time of diagnosis. However, seropositivity does not mean that infection is present. After eradication, it can take 5-10 years for seropositive cases to become seronegative. Many children serorevert after childhood infection and in adults the conversion/reversion rates per annum vary between 0.5% and 1%. An approach along these lines therefore lacks scientific reliability.

Dose-response relationship?

The smallest dose is zero. Many patients develop a DU in the absence of infection with *H pylori*. This fact is usually explained by invoking 'special' causes of DU such as Zollinger-Ellison syndrome and non-steroidal anti-inflammatory agents (NSAIDs) (see later), but such causes are not always apparent.

Before the *H pylori* era, excess gastric hydrochloric acid was the favoured aetiology of DU. 'No acid, no ulcer' has been dogma since Schwartz^[9], and there has been no contrary evidence. However, acid is 'statistically' greater than the normal range in only about 15% of (patients with) DU, the rest having acid in the normal range^[10], albeit with a tendency to be greater than in the normal

population.

In many countries there is no information about the actual prevalence of DU in the overall population, and available information is based on figures obtained from hospital statistics or small population surveys. From information that is available, there is no evidence that there is a higher overall prevalence of DU in those countries where there is a higher prevalence of *H pylori* infection than in other countries. There is evidence from India, China and Africa, however, of differences in DU prevalence between areas known to have a high prevalence of *H pylori* infection^[3,11-18] these differences being related to the staple diets of the regions^[15-24] rather than to smoking, genetic or other factors such as duodenal gastric metaplasia. There is evidence that different foods contain agents that are either ulcerogenic or ulceroprotective^[24-27].

In developed countries, where *H pylori* prevalence is about 35% overall, DUs are about 70% *H pylori*-positive^[6,28-38]; in developing countries, *H pylori* prevalence is about 70% overall, and DUs are *H pylori*-positive in about 90% of patients^[16,28,29,39-50]. Therefore in all countries *H pylori*-positivity is greater in DU than in non-DU. With reference to further discussion, it is notable that in areas of low *H pylori* prevalence there is a high prevalence of *H pylori*-negative, non-NSAID, ulcers^[4,6,16,28,29,34,38,39,51-63].

As mentioned above there is no evidence that the prevalence of DU is any greater in countries with a high prevalence of *H pylori* than in those with a low prevalence (this finding in itself argues against *H pylori* being the prime cause of DU). The prevalence of DU in London is about 11%^[10]. Applying this figure to other developed countries, from the figures quoted previously in every 100 of the population, 35 are *H pylori*-positive and 65 *H pylori*-negative. There are 11 patients with DU, of whom perhaps only one is *H pylori*-negative, so only 10 of the 35 *H pylori*-positive subjects get DU. The remaining 25 (25/35, 71%) do not. A similar argument in the developing countries (again assuming an 11% prevalence) yields an estimate that only 10 of the 70 *H pylori*-positive subjects get DU. The remaining 60 of the 70 (86%) do not. The belief that *H pylori* is the prime cause of DU demands an explanation of why in 71%-86% of individuals it does *not* produce a DU.

Weight of infection can be measured by use of the breath test, but no-one has suggested that the greater the weight of infection, the greater is the risk of developing DU. However, there is excellent evidence that the risk of developing DU increases with the rate at which the subject secretes gastric juice when maximally stimulated with intravenous histamine^[10]. The *H pylori*-lobby suggests that we cannot demonstrate a dose-relationship of DU with *H pylori* because only some strains of the organism possess virulence factors (of which many have been reported). It is beyond the scope of this paper to go into that topic, but there is considerable evidence that virulence factors have no relationship to clinical outcome^[2].

Does recurrence of DU correspond with *H pylori*-status?

The answer is, apparently not very well. Ulcers heal with effective medical suppression of acid without eradication

of *H pylori*^[64,65], and after surgical procedures ulcers remain healed despite persistent *H pylori* infection^[66-75].

When *H pylori* was discovered and the first results came in about the effect of its extirpation, it was claimed that removing *H pylori* 'cured' the disease and that relapses never occurred. As time passed that picture had to be modified: there is no doubt that relapses are much less frequent and many patients have no further trouble, but there is increasing evidence of a significant recurrence rate after eradication of *H pylori* despite lack of recurrence of the infection. Excluding subjects taking NSAIDs, 9 papers, involving 2928 DU patients in whom *H pylori* had been eradicated as proven by multiple tests, reported recurrent ulceration in 182 (6.1%) over a period up to 5 years^[76-84]. One meta-analysis by Laine of 7 trials subjected to strict criteria reports a recurrence rate of 20% within 6 mo^[81]. Interestingly, a recurrence rate of 6.6% (571/8693) up to 2 years is given in 12 papers (including 6 meta-analyses)^[76,84-96] involving 8693 cases of DU, not excluding NSAIDs, in whom *H pylori* had been eradicated. These recurrence rates, with and without NSAIDs, are virtually identical ($P = 0.4883$). In other words, recurrence after eradication of *H pylori* cannot be attributed to NSAIDs. The use of multiple tests for *H pylori* reduced the risk that we are dealing here with difficulty in demonstrating the presence of *H pylori* after eradication.

What does *H pylori*-negative DU tell us?

The phenomenon of *H pylori*-negative DU is an argument against a blanket role for *H pylori* as a "cause preceding effect". As stated above, this prevalence is greater in countries with a low, compared with countries with a high prevalence of the organism, even after excluding DU-associated factors such as Crohn's disease and the taking of NSAIDs. There are 20 such reports^[4,6,28,29,34,38,39,51-65] from countries with a low prevalence of *H pylori* infection giving a mean of 14.4% (829/5745) of *H pylori*-negative DU and 5 reports^[47,96-99] with a mean of 3.9% (52/1325), $P < 0.0001$ from countries with a high prevalence.

Three papers^[100-102] suggest that despite the low *H pylori* prevalence in a population with an increased prevalence of *H pylori*-negative DU, there is no decrease in overall DU prevalence. If *H pylori* were the primary cause of DU then one would expect a lower prevalence of DU.

We can offer one supplementary consideration. Perforation of duodenal ulceration might reasonably be expected to signify an especially large secretion of gastric hydrochloric acid. In this context it is interesting that perforation does not seem to be associated with *H pylori*. In 4 reports about patients operated on for perforated duodenal ulcer *H pylori* prevalence was significantly less than in uncomplicated duodenal ulceration^[103-106] (in 2^[103,104] they were indistinguishable from normal controls). The only dissenting evidence was from a report by Matsukara^[107].

INTERPRETATION

How are we to interpret the undoubted relationships between DU, *H pylori* and gastric acid? The present

majority view is that *H pylori* causes DU, not that DU causes *H pylori*. The favourable evidence for the former inference is the greater proportion of *H pylori*-positive cases in DU compared with non-DU subjects, and the fact that clearing the organisms converts the clinical course of DU from chronic relapsing to (mostly) stable healing. However, the second of these points is not proof of initial causation, merely of an interference with healing leading to chronicity of the ulceration.

If *H pylori* is not the initial cause of DU?

If we reject *H pylori* as the cause of DU, how can we explain the greater proportion of *H pylori* in DU compared with non-DU subjects? *H pylori* can only live within a relatively narrow band of pH. Both highly acid and highly alkaline conditions kill the organism^[108,109]. For example, in pernicious anaemia the patient is usually *H pylori*-positive in the early stages (acid production is reduced but still abundant) and then becomes *H pylori*-negative in the later stages (when all acid production has ceased and the stomach is exposed to alkaline reflux from the duodenum)^[110,111].

These facts suggest that some patients who develop a DU may well have so much acid that they are *H pylori*-negative. When treated with acid suppression for their early symptoms, the gastric acidity may fall enough to encourage infection with the organism. At this stage they are investigated and found to be *H pylori*-positive. Strange as it may at first seem, we are postulating that one interpretation of the link between *H pylori* and DU in cases that are initially *H pylori*-negative is that DU (*via* its treatment) causes the infection. This would explain the greater prevalence of *H pylori* in the subjects with DU as an outcome of treatment with acid-suppressing drugs. If the likelihood of a first infection increases with the presence of virulence factors in the organism - as seems reasonable - this explains why the virulence factors are more prevalent in the DU than in the non-DU subjects^[2].

In developing countries with a high prevalence of *H pylori* infection, and where people do not have access to acid-suppressing drugs and only come to hospital with long-standing chronic conditions, there is another possible explanation. With a high *H pylori* prevalence of 70% it follows that 30% of DU patients initially would be *H pylori* negative and 85% of them will not be hypersecretors of acid (See 'Dose Relationship' above). As a result of continued exposure to the high prevalence of *H pylori* a number of these may become infected, resulting in their ulceration becoming unremitting and chronic, and causing them to seek medical help. The result again would be a higher prevalence of *H pylori* infection in those diagnosed with duodenal ulceration.

In addition, the known lability of *H pylori* infection could result in some *H pylori* positive DUs healing as a result of spontaneous disappearance of the infection, leaving a preponderance of DU cases with persisting infection, thus resulting in a higher prevalence of infection in the DU population.

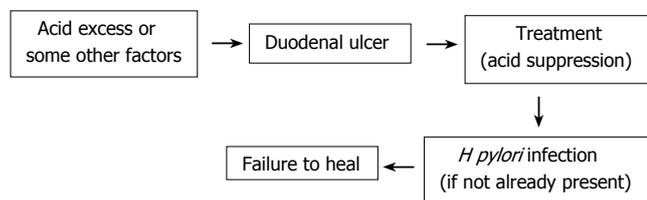

It is possible to calculate the relationship between the fraction of established duodenal ulcer patients who are

H pylori-positive, the fraction of the whole population who are *H pylori*-positive, and the fraction, X, of those initially *H pylori*-negative duodenal ulcer patients who become infected so as to produce the observed increase in established DU patients. We have performed these calculations on data from 18 reports from countries with a high prevalence^[16,28,29,35,39-50,112] and 13 reports from countries with a low prevalence of *H pylori* infection^[5,28-38,113]. The values of X were 0.6 in the developing countries, 0.58 in the developed. The congruence between these two estimates, while certainly not proof of our hypothesis, at least suggests that our hypothesis should not be rejected out of hand. Details of the derivation of the formula and the statistical interpretations are given in the Appendix.

There remain two important problems. (1) Most patients with DU have gastric secretion within the range of normal (though the chance of getting DU does increase with the rate of secretion). There must be some other factor to explain why some get an ulcer and others do not. Our work^[114] demonstrated that this factor was unlikely to be *H pylori*. We favour the idea that the causative agent nevertheless involves interference with wound-healing. NSAIDs can interfere with the healing of *H pylori*-negative ulcer, so they may be responsible for part of the problem, but there is almost certainly more to discover; (2) We still do not know how *H pylori* (which can only live in gastric, not in true duodenal mucosa), makes the ulcer difficult to heal. The presence of colonised gastric mucosa within the duodenum might be a factor. *H pylori* infection inhibits healing of wounded duodenal epithelium in vitro due to vacA^[115]. Another factor might be the effect that the organism has of increasing sub-maximally (gastrin-) stimulated gastric juice^[116]. While the mechanism is in doubt, the relationship is clear and is the fundamental reason why the discovery of *H pylori* is of such enormous importance for the treatment of duodenal ulcer.

CONCLUSION

Our present view is that the relationship between duodenal ulcer, *H pylori* and gastric acid secretion is most likely to be:

APPENDIX

Fraction (= X) of *H pylori* -ve duodenal ulcers becoming *H pylori* + ve, possibly as a result of antacid treatment

$$X = \frac{\% \text{ Hp+ve DU minus } \% \text{ Hp+ve NUD or Controls}}{\% \text{ Hp -ve NUD or Controls}}$$

Hypothesis

Whether or not a subject is *H pylori*-positive (+ve) or *H pylori*-negative (-ve) makes no difference to the likelihood that s/he will develop a duodenal ulcer (DU).

The diagnosis of most subjects with a DU is only made after the patient has already been treated with agents that reduce gastric acid secretion.

Reduction in gastric secretion is likely to increase the chance that a -ve patient becomes +ve.

When first diagnosed, most DU patients will include some who were +ve before they developed DU and others who had been -ve but became positive during their initial treatment and before diagnosis.

Calculation

Let

P = population

U = fraction having DU

F = fraction of population *H pylori* +ve
(so 1-F = fraction negative)

Then

Confirmed DU (say after 6/12)

$$= U \times P$$

However, the confirmed DU is made up of two moieties, one originally +ve, the other originally negative.

The originally positive DU number

$$= F \times U \times P$$

The originally negative DU number

$$= (1-F) \times U \times P$$

Let a fraction X of the originally negative DU be infected as a result of acid-suppression. Then after 6/12 these will number

$$= (1 - F) \times U \times P \times X$$

Therefore the observed positive DUs can be expressed as $(F \times U \times P) + X[(1-F) \times U \times P]$.

Therefore, the observed proportion of DUs who are positive is given by

$$\{(F \times U \times P) + X(1-F) \times U \times P\} / (U \times P)$$

or, dividing by $U \times P$,

$$F + X(1-F)$$

Therefore, observed +ve DU/(total DU) = $\{F + X(1-F)\}$

$$= F + X - FX$$

Therefore, $X(1-F) = [\text{observed DU+ve}/\text{total DU}] - F$

And $X = \{[\text{observed DU+ve}/\text{total DU}] - F\} / (1 - F)$

Analysis of the figures quoted

High prevalence countries: Mean Hp+ DUs = 89.395; (SD 7.602, SE 1.700). Mean Hp+ NUD = 68.350 (SD 12.759, SE 2.853). Mean X = 60.565 (SD 26.466, SE 5.918).

Low prevalence countries: Mean Hp+DU = 70.221; (SD 14.319, SE 3.183). Mean Hp + NUD = 33.286; (SD 16.014, SE 4.280). Mean X = 58.279; (SD 17.773, SE 4.750)

Difference between high prevalence and low prevalence countries: for Hp + DU, $P = 0.0002$ (highly significant); for X, $P = 0.4109$ definitely non-significant.

This hypothesis suggests that in all countries there is much the same chance of originally *H pylori*-negative becoming infected as the ulcer progresses. This fact provides circumstantial evidence, though certainly not proof, of our hypothesis.

Abstract

Mannose-binding lectin (MBL) is a pattern-recognition molecule that binds to characteristic carbohydrate motifs present on the surface of many different pathogens. MBL binding stimulates the immune system *via* the lectin pathway of complement activation. In certain clinical situations, often characterized by pre-existing immune compromise, MBL deficiency increases the risk of infectious and other disease-specific complications. Many of the key pathogenic processes inherent to common gastroenterological diseases, such as infection, immunological damage, and carcinogenesis, have been linked to MBL. This editorial reviews the biology of MBL, outlines key disease associations to document the breadth of influence of MBL, and finally, highlights the relevance of MBL to both gastroenterological health and disease.

INTRODUCTION

Mannose-binding lectin (MBL) is an important component

of the innate immune system. MBL is primarily produced by the liver, circulates throughout the body, and is able to recognize a wide array of common pathogens through repeating carbohydrate sequences present on microbial surfaces. MBL binding of pathogens initiates complement activation via the lectin pathway. There have been a large number of studies addressing the influence of MBL deficiency on infection, autoimmunity, and carcinogenesis, all critical processes in the pathogenesis of gastrointestinal disease. Genetically determined MBL deficiency increases the risk and manifestations of a wide range of diseases, particularly when the immune system is already compromised. This editorial provides an introduction to the structure, function and regulation of MBL and explores its clinical relevance, placing it in the context of common medical and, in particular, gastrointestinal conditions.

THE BIOLOGY OF MANNOSE-BINDING LECTIN

The MBL2 Gene

The capacity of MBL to recognize and eradicate pathogens is extremely variable. Within any given population there are individuals that have varying functional levels of circulating MBL. The relative sufficiency of MBL function for any given individual is largely determined by polymorphisms within the *MBL2* gene, on chromosome 10. Three missense mutations within the first exon of *MBL2* significantly effect MBL function (codon 54 'B', codon 57 'C', and codon 52 'D') (Figure 1). These coding mutations are collectively designated 'O', and the wild-type, sufficient allele is represented by 'A'. An Australian study of healthy blood donors found that the prevalence of *MBL2* wild-type coding genotype *A/A* was 57.6%, coding mutation heterozygosity (*A/O*) was 34.8% (*A/D* 11%, *A/B* 19.9%, *A/C* 3.8%), and coding mutation homozygosity (*O/O*) was 7.6% (*B/B* 2.1%, *B/C* 2.1%, *B/D* 2.5%, *D/D* 0.9%)^[1]. These frequencies are consistent with other Caucasian populations^[2-4]. In Asian communities, the most common mutation is also the 'B' allele, but the 'D' allele is virtually absent^[5].

Further variability of MBL function is due, at least in part, to other polymorphisms within the promoter (position -550, G to C substitution, alleles 'H' and 'L' and position -221, G to C substitution, alleles 'X' and 'Y'); and 5'-untranslated (position +4, C to T, alleles 'P' and 'Q') regions of the gene (Figure 1). When inherited in the context of a normal coding allele (*A*), the promoter region haplotypes

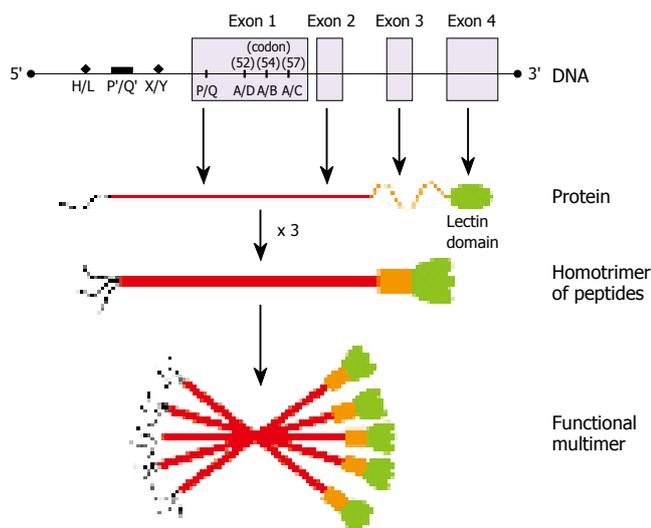

Figure 1 Schematic representation of the four exons of the *MBL2* gene, with the important polymorphisms identified. The peptides self associate into a homotrimer (structural subunit). Each peptide contains a lectin domain (green) to bind the specific, microbial carbohydrate motifs. Functional MBL circulates in higher-order multimers.

HY, *LY*, and *LX* are associated with high, intermediate, and low serum MBL concentrations, respectively. The genotypes *O/O*, *A/O* and *LXA/LXA*, are all associated with low antigenic and functional levels of MBL (compared to *A/A*). The *O/O* genotype is correlated with the most extreme MBL deficit (Figure 2). Low levels of MBL associated with the common polymorphic variants appear to result from impaired oligomerization of the MBL triple helix (see below) into functional higher order multimers^[6], as well as increased susceptibility to degradation by metalloproteinases^[7].

The MBL Protein

The basic structural subunit of MBL is a homotrimer of MBL peptides, entwined in a triple helix (Figure 1). Each peptide contains a lectin domain to bind the specific oligosaccharide motifs present on the surface of many different microorganisms^[8]. Functional MBL circulates as a higher-order multimer (tetramers, pentamers and hexamers) of the basic MBL subunit. This oligomerization allows high-affinity interaction between MBL and the microorganism. Binding of MBL to pathogens causes a conformational change in the MBL multimer, and activation of associated molecules, the MBL-associated serine proteases (MASPs), that initiate the lectin-complement pathway.

The lectin-complement pathway

The enzymatic cascade of complement activation is a vital aspect of innate immunity. Complement-derived opsonization also provides an effective means of articulation with adaptive immunity through subsequent phagocytosis and antigen processing. The classical complement pathway is initiated by the binding of the C1 complex (C1q, r and s) to bound antibody on pathogen surfaces and the alternative pathway by binding of C3b to hydroxyl or amino groups on cell-surface molecules, as a result of spontaneous C3 turnover^[9]. The lectin-

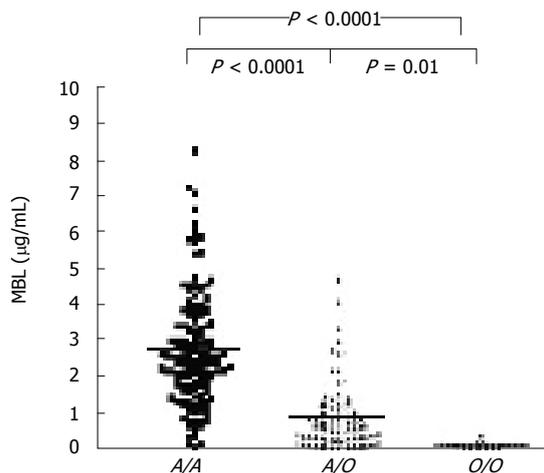

Figure 2 Distribution of plasma MBL levels within a normal population, stratified by *MBL2* genotype (Figure reproduced from Worthley *et al.*^[82] with permission). The *O/O* genotype is associated with the most extreme deficit in circulating MBL level (shown) and activity.

complement pathway is the third arm of complement activation. Higher order MBL multimers circulate in a functional complex with three serine proteases MASP-1, MASP-2, MASP-3 and one non-protease molecule, MAP19^[8]. This complex is analogous to the C1 complex that initiates the classical complement pathway, except that MBL binds to pathogens independently of antibody. Once activated, MASP-2, like its classical-pathway counterpart C1s, cleaves C4 to C4b, producing C4b2a, the C3 convertase. Subsequent production of C3b, also a key opsonin, generates the C5 convertase, which in turn produces the chemoattractant C5a, and, through C5b, the formation of the membrane-attack complex, C5b-C9 (Figure 3).

Recently, an additional mechanism of lectin-mediated complement activation, which bypasses the classical pathway proteins, has been described. Selander *et al.*^[10] demonstrated that an MBL-dependent alternative pathway mediated C3 deposition in C2 deficient serum. This bypass pathway may be of particular significance in the presence of complement deficiencies^[11].

THE CLINICAL RELEVANCE OF MANNOSE-BINDING LECTIN

MBL binds a broad range of bacteria, viruses, fungi and protozoa (Table 1). Its affinity for Gram-negative and Gram-positive bacteria is mediated through cell surface components, such as lipopolysaccharide (endotoxin) and lipoteichoic acid, respectively. MBL deficiency increases *in vivo* susceptibility to many common bacterial infections, including *Neisseria meningitidis*^[12], *Streptococcus pneumoniae*^[13], and *Staphylococcus aureus*^[14]. MBL deficiency may also increase the risk of several viral infections and some of the most compelling data in this area have been conducted in viral hepatitis, discussed below.

The balance of evidence suggests that MBL deficiency is most relevant when immunity is already compromised as a consequence of immunological immaturity, for example

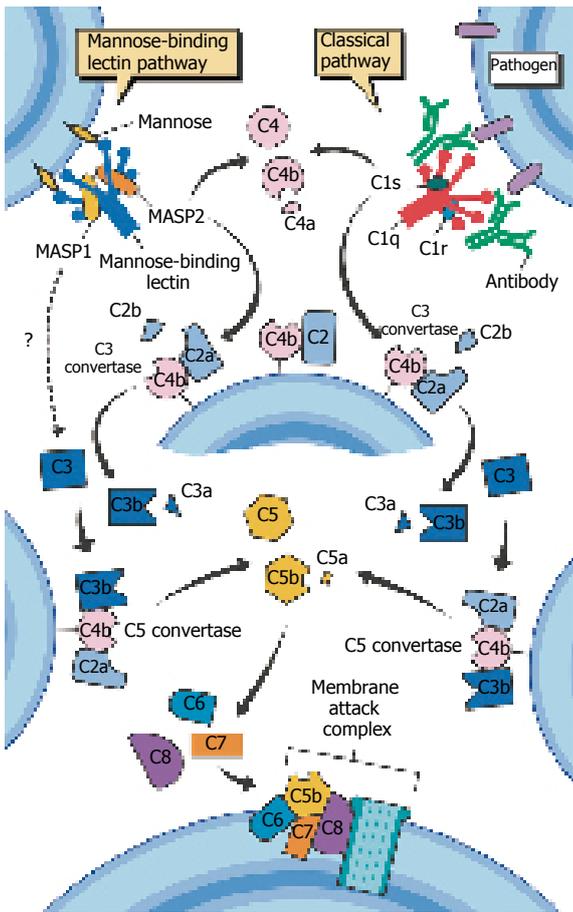

Figure 3 The lectin and classical complement pathways (Figure reproduced from Worthley *et al*^[22] with permission).

in young children^[15], or is impaired by comorbidity or medical therapy, such as in cystic fibrosis^[16], after chemotherapy^[17,18], or following transplantation^[19,20]. In the pediatric population, MBL exerts greatest influence during an immunological “window of vulnerability”, between the decline in maternal passive immunity but before the development of a fully mature adaptive immune system. There is a strong association between MBL deficiency and childhood infection, which has been found for both milder respiratory tract infections managed within the community^[21], as well as more severe infections requiring hospitalization^[15]. In cystic fibrosis (CF), innate immunity is compromised in part by impaired mucociliary clearance and bronchiectasis. In one series of CF patients, those with mutant *MBL2* alleles had worse pulmonary function and shorter survival to end-stage CF^[16]. The same investigators reported successful MBL replacement in the management of one patient with rapidly progressive CF^[22]. Several studies have shown an association between MBL deficiency and risk or severity of infection following chemotherapy^[17,18].

A number of autoimmune disorders are associated with MBL. This may in part relate to the role of MBL in removing pathogens and apoptotic bodies, thus minimizing the emergence of cross-reactivity or auto-immunogenic epitopes^[23]. Inherited deficiencies within the classical complement pathway predispose to systemic lupus erythematosus (SLE), thus it was logical to evaluate the role of MBL

Table 1 Some clinically relevant microorganisms recognized by MBL

Bacteria	Viruses	Fungi	Protozoa
<i>Staphylococcus aureus</i>	HIV-1 and 2	<i>Aspergillus fumigatus</i>	<i>Plasmodium falciparum</i>
<i>Streptococcus pneumoniae</i>	Herpes simplex 2	<i>Candida albicans</i>	<i>Cryptosporidium parvum</i>
<i>Streptococcus pyogenes</i>	Influenza A	<i>Cryptococcus neoformans</i>	<i>Trypanosoma cruzi</i>
<i>Enterococcus spp.</i>	Hepatitis B virus	<i>Saccharomyces cerevisiae</i>	
<i>Listeria monocytogenes</i>	Hepatitis C virus		
<i>Haemophilus influenzae</i>			
<i>Neisseria meningitidis</i>			
<i>Neisseria gonorrhoeae</i>			
<i>Escherichia coli</i>			
<i>Klebsiella spp.</i>			
<i>Pseudomonas aeruginosa</i>			
<i>Salmonella montevideo</i>			
<i>Salmonella typhimurium</i>			
<i>H pylori</i>			
<i>Chlamydia trachomatis</i>			
<i>Chlamydia pneumonia</i>			
<i>Propionibacterium acnes</i>			
<i>Mycobacterium avium</i>			
<i>Mycobacterium tuberculosis</i>			
<i>Mycobacterium leprae</i>			
<i>Leishmania chagasi</i>			

in this condition. A recent meta-analysis concluded that deficient *MBL2* genotypes increase the risk of developing SLE^[24]. Other studies have shown that MBL deficiency increases the risk of SLE-related complications, such as arterial thrombosis^[25]. The effect of variant MBL and risk of vascular complications extend beyond patients with SLE. Several studies have now demonstrated an association between *MBL2* mutations and risk of coronary artery disease^[26-28]. These results have been supported by a population-based study from Denmark, that genotyped 9 245 individuals for *MBL2* coding mutations^[29]. Although MBL deficiency did not greatly increase the rate of morbidity or mortality within the population, those with biallelic mutations had a significantly greater risk of hospitalization for cardiovascular disease compared to those without deficient alleles [RR = 1.2 (1.0-1.4), *P* = 0.02]^[29].

To this point, all of the disease associations presented have identified the wild-type (*A/A*) *MBL2* gene as advantageous. The global preservation of *MBL2* -deficient haplotypes, however, hints at a selective advantage, at least under certain circumstances, of the deficient state. The concept of heterosis, whereby a heterozygous trait may demonstrate a selective advantage, has many well known examples, such as the $\Delta F508$ mutation in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene and resistance to cholera toxin^[30]. MBL-facilitated opsonization and phagocytosis could theoretically enhance the infectivity of some intracellular pathogens. The dichotomous nature of MBL deficiency is supported by several clinical

studies that show it to be protective against several obligate intracellular organisms, including *Mycobacterium leprae*^[31], *M. tuberculosis*^[32], and *Leishmania chagasi*^[33].

Both plasma-derived as well as recombinant MBL are now available for therapeutic use, albeit that the indications for replacement are still evolving. The results from the first phase I trial conducted in healthy, MBL-deficient individuals, has been published^[34]. This study confirmed that MBL replacement is a technically viable option. Phase II trials are eagerly awaited.

MALADIES OF THE BOWEL AND LIVER

Innate immunity has developed multiple strategies for protecting us against microbiological threats. Pattern-recognition molecules, such as toll-like receptors (TLR), *NOD2/CARD15*, and MBL, are particularly important in the alimentary tract, characterized by its large surface area and intimate relationship to the bowel contents, particularly the extreme microbial burden found within the colonic lumen. In addition to initiating inflammation, the capacity for immune tolerance is critical for normal bowel function. Although it is clear that the liver is the chief contributor to plasma MBL, mucosal MBL production may be relevant in localized immune defence, particularly within the alimentary tract^[35]. The following examples present some of the better developed areas of gastroenterological MBL research, including inflammatory bowel disease, carcinogenesis, gastrointestinal and hepatotropic infection, and chronic liver disease.

MBL and inflammatory bowel disease

Inflammatory bowel disease (IBD) is a pathological spectrum encompassing ulcerative colitis (UC), Crohn's disease (CD), and indeterminate colitis. The resultant IBD phenotype is the consequence of multiple interactions between environmental factors, particularly enteric flora, and the host response to this environment, determined by immunogenetic, epithelial, and other non-immune genetic factors^[36]. MBL, as an important component of innate immunity, has engendered considerable research interest. In an early study of 340 unrelated patients with IBD genotyped for *MBL2* exon 1 coding mutations, the frequency of deficient alleles was significantly lower in patients with UC than either the control group ($P = 0.02$), or those with CD ($P = 0.01$)^[37]. This study suggests that MBL deficiency could be protective against UC; alternatively, it could be interpreted that MBL deficiency, in individuals otherwise predisposed to IBD, may skew the phenotype away from the UC spectrum of disease towards CD. This concept is supported by another study that genotyped *MBL2* in patients with CD, UC, or healthy controls^[38]. In this study the allele frequency of coding mutations was approximately 30% in patients with CD, 8% in UC, and 16% in healthy controls. In addition, the frequency of homozygosity or compound heterozygosity for coding mutations (i.e. *O/O MBL2* genotype) within the IBD group was significantly higher than in the healthy control population and the association was strengthened if the small number of UC patients were excluded from the analysis (16% *vs* 0%; $P =$

0.05)^[38]. The study also assessed anti-*Saccharomyces cerevisiae* antibody (ASCA) and MBL levels within the same subsets of patients, albeit slightly different numbers within each group^[38]. CD patients with MBL deficiency were significantly more likely to be positive for ASCA and for their lymphocytes to proliferate in response to mannan. Thus, it appears that MBL deficiency could impair normal processing of mannan-expressing microbial antigens, such as those found on the cell surface of many common microorganisms. The accumulated antigens could then stimulate the immune system, and contribute to the production of ASCA and possibly the pathogenesis of Crohn's disease^[38]. ASCA is a well established phenotypic marker of IBD, tending to aggregate with Crohn's rather than the ulcerative colitis phenotype, and within CD the presence of ASCA is particularly associated with the fibrostenosing phenotype and ileal inflammation^[39]. Thus, MBL deficiency might act primarily to influence IBD-specific phenotype in these patients. It should be noted, however, that a follow-up study, testing a larger cohort of CD patients ($n = 241$), failed to confirm the significant association between variant MBL genotypes and ASCA positivity^[40]. The observed trend, however, did show that the frequency of ASCA positivity was proportional to the relative deficiency of the coding genotype, with 54% ASCA positivity for *A/A*, 58% for *A/O*, and 67% for *O/O*^[40]. Nevertheless, further studies into the role of MBL as a marker or regulator of IBD phenotype are warranted. Finally, the contribution of *M. avium* subspecies *paratuberculosis* to the pathogenesis of Crohn's disease is controversial^[41]. Nevertheless, it would be interesting to investigate whether, in a fashion analogous to *M. tuberculosis*, MBL might predispose to Crohn's disease by facilitating the infectivity of this obligate intracellular pathogen.

MBL and coeliac disease

Coeliac disease is an important autoimmune disorder involving the alimentary tract^[42]. The majority of patients with coeliac disease express the major histocompatibility complex (MHC) molecule DQ2 and the remainder usually carry DQ8^[42]. But HLA genes convey only about 40% of the genetic risk, and although 30%-40% of Caucasians carry DQ2 or DQ8, less than 3% of these will develop coeliac disease^[42]. In one study, 117 patients with histologically and serologically confirmed coeliac disease were genotyped for *MBL2* exon 1 mutations, and compared to a healthy blood donor population. There was a significant difference in the frequency of the *O/O* genotype between those with coeliac disease (13%) and the control group (5%) ($P = 0.04$)^[43]. A follow-up study included a detailed assessment of the coeliac disease patients' MHC^[23]. HLA susceptibility alleles and *MBL2* exon 1 coding mutations were genotyped in 147 healthy controls and 149 patients with coeliac disease, enriched with 29 coeliac disease patients known to be negative for DQ2 and DQ8, which is extremely rare^[23]. As in their first study, patients with coeliac disease had a greater frequency of the *O/O* genotype than healthy controls, but in addition, the association between coeliac disease and MBL deficiency was even stronger in the small number of patients negative for DQ2 and DQ8.

It is likely that in those rare cases of coeliac disease that are negative for DQ2 and DQ8, the non-HLA susceptibility genotypes would exert a greater effect. Their study also analyzed apoptosis within small intestinal biopsy specimens, and showed that MBL tended to aggregate to areas of apoptosis within the epithelium. MBL has been implicated in the normal clearance of apoptotic bodies^[44,45]. The authors postulated that the association between MBL and coeliac disease, and indeed other autoimmune conditions, could relate to impaired apoptosis, whereby MBL deficiency impairs the normal removal and clearance of apoptotic cells, that may subsequently reveal previously hidden self-antigen, causing loss of self-tolerance, and spreading of autoimmunity^[23]. The association between variant *MBL2* alleles and coeliac disease has also been confirmed within the Finnish population^[46].

MBL and colorectal cancer

Experimentally there is the suggestion that MBL (both wild-type and the mutant *B* allele) may possess anti-colorectal cancer tumour activity^[47]. *In vitro* MBL binds specifically to oligosaccharide moieties on colorectal cancer cell line SW1116^[47]. The investigators transplanted SW1116 cells subcutaneously in nude mice, resulting in palpable tumor masses at three weeks. In order to evaluate the *in vivo* anti-tumoral activity of MBL, the mice were administered one of four different intra-tumoral injections. The first group received an injection with vaccinia virus carrying the wild-type (*A*) *MBL2* allele, the second group with the variant *B*' allele and the two control groups received vaccinia virus alone, or saline alone. Intra-tumoral administration of the recombinant vaccinia virus carrying a *MBL2* gene (either the *A*' or *B*' allele) significantly reduced tumor size as compared with the two control groups ($P < 0.005$), and also prolonged survival^[47]. These laboratory results have not, however, been reflected in clinical trials. In fact, patients with colorectal cancer have increased activation of the lectin-complement pathway and increased levels of serum MBL^[48]. In patients undergoing surgery for colorectal cancer, however, low preoperative levels of serum MBL has been linked to an increased risk of developing post-colectomy pneumonia^[49]. Most recently, increased preoperative serum levels of MASP2 predicted adverse outcome following colorectal cancer surgery, both in terms of disease recurrence ($P = 0.03$; HR = 1.4, 1.0-2.0) and survival ($P = 0.0005$; HR = 1.4, 1.2-1.7)^[50]. There are several possible explanations for these results. A preoperative elevation in acute phase markers, such as CRP, is known to predict worse outcome^[51], and the elevation in MASP2 may simply reflect a heightened inflammatory state. Alternatively, MASP2 may meaningfully influence tumor progression. Further studies are required to clarify the role of the lectin-complement pathway in cancer.

MBL and gastrointestinal infection

Despite the well-established role of MBL in innate immunity, there have been relatively few studies detailing the clinical effect of MBL deficiency in enteric infections. One notable exception analyzed the association between MBL deficiency and risk of *Cryptosporidium parvum* enteri-

tis. This study included 72 African patients with acquired immunodeficiency syndrome (AIDS) and diarrhea. They were genotyped for exon 1 *MBL2* mutations and had their duodenal aspirates tested for MBL. Patients with biallelic coding mutations (*O/O*) had a significantly greater chance of cryptosporidiosis compared to those who were either wild-type or heterozygous for *MBL2* mutation (*A/A* or *A/O*, respectively) (OR = 8.2; 95% CI: 1.5-42; $P = 0.02$)^[52]. This study places MBL's anti-microbial function back in the context of the 'window of vulnerability' hypothesis. Of further interest from this study was the detection of MBL within some of the duodenal aspirates. The presence of albumin in the intestinal lumen led the authors to postulate that MBL entered the bowel through mucosal leakage of serum; however, local intestinal production could not be excluded. The association between MBL deficiency and cryptosporidiosis was recently confirmed in a second case-control study, this time in young (< 3 year) Haitian children. Mean serum MBL levels were significantly lower in the cases (1110 vs 2395 ng/mL, $P = 0.002$), and 37% of the cases compared to only 10% of the healthy controls were found to be deficient in MBL (level ≤ 70 ng/mL) ($P = 0.005$)^[53]. Unlike the earlier study, *MBL2* genotyping was not performed, and thus MBL deficiency secondary to enteric protein loss, as a consequence of cryptosporidiosis, could not be excluded. When considered together, however, these two studies present compelling evidence for the role of MBL in the host defense against *Cryptosporidium spp.* infection.

Another study analyzed serum MBL levels in a pediatric population presenting with *Escherichia coli* 0157: H7 colitis. MBL levels were measured in patients with uncomplicated *E. coli* 0157:H7 colitis, patients in whom the colitis was complicated by haemolytic uraemic syndrome (HUS), and in normal and disease (rotavirus enteritis) control groups^[54]. MBL deficiency was not associated with an increased risk of either infection nor the complication of HUS, albeit that without analysis of *MBL2* genotype, overall MBL status may be more difficult to assess.

H pylori is one of the most common human bacterial infections, affecting approximately 50% of humans, although only 10%-20% of those affected will develop a clinical disorder^[55]. Several immunogenetic polymorphisms are associated with clinical outcomes in *H pylori* infection^[56], as well as with the risk of infection itself^[57,58]. *H pylori* activates MBL *in vitro*^[59], and a recent study demonstrated that *H pylori*-related chronic gastritis causes an increase in gastric mucosal MBL expression, but no association was found between *MBL2* genotype and risk of chronic gastritis^[60]. A recent study was performed to investigate whether MBL deficiency increased the risk of *H pylori* infection^[61]. Two normal populations (166 blood donors and 108 stem cell donors) were included in the analysis. All individuals were genotyped for *MBL2*, had their peripheral MBL activity characterized by level and functional assays, and were tested for serological evidence of *H pylori* infection. In this study, MBL deficiency did not increase the risk of *H pylori* infection, and in one population greater MBL activity actually increased the risk of infection.

It is worth noting that MBL has been implicated in

mediating gastrointestinal ischemia/reperfusion injury in mice^[62]. MBL-null mice (deficient in the two murine genes encoding MBL) developed only minor gut injury after induced ischemia/reperfusion insult compared to the wild-type mice. MBL has been implicated as a mediator of ischemia/reperfusion injury in both the myocardium^[63] and the kidney^[64] and thus clinical correlation of MBL status and risk or outcome following mesenteric ischemia may yield interesting results.

MBL and viral hepatitis

MBL was first isolated from hepatocytes^[65], and the liver produces most if not all of the circulating MBL^[20]. There is obviously considerable functional reserve in hepatic MBL production, because in the setting of cirrhosis, unlike many other hepatic proteins, MBL production appears to be increased^[66]. The viral hepatitis have stimulated considerable MBL-related research. In one study of chronic hepatitis B virus (HBV) infection, MBL codon 54 (*B*) mutations were significantly associated with risk of developing both symptomatic cirrhosis and spontaneous bacterial peritonitis (SBP)^[67]. The increased risk of SBP in patients with MBL deficiency is biologically plausible, given that low levels of ascitic fluid opsonins are important in the pathogenesis of SBP, and MBL deficiency would be likely to compound this deficit^[68]. A second study by the same investigators recently confirmed the association, extending the results from their previous study, to include the low expression haplotype *XA* as a risk factor, as well as the '*B*' allele. The odds ratio for developing cirrhosis and hepatocellular carcinoma was 1.97 for patients with *XA* and 1.90 for those with *YB* ($P = 0.002$)^[69]. A study from the U.S. confirmed these findings, which is important given that the age and route of acquisition of HBV may vary between different countries^[70]. It is likely that MBL plays an important role in the pathogenesis of HBV-related chronic disease, even though some small studies have failed to confirm the association^[71,72]. It will be interesting to examine the influence of MBL status upon the rate or type of drug resistance that emerges in individuals during long-term antiviral therapy.

Many of the studies analyzing MBL in chronic hepatitis C virus (HCV) infection have investigated the role of MBL mutations on rate of sustained viral response following interferon alpha (IFN- α) monotherapy. Two studies, from the same Japanese group, reported that patients who failed to eradicate HCV following IFN monotherapy were more likely to have variant *MBL2* alleles, either the '*B*' coding mutation^[73,74] or the '*LXPA*' haplotype^[73]. A third Japanese study addressed whether MBL deficiency altered the course of HCV chronic liver disease^[75]. In their cross-sectional study, 52 patients with chronic HCV and 50 controls were genotyped for the '*B*' coding mutation in exon 1 of *MBL2*. All patients with HCV had the stage and activity of their liver disease categorized as "chronic inactive hepatitis", "chronic active hepatitis" (CAH), or cirrhosis. No significant differences in the frequency of mutations was found between the patients and the controls, but within the HCV-infected group, all of the patients with heterozygous or homozygous codon 54 mutations had either CAH

or cirrhosis, whilst none of those in the "chronic inactive hepatitis" group had mutations. This represented a significantly higher frequency of mutation in the advanced (CAH plus cirrhosis) liver disease group ($P = 0.0405$)^[75]. A final study from Scotland sought to test the Japanese findings in a Caucasoid population^[76]. This study failed to find an association between MBL deficiency and either progression of liver disease or response to IFN- α therapy. This study, however, did not perform *MBL2* genotyping, but stratified MBL concentrations into four groupings for comparison. On balance, there appears to be an association between MBL status and HCV in terms of both disease progression and response to monotherapy, at least in the Japanese population. The development of newer anti-viral treatment regimens, including pegylated-IFN in combination with ribavirin treatment, makes it necessary to re-evaluate immunogenetic influences, at least, any which are hoped to inform therapy.

MBL and liver transplantation

One of the more exciting recent reports regarding MBL and hepatobiliary disease, addressed the role of MBL deficiency following orthotopic liver transplantation (OLT)^[20]. OLT provides the unique opportunity not only to evaluate the role of MBL in post-transplant infection, but also to assess the contribution of hepatic and extra-hepatic MBL production, because in many recipients the *MBL2* genotype will be different in the liver. The study reported the clinical results from 49 transplants, in which 49 of the donors were genotyped for *MBL2*, 25 of the recipients were genotyped, and serum samples were collected from 25 of the recipients to evaluate the change in serum MBL concentration post-transplant. There was an impressive correlation between the risk of post-transplant clinically significant infection and the relative deficiency of the donor *MBL2* genotype, with infection occurring in 12% receiving a wild-type *A/A* liver, 39% of those receiving an *A/O* liver, and in 67% of those receiving an *O/O* donor liver ($P = 0.01$)^[20]. In addition, the post-transplantation serum MBL level was predicted by the hepatic, not the extra-hepatic, genotype. Nevertheless, as only 25 of the recipients, and thus only 25 extra-hepatic genotypes were analyzed, this study was too small to detect more subtle changes in the risk of infection, conferred through local, extra-hepatic MBL production^[77].

MBL and hepatic synthesis

The site of MBL production has been a contentious area. Undoubtedly, the liver produces the majority of MBL and most if not all of the circulating MBL within peripheral blood. This view is supported by the liver transplantation study above, as well as a report documenting that successful allo-SCT failed to correct peripheral blood MBL deficiency^[20,78]. Nevertheless, MBL mRNA is expressed in extra-hepatic tissue^[35,79,80] possibly including haemopoietic lineages^[35], and there have now been two allo-SCT studies that support a contribution from donor (i.e. hematopoietic) *MBL2* genotype, and risk of post-transplant infection^[4,81]. The most important issue is not whether extra-hepatic MBL production significantly influences peripheral

blood MBL levels, but whether it contributes in a clinically meaningful way to local, tissue-specific immunity.

CONCLUSION

MBL has stimulated a great deal of basic and clinical gastroenterological research and has provided new insights to the pathogenesis of infectious and immune disorders within the bowel and liver. The possibility of a local, mucosal effect of MBL as suggested by gene expression^[35,79,80], as well as clinical studies^[23,60] is an exciting discovery. Further work is needed to clarify whether mucosal production occurs, and if so whether it contributes to local immune surveillance in health, or under certain situations, even exacerbates alimentary tract disease.

Despite the promise of replacement therapy and the value of MBL in predicting the risk of disease and disease-specific complications, for now investigation of MBL status remains primarily a research tool. Future studies more rigorously examining MBL status by both measurement of MBL levels and *MBL2* genotyping in large patient cohorts will help clarify the most important disease associations and identify those clinical settings in which MBL replacement therapy is most likely to be beneficial. Now that MBL replacement has been shown to be feasible, the first trials of MBL replacement therapy in several clinical settings, including recurrent infection, severe sepsis, and liver transplantation, are likely to be reported in the next few years. This prospect of MBL replacement therapy represents the culmination of several decades of basic and translational research and is an exciting advance in the field of innate immunity.

Abstract

The liver is considered the major "control center" for maintenance of whole body cholesterol homeostasis. This organ is the main site for *de novo* cholesterol synthesis, clears cholesterol-containing chylomicron remnants and low density lipoprotein particles from plasma and is the major contributor to high density lipoprotein (HDL; good cholesterol) formation. The liver has a central position in the classical definition of the reverse cholesterol transport pathway by taking up periphery-derived cholesterol from lipoprotein particles followed by conversion into bile acids or its direct secretion into bile for eventual removal *via* the feces. During the past couple of years, however, an additional important role of the intestine in maintenance of cholesterol homeostasis and regulation of plasma cholesterol levels has become apparent. Firstly, molecular mechanisms of cholesterol absorption have been elucidated and novel pharmacological compounds have been identified that interfere with the process and positively impact plasma cholesterol levels. Secondly, it is now evident that the intestine itself contributes to fecal neutral sterol loss as a cholesterol-secreting organ. Finally, very recent work has unequivocally demonstrated that the intestine contributes significantly to plasma HDL cholesterol levels. Thus, the intestine is a potential target for novel anti-atherosclerotic treatment strategies that, in addition to interference with cholesterol absorption, modulate direct cholesterol excretion and plasma HDL cholesterol levels.

INTRODUCTION

Maintenance of cholesterol homeostasis in the body requires accurate metabolic cross-talk between processes that govern *de novo* cholesterol synthesis and turnover to adequately cope with (large) fluctuations in dietary cholesterol intake. Imbalance may lead to elevated plasma cholesterol levels and increased risk for cardiovascular diseases (CVD), the main cause of death in Western society. A multitude of epidemiological studies has shown the direct link between high plasma cholesterol, particularly of low density lipoprotein (LDL) cholesterol, and risk for CVD. Treatment of high plasma cholesterol has been focused for many years on interference with cholesterol synthesis by application of statins. Statins are competitive inhibitors of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, the rate-controlling enzyme in the cholesterol biosynthesis pathway^[1]. Inhibition of cholesterol synthesis leads to reduced production of very low density lipoprotein (VLDL) particles by the liver and particularly, up-regulation of LDL receptor activity. Both processes contribute to lowering of plasma LDL-cholesterol levels^[2]. Large clinical trials have established the beneficial effects of statin treatment^[3]. However, a relative large number of hypercholesterolaemic patients do not adequately respond to statin therapy or remain at risk for CVD despite substantial reductions in LDL cholesterol^[4,5]. Consequently, alternative strategies are currently actively pursued, particularly high density lipoprotein (HDL)-raising approaches. These approaches are considered particularly promising, as data from epidemiological studies indicate that every 1 mg/dL increase in HDL cholesterol reduces CVD risk by 2%-3%^[6,7]. In addition, strategies aiming at interference with intestinal cholesterol metabolism are gaining interest. A major development has been the introduction of ezetimibe, a potent inhibitor of intestinal cholesterol absorption that reduces plasma LDL-cholesterol by approximately 20% in mildly

hypercholesterolemic patients^[8]. Likewise, phytosterol/stanol (esters)-enriched functional foods have successfully been introduced for lowering of plasma cholesterol levels through interference with cholesterol absorption^[9].

Recently obtained insights in intestinal cholesterol trafficking may open even more promising avenues for further developments. It appears that the intestine actively excretes cholesterol and thereby, significantly contributes to fecal sterol excretion. In addition, it appears that the intestine is an important source of HDL-cholesterol, also known as “good” cholesterol. Thus, the intestine is an attractive target for new therapeutic strategies aimed to alter plasma cholesterol profiles and to reduce the risk for CVD. This review summarizes the important new findings regarding the mechanism(s) of intestinal cholesterol absorption, with specific focus on newly identified transporter proteins, the novel concept of direct intestinal cholesterol secretion and the role of the intestine in HDL biogenesis.

SOME BASIC FEATURES OF CHOLESTEROL

Cholesterol is essential for mammalian life as a structural component of cellular membranes, influencing membrane organization and thereby membrane properties^[10]. Cholesterol is the precursor molecule of steroid hormones and therefore, essential for metabolic control. In the liver, cholesterol can be converted into bile salts, which represents the major pathway for cholesterol metabolism in quantitative sense. Bile salts are amphipathic molecules that facilitate the absorption of dietary cholesterol, fats and fat-soluble vitamins in the small intestine. Recently, it has become clear that bile salts are able to regulate gene expression through activation of the nuclear receptor, the farnesoid X receptor (FXR)^[11-13]. Cholesterol or more correctly, oxidized cholesterol acts as a ligand for the nuclear liver X receptor (LXR or NRH2 or NRH3) and directly contributes to regulation of expression of genes involved in cholesterol, lipid, and glucose metabolism. Accumulation of free cholesterol rather than cholesterylesters, has been shown to induce apoptosis in macrophages by activating the Fas pathway^[14]. Thus, cholesterol is a key component in cellular and whole-body physiology and cholesterol homeostasis is tightly regulated at a variety of levels.

Body cholesterol derives from two sources, i.e., *de novo* biosynthesis and diet. Cholesterol is synthesized from two-carbon acetyl-CoA moieties. The rate-controlling enzyme in the synthetic pathway is HMG-CoA reductase, a highly regulated enzyme that catalyses the conversion of HMG-CoA into mevalonate. Cholesterol itself regulates feed-back inhibition of HMG-CoA reductase activity, as accumulation of sterols in the endoplasmic reticulum (ER) membrane triggers HMG-CoA reductase to bind to Insig proteins, which leads to ubiquitination and degradation of HMG-CoA reductase^[15,16]. In addition, cholesterol regulates the gene expression of HMG-CoA reductase indirectly by blocking the activation of the transcription factor, sterol regulatory element-binding protein 2 (SREBP2). Under low-cholesterol conditions, SREBP2 in the ER binds to the SREBP cleavage activating protein

(SCAP), which escorts SREBP2 to the Golgi. In the Golgi, SREBP2 is cleaved to generate its transcriptionally active form, which activates transcription of the HMG-CoA reductase encoding gene. Upon accumulation of sterols in the ER-membrane, binding of cholesterol to the sterol-sensing domain of SCAP causes a conformation change, which induces binding of SCAP to the ER anchor protein Insig, preventing exit of SCAP-SREBP2 complexes to the Golgi thereby preventing activation of SREBP2^[17].

The contribution of the two sources to the total pool of cholesterol differs between species and prevailing diet composition, but the total cholesterol pool is similar in rodents and humans when expressed on the basis of body weight^[18]. Cholesterol synthesis in the liver is highly sensitive to the amount of (dietary) cholesterol that reaches the liver from the intestine via the chylomicron-remnant pathway^[19]. The Western-type human diet provides approximately 400 mg of cholesterol per day. On top of this, the liver secretes approximately 1 gram of cholesterol into bile per day^[20]. Intestinal cholesterol absorption efficiency in humans is highly variable, ranging from 15% to 85% in healthy subjects^[21]. After uptake by enterocytes, cholesterol is packed with triglycerides into chylomicrons and secreted into the lymph. In the circulation, the triglycerides are rapidly hydrolyzed and free fatty acids are taken up by the peripheral tissues. Cholesterol-enriched chylomicron remnants are subsequently cleared by the liver. Since chylomicron remnants, which contain most of the cholesterol that is being absorbed from the intestine, are rapidly taken up by the liver, interference with the absorption process directly influences hepatic cholesterol synthesis.

The healthy liver is perfectly equipped for handling large amounts of cholesterol. When relatively large amounts of cholesterol reach the liver, *de novo* synthesis and LDL uptake are rapidly down-regulated. In addition, the liver can dispose excess cholesterol molecules in several ways. A rapid response involves esterification of cholesterol by Acyl CoA cholesterol acyltransferase (ACAT) 2 for storage as cholesterylesters in cytoplasmic lipid droplets. Cholesterylester can be hydrolyzed when necessary and this esterification/hydrolysis cycle provides cells with short-term buffering capacity for cholesterol. The liver, like the intestine, is able to produce and secrete VLDL particles, which consist of a neutral lipid core composed of cholesterylesters and triacylglycerols and a monolayer surface containing phospholipids, free cholesterol, and a variety of apolipoproteins. Finally, cholesterol can be converted into bile acids by the hepatocytes, followed by their secretion into the bile along with significant amounts of free cholesterol and phosphatidylcholine. In humans, cholesterol lost via the feces consists of approximately 50% acidic (= bile acids) and 50% neutral sterols, emphasizing the point that conversion into bile acids represents a major pathway for cholesterol elimination.

Peripheral cells, e.g., macrophages, muscle and fat cells, are not able to form lipoproteins or to metabolize cholesterol extensively. Therefore, these cell types depend massively on efflux pathways for removal of their excess cholesterol. It is generally assumed that HDL is the

primary acceptor for cholesterol efflux from cells. HDL cholesterol can subsequently be taken up by the liver for further processing. This pathway is generally referred to as the reverse cholesterol transport (RCT) pathway. The RCT pathway is particularly important for removal of excess cholesterol from macrophages, as accumulation of esterified cholesterol in these cells is considered a primary step in the development of atherosclerosis. Several epidemiological studies have shown that plasma HDL is an independent, negative risk factor for the development of CVD. The common hypothesis is that high HDL cholesterol levels decrease the risk for CVD by removing the excess of cholesterol from the macrophages and enhancing RCT. Recent work, however, indicates that this is an oversimplification and that current concepts of RCT require re-definition^[22]. In addition, the anti-inflammatory and anti-oxidant features of molecules rather than cholesterol associated with the HDL particles, like paraoxonase, platelet activating factor-acetylhydrolase or lysophospholipids, are becoming increasingly apparent^[23-25].

TOWARDS UNDERSTANDING OF INTESTINAL CHOLESTEROL ABSORPTION

In the past years, insight in regulation of cholesterol absorption has greatly increased by identification of transporter proteins involved. In addition, unraveling of molecular regulation of their expression is progressing. Yet, it should be realized that besides transporter proteins, the presence of bile acids in the intestinal lumen is an essential prerequisite for absorption to occur^[26]. Micellar solubilization of (dietary/biliary) cholesterol is necessary for its absorption as exemplified by the fact that fractional cholesterol absorption is virtually zero in bile-diverted rats and *Cyp7a1*-deficient mice with a strongly diminished bile acid pool size^[26].

Identification of novel proteins involved in cholesterol absorption

Cholesterol absorption has long been considered a merely passive process, despite the fact that the process is clearly selective since dietary cholesterol is absorbed with a relative high efficiency whereas structurally similar phytosterols are not. Several candidate intestinal cholesterol transporters have been proposed during the past couple of years, e.g., SR-B1^[27] and aminopeptidase N^[28], but their role (if any) has remained elusive so far. The recent identification of the Niemann-Pick C1 like 1 (NPC1L1) protein as a crucial molecule involved in cholesterol uptake by enterocytes^[29] and of *Abcg5* and *Abcg8* proteins as (intestinal) cholesterol efflux transporters^[30-32], has provided definite proof that cholesterol absorption is a protein-mediated, selective and active process.

The identification of NPC1L1 is strongly facilitated by the discovery of a powerful cholesterol absorption inhibitor named ezetimibe^[33]. Ezetimibe and analogs comprise a new class of sterol absorption inhibitors that reduce diet-induced hypercholesterolemia in mice, hamsters, rats, rabbits, dogs, monkeys and humans^[8,33-37]. Using a bioinformatics approach, Altmann *et al.*^[29] have

identified the NPC1L1 protein as a putative cholesterol transporter in intestinal cells. NPC1L1 is expressed in the intestine at the brush border membrane and *Npc1l1*-deficient mice show a 69% reduction in fractional cholesterol absorption. Importantly, treatment with ezetimibe could not further reduce fractional cholesterol absorption efficiency in these mice, indicating that NPC1L1 at least is involved in a pathway targeted by ezetimibe^[29]. In support of this, recent studies have shown that ezetimibe glucuronide, the active molecule, indeed binds to cells expressing NPC1L1^[38]. Using intestinal brush border membrane (BBM) fractions, the authors showed that ezetimibe binds specifically to a single site in the brush border membrane and that this binding is lost in BBM fractions of *Npc1l1*-deficient mice^[38]. The exact cellular localization of NPC1L1 is, however, still under debate. Iyer *et al.*^[39] showed that NPC1L1 is glycosylated and enriched in the BBM of rat enterocytes. Davies *et al.*^[40] who were the first to identify NPC1L1 as a homolog of the Niemann Pick type C (NPC) protein^[40], showed in HepG2 cells that NPC1L1 is localized to a subcellular vesicular compartment but not in the plasma membrane. Using immortalized fibroblasts from wild-type and *Npc1l1* knock-out mice these authors also showed that lack of NPC1L1 activity causes dysregulation of caveolin transport and localization, suggesting that the observed sterol transport defect may be an indirect result of the inability of *Npc1l1*-deficient cells to properly target and/or regulate cholesterol transport in the cells.

Another possible mechanism of action of ezetimibe has been proposed by Smart and colleagues^[41]. These authors described the presence of a stable complex of annexin (ANX) 2 and caveolin (CAV) 1 located in enterocytes of zebrafish and mouse. Disruption of this complex by morpholino antisense oligonucleotides in zebrafish prevented normal uptake of cholesterol. Ezetimibe treatment of zebrafish, C57Bl/6 mice fed a Western type diet and LDL receptor knock-out mice disrupted the ANX2-CAV1 complex, suggesting that ANX2 and CAV1 are components of an intestinal sterol transport complex and targets for ezetimibe. Interestingly, C57Bl/6 mice fed a standard diet did not show disruption of the ANX2-CAV1 complex upon ezetimibe treatment, but did show decreased cholesterol absorption^[41]. Moreover, recent research using CAV1-deficient mice revealed that inhibition of cholesterol absorption by ezetimibe did not require the presence of CAV1^[42]. In addition, rabbits did not appear to form the ANX2-CAV1 complexes, yet, their cholesterol absorption efficiency was still inhibited by ezetimibe^[43]. Collectively, these studies make a mode of action in which ezetimibe acts by deregulating the ANX2-CAV1 complex less likely.

Other proteins critical in control of sterol absorption are the ATP-binding cassette (ABC) transporter proteins, G5 and G8. ABCG5 and ABCG8 act as functional heterodimers^[44] and are localized at the canalicular membrane of hepatocytes and at the brush border membrane of enterocytes. Mutations in the human genes encoding ABCG5 or ABCG8 have been shown to cause the inherited disease sitosterolemia^[30-32], which is characterized by an accumulation of plant sterols

(e.g., sitosterol, campesterol) in blood and tissues due to their enhanced intestinal absorption and decreased biliary removal. Thus, ABCG5/ABCG8 limit plant sterol absorption by effective efflux back into the intestinal lumen. Since ABCG5/ABCG8 also accommodate cholesterol, as evidenced from the fact that *Abcg5/g8*-deficient mice show a strongly reduced biliary cholesterol secretion^[45], this system also provides a means to control cholesterol absorption efficiency. Yet, *Abcg5* and/or *Abcg8* deficiency in mice clearly enhances phytosterol absorption^[45-47], but reported effects on cholesterol absorption efficiency are minimal^[45,46]. On the other hand, overexpression of *ABCG5* and *ABCG8* in mice as well as pharmacological induction of their expression did lead to a strongly decreased fractional cholesterol absorption^[46,48,49], indicating that ABCG5 and ABCG8 play a role in control of cholesterol absorption under certain conditions.

Other transporter proteins, like the scavenger receptor BI (SR-BI) and ABCA1 have been suggested to play a role in control of cholesterol absorption. In the small intestine, SR-BI is localized both at the apical membrane and at the basolateral membrane of enterocytes, with different expression levels along the length of the small intestine^[50]. It was reported that mice deficient in SR-BI, however, show only a small increase in fractional cholesterol absorption efficiency and a small decrease in fecal neutral sterol output^[51]. On the other hand, intestine-specific overexpression of SR-BI in mice did lead to increased cholesterol and triglyceride absorption in short-term absorption experiments^[52], indicating that SR-BI might have a role in cholesterol absorption.

Although earlier reports^[53] have suggested an apical localization, it is evident that ABCA1 is localized at the basolateral membranes of chicken enterocytes^[54] and human CaCo-2 cells^[55]. The conflicting results yielded in studies assessing intestinal cholesterol absorption in mice lacking *Abca1*^[56,57], suggest that the overall effect of *Abca1* on absorption is very minor. However, as will be described later, this protein does have an important function in intestinal cholesterol metabolism.

After uptake, cholesterol is esterified by the enzyme ACAT 2 in the endoplasmic reticulum (ER) of enterocytes. It was reported that *Acat2*-deficiency in mice on a low-cholesterol chow diet did not affect cholesterol absorption efficiency, however, *Acat2*-deficient mice did show a clear reduction in cholesterol absorption upon feeding a high-fat/high-cholesterol diet and as a consequence, are resistant to diet-induced hypercholesterolemia^[58]. Other proteins crucial for cholesterol absorption are those involved in chylomicron formation, like apolipoprotein B (apoB) and microsomal triglyceride transfer protein (MTP), and proteins involved in intracellular chylomicron trafficking such as SARA2. Mutations in the MTP gene result in abetalipoproteinemia, an inherited human disease characterized by extremely low plasma cholesterol and triglyceride levels and absence of apoB-containing particles. Patients suffer from fat and cholesterol malabsorption and neurological diseases due to malabsorption of lipid-soluble vitamins. Mutations in SARA2 cause chylomicron retention disease or Anderson disease^[59], both of which are characterized by the inability to secrete chylomicrons

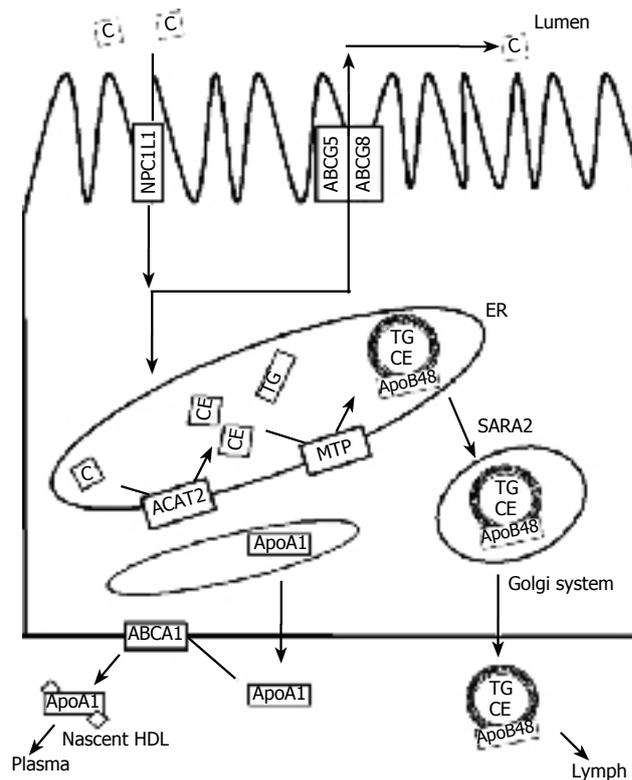

Figure 1 Schematic overview of the major routes of cholesterol in enterocytes. Dietary and biliary cholesterol are taken up via the action of NPC1L1. In the ER, cholesterol is esterified and incorporated into chylomicrons, which are subsequently secreted into lymph. Non-esterified sterols can be re-secreted into the intestinal lumen via the action of ABCG5/G8 or secreted towards ApoA1 via the action of ABCA1. ABCA1, ABCG5, ABCG8: ATP-binding cassette transporter A1, G5, G8; ACAT2: Acyl-coenzyme A: Cholesterol acyl transferase 2; ApoA1, ApoB48, apolipoprotein A1, B48; C: Cholesterol; CE: Cholesterylester; ER: Endoplasmatisch reticulum; MTP: Microsomal triglyceride transfer protein; NPC1L1: Niemann Pick C 1 like 1 protein; SARA2: Sar1-ADP-ribosylation GTPase 2; TG: Triglycerides.

causing severe fat malabsorption and accumulation of chylomicron-like particles in enterocytes. SARA2 belongs to the Sar1-ADP-ribosylation factor family of small GTPases and is involved in intracellular trafficking of chylomicrons through the secretory pathway^[59].

The major routes of cholesterol in enterocytes and the proteins involved are depicted schematically in Figure 1.

Regulation of cholesterol absorption

As indicated above, cholesterol can be taken up from the intestinal lumen by NPC1L1 and effluxed back into the lumen *via* ABCG5 and ABCG8. When both processes are active and present in the same cells, a classical futile cycle arises, enabling very sensitive regulation. Interference with this system has a great potential for reducing plasma cholesterol.

An established application hereof is provided by ezetimibe that interferes with NPC1L1 activity^[29,38]. Lowering of NPC1L1 expression provides another potential means to reduce cholesterol absorption. Mechanisms involved in transcriptional control of NPC1L1 are beginning to be unraveled. The nuclear receptor peroxisome proliferator-activated receptor (PPAR) δ/β (NR1C2) has been shown to decrease cholesterol absorption, presumably by decreasing

NPC1L1 expression^[60]. Activation of PPAR δ/β by the synthetic agonist GW610742 resulted in a 43% reduction of cholesterol absorption in mice, which coincides with unchanged intestinal expression of *Abcg5* and *Abcg8* but a decreased intestinal expression of *Npc1l1*. Treatment of human colon-derived CaCo-2 cells with ligands for PPAR δ/β , but not for PPAR γ or PPAR α , decreased *NPC1L1* expression as well^[60]. Whether PPAR δ/β regulates *NPC1L1* directly or indirectly via transcriptional repression, is still under investigation.

The major regulatory pathways in cholesterol metabolism are controlled by the nuclear receptor liver X receptor (LXR). Two LXR isotypes have been identified in mammals, i.e., LXR α (NR1H3) which is mainly expressed in the liver, kidney, intestine, spleen and adrenals, and LXR β (NR1H2) which is expressed ubiquitously. Natural ligands for both LXRs are oxysterols. After activation, LXR heterodimerizes with retinoid X receptor (RXR)^[61,62]. Activated RXR/LXR heterodimers bind to specific LXR response elements (LXREs) in the promoter regions of their target genes and activate gene transcription. LXR target genes include many genes involved in cellular cholesterol efflux like *ABCA1*, *ABCG1*, *ABCG5*, and *ABCG8*^[53,63,64], genes involved in bile acid synthesis [*cholesterol-7 α -hydroxylase* (*Cyp7a1*)] in rodent models and genes involved in lipogenesis like sterol regulatory element-binding protein (SREBP) 1C, fatty acid synthase (FAS) and *acetyl-CoA* carboxylase (ACC). Global LXR activation by synthetic agonists therefore has a plethora of effects including elevated HDL levels, hypertriglyceridemia, hepatic steatosis, increased biliary cholesterol excretion, reduced intestinal cholesterol absorption efficiency and increased neutral sterol loss *via* the feces^[65,66]. The decreased intestinal cholesterol absorption is primarily due to increased cholesterol efflux of cholesterol towards the intestinal lumen due to increased *Abcg5* and *Abcg8* expression, as fractional cholesterol absorption was reduced upon LXR activation in wild-type mice but remained unaltered in *Abcg5/g8*-deficient mice^[49] and *Abcg5*-deficient mice^[46] under these conditions. Other mechanisms, such as reduced intestinal *Npc1l1* expression after LXR activation contribute to reduced cholesterol absorption, as recently shown in *ApoE2*-knock-out mice^[67].

Dietary phytosterols and phytostanols and their esters have been introduced in functional foods to suppress intestinal cholesterol absorption and hence to reduce the risk for CVD^[9]. Phytosterols and stanols are thought to decrease cholesterol absorption by competing with cholesterol for incorporation into mixed micelles in the intestinal lumen^[68]. However, several recent studies suggested additional mechanisms involving alterations of intestinal gene expression. Igel and colleagues^[69] showed for the first time that phytosterols and stanols are actually taken up by the enterocytes and subsequently re-secreted into the gut lumen, most probably through the action of *Abcg5/Abcg8* transporters. This finding indicated that phytosterols and stanols, in addition to modes of action within the intestinal lumen, exert metabolic actions from inside the enterocytes. Moreover, dietary phytostanol consumption (2.5 g) once a day reduces LDL cholesterol as effective as consumption

of 2.5 g phytosterols ingested in three daily portions^[70], suggesting that luminal concentrations may not be the key to the control of metabolic actions. The identification of a phytosterol-derived agonist for the nuclear receptor LXR^[71] has led to the proposal that phytosterols and stanols decrease cholesterol absorption via activation of intestinal LXR. *In vitro* studies in CaCo-2 cells indicated that phytosterols indeed are able to induce the expression of *ABCA1*, an established LXR target gene^[72]. Recent *in vivo* studies, however, showed that dietary phytosterols and phytostanols decrease cholesterol absorption without activating LXR in rodent models. Field *et al.*^[73] showed that addition of 2% phytosterols to a chow diet do not affect intestinal expression of *ABC sterol transporters* and *Npc1l1* in male golden Syrian hamsters. Likewise, Calpe-Berdien *et al.*^[74] showed very recently that decreased cholesterol absorption upon addition of 2% phytosterol to a Western type diet is not associated with transcriptional changes in *Abca1*, *Abcg5*, *Abcg8* or *Npc1l1* in C57BL/6J, ApoE^{-/-} and LDLr^{-/-} mice. Plösch and colleagues^[66] have shown similar results using 0.5% phytosterol or phytostanol in a semi-synthetic diet containing 0.2% cholesterol in C57BL mice. Additionally, these authors showed that the plant sterol/stanol-induced reduction of cholesterol absorption in mice is not influenced by *Abcg5*-deficiency (J. Nutr., in press), indicating that intra-luminal events are most relevant for the inhibitory effect of these dietary compounds.

The modes of action of the different cholesterol absorption decreasing compounds are schematically depicted in Figure 2.

NOVEL ROLE OF THE INTESTINE IN REVERSE CHOLESTEROL TRANSPORT

It is clear that the intestine plays a major role in cholesterol homeostasis as a cholesterol absorbing organ. However, recent studies revealed that the intestine also acts as an excretory organ in the reverse cholesterol transport (RCT) pathway^[66,75]. This pathway is classically defined as the HDL-mediated flux of cholesterol from peripheral cells to the liver, followed by its secretion into bile and disposal *via* the feces. RCT is extremely important in prevention of CVD as it removes excess cholesterol from macrophages present in the arterial vessel wall. The amount of cholesterol secreted into bile is substantial. As only part of it is absorbed by the intestine, it contributes significantly to cholesterol loss *via* the feces. However, a novel pathway that contributes to fecal cholesterol loss has recently been established.

Already in the nineteen-sixties, it was suggested that non-dietary cholesterol present in the intestinal lumen consists of a fraction secreted by the liver into the bile and a second fraction directly secreted by the intestine. Measuring dietary cholesterol, cholesterol absorption and cholesterol loss *via* the feces in patients with complete obstruction of common bile duct due to carcinoma of the head of the pancreas unequivocally established the presence of intestinally secreted cholesterol in the feces^[76]. By intestinal perfusion studies in humans, Simmonds *et al.*^[77] have tried to quantify this route. In a triple lumen tube system, perfusion studies were carried out using micellar solutions

with radio-labeled cholesterol. Decrease in specific activity was interpreted as secretion of endogenous cholesterol from the intestine and the contribution of endogenously secreted cholesterol from the intestine was estimated to be about 44% of total fecal output, but direct proof for the existence of this pathway could not be provided^[77].

Since these early experiments, the focus of research has shifted more towards the liver. Biliary cholesterol and bile acid secretions are believed to represent the major pathways for removal of excess cholesterol. However, recent calculations of cholesterol fluxes in different mouse models again emphasize the relevance of intestinal cholesterol secretion. A striking example is provided by the *Cyp7a1*-deficient mouse^[78]. *Cyp7a1* is important for converting cholesterol into bile acids and catalyzing the formation of 7 α -hydroxycholesterol^[79]. As *Cyp7a1* is rate-controlling in this pathway, it is regulated in a complex manner involving multiple nuclear receptors. *Cyp7a1*-deficiency in mice leads to significantly decreased fecal bile acid loss and bile acid pool size. Surprisingly, fecal neutral sterol output is increased two times in *Cyp7a1*^{-/-} mice, although biliary cholesterol concentration remains unaffected^[78]. As dietary intake and cholesterol absorption are known, it can be calculated from these data that direct intestinal cholesterol secretion contributes at least 30% to the increased fecal neutral sterol output.

Plösch and colleagues^[66] showed that the pathway of intestinal cholesterol secretion can be induced in mice by treatment with the synthetic LXR agonist T0901317. In C57BL/6 mice, efflux of cholesterol from the intestinal epithelium into the lumen, calculated from the difference between dietary and biliary input minus fecal output, contributed up to 36% of the total fecal cholesterol loss. Pharmacological LXR activation in these mice tripled the intestinal cholesterol secretion, showing that this represents a valid, inducible pathway for removal of cholesterol in mice.

To further characterize this route, Kruit *et al*^[75] studied the effects of LXR activation by the synthetic agonist GW3965 in wild-type and *Mdr2*-deficient mice. *Mdr2*-Pgp (or *Abcb4* according to the new nomenclature) mediates the ATP-dependent translocation of phospholipids at the canalicular membrane of hepatocytes. Consequently, *Mdr2*-deficiency leads to the inability to secrete phospholipids into the bile. Due to the tight coupling of phospholipid and cholesterol secretion, these mice also show a severely impaired biliary cholesterol secretion^[80,81]. Despite the impaired biliary cholesterol secretion, chow-fed *Mdr2*^{-/-} mice showed a similar fecal neutral sterols loss as wild-type mice, suggesting that the intestine indeed contributes to the fecal neutral sterol loss. LXR activation increased fecal neutral sterol output to a similar extent in *Mdr2*^{-/-} and wild-type mice, although biliary cholesterol secretion remained impaired in *Mdr2*^{-/-} mice but increased in wild-type mice. These data show that the increased fecal cholesterol loss upon LXR activation is independent of biliary cholesterol secretion. Although fractional cholesterol absorption decreased to a greater extent in *Mdr2*^{-/-} mice compared to wild-type mice upon LXR activation, it could be calculated that at least 57% of fecal cholesterol originates from intestinal secretion in *Mdr2*^{-/-} mice^[75].

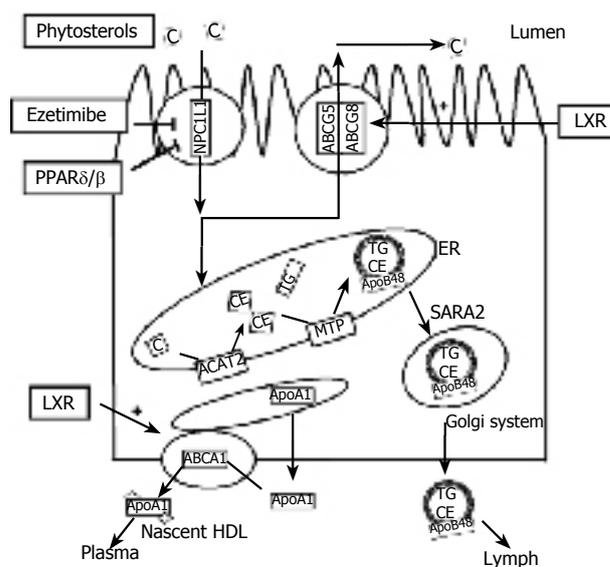

Figure 2 Schematic overview of the regulation of cholesterol transport in enterocytes. Plant sterols, ezetimibe PPAR δ/β agonists and LXR agonists all reduce cholesterol absorption through different mechanisms. Plant sterols interfere with micellisation of cholesterol. Ezetimibe binds to NPC1L1 and thereby interferes with the cholesterol uptake. Agonists for PPAR δ/β reduce expression of NPC1L1 and thereby the amount of NPC1L1 protein. Agonists for LXR increase the expression of ABCG5 and ABCG8 and thereby enhance the efflux of cholesterol towards the intestinal lumen. LXR: Liver X Receptor; PPAR δ/β : Peroxisome proliferators-activated receptor δ/β .

The most intriguing question, namely the origin of intestine-derived cholesterol has remained unanswered so far. Part of the cholesterol could, in theory, originate from enhanced sloughing of intestinal cells or reflect a consequence of increased intestinal *de novo* cholesterol synthesis. Indeed, increased intestinal cholesterol synthesis has been found in *Cyp7a1*^{-/-} mice^[78]. Upon LXR activation, however, intestinal *HMGCoA reductase* gene expression remained unchanged^[66,75], indicative for unchanged cholesterol synthesis, while fecal sterol loss increased 3 times. Staining for the proliferation marker Ki-67 has revealed no signs of increased intestinal cell proliferation upon LXR activation, making the possibility of enhanced cell shedding less likely^[75]. Using intravenously injected radiolabeled cholesterol as a marker, Kruit and colleagues^[75] additionally showed that fecal loss of plasma-derived cholesterol is 1.7-fold higher upon LXR activation in *Mdr2*^{-/-} mice, suggesting that the intestine plays an important role independently of biliary cholesterol in cholesterol transport from plasma to the feces.

Further research should be done to identify the putative proteins involved in this pathway. The sterol efflux proteins, ABCG5/ABCG8, seem to be good candidates, as increased fecal neutral sterol output upon LXR activation requires the presence of *Abcg5* and *Abcg8*^[49] and transgenic mice overexpressing human *ABCG5* and *ABCG8* (*bG5G8Tg*) showed significantly-increased fecal neutral sterol loss^[48]. However, deficiency of *Abcg5* and/or *Abcg8* leads to only mild^[45,49] or no^[46] decrease in fecal neutral sterol loss and the increased fecal neutral sterol excretion loss in the *bG5G8Tg* mice was inhibited in *bG5G8Tg* mice lacking *Mdr2* (*Mdr2*^{-/-}*bG5G8Tg* mice),

suggesting that biliary cholesterol secretion is responsible for the increased fecal sterol loss in *bG5G8Tg* mice^[82]. However, *bG5G8Tg* mice showed a high expression of human *ABCG5* and *ABCG8* in the liver but their expression in the intestine was far less pronounced^[48]. Thus, the question whether intestinal *ABCG5* and *ABCG8* are important for intestinal cholesterol efflux under normal conditions still remains unanswered.

Virtually nothing is known about transporter systems involved in uptake of plasma cholesterol by enterocytes prior to its excretion into the intestinal lumen. LXR activation can upregulate a number of cholesterol transporters, of which only SR-BI is known to be involved in cholesterol uptake, at least in the liver. Chow-fed *SR-BI*^{-/-} mice show only a small decrease in fecal neutral sterol loss, suggesting a relatively small contribution of intestinal SR-BI to the control of fecal cholesterol excretion. However, basolaterally localized SR-BI in enterocytes could theoretically play a role in cholesterol. When free cholesterol in enterocytes decreases due to activation of *ABCG5* and *ABCG8*, uptake of the sterol from the plasma compartment may become energetically favorable.

INTESTINAL CONTRIBUTION TO HDL BIOGENESIS

The intestine along with the liver, has been known for many years to synthesize and secrete apolipoprotein A-I (ApoA-I), the principal apolipoprotein of HDL. Already in 1977, Glickman and Green^[83] have described the synthesis of ApoA-I by the intestine of rats. One year later, Wu and Windmueller^[84] estimated that intestinally synthesized ApoA-I contributes up to 56% of total plasma ApoA-I in rats. A potential role for the intestine in HDL particle assembly was initially suggested from experiments in hepatectomized dogs and studies describing the presence of HDL in mesenteric lymph^[86-89]. More recently, *in vitro* studies using the human colon carcinoma cell line CaCo-2 showed that basolateral efflux of cholesterol occurs in high density ApoB-free, ApoA-I containing lipoproteins^[90,91].

In addition to ApoA-I, ATP-binding cassette (ABC) transporter 1 (ABCA1) is of crucial importance for HDL formation. Three different groups have independently reported mutations of the ABCA1 gene as the cause of Tangier disease^[92-94]. Tangier disease is characterized by almost complete absence of plasma HDL, abnormal accumulation of cholesteryl esters in reticuloendothelial cells of many tissues and early incidence of atherosclerosis. No abnormalities in the ApoA-I protein^[95] or in protein synthesis have been found. These findings and the subsequent generation of *Abca1*^{-/-} mice which also lack plasma HDL^[57], underscore that ABCA1 is crucial for HDL formation.

ABCA1 performs the rate-controlling step in HDL formation by mediating the efflux of cholesterol and phospholipids to nascent ApoA-I. ABCA1 is widely expressed throughout the body^[96], however not all tissues are important for the regulation of plasma HDL. Bone marrow transplantation studies in which bone marrow of wild-type and *Abca1*^{-/-} mice was transplanted into *Abca1*^{-/-}

or wild-type mice, respectively, revealed that macrophage expression of *Abca1* contributes only minimally to plasma HDL^[97]. Macrophage ABCA1 is, however, important for the development of atherosclerosis because deficiency of *Abca1* in bone marrow-derived cells increased the susceptibility to atherosclerosis in sensitive strains of mice^[98,99]. Conversely, overexpression of *ABCA1* in bone marrow-derived cells inhibited the progression of atherosclerotic lesions in such mice^[100].

As both the liver and intestine synthesize ApoA-I and express significant levels of ABCA1, they are prone to contribute to plasma HDL levels. Indeed, mice overexpressing human *ABCA1* in the liver and macrophages showed increased plasma HDL levels. Since macrophage ABCA1 can only minimally increase plasma HDL^[97], this indicates that plasma HDL is controlled by hepatic ABCA1. A similar conclusion can be drawn from studies employing adenoviral *Abca1* transfer to mouse liver *in vivo*^[101,102]. Basso *et al* showed that treatment of C57BL/6 mice with adenovirus containing *rABCA1-GFP* resulted in a 2-fold increase in plasma HDL levels. Wellington *et al*^[102] treated mice with increasing doses of *ABCA1*-containing adenoviruses, resulting in a dose-dependent increase in hepatic ABCA1 protein expression. HDL cholesterol was increased in mice injected with low doses of *adABCA1*, but surprisingly higher doses did not further raise plasma HDL levels^[102]. Liver-specific *Abca1* knockdown by 50% in mice using siRNA resulted in a 40% decrease of plasma HDL cholesterol levels, indicating that hepatic *Abca1* expression correlates with plasma HDL levels in mice^[103].

The creation of liver-specific *Abca1* knock-out (*Abca1*^{-L/-}) mice definitively showed that the liver is the major contributor to plasma HDL as liver-specific deficiency of *Abca1* results in a decrease of plasma HDL cholesterol levels by 80%. Further analysis revealed that *in vivo* catabolism of HDL ApoA-I isolated from wild-type mice was 2-fold higher in *Abca1*^{-L/-} mice due to a 2-fold higher rate of catabolism of ApoA-I in the kidneys^[104]. These data unequivocally demonstrate that hepatic *Abca1* is responsible for the maintenance of the circulating plasma HDL by direct lipidation of lipid-poor ApoA-I containing particles. These data also show that, although the liver is the major organ responsible for HDL levels, additional extra-hepatic sites also contribute to HDL biogenesis.

To address the contribution of intestinal *Abca1* to plasma HDL, intestine-specific *Abca1* knockout (*Abca1*^{-I/-}) mice were created using the Cre/Lox system with the Cre transgene under the control of the villin promoter^[105]. Brunham *et al* showed that intestinal *Abca1* deficiency resulted in a 30% decrease in plasma HDL cholesterol levels, indicating that intestinal *Abca1* is critically involved in HDL biogenesis. Combined deletion of both hepatic and intestinal *Abca1* resulted in a 90% decrease of plasma HDL, which was similar to the level found in the whole-body *Abca1*^{-/-} mice, proving that the liver and intestine are really the two major sites for HDL biogenesis. Absence of intestinal *Abca1* resulted in decreased transport of dietary cholesterol into plasma HDL, but total intestinal cholesterol absorption was not affected. Surprisingly, lymphatic HDL content was hardly affected in *Abca1*^{-I/-} mice. In contrast, HDL was virtually

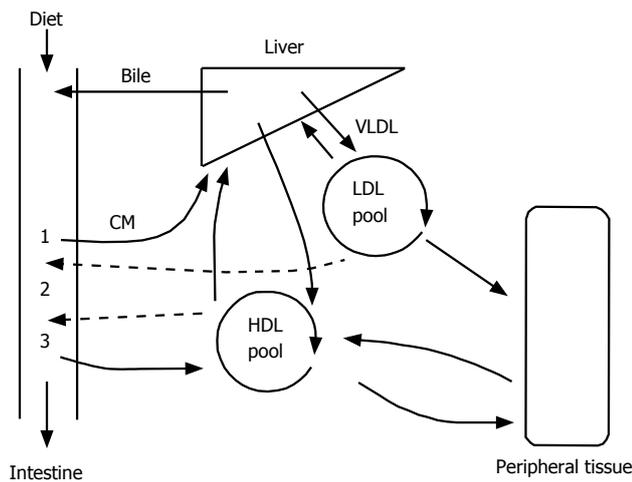

Figure 3 Schematic overview of the involvement of the intestine in cholesterol homeostasis. The intestine is critically involved in the control of plasma cholesterol due to its role in intestinal cholesterol absorption (1), direct cholesterol excretion into the intestinal lumen (2), and HDL biogenesis (3). CM: Chylomicron; HDL: High density lipoprotein; LDL: Low density lipoprotein; VLDL: Very low density lipoprotein.

absent in lymph of *Abca1*^{-/-} mice, indicating that lymph HDL originates from the plasma compartment rather than directly from the intestine^[105]. This finding has solved a long-lasting debate on the origin of lymphatic HDL^[83,86-88,106,107]. It would be interesting to see whether lack of intestinal *Abca1* influences the development of atherosclerosis.

Modulation of plasma HDL by intestine-specific LXR activation

As discussed above, LXR is a major regulator of cholesterol metabolism and LXR agonists are considered promising candidates for novel treatment strategies against atherosclerosis. Indeed, treatment of *ApoE*^{-/-} and *LDLr*^{-/-} mice, both are sensitive to atherosclerosis development, with synthetic LXR agonists inhibited the development of atherosclerosis^[108,109]. However, general LXR activation also leads to increased lipogenesis, hypertriglyceridemia and hepatic steatosis in rodents^[65] and is therefore not recommended for its use in humans. Specific LXR activation in the intestine may be beneficial in this respect, as it can theoretically lead to decreased cholesterol absorption, increased intestinal cholesterol excretion and plasma HDL levels. The preliminary data from our laboratory, using an intestine-specific LXR agonist in Wistar rats, showed that intestine-specific LXR activation indeed has the desired effect in this model without adverse effects on triglyceride metabolism.

CONCLUSION

During the past 5 years, a number of developments have greatly contributed to appreciation of the important role of the intestine in maintenance of cholesterol homeostasis (Figure 3). The most important developments include the identification of transporter proteins involved in uptake and secretion of cholesterol by enterocytes, the establishment of the direct cholesterol excretion pathway

of the intestine, and the definition of the role of the intestine in HDL biogenesis.

A wealth of data indicate that the intestine should be considered a promising target for development of anti-atherosclerotic drugs that, in addition to interference with cholesterol absorption, may directly modulate cholesterol excretion and plasma HDL cholesterol levels.

Abstract

Trichinosis is one of the most common food-borne parasitic zoonoses in Thailand and many outbreaks are reported each year. This paper reviews the history, species, and epidemiology of the disease and food habits of the people with an emphasis on the north, northeast, central and south regions of Thailand. The earliest record of trichinosis in Thailand was in 1962 in the Mae Sariang District, Mae Hong Son Province. Since then, about 130 outbreaks have been reported involving 7392 patients and 97 deaths (1962-2005). The highest number of cases, 557, was recorded in 1983. The annual epidemiological surveillance reports of the Bureau of Epidemiology, Department of Disease Control, Ministry of Public Health, Thailand, show that trichinosis cases increased from 61 in 1997 to 351 in 1998. In contrast to these figures, the number of reported cases decreased to 16 in 1999 and 128 cases in 2000. There was no record of trichinosis in 2001, but then the figures for 2002, 2003 and 2004 were 289, 126 and 212 respectively. The infected patients were mostly in the 35-44 years age group and the disease occurred more frequently in men than women at a ratio of 1.7-2.0:1. There were 84 reported cases of trichinosis in Chiang Rai, Nan, Chiang Mai, Si Sa ket, Nakhon Phanom, Kalasin, Nakhon Ratchasima, Nakhon Nayok, Nakhon Pathom and Surat Thani, provinces located in different parts of Thailand in 2005. The outbreaks were more common in the northern areas, especially in rural areas where people ate raw or under-cooked pork and/or wild animals. This indicates the need for health education programs to prevent and control trichinosis as soon as possible in the high-risk areas.

INTRODUCTION

Trichinosis is one of the most widespread helminthic zoonoses. Unlike other parasitic infections, it has been a major public health problem and reported in many Asian countries, including China, Japan, Korea and Thailand^[1-7]. Since 1835, controversy has surrounded the discovery and description of *Trichinella*. In that year the organism, *T. spiralis*, was initially observed by a first-year medical student, James Paget, later famous for other medical achievements, but it was named and described by his professor, Richard Owen. Until recently, that species was the only one known^[8]. However, seven distinct species of *Trichinella* are now recognized, *T. spiralis*, *T. pseudospiralis*, *T. native*, *T. nelsoni*, *T. britovi*, *T. papuae* and *T. murrelli*^[9-16]. In Thailand, human trichinosis was first reported in June 1962. The causative agent of most outbreaks of this disease has been identified as *T. spiralis*^[11], but an outbreak in the Ta Sae District, Chumphon Province in 1994 was due to *T. pseudospiralis*^[17]. Trichinosis infections in humans are characterized by an initial phase dominated by gastro-intestinal symptoms (vomiting and diarrhea), followed by a stage lasting about 2 mo, of fever, sub-cutaneous edema, muscle pain, cachexy, myocardiosis and weakness. Death occurs in up to 40% of cases either due to anaphylactic shock or the consequences of the myocardiosis^[17,18-23]. In eight cases of childhood trichinosis reported in Thailand, major symptoms and signs were fever, myalgia, puffy face and eyelids. Laboratory examinations showed leukocytosis, eosinophilia and elevation of muscle enzymes^[24]. The outbreaks of trichinosis in Thailand seem to depend in part on the density of *Trichinella* contamination in domestic and wild animals, but they are also influenced by social and other factors, including people's eating habits^[25-30]. This study includes a review of the history, species, epidemiology of trichinosis and food habits of Thai people based on previous studies and the annual epidemiological surveillance reports from 2002-2005 from the Bureau of Epidemiology, Department of Disease Control, Ministry of Public Health, Thailand.

HISTORICAL REVIEW OF TRICHINOSIS IN THAILAND

The first outbreak of trichinosis in Thailand was in 1962 and involved 56 patients resulting in 11 deaths in the Mae Sariang District, Mae Hong Son Province. Meat from pigs was the source of outbreak^[1]. The number of outbreaks has tended to increase in recent years. The annual epidemiological surveillance report dated 15 November 2005 recorded 7392 patients and 97 deaths. The highest annual number of hospital recorded trichinosis cases was 557 in 1983. This figure is considered an underestimation of the actual number of cases involved in the outbreaks^[31-36]. In April 1973, an outbreak of trichinosis occurred in the Mae Sruay District, Chiang Rai Province. Thirty-one persons were involved, ranging from 9 to 72 years, and one adult female died^[37]. In 1980, trichinosis was reported in the Pluak Dang District of Rayong Province, the infection being caused by the consumption of wild squirrel^[38,39]. An epidemic of trichinosis involving 177 patients and 13 deaths occurred in April 1981 in Kok-Ta-Back Village, Nong-Pai District, Petchabun Province, and reported the fourteenth outbreak of human trichinosis in Thailand^[40-42]. Khambooruang^[43] reported 118 discrete outbreaks of the disease involving 5400 patients and 95 deaths. In the south of Thailand, an outbreak of trichinosis affecting 59 individuals resulting in one death occurred in Chumporn Province during 1994-1995. This was the first report of an epidemic of human infection caused by *T. pseudospiralis*^[7].

Takahashi *et al.*^[35] reported 120 outbreaks from 1962 to 2000 involving nearly 6700 patients and 97 deaths. The highest number of cases was in Chiang Mai, Chiang Rai and Nan provinces, 1776, 1739 and 894 respectively. Chotmongkol *et al.*^[7] presented the case of a 49-year-old man with progressive generalized muscle hypertrophy and weakness for 3 mo. Histologic findings from muscle biopsy demonstrated a nurse cell-larva complex. Treatment with albendazole resulted in a very favorable outcome. Trichinosis remains a major public health problem in Thailand, often associated with rural people celebrating local and traditional festivals, such as the northern Thai New Year and wedding ceremonies, at which raw and/or under-cooked wild animals are eaten.

SPECIES OF TRICHINOSIS IN THAILAND

Seven species belonging to the *Trichinella* genus, five with encapsulated larvae and two with non-encapsulated larvae in host muscles and three additional genotypes, have been described to date: *T. spiralis*, *T. nativa*, *T. britovi*, *T. murrelli*, *T. nelsoni*, *T. pseudospiralis*, and *T. papuae*. In Southeast Asia, *T. spiralis* and *T. pseudospiralis* have been documented in domestic animals and/or humans in Cambodia, Indonesia (Bali and Sumatra), Lao PDR, Malaysia, Myanmar and Thailand^[10,12,14,15,44]. In Thailand, the causative agent of most outbreaks of trichinosis has been identified as *T. spiralis*^[1] (Figure 1). Meanwhile, Jongwutiwes *et al.*^[7] reported human infection by *T. pseudospiralis* (Figure 2). An outbreak

of trichinosis affecting 59 individuals, of whom one died, occurred in south Thailand during 1994-1995. After that, there were no reports of other species of *Trichinella* in this country in either humans or animals^[35]. Until recently, *T. spiralis* and *T. pseudospiralis* were the only human-infecting species in Thailand.

EPIDEMIOLOGY OF TRICHINOSIS IN THAILAND

Trichinosis is more common in temperate regions than in tropical regions. The epidemiology of trichinosis was first reported in 1962 in patients who consumed pig meat^[1]. The second outbreak was in 1963 at Prao District, Chiang Mai Province. Since then, outbreaks have occurred each year, mostly in the northern part of Thailand where people have eaten raw or under-cooked pork and/or wild animals^[45-47]. The annual epidemiological surveillance reports indicated that trichinosis cases increased from 61 in 1997 to 351 in 1998. In 1999 and 2000, the number of reported cases decreased to 16 and 128 respectively. No cases were recorded in 2001, hospital based or by the Bureau of Epidemiology, that clearly showed a human trichinosis case this year, but then 289, 126 and 212 occurred in 2002, 2003 and 2004 respectively. In 2005, 75 cases were reported by the Bureau of Epidemiology, Department of Disease Control, and Ministry of Public Health (Figure 3). Since then, about 130 outbreaks have been reported totaling 7392 patients and 97 deaths.

Since 2002, the distribution of human trichinosis cases by age groups has been considered by the annual epidemiological surveillance reports which data were the hospital based. The youngest patient was about 1 year old. Charkrit^[44] reported a patient of the same age. It is not uncommon to see patients in the 10-14 and 65+ age groups, but most patients are in the age 35-44 groups, morbidity rate was 0.04 per 100000 of people (Figure 4). Infection occurs in men more frequently than women at the ratio of 1.7-2:1 (calculated from trichinosis cases of 2002-2005). This result was similar to the 1.2-2.6:1 found by Charkrit^[44].

The epidemiological surveillance reports of trichinosis have been conducted almost every year and data investigation reveals that the outbreaks have occurred predominantly in rural areas. The north part of Thailand is responsible for 96.4% of all cases reported from 1962 to 2000^[35]. The annual epidemiological surveillance reports from 2002 to 2005 found consistently high numbers of cases (289, 126, 30 and 60 respectively) in the north region. The figures for 2004 reported 124 in the northeast, the first time that a region other than the north has had the highest number of cases. Only small numbers of trichinosis cases were recorded in the central and south regions in 2005 (Figure 5). In 2005, 75 trichinosis cases were reported, the highest number occurring in October, August, March and September, 36, 16, 7 and 5 respectively. The cases were reported in Chiang Rai, Nan, Chiang Mai, Si Sa ket, Nakhon Phanom, Kalasin, Nakhon Ratchasima, Nakhon Nayok and Surat Thani, all provinces located in different parts of Thailand. The main age group was 35-44 years and the

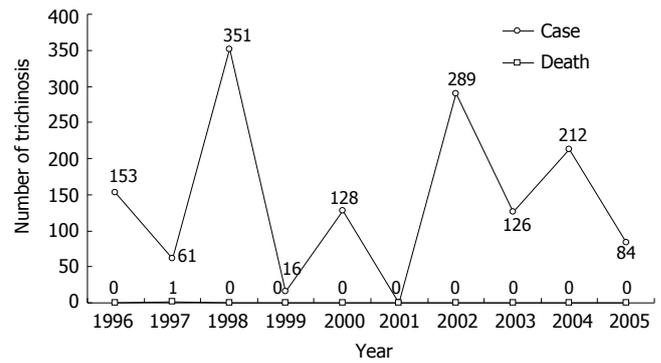

Figure 3 Trichinosis cases in Thailand from 1995-2005.

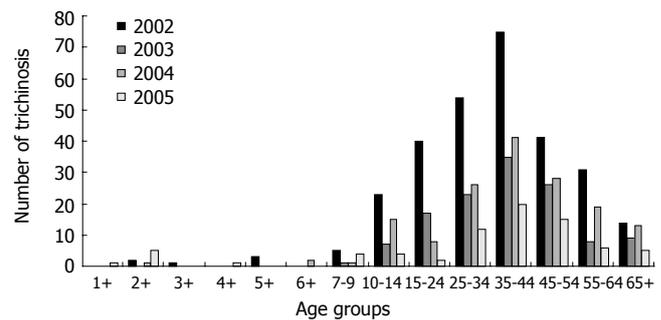

Figure 4 Human trichinosis cases in Thailand from 2002-2005.

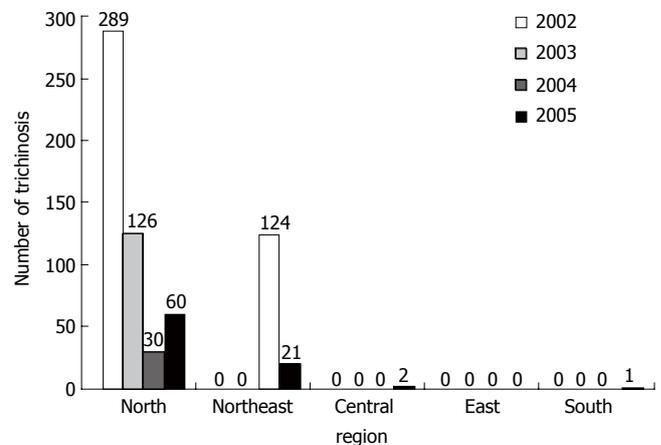

Figure 5 Human trichinosis by region in Thailand from 2002-2005.

youngest patient was 1.

Most outbreaks occurred in the north region, including 60.84% of all cases reported from 1962 to 2005. These results were different from those of Takahashi *et al* (2000) that reported the north region was responsible for 96.4% of all cases. The most severely affected areas in the north region were the highland provinces of Chiang Rai, Nan, Chiang Mai, Mae Hong Son and Payao. (Figure 6). The numbers of cases in other parts of Thailand were very few. In the central region, Uthai Thani, Karnchanaburi Nakhon Pathom and Nakhon Nayok provinces reported 0.28% of the total number of cases. Chumporn, Songkla and Surat Thani were the only three provinces of the south region in

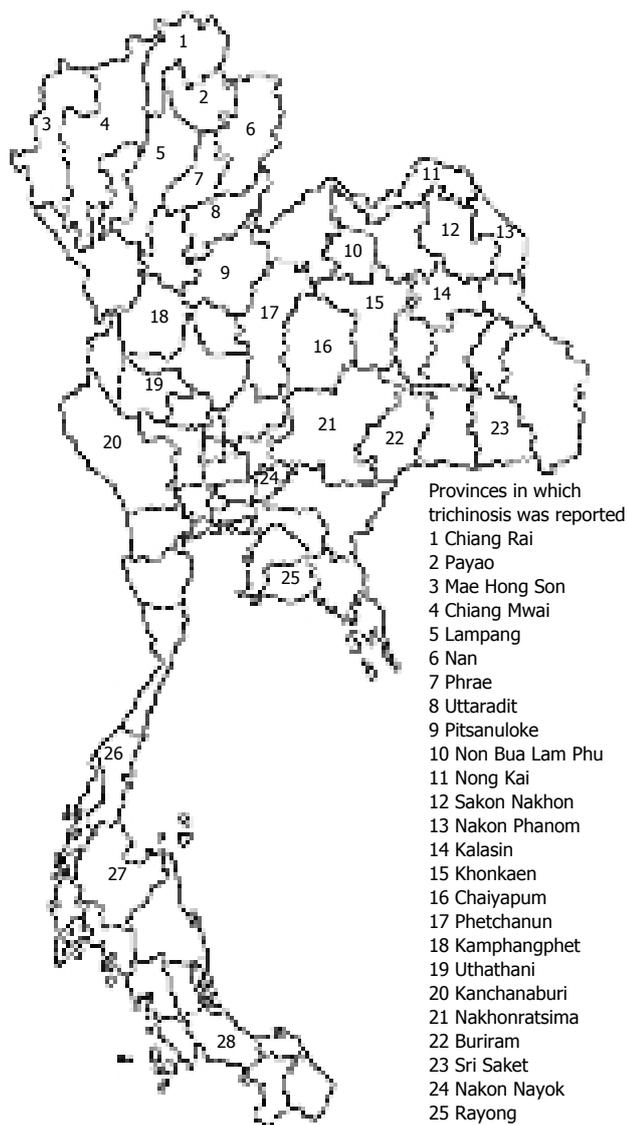

Figure 6 Provinces trichinosis reported in Thailand from 1962-2005.

Table 1 Distribution of trichinosis in humans by province in Thailand from 2002-2005

Region	Province	Total cases (%)
North	Chiang Mai, Chiang Rai, Nan, Phrae, Uttaradit, Payao, Mae Hong Son, Petchabun, Kamphaengphet, Pitsanuloke, Lampang	60.87
Northeast	Nong Bua Lam Phu, Buri Rum, Kalasin, Sakol Nakorn, Sri Saket, Nong Kai, Khon Kaen, Nakhon Phanom, Nakhon Ratchasima	38.59
East	Rayong	0.18
Central	Uthai Thani, Karnchanaburi, Nakhon Nayok, Nakhon Pathom	0.18
South	Chumporn, Songkla, Surat Thani	0.18

which cases of trichinosis were observed, these accounting for only 0.28% of cases (Table 1). The northeast of Thailand was responsible for the highest number of cases in 2004 and the second highest (38.5%) in 2005. Provinces

Figure 7 The dishes of raw or under-cooked wild boar are the favorite local foods that are the major sources of infection in Thailand. A: Lahb is made from wild pig or reptile; B: Nham is also made from wild pig and fermented for a few days.

involved were Nong Bua Lam Phu, Buri Ram, Kalasin, Sakol Nakorn, Sri Saket, Nong Kai, Khon Kaen, Nakhon Phanom and Nakhon Ratchasima. These results showed trichinosis as a serious problem, particularly in the north and northeast regions of Thailand.

SOURCE OF THAI HUMAN INFECTION

Trichinosis is a parasitic disease of mammals caused by the nematode parasite *Trichinella* spp. It has an important zoonosis with humans becoming infected by eating raw or inadequately cooked infected meat. Infection is more common in omnivores (horses, humans, pigs and rats) and carnivores (cats, dogs, and seals). Pigs and rodents seem to play the most important role in the epidemiology of the disease. The main source of infection in Thailand has been pigs, but wild boar, jackal and black bear were also reported as sources of trichinosis^[45,46]. All trichinosis cases gave a history of having consumed raw pork in the form of “lahb” and “nahm,” favorite dishes of north Thailand^[37] (Figure 7). Lahb is made from chopped raw pork mixed with lemon juice, roasted rice powder, finely cut red onion and parsley (Figure 7A). Nham is also made from chopped raw pork mixed with salt, garlic and chili, tightly wrapped in banana leaves for a few days for fermentation (Figure 7B)^[35]. Some Thai dishes are proven as viable *T. spiralis* larvae sources due to cooking procedures^[47]. Srikitjakarn *et al*^[48] reported *T. spiralis* was found in 1.67% of 421 dogs in Taree District, Sakonnakhon Province. Raw dog meat was a source of infection in Kaeng Khlo District, Chaiphaphum Province

in December 1984^[49]. The incidence of *T. spiralis* larvae in dog meat in the areas favoring dog meat consumption is a major public health problem in the future. The major source of infection is wild boar, free roaming pigs located in the north, and wild animals from Laos and Myanmar sold in Thailand^[2].

In conclusion, various studies of trichinosis in Thailand since the first outbreak up until recent years have shown that most of the outbreaks occurred in the north of the country, an area in which some of the favorite traditional dishes involve meat from pigs and wild boars, often eaten raw or under-cooked. No vaccines have yet been developed. Treatment exists for humans if diagnosis is done promptly. Better prevention and control of trichinosis require health education to stop the consumption of infected and under-cooked meats.

Abstract

AIM: To study whether indomethacin (IND), a nonselective cyclooxygenase (COX) inhibitor or NS-398 (NS), a COX-2-selective inhibitor, induces apoptosis in human colon cancer cells and which apoptosis-related genes and pathways are involved.

METHODS: Human colon cancer Caco-2 cells were treated with either: placebo, IND (0.05-0.5 mmol/L) or NS (0.01-0.2 mmol/L) for 1, 5 and 18 h. We then studied: (1) Cell death by the TUNEL method, (2) mRNA expression of 96 apoptosis-related genes using DNA microarray, (3) expression of selected apoptosis related proteins by Western blotting.

RESULTS: Both IND and NS induced apoptosis in 30%-50% of Caco-2 cells in a dose dependent manner. IND (0.1 mmol/L for 1 h) significantly up-regulated pro-apoptotic genes in four families: (1) TNF receptor and ligand, (2) Caspase, (3) Bcl-2 and (4) Caspase recruiting domain. NS treatment up-regulated similar pro-apoptotic genes as IND. In addition, IND also down-regulated anti-apoptotic genes of the IAP family.

CONCLUSION: (1) Both non-selective and COX-2-selective NSAIDs induce apoptosis in colon cancer cells in a dose dependent manner. (2) Both NSAIDs induce apoptosis by activating two main apoptotic pathways: the death receptor pathway (involving TNF-R) and the mitochondrial pathway. (3) IND induces apoptosis by up-regulating pro-apoptotic genes and down-regulating anti-apoptotic genes, while NS only up-regulates pro-apoptotic genes. (4) Induction of apoptosis in colon

INTRODUCTION

Colorectal cancer (CRC) is the second most lethal cancer in the USA. Numerous studies suggest that nonsteroidal anti-inflammatory drugs (NSAIDs) have antineoplastic effects. Epidemiological studies have shown a reduction in the risk of death from colorectal cancer associated with the use of NSAIDs^[1]. Perhaps the most compelling evidence for the chemopreventive role of NSAIDs is provided by the clinical studies in patients with familial adenomatous polyposis (FAP), an inherited predisposition for CRC^[2-6]. In these studies, the NSAID sulindac and the selective cyclooxygenase-2 inhibitor (COX-2) celecoxib, reduced both the number and the size of colorectal adenomas in FAP patients. Similarly, NSAIDs prevent tumor formation in a variety of animal models of CRC^[7,8].

How exactly do NSAIDs exert their effects to prevent tumorigenesis? A large body of evidence suggests that NSAIDs exert their chemopreventive actions by: (1) inhibition of cell growth and proliferation and (2) induction of apoptosis^[9]. The mechanisms by which NSAIDs achieve these processes are still incompletely understood. One widely studied mechanism is *via* the COX-2 dependent pathways.

NSAIDs are known as the inhibitors of the cyclooxygenase (COX-1 and COX-2) enzymes, which are involved in the conversion of arachidonic acid to eicosanoids. COX-1 is expressed constitutively in a variety of tissues and plays a role in platelet aggregation and gastric cytoprotection. COX-2, is inducible particularly during inflammation in cells such as endothelial cells, macrophages and intestinal epithelial cells^[10]. Interestingly,

COX-2 expression has been shown to be dramatically increased in colon cancer cells compared to normal colonic mucosa and is associated with a several-fold increase in concentration of prostaglandin E₂ (PGE₂)^[11-13]. Studies from our lab demonstrated that COX-2 generated PGE₂ promotes colon cancer cell growth by transactivating epidermal growth factor receptor^[14]. The increased expression of COX-2 also seems to prevent cancer cells from undergoing programmed cell death, at the same time, promoting angiogenesis, enhancing metastatic potential and modulating cell proliferation. Direct evidence for the role of COX-2 in colon cancer tumorigenesis has been reported in many studies. Using APC knockout mice, which develop polyps in their intestinal tracts due to the mutation of the APC gene, Oshima and colleagues were able to show a significant reduction of intestinal polyps when either one or both of COX-2 alleles were deleted^[15,16]. Furthermore, the COX-2 selective inhibitor NS-398, has been reported to suppress tumor growth in different cancer cell lines, to induce apoptosis in human colon cancer cells and to have anti-angiogenic effects^[9,17-19].

However, recent data suggest that COX-2 may not be the sole target for the action of NSAIDs. The anti-neoplastic effects of NSAIDs are also seen in tumor cells that do not express COX^[20]. Similarly, NSAID derivatives such as sulindac sulfone, which lacks the ability to inhibit COX, is shown to inhibit colon cancer growth^[21]. Furthermore, NSAIDs affect other mechanisms that regulate cell proliferation and death. For example, NSAIDs regulate PPAR δ , the NF κ B pathway and the lipoxygenase pathway, all of which play a critical role in the regulation of cell survival and death^[22-24].

In order to better understand the complex mechanisms underlying the cancer chemopreventive properties of NSAIDs, it is important to understand the signaling pathways and the genes that directly lead to the inhibition of proliferation and/or the induction of apoptosis in colon cancer cells. With the recent development of DNA microarray technology, identification of genes and pathways can be easily achieved by using microarray chips that contain the genes of interest.

This study was aimed to provide in depth insight into the pro-apoptotic actions of Indomethacin (IND), a nonselective COX inhibitor and NS-398 (NS), a COX-2 selective inhibitor on colon cancer Caco-2 cells, and identify specific pathways and genes involved.

MATERIALS AND METHODS

Cell culture

Human colon cancer (Caco-2) cells (ATCC, Rockville, MD, USA) were grown in DMEM/F12 medium supplied with 20% fetal bovine serum and antibiotics at 37°C in a humidified incubator containing 50 mL/L of CO₂.

Treatment of cells with Indomethacin and NS-398

A 100 mmol/L stock solution IND (Sigma Chemical, St. Louis, MO, USA) was freshly prepared by dissolving the compound in 0.2 mol/L Na₂CO₃ and 1 mol/L NaH₂PO₄, and kept at 37°C before treatment. A 50 mmol/L stock solution of NS (Cayman Chemical, Ann Arbor, MI)

was prepared by dissolving the compound in dimethyl sulfoxide. Caco-2 cells were plated in dishes (100 mm × 20 mm) at a density of 1 × 10⁶ and kept in serum-free medium for 24 h before treatment. The cells were subsequently treated with IND (0.05 mmol/L, 0.1 mmol/L and 0.5 mmol/L) or NS (0.01 mmol/L, 0.1 mmol/L and 0.2 mmol/L) for 1, 5 and 18 h at 37°C.

Cell death detection assay

Cells were plated in 8-well chamber slides and grown until 50%-75% confluent. They were subsequently treated with IND and NS in the same way as described above. Cell death was evaluated by terminal deoxynucleotide transferase (TdT)-mediated dUTP nick end-labeling (TUNEL) using a commercial kit (Roche Diagnostics, Indianapolis, IN, USA, Cat No. 1684817). Briefly, cell monolayers were air-dried and fixed with 4% paraformaldehyde for 1 h at room temperature. 3% H₂O₂ was then used to block endogenous peroxidase. The TUNEL reaction mixture was applied to the cells and incubated for 1 h. Following incubation with anti-fluorescein antibody conjugated with horseradish peroxidase (HRP), diaminobenzidine substrate was then used as developing the agent. Cells treated with culture medium without NSAIDs served as controls. Apoptosis was evaluated by counting the number of apoptotic and total cells in five random fields per chamber in each slide. Apoptotic index was expressed as percentage of apoptotic cells in total number of counted cells.

cDNA microarray study

Serum starved Caco-2 cells were treated with IND or NS in the same way as described above. Total RNA was isolated with Trizol reagent (Invitrogen, Carlsbad, CA, USA, Cat No. 15596-026). Equal amount of RNA from each treatment was used as templates for cDNA synthesis. Radiolabeled probes were synthesized using ³²P dCTP following the manufacturer's protocol provided with the microarray study kit (GEArray Q series, SuperArray Inc. Bethesda, MD, USA). The denatured cDNA probes were added to the arrays containing the genes to be studied. Each of the arrays contains 96 cDNA fragments from genes associated with a specific apoptotic pathway. After overnight hybridization at 60°C with continuous agitation, the arrays were washed for 4 × 15 min with each washing solution (2 × SSC, 1% SDS, then 0.1 × SSC, 0.5% SDS). The arrays were then developed using X-ray films. Quantification of the images was accomplished by the ImageQuant software (Molecular Dynamics, Sunnyvale, CA, USA). Results were expressed in fold change.

Western blotting

Serum starved Caco-2 cells were treated with IND or NS in the same way as described above. Total protein was isolated in a lysis buffer containing 20 mmol/L Tris-HCl pH 7.5, 1 mmol/L EDTA, 300 mmol/L NaCl, 0.2 mmol/L Sodium vanadate, 1% Triton x-100 and 1% NP-40. Equal amount of protein lysate from each treatment was separated by SDA-PAGE and then transferred electrophoretically to a nitrocellulose membrane. The blots were probed with the following antibodies: APAF1

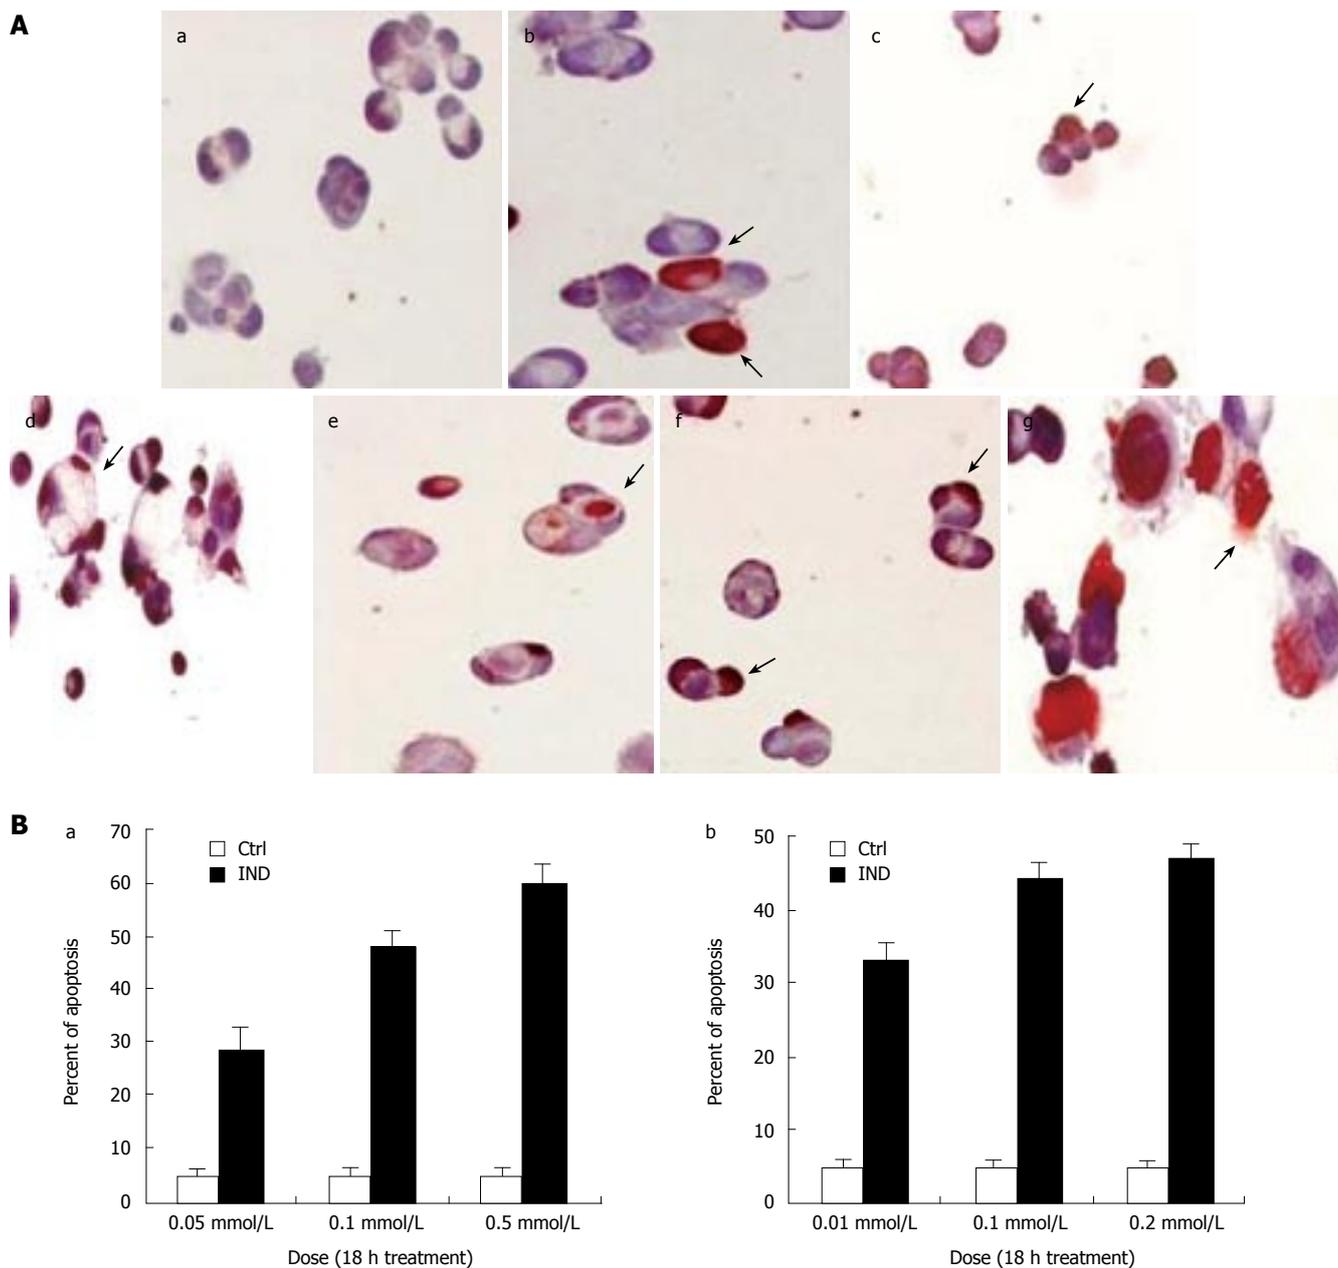

Figure 1 A: TUNEL staining of Caco-2 cells. IND and NS treatment cause apoptosis in a dose dependent manner after 18 h. (a) Control; (b) IND 0.05 mmol/L; (c) IND 0.1 mmol/L; (d) IND 0.5 mmol/L; (e) NS 0.01 mmol/L; (f) NS 0.1 mmol/L; (g) NS 0.2 mmol/L. Experiments performed in triplicates; **B:** Apoptosis in Caco-2 cells is dose dependent after treatment with (a) IND and (b) NS for 18 h. Experiments performed in triplicates.

(apoptotic protease activating factor), BAK (BCL2-antagonist/killer 1), BAX (BCL2-associated X protein), DFPA (DNA fragment factor-45), XIAP (X-linked IAP) and Survivin. The signal was visualized by the chemiluminescence method using ECL detection reagents (Amersham Life Sciences, Arlington Heights, IL). Signals were quantified by densitometry scanning.

Statistical analysis

Results from the TUNEL study are expressed as the mean \pm the standard error. Student's *t* test was used to determine statistical difference between controls and treatments. A *P* value of < 0.05 was considered statistically significant. Comparisons of data between multiple groups were performed with ANOVA.

RESULTS

Apoptotic cell death detection

Using TUNEL method, we found a significant increase in apoptotic cell death in Caco-2 cells treated with both the nonselective COX inhibitor IND and the COX-2-selective inhibitor NS as compared to placebo. The IND and NS-induced apoptotic cell death was dose dependent (Figure 1A and B). Treatment with IND at 0.05 mmol/L, 0.1 mmol/L and 0.5 mmol/L resulted in $28\% \pm 5\%$, $48\% \pm 3\%$ and $60\% \pm 4\%$ of apoptosis respectively (all $P < 0.001$ vs control). On the other hand, treatment with NS at 0.01 mmol/L, 0.1 mmol/L and 0.2 mmol/L induced apoptosis in $33\% \pm 3\%$, $44\% \pm 2\%$ and $47\% \pm 1\%$ respectively (all $P < 0.001$ vs control). In addition, at 0.1 mmol/L concentration, IND induced apoptosis in $33\% \pm 4\%$, 31%

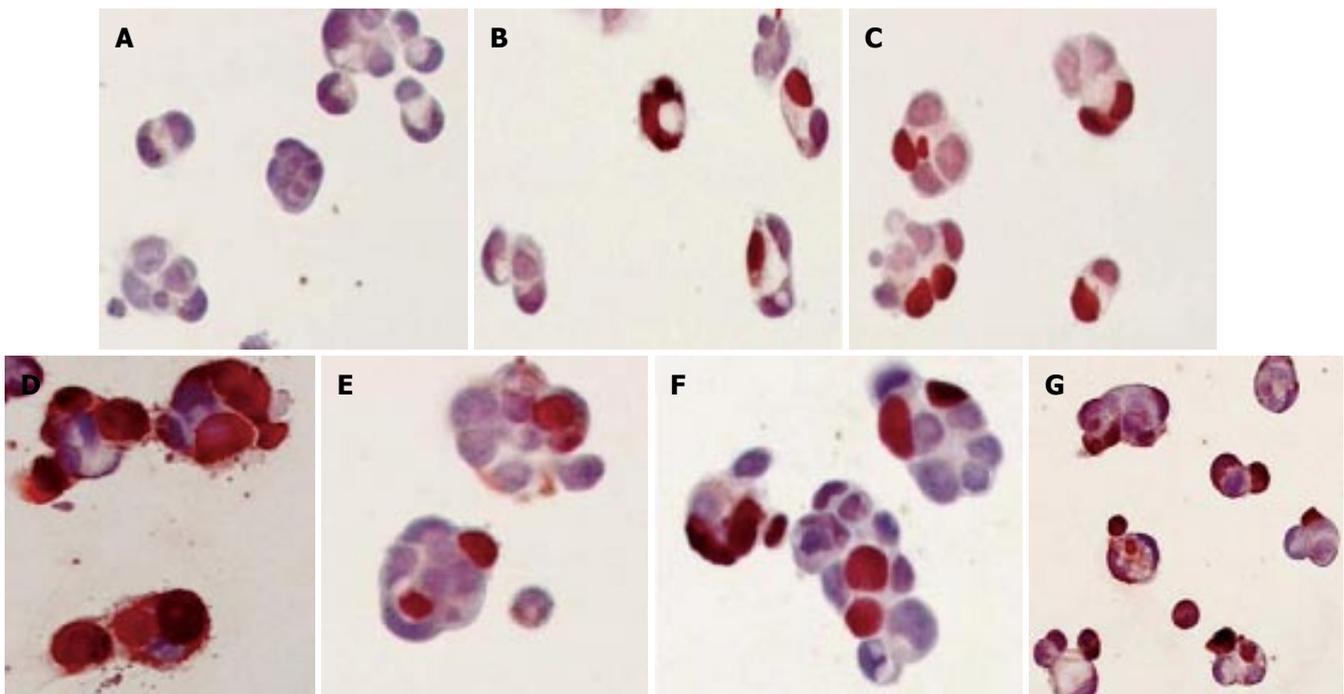

Figure 2 TUNEL staining of Caco-2 cells treated with IND (0.1 mmol/L) and NS (0.1 mmol/L) for 1, 5 and 18 h. (A) Control; (B) IND for 1 h; (C) IND for 5 h; (D) IND for 18 h; (E) NS for 1 h; (F) NS for 5 h; (G) NS for 18 h.

$\pm 2\%$ and $48\% \pm 5\%$ (all $P < 0.001$ *vs* control) of cells and NS induced apoptosis in $29\% \pm 3\%$, $26\% \pm 4\%$ and $46\% \pm 6\%$ (all $P < 0.001$ *vs* control) of cells at 1, 5 and 18 h, respectively (graph not shown).

IND and NS treatment induced morphological changes consistent with apoptosis (cell shrinkage, condensation of chromatin, cytoplasmic budding, apoptotic bodies), which occurred as early as 1 h post-treatment and became extensively evident in 5 and 18 h (Figure 2).

cDNA microarray study of 96 apoptosis related genes

IND treatment (0.1 mmol/L for 1 h) caused a significant up-regulation of pro-apoptotic genes in mainly four families: (I) TNF receptor and ligand (TRAIL-R4-A by 27-fold, TNFSF11 by 3-fold); (II) Caspase (CASP4 by 14-fold, CASP6 by 19-fold); (III) BCL-2 (BCL2L11/bimL by 6-fold, Blk by 10-fold); (IV) Caspase recruiting domain (Apaf-1 by 3-fold, NOD/CARD4 by 14-fold).

In addition, IND significantly up-regulated other genes such as DNA fragmentation factor 45/DFFA (by 48-fold) and CRADD (by 24-fold). In addition to the genes up-regulated by IND, NS up-regulated some other genes within these families such as CASP13 (7-fold), Asc (5-fold), TRAIL receptor 2 (3-fold) and Bak (3-fold). The transcriptional up-regulation of these pro-apoptotic genes occurred as early as 1 h after drug exposure. We also found that IND, but not NS, down-regulated most of the anti-apoptotic genes in the IAP (inhibitor of apoptosis protein) family such as IAP2, XIAP (9-fold), survivin (7-fold) and Bruce (3-fold) (Figure 3). Significant up-regulation and down-regulation of apoptotic-related genes in our study is determined by a 3 or more fold change from control.

Protein analysis

The protein expression of several significantly up-regulated

or down-regulated genes is shown in Figure 4. Both IND and NS treatments up-regulated the pro-apoptotic protein Apaf-1 significantly by 9, 12, and 4 fold at 1, 5, and 18 h, respectively (IND); by 96%, 160% and 102% at 1, 5 and 18 h, respectively (NS) (all $P < 0.01$ *vs* control). In addition, both of these drugs also increased Bak protein expression. However, IND treatment also down-regulated anti-apoptotic proteins such as XIAP by 40% and 22% at 1 and 5 h respectively ($P < 0.05$ *vs* control), while NS treatment did not alter it significantly.

DISCUSSION

The cure for colorectal cancer remains a challenge despite all currently available medical and surgical treatment modalities. The cure rate is particularly low in advanced disease, making chemoprevention an attractive alternative. In recent years, the NSAIDs have attracted a great interest as a potential candidate for the chemoprevention of colorectal cancer. There is now a great body of evidence supporting the role of NSAIDs in tumor chemoprevention by the induction of apoptosis. However, little is known about the exact mechanisms of NSAIDs action on colorectal cancer cells.

With the advent of microarray technology, thousands of genes can be assayed in a single experiment. We applied the microarray technology and focused on apoptosis related genes. By creating a profile of genes linked to a particular biological pathway, the expression of particular genes in a colon cancer cell line treated with NSAIDs, may suggest the activation of specific pathways. Furthermore, comparing the action of a nonselective COX inhibitor *vs* a COX-2-selective inhibitor can reveal mechanistic differences between these two NSAIDs in the induction of apoptotic cell death.

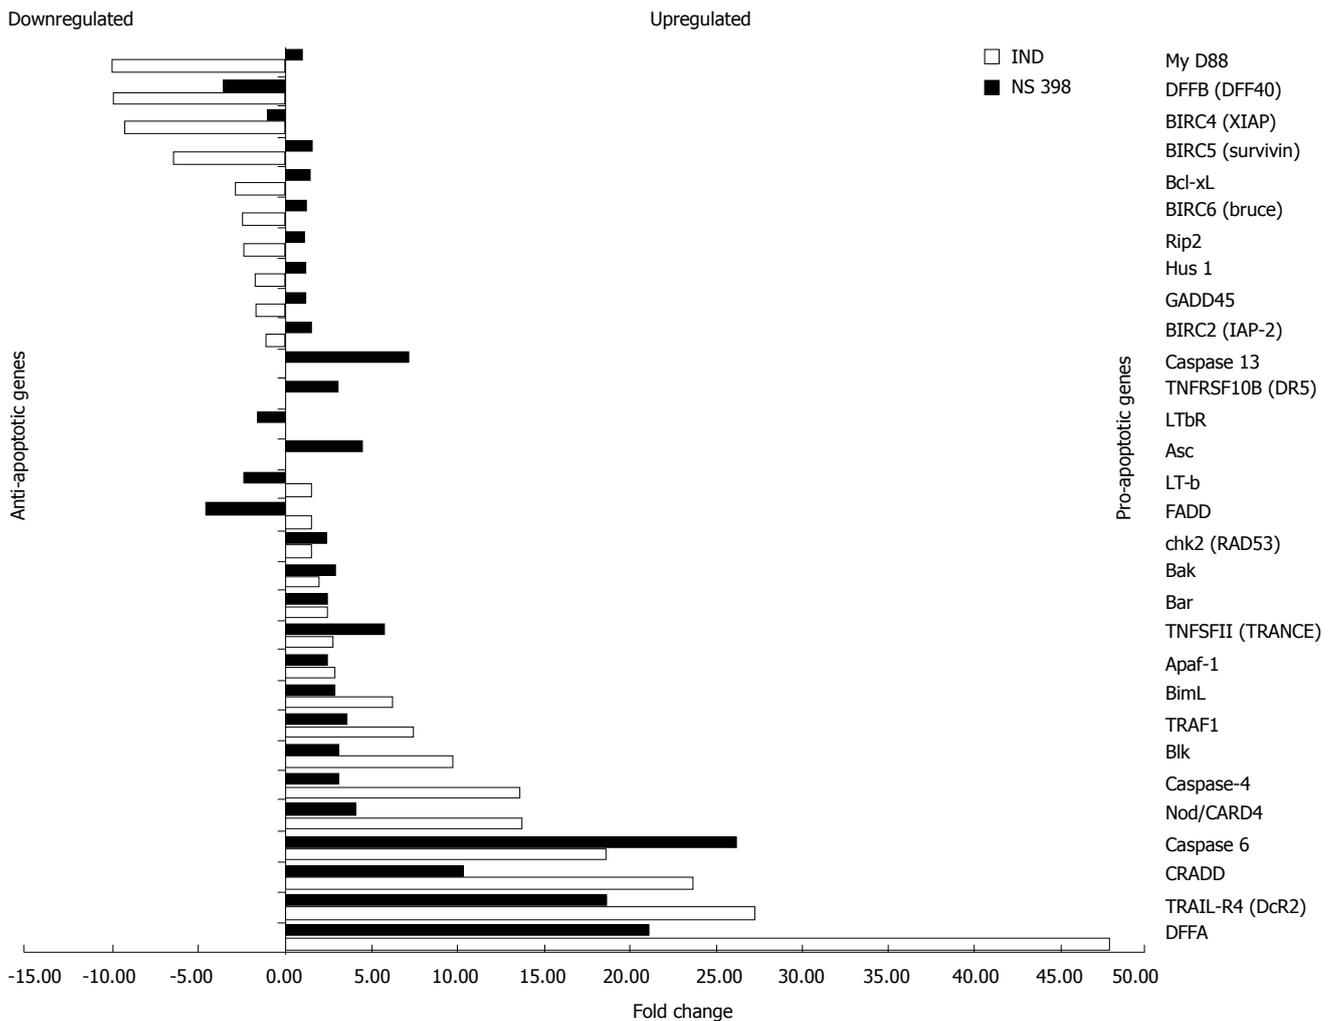

Figure 3 Genes up-regulated and down-regulated by IND and NS treatment identified by cDNA microarray. Up-regulation or down-regulation is expressed as a fold change. Down-regulated genes are shown on the top of the graph in a decreasing order toward mid graph, while up-regulated genes in an increasing order toward the bottom of the graph. Anti-apoptotic genes lie mostly in the upper half while pro-apoptotic genes lie mainly in the bottom half.

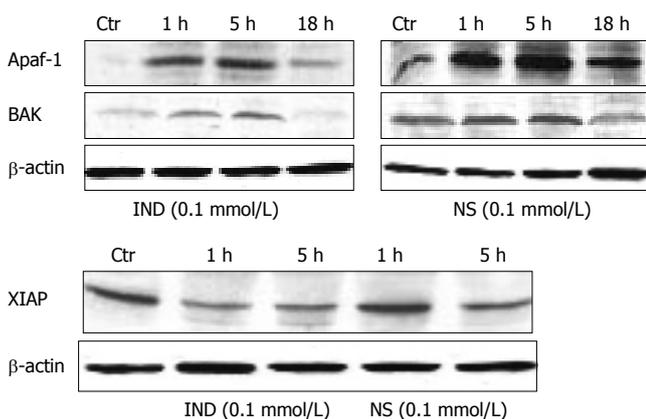

Figure 4 Protein expression by Western blotting of pro-apoptotic genes Apaf-1 and Bak (upper panel), expression of XIAP (lower panel). Blots are representative of triplicate experiments.

Our results suggest that both the nonselective COX inhibitor indomethacin and the COX-2-selective inhibitor NS-398 trigger apoptosis in Caco-2 cells through at least two major well known pathways, an extrinsic, death receptor-transmembrane pathway and an intrinsic, mitochondrial pathway.

The transmembrane pathway of apoptosis involves the tumor necrosis factor (TNF) ligand and receptor superfamily. Members of this family include TNF α , Fas ligand and TRAIL (TNF-related apoptosis-inducing ligand). These ligands when coupling to their respective receptors trigger a number of intracellular events that lead to apoptotic cell death^[25,26]. The final steps of apoptosis induced through this pathway depends on the activation of caspases, cysteine proteases that cleave the aspartate residues^[27,28]. Several members of the TNF family of receptors contain intracellular death domains that interact with other molecules that contain death domains and with caspase recruitment domains (CARD), propagating the apoptotic cascade^[29,30]. We found that both IND and NS-398 up-regulated several genes within the TNF ligand and receptor family such as TNFSF11 (Tumor necrosis factor superfamily member 11), TRAIL-R4, TRAIL-R2. We also detected up-regulation of other genes encoding downstream molecules associated with this pathway such as CRADD (CASP2 and RIPK1 domain containing adaptor with death domain), ASC (Apoptosis-associated speck-like protein containing a CARD), NOD1 (caspase recruitment domain 4), APAF (apoptotic protease activating factor). Our data strongly suggest that NSAIDs

induce apoptosis in Caco-2 cells by up-regulating genes of the TNF ligand and receptor pathway, likely mediated by TNF receptors and TRAIL receptors. This mechanism may explain in part the chemopreventive properties of NSAIDs in colorectal cancer. Several studies have shown promise in using TNF α and TRAIL as potential chemotherapeutic agents in a variety of tumors^[31-34]; however, toxicity remains a concern when these agents are used systemically. Our study provides further evidence that NSAIDs likely sensitize colorectal cells to death through TNF and TRAIL receptor. This suggests NSAIDs to be potentially useful as an adjunct chemotherapeutic agent by increasing the therapeutic window of TNF α and TRAIL and decreasing their toxicity.

Our study suggests that NSAIDs also affect the mitochondrial pathway of apoptosis. This intrinsic pathway is usually triggered by chemicals, growth factor deprivation or irradiation. The major steps in this pathway involve the release of cytochrome c with subsequent increase in mitochondrial membrane permeability that is controlled by a variety of pro-apoptotic and anti-apoptotic members of the Bcl-2 family. The release of cytochrome c triggers the assembly of Apaf-1 (Apoptotic protease-activating factor) and pro-caspase 9 to form an apoptosome. The activated caspase 9 then activates other downstream molecules to initiate apoptosis^[35-37]. Several members of the Bcl-2 family were shown to be up-regulated or down-regulated in Caco-2 cells treated with IND and NS. The pro-apoptotic members up-regulated by NSAIDs include Bak (Bcl2-antagonist/killer 1), Blk (B lymphoid tyrosine kinase) and Bim (Bcl2 like 11, apoptosis facilitator). Bcl-x (Bcl2-like 1), an antiapoptotic member, was down-regulated. These data suggest that NSAIDs, both COX nonselective and COX-2 selective likely induce apoptosis *via* the death receptor pathways and the mitochondrial pathway.

There was one major difference in the pattern of genes expressed in Caco-2 cells treated with IND and NS-398. While both IND and NS-398 up-regulated pro-apoptotic genes, IND also down-regulated anti-apoptotic genes, particularly the IAP (inhibitors of apoptosis proteins) family. This family has been described consisting of at least six members and can efficiently inhibit the caspases^[38-40]. In our study, IND treatment of Caco-2 cells caused significantly down-regulated IAP2, XIAP, Survivin and Bruce, while treatment with NS-398 did not affect these genes. This may suggest a mechanistic difference by which non-selective COX and COX-2 specific NSAIDs induce apoptosis. This finding indicates that COX-1 may play a role in the different genetic expression of the IAP family between IND and NS treatments. Further functional studies exploring this difference may contribute to a better understanding of the chemopreventive properties of NSAIDs.

Abstract

AIM: To develop an animal model of liver infection with *Chlamydia pneumoniae* (*C. pneumoniae*) in intraperitoneally infected mice for studying the presence of chlamydiae in Kupffer cells and hepatocytes.

METHODS: A total of 80 BALB/c mice were inoculated intraperitoneally with *C. pneumoniae* and sacrificed at various time points after infection. Chlamydiae were looked for in liver homogenates as well as in Kupffer cells and hepatocytes separated by liver perfusion with collagenase. *C. pneumoniae* was detected by both isolation in LLC-MK2 cells and fluorescence *in situ* hybridization (FISH). The releasing of TNF- α by *C. pneumoniae* *in vitro* stimulated Kupffer cells was studied by enzyme-linked immunosorbent assay.

RESULTS: *C. pneumoniae* isolation from liver homogenates reached a plateau on d 7 after infection when 6 of 10 animals were positive, then decreased, and became negative by d 20. *C. pneumoniae* isolation from separated Kupffer cells reached a plateau on d 7 when 5 of 10 animals were positive, and became negative by d 20. The detection of *C. pneumoniae* in separated Kupffer cells by FISH, confirmed the results obtained by culture. Isolated hepatocytes were always negative. Stimulation of Kupffer cells by alive *C. pneumoniae* elicited high TNF- α levels.

CONCLUSION: A productive infection by *C. pneumoniae* may take place in Kupffer cells and *C. pneumoniae* induces a local pro-inflammatory activity. *C. pneumoniae* is therefore, able to act as antigenic stimulus when localized in the liver. One could speculate that *C. pneumoniae*

INTRODUCTION

Chlamydia pneumoniae (*C. pneumoniae*) is a common cause of respiratory infections in humans^[1,2], and it is also associated with outcomes other than respiratory disease, including coronary heart disease and myocardial infarction^[3,4]. Systemic disease has also been reported in which *C. pneumoniae* was detected by polymerase chain reaction in lymph nodes and/or liver and spleen^[5]. In addition, recent reports suggest a possible association of *C. pneumoniae* infection in patients with primary biliary cirrhosis (PBC)^[6]. This disease is characterized by the presence of anti-mitochondrial autoantibodies and is considered as an autoimmune disease, although precise etiopathogenetic mechanisms remain unknown^[7]. Infectious agents have been proposed as triggers in susceptible individuals through a mechanism known as molecular mimicry^[8]. It seems therefore possible that antigens from dissociated or alive microbes in Kupffer cells, in other macrophages and lysed cells can trigger immunologically-mediated disorders of the liver such as those observed in PBC^[9].

In intranasally infected mouse, *C. pneumoniae* infection has been shown to spread systemically *via* infected macrophages from the initial infection site, the lung, to other organs, including the spleen and occasionally the liver^[10]. Here, we report on *C. pneumoniae* infection of the liver in intra-peritoneally infected mice and the involvement of Kupffer cells.

MATERIALS AND METHODS

Animal infection

The animals used in the studies were adult (10-11 wk old) Balb/c mice (Morini, S. Polo D'Enza, Italy). Animals anaesthetised with Ketamine, were inoculated intraperitoneally with purified^[11] *C. pneumoniae* elementary body (EB) suspension^[11]. Infected animals received 0.1 mL of organism suspension: the inoculum preparation contained 2.0×10^7 inclusion-forming units (IFU) of EBs. At d 2, 7, 10, and 20 after infection, anaesthetized animals were sacrificed. The protocol was approved by the ethical committee of the University of Bologna.

C. pneumoniae isolation from the liver

Ten animals were tested at each time point: i.e. at 2, 7, 10 and 20 d after infection. The liver was removed, weighed and homogenized in a mortar to obtain a 10% (wt/vol) suspension in cold sucrose phosphate-glutamic acid (SPG) buffer. Tissue suspensions were centrifuged at $300 \times g$ for 10 min at 4°C to remove coarse debris. The clarified homogenates (200 μ L) were inoculated in duplicate onto LLC-MK2 cells (a continuous cell line derived from Rhesus monkey kidney tissue, used to isolate chlamydiae) seeded into plastic individual wells of a 24-well plate, incubated at 37°C for 72 h in chlamydial growth medium (Eagle's minimal essential medium supplemented with 10% heat inactivated fetal calf serum, containing 2 mmol/L glutamine, 5 mg/L glucose and 1 ng/L cycloheximide) and then fixed in methanol. Chlamydial inclusions were visualized by immunofluorescence.

Isolation of Kupffer cells and hepatocytes

To isolate Kupffer cells and hepatocytes, animals, infected as above, were anaesthetized with Ketamine and sacrificed 2, 7, 10 and 20 d after infection: 10 animals were tested at each time. Kupffer cells and hepatocytes were harvested and separated following the procedure of Smedsrød and Pertoft^[12] with minor modifications, as previously described^[13,14]. Briefly, the liver was perfused with 30 mL of calcium- and magnesium-free Hanks' balanced salt solution (BSS) followed by Hanks' (BSS) containing 0.05% collagenase (type IV; Sigma) for 10 min. The liver was then excised and the cells dispersed in calcium- and magnesium-free Hanks' (BSS). The cells were then centrifuged at $50 \times g$ at 4°C for 2 min, in a Beckman J6B centrifuge (Beckman Instrument, Palo Alto, Calif.). The non-parenchymal cell-enriched supernatant was centrifuged at $800 \times g$ for 10 min, the pellet resuspended in 40 mL of PBS, and portions of 10 mL were layered on top of preformed two-step Percoll gradient (the bottom cushion with a density of 1.066 g/mL and an osmolality of 310 mOsm; the overlying cushion with a density of 1.037 g/mL and an osmolality of 300 mOsm), and centrifuged at $400 \times g$ for 15 min at 4°C. Purified non-parenchymal cells enriched in Kupffer cells extended throughout the lower Percoll cushion. The pellets consisted of erythrocytes, non-parenchymal liver cells, and other small white cells. The Kupffer cells-enriched fraction was diluted in PBS and centrifuged at $800 \times g$ for 10 min. The resulting pellet was resuspended in culture medium (RPMI 1640 with 10% fetal calf serum) at a concentration of 1.0×10^6 cells/mL. A 0.5-mL portion of cell suspen-

sion was added to 8-well culture plate (Lab-Tek, Nalge Nunc International, Naperville, IL, USA). Kupffer cells were selected by allowing them to adhere for 2 h at 37°C in an atmosphere with 50 mL/L CO₂. After nonadherent cells were removed by gentle washing, adherent cells were incubated in RPMI 1640. More than 95% of adherent cells were esterase-positive. The purity of Kupffer cell preparations was also validated using the FITC labelled anti-mouse F4/80 monoclonal antibody (Tebu-bio, Magenta, Italy). Hepatocytes were obtained by differential centrifugation of the initial suspension of mouse liver cells followed by an additional purification step, consisting of sedimentation of the cells through a single cushion of Percoll (density 1.08 g/mL). The hepatocytes were seeded on fibronectin-coated slides and grown in RPMI 1640 with 10% fetal calf serum. Kupffer cells and hepatocytes were also separated from uninfected animals.

In vitro infection of Kupffer cells and hepatocytes by *C. pneumoniae*

When required, Kupffer cells from uninfected animals were obtained as above described and seeded into 8-well culture plate (1.5×10^5 cells/well) and cultured in RPMI 1640 medium for 24 h at 37°C in an atmosphere with 5% CO₂. Cultures of Percoll-separated hepatocytes were likewise established from uninfected animals by seeding on fibronectin and grown in RPMI 1640 medium, in 8-well culture plate (Lab-Tek). Kupffer cells and hepatocytes were then infected with *C. pneumoniae* EBs (5×10^5 inclusion forming units/mL) and examined for inclusion formation and infectivity at various times after infection by culturing of infected preparations in LLC-MK2 cells.

Detection of viable chlamydiae

To detect the presence of viable chlamydiae in separated Kupffer cells and hepatocytes either from infected animals or from *in vitro* infected Kupffer cells and hepatocytes. Both Kupffer cells and hepatocytes were resuspended in chlamydial growth medium, sonicated and clarified by low speed centrifugation. The supernatant was then inoculated onto LLC-MK2 cells. Chlamydial inclusions were detected by immunofluorescence.

Detection of *C. pneumoniae* by immunofluorescence assay (IFA)

The detection of *C. pneumoniae* by IFA was performed by fixing separated Kupffer cells and hepatocytes or LLC-MK2 cells with methanol for 10 min at room temperature. Inclusions were then visualized using fluorescein-conjugated *C. pneumoniae* species-specific (Chlamydia-cell, Cellabs PTY LTD Brookvale, Australia) monoclonal antibody for 35 min at room temperature. Slides were observed under a Zeiss UV microscope.

Detection of *C. pneumoniae* 16S RNA by fluorescence in situ hybridization (FISH)

The *C. pneumoniae* 16S rRNA detection by FISH was performed by fixing mouse Kupffer cells and hepatocytes within the Lab-Tek culture plates with 2% paraformaldehyde for 30 min at 4°C and prior to FISH, cells were dehydrated with increasing concentrations of ethanol (50%, 80% and 100%). The *Chlamydia*-specific probes used in this

study have been previously described by Poppert *et al.*¹⁵ and deposited in ProbeBase (<http://www.microbial-ecology.de/probebase/index.html>). Cpn-0974 (5'-AAGTCCAG-GTAAGGTCCT-3') was the species-specific 16S rRNA-targeted oligonucleotide probe that was 5' end labelled with Cy3 fluorochrome (Tib Molbiol, s.r.l., Genova, Italy) giving a red-orange signal. For Kupffer cells and hepatocytes hybridization, a 10 µL aliquot of the hybridization buffer (0.9 mol/L NaCl, 20 mol/L Tris-HCl pH 8, 0.01% SDS and from 0% to 30% formamide) containing 5 pmol of each fluorescent probe was applied to each well of Lab Tek culture plate. After 1 h of incubation in a moist chamber at 46°C in the dark, the slides were washed for 15 min in pre-heated washing buffer containing 20 mmol/L Tris-HCl pH 8, from 0.9 mol/L to 0.15 mol/L NaCl (depending on formamide concentration) and 0.01% SDS. The slides were air dried and mounted with Citifluor AF1 (Citifluor Ltd, London, United Kingdom). The slides were viewed under an epi-fluorescence microscope (Eclipse E600, Nikon) equipped with a super high pressure mercury lamp and Plan Fluor DLL 10 ×, 40 ×, 100 × objectives. Epi-fluorescence filter G-2A was used to analyse Cy3 signal at a magnification of 1000 ×. Photomicrographs were taken using a DXM-1200 digital camera (Nikon, Japan) and image processing was performed with ACT-1 for DXM-1200 software.

TNF-α production by Kupffer cells

To evaluate the TNF-α induction in Kupffer cells infected by *C. pneumoniae* *in vitro*, Kupffer cells, purified as above reported, were added (5×10^5) to each well of an 8-well culture plate (Lab-Tek). After 2 h at 37°C, non-adherent cells were removed by washing three to five times with RPMI 1640 supplemented with 10% fetal calf serum, 2 mmol/L L-glutamine. Cells were stimulated for 6 h with either LPS (10 mg/L) (Sigma) or viable *C. pneumoniae* at a ratio of 100 EBs/cell. The supernatants were then harvested and tested by enzyme-linked immunosorbent assay (ELISA) kit for TNF-α (Bender MedSystems GmbH, Wien, Austria),

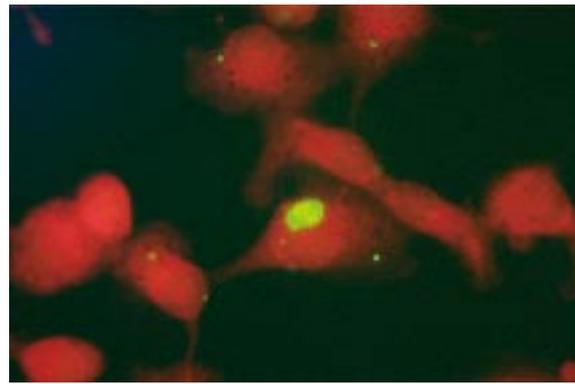

Figure 1 IFA for the detection of *C. pneumoniae* antigens in separated Kupffer cells. 1000 ×. Kupffer cells separated from intraperitoneally infected mice sacrificed 7 d after infection were tested by immunofluorescence assay (IFA) with specific fluorescein-conjugated monoclonal antibodies. A positive Kupffer cell is clearly evident for the presence of an apple-green intracytoplasmic bacterial inclusion. The inclusion represents an intracytoplasmic bacterial microcolony.

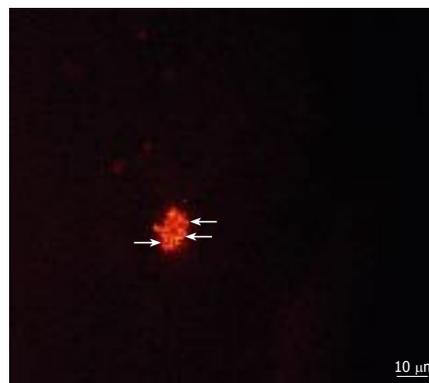

Figure 2 FISH for *C. pneumoniae* 16S rRNA in separated Kupffer cells. *In situ* hybridization was performed on Kupffer cells separated from intraperitoneally infected mice, sacrificed 7 d after infection. An infected Kupffer cell is evidenced with Cpn-0974 specific probe: the granular inclusion stained red.

according to the manufacturer's protocol. When required, preincubation of material with polymyxin B (10 mg/L) (Sigma) was used to abrogate the effect of LPS.

RESULTS

Four groups of infected animals (10 for each group) were sacrificed 2, 7, 10 and 20 d following intraperitoneal infection by *C. pneumoniae* and isolation of viable chlamydiae was performed from liver homogenates. The peak of *C. pneumoniae* isolation from the liver was obtained on d 7 after infection, thereafter the infectivity decreased, all the animals became negative by d 20 of infection (Table 1).

In order to verify whether *C. pneumoniae* was able to infect *in vivo* Kupffer cells and/or hepatocytes, purified liver cells were tested by IFA, to detect chlamydial antigens and by FISH to detect chlamydial rRNA. Four further groups of infected animals (10 for each group) were sacrificed 2, 7, 10, and 20 d after infection, respectively, then isolated Kupffer cells and hepatocytes were analysed. Positive Kupffer cells were observed in preparations obtained on d 7 and 10 (Table 2), both by IFA and FISH, thus confirming the results obtained by culture. Kupffer cells purified 20 d after infections were negative. Positive cells showed

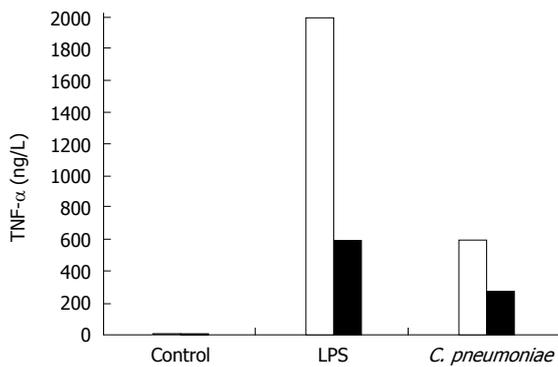

Figure 3 TNF- α release by Kupffer cells following *in vitro* exposure to alive *C. pneumoniae*. Kupffer cells were stimulated for 6 h with alive *C. pneumoniae*. Control LPS was used at 10 mg/L. Stimulation was performed with (black) or without (white) polymyxin B at concentration of 10 mg/L.

cytoplasmic apple-green inclusions by IFA (Figure 1) and red granular inclusions by FISH (Figure 2). The number of positive cells was 10/100 in preparations obtained 7 d after infection, and 5/100 in preparations obtained 10 d after infection. The preparations from animals sacrificed 20 d after infection were negative. The passage of the content of Kupffer cells obtained from IFA- and FISH-positive animals induced chlamydial inclusion formations in LLC-MK2 cells. Hepatocytes were always negative by IFA and FISH and by culture in LLC-MK2 cells.

The *in vitro* infection of purified mouse Kupffer cells and hepatocytes by *C. pneumoniae* was followed by FISH and by culture: Kupffer cells were positive for the presence of inclusions detectable by 12 h of infection. Sub-culturing Kupffer cells in LLC-MK2 mono-layers three days after infection allowed re-isolation of *C. pneumoniae*. Hepatocytes infected *in vitro* by *C. pneumoniae* and studied by IFA and FISH was negative 12, 24, and 48 h after infection. Sub-culturing hepatocytes in LLC-MK2 cells three days after infection did not allow re-isolation of *C. pneumoniae*, demonstrating that *C. pneumoniae* is unable to infect hepatocytes.

In vitro stimulation of Kupffer cells by alive *C. pneumoniae* elicited cellular responses resulting in the production of TNF- α (Figure 3). Pretreatment of chlamydiae with polymyxin B, which binds and inactivates LPS^[16], substantially diminished the ability of bacteria to stimulate Kupffer cells (Figure 3).

DISCUSSION

Chlamydiae are obligate intracellular bacteria parasitizing eukaryotic cells. Chlamydiae replicate in the cytoplasm of infected cells within an inclusion that does not fuse with lysosomes^[17]. Within the genus *Chlamydia*, various species preferentially infect different target cells and cause a variety of diseases all ultimately due to inflammatory responses. In particular, *C. pneumoniae* has been associated with respiratory human infections and with the development of atherosclerosis and cardiovascular disease^[18-21]. *C. pneumoniae* has been also associated with sarcoidosis and it was detected in 4 of 38 liver biopsies from autopsy specimens of patients with sarcoidosis^[22]. In a rabbit model of *C. pneumoniae* in-

fection, three of 10 infected rabbits had evidence of *C. pneumoniae* elementary bodies in their livers by immunocytochemical staining and *C. pneumoniae* was cultured in two of them^[23]. In a hamster model of *C. pneumoniae* infection, similarly *C. pneumoniae* was isolated from the liver of the infected animals^[24]. These studies altogether indicate that *C. pneumoniae* can potentially persist in liver tissues.

More recently, Abdulkarim *et al*^[6] reported the presence of *C. pneumoniae* antigens and rRNA in liver tissue of patients with end-stage primary biliary cirrhosis, suggesting a potential role of *C. pneumoniae* in the etiology and pathogenesis of the disease, in contrast with serological data by Liu *et al*^[25] that do not support the concept that *Chlamydia pneumoniae* can be a triggering or causative agent in PBC.

To get further insight into a possible role of *C. pneumoniae* in liver related pathologies, evidence was to be produced as to the possible localization and/or replication of *C. pneumoniae* in parenchymal and not parenchymal liver cells, mainly in Kupffer cells, where chlamydiae could act as a trigger for cellular immunologically-mediated alterations. Kupffer cells constitute the largest population of fixed tissue macrophages found in the body, and blood-clearance and elimination of bacteria taken up by the liver are widely attributed to Kupffer cells. Sometimes microorganisms can survive or even multiply in Kupffer cells, as observed in *Leishmania* and *Salmonella typhi* infections in mice and humans^[26,27]. In this study, we have described a mouse model of *C. pneumoniae* infection where the organism demonstrated the ability to infect and to multiply in Kupffer cells both *in vivo* and *in vitro*, and to trigger the release of the proinflammatory cytokine TNF- α , by these macrophages. In our animal model, mice eliminated *C. pneumoniae* by d 20 of infection and a chronic infection was not established. However, it is well known that persistence, for as yet unpredictable reasons, is a frequent case of human chlamydial infections^[28].

PBC is a chronic liver inflammatory disease whose etiology and pathogenesis remain still unknown. A wide range of data suggest an autoimmune pathogenesis for the disease^[29,30], mostly based on the presence of anti-mitochondrial autoantibodies and autoreactive T cells directed against autoantigens. Despite the fact that the autoimmune reaction is directed against ubiquitous mitochondrial autoantigens, the ensuing damage involves primarily biliary epithelial cells^[7]. Infectious agents have been proposed as triggers in susceptible individuals through a mechanism known as molecular mimicry^[8]. However, over the past years several studies failed to demonstrate a specific chronic microbial^[8,31], viral^[32,33] or bacterial^[34-36] infection. Recently, it has been proposed that an aberrant innate immune response to infections has the potential to initiate the development of autoimmunity^[37]. The ability of *C. pneumoniae* to survive and to replicate in Kupffer cells, as documented in this study, demonstrates the ability of this bacterium to escape, under certain conditions, the defence mechanisms of natural immunity. This characteristic can favour, as suggested by Liu *et al*^[25], the production of highly immunogenic substrates and/or provide an inflammatory microenvironment to enhance the self-reactivity of pathogenic T lymphocytes, or can activate pre-existing autoreactive cellular repertoire.

Abstract

AIM: To determine the effects of prophylactic peroxisome proliferator-activated receptor (PPAR γ) agonist administration in an experimental model of post-endoscopic retrograde cholangiopancreatography (post-ERCP) acute pancreatitis.

METHODS: Post-ERCP pancreatitis was induced in male Wistar rats by infusion of contrast medium into the pancreatic duct. In additional group, rosiglitazone, a PPAR γ agonist, was administered 1 h before infusion of contrast medium. Plasma and pancreas samples were obtained 6 h after the infusion.

RESULTS: Infusion of contrast medium into the pancreatic duct resulted in an inflammatory process characterized by increased lipase levels in plasma, and edema and myeloperoxidase activity (MPO) in pancreas. This result correlated with the activation of nuclear factor κ B (NF κ B) and the inducible NO synthase (iNOS) expression in pancreatic cells. Rosiglitazone reduced the increase in lipase and the level of edema and the increase in myeloperoxidase as well as the activation of NF κ B and iNOS expression.

CONCLUSION: A single oral dose of rosiglitazone, given 1 h before post-ERCP pancreatitis induction is effective in reducing the severity of the subsequent inflammatory process. The protective effect of rosiglitazone was associated with NF κ B inhibition and the blockage of leukocyte infiltration in pancreas.

INTRODUCTION

Acute pancreatitis is one of the major and serious complications after diagnostic or therapeutic endoscopic retrograde cholangiopancreatography (ERCP). Despite the technical improvements of recent years and the experience of endoscopists, the incidence has not decreased and it ranges from 1% to 10% of patients^[1]. The most severe forms of pancreatitis, with pancreatic necrosis, multi-organ failure and even death, occurs in 0.3%-0.6% of patients, but a silent increase in serum pancreatic enzymes could be observed in up to 70% of patients^[2]. The triggering mechanism of the inflammatory response remains unclear and different pharmacological agents has been tested to prevent post-ERCP pancreatitis including anti-inflammatory steroids, somatostatin analogs, heparin, protease inhibitors and anti-inflammatory cytokines^[3-6]. Only few drugs showed some efficacy to prevent post-ERCP pancreatitis like recently nitrate therapy by decreasing the pancreatic ductal pressure or diclofenac by lowering inflammatory process^[7,8]. Therefore, the availability of effective drugs and strategy of chemoprevention remain as unsettled points in the pharmacological prophylaxis of post-ERCP pancreatitis^[5,8], leading to the apparition of endoscopic procedure such as pancreatic sphincterotomy to try to decrease the risk of post-ERCP pancreatitis^[9].

Recent evidences indicate an important role for the peroxisome proliferator-activated receptors (PPARs) in the regulation of both inflammation and lipid metabolism^[10]. In particular, it has been reported, using an experimental model of cerulein-induced pancreatitis, that the pancreatic inflammation and tissue injury was markedly reduced by the administration of PPAR γ agonists^[11]. PPAR γ is a member of the nuclear hormone receptor superfamily originally reported to be expressed at high levels in

adipose tissue and to play a critical role in adipocyte differentiation, glucose metabolism and lipid storage. In an experimental model of intestinal ischemia-reperfusion, a more severe injury was observed in PPAR γ -deficient mice and protection against local and remote tissue injury in mice treated with a PPAR γ -activating ligand^[12]. Then, it has been demonstrated that PPAR γ ligands can inhibit the inflammatory response by decreasing IL-6, IL-1 β , TNF α and the inducible NO synthase (iNOS) by interfering with nuclear factor κ B (NF κ B) and AP1^[13,14]. The aim of this study was to investigate the efficacy of prophylactic PPAR γ agonist treatment in reducing the pancreatic damage in an experimental post-ERCP acute pancreatitis model.

MATERIALS AND METHODS

Reagents

Reagents for SDS-PAGE and nitrocellulose membranes were from Amersham Pharmacia (Buckinghamshire, England). Antibodies against p65, PPAR γ and Histone H1 were obtained from Santa Cruz Biotechnology (Santa Cruz, CA), antibody against iNOS was obtained from BD Transduction (Heidelberg, Germany), antibody against β -actin and the secondary antibody linked to horseradish peroxidase were from Sigma Chemicals (St Louis, MO). The following reagents were obtained from Sigma Chemicals (St Louis, MO): NaVO₃, NaF, Nonidet P40, ethidium bromide, Hexadecyltrimethylammonium bromide, Tetramethylbenzidine, DMSO, H₂O₂.

Post-ERCP pancreatitis model

Male Wistar rats (250–300 g) were used for all experiments. Animals were housed in light-dark cycle regulated, air conditioned (23°C) and air humidity (60%) animal quarters, given free access to drinking water and standard food pellets until 12 h prior to the experiment, at which point food was withdrawn. Animal care was in compliance with the European Community (Directive 86/609/EEC) for the use of experimental animals and the institutional committee of animal care and research approved it. Rats were anaesthetized with ip injection of sodium pentobarbital (10 μ L/kg). The biliopancreatic duct was cannulated through the duodenum and the hepatic duct was closed by a small bulldog clamp. Post-ERCP pancreatitis was induced by retrograde infusion into the biliopancreatic duct of low osmolarity contrast medium Meglumine/Sodium Ioxaglate (Hexabrix 320) in a volume of 10 μ L/kg using a Harvard '22' infusion pump (Harvard Instruments, Edenbridge, UK). Control animals were subjected to anesthesia and laparotomy^[15].

Experimental design

In the first set of experiments, we evaluated the severity of pancreatic damage and tissue inflammation after the infusion of contrast medium into the pancreatic duct. For this purpose, rats ($n = 6$ for each group) were sacrificed at 0, 3, 6 and 24 h after infusion and samples of pancreatic tissue and plasma were obtained, immediately frozen and maintained at -80°C until assayed.

In a second series of experiments, a PPAR γ agonist (Rosiglitazone, AVANDIA[®] GlaxoSmithKline, Brentford,

UK) was administered (10 mg/kg intragastric bolus) 1 h before infusion of contrast medium ($n = 8$ for each group)^[11]. Samples of plasma and pancreas were obtained 6 h after infusion.

Edema

The extent of pancreas edema was assayed by measuring tissue water content. Freshly obtained samples of pancreas were weighted on aluminum foil, dried for 24 h at 95°C and reweighed. The difference between wet and dry tissue weight was calculated and expressed as a tissue wet: dry mass ratio.

Myeloperoxidase activity

Neutrophil infiltration was assessed by measuring myeloperoxidase (MPO) activity. Myeloperoxidase was measured photometrically with 3,3',5,5'-tetramethylbenzidine as a substrate^[16]. Samples were macerated with 5 g/L hexadecyltrimethylammonium bromide in 50 mmol/L phosphate buffer pH 6.0. Homogenates were then disrupted for 30 s using a Labsonic (B.Braun) sonicator at 20% power and submitted to three cycle of snap freezing in dry ice and thawing before a final 30 s sonication. Samples were incubated at 60°C for 2 h and then spun down at 4000 g for 12 min. Supernatants were collected for myeloperoxidase assay. Enzyme activity was assessed photometrically at 630 nm. The assay mixture consisted of 20 μ L supernatant, 10 μ L tetramethylbenzidine (final concentration 1.6 mmol/L) dissolved in DMSO and 70 μ L H₂O₂ (final concentration 3.0 mmol/L) diluted in 80 mmol/L phosphate buffer pH 5.4. An enzyme unit is defined as the amount of enzyme that produces an increase of 1 absorbance unit per minute.

NF κ B and PPAR γ DNA binding

Binding of NF κ B p65 subunit to the NF κ B binding consensus sequence 5'-GGGACTTCC-3' and binding of PPAR γ to the PPRE binding consensus sequence 5'-AACTAGGTCAAAGGTCA-3' were measured with the ELISA-based TransAM kits (Active Motif, Carlsbad, CA) using tissue nuclear extracts. This assay is performed in 96-well plates coated with an oligonucleotide containing the binding consensus sequence. The active forms in nuclear extracts can be detected using specific Abs for epitopes that are accessible only when the subunits are activated and bound to its target DNA. Specificities were checked by measuring the ability of soluble wild-type oligonucleotides to inhibit binding.

Western blot

Pancreatic tissue was lysed by using the Nuclear Extract Kit from Active Motif (Carlsbad, CA) following the manufacturer conditions for preparation of cytoplasmic and nuclear extracts. SDS-PAGE was performed using 100 g/L or 120 g/L acrylamide gels. Proteins were electrotransferred to nitrocellulose membrane and probed with primary Ab (anti-p65, 1/1000; anti-PPAR γ , 1/200; anti-iNOS, 1/400; anti- β -actin, 1/400; anti-Histone H1, 1/500). The membranes were incubated with corresponding horseradish peroxidase-linked secondary Ab, washed and subsequently incubated with ECL reagents

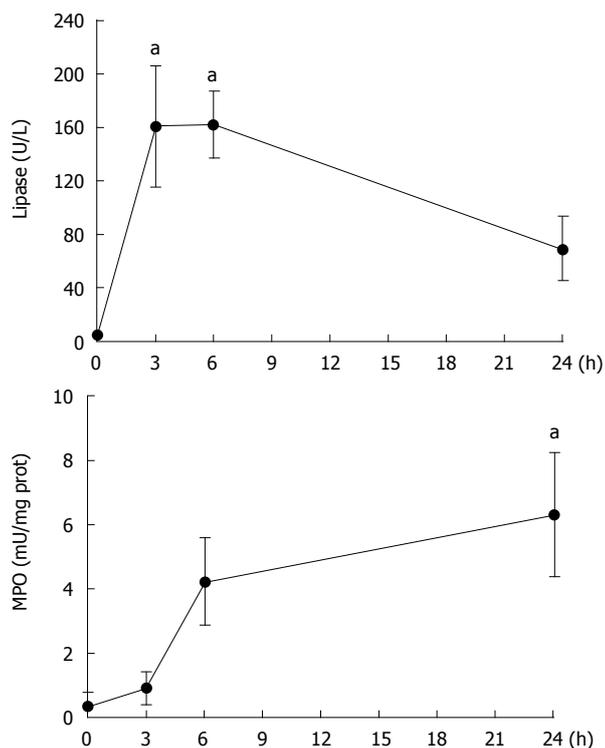

Figure 1 Plasma lipase and pancreas MPO activity after retrograde infusion of contrast media. (^a $P < 0.05$ vs $t = 0$).

from Amersham Pharmacia (Buckinghamshire, England) before exposure to high performance chemiluminescence films. Gels were calibrated using Bio-Rad standard proteins (Hercules, CA) with markers covering a 7-240 kDa range.

Protein measurement

Total protein concentration in homogenates was determined using a commercial kit from BioRad (Munich, Germany).

Lipase

Plasma lipase was determined by using commercial kits from Randox (Antrim, UK), according to the supplier's specifications.

Histological study

Pancreatic tissue samples were taken and fixed in 40 g/L neutral buffered formaldehyde solution, paraplast-embedded, cut into 5 μ m sections and stained with hematoxylin-eosin for light microscopy. Two different observers evaluated randomly ten fields from each animal and cell infiltration was recorded blindly on photomicrographs.

Statistical analysis

Data have been expressed as mean \pm SE. Means of different groups were compared using a one-way analysis of variance. Tukey's multiple comparison test was performed for evaluation of significant differences between groups. Differences were assumed to be significant when $P < 0.05$.

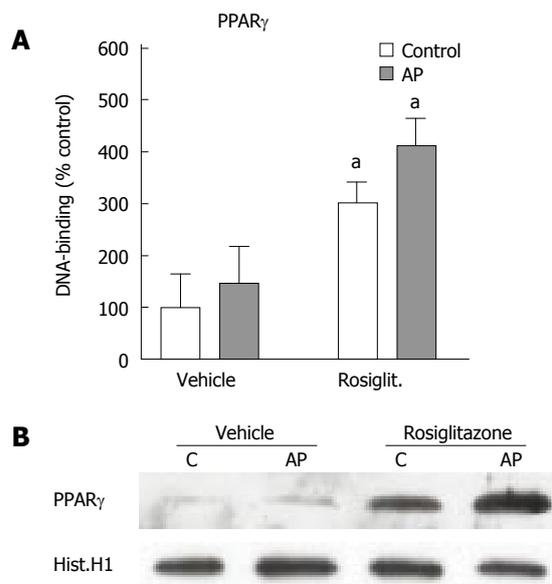

Figure 2 PPAR γ activation. **A:** PPAR γ DNA binding activity of pancreas nuclear extracts expressed as % of control activity. No significant differences were observed on PPAR γ binding to DNA after pancreatitis induction. By contrast, PPAR γ binding to DNA is strongly induced by rosiglitazone in both control and pancreatitis groups. ^a $P < 0.05$ Rosiglitazone-treated vs vehicle-treated groups. **B:** Western blot of nuclear PPAR γ confirmed the nuclear translocation of PPAR γ protein after rosiglitazone administration in both control and pancreatitis groups. Western blot was representative of three different experiments.

RESULTS

ERCP-induced pancreatic damage

The evolution of pancreatic damage was evaluated by measuring plasma lipase and tissue MPO activity at different time points after pancreas infusion of contrast medium (Figure 1). A rapid and significant increase was observed in plasma lipase activity that achieved a peak between 3 and 6 h after surgery. By contrast, MPO activity was not increased until 6 h after infusion and remained increased until the end of experiment (24 h). Since in this model the inflammation required 6 h to be established, we selected this time point for the rest of experiments.

Treatment with rosiglitazone induced pancreatic activation of PPAR γ

To evaluate the efficacy of rosiglitazone to induce PPAR γ activation in the pancreatic tissue, we measured, on nuclear extracts, the levels of DNA binding activity to an immobilized oligonucleotide containing the PPRE sequence. Binding activity was significantly increased in rosiglitazone-treated animals (Figure 2A). By contrast, in non-treated animals, ERCP-induced pancreatitis was not associated with changes in pancreatic PPAR γ activity. These results were confirmed by western blot analysis of the translocation of PPAR γ into the nuclear fraction upon rosiglitazone treatment (Figure 2B).

Rosiglitazone reduced the ERCP-induced pancreatic damage

Both tissue edema and plasma lipase activity showed

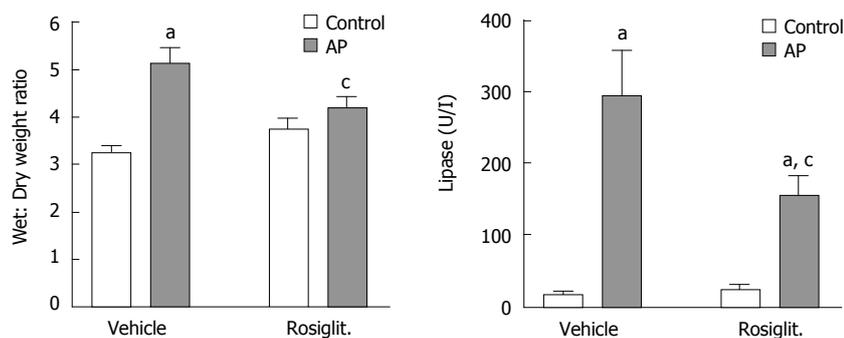

Figure 3 Pancreatic tissue edema and plasma lipase activity 6 h after contrast medium infusion. Retrograde administration of contrast medium induced increases in edema and lipase activity. These increases were partially prevented by pre-treatment of rosiglitazone. ^a*P* < 0.05 AP vs their corresponding control; ^c*P* < 0.05 rosiglitazone-treated AP group vs vehicle-treated AP group.

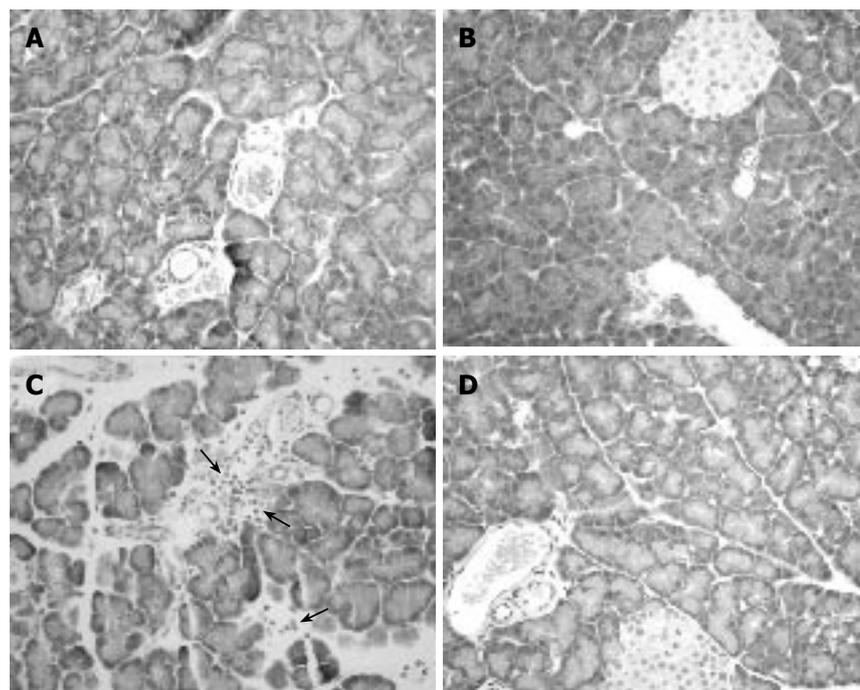

Figure 4 Histological examination of the pancreas (x 200). **A:** Control pancreas showed normal acinar structure; **B:** No morphological changes were observed after rosiglitazone administration in control animals; **C:** Experimental ERCP-induced pancreatic damage reflected in interlobular and interacinar edema and areas of leukocyte infiltration (arrows). Acinar necrosis was not observed; **D:** Rosiglitazone pre-treatment before contrast medium infusion resulted in a reduced edema and absence of leukocyte cell infiltration.

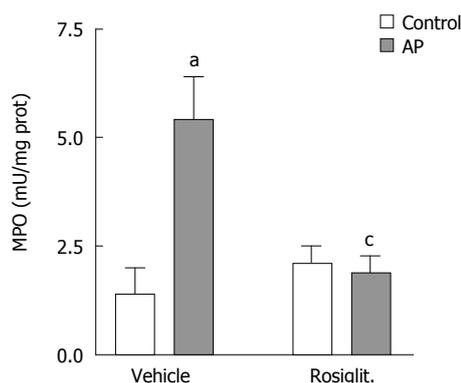

Figure 5 Myeloperoxidase activity in pancreas. MPO activity was significantly increased in post-ERCP induced pancreatitis in comparison with vehicle. Rosiglitazone treatment prevented this increase. ^a*P* < 0.05 AP vs control; ^c*P* < 0.05 rosiglitazone-treated AP group vs Vehicle-treated AP group.

increased levels 6 h after contrast media infusion (Figure 3). Pre-treatment with rosiglitazone significantly reduced these increases, but not to control levels. Histological findings also showed a clear reduction on pancreatic interlobular edema (Figure 4). No acinar necrosis was observed after contrast-media infusion.

ERCP-induced inflammatory response was inhibited by rosiglitazone

When measuring the MPO activity, we observed that the increase induced by contrast medium infusion was completely abrogated by pre-treatment with rosiglitazone (Figure 5). This result was confirmed by histological results. In ERCP group, areas of intense cell infiltration with extravasation of leukocytes to the interacinar space were observed (Figure 4C). Treatment with rosiglitazone completely prevented the infiltration of leukocytes (Figure 4D).

Rosiglitazone prevented the ERCP-induced NF κ B-activation

In order to evaluate the possible involvement of NF κ B on this anti-inflammatory effect, we measured the levels of p65 DNA binding activity in pancreatic nuclear extracts. Results indicated that infusion of contrast media into the pancreatic duct induced a significant activation of NF κ B (Figure 6A). This increase was completely prevented by pre-treatment of rosiglitazone. The effect of the PPAR- γ agonist on NF κ B was confirmed by detecting, by western blot, the presence of p65 subunit of NF κ B into the nuclear fraction (Figure 6B). In the ERCP group, p65

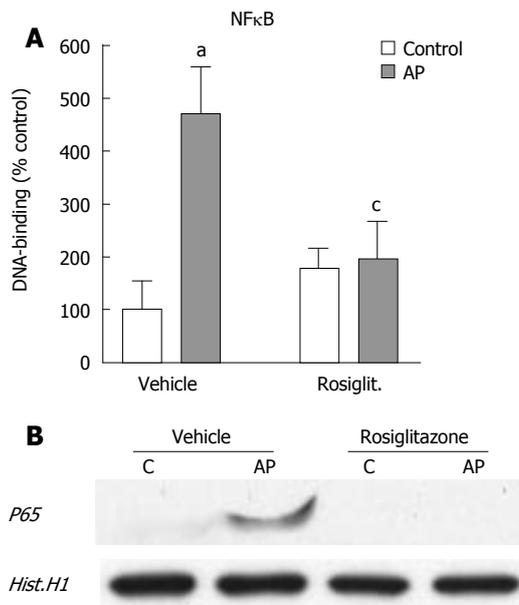

Figure 6 NF κ B activation. **A:** NF κ B DNA binding activity of pancreas nuclear extracts expressed as % of control p65 activity. Post-ERCP induced pancreatitis resulted in increased levels of p65 binding activity. This increase was inhibited by rosiglitazone pre-treatment. * $P < 0.05$ AP vs Control; * $P < 0.05$ rosiglitazone-treated AP group vs vehicle-treated AP group; **B:** Western blot of nuclear p65 confirmed the nuclear translocation of p65 protein during ERCP-induced pancreatitis. This nuclear translocation was not observed after rosiglitazone administration. Western blot was representative of three different experiments.

translocated into the nucleus and this translocation was prevented by pre-treatment of rosiglitazone.

Rosiglitazone prevented ERCP-induced expression of iNOS

Finally, similar result was found when determining the expression of iNOS, an NF κ B-dependent enzyme (Figure 7). In ERCP group, iNOS was strongly induced, and pre-treatment with rosiglitazone prevented this increase. Interestingly, the enzyme, that is undetectable in control animals showed a weak expression in control animals treated with rosiglitazone.

DISCUSSION

Since pancreatitis represents the most common complication after ERCP, different drugs, including IL-10, gabexate mesylate, heparin or somatostatin, nitrate derivatives or diclofenac have been tested to reduce the incidence and severity of post ERCP-pancreatitis. Many of these studies, despite the use of randomized procedures were criticized because of non reproducible results^[3]. In addition, the multifactorial etiology and pathophysiology of post-ERCP pancreatitis needs to be taken into account. Simplified procedures and the absence of adverse effects are required to deliver prophylactic treatment for post-ERCP pancreatitis. Our study shows that administration of a PPAR γ agonist in a single oral dose before starting ERCP decreases the severity of the inflammatory reaction triggered by this procedure. Evidence has been accumulated indicating that PPAR γ plays a role modulating the inflammation. Several studies have demonstrated that the use of PPAR γ ligands inhibits the intensity of the

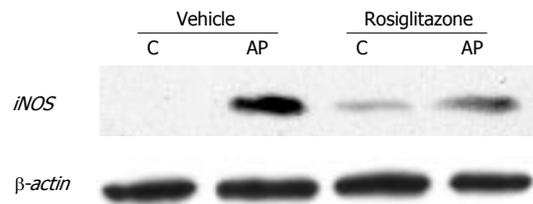

Figure 7 Inducible NO synthase (iNOS) expression. Western blot of cytoplasmic iNOS showed increased expression of this protein during post-ERCP induced pancreatitis. This increase was reduced by rosiglitazone pre-treatment. Results are representative of three separate experiments.

inflammatory response in different processes including colitis^[17], adjuvant-induced arthritis^[14], and cerulein-induced pancreatitis^[11]. In vitro, the expression of inflammatory mediators such as TNF α , IL-1 β , IL-6, iNOS or MMP-9^[13,18] could be inhibited by PPAR γ ligands. These findings have raised the possibility that these agents could be useful for the treatment of the inflammatory disorders.

Our results indicate that administration of rosiglitazone before experimental ERCP completely prevented the inflammatory response in the pancreas, reflected in a reduced MPO activity and the lack of leukocytes infiltrate observed in pancreas. By contrast, increases in lipase plasma activity and edema were only partially prevented by rosiglitazone. This fact was not unexpected, since rosiglitazone prevents the activation of the inflammatory response, but has no effect on the mechanical damage related with changes in osmolarity or increased intraductal pressure. Pancreatic damage results from both mechanical and inflammatory processes associated with intraductal activation of pancreatic proenzymes. Nitrate derivatives or pancreatic stenting have been proposed to increase pancreatic out-flow, diclofenac or IL-10 following inflammatory response and somatostatin to decrease the intraductal concentration of pancreatic proenzymes^[5-9]. Rosiglitazone was supposed to act only on the inflammatory-related increases in lipase and edema.

It is known that the activation of PPAR γ results in a reduction of the inflammatory response due to its inhibitory effect on main inflammatory signal transduction pathways, in particular, NF κ B. It has been reported, in several experimental models of pancreatitis, that pancreatic damage was associated with increased nuclear translocation of NF κ B dimers p65/p50 that trigger the transcription and generation of a broad spectrum of inflammatory mediators by pancreatic cells^[19]. These mediators, including cytokines, chemokines and adhesion molecules, generate a microenvironment that promotes the recruitment and activation of inflammatory cells and contributes to increasing the extension of the pancreatic damage. Consequently, we have evaluated the involvement of NF κ B in the observed anti-inflammatory effect of PPAR γ in post-ERCP pancreatitis. For this purpose we have measured the nuclear translocation and DNA binding of p65, the key component of NF κ B. The results indicate that nuclear translocation of p65 was significantly increased after experimental ERCP and this increase was completely prevented by pre-treatment of rosiglitazone. This inhibition could explain the lack of inflammatory

infiltrate observed in pancreas, since NF κ B activation is a requisite for the generation of the main pro-inflammatory mediators involved in pancreatitis.

Similar results were observed when measuring the expression of iNOS in pancreatic tissue. This enzyme was induced mainly in activated leukocytes in order to generate nitric oxide at a cytotoxic concentration as a part of the bactericidal mechanism of these cells. The presence of iNOS in pancreas in post-ERCP pancreatitis confirms that an intense inflammatory process was triggered. Since the synthesis of this enzyme is strongly dependent on NF κ B, it is not a surprise that rosiglitazone treatment downregulates the expression of iNOS. On the other hand, the reduced levels of iNOS could also reflect the lack of cell infiltration that occurs under these conditions.

The blockage of NF κ B activation and the resulting inhibition in the NF κ B-dependent mediators is of importance not only for the local inflammation, but also in order to prevent the release into the circulatory bloodstream of pro-inflammatory cytokines that could trigger a systemic inflammatory response. Although this occurs in a reduced percentage of patients, the severity of the process justifies the use of prophylactic measures to prevent it despite the failure or the weakness of many previous series.

In conclusion, despite the general limitations of all the animal models relative to clinical setting and the multifactorial etiology of post-ERCP pancreatitis, these results suggest that rosiglitazone and other PPAR γ agonists are potential new therapeutic agents for the prevention of post-ERCP-induced acute pancreatitis. It could be administered in an oral dose to the patients, shortly before the ERCP. However, further studies are needed to determine the proper dose and time-point of administration in human patients.

Abstract

AIM: To study whether matrix metalloproteinase-9 (MMP-9) is a key factor in epithelial damage in the dextran sodium sulphate (DSS) model of colitis in mice.

METHODS: MMP-9-deficient and wild-type (wt) mice were given 5% DSS in drinking water for 5 d followed by recovery up to 7 d. On d 5 and 12 after induction of colitis, gelatinases, MMP-2 and MMP-9, were measured in homogenates of colonic tissue by zymography and Western blot, whereas tissue inhibitor of metalloproteinases (TIMPs) were measured by reverse zymography. The gelatinolytic activity was also determined in supernatants of polymorphonuclear leukocytes (PMN) isolated from mice blood. Moreover, intestinal epithelial cells were stimulated with TNF- α to study whether these cells were able to produce MMPs. Finally, colonic mucosal lesions were measured by microscopic examination.

RESULTS: On d 5 of colitis, the activity of MMP-9 was increased in homogenates of colonic tissues (0.24 ± 0.1 vs 21.3 ± 6.4 , $P < 0.05$) and PMN from peripheral blood in wt (0.5 ± 0.1 vs 10.4 ± 0.7 , $P < 0.05$), but not in MMP-9-deficient animals. The MMP-9 activity was also up-regulated by TNF- α in epithelial intestinal cells (2.5 ± 0.5 vs 14.7 ± 3.0 , $P < 0.05$). Although colitis also led to increase of TIMP-1 activity, the MMP-9/TIMP-1 balance remained elevated. Finally, in the MMP-9-deficient colitic mice both the extent and severity of intestinal epithelial

injury were significantly attenuated when compared with wt mice.

CONCLUSION: We conclude that DSS induced colitis is markedly attenuated in animals lacking MMP-9. This suggests that intestinal injury induced by DSS is modulated by MMP-9 and that inhibition of this gelatinase may reduce inflammation.

INTRODUCTION

Matrix metalloproteinases (MMPs) comprise a group of zinc and calcium-dependent endopeptidases that exhibit differential proteolytic activity against extracellular matrix (ECM) proteins. Based on substrate specificity, MMPs have been classically divided into collagenases, gelatinases (MMP-9 and MMP-2) and stromelysins. These proteinases are secreted as latent enzymes that require proteolytic cleavage for activation. However, a subset of MMPs, known as membrane-type MMPs (MT-MMPs) are not secreted but instead remain attached to cell surfaces and activate secreted MMPs^[1,2]. The MMP activity is tightly controlled by specific endogenous inhibitors of these enzymes (TIMPs), which complex with MMPs. Four TIMPs have been described until now and TIMP-1 seems to be the most important endogenous inhibitor, which binds to activated interstitial collagenase and gelatinases^[3-5].

Ulcerative colitis (UC) is a chronic inflammatory disease affecting primarily the distal colon and rectum of young adults and its etiology still remains unclear. Degradation and remodeling of the ECM is increasingly implicated in the pathogenesis of several inflammatory disorders,

such as periodontal disease and rheumatoid arthritis^[6-8]. In physiological conditions, MMPs act as part of the normal connective tissue turnover. However, MMPs released by diverse cells in response to several cytokines during inflammation, may lead to excess degradation of ECM and tissue injury. Previous studies have found both increased activity and expression of MMPs in colonic tissues of patients with inflammatory bowel disease (IBD)^[9-13]. Moreover, MMP-9 may be a key factor responsible for accelerated breakdown of ECM in UC, because it was demonstrated that MMP-9 is abundantly expressed in patients with UC compared with controls^[9]. Hence, MMP inhibition has emerged as a potential therapeutic approach in colonic inflammatory disorders^[14-16]. Furthermore, we have previously demonstrated a significant up-regulation of MMP-9 expression and activity in a rat model of colitis induced by dextran sulphate sodium (DSS). In this experimental model, a synthetic MMP inhibitor (CGS-27023-A) significantly reduced the extent and severity of tissue injury^[17]. However, this compound is a broad spectrum MMP inhibitor and the relative contribution of MMP-9 in this experimental model still remains unclear.

In the present investigation, we sought to determine whether MMP-9 extinction could alter intestinal damage in a mouse model of colitis induced by DSS. This model exhibits clinical and morphological features resembling human UC, including diarrhea and rectal bleeding, diffuse lesions circumscribed to the mucosa, and predominance of distal involvement of the large intestine^[18]. Our findings support the conclusion that MMP-9 modulates colonic mucosal injury in this entity.

MATERIALS AND METHODS

Animals

Our studies used the homozygous MMP-9-deficient male mice with FVB background and wild-type (wt) purchased from Jackson Laboratories (Ca, USA). The animals were 8 wk to 10 wk old and weighted from 25 g to 30 g. They were maintained in a restricted-access room with controlled temperature (23°C) and light-dark cycle (12 h:12 h) and were housed in rack-mounted cages with a maximum of 10 mice per cage. Mice were allowed to drink and feed *ad libitum*. The study was approved by the local Animal Welfare Committee and conformed to the principles of laboratory animal care and use (NIH publication 86-23).

Genotyping analysis

Liver samples from selected mice were collected and genotype was verified by polymerase chain reaction (PCR) using a sense oligonucleotide primer (5'-GCATACTTGTACCGCTATGG-3') and an antisense oligonucleotide primer (5'-TAACCGGAGGTCCAAACTGG-3'). For the neomycin cassette, we also used a sense oligonucleotide primer (5'-GAAGGGACTGGCTGCTATTG-3') and an antisense primer (5'-AATATCACGGGTAGCCAACG-3'). All procedures were performed blind with respect to genotype.

Experimental design

Distal colitis was induced by oral DSS (molecular wt 40000; ICN Biomedicals, Aurora, OH) at 5% in tap water *ad libitum* for 5 d in wt and MMP-9 deficient mice and then switched to water and monitored for 7 additional days. At least 15 age and sex matched wt and MMP-9 deficient mice were studied at the end of 5 d with DSS treatment and at 7 d after DSS (recovery phase), whereas 15 control wt and 15 control MMP-9 deficient mice were allowed free access to drinking water. Body weight was routinely obtained every second day and mortality was recorded at any time. Mice were euthanized by cervical dislocation on d 5 and 12 after induction of colitis. With the use of sterile equipment, a mid laparotomy was performed, the colon was removed, opened longitudinally, rinsed with sterile saline, and divided into two parts by a longitudinal section. One specimen was homogenized and stored at -20°C for MMPs, TIMPs, TNF- α and myeloperoxidase (MPO) assay. The second specimen was used for microscopic assessment of mucosal lesions.

Isolation of neutrophils

Mice were anesthetized by an intraperitoneal injection of ketamine (100 mg/kg, Park Davis, Morris Plains, NJ). Blood samples were collected from the abdominal aorta. Neutrophils were isolated using Histopaque (Sigma Ltd, England) and erythrocyte removed using hypotonic lysis with ammonium chloride. The neutrophil count was determined by using a Neubauer hemocytometer and cell viability was assessed by trypan blue exclusion. Typically, the neutrophil preparations were > 98% pure and > 94% viable. The isolated neutrophils were washed and resuspended in HBSS with calcium and magnesium at a concentration of 5×10^9 cells/L and incubated for 12 h at 37°C. The release of MMPs was determined in the supernatant by zymography^[19].

Cell culture

Caco-2 cells, a human intestinal epithelial cell line, were obtained from the American Type Culture Collection (ATCC, Rockville, MD). Cells were cultured in 75-cm² flasks in a humidified atmosphere containing 5% CO₂ at 37°C. Cells were grown in minimum essential medium supplemented with pyruvate, sodium bicarbonate, 20% fetal bovine serum, gentamycin sulfate (0.05 mg/mL), penicillin G (0.06 mg/mL) and streptomycin sulfate (0.01 mg/mL). The medium was changed every two days and cells were sub-cultured three times each week. When confluent, cells were detached using a Trypsin-EDTA solution. For the *in vitro* experiments, Caco-2 cells were seeded into 24-well plates (30000 cells per well) in free serum-medium and cultured in the presence or absence of human recombinant TNF- α (1 or 10 μ g/L) for 24 h. Afterwards, conditioned media was collected and stored at -20°C for the zymography assay and Western blot analysis.

Analytical Methods

Zymography: The activity of pro-MMP-9 was measured as previously described^[20,21] in homogenates of colonic

tissue, supernatants of purified neutrophils and Caco-2 conditioned media. Briefly, samples were subjected to 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) with copolymerized gelatin (0.2%; Sigma Chemical Co, St. Louis, Mo). After electrophoresis, the gels were washed with 2% Triton X-100 (2 times, 20 min each), and then incubated in development buffer (50 mmol/L Tris HCl, 200 mmol/L NaCl, 10 mmol/L CaCl₂ and 1 μmol/L ZnCl₂, pH = 7.5) at 37°C overnight. Human recombinant MMP-9 and MMP-2 (Oncogene Research, Nottingham, UK), conditioned medium of HT-1080 human fibrosarcoma cells and molecular weight markers were used as standards. After incubation, gels were fixed and stained in 40% methanol, 10% acetic acid and 0.1% (wt/v) Coomassie Blue for 1 h and then de-stained. The low availability of active MMP-9 seen in the zymographies may be due to its high level of instability and the removal of active enzyme during the washing of specimens, as it has been previously suggested^[22].

Reverse zymography: The TIMP-1 activity was analyzed in homogenates of colonic tissues, as previously described^[23]. Briefly, samples were subjected to 15% SDS-PAGE with copolymerized 0.2% gelatin and human recombinant MMP-2 (160 μg/L). Human recombinant TIMP-1 was used as the internal standard. TIMP-1 activity was identified by inhibition of gelatinolysis when compared with the standard.

Western-blot: Western-blot analysis of MMP-9 was performed in homogenates of colonic tissue and Caco-2 conditioned media, as previously described^[20]. Samples were denatured and loaded (50 μg/lane) onto 10% (vol/vol) polyacrylamide gels. Following electrophoresis, proteins were transferred onto a nitrocellulose membrane (Protran, Schleider&Schuell) and detected using a rabbit monoclonal anti-MMP-9 antibody (Chemicon, Ca, USA) at 1:1000 concentration and a chemiluminescent substrate (Pierce, Rockford, USA). To account for the inter-blot variations in MMP immunoreactivity, an internal standard (conditioned medium of HT-1080 cells, and recombinant MMP-9) was used^[18]. Western Blotting with monoclonal anti-beta-actin (Sigma Chemical Co, St. Louis, Mo) was performed as an internal control.

Bands quantification: Clear bands were analyzed using a calibrated densitometer (GS-800, BioRad) and Quantity One Quantitation analysis software (BioRad, version 4). Each band was measured in terms of Optical Density Units of trace quantity (ODu) × mm.

Quantification of TNF-α by ELISA: TNF-α expression was assayed in colonic tissues. Fragments of colon (40-50 mg) from the proximal region of the rectum were collected from wt and KO animals treated as described above. Afterwards, colon tissues were placed in 500 mL ice-cold PBS containing 20 μL of a proteinase inhibitor cocktail (Roche Diagnostic GmbH, San Francisco, CA) and immediately sonicated. After 10 min in ice, cellular debris was removed by centrifugation at 10000 g for 10 min at 4°C and the protein content of the supernatant was assayed by Bradford's method. The specific ELISAs for mouse TNF-α used in these experiments were purchased from BD Biosciences (San Diego, CA). Murine TNF-α concen-

Grade of inflammation, epithelial regeneration or crypt distortion	Score
Absent	0
Mild	1
Moderate	2
Severe	3

Crypt lesion, acute and chronic inflammation, epithelial regeneration and crypt distortion are scored separately.

trations in tissue extracts were assayed in duplicate wells following the manufacturer's recommendations. The sensitivity of ELISA for TNF-α in our laboratory was 20 ng/L. Data were expressed as pg TNF-α/μg of total protein.

MPO assay: For the MPO activity assay^[24], the colonic specimen was homogenized in 2 mL phosphate-buffered saline, using a Tissue Tearor (model 985-370, Biospec, Racine, WI), and centrifuged. The pellets were again homogenized in an equivalent volume of phosphate buffer (50 mmol/L, pH 6) containing 0.5% hexadecyltrimethylammonium bromide (Sigma) and 5 mmol/L EDTA, sonicated three times for 30 s each time (Labasonic 2000, Braun), and centrifuged. Supernatants were used for determination of tissue MPO activity by a kinetic method. One unit of enzyme activity is defined as the amount of MPO that degrades 1 mmol of peroxide per minute at 25°C.

Histological Measurement of Colonic Lesions

Colonic specimens were fixed in formalin and coded for blind microscopic measurement of mucosal lesions. Samples were embedded in paraffin using a "Swiss roll" technique, and longitudinal sections from cecum to rectum were prepared and stained with hematoxylin and eosin. This procedure allows the examination of the entire specimen from cecum to rectum in every section. Two pathologists who were unaware of the treatment measured the extent of mucosal surface involved by crypt lesions as a percentage of the total colonic surface. For each specimen, a crypt damage score was obtained by summation of the products of each grade of crypt damage times the extent of mucosal surface involved by this grade of damage (Table 1). In addition, the specimens were graded 0 to 3 for inflammation (acute + chronic), regenerative changes (hyperplastic epithelium) and crypt distortion (distorted epithelium) using the criteria described by Cooper *et al*^[25]. Acute inflammation scores evaluated of the presence of polymorphonuclear neutrophils in the infiltrate, whereas chronic inflammation scores evaluate the presence of mononuclear cells.

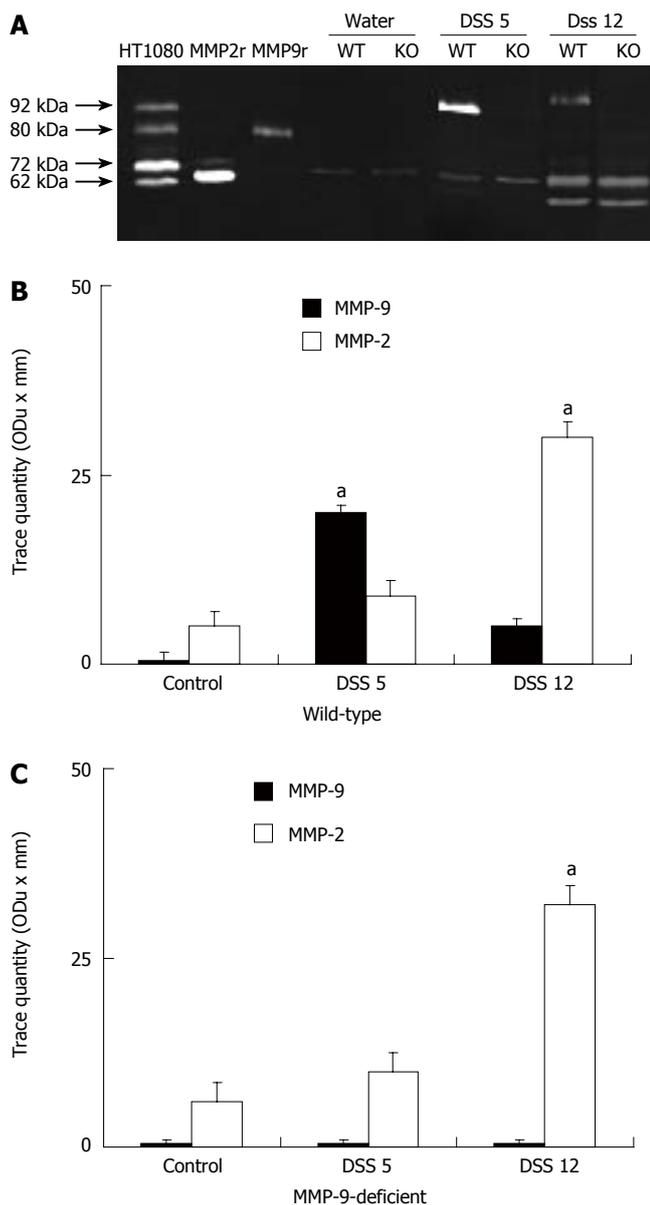

Figure 1 Gelatinase activity in colonic homogenates. **A:** Representative zymogram in wild-type (wt) and MMP-9-deficient (KO) animals on d 5 (DSS 5) and 12 (DSS 12) after induction of colitis ($n = 9$ in each group). Supernatant of HT1080 cells, human recombinants MMP-9 (rMMP9) and MMP-2 (rMMP2) were used as positive controls. Gelatinases with molecular weights of 62, 72 and 92 kDa corresponding to activated MMP-2, pro-MMP-2 and pro-MMP-9, respectively, were detected. Quantitative data of pro-MMP-9 and total MMP-2 (pro-MMP-2 and MMP-2) ($^*P < 0.05$ vs control) in wt (**B**) and MMP-9-deficient mice (**C**).

Statistical analysis

Results are presented as mean \pm SE. The statistical difference between means was determined using one way analysis of variance for overall comparison and the Student-Newman-Keuls test as post-test for single comparisons. The mortality data were analyzed by Kaplan-Meier survival curves.

RESULTS

DSS Colitis

Exposure to 5% DSS in drinking water for 5 d induced diarrhea and rectal bleeding in all mice. Furthermore, DSS treatment resulted in a significant increase in MPO activity

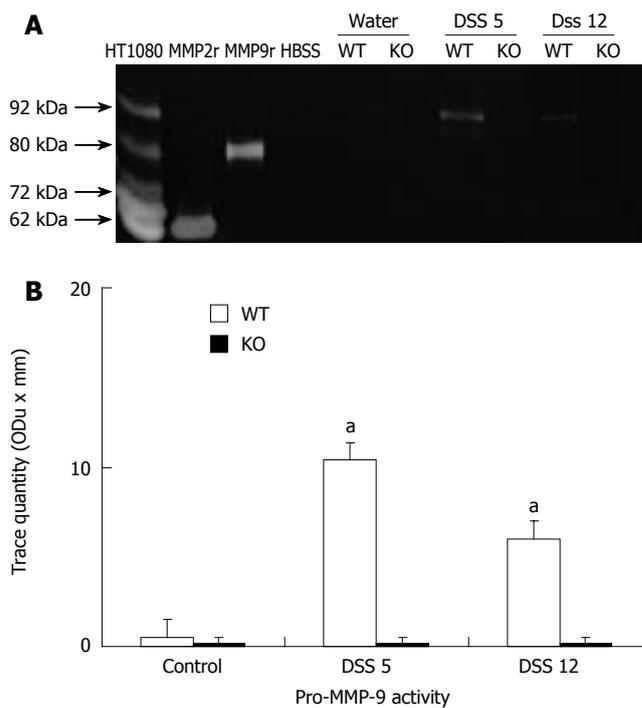

Figure 2 Gelatinase Activity in purified Neutrophils. **A:** Representative zymogram in wild-type (wt) and MMP-9-deficient (KO) animals on d 5 (DSS 5) and 12 (DSS 12) after induction of colitis ($n = 15$ in each group). Supernatant of HT1080 cells, human recombinants MMP-9 (rMMP9) and MMP-2 (rMMP2) were used as positive controls. HBSS was used as negative control. Pro-MMP-9 was detected in neutrophils from colitic wt animals; **B:** Quantitative data ($^*P < 0.05$ vs controls).

in the colonic tissues of both MMP-9 deficient mice (colitic: 2.5 ± 0.82 vs control: 0.3 ± 0.05 mU/mg protein, $P < 0.05$) and wt (colitic: 1.95 ± 0.67 vs control: 0.25 ± 0.06 mU/mg protein, $P < 0.05$). Histological examination of colonic sections revealed that administration of DSS resulted in epithelium injury and loss of normal crypt architecture, with some areas of erosion. Mixed infiltrate of neutrophils and mononuclear cells was observed in the lamina propria and submucosa. The muscularis propria was not involved. These changes were diffuse but predominated at distal parts of the colon. Histological examination revealed no changes in colons from normal control mice.

Gelatinase activity in DSS colitis

Zymographies revealed that MMP-2 but not pro-MMP-9, was a dominant gelatinase in colonic homogenates from non-colitic animals in both wt and deficient animals (Figure 1A). However, DSS treatment resulted in a significant up-regulation of pro-MMP-9, but not MMP-2 activity in colitic wt animals in comparison to deficient animals on d 5 after the induction of colitis (Figure 1A and B). On d 12, pro-MMP-9 activity was still up-regulated in wt animals, although to a lesser extent than in d 5. In addition, there was an up-regulation of MMP-2 in both groups (Figure 1A and B). In peripheral neutrophils isolated from wt animals pro-MMP-9 activity was also markedly enhanced on d 5 and, to a lesser extent, on d 12 following the induction of colitis, but not from MMP-9 deficient mice (Figure 2A and B). By contrast, no MMP-2 activity was shown in neutrophils isolated from any animal group in the presence or absence of DSS treatment.

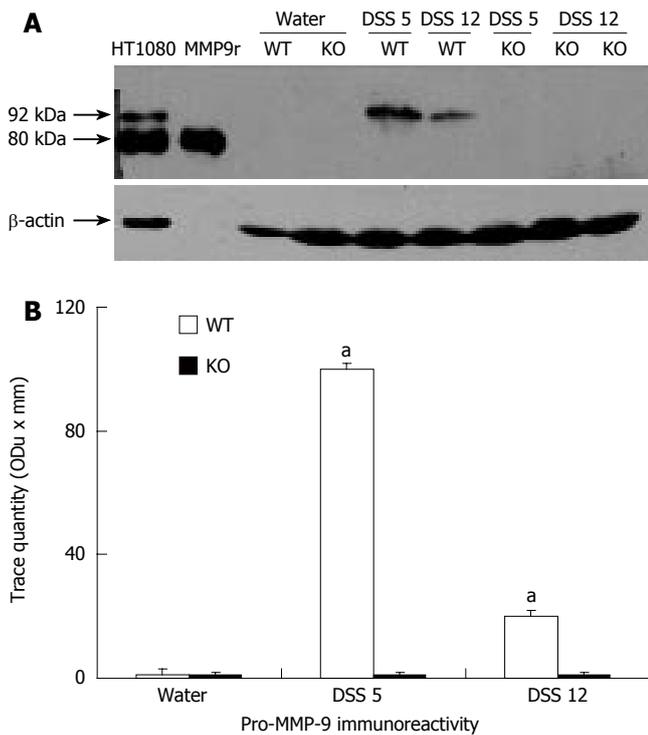

Figure 3 Pro-MMP-9 immunoreactivity in colonic homogenates. **A:** Representative immunoblot in wild-type (wt) and MMP-9-deficient (KO) ($n = 9$ in each group) animals on d 5 (DSS 5) and 12 (DSS 12) after colitis induction. Supernatant of HT1080 cells and human recombinants MMP-9 (rMMP9) were used as positive controls. A band of 92 kDa corresponding to pro-MMP-9 was detected in colitic samples. **B:** Quantitative analysis ($^aP < 0.05$ vs control).

DSS Colitis Enhanced MMP-9 Immunoreactivity

As shown by the immunoreactive band migrating at 92 kDa, a significant up-regulation of pro-MMP-9 was observed in wt, but not in controls or MMP-9 deficient mice, on d 5 and 12 following the induction of colitis (Figure 3).

TIMP-1 Activity in DSS Colitis

Colitis resulted in a significant up-regulation of TIMP-1 in wt animals receiving DSS compared to controls on d 5 and this increase remained elevated on d 12 after induction of colitis (Figure 4A and B). In wt mice the pro-MMP-9/TIMP-1 ratio was significantly higher ($P < 0.05$) than in control mice on d 5 and 12 after the induction of colitis. In addition, the pro-MMP-9/TIMP-1 ratio was not altered by colitis in MMP-9-deficient mice (Figure 4C).

TNF- α Content in DSS Colitis

Figure 5 shows that wt and MMP-9-deficient animals exposed to DSS for during 5 d showed a significant increase in TNF- α concentration as compared with non-colitic animals. In addition, the TNF- α level remained elevated in wt animals on d 12 after colitis induction, whereas returned to base line levels in MMP-9 deficient animals.

Effect of TNF- α Treatment

Since in DSS-induced colitis the predominant lesions are circumscribed to the mucosa, we measured the MMP activity in intestinal epithelial (Caco-2) cells in response to TNF- α . Zymographies showed that, under basal conditions, MMP-2 was the predominant gelatinase in Caco-2

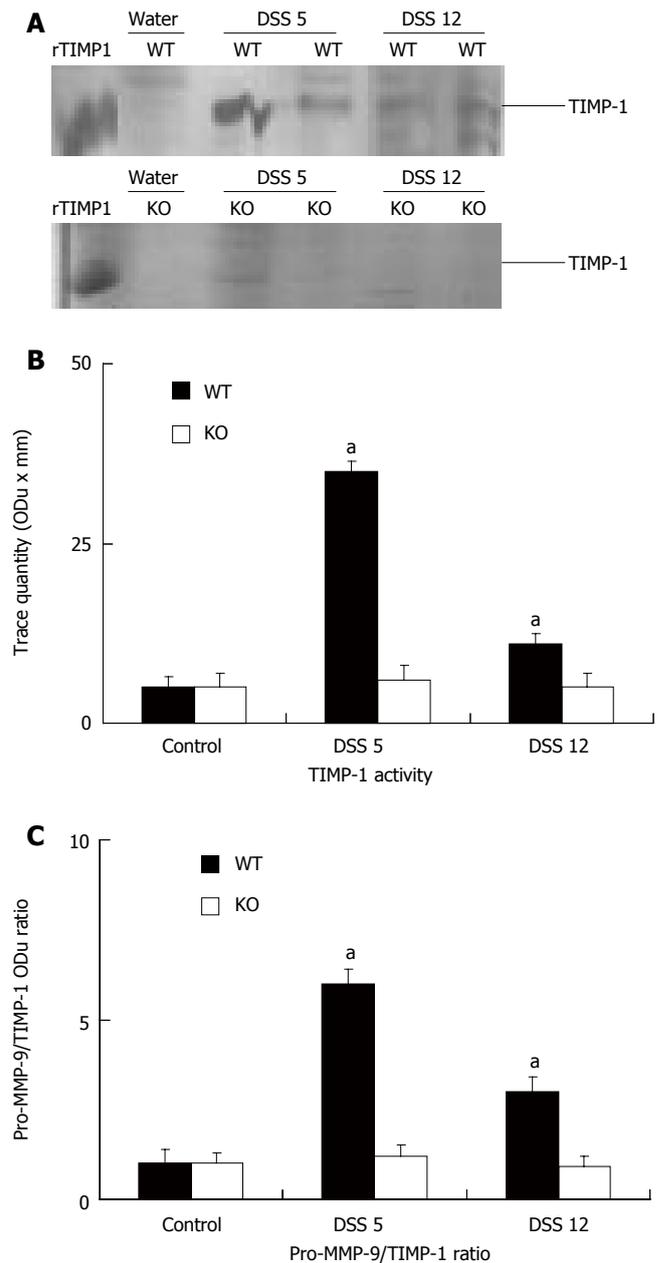

Figure 4 TIMP-1 activity in DSS-induced colitis: **A:** Representative reverse zymograms in homogenates of colonic tissue in wild-type (wt) and MMP-9-deficient (KO) animals on d 5 (DSS 5) and 12 (DSS 12) after induction of colitis; **B:** Quantitative data of TIMP-1 activity ($^aP < 0.05$ vs control) ($n = 5$ in each group); **C:** wt mice had a pro-MMP-9/TIMP-1 ratio significantly ($^aP < 0.05$) higher than controls on d 5 (DSS 5) and 12 (DSS 12) following the induction of colitis. The pro-MMP9/TIMP-1 ratio was not modified by DSS-induced colitis in KO mice.

cells. Interestingly, TNF- α treatment resulted in a dose-dependent significant increase of pro-MMP-9 activity whereas MMP-2 activity remained unchanged (Figure 6A and C). In addition, Western blot analysis corroborated that TNF- α treatment significantly increased pro-MMP-9 immunoreactivity in intestinal epithelial cells (Figure 6B and D).

Impact of MMP-9-silencing on DSS-colitis outcome

Both wt and MMP-9-deficient mice developed diarrhea and rectal bleeding with DSS. Percent loss of body weight is shown in Figure 7A. Neither deficient nor wt mice showed major loss of body weight during DSS treatment.

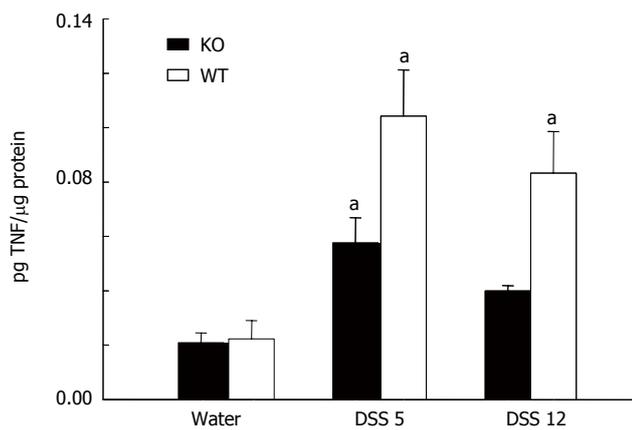

Figure 5 TNF- α content in colonic tissue. Concentration of TNF- α protein in homogenates of colonic tissue from wild-type (wt) ($n = 5$) and deficient (KO) ($n = 5$) animals on d 5 (DSS 5) and 12 (DSS 12) after colitis induction ($^{\ast}P < 0.05$ vs control).

However, during the recovery phase, wt mice showed significant weight loss. In addition, the mortality was significantly higher in wt than in MMP-9 KO mice (Figure 7B). The mean of severity of crypt damage, inflammation, epithelial regeneration and crypt distortion scores are summarized in Table 2. MMP-9 deficient mice showed a significant decrease in the crypt damage scores when compared with wt mice on d 5 and 12 after colitis induction. Moreover, deficient mice showed significantly lower scores of acute and chronic inflammation on d 12. Epithelial regeneration and crypt distortion scores were almost absent on d 5, and no differences were found between both groups at any time.

DISCUSSION

The etiology and the cascade of the events resulting in intestinal injury of UC patients still remain unclear. There is growing evidence that MMPs are implicated in tissue remodeling and destruction associated with several inflammatory conditions^[6-8], including IBD^[9-13]. Moreover, increased gelatinase activity has been shown in diverse animal experimental models of colitis^[17,26]. Our study revealed that MMP-9-deficient animals showed improved survival and indices of epithelial injury, suggesting that MMP-9 is a key factor in tissue damage in DSS-induced colitis.

The destructive effect of MMPs in the gut has been shown by several *in vitro* studies^[27-29]. In addition, previous reports have found increased levels of MMP-9 in colonic tissues of patients with IBD. For instance, Bailey *et al*^[30] have shown an increased MMP-9 protein in patients with IBD by immunohistochemical techniques. Furthermore, Baugh *et al* have found that MMP-9 activity measured by zymography was the most abundant MMP expressed in intestinal tissues of patients with UC compared with normal controls^[9]. Moreover, Tartlon *et al*^[26] have also shown increased gelatinase activity in a transmural experimental model of colitis induced in immunodeficient mice. Finally, we have previously found that MMP-9 is up-regulated in intestinal tissues from rats with DSS-induced

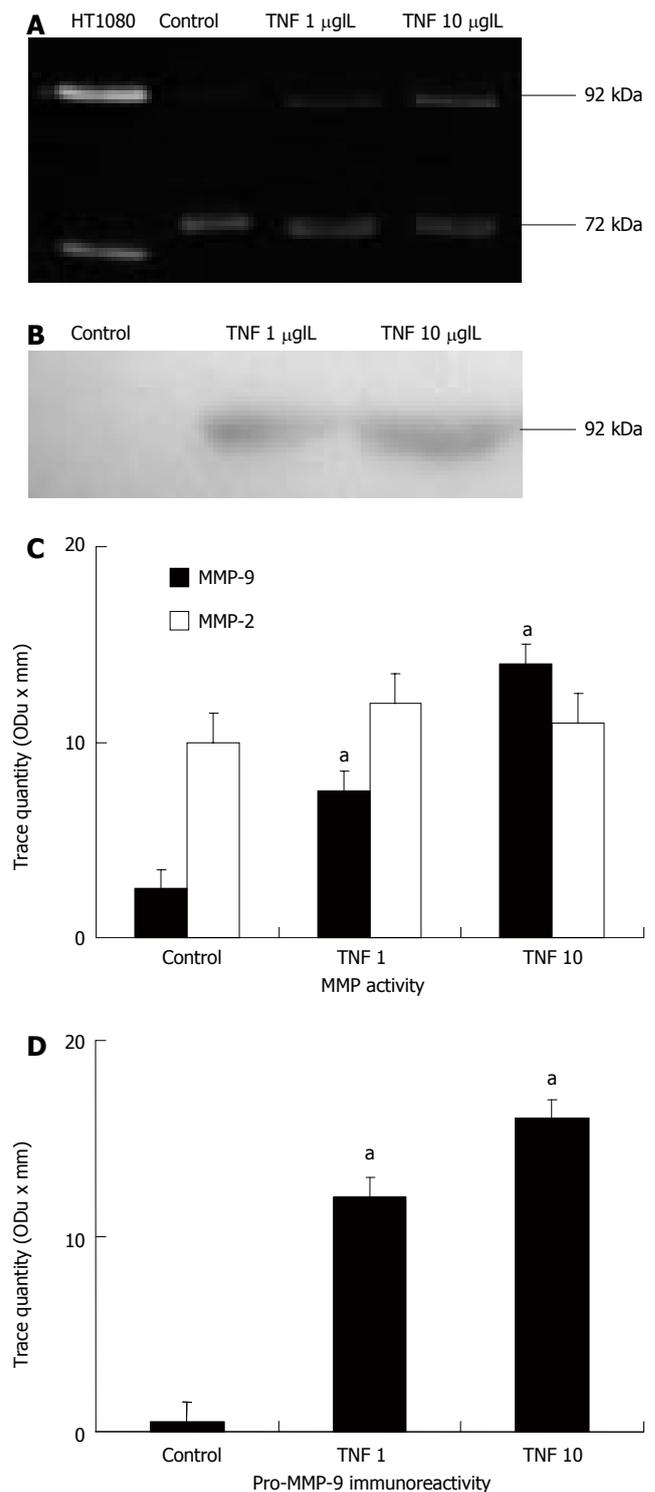

Figure 6 Activity of gelatinases in Caco-2 cells in absence (control) or presence of TNF- α (1 μ g/L or 10 μ g/L). **A**: Representative zymogram of gelatinases with molecular weights of 72 and 92 kDa corresponding to pro-MMP-2 and pro-MMP-9, respectively, were detected. Supernatants of HT1080 cells were used as controls. **B**: Representative immunoblot of pro-MMP-9 (92 kDa) protein in Caco-2 cells as above. **C**: Quantitative zymographic analysis ($^{\ast}P < 0.05$ vs control). **D**: Quantitative western-blot analysis ($^{\ast}P < 0.05$ vs control) ($n = 3$ in each group).

colitis^[17]. Our present study shows that DSS treatment induced an increased activity and expression of pro-MMP-9 in wt mice compared to the MMP-9 deficient group. It could be surprising that DSS did not induce the active form of MMP-9, however, the low availability

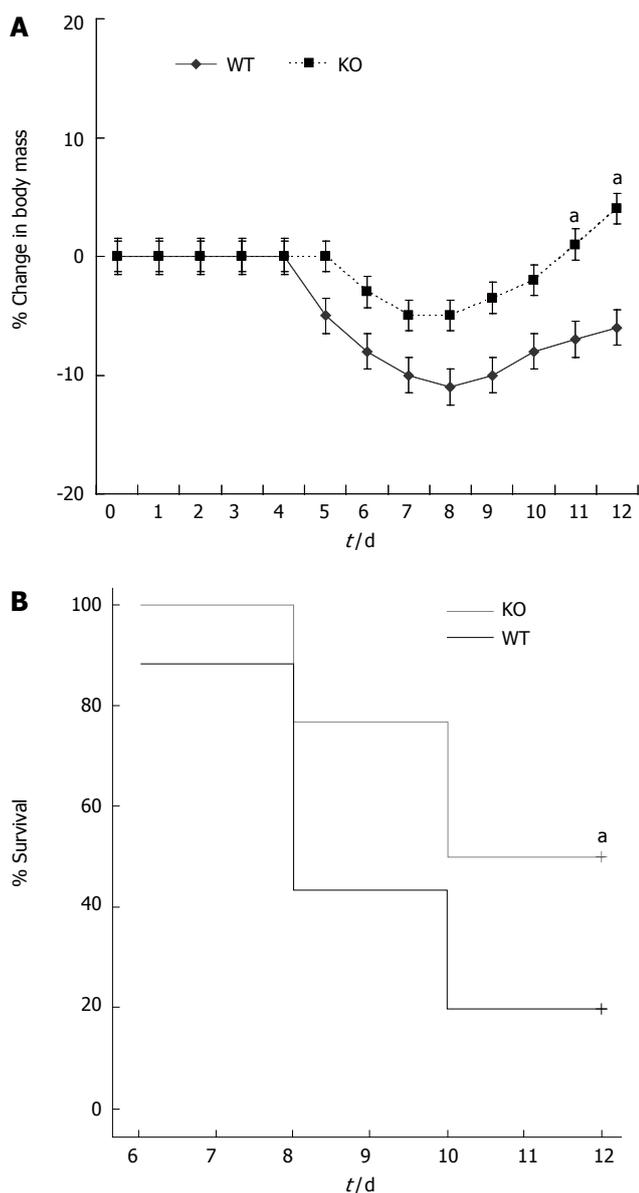

Figure 7 A: Percentage of body weight change during DSS-induced colitis in wild-type (WT) and deficient (KO) animals ($n = 30$ in each group). Values are mean \pm SE of percentage body weight change in each animal relative to weight at the start of DSS treatment. WT animals showed more weight loss than deficient mice ($^{\#}P < 0.05$). **B:** Survival curve of both colitic groups. The mortality was significantly higher in wt animals compared to deficient mice ($^{\#}P = 0.015$).

of this enzyme may be due to the removal of the active form of MMP-9 during the washing of specimens, as it has been previously suggested^[22]. Our data also show that colitis induced by DSS was enhanced in wt animals. In fact, histological evidence of less mucosal damage was observed in MMP-9 deficient animals on d 5 and 12 after induction of colitis. In addition, the higher weight loss and mortality of wt mice compared with deficient animals supports this hypothesis. In our experiments the indices of DSS-induced colitic injury correlated well with pro-MMP-9, but not with MMP-2 up-regulation. By contrast, whereas MMP-2 activity was elevated during the recovery phase of colitis, the activity and expression of pro-MMP-9 decreased on d 12 after colitis induction. These data suggest that MMP-9 is mainly implicated in mucosal injury at the early stage of colitis, whereas MMP-2 seems to be linked to mucosal

Table 2 Histologic scores on d 5 and 12 after Induction of colitis by DSS

	D 5		D 12	
	WT	KO	WT	KO
Crypt lesion	40.0 \pm 4.0	21.0 \pm 5.0 ^a	18.0 \pm 2.4	9.5 \pm 2.4 ^a
Acute inflammation	1.0 \pm 0.2	0.9 \pm 0.1	1.8 \pm 0.2	0.5 \pm 0.15 ^a
Chronic inflammation	0.5 \pm 0.1	0.6 \pm 0.1	1.5 \pm 0.10	0.4 \pm 0.1 ^a
Epithelial regeneration	0.2 \pm 0.05	0.1 \pm 0.02	1.2 \pm 0.15	0.95 \pm 0.2
Crypt distortion	0	0	0.6 \pm 0.10	0.5 \pm 0.2

^a $P < 0.05$ vs WT.

repair, although MMP-2 deficient animals should be tested to confirm this hypothesis. Therefore, further investigation is warranted.

In many inflammatory conditions, the excess degradation of ECM may result from an imbalance between MMP and TIMP activity^[31]. Since TIMP-1 seems to be the major inhibitor of gelatinase activity^[3] we studied the activity of this inhibitor in DSS-induced colitis. We found that TIMP-1 was increased in colitic wt animals on d 5 after induction of colitis in comparison with non-colitic mice. However, our results showed an imbalance between pro-MMP-9 and TIMP-1 activity in colitic wt animals in favour of MMP-9, suggesting that the increase of TIMP-1 was insufficient in preventing pro-MMP-9 from exerting its biologic effects in DSS-induced colitis. Interestingly, in MMP-9 deficient animals DSS treatment did not increase TIMP-1 activity, which could suggest an adapted regulatory response of this endogenous inhibitor to the levels of pro-MMP-9. Our results are consistent with previous studies in human IBD where an imbalance between MMPs and their endogenous inhibitors has been shown^[10,12].

We next studied the cellular origin of MMP-9 in DSS-induced colitis. MMP-9 released from neutrophils could be an important factor for transmigration and proteolysis of ECM in several inflammatory conditions contributing to tissue injury^[19,32]. We found that pro-MMP-9 is expressed by neutrophils only in colitic wt animals. However, DSS treatment did not induce any significant difference in MPO activity and inflammation score (markers of neutrophilic infiltration) between wt and MMP-9 deficient animals on d 5. This is consistent with the fact that inflammation is thought to be a secondary event that follows epithelial damage in this experimental model of colitis^[25]. Therefore, it seems reasonable that other cells may also generate MMP-9 contributing to crypt damage during the initial phase of DSS-induced colitis. Intestinal epithelium plays an important role in the immunomodulatory response of the intestinal mucosa^[33,34]. Indeed, the loss of intestinal epithelium integrity could lead to an interaction between the luminal antigenic stimuli with the mucosal immune system, resulting in intestinal inflammation^[35-37]. We used a human intestinal epithelial cell line to confirm whether MMP-9 and MMP-2 are up-regulated by inflammatory stimuli, as previously described^[38]. Consistent with the colonic tissue samples, we found that TNF- α treatment only resulted in up-regulation of pro-MMP-9 activity in intestinal epithelial cells. These data therefore suggest that MMP-9 could

be released from inflamed intestinal epithelial cells with the subsequent loss of mucosal integrity, thus facilitating the penetration of inflammatory cells such as PMN into inflamed tissue in the late inflammatory phase of DSS-induced colitis. Our results are consistent with a recent study where epithelial MMP-9 has been shown as an important factor for tissue damage using the Caco-2 intestinal cell line, since MMP-9 inhibited cell attachment and wound healing in an *in vitro* model^[39]. In addition, epithelial protection in MMP-9-deficient mice during the early phase of colitis could also account for a mitigated inflammatory response in the late phase of this experimental model. In fact, only on d 12 after DSS administration MMP-9-deficient animals showed lower inflammation scores than wt animals. These results are consistent with our previous study, where MMP inhibition with CGS-27023-A treatment in rats with DSS-induced colitis significantly reduced the inflammation scores only during the recovery phase of the colitis^[17].

In conclusion, this study presents direct evidence that DSS-induced colitis is attenuated in mice deficient in MMP-9. The reduction in inflammatory indices and pathological scoring suggests a link between MMP-9 and DSS-induced colitis that might help elucidate the physiopathology of UC. These results suggest that selective inhibition of this gelatinase could be a novel therapeutic strategy for patients with UC.

Abstract

AIM: To determine the gene expression profile data for the whole liver during development of dimethylnitrosamine (DMN)-induced hepatic fibrosis.

METHODS: Marker genes were identified for different types of hepatic cells, including hepatic stellate cells (HSCs), Kupffer cells (including other inflammatory cells), and hepatocytes, using independent temporal DNA microarray data obtained from isolated hepatic cells.

RESULTS: The cell-type analysis of gene expression gave several key results and led to formation of three hypotheses: (1) changes in the expression of HSC-specific marker genes during fibrosis were similar to gene expression data in *in vitro* cultured HSCs, suggesting a major role of the self-activating characteristics of HSCs in formation of fibrosis; (2) expression of mast cell-specific marker genes reached a peak during liver fibrosis, suggesting a possible role of mast cells in formation of fibrosis; and (3) abnormal expression of hepatocyte-specific marker genes was found across several metabolic pathways during fibrosis, including sulfur-containing amino acid metabolism, fatty acid metabolism, and drug metabolism, suggesting a mechanistic relationship between these abnormalities and symptoms of liver fibrosis.

CONCLUSION: Analysis of marker genes for specific hepatic cell types can identify the key aspects of fibro-

INTRODUCTION

The pathological relationship between chronic inflammation and formation of fibrosis has been established in various organs, including the liver, kidney, lung and pancreas. Although liver fibrosis has been studied extensively, the underlying mechanisms remain unclear and drugs to prevent and treat fibrosis are only partially effective. DNA microarray technology offers an approach to this kind of complex problems, and microarray analyses of the whole liver have been reported for liver fibrosis^[1,2]. However, these analyses did not address the behavior of individual hepatic cell-types and the interactions of hepatic cells during fibrosis. Therefore, in the current study we identified hepatic cell-specific marker genes that could be used to understand the *in vivo* behavior of each type of hepatic cells during fibrogenesis.

About 70%-80% of hepatic cells are parenchymal hepatocytes, while the non-parenchymal cells are mainly composed of Kupffer cells, hepatic stellate cells (HSC) and sinusoidal endothelial cells (SECs)^[3,4]. Kupffer cells are the resident monocytes in liver, and act in phagocytosis of foreign substances such as microorganisms, as well as management of inflammatory processes. Kupffer cells and infiltrated monocytes and lymphocytes are considered to trigger inflammation in the early phase of hepatitis and then maintain chronic inflammation. HSCs control hepatic and cardiovascular contraction, and produce extracellular

matrix (ECM) components and cytokines for repair of organs. HSCs are also believed to have a central role in hepatic fibrosis formation. Hepatocytes fulfill the main functions of the liver, including regulation of nutrition, production of major serum proteins, and elimination of unnecessary materials to maintain homeostasis of the whole body^[4].

In the current study, we first examined gene expression profiles of hepatic cells that were isolated at different time points during liver fibrosis. Marker genes specific for different types of hepatic cells were obtained by comparing these profiles and using information from previous studies. DNA microarray data for the whole liver were then interpreted during liver fibrogenesis using the hepatic cell-type specific marker genes. Our results suggest that new pathological properties and intracellular events are associated with each cell type during liver fibrogenesis, and provide candidates for diagnostic markers of liver fibrosis.

MATERIALS AND METHODS

Animals and experimental protocols

Male Sprague-Dawley rats (Charles River Japan, Yokohama, Japan) weighing 160-190 g were housed with unrestricted access to food (CRF-1, Oriental Yeast, Tokyo, Japan) and water in air-conditioned animal quarters with a 12 h light/dark cycle (light between 07:00 and 19:00 h). Hepatic fibrosis was induced by intraperitoneal injection of 0.5% dimethylnitrosamine (DMN; Wako Pure Chemical Industries, Osaka, Japan) at 2 mL/kg of body weight for three consecutive days each week for four weeks. Blood samples were drawn from the inferior vena cava on d 0, 4, 7, 14, 21 and 28, respectively. Liver specimens obtained on these days were dissected and immediately frozen in liquid nitrogen. Fibrosis was confirmed by haematoxylin and eosin (HE) staining of the liver tissue. The hydroxyproline content of liver specimens was determined as previously described by Horie *et al*^[5]. Plasma alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were measured using commercial kits (Fuji Film, Tokyo, Japan), and hyaluronic acid levels were determined using a commercial ELISA kit (Fujirebio, Tokyo, Japan). The animal facilities and protocol were reviewed and approved by the Institutional Animal Care and Use Committee of Ajinomoto Co., Inc.

Preparation of HSCs, inflammatory cells (including Kupffer cells) and hepatocytes

HSCs were isolated from rat liver using the pronase-collagenase digestion method as previously reported^[6]. Kupffer cell fraction was prepared with an elutriator, using essentially the same method as previously described^[6], and hepatocytes were isolated as previously described^[7].

Selection of marker genes for hepatic cells

Hepatic cells (HSCs, Kupffer cell fraction and hepatocytes) were isolated from the liver on d 0, 4, 7, 14, 21 and 28 during liver fibrogenesis. The isolated hepatic cells at each time point were subjected to DNA microarray analysis. If

the maximum or minimum expression of a gene in hepatocytes was ten times higher or lower than that of the same gene in HSCs and the Kupffer cell fraction, the up- or down-regulated gene was defined as a hepatocyte-specific marker gene. If the maximum or minimum expression of a gene in HSCs was ten times higher or lower than that of the same gene in hepatocytes and three times higher or lower than the same gene in the Kupffer cell fraction, this gene was defined as a HSC-specific marker gene. Similarly, if the maximum or minimum expression of a gene in the Kupffer cell fraction was ten times higher or lower than that of the same gene in hepatocytes and three times higher or lower than the same gene in HSCs, the gene was defined as an inflammatory cell-specific marker gene. An explanation of the use of the term 'inflammatory cell', rather than 'Kupffer cell', was given in the Results section. The ratios used to determine cellular specificity were based on previous reports^[8,9]: the number of hepatocytes was about ten times higher than that of the inflammatory cell fraction or HSCs, while the number of Kupffer cells was similar to that of HSCs. Use of a high ratio improved the definition of cellular specificity, but also decreased the number of marker genes. However, we found that these ratios were the most appropriate for identification of a set of genes for analysis of liver fibrogenesis.

Microarray analysis

RNAs both from frozen liver tissues and from each isolated cell type were prepared using Isogen reagent (Nippon Gene), and the quality and quantity of each RNA sample were assessed using an Agilent Bioanalyzer 2100 (Agilent Technologies, Inc.). RNA samples were reverse-transcribed with a poly (dT) oligonucleotide attached to a T7 promoter and copied into dsDNA (Invitrogen). *In vitro* RNA transcription was performed to incorporate biotin-labeled ribonucleotides into the cRNA transcripts using a RNA transcript labeling kit (Enzo Biochem). Some of the RNA (15 g) was utilized for hybridization to a rat genome U34A array (Affymetrix) and a quality assay using test 3 array probe chips was performed according to the manufacturer's protocol. After hybridization and subsequent washing using the Affymetrix Fluidics Station 400, fluorescence signals amplified with streptavidin phycoerythrin were measured using the Affymetrix scanner, and the results were analyzed using the MicroArray suite software. In the whole liver analysis, two rats and two arrays were used at each time point (d 4, 7, 14, 21 and 28). In the cell-type-specific analysis, one rat which was selected by ALT/AST score and one array were used at each time point (d 4, 7, 14, 21 and 28).

Statistical analysis

Clustering of K-means was performed using the TIGR MeV (MultiExperiment Viewer)^[10]. Gene expression profiles in the chronic phase were clustered into 10 patterns using K-means analysis. Clustered genes with a tendency to temporally decrease (clusters 1, 3 and 10) or increase (clusters 7 and 9) were selected as gene markers that had a strong relationship with fibrogenesis.

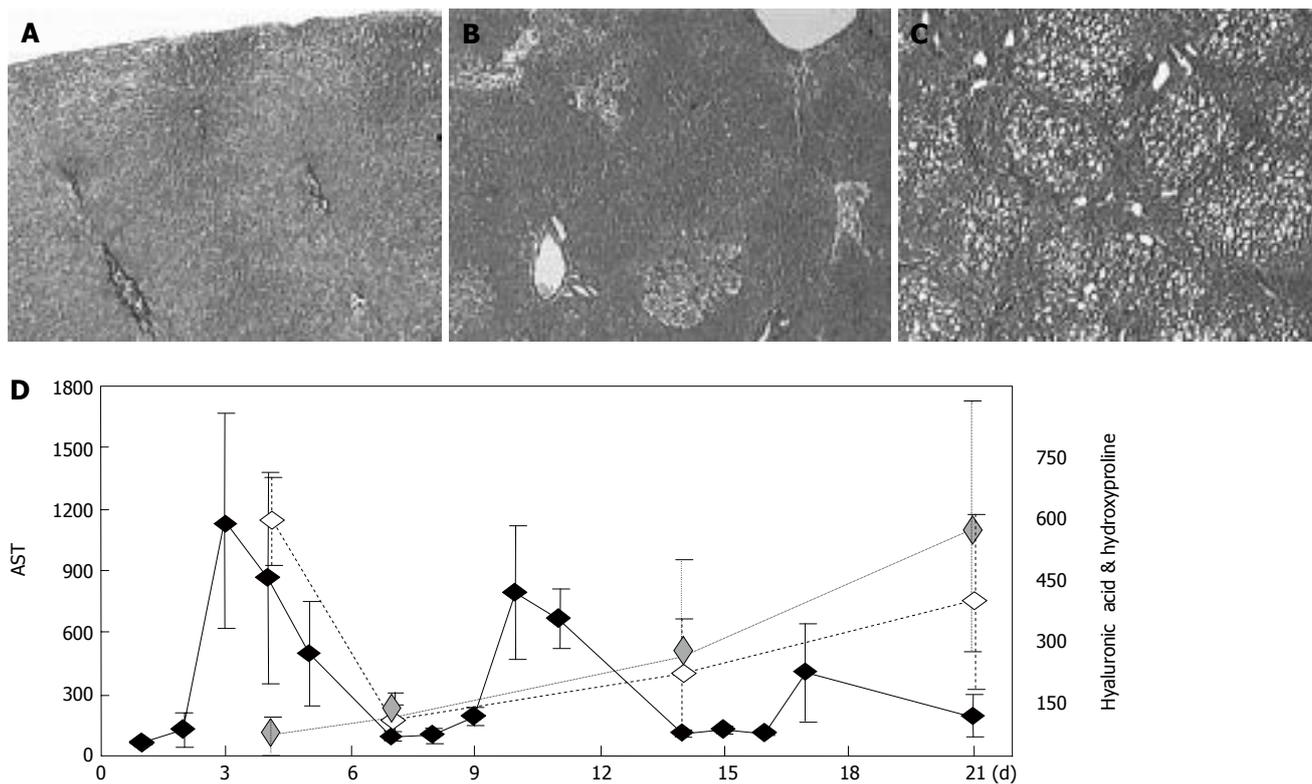

Figure 1 Histological and biochemical analyses of fibrogenesis. **A-C:** Histological staining (HE staining) of control liver sections (**A**) and sections obtained on d 4 (**B**) and d 21 (**C**), respectively, after DMN administration; **D:** Biochemical analysis of fibrogenesis showing plasma AST levels (IU/L, solid line), plasma hyaluronic acid levels (ng/mL, dashed line), and liver hydroxyproline levels (ng/mL, dotted line). The x-axis shows the days of fibrogenesis, and each value on the graph is shown as the mean \pm SE, $n = 5$.

RESULTS

Time course of gene expression profiles for the whole liver during fibrogenesis

Administration of DMN for three days induced an inflammatory reaction in liver cells simulating the active phase in hepatitis, and the subsequent lack of administration of DMN for four days was used to simulate the remission phase in hepatitis. Repetition of this cycle led to fibrosis in three or four weeks, as shown in Figure 1. AST (GOT) and ALT (GPT) increased on the days of DMN administration and decreased on the days during which DMN was not administered (Figure 1), but both AST and the hyaluronic acid content in serum, a marker of fibrosis^[11], gradually increased on days without DMN administration. The inflammatory reaction in periods without DMN administration was weaker than that in periods with DMN-administration, but gradually increased in intensity and response. Based on the behavior shown in Figure 1, gene expression profiles on d 4 (just after a period of DMN administration) were defined as representative of the acute phase response, and those on d 7, 14, 21 and 28 (just before a period of DMN administration) were defined as representative of the chronic phase response.

Marker genes indicating fibrotic activity of HSCs

HSCs were isolated from liver at each time point over the time course of development of DMN-induced fibrosis. Marker genes expressed mainly in HSCs were selected from a DNA microarray analysis, as described in the Materials and Methods, and the selected HSC-specific marker

genes are listed in Figure 2. In addition, HSCs isolated from normal rats were cultured *in vitro* for 7 d and DNA microarray analysis of these cells was performed on d 0, 4, and 7, respectively. Marker genes identified in isolated HSCs in the DMN-induced fibrosis model showed the same behavior in the *in vitro* culture, supporting the HSC specificity of the selected marker genes. The behavior of HSC-specific marker genes *in vivo* during fibrogenesis was analyzed using DNA microarray data for the whole liver at each time point during development of DMN-induced fibrosis. These data could indicate the actual behavior of the marker genes *in vivo*, since the data from isolated HSCs might contain some bias due to isolation stimuli. The behavior of HSC-specific marker genes is shown in Figure 2, and supplemental background data are provided in Figure 3. The genes were separated into 2 groups as shown in Figure 2. Group 1 contained marker genes that were linearly up-regulated during fibrogenesis and in the acute inflammation phase, whereas group 2 contained marker genes that were linearly up-regulated during fibrogenesis but not in the acute inflammation phase. Both groups could be further separated into 2 subgroups. Group 1-1 included marker genes that were linearly up-regulated during fibrogenesis and remained in an up-regulated state on d 28, and group 1-2 included marker genes that were also linearly up-regulated during fibrogenesis but then decreased in expression on d 28. Group 2 was similarly separated into groups 2-1 and 2-2. In summary, two groups of HSC-specific marker genes were identified, one in which the genes responded to inflammatory stimuli and the other in which the genes did not respond to such stimuli. Furthermore,

Expression profiles of the whole liver and *in vitro* cultured isolated HSCs were obtained using a rat genome U34A array (Affymetrix). Gene markers for HSCs are listed. For analysis of HSCs in the whole liver, expression intensities are given for d 0, and expression intensity data for d 4, 7, 14, 21 and 28 are shown as ratios to the d 0 expression data. The classification of group1 (2) corresponds to the presence (absence) of up-regulated peak in the acute inflammation phase. For analysis of *in vitro* cultured HSCs, expression levels for d 0 are also shown, and data for d 4 and 7 are similarly shown as ratios to the expression level on d 0. Italicized values indicate an "absent" call by the Affymetrix software. Bold text indicates the highest ratio in the chronic phase (d 7, 14, 21 and 28). □ between 0.667 and 1.5; ■ ≥ 1.5; ▨ ≤ 0.667.

HSC-specific marker genes were found that could identify biological changes in HSCs in the late phase of fibrosis.

Marker genes indicating inflammatory activity in immune cell populations

The Kupffer cell fraction was separated from other hepatic cells at each time point during the course of fibrosis development, and marker genes expressed mainly in the Kupffer cell fraction were selected from the DNA microarray analysis. These marker genes are shown in Figure 4, and supplemental background data are provided in Figure

5. Marker genes in the Kupffer cell fraction indicated the presence of other hematopoietic cells, such as mast cells, lymphocytes, erythrocytes and their progenitors in this fraction, as shown in Figures 4 and 5. Since the source cell population for these marker genes could not be confirmed, a particular hematopoietic cell was postulated to be the source of each marker gene based on previous reports as shown in supplemental Table 1. These data indicated that the method used for isolation of Kupffer cells was not appropriate in fibrotic liver, although it was effective for isolation of normal liver cells. However, despite this

Table 2 Marker genes in hepatic stellate cells (HSC)

Expression profiles of the whole liver, of isolated HSCs during fibrogenesis, and of in vitro cultured isolated HSCs were obtained using a rat Genome U34A Array (Affymetrix). Marker genes for HSCs are listed. Expression intensities are shown for d 0, and expression intensity data for d 4, 7, 14, 21 and 28 are displayed as ratios to the d 0 expression levels for the analysis of whole liver and isolated HSCs. For in vitro cultured HSCs, the d 0 data are similarly shown as expression intensities, and data on d 4 and 7 are shown as ratios to the expression levels on d 0. Italics indicate an "absent" call by the Affymetrix software, and bold text indicates the highest ratio in the chronic phase (d 7, 14, 21 and 28). □ between 0.667 and 1.5; ▤ ≥ 1.5; ▥ ≤ 0.667.

drawback, the marker genes could be used to study the behavior of inflammatory cells during fibrogenesis, and these genes were therefore defined as inflammatory cell-specific marker genes. The behavior of the inflammatory cell-specific marker genes *in vivo* during fibrogenesis was analyzed using DNA microarray data for the whole liver at each time point during DMN-induced fibrogenesis of marker genes, as summarized in Figures 4 and 5.

The acute phase response was followed by an immunological response, based on the increase in expression of Kupffer cell (or macrophage) markers such as *Lyz*, *Gzmb*, and *Il1b*, as well as surface markers of T cells, such as T-cell receptor, *Il2rb*, *Cd8*, *Cd76*, and *Cd45*. The up-regulated expression of these genes seemed to indicate activation of Kupffer cells and T lymphocytes, as well as activation of the interaction between these cells, around d 7. Temporary up-regulation of mast cell markers such as chemokines and mast cell proteases indicated the invasion and/or activation of mast cells around d 14, which is of interest since mast cells are known not only to cause acute inflammation, but also to have a role in the induction of chronic inflammation^[12-14]. However, whether activation of mast cells is essential for liver fibrosis is unknown. Peak expression of B cell markers such as immunoglobulin occurred on d 21 or d 28, and therefore activation or invasion of B cells seemed to reach its peak in the late phase. Overall, these results showed that inflammatory cell-specific marker genes could be used to monitor the transition of active inflammatory cell populations in fibrosis, and this sequential activation or invasion of inflammatory cells might be related to the stage of fibrotic progression.

Marker genes indicating damage to hepatocytes

Hepatocytes were separated from other hepatic cells at each time point during the course of DMN-induced fibrogenesis, and marker genes expressed mainly in hepatocytes were selected by DNA microarray analysis. The behavior of hepatocyte-specific marker genes *in vivo* during fibrogenesis was analyzed using DNA microarray data for the whole liver at each time point during fibrosis development. Marker genes were categorized based on their functions, as shown in Figure 6. Many abnormally expressed genes were identified and temporal analysis revealed groups of genes showing consistent variation in expression. Gene expression profiles in the chronic phase (d 7, 14, 21 and 28) were clustered into 10 patterns using K-means analysis. Clustered genes with a tendency to temporally decrease (clusters 1, 3 and 10) or increase (clusters 7 and 9) were selected, and then genes were further selected based on a strong correlation coefficient (≥ 0.7 or ≤ -0.7) with fibrosis stage (that is, d 7, 14, 21 and 28). The time courses of expression ratios are shown in Figure 7 as supplemental data. The 41 down-regulated and 19 up-regulated genes that were finally selected are shown in Table 2. These genes appeared to have a strong relationship with progression of fibrosis, and might also share common regulatory expression mechanisms.

Down-regulation of the expression of *Cdo1* and *Csad* showed a strong relationship with fibrotic stage, while expression of *Gsta2* was simultaneously up-regulated. Down-regulation of other metabolic enzymes in sulfur-containing metabolic pathways is also shown in Figure 6. These data suggested a broad range of abnormalities in sulfur-containing amino acid metabolic pathways in

Expression profiles of the whole liver and the isolated Kupffer cell fraction during fibrogenesis were obtained using a rat genome U34A array (Affymetrix). Marker genes for hematopoietic cells in the Kupffer cell fraction are listed. Expression intensities are given for d 0, and expression intensity data for d 4, 7, 14, 21 and 28 are shown as ratios to the d 0 expression data for analysis of hematopoietic cells in whole liver. The classification of genes into groups 1-4 and corresponds to the maximum change of expression at the different time points on d 7, 14, 21, 28 and 4, respectively. Italicized values indicate an "absent" call by the Affymetrix software. The bold values indicate the highest or lowest ratio in the chronic phase (d 7, 14, 21 and 28). □ between 0.667 and 1.5; ▣ ≥ 1.5; ▤ ≤ 0.667. Cell types in the inflammatory cell fraction are as follows: M: Monocytes and their progenitors; L: Lymphocytes and their progenitors; E: Erythrocytes and their progenitors; P: Platelets and their progenitors; Leu: Other kinds of leukocytes and their progenitors.

fibrosis. Regarding other genes, Hao2 and Hpcl2 had a role in fatty acid oxidation in peroxisome, while Amacr was associated with beta-oxidation of pristanoyl-CoA and C27-bile acyl-CoAs. The down-regulation of these genes and other metabolic enzymes related to fatty acid oxidation (Figure 6) suggested abnormalities in the fatty acid oxidation process in fibrosis. The expression of Amacr might be related to that of the nuclear receptor subfamily 0, group B, member 2 (Nr0b2), and changes in NrOb2 expression may affect one of the key molecules in cholesterol biosynthesis. Up-regulation of Gk and down-regulation of Pepck1, PC and Slc37a4 suggested abnormalities in gluconeogenesis, glycogen storage and glycolysis, while down-regulation of Ste and Hsd17b2 suggested an abnormality of estrogen metabolism in the liver. Decreased expression of many Cyp drug metabolism enzymes was also found in progression of fibrosis, and

abnormalities in hormonal signaling were suggested by the down-regulation of Inhbe, Ghr and Dio1. These results showed that identification of hepatocyte-specific marker genes could allow analysis of functional changes in fibrosis, and all the identified abnormalities might have major effects on hepatic function.

DISCUSSION

Marker genes for HSCs

Markers of HSCs such as Acta 2, Cryab, Spp1, Prnp, and Pai-1 were strongly up-regulated on d 4, and then quickly decreased in expression following a gradual up-regulation. On the other hand, other HSC markers such as Gpc3, Lox, and Mgp did not show marked up-regulation on d 4, but their expression level increased linearly during fibrogenesis. Therefore, HSCs may be associated with events in two

Expression profiles of the whole liver and the isolated Kupffer cell fraction during fibrogenesis were obtained using a rat Genome U34A Array (Affymetrix). Marker genes of hematopoietic cells in the Kupffer cell fraction are listed. Expression intensities are shown for d 0, and the expression intensity data for d 4, 7, 14, 21 and 28 are displayed as ratios to the d 0 expression levels. Italics indicate an "absent" call by the Affymetrix software. Bold values indicate the highest or lowest ratio in the chronic phase (d 7, 14, 21 and 28). □ between 0.667 and 1.5; ■ ≥ 1.5; ■ ≤ 0.667. The cell types in the inflammatory cell fraction are as follows: M: Monocytes and their progenitors; L: Lymphocytes and their progenitors; E: Erythrocytes and their progenitors; P: Platelets and their progenitors; Leu: Other kinds of leukocytes and their progenitors.

Table 5 References used in the definition of types of hematopoietic cells in the Kupffer cell fraction

The reference numbers correspond to the numbers in Table 4 in the supplementary data.

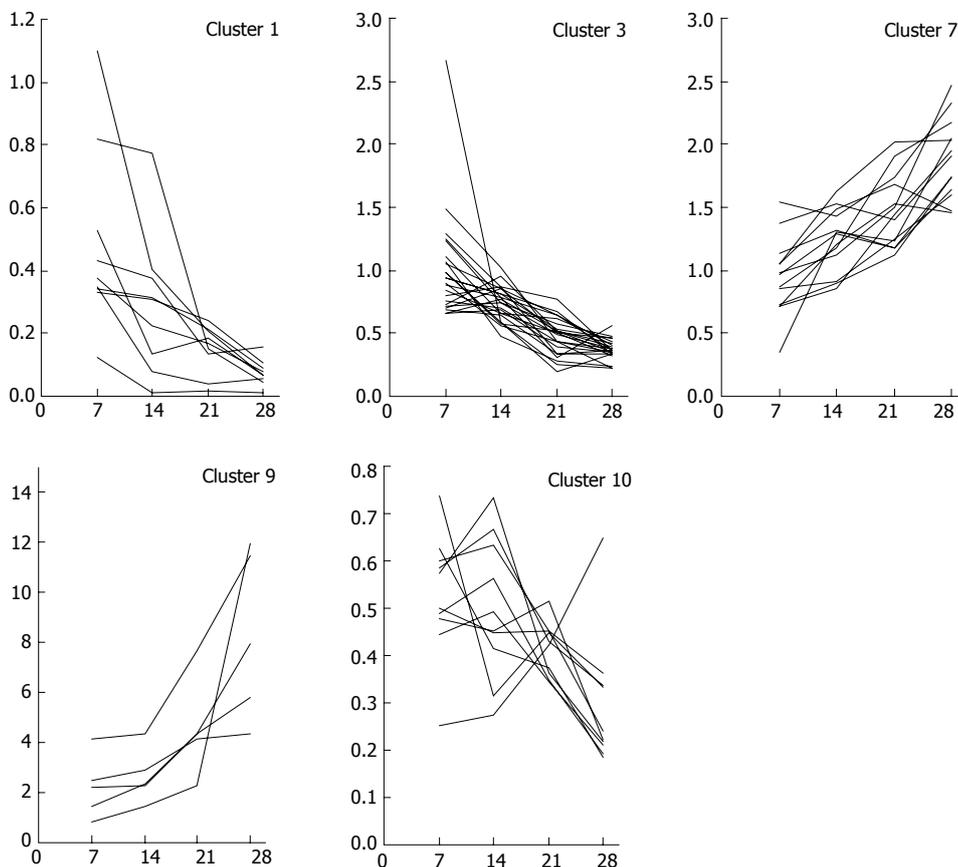

Figure 2 Cluster of genes that increased or decreased in expression with progression of fibrogenesis. Gene expression profiles in the chronic phase (d 7, 14, 21 and 28) were clustered into 10 patterns using K-means analysis. Clustered genes with a tendency to temporally decrease (clusters 1, 3 and 10) or increase (clusters 7 and 9) were selected as gene markers that had a strong relationship with fibrogenesis.

Table 6 Marker genes for hepatocytes

Expression profiles of whole liver or isolated hepatocytes during fibrogenesis were obtained using a rat Genome U34A Array (Affymetrix). Marker genes for hepatocytes, which are the main contributors to the expression profile of the whole liver, are listed. Expression intensities are given for d 0, and expression intensity data for d 4, 7, 14, 21 and 28 are displayed as ratios to the d 0 expression data. Italics indicate an "absent" call by the Affymetrix software. Genes with the highest or lowest ratio in the chronic phase are shown in bold text. □ between 0.667 and 1.5; ■ ≥ 1.5; ■ ≤ 0.667.

different phases, such as repair in the acute phase response and fibrosis in the chronic phase response. These two groups of HSC marker genes may also be differentially regulated. Marker genes in one group may be expressed both in undifferentiated and in differentiated HSCs, while marker genes in the other group may be expressed mainly in differentiated HSCs. The functional changes associated with differentiation of HSCs during fibrosis are not clear. Schnabel *et al.*^[15] have temporally divided the activation process of HSCs into an initiation phase and a perpetuation phase, and HSCs in the initiation phase may play a role in wound healing^[16,17] and are then eliminated

by apoptosis^[18,19], although some HSCs in the initiation phase differentiate into cells in the perpetuation phase. The two kinds of marker genes found in our work may be associated with the two phases.

In the present study, gene expression in HSCs *in vivo* was mostly similar to that found *in vitro*, suggesting that HSCs can be activated and produce ECM with few factors contributed by other cell types. Since HSCs also produce auto-stimulating factors such as TGF-beta, chemokines, PDGF, and IGF-1, our results strongly suggest that HSCs have self-supporting properties and few exogenous factors are required for their activation and differentiation. Even if

Table 7 Marker genes for hepatocytes that showed a strong relationship with fibrogenesis

Functional category	Cluster No.	Direction of change	Annotation	Symbol	Common

Gene expression profiles in the chronic phase (d 7, 14, 21 and 28) were clustered into 10 patterns using K-means analysis. Clustered genes that showed a tendency to temporally decrease (clusters 1, 3 and 10) or increase (clusters 7 and 9) were selected, as shown in Table 5 in the supplemental data. Among these genes, those showing a strong relation with fibrogenesis were further selected based on a *t*-test statistical analysis of the rate of change in expression intensity and the number of days of fibrosis. Hepatocyte-specific gene markers showing a strong relation with fibrogenesis are listed.

Inflammation induced by virus activation stimulates long-term or weak hepatitis, HSCs may be able to autonomously activate and promote fibrosis, and this property of HSCs may be central to promotion of fibrogenesis. Sancho-Bru *et al.*^[20] have recently reported that a culture model of HSCs could not exactly match the activated phenotype found in DNA microarray analysis of isolated HSCs from cirrhotic human livers, because in culture marker genes for HSCs in the perpetuation phase are predominantly expressed, relative to those in the initiation phase. However, isolation of HSCs may also alter the expression of some genes, especially the expression of genes associated with inflammation, as shown in Figures 2 and 4. Therefore, compared to studies of isolated HSCs, our approach reveals the actual behavior of HSCs *in vivo* during fibrosis.

Gpc3 has been recently proposed as a serum and histochemical marker for hepatocellular carcinoma^[21,22], since it is only weakly expressed in hepatocytes in normal and cirrhotic livers. However, in our study, Gpc3 was expressed in isolated HSCs during fibrogenesis, but weakly in cultured HSCs, suggesting that HSCs require extracellular factors for expression of Gpc3 during fibrogenesis, or that Gpc3-expressing cells with abnormal characteristics may contaminate the HSC fraction. The cell type showing expression of Gpc3 requires further study.

Marker genes for inflammatory cells

In the present study, gene expression in the inflammatory cell-fraction indicated the presence of several kinds of hematopoietic cells in this fraction, leading to some uncertainty in the data from the rat fibrosis model. However, the behavior of mast cells is of note, since temporary up-regulation of mast cell markers such as chemokines and mast cell proteases indicated invasion and/or activation of mast cells around d 14. Invasion of a marked number of mast cells could not be detected with HE staining, and therefore the number of invading mast cells must be small. Mast cells not only cause acute inflammation, but also have a role in induction of chronic inflammation^[12,14], and involvement of mast cells in hepatic fibrosis has been reported^[12,23-25]. RANTES, a chemokine that is produced by T cells and stimulates mast cells^[26,27], showed its peak expression on d 14, as shown in Figure 4. RANTES has been suggested to be a mediator of progression from acute to chronic inflammation in colitis^[28], and further studies are of importance to determine whether RANTES activation of mast cells is essential for liver fibrosis.

Marker genes for hepatocytes

DNA microarray analysis of whole liver in experimental animal models of hepatic fibrosis has been reported^[1,2], and characteristic behavior of hepatocyte-specific marker genes over the time course of fibrogenesis was found in this study. DNA microarray data for the whole liver are similar to those for hepatocytes, since 70% of hepatic cells are hepatocytes^[8,9], and data on d 28 are generally similar to those in previous reports. However, our temporal data indicate progressive abnormal gene expression in fibrogenesis, including in the early phase of fibrogenesis. Furthermore, since our data did not contain genes expressed in other hepatic cells, the hepatocyte-specific gene set allowed examination of the molecular network in hepatocytes.

Clustered abnormalities were found in genes associated with metabolism of sulfur-containing amino acids in this study. Similar abnormalities in metabolism of sulfur-containing amino acids have been reported^[29,30], and an increase in methionine concentration in blood has been found in cirrhosis^[31,32], which may be related to changes in gene expression in sulfur-containing amino acid metabolism. Furthermore, S-adenosylmethionine has an important role in methylation, including the methylation of DNA. Since abnormalities likely induce tumorigenesis due to DNA instability, it is of note that long-term suppression of S-adenosylmethionine synthetase increases the risk of tumorigenesis^[33]. Glycine methyltransferase also has been implicated in DNA instability^[34,35], and long-term suppression of this enzyme also has an associated risk of tumorigenesis during liver fibrosis. A metabolite of methionine, homocysteine, is also suspected as a risk factor for cardiovascular disease^[36,37], and an increase in the concentration of homocysteine has been found in cirrhosis^[38]. Abnormal homocysteine metabolism may also have an important role in the pathogenesis of liver failure, including fatty liver, activation of HSCs (i.e., enhancement of fibrosis), cardiovascular disease, and HCC. Finally, biosynthesis of taurine from cysteine may be suppressed, possibly leading to painful muscle cramps, which are a complication of cirrhosis caused by taurine deficiency^[39]. Therefore, in summary, it is apparent that abnormalities in sulfur-containing amino acid metabolism can result in development of serious diseases.

Down-regulation of enzymes related to beta-oxidation in TAA-induced experimental fibrosis has been reported^[29]. Studies of the Aox knockout mouse^[40] suggest that metabolites of fatty acids in beta oxidation accumulate in

the liver and stimulate PPAR-alpha, resulting in peroxisome proliferation, and tumorigenesis is a potential risk in long-term administration of PPAR-alpha agonists and in the Aox-1 knockout mouse^[40,41]. Radical accumulation by blocking metabolic enzymes associated with beta-oxidation has been suggested as one explanation of tumorigenesis in Aox knockout mice, and furthermore, microarray analysis of Aox-deficient mice can show up-regulation of Lcn2, a marker of carcinogenesis^[42]. Interestingly markers such as Lcn2 and Cd36 were up-regulated in hepatocytes during fibrogenesis and in the inflammatory cell fraction in the late phase in our model. Although tumorigenesis due to PPAR alpha agonist is thought not to occur in humans^[41,43], abnormalities in lipid metabolism during liver fibrosis may have a role in steatofibrosis and/or enhancement of fibrosis and HCC.

Up-regulation of Gck and down-regulation of Pck1 in hepatocytes suggest a decrease in gluconeogenesis, and suppression of gluconeogenesis has been reported in cirrhosis^[44]. A deficiency of Scl37a4 enzyme activity in humans causes glycogen storage disease type 1 (GSD-1) genetic disorders^[45] and suppression of this molecule is associated with hepatic steatosis^[46]. Abnormalities in metabolism and synthesis of sex hormone have also been found in fibrotic liver, and an increased ratio of estrogen to testosterone in serum induces feminization, which is a complication in cirrhotic males^[47]. Abnormality of sex-hormone metabolism is also related to liver malignancies^[48,49].

Down-regulation of Ghr is also found in hepatocytes, and long-term suppression of growth signals may greatly influence fundamental hepatic vitality and produce abnormal hepatic regeneration. Insensitivity to growth hormones in cirrhosis has been reported^[50,51], and administration of growth hormone protects against experimental liver fibrosis^[52]. Rgn, a regulator of calcium signaling, may have an important role in regulation of proliferation and apoptosis of hepatocytes, as well as in formation of HCC^[53,54], and down-regulation of regucalcin in our model suggested a risk of HCC development. An association of Afp, Ste, Mt1a, Lcn2, Abcb1 Cml1 (Nat8) and Ca3 with hepatocellular carcinoma (HCC) formation has also been reported. Accumulation of estrogen in the liver is suspected to promote HCC^[55,56], and NAT8 polymorphism may be related to HCC^[57,58]. Down-regulation of metallothionein^[59-61] and carbonic anhydrase^[62,63], up-regulation of Mdr/Tap^[64] and Lcn^[42,65] occur in HCC, and proliferation of hepatoma cells is suppressed by over-expression of Rgn^[53,66]. The abnormal expression of all these genes in our model is similar to that in HCC, suggesting the importance of understanding whether such changes in gene expression reflect a tumorigenic environment or even promote tumorigenesis.

Differential regulations of genes involved in key events of liver fibrosis

In addition to the expression profiles of cell type specific marker genes discussed above, we here describe how genes involved in key events of liver fibrogenesis are differentially regulated. Gene expression profiles of the whole liver for different functional categories in liver fibrogenesis, such as ECM synthesis/degradation, inflammation and oxidative

stress, are shown in Figure 8. Since both synthesis and degradation of ECM occur simultaneously, both genes are put together. Figure 8 shows that most genes in each category have a common and mutually correlated expression pattern, showing different regulations for different categories. Most genes of ECM synthesis/degradation as shown in Figure 8A have a peak of up-regulation on d 4 and a following gradual up-regulation along with the progression of fibrosis, and interestingly these genes are classified into group 1 of the HSC-specific genes as shown in Figure 2. Another type of genes of ECM synthesis/degradation as shown in Figure 8B have no peak on d 4 and only a gradual up-regulation along with the progression of fibrosis, and are classified into group 2 of the HSC-specific genes as shown in Figure 2. Many genes are also involved in the inflammatory category, and here only some of them are plotted as representative in Figure 8C. Most genes of inflammation have a peak on d 4 or 7 commonly, and are classified in group 1 of the Kupffer cell fraction specific genes as shown in Figure 4. Most genes in the category of oxidative stress in Figure 8D have a minimum expression on d 4, in contrast to the genes of inflammation having a peak on d 4 or 7, and are involved in hepatocyte specific genes as shown in Figure 6.

Gene expression profiles viewed from both cell types and functional categories have made more clear image on how the temporal expression pattern are closely associated in terms of both the cell specificity and functions in liver fibrosis, and are regulated differently in different categories but in a mutually correlated manner within the same category.

Pathological overview of the behavior of HSCs, inflammatory cells, and hepatocytes in fibrogenesis

Our results from gene-expression profiling using hepatic cell-specific marker genes support the hypothesis shown in Figure 9. Comparisons of gene expression in HSCs *in vivo* and *in vitro* strongly suggest that HSCs have self-supporting properties and that few exogenous molecules are required to activate and differentiate HSCs. Hepatocytes have been shown to suffer from serious stress during fibrogenesis, and signals from suppressed hepatocytes, such as radicals, proinflammatory substances and toxic metabolites due to abnormal metabolism, are able to stimulate Kupffer cells and HSCs, leading to subsequent production of HSC-stimulating-factors such as TNF- α and IL-1 by Kupffer cells. Therefore, HSCs, Kupffer cells and other inflammatory cells produce factors such as TGF-beta that suppress hepatocyte vitality and result in hepatocyte injury. Sequential activation of inflammatory cells such as lymphocytes and mast cells may be essential in this process, and even if this stimulatory circuit is small in scale during early remission of fibrogenesis, it can be maintained with appropriate stimulation even at long intervals, with small-scale inflammation induced by C-type hepatitis virus propagation. The self-supporting characteristics of HSCs may have a central role in maintenance of this circuit.

ACKNOWLEDGMENTS

We thank Ms. Sonoko Ishizaki of Ajinomoto Co., for

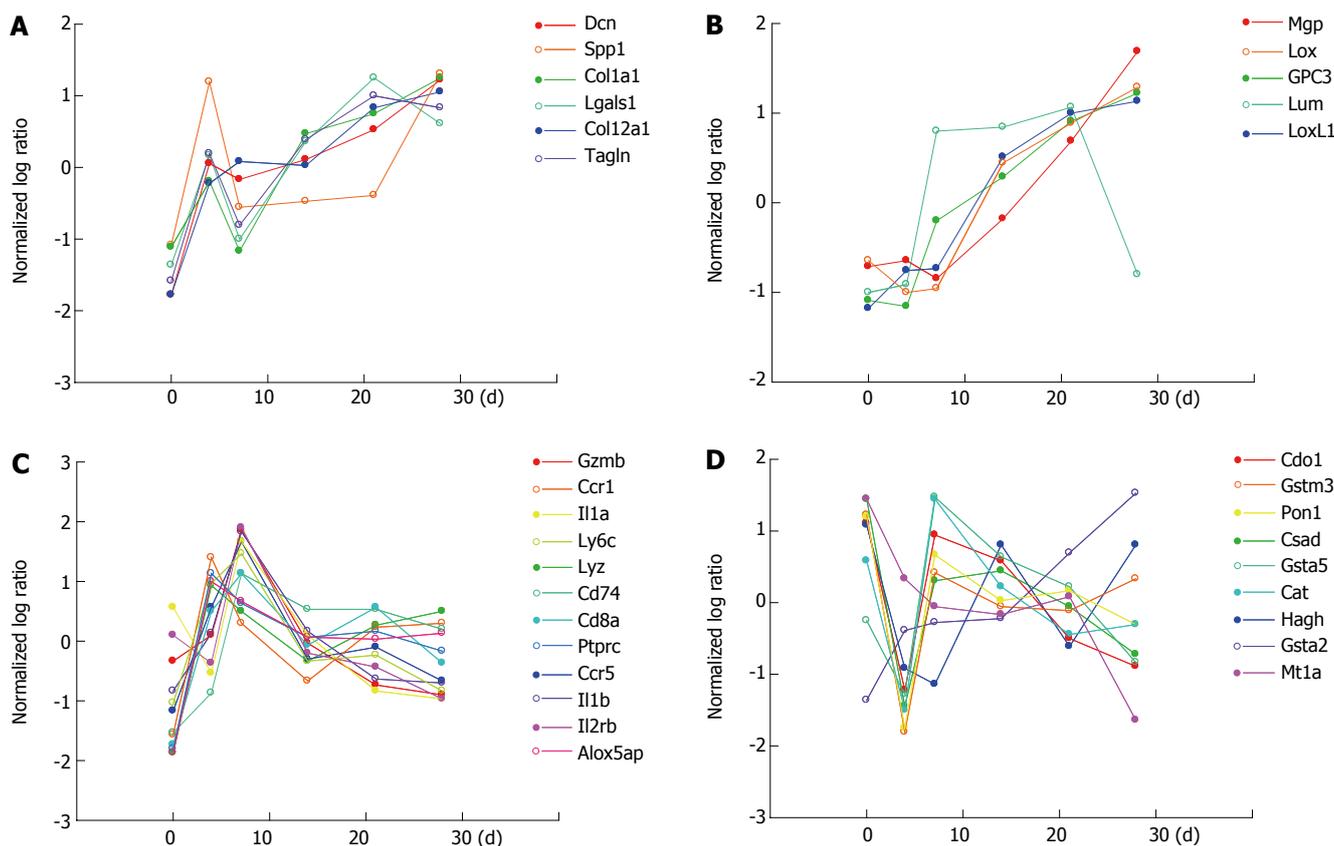

Figure 3 Differential regulations of genes involved in key events of liver fibrosis. Gene expression profiles of different events in liver fibrogenesis such as ECM synthesis/ degradation, inflammation and oxidative stress, are shown. The x-axis showing the days of fibrogenesis (d 0, 4, 7 14, 21, 28) and the y-axis the normalized log ratio(scaled in terms of mean and SD, and the log base 2) of the whole liver gene expression. **A** and **B**: genes of ECM synthesis/degradation classified into group 1 (2) of HSCs as shown in Table 1; **C**: genes of inflammation involved in the Kupffer cell fraction as shown in Table 3; **D**: genes of oxidative stress involved in the hepatocytes as shown in Table 6.

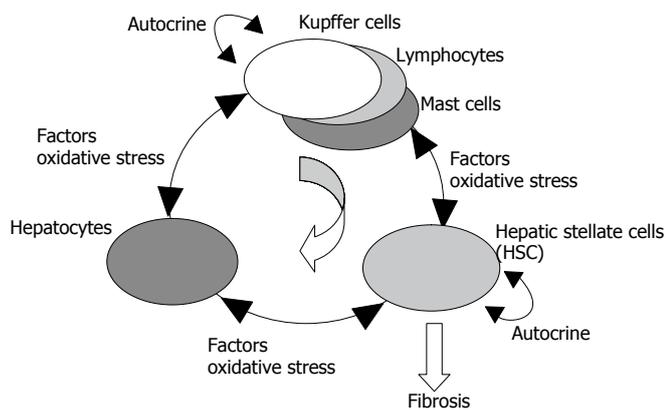

Figure 4 Circuit model of hepatic cells in fibrogenesis. Gene expression profiles show that HSCs have self-activating properties, and that widespread damage to hepatocytes occurred in development of fibrosis, suggesting a self-activating circuit model of fibrogenesis. After an initial stimulatory trigger caused by events such as virus infection, hepatic cells are able to stimulate each other, and the self-activating properties of HSCs maintain this cycle over the long term. Details are given in the text.

preparation of Kupffer cells. Additionally, we thank Mr. Kazuhisa Takemoto and Ms. Kunie Shimode for experimental assistance and manuscript preparation, respectively.

CONCLUSION: A new cell line derived from peripheral cholangiocarcinoma of a Thai patient has been established. This cell line shows a low level of *in vitro* invasiveness, but a high degree of motility. It will serve as a valuable tool for further studies on tumor biology, molecular pathogenesis, metastatic mechanism and response to therapeutic drugs of cholangiocarcinoma.

Abstract

AIM: To establish and characterize a new cell line derived from peripheral cholangiocarcinoma of a Thai patient.

METHODS: The peripheral cholangiocarcinoma specimen surgically obtained from the patient was aseptically processed by washing and mincing before culturing in Ham's F12 medium containing 10% fetal bovine serum. After 3 mo, when the cell line has become homogeneous and stabilized, several features were investigated, including growth characteristics, immunofluorescence staining for cytokeratins, expression of tumor markers, chromosomal analysis by G-banding and multicolour fluorescence *in situ* hybridization (mFISH), *in vitro* migration and invasion characteristics.

RESULTS: The RMCCA-1 cell line has been established. These cells proliferated as a monolayer with a population doubling time of 48 h. Immunofluorescence staining showed positive staining for human cytokeratin 7 and 19 verifying the biliary epithelial origin. RMCCA-1 secreted carbohydrate antigen 19-9 (CA19-9), but insignificant levels of carcinoembryonic antigen (CEA) and α -fetoprotein (AFP). Chromosome analysis identified aneuploidy karyotypes with a modal chromosome number of 59. RMCCA-1 exhibited a low level of *in vitro* invasiveness, but a high degree of motility. The cell line exhibited a significant number of chromosomal aberrations as shown by mFISH and G-banding methods.

INTRODUCTION

Cholangiocarcinoma is a highly malignant epithelial neoplasm that arises within the intrahepatic and extrahepatic biliary tract^[1]. The pathogenesis of this disease has been strongly associated with chronic inflammation and cellular injury within bile ducts, as well as partial obstruction of bile flow, manifested by various high risk conditions such as PSC (primary sclerosing cholangitis), hepatolithiasis and infestation by liver fluke (*Ophisthorchis viverrini* or *Clonorchis sinensis*)^[2,3]. Although considered as a rare disease, cholangiocarcinoma occurs at a particularly high rate in Northeastern Thailand, with 84.6:100 000 males and 36.8:100 000 females affected by the disease. This is the area where the incidence rate of cholangiocarcinoma is the highest in the world, largely accounted by the habit of consuming uncooked cyprinoid fish, which are infected with the liver fluke^[4].

Cholangiocarcinoma has become a serious threat to public health due to increasing worldwide incidence and mortality rates associated with lack of early detection and limited therapeutic options. At diagnosis, most patients are presented with advanced disease, possibly with undetected metastasis, resulting in less than 12 mo survival. Even those with operable tumor, the recurrence rate was extremely high, with a 5-year survival rate of less

than 40%^[2,5]. Various routes of tumor spreading have been reported in cholangiocarcinoma, including direct invasion, infiltration along the biliary tree, vascular and lymphatic permeation and perineural or intraneural invasion^[6].

Progress in understanding the molecular mechanisms governing cholangiocarcinoma invasion and metastasis has been limited by the lack of suitable cell lines and experimental models. Here, we described an establishment and preliminary characterization of a human cell line originated from a Thai patient presented with peripheral cholangiocarcinoma. This new cell line, which we named RMCCA-1, exhibits various characteristics typical of the biliary epithelial cells, as well as invasiveness and motility as shown by the *in vitro* assay. Thus this cell line will be useful for the studies of not only the tumor biology, molecular pathogenesis and drug response, but also the molecular mechanisms governing the metastatic spread of cholangiocarcinoma.

MATERIALS AND METHODS

Clinical specimen

A 40-year-old male patient was admitted to Rajavithi Hospital, Bangkok, Thailand with a professional diagnosis of peripheral cholangiocarcinoma. The patient's serum was analyzed for alkaline phosphatase (ALP), total bilirubin and direct bilirubin using a COBAS Integra 800 instrument (Roche, USA), whereas CA19-9, carcinoembryonic antigen (CEA), and α -fetoprotein (AFP) were analyzed on a ELECHYS 2012 instrument (Roche, USA). Significant laboratory analysis at admission showed elevated serum levels of ALP (374 U/L, normal 39-117 U/L), total bilirubin (19.73 mg/dL, normal 0.0-1.5 mg/dL), direct bilirubin (15.45 mg/dL, normal 0-0.5 mg/dL), CA19-9 (85.05 U/mL, normal 0-39 U/mL) and CEA (7.56 ng/mL, normal 0.0-3.4 ng/mL), whereas the AFP (2.24 U/mL, normal 0.0-5.8 U/mL), and CA125 (19.71 U/mL, normal 0.0-35 U/mL) levels were normal.

The CT examination evaluated for this study was performed on a helical CT scanner (Somatom Plus 4, Siemens Medical Solutions) using the following parameters: 5-mm collimation, 5-mm reconstruction interval, and a 1:1 table pitch. Both unenhanced and contrast-enhanced CT scans were obtained. With intravenous injection of 120 mL of nonionic contrast material [iopromide (Ultravist 370, Schering)], both hepatic artery phase (HAP) and portal venous phase (PVP) images were obtained with a scanning delay of 30 and 65 s, respectively. The results showed an ill defined hypo-density mass occupying the whole left lobe of the liver. At laparotomy, no ascites was found, and the surface of liver was smooth. Intraoperative ultrasonography revealed a solitary mass at left lobe of liver with moderate dilatation of left intrahepatic duct. The patient was then subjected to left hepatectomy and lymph node dissection. The tumor specimen was removed and subjected to histopathological study and to tissue culture under the approval of the Ethics Committee of Rajavithi Hospital.

Tumor histopathology

The lesion was classified as a well-differentiated peripheral

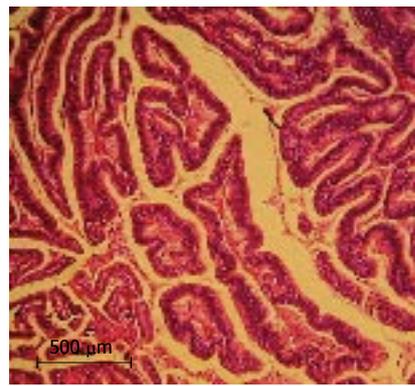

Figure 1 Hematoxylin and Eosin staining of the liver specimen (10 × magnification). The histopathological analysis of the specimen indicates a well-differentiated peripheral cholangiocarcinoma with no vascular invasion.

cholangiocarcinoma at stage T2N0M0 according to the UICC standardization (Figure 1).

Primary culture

After the tumor tissue was surgically removed from the patient, it was immediately suspended in transfer medium [HAM's F12 (GIBCO, Grand Island, NY, USA) containing antibiotics (GIBCO, Grand Island, NY, USA)] at 4°C. The tissue was quickly washed in PBS pH 7.4 several times before being minced. Later the cell suspension was placed in a 100 mm × 20 mm plastic tissue culture dish (CORNING, New York, USA) containing 10 mL of growth medium (HAM's F12, 20% fetal bovine serum (FBS) (GIBCO, Grand Island, NY, USA), 1×10^{-5} g/L epidermal growth factor (EGF) (Pacific Science, Peptidech, New Jersey, USA), 0.1 U/L penicillin G sodium, 0.1 g/L streptomycin sulfate and 2.5×10^4 g/L amphotericin B). The cell cultures were then incubated at 37°C in a humidified 50 mL/L CO₂ atmosphere and observed daily. Tumor cells were separated from the contaminating fibroblast cells by manually dropping 2.5 mL/L trypsin containing 0.2 mL/L EDTA (GIBCO, Grand Island, NY, USA) in PBS onto an isolated tumor colony. Subsequently the detached tumor cells were transferred by pipettes to a new culture dish under a phase contrast microscope. After about 1 mo, a homogeneous layer of epithelial tumor cells with sustained growth pattern was established.

Growth kinetics

A suspension of 2×10^3 cells was cultured in triplicates in 100 μ L of Ham's F12 medium supplemented with 100 mL/L FBS in a 96-well plate (CORNING, New York, USA). At time intervals, 10 μ L of 5 mg/mL MTT (USB, Cleveland, OH, USA) solution was added to the individual wells, followed by incubation for 4 h at 37°C in a humidified atmosphere containing 50 mL/L CO₂. MTT converted to insoluble formazan dye in live cells was then dissolved by addition of 200 μ L DMSO (Sigma, St. Louis, MO, USA) before the absorbency was read at 540 nm. The doubling time of the cell population was determined from the exponential phase of the growth curve.

Immunofluorescence staining

The monoclonal antibody mixture AE-1/AE-3 (DAKO, Denmark) recognized all known basic and most acidic keratin, thus it was used as a general marker of epithelial cells. Cytokeratin 7 (monoclonal mouse Anti-Human

Cytokeratin 7, DAKO, Denmark) and cytokeratin 19 (monoclonal mouse Anti-Human Cytokeratin 19, DAKO, Denmark) were used to specifically distinguish biliary epithelial cells from hepatocytes^{17,81}. RMCCA-1 cells were grown on sterile coverslips until confluent before being fixed in methanol for 15 min, blocked in 10 mg/L bovine serum albumin (BSA), and incubated with primary antibody for 60-min. After that, a secondary antibody conjugated with fluorescein isothiocyanate (DAKO, Denmark) was added and the incubation was allowed to proceed for 60 min at 37°C. After washing, the coverslips were examined under a fluorescence microscope (Nikon Eclipse TE 2000-U, Kanagawa, Japan).

Chromosome preparation and G-banding analysis

The established tumor cells at 12th passage were subjected to chromosomal analysis. The cells were treated with 10 µmol/L Colchicine (Sigma, St. Louis, MO, USA) for 30 min and suspended in hypotonic solution, 0.075 mol/L KCl (Sigma, St. Louis, MO, USA), for 7 min, fixed in Carnoy's fixative and spreaded onto cold glass slides. The cells were stained with Giemsa and the representative chromosome sets were photographed for karyotype analysis. Interpretation of the karyotype was based on ISCN (1995). The modal chromosome number was determined from 20 cells.

Multicolour fluorescence in situ hybridization (mFISH) analysis

A duplicate slide, prepared from the same culture used for G-banding, was subjected to mFISH analysis according to the manufacturer's protocol (Metasystem, Germany). The 24 XCyte mFISH kit (Metasystem, Germany) with five fluorophors were used for hybridization, including FITC, Spectrum Orange, Texas Red, Cy5 and DEAC. Each chromosome (1-22, X and Y) was painted with different colors using various combinations of the fluorophores. After hybridization, the slides were evaluated under a fluorescence microscope (Axioimage, Zeiss, Germany), and the images were captured and analyzed using the Program Isis (Metasystem, Germany).

Tumor marker detection

A suspension of 10⁵ tumor cells was cultured in serum-free HAM's F12 medium for 24 h before the conditioned medium was collected and centrifuged at 1800 r/min for 10 min. The supernatant was then collected for detection of CA 19-9, CEA and AFP by using chemiluminescence detection system on an ELECHYS 2012 instrument (Roche, USA).

In vitro invasion assay

Cancer cell invasiveness was determined using transwell chamber (Costar, Cambridge, MA, USA) coated with 0.3 g/L matrigel (Collaborative Research Inc., Bedford, MA, USA). Approximately, 1 × 10⁵ cells (RMCCA-1, KKKU-100, KKKU-213 and HuCCA-1) in culture medium containing FBS were added into the upper compartment of the transwell, and incubated at 37°C in a humidified atmosphere containing 50 mL/L CO₂ for 6 h. The lower compartment contained culture medium plus FBS. The

filters were fixed with methanol and stained with 0.5% crystal violet in 25% methanol for 1 h, before rinsing with tap water several times. The cells on the upper surface of the filters were gently removed using cotton swabs and the cells that have invaded into the lower surface were counted under a microscope. The numbers of invaded cells in five random × 10 microscopic fields were counted and expressed as number of cells per well. The results shown represented mean ± SE of the number of invaded cells from three independent experiments, each carried out in triplicates.

In vitro motility assay

Motility assay was performed in a similar fashion to the invasion assay, except no matrigel coating was applied to the upper surface of the transwell filters. The numbers of migrating cells in five random × 10 microscopic fields were counted and expressed as number of cells per well. The results shown represented mean ± SE of the number of migrating cells from three independent experiments, each carried out in triplicates.

Gelatin zymography assay

Cells were starved by culturing in the medium without FBS for 24 h before collection of the conditioned medium. The conditioned medium was mixed with 5 × SDS-sample buffer before separation in a 120 g/L SDS-PAGE containing 1 mg/mL gelatin (Sigma, St. Louis, MO, USA). After electrophoresis at 200 V for 1 h, the gel was washed in a 25 mL/L Triton X-100 (Amersham, Piscataway, NJ, USA) solution twice. The gel was then incubated in buffer containing 50 mmol/L Tris-HCl (Amersham, Piscataway, NJ, USA), pH 7.5, 10 mmol/L CaCl₂ (Merck, Denmark), 1 mmol/L ZnCl₂ (Merck, Denmark), 10 mL/L Triton X-100 for 16-18 h, after which the gel was stained with 5 g/L Coomassie blue in 300 mL/L methanol and 100 mL/L acetic acid. After destaining, the clear band of gelatinolytic activity was documented for size determination using a Biorad GS700 gel scanner (Biorad, Hercules, CA, USA)¹⁹.

RESULTS

Primary cell culture

The human CCA tissue fragments adhered to the dish after plating for 6 h. After three weeks, a layer of epithelial cells appeared, from which contaminating spindle-shaped fibroblasts could be readily distinguished and separated from the epithelial tumor cells by differential trypsinization. After successive 16 passages, a homogeneous immortalized culture of tumor cells was established and was named RMCCA-1. The cells from passages 16th and 30th were then used for morphological analysis. These cells exhibited circular to spindle shape with many processes and ornamental fringes. The nucleus and cytoplasm appeared granulated (Figure 2).

Growth kinetics

RMCCA-1 cells were in lag phase until d 5, after which they entered a logarithmic growth phase. The doubling time determined from the slope of the growth curve was 48 h (Figure 3).

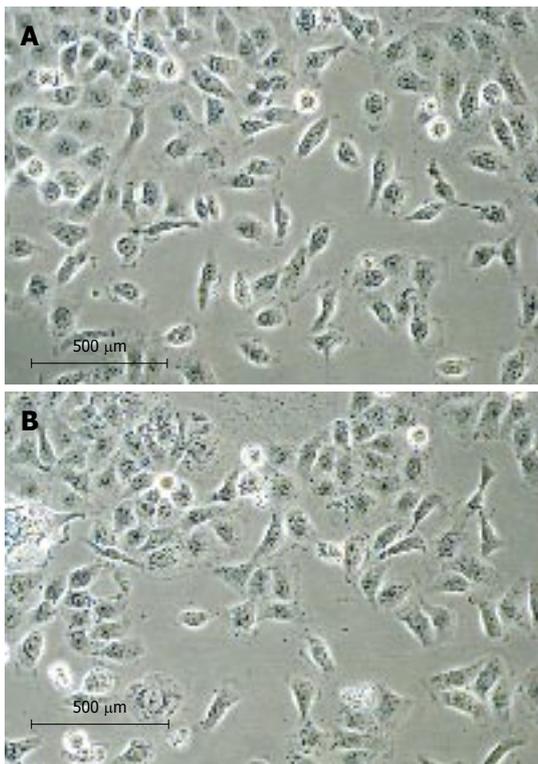

Figure 2 The RMCCA-1 culture under a phase contrast microscope at 20 × magnification. (A) at 16th passage; (B) at 30th passage. The RMCCA-1 cells exhibited circular to spindle shape with many processes and ornamental fringes. The nucleus and cytoplasm appeared granulated.

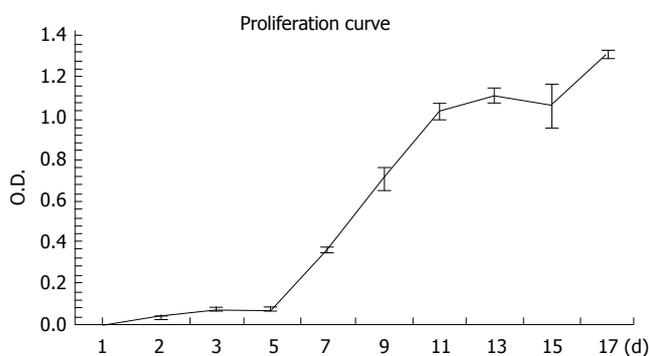

Figure 3 Growth kinetics of the RMCCA-1 cell line *in vitro* as analyzed by MTT assay. The tumor doubling time during the exponential phase of growth was 48 h. Each point represents mean ± SE from 3 independent experiments, each performed in triplicates.

Immunofluorescence staining

All RMCCA-1 cells showed positive staining with the AE-1/AE-3 monoclonal antibody mixture (Figure 4B), which recognizes the human epidermal cytokeratins, the signature of epithelial cells that distinguishes them from fibroblasts. Furthermore, specific markers for the adenocarcinoma and transitional cell carcinomas, cytokeratin 7 (Figure 4A) and 19 (data not shown), were also positive.

Chromosome analysis

The G-banding analysis demonstrated aneuploidy karyotype with marked structural abnormalities of the

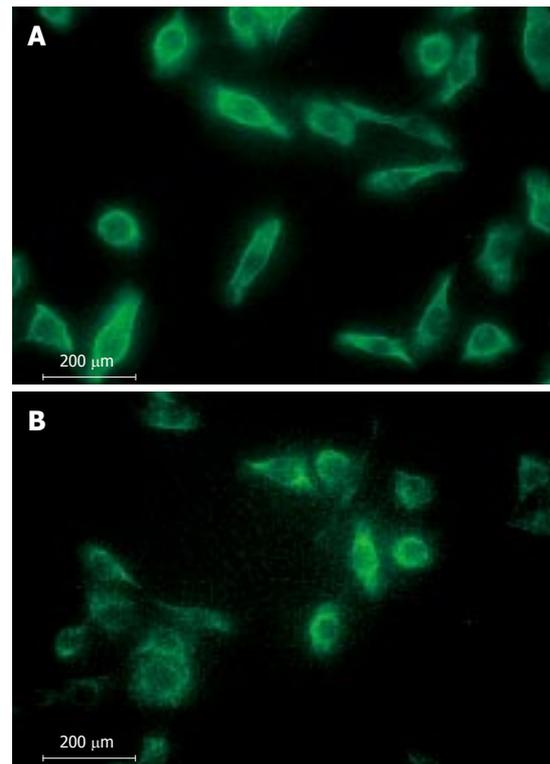

Figure 4 Immunofluorescence staining of RMCCA-1 cells with antibodies against (A) Cytokeratin 7; (B) AE-1/AE-3 at 40 × magnification.

chromosomes (Figure 5A and B). Although this cell line was established from a male patient, it lacks a Y chromosome and, instead, possesses two X chromosomes. The number of chromosomes ranges between 54 and 61, with a modal chromosome number of 59. The final karyotype was determined by consolidating the G-banding and mFISH results. Sixteen structural rearrangements were found, including 9 unbalanced translocations and 2 balanced translocations. In addition, the absence of Y chromosome in this cell line was also confirmed by both G-banding and mFISH techniques.

Tumor markers in spent media

The level of CA19-9 in the spent medium of RMCCA-1 cells (72.92 ± 4.35 U/mL) was similar to that of the patient's serum at admission (85.05 U/mL); both of which were about twice the maximum value of the normal range (39 U/mL, Table 1). The levels of CEA and AFP were normal (Table 1).

Invasiveness and motility

An important characteristic of metastatic cancer is the ability to migrate and invade the underlining basement membrane, the surrounding tissues and the blood vessels. We thus examine the invasiveness and motility of the RMCCA-1 cells, compared with those of three other established Cholangiocarcinoma cell lines from Thai patients (KKU-100, KKU-213 and HuCCA-1), using *in vitro* invasion and motility assay, respectively^[10]. RMCCA-1 exhibited relatively higher migration rate ($1,688 \pm 207$ cells/well) compared with the other 3 cell lines ($1,514 \pm 152$ cells/well, $1,123 \pm 163$ cells/well, 40 ± 17 cells/well

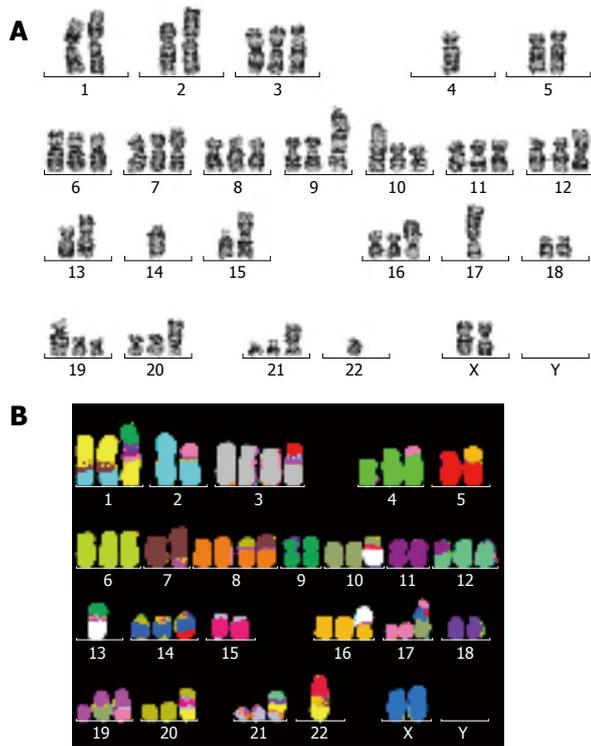

Figure 5 Representative karyotypes of RMCCA-1 cell line as assessed by (A) G-banding; (B) mFISH technique. The karyotype showed 54-61(3n)XX, -Y, der(1), t(1;2;7)(q31;q31;q22), t(2;17)(q33;q12), der(3)t(3;15)(q21;q?), t(4;17)(p14;q?), der(7)t(7;15)(p22;q?), der(8)t(8;7)(p12;?), der(10)t(10;13)(q21;q11), der(12)t(11;12)(q?,p11.2), der(13)t(13;9)(q11;q11), der(14)t(15;14)(q34;q32), der(16)t(13;16)(q11;p13.3), der(17)t(X;10;17)(p?,p?,p11.2), der(19)t(10;19)(q11.2;p13.3), der(19)t(17;19)(q?;q?), der(21)t(1;9;21)(?;?;q11), der(22)t(1;15;22)(?;?,?).

for KKU-213, KKU-100 and HuCCA-1, respectively). Surprisingly, the invasiveness of RMCCA-1 was significantly lower than those of KKU-213 and KKU-100 (181 ± 54 cells/well for RMCCA-1 *vs* 1021 ± 5 cells/well for KKU-213 and 765 ± 244 cells/well for KKU-100), while slightly higher than that of HuCCA-1 (38 ± 21 cells/well) (Figure 6).

Gelatin zymography

Most metastatic cells secrete proteinases to facilitate its invasion through tissue barriers. One of the most characterized families of tissue-degrading enzymes from cancer is the matrix-metalloproteinases (MMPs). Here we examined the ability to secrete the MMPs from RMCCA-1 cells by gelatin zymography. KKU-100 secretes a high level of *Mr* 72000 band previously shown to correspond to MMP-2 (Figure 7)^[11,12]. A *Mr* 72000 band is also present in FBS. Presumably, this band corresponds to the endogenous gelatinase activity present in the FBS (our unpublished observation). In contrary, the conditioned medium of RMCCA-1 lacks the activity (Figure 7).

DISCUSSION

Cholangiocarcinoma (CCA) is a cancer arising from the bile duct epithelium. It is a lethal disease of which little is known about its biology, pathogenesis and behavior. Up to present, there has been no effective early detection protocol or curative strategy for the disease; most patients

Table 1 Tumor marker levels in the spent media of RMCCA-1 and in the patient's serum at admission

	CEA (ng/mL)	AFP (U/mL)	CA 19-9 (U/mL)
¹ RMCCA-1	< 0.200	< 0.500	72.92 ± 4.35
Patient's serum	7.56	2.24	85.05
Normal serum	0.0-3.4	0.0-5.8	0.0-39

¹The results shown represented mean ± SE from three independent experiments.

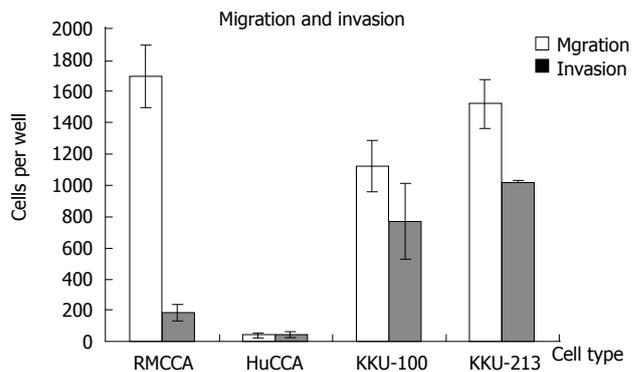

Figure 6 Invasion and migration rates of RMCCA-1 compared with KKU-213, KKU-100 and HuCCA-1 cell lines as determined by *in vitro* invasion and motility assay. Approximately 1×10^5 cells were seeded into the upper chamber of a transwell, and incubated for 6 h before the filter was fixed, stained, and the invading/migrating cells were counted under microscope.

Figure 7 MMPs activity as determined by gelatin zymography. An intense band at *Mr* 72000 was shown in the FBS (fetal bovine serum) and the conditioned medium of KKU-100, but not of the RMCCA-1 cells. The *Mr* 72000 band in KKU-100 has previously been shown to correspond to MMP-2 activity in many cell lines^[11,12].

seek curative treatment at advanced stage with poor prognosis. Therapeutic options for cholangiocarcinoma have been limited due to poor response to chemotherapy and radiation therapy. Surgery is perhaps the only effective cure although the 5-year survival after surgical treatment is less than 40%^[2,5]. Therefore, it is urgently required that the molecular markers for early detection are mapped and molecular targets for effective treatment are deciphered. One way to understand the nature of such disease is by studying the behavior of cell lines derived from the tumor *in vitro*. Here we describe the establishment and preliminary characterization of a cell line derived from a peripheral cholangiocarcinoma of a Thai patient which we have named RMCCA-1.

The population doubling time of this cell line was about 48 h, where those of other cholangiocarcinoma cell lines originated from Thai patients were 55 h for HuCCA1^[7] and 72 h for KKU100^[8]. Although we have not yet deciphered the mechanism of growth regulation for

RMCCA-1, growth regulation mediated by COX-2, PGE₂, EGFR and Akt had been demonstrated in a number of cholangiocarcinoma cell lines, including CCLP1, HuCCT1, SG231^[13].

Analysis of the spent medium from RMCCA-1 cells showed that these cells have retained some functional characteristics of the original tumor, including over expression of the tumor marker CA19-9. The levels of CA19-9 in the spent medium of RMCCA-1 cells (72.92 ± 4.35 U/mL) was similar to that of the patient's serum at admission (85.05 U/mL); both of which were approximately twice the maximum value of the normal range (39 U/mL, Table 1). CA19-9 was often detected in patients with malignant cholangiocarcinoma and pancreatic cancer^[14]. Many kinds of cancer cell lines also secrete CA19-9, including those derived from cholangiocarcinoma (TK)^[15], pancreatic carcinoma (SUIT-2)^[16] and colon cancer (SW1116)^[17].

Analysis by immunofluorescence staining using monoclonal antibodies to AE1 and AE3 showed positive staining for human cytokeratins, verifying the epithelial origin of the tumor. RMCCA-1 also stained positively with antibodies to cytokeratins 7 and 19, distinguishing the bile duct epithelial cells from the hepatocytes. Together, these data confirm that RMCCA-1 indeed derived from the epithelium of the bile duct.

Tumor metastasis involves a series of complex processes including dysregulation of cell adhesion, cell motility, and enzymatic proteolysis of basement membrane and extracellular matrix. The RMCCA-1 cells exhibit a high level of migration rate, contradicting the relatively low level of invasiveness and the absence of MMP activity (Figures 6 and 7). The low level of invasiveness in RMCCA-1 can, at least in part, be explained by the lack of MMP activity in this cell line. Unlike the RMCCA-1 cells, KKU-100 exhibits a high degree of invasiveness, correlating with a high level of MMPs activity (Figures 6 and 7). Karyotype analysis by G-banding revealed a complex pattern of chromosomal abnormalities. Most of the chromosomes were triplicates, suggesting that the cell line was originated from a triploid cell. The lost of Y chromosome was not unusual as similar finding has been shown in human sarcomatous cholangiocarcinoma (SCK) cells^[18]. Other aberrations involving Y chromosome have also been reported, including the translocation between Y chromosome and chromosome 1 as shown in a human cholangiocarcinoma cell line, PCI-SG231^[19].

With recent development of mFISH technique, it has become possible to identify and characterize complex chromosomal aberrations, previously unrevealed by G-banding analysis. This technique has allowed us to characterize the karyotype of RMCCA-1 in much greater detail with a high level of accuracy.

We have detected aberrations of chromosomes 1, 5, 7, and 12 in the RMCCA-1 cells, which were consistent with those of the other human cholangiocarcinoma cell lines including SCK, JCK, Cho-CK, Choi-CK, CC-SW-I, CC-LP-I, PCI: SG231, and RPMI-7451, and a rat cholangiocarcinoma cell line, CC-62^[18-21]. In contrast, we did not detect structural rearrangement of X chromosome and chromosome 6 in the RMCCA-1 cells, nor did we

detect the lost of chromosome 18, as found in SCK, JCK, Cho-CK, and Choi-CK^[18].

In conclusion, we successfully established a new cholangiocarcinoma cell line which we named RMCCA-1. We have also performed preliminary characterization of its growth characteristics, karyotype, secreted tumor markers and invasive properties. This cell line will be further used in our research towards understanding and combating against cholangiocarcinoma.

ACKNOWLEDGMENTS

We are grateful to Associate Professor Banchop Sripa who kindly provided KKU-100 and KKU-213 cell lines, and Professor Sitaya Sirisinha who kindly provided HuCCA-1 cell line.

Abstract

AIM: To investigate interleukin-18 (IL-18) in patients with chronic pancreatitis (CP).

METHODS: We studied 29 patients with CP and 30 healthy controls. Peripheral blood mononuclear cells (PBMC) were isolated and incubated with 50 mmol/L ethanol, lipopolysaccharide (LPS) (doses 25 g/L, 250 g/L, 2500 g/L) and both agents for 24 h. Levels of IL-18 in the supernatants, and levels of IL-18, IL-12, interferon (IFN)- γ and soluble CD14 in the serum were analysed by ELISA technique. Expression of IL-18 in PBMC was investigated by reverse-transcription (RT)-PCR. IL-18 protein levels in CP tissue and in normal pancreas were studied by ELISA technique. IL-18 levels in PBMC and pancreatic tissue were determined by Westernblot. Immunohistochemistry for pancreatic IL-18 expression was performed.

RESULTS: In patients, IL-18 serum levels were significantly enhanced by 76% (mean: 289.9 ± 167.7 ng/L) compared with controls (mean: 165.2 ± 43.6 ng/L; $P < 0.0005$). IL-12 levels were enhanced by 25% in patients (18.3 ± 7.3 ng/L) compared with controls (14.7 ± 6.8

ng/L, $P = 0.0576$) although not reaching the statistical significance. IFN- γ and soluble CD14 levels were not increased. *In vitro*, LPS stimulated significantly and dose-dependently IL-18 secretion from PBMC. Incubation with ethanol reduced LPS-stimulated IL-18 secretion by about 50%. The mRNA expression of IL-18 in PBMC and the response of PBMC to ethanol and LPS was similar in CP patients and controls. In PBMC, no significant differences in IL-18 protein levels were detected between patients and controls. IL-18 protein levels were increased in CP tissues compared to normal pancreatic tissues. IL-18 was expressed by pancreatic acinar cells and by infiltrating inflammatory cells within the pancreas.

CONCLUSION: IL-18 originates from the chronically inflamed pancreas and appears to be involved in the fibrotic destruction of the organ.

INTRODUCTION

Chronic pancreatitis represents an inflammatory disease characterized by repeated attacks of acute pancreatitis, severe abdominal pain, progressive destruction of the pancreatic tissue with fibrous replacement of the parenchyma leading to both exocrine and endocrine insufficiency^[1]. In industrialized countries, excessive alcohol consumption is associated with the development of chronic pancreatitis in the majority of patients^[2,3]. The early stages of the human disease remain almost inaccessible to investigation. Recent genetic findings suggest that premature digestive enzyme activation with subsequent pancreatic autodigestion represents a dominant factor in the initiation of acute pancreatitis^[4,5]. These genetic studies also support a progressive link between repeated episodes

of acute pancreatitis and the development of chronic pancreatitis^[5]. However, the exact immune mechanisms underlying the progression of chronic pancreatitis remain unclear.

The identification and characterization of pancreatic stellate cells (PSC) provided deep insights into the development of pancreatic fibrosis^[6,7]. Activated PSC synthesize and secrete increased amounts of extracellular matrix proteins resulting in the fibrotic destruction of the pancreas^[6,7]. Recent *in vitro* studies have demonstrated that alcohol and its metabolite acetaldehyde^[8], oxidative stress^[8], growth factors such as platelet derived growth factor^[6], and the cytokine transforming growth factor (TGF)- β 1^[6] have the capacity to activate PSC during pancreatic injury. More recently, it was shown that PSC also responds to additional proinflammatory cytokines such as tumor necrosis factor (TNF)- α , interleukin (IL)-1, IL-6, and antiinflammatory cytokines such as IL-10^[9].

During chronic pancreatitis, lymphocytes and mononuclear cells infiltrate the pancreas and contribute to the local progression of the disease through T-lymphocyte mediated cytotoxicity and production of cytokines^[10-14]. However, data regarding the role of cytokines in chronic pancreatitis remain limited. IL-18 represents a proinflammatory cytokine that plays an important role in the Th-1 response due to its ability to induce interferon (IFN)- γ production in T-cells and natural killer cells^[15,16]. IL-18 has been investigated in a variety of inflammatory and autoimmune human diseases^[17]. In previous studies, our group and others have demonstrated an upregulation of serum IL-18 levels in patients with acute pancreatitis^[18-20]. *In vitro* studies have shown that endotoxin induces IL-18 gene expression and secretion in human peripheral blood mononuclear cells (PBMC)^[21]. In a previous investigation, the serum levels and gene expression of IL-18 in PBMC of patients with alcoholic liver cirrhosis were significantly enhanced compared to healthy controls, and IL-18 levels correlated with plasma endotoxin levels^[22].

These data raise the possibility that IL-18 also participates in the immune mechanisms that result in the fibrotic destruction of the pancreas during chronic pancreatitis. Thus, the aim of the present study was to investigate this cytokine in patients with chronic pancreatitis. We determined the serum levels of IL-18, IFN, IL-12 and soluble CD14 in patients with chronic pancreatitis and healthy controls. We performed several *in vitro* studies with PBMC. We determined the protein expression of IL-18 in chronic pancreatitis tissue and in normal pancreas, and conducted immunohistochemical investigations in human pancreatic tissues.

MATERIALS AND METHODS

Patients

A total of 29 patients (22 males, 7 females; mean age 52 ± 11 years) with alcoholic and non-alcoholic chronic pancreatitis and 30 healthy controls with no history of alcohol abuse (10 males, 20 females; mean age 39 ± 11 year) were prospectively enrolled into the study at the University Hospital of Heidelberg at Mannheim,

Mannheim, Germany. The study was approved by the Ethics Committee of the Faculty of Clinical Medicine Mannheim, University of Heidelberg, Germany. Written informed consent was obtained from each participant.

Data on the history of both alcohol consumption and the clinical course of pancreatic disease were assessed by patient self-report and review of the medical records. In each participant, a detailed history of alcohol intake was established using different screening methods, including the Lübeck alcohol dependence and abuse screening test (LAST)^[23], the alcohol use disorders identification test (AUDIT)^[24], the lifetime drinking history (LDH)^[25], and a patient interview questioning ICD-10 criteria of chronic alcohol dependence^[26]. Alcoholic disease etiology was established with the presence of at least one of the following criteria: (1) patient self-report of alcohol abuse as cause of the disease, (2) patient self-report with a history of excessive alcohol intake of at least 80 g per day in males and 60 g per day in females for some years, or (3) smaller amounts of daily alcohol intake in combination with answers gained from the above mentioned screening methods for alcohol consumption that allowed the diagnosis of chronic alcohol abuse.

The diagnosis of chronic pancreatitis required the typical clinical features of chronic pancreatitis with or without recurrent episodes of acute pancreatitis, and was based on the determination of pancreatic exocrine and endocrine function, pancreatic imaging or histological tissue examination. Pancreatic imaging was performed either by endoscopic retrograde pancreatography (ERP), computed tomography (CT), magnetic resonance imaging (MRI), or endosonography. In each patient, abdominal ultrasound was performed. According to the definitions of an international workshop on chronic pancreatitis^[27], patients were further classified as suffering "definite" or "probable" chronic pancreatitis. Briefly, the classification of "definite" chronic pancreatitis required a typical clinical history of chronic pancreatitis and one or more of the following criteria: (1) calcifications in the pancreas, (2) moderate to marked ductal lesions, (3) marked exocrine insufficiency, and (4) typical histology of an adequate surgical specimen^[27]. For the diagnosis of "probable" chronic pancreatitis, one or more of the following criteria were present in addition to the typical clinical features: (1) mild ductal alterations, (2) recurrent or persistent pseudocysts, (3) pathological secretin test, and (4) endocrine insufficiency^[27].

In all patients, an episode of acute pancreatitis at the time of recruitment or within the last two months before inclusion into the study was excluded. Additional exclusion criteria were infections with fever or leukocytosis, liver cirrhosis and surgical or endoscopic interventions within 2 mo before examination.

Routine laboratory parameters

Routine laboratory parameters were determined in serum samples taken at the same time as samples for cytokine and endotoxin measurement. These parameters included serum concentrations of amylase, lipase, C-reactive protein (CRP), creatinine, and total white blood cell count. Endocrine pancreatic insufficiency was determined by the presence

of diabetes mellitus requiring antidiabetic treatment or records of an abnormal oral glucose tolerance test. Exocrine pancreatic insufficiency was defined by diarrhea, steatorrhea or maldigestion that was markedly reduced by enzyme supplementation. In some patients, pancreatic exocrine function was determined by using one or more of the following commercially available tests according to the manufacturer's recommendations: measurement of fecal chymotrypsin by a colorimetric method (Chymo, Boehringer, Germany), determination of fecal fat excretion by infrared reflection method (Esetek Analyser Fenir 8820, TSZ Stimotron AG, Wettengel-Launsbach, Germany), measurement with the Pankreolauryl test N (Temmler Pharma GmbH, Marburg, Germany) or application of the pancreozymin-secretin-test (Sekretolin Diagnostikum, Hoechst AG, Germany or Takus, Pharmacia GmbH, Erlangen, Germany).

PBMC isolation and incubation with ethanol and endotoxin

Peripheral venous blood was collected from patients and healthy controls into sterile, pyrogen-free disposable syringes with endotoxin-free heparin (10 ku/L). As reported previously^[22], PBMC was separated by standard density gradient centrifugation (Ficoll-Paque method) and adjusted to 3×10^9 cells/L in RPMI 1640 supplemented with 100 mL/L heat inactivated fetal bovine serum. PBMC were incubated with or without lipopolysaccharide (LPS) (doses 25 g/L, 250 g/L, 2500 g/L), in the absence or presence of 50 mol/L ethanol for 24 h. Cells were spun down, and PBMC supernatants were stored at -20°C until measurement of cytokine levels. For RNA extraction, cells were stored at -80°C in 4 mol/L GTC extraction buffer.

Immunoassay for IL-18, IFN, IL-12, soluble CD14

Concentrations of IL-18 in the serum, supernatants of PBMC and pancreatic tissues were determined by a specific sandwich enzyme linked immunoassay (ELISA; Fujisaki Institute, Hayashibara Biochemical Laboratories, Inc., Okayama, Japan) with minor modifications as described previously^[22]. Serum concentrations of IFN were determined by a specific ELISA using two monoclonal antibodies as described previously^[28]. Serum concentrations of IL-12 and soluble CD14 were also determined by ELISA technique as described previously^[28].

RNA isolation and IL-18 RT-PCR analysis in PBMC

RNA extraction from PBMC was performed using acid phenol-chloroform extraction^[22]. The RNA concentration was quantified spectrophotometrically. Complementary DNA of PBMC was obtained by reverse-transcription (RT) using 1 μg RNA and oligo d(T) primers. PCR for IL-18 and the housekeeping enzyme glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was performed as described previously^[22]. Densitometric assessment of the PCR products was performed using EASY Plus 3.2 software (Herolab, Wiesloch, Germany). Semiquantitative PCR results were obtained by grading a ratio between the densitometry results of IL-18 and GAPDH.

Endotoxin assay

Plasma endotoxin levels were determined using an

automated kinetic turbidimetric limulus amoebocyte lysate microtiter test as described previously^[22].

Pancreatic tissue samples

Pancreatic tissue samples were obtained from 8 patients with chronic pancreatitis and from 2 individuals without pancreatic disease. Two of these patients with chronic pancreatitis were obtained from the present investigation and had later to be operated due to the development of a benign pancreatic mass and intractable pancreatic pain. The remaining 6 patients with chronic pancreatitis and the 2 individuals without pancreatic disease were obtained from clinical routine interventions. In 4 of these patients with chronic pancreatitis, surgery was necessary due to the development of pancreatic cancer.

Human pancreatic tissue and cell lysates of PBMC were homogenized in 5 mmol/L HEPES, pH 7.0, 280 mmol/L mannitol, 10 mmol/L KCl, 1 mmol/L MgCl₂, 1 mmol/L benzamide, 20 mg/L trypsin inhibitor, 1 $\mu\text{mol/L}$ leupeptin, and 0.2 mmol/L PMSF and boiled in electrophoresis sample buffer. Proteins were electrophoretically separated on SDS-125 g/L polyacrylamide gels. Electrotransfer to nitrocellulose membranes was done as described previously^[29]. After staining with 2 g/L Ponceau S to check the efficiency of the transfer, free binding sites of the membrane were blocked with 10 g/L bovine serum albumin in Tris-buffered saline (10 mmol/L Tris-HCl, pH 8.0, and 150 mmol/L NaCl) for 60 min, followed by 75 min incubation with anti-IL-18 antibody (NatuTec, Frankfurt, Germany) diluted in Tris-buffered saline plus 2 mL/L Tween 20. Bound antibodies were visualized with secondary antibodies conjugated to horse radish peroxidase using an enhanced chemiluminescence detection kit (Amersham Pharmacia Biotech, Freiburg, Germany) and autoradiography film (Fujifilm Super HR-E 30, Fuji photo film, Düsseldorf, Germany).

Immunohistochemistry

Frozen tissue specimen were cut in 10 μm cryostat sections, transferred on glass slides and air-dried overnight. Immunohistochemistry was performed according to the streptavidin-biotin method. Sections were washed in tris-buffered saline (TBS) and incubated with 30 g/L bovine serum albumine (BSA) for 10 min at room temperature to block non-specific antibody reactions. The sections were incubated overnight at 4°C with the primary antibody at a 1:5000 dilution (anti-human IL-18 polyclonal antibody, NatuTec, Frankfurt am Main, Germany). The slides were then rinsed repeatedly with TBS and were incubated with a biotin-streptavidin-conjugated secondary antibody (goat anti-rabbit immunoglobulin-specific antibody, Jackson Immuno Research, West Grove, USA) for 30 min at room temperature. The slides were washed again with TBS and were treated with a streptavidin-alkaline-phosphatase complex. Liquid diaminobenzidine was added as chromogen, and counterstaining was performed with hematoxylin. Controls were performed by using mouse serum (Sigma, Saint Louis, USA) as primary antibody and by administration of recombinant human IL-18 (MoBiTec, Göttingen, Germany) in excess to the primary antibody

before incubation. Light microscopical investigations were performed using a Zeiss Axioskop microscope.

Statistical analysis

We used the *t* test, if necessary with the Welch correction for unequal variances, for analysis of IL-18, IFN, IL-12 and soluble CD14 levels between patients and controls. These data are expressed as mean \pm SD. $P < 0.05$ was considered significant. We used paired *t* tests for the comparison of IL-18 secretion from PBMC. The Bonferroni-Holm correction was applied to adjust for calculating three tests at a time to compare the IL-18 secretion from PBMC after different stimulations.

RESULTS

Clinical characteristics

Alcoholic chronic pancreatitis was diagnosed in 23 patients, and non-alcoholic chronic pancreatitis was found in 6 patients (Table 1). According to the recommendations of a workshop on chronic pancreatitis, 21 patients were classified with "definite" chronic pancreatitis, and 8 patients were classified with "probable" chronic pancreatitis (Table 1). An episode of acute pancreatitis was excluded in all patients by physical examination, abdominal ultrasound and determination of routine laboratory parameters (Table 2).

Serum levels of IL-18, IL-12 and IFN in CP patients

The fasted serum IL-18 levels were significantly enhanced by 76% in 29 patients with chronic pancreatitis (mean \pm SD: 289.9 \pm 167.7 ng/L) compared to healthy controls ($n = 30$; 165.2 \pm 43.6 ng/L; Welch's *T* test, $P < 0.0005$). The IL-12 levels were enhanced by 25% in patients ($n = 27$ due to lack of sample in 2 patients; mean \pm SD: 18.3 \pm 7.3 ng/L) compared to controls ($n = 30$, 14.7 \pm 6.8 ng/L). We observed a trend towards a statistically significant difference between patients and control subjects (*T* test, $P = 0.0576$). Serum IFN levels were not increased in patients ($n = 25$ due to lack of sample in 4 patients; 28 \pm 15.4 ng/L) compared to controls ($n = 24$ due to lack of sample in 6 controls; 34.4 \pm 18.0 ng/L; *T* test, $P = 0.18$).

Serum soluble CD14 and plasma endotoxin levels in CP patients

Serum levels of soluble CD14 were similar in patients ($n = 16$, mean \pm SD: 2723.3 \pm 649.2 ng/L) and healthy controls ($n = 26$, mean \pm SD: 2630.6 \pm 480.3 ng/L; Welch's *T*-test: $P = 0.63$). Endotoxemia was not detectable in patients ($n = 29$) and controls ($n = 30$).

Expression of IL-18 mRNA in PBMC of CP patients

We investigated the IL-18 mRNA expression in PBMC of patients with chronic pancreatitis by RT-PCR to determine if the enhanced serum IL-18 levels in chronic pancreatitis represent a result of an increased gene expression in PBMC. No significant difference was found between the mRNA expression of IL-18 in patients with chronic pancreatitis ($n = 5$ patients with highest IL-18 serum levels) in comparison to healthy controls ($n = 5$ control individuals with lowest IL-18 serum levels) (Figure 1). The semiquan-

Table 1 Clinical characteristics of patients with chronic pancreatitis and healthy controls

Lipase	< 190 U/L	182.0 \pm 98.0	161.0 \pm 64.0

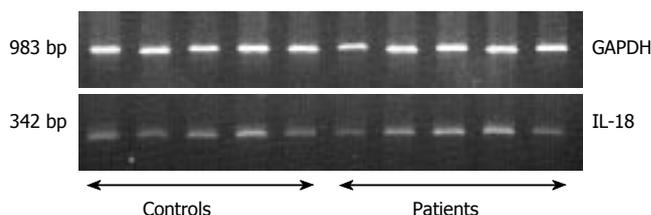

Figure 1 Analysis of RT-PCR amplification of IL-18 in PBMC of CP patients.

tative analysis of the ratio between the densitometric results from the PCR-products of IL-18 and GAPDH did not reveal a significant difference. The ratio for patients with chronic pancreatitis and healthy controls was 0.438 \pm 0.074 and 0.410 \pm 0.082, respectively.

IL-18 protein levels in pancreatic tissues

IL-18 protein levels in pancreatic tissues were determined by ELISA technique in two patients with chronic pancreatitis, and in two individuals without pancreatic disease. The protein levels of IL-18 in chronic pancreatitis tissue ($n = 2$, 50.5 ng/L and 86.1 ng/L) were enhanced compared to pancreatic tissue from individuals without pancreatic disease ($n = 2$, 33.6 ng/L and 25.1 ng/L). In these patients and control subjects, IL-18 protein levels in the pancreas were also determined by Westernblot (Figure 2A). The IL-18 protein levels were again enhanced in patients with chronic pancreatitis compared to the control individuals (Figure 2A).

IL-18 protein levels in cell lysates of PBMC

IL-18 protein levels were determined in cell lysates of PBMC by Westernblot investigations (Figure 2B). We

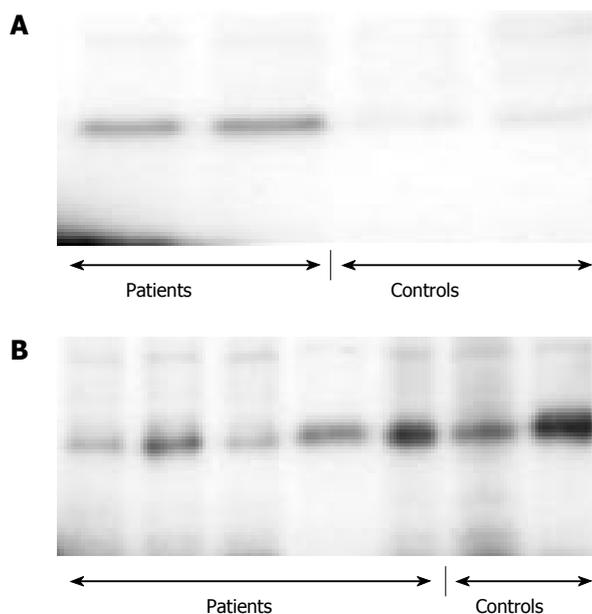

Figure 2 IL-18 in cell lysates of PBMC and in pancreatic tissue of CP patients. **A:** In the pancreatic tissue; **B:** In cell lysates of PBMC.

studied PBMC cell lysates from 5 patients with chronic pancreatitis and from 2 control individuals to determine if the elevated levels of IL-18 in patients with chronic pancreatitis result from an increased expression of IL-18 in PBMC. We confirmed IL-18 protein expression in the cell lysates of both patients and controls. However, we did not detect significant differences in IL-18 protein expression between cell lysates from patients and controls (Figure 2B).

IL-18 levels in the supernatants from PBMC after incubation with ethanol and LPS

We investigated the IL-18 levels in the supernatants of PBMC from all patients ($n = 29$) and all controls ($n = 30$). We stimulated the PBMC with ethanol and LPS to detect a possible influence of these agents on IL-18 secretion from PBMC and to reveal possible differences between PBMC from patients and control subjects. These *in vitro* studies demonstrated that the basal secretion of IL-18 from PBMC was similar in patients and control individuals.

The stimulation of PBMC with LPS (25 g/L, 250 g/L and 2500 g/L) and the stimulation with LPS (25 g/L, 250 g/L and 2500 g/L) together with ethanol (50 mmol/L) resulted in a dose related and statistically significant enhancement of IL-18 secretion from PBMC of patients and controls (T tests; $P < 0.0007$) (Figure 3A and B). However, we did not detect significant differences in the secretion patterns of IL-18 between PBMC from patients and control individuals.

The incubation with ethanol alone for 24 h did not affect basal IL-18 secretion, but ethanol significantly reduced LPS-stimulated IL-18 secretion by about 50% compared to LPS stimulation alone (T tests; $P < 0.0001$) (Figure 3A and B).

The application of the Bonferroni-Holm correction did not change the significance of previously obtained P values.

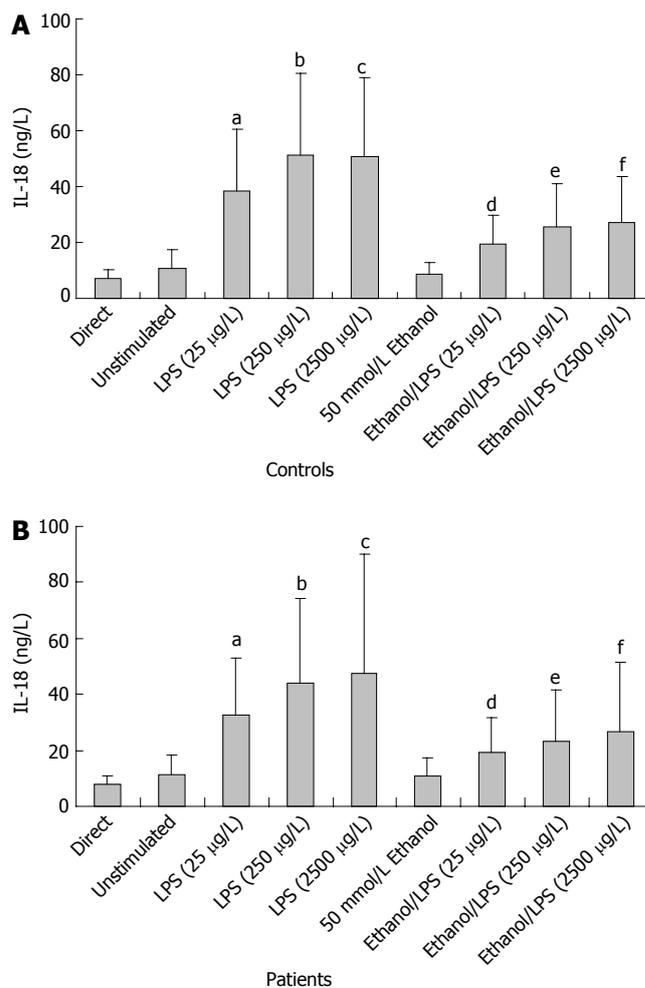

Figure 3 *In vitro* IL-18 secretion from PBMC of CP patients. ^a $P < 0.0007$ 25 µg/L LPS vs unstimulated; ^b $P < 0.0007$ 250 µg/L LPS vs unstimulated; ^c $P < 0.0007$ 2500 µg/L LPS vs unstimulated; ^d $P < 0.0001$ Ethanol/25 µg/L LPS vs 25 µg/L LPS; ^e $P < 0.0001$ Ethanol/250 µg/L LPS vs 250 µg/L LPS; ^f $P < 0.0001$ Ethanol/2500 µg/L LPS vs 2500 µg/L LPS.

Immunohistochemistry

We performed immunohistochemical investigations for IL-18 in pancreatic tissues from 6 patients with chronic pancreatitis. In 4 of these patients with chronic pancreatitis, invasive ductal adenocarcinoma of the pancreas had developed and was the reason for pancreatic surgery. In these patients, we investigated the chronic pancreatitis tissue which was free of pancreatic carcinoma tissues. The immunohistochemical analysis of the chronic pancreatitis tissue revealed that clusters of infiltrating mononuclear cells were stained positive for IL-18 by using anti-IL-18 antibody (Figure 4A). In chronic pancreatitis tissue, clusters of pancreatic acinar cells were also stained positive for the expression of IL-18 (Figure 4B). Thus, IL-18 appears to be expressed in both infiltrating inflammatory cells and pancreatic acinar cells during chronic pancreatitis. In addition, we studied sections from pancreatic carcinoma tissue, and detected positive staining for anti-IL-18 antibody in pancreatic carcinoma cells as well. In general, staining for IL-18 was more pronounced in the samples with pancreatic carcinoma than in the samples from patients with chronic pancreatitis without pancreatic carcinoma. Control investigations with mouse serum and with the IL-18-

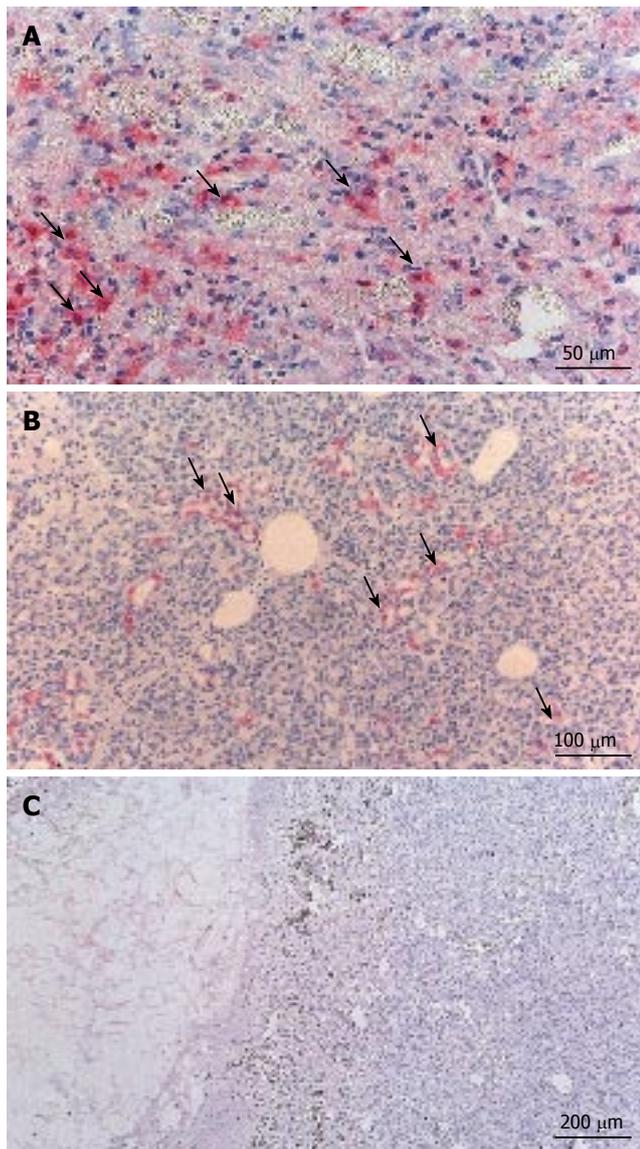

Figure 4 IL-18 expression in pancreatic tissue of CP patients. **A:** Clusters of infiltrating mononuclear cells stained positive; **B:** Clusters of pancreatic acinar cells also stained positive for the expression of IL-18; **C:** No positive staining for IL-18 in the negative control (mouse serum with IL-18 antigen-antibody mixture).

antigene-antibody-mixture revealed no positive staining for IL-18 and confirmed the accuracy of the method (Figure 4C).

DISCUSSION

The major findings of the present investigation are: (1) the fasted serum levels of IL-18 are significantly enhanced by 76% in patients with chronic pancreatitis compared to healthy control individuals; (2) the mRNA expression of IL-18, the protein levels of IL-18, and the *in vitro* secretion of IL-18 after stimulation with ethanol and endotoxin is similar in PBMC from patients with chronic pancreatitis and from healthy control subjects; (3) *in vitro*, ethanol significantly reduces endotoxin-stimulated IL-18 secretion by about 50%; (4) the IL-18 protein levels in chronic pancreatitis tissue are increased; and (5) IL-18 is expressed in pancreatic acinar cells and infiltrating inflammatory cells

within the pancreas.

These results suggest that PBMC are not the main source of the enhanced serum levels of IL-18 in patients with chronic pancreatitis. It rather appears that IL-18 originates from the chronically inflamed pancreas. Indeed, there is increasing evidence that immunological mechanisms play an important role in the development and progression of chronic pancreatitis^[9-13,30,31]. Cytokines, growth factors and other immunological mediators are produced by resident cells and recruited cells within the chronically inflamed pancreas and contribute to pancreatic fibrosis^[14]. In addition, pancreatic acinar cells also produce, release and respond to cytokines^[32]. Thus, we assume that IL-18 participates in the destruction of the pancreas during chronic pancreatitis.

Alcohol consumption represents an important risk factor for the development of chronic pancreatitis. Chronic alcohol consumption leads to an increased gut permeability with subsequent endotoxemia, and endotoxin has been reported as a mediator of alcohol induced liver damage^[33]. Studies in ethanol-fed rats also suggest a role of endotoxin in the development of pancreatic injury^[34]. Endotoxin strongly induced IL-18 gene expression in PBMC, and the response to endotoxin was mainly regulated by the expression of CD14^[21]. In our study, we did not detect endotoxin in the plasma of patients with chronic pancreatitis, and the soluble CD14 levels were similar in patients and control individuals. However, it has to be stressed that the present study was not designed to investigate the full impact of endotoxin on the development of pancreatic damage. Enhanced endotoxin plasma levels may only be detectable for short periods of time during acute ethanol consumption in humans, whereas the patients in our study had not consumed alcohol on the day of the investigation. In addition, not all patients with alcoholic chronic pancreatitis were still abusing alcohol at the time of recruitment into the study. Therefore, it appears that the enhanced blood levels of IL-18 do not result from endotoxin-mediated mechanisms.

Interestingly, our *in vitro* studies showed that the incubation of PBMC with ethanol decreased the endotoxin-stimulated secretion of IL-18 by PBMC thereby suggesting that ethanol consumption modulates the IL-18 expression in the pancreas. However, the role of IL-18 in alcoholic pancreatitis remains speculative since only limited data are available regarding the probably pleiotropic immunological function of IL-18 in chronic pancreatitis.

IL-18 participates both in Th1 and Th2 immune responses^[16]. IL-18 induces the production of cytokines such as TNF- α and IL-1 and enhances the production of further chemokines such as IL-8 and MCP-1^[35] that are increased in chronic pancreatitis tissue^[10,31,36]. Of note, IL-8 plays a major role in the recruitment of infiltrating neutrophils to the site of inflammation^[37]. The simultaneous presence of IL-12 and IL-18 results in a marked production of nitric oxide and reactive oxygen intermediates in macrophages and neutrophils^[38] which may also facilitate premature intrapancreatic trypsin activation and pancreatic autodigestion^[39]. The predominantly antiinflammatory cytokine IL-10 inhibits the synthesis of

proinflammatory cytokines such as TNF- α , IL-1, IL-6 and IL-8 and may play a dominant role in protecting the pancreas during pancreatic inflammation^[40,41]. There was only minimal induction of the antiinflammatory cytokines IL-1 receptor and IL-10 through IL-18^[35], and IL-10 failed to inhibit IL-18 production in response to inflammatory stimuli^[42]. Therefore, IL-18 may escape the influence of IL-10 during pancreatic inflammation.

Finally, among its pleiotropic effects, IL-18 strongly induces IFN- γ production^[15,16]. Increased levels of IFN were reported in chronic pancreatitis tissue from humans and animals^[13,43,44]. Interestingly, the fibrosis in chronic pancreatitis seems to be driven by TGF- β 1^[45], and IFN- γ and TGF- β 1 are linked by an antagonistic relationship^[46,47]. INF- γ possesses several antifibrotic characteristics, and IFN- γ has already been used therapeutically in animals and humans with fibrotic diseases^[47-49]. The recruitment and activation of infiltrating cells may depend on the local production of inflammatory mediators such as TGF- β 1 and IFN- γ ^[11,31]. Recent *in vitro* studies have demonstrated that TGF- β 1 strongly suppressed the production of IFN- γ that had been induced by costimulation with IL-18 and phytohaemagglutinin, a strong stimulator of IFN- γ synthesis, or by costimulation with IL-18 and IL-12^[50]. However, the role of IFN- γ in chronic pancreatitis is not completely clarified, and further studies are required to reveal the role of IL-18 during pancreatic fibrosis.

In conclusion, PSC are activated during pancreatic injury, and these cells produce and release increased amounts of extracellular matrix proteins thereby leading to the fibrotic destruction of the pancreas^[6,7]. Pancreatic stellate cells are activated and regulated on exposure to various proinflammatory cytokines^[9]. Thus, future studies should address the role of IL-18 in the context of PSC activation and regulation.

Abstract

AIM: To study the prognostic value of adjuvant chemotherapy in patients with pancreatic, ductal adenocarcinoma.

METHODS: Lymph nodes from 106 patients with resectable pancreatic ductal adenocarcinoma were systematically sampled. A total of 318 lymph nodes classified histopathologically as tumor-free were examined using sensitive immunohistochemical assays. Forty-three (41%) of the 106 patients were staged as pT_{1/2}, 63 (59%) as pT_{3/4}, 51 (48%) as pN₀, and 55 (52%) as pN₁. The study population included 59 (56%) patients exhibiting G_{1/2}, and 47 (44%) patients with G₃ tumors. Patients received no adjuvant chemo- or radiation therapy and were followed up for a median of 12 (range: 3.5 to 139) mo.

RESULTS: Immunostaining with Ber-EP4 revealed nodal microinvolvement in lymph nodes classified as "tumor free" by conventional histopathology in 73 (69%) out of the 106 patients. Twenty-nine (57%)

of 51 patients staged histopathologically as pN₀ had nodal microinvolvement. The five-year survival probability for pN₀-patients was 54% for those without nodal microinvolvement and 0% for those with nodal microinvolvement. Cox-regression modeling revealed the independent prognostic effect of nodal microinvolvement on recurrence-free (relative risk 2.92, *P* = 0.005) and overall (relative risk 2.49, *P* = 0.009) survival.

CONCLUSION: The study reveals strong and independent prognostic significance of nodal microinvolvement in patients with pancreatic ductal adenocarcinoma who have received no adjuvant therapy. The addition of immunohistochemical findings to histopathology reports may help to improve risk stratification of patients with pancreatic cancer.

INTRODUCTION

Pancreatic adenocarcinoma is the fifth leading cause of death among all malignancies^[1], leading to approximately 40 000 deaths each year in Europe^[2]. Reported probabilities of five-year survival after curative surgery are still below 10 percent^[3]. Stage, grade and resection margin status are currently accepted as the most accurate pathologic variables predicting survival^[4-10]. Pathologic staging only insufficiently reflects the individual risk to develop tumor recurrence which is even high in early tumor stages. Thus, effort continues to identify new prognosticators of tumor

relapse that indicate the need of adjuvant therapy.

Occult residual tumor disease is suggested when either bone marrow or lymph nodes from which tumor relapse may originate are affected by micrometastatic lesions undetectable by conventional histopathology^[11]. The clinical significance of antibodies against tumor-associated targets both in lymph nodes^[12-15] and in bone marrow^[15,16] is still controversial^[16-26]. Various monoclonal antibodies are in use for micrometastatic detection, thus contributing to the incongruity of data and validity of results. These assays have been rarely used in patients with pancreatic carcinoma^[27-31]. Recently, our group showed that immunohistochemical staining with the monoclonal antibody Ber-EP4 is a sensitive and specific method for detecting isolated or clusters of tumor cells in lymph nodes from patients with lung^[13], esophageal^[25], or pancreatic carcinomas^[28]. Ber-EP4 is an antibody against two glycopolypeptides of 34 and 49 kD on the surface and in the cytoplasm of all epithelial cells (except parietal cells, hepatocytes, and the superficial layers of squamous epithelium).

The present study was to increase our knowledge gained in the previous studies on lymph node micrometastasis^[25,28,31,32]. In non-small cell lung carcinoma^[32], the risk to develop tumor relapse in pN1 patients is overall greater than in pN0 patients. However, we have shown that further risk stratification for patients with histopathological involvement may be performed according to their immunohistochemical status. Therefore, here we have extended our previously published study on lymph node-negative patients with pancreatic cancer^[31] with patients staged as pN1 through conventional histology as well as the bone marrow data from those patients that gave us written consent. The primary aim of this study was to assess the role of immunohistochemically detectable micrometastases in lymph nodes of an unselected group of patients with "curatively" resected pancreatic ductal adenocarcinoma. The secondary aim was to assess whether lymph node microinvolvement is correlated to bone marrow micrometastasis and which of these two sites is a better indicator for tumor cell dissemination in pancreatic cancer.

MATERIALS AND METHODS

Patients and study design

The local ethical committee of Hamburg approved this study. Informed consent was obtained from all patients before inclusion in the study. Tumor samples, lymph nodes, and bone marrow aspirates of the upper iliac crest were collected from 487 patients with pancreatic and periampullary malignancies. Out of these patients, 171 (35%) had carcinomas of the papilla of Vater, 47 (10%) exhibited carcinoma of the distal common bile duct, and 269 (55%) had pancreatic carcinoma. Out of these 269 patients, 49 (18%) had neuroendocrine tumors and 220 (82%) had true pancreatic carcinoma.

Our study population included 106 patients with resectable pancreatic ductal adenocarcinoma who had undergone curative surgery and had given informed consent for immunohistochemical analysis of lymph

nodes. Patients with cystic malignancies (IPMN, cystadenocarcinoma), acinar cell and squamous cell carcinomas were not considered for this study. The most frequent surgical procedure was pancreatoduodenectomy. Lymph node dissection was performed as previously described by Pedrazzoli *et al*^[33]. A total of 1643 lymph nodes were removed with a median number of 16 (range 7 to 38) lymph nodes per patient. Among all histopathologically negative lymph nodes, 318 were selected in a representative fashion as described most recently for subsequent immunohistochemical screening^[31]. Tumor stage and grade were classified according to the 6th edition of the tumor-node-metastasis classification (TNM) of the International Union against Cancer^[34] by investigators unaware of the immunohistochemical findings.

Follow-up evaluations at three-month intervals included a physical examination, abdominal ultrasonography, computed tomography of the abdomen and studies of tumor markers, i.e. carcinoembryonic antigen and CA 19-9. Out of all 106 patients studied, the vital status in 89 patients could be determined at the end of the study. Seventeen patients were excluded from the survival analysis because they were either censored or died within 90 d after surgery. From 3 patients, only information about the date of death but not of recurrence was available

Tissue preparation and immunohistochemical analysis

Lymph nodes were divided into two parts, one for conventional histopathology, the other was snap-frozen in liquid nitrogen within three hours after their removal and stored at -80°C until use. Only histopathologically "tumor-free" lymph nodes were screened by immunohistochemistry with the anti-epithelial-cell monoclonal antibody Ber-EP4 (IgG1; Dako, Hamburg, Germany) as described previously^[14]. Ber-EP4 is an antibody against two glycopolypeptides of 34 and 49 kD on the surface and in the cytoplasm of all epithelial cells (except parietal cells, hepatocytes, and the superficial layers of squamous epithelium). The antibody does not react with mesenchymal tissue, including lymphoid tissue^[15,23].

Cryostat sections (5 to 6 µm thick) were cut at three different levels in each node and transferred onto glass slides treated with 3-triethoxysilylpropylamin (Merck, Darmstadt, Germany). One section of the sample obtained at each level was stained by the alkaline phosphatase-antialkaline phosphatase technique combined with the new fuchsin stain (Sena, Heidelberg, Germany) for the visualization reaction^[23].

In 16 control patients with nonepithelial tumors or inflammatory diseases, lymph nodes were consistently stained negative. Sections of normal colon served as positive staining controls and isotype-matched, irrelevant murine monoclonal antibodies served as negative controls (purified immunoglobulin mouse myeloma protein for IgG1; Sigma, Deisenhofen, Germany).

The slides were evaluated in a blinded fashion by two observers working independently (D.B., J.T.K.). Minimal tumor cell involvement in a lymph node that was considered to be tumor-free by conventional histopathological staining was defined as the presence of

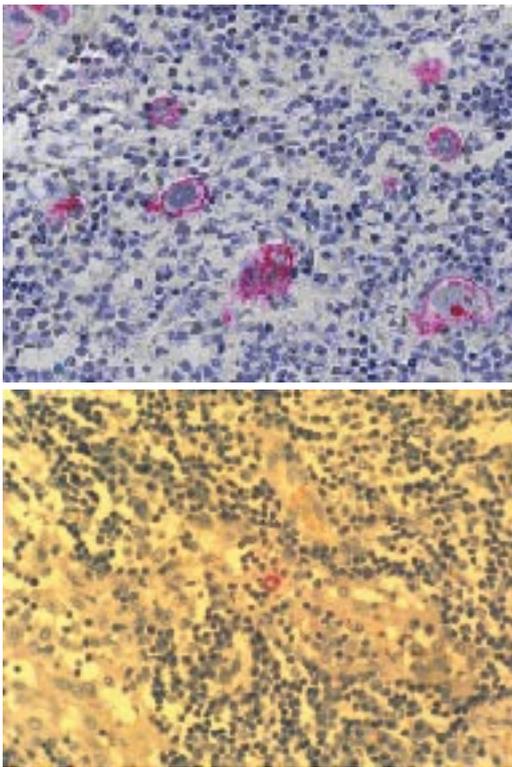

Figure 1 Immunohistochemically detectable nodal microinvolvement with monoclonal antibody Ber EP4 ($\times 400$).

one to ten positive cells in the body of the node (Figure 1). If more than 10 cells were detected (2 lymph nodes in two patients), a HE re-staining was conducted. Under routine histology both lymph nodes were judged as negative.

Aspirates of 4 to 8 mL of bone marrow from the iliac crest were obtained from those patients who gave additional written consent for sampling bone marrow (59 patients) and were processed as previously described^[16]. The specimens were collected in heparin, and mononuclear cells isolated by density-gradient centrifugation through Ficoll-Hypaque (Pharmacia, Freiburg, Germany) at 400 r/min for 30 min, were deposited onto glass slides by cytocentrifugation at 150 r/min for 3 min. To detect tumor cells in bone marrow (Figure 2), we used the monoclonal antibody A45-B/B3 (IgG1; Micromet, Munich, Germany) that detects an epitope on a variety of cytokeratin components, including cytokeratins^[14,15,18,20].

Statistical analysis

All statistical calculations concerning survival (overall and recurrence-free survival) were based on the group of 89 patients who were available for follow-up. The primary outcome measure was the five-year survival probability. Secondary outcomes were the incidence of local recurrence and distant metastases of the disease. Survival was calculated from the date of resection until the date of death from any cause. For patients lost to follow-up, data were censored on the date the patient was last seen alive. Associations between categorical variables were assessed using Fisher's exact test. Survival estimates were derived using the method proposed by Kaplan and Meier^[35] and the log-rank test was used to assess differences in survival

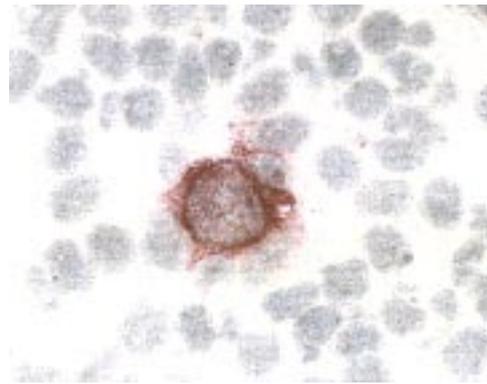

Figure 2 Immunohistochemically detectable bone marrow microinvolvement with monoclonal antibody AE1/AE3 ($\times 400$).

estimates among the groups. Point and interval estimates of the survival probabilities at 60 mo were calculated. For comparison purposes, log-rank test and exact stratified log-rank test were performed. Cox proportional-hazards modeling^[36] was used to investigate and adjust the major prognostic and stratification factors. $P < 0.05$ was considered statistically significant.

Since this analysis was intended to be explorative, no adjustment for multiple testing was carried out.

RESULTS

Characteristics of patients and comparison of staining procedures

One hundred and six patients [47 (44%) women and 59 (56%) men] with pancreatic ductal adenocarcinoma were included in the study. Their mean age was 61 years (range 32 to 83 years, median 61 years). Table 1 shows the characteristics of patients and tumors.

A total of 318 lymph nodes classified to be "tumor-free" by conventional histopathology were analyzed. Positive cells in the sinuses, the lymphoid interstitium, or in both locations were found in 132 lymph nodes (42%). These 132 positive lymph nodes were found from 73 (69%) of the 106 patients by immunostaining. Whereas the presence of Ber-EP4 cells was significantly associated with nodal metastases (pN1) identified through conventional histopathology ($P = 0.012$), no correlation between tumor stage and tumor grade was found.

Survival

After an average observation period of 18 mo (range 3 to 137 mo, median 12 mo), the presence of nodal microinvolvement was associated with significantly reduced recurrence-free and overall survival probabilities. The Kaplan-Meier overall survival curve for all patients who were stratified according to the presence or absence of occult tumor cells in lymph nodes showed a significant survival benefit for patients negative in immunohistochemistry (median not yet reached-NYR *vs* 13 mo; 2-year survival 66% *vs* 20%; 5-year survival 50% *vs* 0%) irrespective of the histopathological classification (pN0/pN1) of lymph nodes (log-rank test; $P < 0.0001$, Figure 3).

Table 1 Characteristics of patients and tumors

Variable	n	Ber-EP4 positive cells in lymph nodes (n)
All patients	106	73
Male	59	42
Female	47	31

Well differentiated (G1)	5	4
Moderately differentiated (G2)	54	35
Poorly differentiated (G3)	47	34
Resection margin		
Negative (R0)	90	59
Positive (R1)	16	14
Tumor cells in Bone marrow		
Yes	14	9
No	45	31
Not analysed	47	33

Nodal status was detected both histopathologically and immunohistochemically. Bone marrow micrometastases were detected by immunohistochemistry. *P* = 0.035.

The analysis of the subset of patients who were staged pN0 in conventional histopathology revealed significantly better survival rates in patients without occult tumor cells as compared with those with nodal microinvolvement (median NYR *vs* 17 mo; 2-year survival 70% *vs* 34%; 5-year survival 61% *vs* 0%; log-rank test; *P*=0.012, Figure 4). Patients without any nodal involvement, as excluded by both conventional histopathology and immunohistochemistry, had a five-year overall survival probability of 61% (standard error: 13%). In contrast, the five-year survival probability of pN0-patients with nodal microinvolvement resembled that of pN1-patients (log-rank test; *P* = 0.059, Figure 4) and in both groups no patient was still alive 5 years after surgery.

The predictive value of nodal microinvolvement was strengthened by the finding that pN1-patients who additionally had disseminated tumor cells in other lymph nodes classified as tumor-free by histopathology had shorter recurrence-free and overall survival probabilities than pN1-patients without occult tumor cells in immunohistochemistry (median survival 33 *vs* 10 mo; 2-year survival 69% *vs* 10%; 5-year survival 69% *vs* 0%; log rank test: *P* = 0.004 and *P* = 0.049, respectively, data not shown).

Although no statistical significance was reached, pN1-patients *without* nodal microinvolvement had better overall survival probabilities (median survival = 33 mo) than pN0-patients *with* nodal microinvolvement (median survival = 17 mo). This could in part confirm the hypothesis that

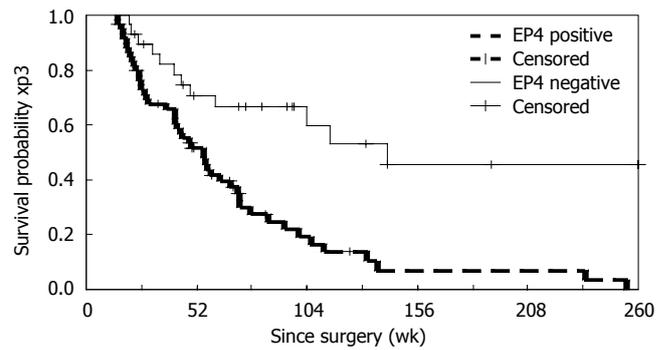

Figure 3 Overall survival according to the presence or absence of nodal microinvolvement in immunohistochemistry for patients alive at least 13 wk after surgery. Median: Not yet reached-NYR *vs* 13 mo; Mean: 81 (SD 15, 95% CI 52-109) *vs* 16 (SD 2, 95% CI 12-20); 2-yr overall survival 66% *vs* 20%; 5-yr overall survival 50% *vs* 0%.

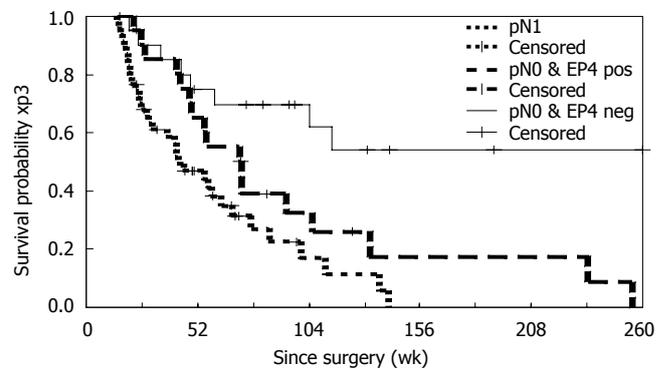

Figure 4 Overall survival according to the presence or absence of nodal metastases in conventional histopathology and immunohistochemistry for patients alive at least 13 wk after surgery. Median: Not yet reached-NYR *vs* 13 mo *vs* 10 mo; Mean: 90 (SD 15, 95% CI 60-119) *vs* 17 (SD 3, 95% CI 11-23) *vs* 14 (SD 2, 95% CI 7-13); 2-yr overall survival 66% *vs* 20%; 5-yr overall survival 50% *vs* 0%.

nodal microinvolvement in patients not burdened with nodal metastases detected through routine histology (pN0) might literally reflect systemic disease, whereas pN1-patients without nodal microinvolvement could be in fact treated as locally advanced disease. This should be discussed very cautiously since only 8 patients were included in the group of pN1-patients without nodal microinvolvement, but all of them were alive at the last follow-up.

Influence of resection margins

A total of 16 patients among the entire study population had positive resection margins (R1-status), only 2 of them belonged to the subset of pN0-patients without nodal microinvolvement. The remaining 14 patients with positive resection margins were either staged pN1 or had nodal microinvolvement which was as reported above, per se associated with a significantly worse prognosis. Due to this distribution of patients with R1-status, log-rank test might not have the sufficient power to assess the influence of the resection margins on overall survival. Therefore, no significant differences were found between patients with positive resection margins, as compared with those with negative resection margins (*P* = 0.976, data not shown).

Table 2 Cox regression analysis showing the presence of occult tumor cells in lymph nodes, tumor grade, and histopathologically detectable lymph node involvement as independent prognostic factors for disease-free and overall survival

Prognostic factor	Reference group	Relative risk	P	Lower bound	Upper bound
				95% confidence interval	
Recurrence-free (<i>n</i> = 86)					
Age at surgery		1.01	0.706	0.98	1.03
Sex	Male	1.42	0.223	0.81	2.49
Stage	pT1-pT2	0.87	0.652	0.48	1.57
Grade	G I - GII	3.14	0.000	1.74	5.68
Nodal involvement	pN0	1.66	0.112	0.89	3.10
Nodal microinvolvement (Ber-EP4)	Negative	2.92	0.005	1.39	6.13

Nodal involvement	pN0	2.18	0.012	1.19	4.00
Nodal microinvolvement (Ber-EP4)	Negative	2.49	0.009	1.25	4.96

Influence of bone marrow micrometastases

Occult tumor cells were detected in 14 of 59 patients who were evaluated with respect to bone marrow micrometastases. No association was found between bone marrow and nodal microinvolvement (Fisher's exact test, $P = 0.75$). Among the 14 patients with bone marrow micrometastases, 9 (64%) had also nodal microinvolvement, whereas 5 (36%) did not. In turn, Ber-EP4-positive cells in lymph nodes were detected in 31 (69%) of the 45 patients with negative bone marrow findings (Table 1). Neither bone marrow micrometastases nor nodal microinvolvement was found in 14 patients. Here, we want to stress the finding (although again not significant due to the small number of patients) that those patients without any nodal involvement (negative both in histopathology and IHC) who had bone marrow micrometastases seemed to have considerably worse overall prognosis (mean survival time: 8 mo) than patients without (mean survival time: 75 mo). This also has to be discussed with considerable caution since we identified only 3 patients with bone marrow micrometastases (without any nodal involvement), although they all died within the first year unlike the other 8 patients without bone marrow micrometastases who were all alive on the last follow-up.

As regards the influence of bone marrow micrometastases alone, no significant differences were found with respect to relapse-free time ($P = 0.55$) and overall survival ($P = 0.14$), respectively. However, these results might be biased by the small number of patients analyzed.

Multivariate analysis

Apart from nodal involvement assessed either by histopathology or immunohistochemistry, the comparison of survival curves revealed also significant differences with respect to grading when G_{1,2} tumors were compared to G₃ tumors (median survival time: 28 mo vs 12 mo; log-rank test: $P < 0.001$).

Cox regression analysis identified the presence of occult tumor cells in lymph nodes, tumor grade, and histopathologically detectable lymph node involvement as

independent prognostic factors for disease-free and overall survival (Table 2). With respect to 5-year recurrence-free time, nodal microinvolvement had a relative risk of 2.92 (95% confidence interval: 1.39 to 6.13; $P = 0.005$), as compared with negative findings in immunohistochemistry. G₃ tumors had a relative risk of 3.14 as compared with G_{1/2} tumors (95% confidence interval: 1.74 to 5.68; $P = 0.000$) with respect to recurrence-free time. A pN₁-stage, as compared to pN₀ patients, carried a relative risk of 2.18 (95% confidence interval: 1.19 to 4.0; $P = 0.012$) as to overall survival time, but had no significant influence on recurrence-free time (relative risk of 1.66; 95% confidence interval: 0.89 to 3.10; $P = 0.112$). Age, sex and tumor stage had no independent prognostic influence on recurrence-free or overall survival.

The analysis of the interaction between pN-status, nodal microinvolvement and grading did not reveal that the proportional assumption was violated. Hence, the Cox model appeared appropriate and grading followed by nodal microinvolvement remained the two most important prognostic variables also in the subset of pN₀-patients.

DISCUSSION

The key finding of this investigation is that isolated tumor cells, detectable in lymph nodes by immunohistochemical analysis, are strong independent prognosticators in pancreatic ductal adenocarcinoma irrespective of the histopathological N-status. We analyzed patients who suffered from pancreatic ductal adenocarcinoma and did not receive any adjuvant chemoradiation or chemotherapy. Two subsets of patients could be identified and were classified as pN₀ in conventional histopathology. One subset with a poor five-year survival probability of 0% which was close to that of patients with overt nodal involvement (pN₁), the other subset had a much better prognosis with a five-year survival probability of over 50% without nodal microinvolvement, suggesting that immunohistochemistry can confirm the cardinal importance of occult tumor cells for the separation of the

respective survival curves in pN0-patients.

Even in patients who were staged as pN1, the detection of occult tumor cells in “tumor-free” lymph nodes had prognostic significance. This finding is consistent with previous observations of our group showing that survival is significantly worsened in both esophageal^[25] and non-small cell lung carcinoma^[32] when histopathological pN1-status is accompanied with nodal microinvolvement. Basically, pN1-status in solid tumors is considered as a local disease which can be potentially cured with surgery, although it generally carries a higher risk of systemic dissemination than pN0-status. Therefore, the finding that pN1 patients with additional nodal microinvolvement in “tumor-free” lymph nodes apart from overt lymph node metastases had significantly shorter recurrence-free survival as compared with pN1-patients without occult tumor cells suggests that immunohistochemistry may help to identify different risk profiles in these patients.

The reliability of these immunohistochemical assays used so far for detection of nodal microinvolvement is questioned^[16-26] and could be also hampered by a sampling error^[25,37]. The sampling error might be influenced by the number of lymph nodes dissected during the course of pancreatoduodenectomy and assessed by immunohistochemistry, as well as the number of lymph node sections and the level of these sections within the lymph nodes. In our present study, the lymph node dissection was performed as previously described by Pedrazzoli *et al*^[33]. A total of 1643 lymph nodes were removed with a median number of 16 (range 7 to 38) lymph nodes per patient. Thus, the first possible cause of a sampling error was diminished, considering the high median lymph node yield of 16 per patient. In another study (oesophagus carcinoma, not yet published) all lymph nodes dissected in the course of esophagectomy were immunohistochemically stained, unlike in this and some other previously published studies^[25] where only 20% of all lymph nodes were stained, showing comparable results in terms of impact on overall and relapse-free survival. We also believe that 6 sections cut from 3 different levels of each lymph node are enough for proper access to the nodal microinvolvement. Analyzing more than 3 sections would not be routinely feasible, and the positive correlation between the result of our assay and clinical outcome indicates that examining 3 lymph node levels are sufficient. The results from this study are in the same line with those published earlier from our group^[25], thus confirming that the random selection of lymph nodes for IHC is enough for access to the nodal microinvolvement.

The strong adverse influence of nodal microinvolvement on outcome was most likely the reason for the lack of prognostic significance of resection margins in this series. In the ESPAC-1 trial, the resection margin status ceased to be an independent, prognostic factor for overall survival when tumor grading and pN-status were co-variables in the regression modeling^[38], suggesting that the unfavorable outcome linked with poorly differentiated tumors with nodal metastases can hardly be impaired by further adverse variables, e.g. R1-status. We therefore assume that the characteristics of patients with R1-status are considerably biased. This hypothesis is strengthened by

our observation that out of the 16 patients with R1-status all except two had occult tumor cells in immunohistochemistry.

Our data also indicate primary dissemination of tumor cells into lymph nodes before blood-borne spread occurs, because only 22% of the patients with nodal microinvolvement had identifiable tumor cells in their bone marrow. The lack of a significant difference in recurrence-free time between patients with nodal microinvolvement alone and those with additional involvement of the bone marrow suggests that the key event in pancreatic cancer progression is the spread of tumor cells to the regional lymph nodes. Nodal microinvolvement seems to indicate a systemic disease in pancreatic carcinoma much more accurately than occult tumor cells in bone marrow. However, these results have to be interpreted cautiously because bone marrow findings may have been biased by the fact that only a subset of patients was analyzed. Therefore, the influence of bone marrow microinvolvement on the outcome of patients with pancreatic carcinoma needs to be clarified in future studies.

Although chemoradiation and/or chemotherapy for adjuvant treatment of pancreatic carcinoma may have severe side effects^[39], in common clinical practice, it is in most instances applied irrespective of tumor stage. This reflects the distrust in the value of conventional tumor-staging nomenclature in terms of reliably predicting the risk of tumor relapse even in patients with early pancreatic cancer (T₁, N₀). Our data indicate that immunohistochemical assessment of lymph nodes can be used to refine the staging system for pancreatic ductal adenocarcinoma and might help us to identify patients who could not be cured by surgery alone and need adjuvant therapy. In turn, patients who are true node-negative both in histopathology and in immunohistochemistry have an excellent five-year survival probability of nearly 60%, even without chemotherapy. Whether this prognosis can be further improved by adjuvant therapy needs further study.

Imamura H, Ikeda M, Furukawa H, Tsujinaka T, Fujitani K, Kobayashi K, Narahara H, Kato M, Imamoto H, Takabayashi A, Tsukuma H. Phase II study of protracted irinotecan infusion and a low-dose cisplatin for metastatic gastric cancer. *World J Gastroenterol* 2006; 12(40): 6522-6526

<http://www.wjgnet.com/1007-9327/12/6522.asp>

Abstract

AIM: To test protracted irinotecan infusion plus a low-dose cisplatin in this Phase II trial to decrease its toxicity.

METHODS: The eligibility criteria were: (1) histologically proven measurable gastric cancer; (2) performance status of 0 or 1; (3) no prior chemotherapy or completion of prior therapy at least 4 wk before enrollment; (4) adequate function of major organs; (5) no other active malignancy; and (6) written informed consent. The regimen consisted of irinotecan (60 mg/m²) on d 1 and 15 by 24-h infusion and cisplatin (10 mg/m²) on d 1, 2, 3, 15, 16, and 17. Treatment was repeated every 4 wk.

RESULTS: Thirty-one patients were registered between April 2000 and January 2001. The response rate for all 31 patients, 20 patients without prior chemotherapy, and 11 patients with prior chemotherapy was 52% (16/31), 60% (12/20), and 36% (4/11), respectively. The median survival time was 378 d. The median number of courses given to all patients was 2. Grade 4 neutropenia occurred in 11 (35%) patients, while grade 3 to 4 diarrhea or nausea occurred in 1 (3%) and 3 (10%) patients, respectively. Fatigue was minimal as grade 1 fatigue was found only in 3 (10%) patients. Other adverse events were mild and no treatment-related deaths occurred.

INTRODUCTION

In Japan, for advanced gastric cancer, surgery is still the most effective treatment and good survival can be achieved if the tumor is resectable. On the contrary, unresectable advanced or recurrent gastric cancer still has a poor prognosis and chemotherapy is the most important treatment for survival prolongation. To date, combination chemotherapy with 5-fluorouracil (5-FU) and cisplatin has been used most widely. This two-drug regimen showed superior response rate in comparison with single-agent 5FU regimen, however, failed to demonstrate survival prolongation^[1-3]. This regimen has response rates ranging from 10% to 35%, and the median survival time (MST) from 6 to 8 mo with around 10% in a 2-year survival^[4]. Advent of new active agents is awaited.

Among new drugs, irinotecan, a derivative of camptothecin, has strong antitumor activity through inhibition of DNA topoisomerase I^[5]. It has a single agent activity with a response rate of 23.3%^[6]. As the response rate is not satisfactory, irinotecan was first investigated in combination with cisplatin. Phase I study was conducted for metastatic gastric cancer and treatment regimen of irinotecan (70 mg/m², d 1 and 15) and cisplatin (80 mg/m², d 1), every 4 wk, was recommended^[7]. Boku's group tested this regimen for metastatic gastric cancer^[8]. The overall response rate was 48% and the median survival time was 272 d. Although no treatment-related deaths occurred, adverse events were severe, including grade 4 neutropenia in

57% of the patients and grade 3 or 4 diarrhea in 20%. As for renal toxicity, they found a total of 34% (grade 1: 23%, grade 2: 11%) serum creatinine increase. This combination study was followed with modification of weekly schedule to reduce toxicity in western countries. Ajani *et al*⁹¹ conducted phase II study with irinotecan (65 mg/m²) with cisplatin (30 mg/m²), both administered intravenously 1 d per week for 4 consecutive weeks, followed by two weeks recovery period. Of the 36 patients registered, 21 achieved complete or partial response with response rate of 58%. They had one treatment-related death of neutropenic sepsis with multiple organ failure. Major toxic effects were diarrhea, neutropenia, and fatigue. The incidence of grade 3 or 4 neutropenia was 37%, however, grade 3 or 4 diarrhea was still found in 22% of patients. Surprisingly, grade 3 or 4 fatigue was 41%, a cause of delays or cancellation of drugs. To decrease adverse events, Fujitani *et al*¹⁰¹ conducted a pharmacokinetic study of continuous infusion of irinotecan for 24 h combined with infusion of cisplatin over 90 min, and demonstrated only mild hematological and nonhematological adverse reactions, while protracted infusion of irinotecan increased the area under the concentration *vs* time curve (AUC) of SN-38.

Accordingly, we further investigated the safety and efficacy of this combined protracted infusion of irinotecan (to maintain a high AUC of SN-38) with a low-dose cisplatin to determine whether this regimen can improve response rate and reduce toxicity.

MATERIALS AND METHODS

Eligibility criteria

Patients were required to satisfy the following eligibility criteria; (1) histologically proven gastric cancer; (2) measurable metastatic lesions; (3) Eastern Clinical Oncology Group scale performance status of 0 or 1; (4) no prior chemotherapy or completion of therapy at least 4 wk before entry; (5) adequate function of the bone marrow WBC count $\geq 4 \times 10^9$ and $\leq 12 \times 10^9$, platelet count $\geq 100 \times 10^9$, and hemoglobin ≥ 95 g/L, liver (serum bilirubin ≤ 25.6 μ mol/L and serum transaminases ≤ 1667 nkat/L), and kidneys (serum creatinine ≤ 133 μ mol/L); (6) normal cardiac function; (7) no other severe medical conditions; (8) no other active malignancy; and (9) ability to give written informed consent. This study was approved by the institutional review boards of all participating hospitals.

Treatment schedule

On d 1, irinotecan (60 mg/m²) was administered as a 24-h infusion; the drug was diluted in 500 mL of saline or 50 g/L glucose and was protected from the light. Cisplatin (10 mg/m²) was administered as a 60-min intravenous infusion with adequate hydration on d 1, 2, and 3. The same doses of irinotecan and cisplatin were repeated on d 15 and 15-17, respectively, to complete one course. Treatment was repeated every 4 wk until the occurrence of disease progression, patient refusal, or unacceptable adverse reactions. On d 15, if the patient had leucopenia or thrombocytopenia of grade 2 or higher, diarrhea of grade 1 or higher, or fever (a temperature $> 38^\circ\text{C}$) due to infection, administra-

tion of the second dose of irinotecan was delayed for one week. If recovery from the adverse reaction did not occur after one week, the second dose was skipped. If a grade 4 hematologic adverse event, grade 3 or 4 diarrhea, fever associated with infection, or omission of the second dose occurred, the dose of irinotecan for the second course was reduced to 50 mg/m². The antiemetic granisetron was given before cisplatin administration. Granulocyte colony-stimulating factor (G-CSF) was used when grade 4 leucopenia and/or neutropenia occurred. If the patient stopped treatment due to toxicity or tumor progression, other chemotherapy or surgery was offered.

Evaluation

The National Cancer Institute Common Toxicity Criteria (Version 2.0) were applied for the assessment of adverse events. The objective response of measurable lesions was evaluated by standard World Health Organization criteria. Both patient eligibility and the response to treatment were reviewed extramurally.

Statistical analysis

The expected efficacy rate of this regimen was hypothesized to be 50%, so the required number of patients was 25 when the 95% confidence interval was set at $\pm 20\%$. Because some patients might be excluded from analysis, the target number of patients for this study was set at 30. Analysis was performed on an intent-to-treat basis. The percentage of patients with complete remission (CR) plus partial remission (PR) among all treated patients was defined as the response rate. The 95% confidence interval (CI) of the response rate was calculated using the normal approximation and precision method. The Kaplan-Meier method was used to calculate the survival period.

RESULTS

Patients characteristics

Thirty-one patients were enrolled from April 2000 to January 2001. One patient was found to be ineligible because the performance status was 2. As analysis was performed on an intent-to-treat basis, this patient was also analyzed for efficacy and safety, so all 31 patients were assessed for efficacy and safety. Their clinical characteristics are shown in Table 1. The median age was 60.5 (range: 26-75 years) and 21 patients (68%) had performance status of 0. Sixteen patients (52%) had intestinal type adenocarcinoma and 14 patients had diffuse tumors. The measurable metastatic lesions were located in the lymph nodes in 20 patients (26 lesions), liver in 13 patients, peritoneum in 3 patients, ovary in 2 patients, and the skin, lung, and rectum in one patient each, respectively. Twenty patients (65%) had not received prior chemotherapy, while the other 11 patients had undergone chemotherapy with 5-FU, cisplatin plus 5-FU, or other drugs. All of the patients who had received prior therapy showed progressive disease before enrollment. The total number of treatment courses was 84 with a median number of 2 cycles per patient (range 1-5). A total of 149 of 168 planned CPT-11 administration was carried out. While a total of 112 of 122 (92%) planned CPT-11 was administered in the first and second cycle, a

total of 37 of 46 (80%) planned CPT-11 administration in the third to fifth cycles. Dose reduction was not required in the first cycle, but it was needed in 8 patients in the second cycle and one patient in the third cycle. Causes of dose reduction were grade 4 neutropenia in 5 patients, grade 4 leukopenia in one patient, and second dose skip in 3 patients. Treatment was stopped due to tumor progression in 8 patients, refusal to continue in 9 patients, and insufficient recovery from adverse reactions in 3 patients. Median duration between the beginning and end of treatment was 75 d. The actual administered dose of CPT-11 in the all courses was 25.7 mg/m² per week and that of cisplatin was 13.0 mg/m² per week, which corresponded to 85.5% and 86.4% of the planned doses.

Response and survival

There were no complete remissions, but partial remission was achieved in 16 patients for a response rate of 52% (16/31 patients, 95% CI: 33% to 70%). The response rate was 60.0% for the 20 patients without prior chemotherapy (12/20 patients, 95% CI: 36% to 81%), while the rate for the 11 patients with prior chemotherapy was only 36% (4/11 patients, 95% CI: 11% to 69%). The response rate of patients with lymph node, liver, and peritoneal

metastasis were 54% (14/26 patients), 54% (7/13 patients) and 33% (1/3 patients), respectively (Table 2). The median duration of response for all the patients was 218 d. The median survival time of all patients was 378 d, while the median survival time of the 20 patients without prior chemotherapy was 509 d. The 1-year and 2-year survival rates were 57% (95% CI: 37%-72%) and 9% (95% CI: 2%-23%), respectively (Figure 1).

Adverse reactions

Adverse reactions to this regimen are shown in Table 3. Grade 4 neutropenia, leukopenia, anemia, and thrombocytopenia were observed in 11 (35%), 3 (10%), 2 (6%), and 1 (3%) of the patients, respectively. The median nadir of the neutrophil count was seen on d 8 (range: d 2-19). G-CSF was administered to 15 patients (48%) during 28 courses. Non-hematologic adverse reactions (nausea, diarrhea, increased AST, and increased bilirubin) were all moderate, with grade 3 nausea (10%) and grade 3 diarrhea (3%) being the maximal reactions. Loperamide or other mild anti-diarrheal medicines were effective for diarrhea, while granisetron and other common anti-emetic medicines were effective for nausea without additional hydration. Renal

toxicity determined by the level of serum creatinine was also mild. We found 8 patients (26%) with only grade 1 abnormal creatinine level. Fatigue was found in only 3 patients and all grade 1. The non-hematologic reactions did not disrupt the treatment schedule and there were no treatment-related deaths.

DISCUSSION

The aim of this phase II study was to confirm the antitumor effects and safety of combined chemotherapy of protracted infusion of irinotecan and low-dose cisplatin^[10]. Protracted infusion of irinotecan significantly increases the AUC of active metabolite, SN-38^[10], suggesting it has the potential to maximize the effect of irinotecan. The response rate to irinotecan as a single agent for gastric cancer was reported to be 23.3%^[6] and that for cisplatin was 20%^[11]. The overall response rate of the 31 patients in the present series was 52% and that of 20 patients without any prior chemotherapy was 60%, with both rates being better than for single agent therapy. These data are consistent with a previous phase II study of cisplatin and irinotecan therapy^[8,9], and confirms the activity of combined therapy of irinotecan and cisplatin.

Diarrhea is a serious toxicity of irinotecan therapy. The incidence of grade 3 or 4 diarrhea was reported to be 18.8% or 35.6% with irinotecan alone and 21.9% or 35.6% with bolus combined administration^[12-15]. In the previous phase II studies of irinotecan and cisplatin, diarrhea was still one of the major cause that could affect treatment schedule and the incidence of grade 3 or 4 diarrhea was around 20%^[8,9]. In the present study, grade 4 diarrhea did not occur and only one patient (3%) suffered from grade 3 diarrhea that did not necessitate a change of schedule.

The incidence of grade 3 or 4 neutropenia (77%) is still high in this study, and Boku *et al*^[8] found the incidence of grade 3 or 4 neutropenia was 89%. Ajani *et al*^[9] demonstrated that 37% grade 3 or 4 neutropenia by weekly administration. Sakaki *et al*^[6] found a positive correlation between the AUC of irinotecan and the decrease of the white cell count, however, diarrhea has a stronger correlation with the AUC of SN-38 than with that of irinotecan. As this treatment regimen has greater AUC of SN-38 while AUC of irinotecan was same in comparison with 90-min infusion of irinotecan^[10], we expected to find more hematological toxicities than diarrhea. To the contrary, we found significantly less common severe diarrhea, and high incidence of grade 3 or 4 neutropenia that was comparable to the previous Japanese trial^[8]. The target dose of irinotecan for this study ($60 \text{ mg/m}^2 \times 2$) was lower than that used by Boku ($70 \text{ mg/m}^2 \times 2$)^[8] or that used to treat lung cancer ($60 \text{ mg/m}^2 \times 3$)^[17,18]. Actual dose of CPT-11 administered in the Boku's study was 28.5 mg/m^2 per week, and that in our study was 25.7 mg/m^2 per week, so our regimen seemed to reduce the incidence and grade of diarrhea while achieving a similar response rate with a lower dose of irinotecan.

Nausea and renal toxicity is a common problem with cisplatin therapy, so we administered a low dose of 10 mg/m^2 on six occasions to achieve a total dose of 60 mg/m^2 . Grade 3 nausea occurred in 3 patients (10%) and there

was no grade 4 nausea. Low-dose, repeated administration has already been reported to decrease the incidence and grade of nausea due to cisplatin^[19-22]. Some Japanese authors have reported that repeated cisplatin administration at a low dose reduces the incidence of nausea and allows outpatient treatment, and that this method achieves a high response rate and longer survival when combined with irinotecan without the need for 24-h infusion of the latter drug^[9,23-25]. As for renal toxicity, Boku *et al* with high-dose cisplatin administration^[8] found grade 1 or 2 serum creatinine increase in 23 and 11 % of patients, respectively. We found only grade 1 abnormality, and the incidence of 26%, demonstrating that renal toxicity with this regimen is minimal. As hydration is not required to prevent renal toxicity with low-dose therapy^[20], continuous infusions are not necessary after finishing irinotecan administration on d 2, 3, 16, and 17.

In order to complete this regimen, hospitalization is required to receive 24-h irinotecan infusions and 6 divided dose of cisplatin. Therefore, this regimen is not applicable for out-patient basis; however, as the incidence of fatigue of this regimen was 10% (only grade 1), severe diarrhea was rare, and hydration was not necessary, it is possible to treat patients on an out-patient basis between infusions. Ajani *et al* demonstrated very high incidence (41%) of grade 3 or 4 fatigue with weekly irinotecan and cisplatin administration, and they discussed cisplatin might contribute to excessive fatigue, thus either the dose of cisplatin might be reduced, or cisplatin might be replaced by other agents. Our results with 10% grade 1 fatigue suggested that low dose cisplatin is a practical alternative for reducing the fatigue.

In conclusion, though hospitalization is required at this time, 24-h infusion of irinotecan combined with a low-dose, repeated administration of cisplatin achieved a high response rate and prolonged the survival of patients with metastatic gastric cancer. This regimen also reduces non-hematologic adverse reactions and thus shortens the time in hospital.

Abstract

AIM: To detect the patients with and without pancreatobiliary maljunction who had pancreatobiliary reflux with extremely high biliary amylase levels.

METHODS: Ninety-six patients, who had diffuse thickness (> 3 mm) of the gallbladder wall and were suspected of having a pancreaticobiliary maljunction on ultrasonography, were prospectively subjected to endoscopic retrograde cholangiopancreatography, and bile in the common bile duct was sampled. Among them, patients, who had extremely high biliary amylase levels (>10 000 IU/L), underwent cholecystectomy, and the clinicopathological findings of those patients with and without pancreaticobiliary maljunction were examined.

RESULTS: Seventeen patients had biliary amylase levels in the common bile duct above 10 000 IU/L, including 11 with pancreaticobiliary maljunction and 6 without pancreaticobiliary maljunction. The occurrence of gallbladder carcinoma was 45.5% (5/11) in patients with pancreaticobiliary maljunction, and 50% (3/6) in those without pancreaticobiliary maljunction.

CONCLUSION: Pancreatobiliary reflux with extremely high biliary amylase levels and associated gallbladder carcinoma could be identified in patients with and without pancreaticobiliary maljunction, and those patients might be detected by ultrasonography and bile sampling.

INTRODUCTION

It is well known that pancreatobiliary reflux is an important risk factor for the carcinogenesis of the biliary system in patients with pancreaticobiliary maljunction (PBM)^[1,2], which is a congenital anomaly defined as an abnormal union of the common bile duct and pancreatic duct that is located outside the duodenal wall where a sphincter system is not present and pancreatic juice freely regurgitates into the biliary tract through the communication^[3].

Recently, we reported that pancreatobiliary reflux with extremely high biliary amylase levels can occur not only in patients with PBM, but also in those without PBM^[4,5], although the latter condition is not well known yet. In the present study, we tried to detect the patients, who had pancreatobiliary reflux with extremely high biliary amylase levels, and examined the clinicopathological findings of those patients.

MATERIALS AND METHODS

Subjects

Between March 2002 and February 2006, 96 patients, who had diffuse thickness of the gallbladder wall above 3 mm and were suspected of having pancreaticobiliary maljunction on ultrasonography, were prospectively subjected to endoscopic retrograde cholangiopancreatography (ERCP). Bile in the common bile duct was sampled as follows and biliary amylase levels were measured in those patients. After selective insertion of an ERCP catheter into the bile duct, bile was aspirated from the common bile duct at a depth of 5 cm. To avoid contamination with pancreatic juice, the first 5 mL of the aspirated bile was not used to measure biliary amylase levels, and another sample of bile was obtained for the measurement. In all patients, serum amylase was measured within 48 h before cholecystectomy. Amylase in the serum and bile was measured by an enzymatic method using 3-ketobutylidene-2-chloro-4-nitrophenyl-maltopentaoside (Diacolor Neonate, Toyobo, Osaka, Japan) as the substrate^[6]. The normal range for serum amylase in our institution is 130 to 400 IU/L. We defined extremely high biliary amylase levels as those above 10 000 IU/L, and patients with extremely high biliary amylase levels were indicated for cholecystectomy. Patients having bile duct stenosis, filling defect in the bile duct, including choledocholithiasis on ERCP, were excluded

from the present study, because their biliary amylase levels in the common bile duct would not correctly reflect pancreatobiliary reflux.

Patients were divided into those with PBM and without PBM (non-PBM). On ERCP images, the two ducts were always communicated in PBM patients, but not in non-PBM patients due to the sphincter contraction. The length of the common channel was measured on ERCP images corrected for magnification using the diameter of the endoscope as a reference.

Informed consent was obtained from all the patients. The study protocol was approved by the ethics committee of our institution.

Tissue specimens and histologic analysis

All specimens were fixed in 10% buffered formalin. The gallbladder tissues embedded in paraffin were cut into 4- μ m serial sections, and the gallbladder mucosa was histologically examined using sections stained with hematoxylin and eosin (HE). All specimens were diagnosed based on light microscopic findings. Carcinoma of the gallbladder was diagnosed according to the criteria reported by Albores-Saavedra *et al*^[7].

RESULTS

Serum amylase was within 600 IU/L in all patients.

Among the 96 patients who underwent ERCP, bile was successfully sampled in 87 patients; four patients underwent unsuccessful ERCP, two had bile duct stenosis, three had choledocholithiasis, and these patients were excluded from the present study. Consequently, 17 patients had extremely high biliary amylase levels in the common bile duct above 10000 IU/L, including 11 PBM patients and 6 non-PBM patients. Among the PBM patients, 4 had a choledocal cyst. All patients with biliary amylase levels above 10000 IU/L underwent cholecystectomy. The main clinical characteristics of PBM and non-PBM patients are shown in Tables 1 and 2. The occurrence of gallbladder carcinoma was 45.5% (5/11) in PBM patients, and 50% (3/6) in non-PBM patients. PBM patients included 1 carcinoma limited within the mucosa, while non-PBM patients included 2 (Table 1, Figure 1).

DISCUSSION

Gallbladder carcinoma is known to carry a poor prognosis^[8]. It is therefore essential to identify patients at a high risk for developing gallbladder carcinoma^[9]. The risk of gallbladder carcinoma associated with PBM is substantial; it was reported that the occurrence of biliary cancer in 388 PBM patients without biliary dilatation was 37.9%, including 93.2% with gallbladder carcinoma and 6.8% with bile duct cancer, while that in 1239 PBM

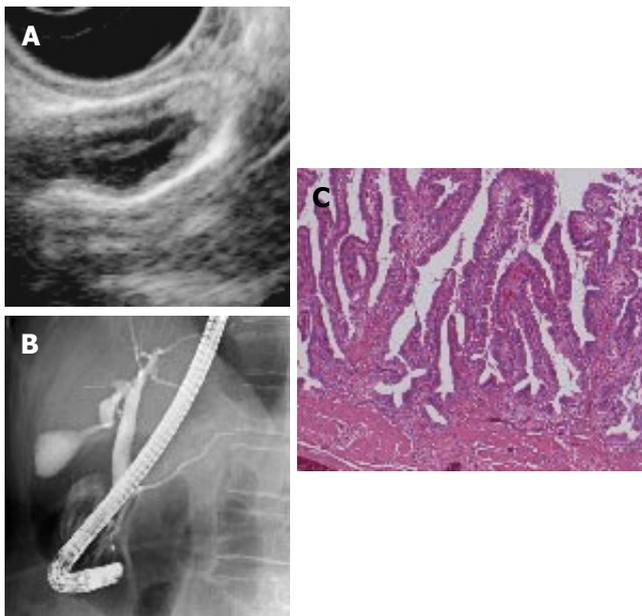

Figure 1 The 52-year old woman who had extremely high biliary amylase level without pancreaticobiliary maljunction and gallbladder carcinoma limited within the mucosa. **A:** Ultrasonography, showing diffuse thickness of the gallbladder wall above 3 mm; **B:** ERCP shows no pancreaticobiliary maljunction and common channel of 7 mm. Biliary amylase levels in the common bile duct was 52600 IU/L; **C:** Gallbladder carcinoma limited within the mucosa (HE, x 40).

patients with choledochal cyst was 10.6%, including 33.6% with extrahepatic bile duct cancer and 64.9% with gallbladder carcinoma^[10]. Numerous studies have shown that pancreatobiliary reflux is a major risk factor for biliary carcinogenesis in patients with PBM; the mixture of bile and pancreatic juice can induce chronic inflammation and genetic alterations and increase cellular proliferation of the biliary tract epithelium, leading to hyperplasia, dysplasia and ultimately carcinoma of the biliary tract mucosa^[11,12].

Pancreatobiliary reflux with extremely high biliary amylase levels was also identified in non-PBM patients in the present study, and 50% of those patients had gallbladder carcinoma. Furthermore it included gallbladder carcinoma limited within the mucosa, and thus detection of pancreatobiliary reflux with extremely high biliary amylase levels might allow management for gallbladder carcinoma at an early stage.

In order to identify pancreatobiliary reflux pre-operatively, secretin-injection magnetic resonance cholangiopancreatography (MRCP) is an option that has proved useful as we have previously reported^[4,5], although high amylase levels in the bile sampled during ERCP is a direct evidence of pancreatobiliary reflux. One of the characteristic findings of ultrasonography associated with pancreaticobiliary maljunction was reported as diffuse thickness of the gallbladder wall above 3 mm, that might reflect mucosal change associated with pancreatobiliary reflux including chronic inflammation and increased cellular proliferation of the gallbladder mucosa^[13]. In the present study, ultrasonographic finding also proved useful to diagnose non-PBM patients with extremely high biliary amylase levels, although the finding was non-specific and was seen in other diseases including chronic cholecystitis with or without gallstone, adenomyomatosis, and liver cirrhosis^[13].

Table 2 Clinicopathological findings in patients with and without pancreaticobiliary maljunction

	non-PBM (n = 6)	PBM (n = 11)
Age (mean ± SD)	63.2 ± 7.2	54.1 ± 12
Female (number)	5/6 (83%)	9/11 (82%)
CBD-Amy (mean ± SD) IU/L	56250 ± 19246	102686 ± 57660
Cholelithiasis (number)	2/6 (33%)	4/11 (36%)
Length of the common channel (mean ± SD) mm	6.7 ± 2.2	23.6 ± 9.2
Gallbladder carcinoma (number)	3/6 (50%)	5/11 (46%)

PBM: Pancreatobiliary maljunction; CBD-Amy: Amylase levels in the common bile duct; SD: Standard deviation.

Reflux of pancreatic juice into the biliary tract is influenced by the function of Oddi's sphincter and the form of the junction of the pancreaticobiliary duct^[14]. One of the mechanisms of pancreatobiliary reflux in non-PBM patients could be a long common channel. Actually, 67% (4/6) of non-PBM patients had a long common channel more than 7 mm in the present study. Misra *et al* reported that a common channel more than 8 mm in length was seen more frequently in patients with gallbladder carcinoma (38%) compared with normal subjects (3%) or patients with gallstones (1%)^[15]. Kamisawa *et al* also reported that the occurrence of gallbladder carcinoma in non-PBM patients with a common channel of more than 6 mm in length was 12%, being significantly higher than that in controls^[16]. They speculated that the longer common channel could be associated with a higher occurrence and a more significant degree of pancreatobiliary reflux, which might be the cause of gallbladder carcinoma, although they did not measure the biliary amylase levels in their study. Another mechanism of pancreatobiliary reflux in non-PBM patients, especially in our two patients with a common channel of 4 mm, might be the dysfunction of the sphincter of Oddi, however, the precise mechanism of pancreatobiliary reflux in non-PBM patients should be further clarified in future studies.

In conclusion, pancreatobiliary reflux with extremely high biliary amylase levels and associated gallbladder carcinoma could be identified in patients with and without pancreaticobiliary maljunction, and those patients might be detected by ultrasonography and bile sampling.

Abstract

AIM: To address the possibility that insulin-like growth factor (IGF)-II is a growth factor and its signaling pathway so as to develop a molecular therapy for hepatoblastoma.

METHODS: Huh-6 and HepG2, human hepatoblastoma cell lines, were used. IGF-II was added to the medium deprived of serum. Western blot analysis was performed to clarify the expression of IGF-I receptor (IGF-IR). Inhibitors of IGF-IR (picropodophyllin, PPP), phosphatidyl-inositol (PI) 3-kinase (LY294002 and Wortmannin), or mitogen-activated protein (MAP) kinase (PD98059) were added to unveil the signaling pathway of IGF-II. Cells were analyzed morphologically with hematoxylin-eosin staining to reveal the mechanism of suppression of cell proliferation.

RESULTS: IGF-II stimulated cells proliferated to 2.7 (269% ± 76%) (mean ± SD) (Huh-6) and 2.1 (211% ± 85%) times (HepG2). IGF-IR was expressed in Huh-6 and HepG2. PPP suppressed the cell number to 44% ± 11% (Huh-6) and 39% ± 5% (HepG2). LY294002 and Wortmannin suppressed the cell number to 30% ± 5% (Huh-6), 44% ± 0.4% (HepG2), 49% ± 1.0% (Huh-6) and 46% ± 1.1% (HepG2), respectively. PD98059 suppressed the cell number to 33% ± 11% for HepG2 but not for Huh-6. When cell proliferation was prohibited, many Huh-6 and HepG2 cells were dead with pyknotic or fragmented nuclei, suggesting apoptosis.

CONCLUSION: IGF-II was shown to be a growth factor of hepatoblastoma *via* IGF-I receptor and PI3 kinase which were good candidates for target of molecular therapy.

INTRODUCTION

Hepatoblastoma (HBL) arises in the liver of infants younger than 3 years of age^[1]. The growth factor and its signaling pathway could be revealed so as to develop a novel molecular therapy for HBL.

Insulin-like growth factor (IGF)-II is a hormone that plays an important role in fetal growth and development. IGF-II is abundantly expressed in fetus, with its concentration decreasing after birth^[2]. Interestingly, IGF-II is detected at high levels in the serum of HBL patients^[3]. Moreover, the expression levels of IGF-II in tumor tissues are higher than those of surrounding non-tumor tissues in surgical specimens from HBL patients due to biallelic expression of the gene by loss of the methylated status of the promoter^[4]. These facts indicate that IGF-II is deeply involved in the carcinogenesis and progression of HBL.

IGF-II binds to insulin receptor (IR), IGF-I receptor (IGF-IR), and IGF-II receptor^[5]. With the binding of IGF-II, IR mediates glucose metabolism, such as insulin. IGF-IR mediates the degradation of IGF-II, acting as a tumor-suppressor gene. It was expected that IGF-IR mediated the stimulation of proliferation by IGF-II. Indeed, antibody to IGF-IR successfully suppressed the proliferation of HepG2^[6]. Once IGF-II binds to IGF-IR, the receptor autophosphorylates and activates phosphatidyl-inositol (PI) 3-kinase or mitogen-activated protein (MAP) kinase. Further down-stream pathways modulate the gene expression to perform the role of IGF-II.

However, it is not clear whether IGF-II promotes the cell proliferation of HBL, or the signaling pathway of IGF-II to mediate the stimulation of cell proliferation.

Here, we tried to address the possibility of IGF-II in HBL as a growth factor. We also tried to clarify its signaling pathway with inhibitors to signaling pathways, pursuing a potential application for a molecular therapy.

MATERIALS AND METHODS

Cell culture

Huh-6 and HepG2 hepatoblastoma cell lines, were purchased from RIKEN Cell Bank (Tsukuba, Japan) and cultured in Dulbecco's Minimum Essential Medium (Sigma, St. Louis, MO) supplemented with 100 g/L fetal bovine serum (FBS) (Trace Scientific, Melbourne, Australia) in 50 mL/L at 37°C in a humidified chamber. Both cell lines are IGF-IR positive^[7]. For hematoxylin-eosin (H&E) staining, cells were spread onto chamber slides.

Cell viability assay

Freshly thawed cells were seeded onto 10 cm dishes (Asahi Techno Glass, Funabashi, Japan). When they reached sub-confluence, they were trypsinized, harvested, and spread onto 96-well flat-bottom plates with (Asahi Techno Glass) at a density of 1000 cells per well. Following 24 h of culture under DMEM with 100 g/L FBS, medium was changed to DMEM without FBS to quench the FBS effects. After 24 h of culture under DMEM without FBS, IGF-II (Wako Pure Chemicals, Osaka, Japan) was added to the medium. Seventy-two hours later, 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium inner salt (MTS) assay was performed according to the manufacturer's instructions (Promega Corporation, Tokyo, Japan). MTS is bioreduced by cells into a colored formazan product that reduces absorbance at 490 nm. The absorbance was analyzed with a multiple plate reader at a wavelength of 490 nm with a BIO-RAD Model 550 microplate reader (Bio-RAD, Hercules, CA). When LY290042 (Wako Pure Chemicals), PD98059 (Wako Pure Chemicals), Wortmannin (Wako Pure Chemicals), and picropodophyllin (PPP) (Wako Pure Chemicals) were used, each was added to the medium 30 min prior to the addition of IGF-II.

Western blot analysis

Twenty microgram of protein isolated from cultured cells was subjected to sodium dodecyl sulphate polyacrylamide gel electrophoresis, and transferred to a nylon filter. Primary antibodies were polyclonal rabbit anti-IGF-IR antibody (Cell Signaling Technology, Danvers, MA) and mouse monoclonal anti-Tubulin- α antibody (Lab Vision, Fremont, CA). Second antibodies were horseradish peroxidase (HRP)-linked anti-rabbit antibody (Amersham Bioscience, Tokyo, Japan) and HRP-linked anti-mouse antibody (Amersham Bioscience). Dilutions were 1:500 for primary antibodies, and 1:1000 for second antibodies. The filter was reprobred with anti-Tubulin- α antibody. The specific antigen-antibody complexes were visualized by enhanced chemiluminescence (GE Healthcare Bio-Sciences Corp, Piscataway, NJ).

Statistical analysis

Cell proliferation, demonstrated by MTS assay, was

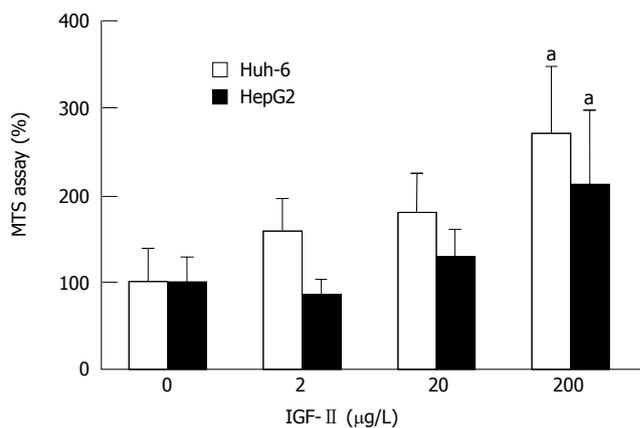

Figure 1 IGF-II stimulated proliferation of hepatoblastoma cells. IGF-II was added to the medium without serum, followed by MTS assay, a modified method of MTT assay ($^*P < 0.05$).

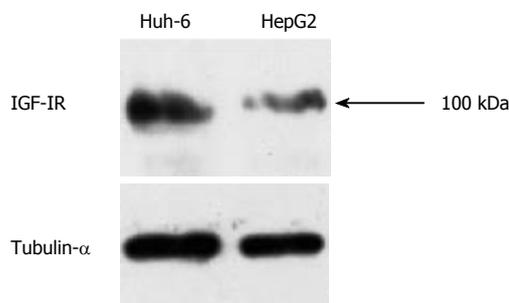

Figure 2 Western blot analysis clearly shows specific bands to IGF-IR. Protein was isolated 72 h after stimulation with IGF-II (200 µg/L). The same membrane was reprobred with anti-Tubulin- α antibody to confirm an equal amount of protein loadings.

analyzed statistically by one-factor analysis of variance. Statistical analysis was performed with JMP5.0J (SAS Institute Japan, Tokyo, Japan). $P < 0.05$ was accepted as statistically significant.

RESULTS

IGF-II stimulated proliferation

Huh-6 and HepG2 proliferated as the concentration of IGF-II increased (Figure 1). When IGF-II was 200 µg/L, cell proliferation of Huh-6 and HepG2 were 2.7 times ($269\% \pm 76\%$) (mean \pm SD) and 2.1 times ($211\% \pm 85\%$) higher than those at 0 µg/L of IGF-II, respectively ($P < 0.05$, $n = 3$).

IGF-IR expressed in Huh-6 and HepG2

Western blot analysis was performed to analyze expression of IGF-IR in Huh-6 and HepG2 since IGF-IR mediates proliferation activity of IGF-II. Protein was isolated from Huh-6 and HepG2 72 h after stimulation with IGF-II (200 µg/L). IGF-IR was expressed in Huh-6 and HepG2 (Figure 2). Tubulin- α was expressed to confirm that equal amount of protein was loaded (Figure 2).

PPP suppressed the stimulation of IGF-II

PPP, a selective inhibitor of IGF-IR, was used to show

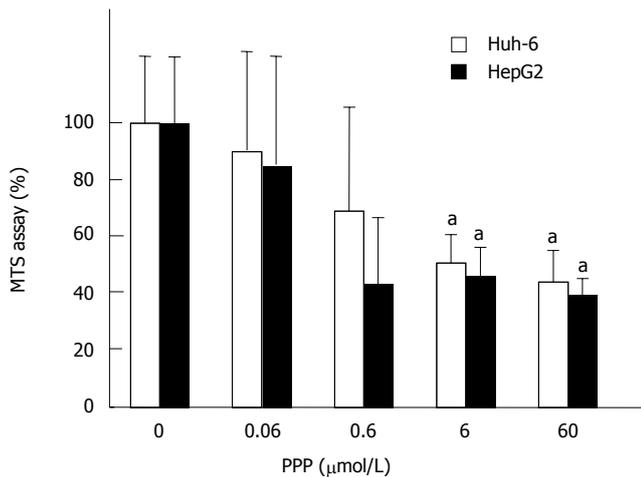

Figure 3 PPP was added to the medium 30 min prior to the stimulation with IGF-II (200 μg/L) and suppressed proliferation of Huh-6 and HepG2 (^a $P < 0.05$).

that IGF-IR mediated the signal of IGF- II (Figure 3). PPP at 60 μmol/L suppressed the cell number of Huh-6 and HepG2 stimulated with 200 μg/L of IGF- II to 44% ± 10% and 39% ± 5%, respectively ($P < 0.05$, $n = 3$).

Stimulation of IGF- II was suppressed by LY294002 and Wortmannin

LY294002 and Wortmannin, specific inhibitors of PI3 kinase, were used to reveal that PI3 kinase mediated the signal of IGF- II (Figure 4). LY294002 at 50 μmol/L and Wortmannin at 200 μmol/L suppressed the cell numbers of Huh-6 and HepG2 stimulated with 200 μg/L of IGF- II to 30% ± 5% and 44% ± 0.4% (Figure 4A) ($P < 0.05$, $n = 3$), and 49% ± 1.0% and 46% ± 1.1% (Figure 4B) ($P < 0.05$, $n = 3$), respectively. PD98059, a specific inhibitor of MAP kinase, was used to clarify whether MAP kinase mediated the signal of IGF- II. PD98059 did not suppress the proliferation of Huh-6 even at 20 μmol/L, while it suppressed that of HepG2 to 33% ± 11%, which was statistically significant ($P < 0.05$, $n = 3$) (Figure 4C).

Suppression of cell proliferation was due to apoptosis

Cultured cells were HE stained to analyze the morphological change 72 h after addition of inhibitors, Huh-6 with PPP, LY294002, and Wortmannin but not with PD98059 while HepG2 with PPP, LY294002, Wortmannin, and PD98059 (Figure 5). Most of the dead cells had pyknotic or fragmented nuclei, indicating apoptosis.

DISCUSSION

The existence of a growth factor in HBL has not been confirmed. It is reported that the expression of IGF- II is elevated in tumor tissues and serum of HBL patients, but its exact role is not clear in terms of carcinogenesis^[8]. In this study, we demonstrated that IGF- II stimulated the proliferation of HBL cell lines. A previous report showed that IGF- II does not stimulate the proliferation of HepG2^[6]. They added IGF- II at a concentration of 200 μg/L as well as fetal bovine serum. We added 200 μg/L of IGF- II to the medium deprived of serum. Serum

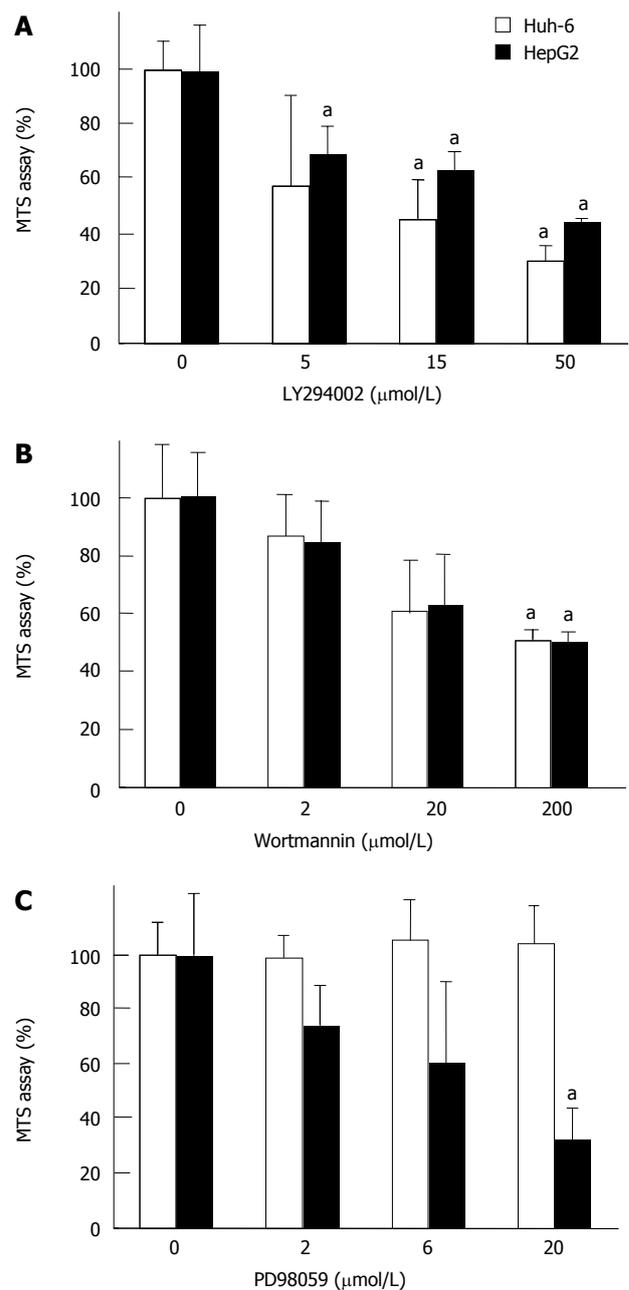

Figure 4 LY294002 or Wortmannin, selective inhibitors of PI3 kinase, or PD98059, a selective inhibitor of MAP kinase, was added to the medium 30 min prior to the stimulation with IGF-II (200 μg/L). LY294002 (A) and Wortmannin (B) suppressed the proliferation of Huh-6 and HepG while PD98059 suppressed HepG2 (C) (^a $P < 0.05$).

stimulates the proliferation of HepG2 to obscure the effect of IGF- II. Moreover, we analyzed Huh-6, another human hepatoblastoma cell line, and revealed that IGF- II stimulated the proliferation of Huh-6^[9]. Our data clearly demonstrated that IGF- II stimulated the proliferation of hepatoblastoma cell lines. Interestingly, HepG2 produces IGF- II and antisense oligonucleotides of IGF- II suppress the proliferation. It may be safe to conclude that IGF- II acts as a growth factor for HBL by autocrine action^[6,10].

The previous report suggested that IGF- II stimulates proliferation *via* IGF-IR^[6]. Our data clearly showed that IGF-IR was expressed in Huh-6 and HepG2. Since IGF-IR mediates proliferation activity of IGF- II, it was expected

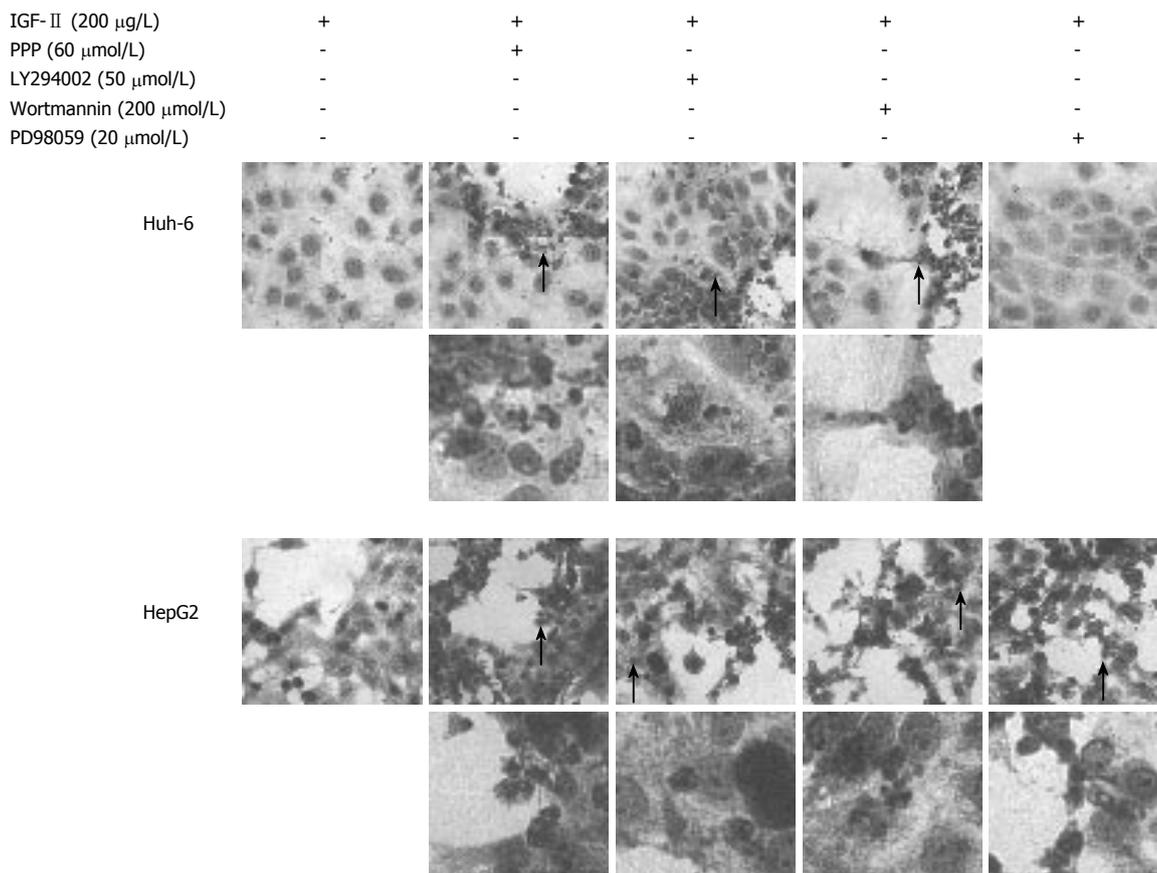

Figure 5 Huh-6 and HepG2 dead due to apoptosis. HE staining was performed to analyze morphological changes after addition of inhibitors. Many Huh-6 cells were dead treated with PPP (60 μ mol/L), LY294002 (50 μ mol/L), or Wortmannin (200 μ mol/L) while HepG2 with PPP, LY294002, Wortmannin, or PD98059 (20 μ mol/L). Most of the dead cells had pyknotic or fragmented nuclei (arrows), suggesting apoptosis. Areas indicated by arrows were magnified (x 400).

that an inhibitor of IGF-IR suppressed proliferation^[5]. NVP-AEW541, a tyrosine kinase inhibitor, suppresses the proliferation of HepG2^[7]. We used the commercially available PPP, another tyrosine kinase inhibitor, and it successfully suppressed the proliferation of Huh-6 and HepG2^[11]. Our data on HepG2 was consistent with that of the previous report, and thus was strong evidence that IGF- II mediated the signaling pathway of IGF- II. Since IGF-IR is not involved in glucose metabolism, an inhibitor of IGF- II would be a good candidate for molecular therapy for hepatoblastoma.

PI3 kinase and MAP kinase are the main downstream molecules of IGF-IR^[5]. It was reported that the proliferation of HepG2 cells is suppressed by LY294002 and PD98059^[12], and our results confirmed this. Our results also showed that LY294002 suppressed the proliferation of Huh-6, but PD98059 did not. One may speculate that the stimulation of IGF- II was transmitted *via* PI3 kinase and MAP kinase in HepG2, but only *via* PI3 kinase in Huh-6. Wortmannin, another inhibitor of PI3 kinase, suppressed the proliferation of Huh-6 and HepG2 stimulated by IGF- II, confirming the results of LY294002.

MTS assay measured cell viability, representing cell proliferation. The mechanism of suppression of cell proliferation, however, was not known. To unveil the mechanism, morphological analysis was performed with

HE staining. Many of Huh-6 cells were dead with PPP, LY294002, and Wortmannin while HepG2 with PPP, LY294002, Wortmannin, and PD98059. Nuclei of dead cells were pyknotic or fragmented, indicating apoptosis. It is reported that DNA ladder formation is observed when HepG2 is treated with LY294002, Wortmannin, or PD98059^[5]. It was suggested that Huh-6 and HepG2 were dead due to apoptosis when IGF-I signaling pathway was inhibited. It may be concluded that PI3 kinase would be a better target than MAP kinase for the molecular therapy of hepatoblastoma.

Abstract

AIM: To investigate the role of the polymorphism of *p53* codon 72 in early gastric cancer (EGC) and advanced gastric cancer (AGC) in Korean patients.

METHODS: DNA was extracted from blood samples of gastric cancer patients ($n = 291$) and controls ($n = 216$). In the *p53* codon 72 genotypes were determined by PCR-RFLP.

RESULTS: Patients with gastric cancer had a significantly higher frequency of the homozygous proline (Pro) allele than the control ($P = 0.032$). Patients with AGC had a significantly higher frequency of the *Arg/Arg* (arginine) allele ($P = 0.038$) than EGC and a similar *Pro/Pro* allele. The signet ring cell type had a higher frequency of the *Pro/Pro* allele than other types ($P = 0.031$). The *Pro/Pro* genotype carries a 3.9-fold increased risk of developing gastric cancer (95% CI, 1.3-15.4, $P = 0.039$) when compared to *Arg/Arg* and *Arg/Pro* genotypes and to develop EGC is a 5.25 fold increased risk (95% CI, 1.8-19.6, $P = 0.021$).

CONCLUSION: The *Pro/Pro* genotype of the *p53* codon 72 polymorphism carries a higher risk for gastric cancer in general and is also associated with a much higher risk for EGC than AGC.

INTRODUCTION

Gastric cancer is one of the most common malignancies worldwide, although the overall incidence of gastric cancer has been decreasing over the past few decades. Chronic *H pylori* infection and dietary factors, such as those high in salt or nitrate, and nutritional deficiencies have been associated with gastric cancer^[1]. Gastric carcinogenesis is a complex, multistep, and multifactorial process, in which many factors are implicated. The majority of gastric cancers are thought to be caused by environmental factors that result in damage to the mucosa and that inhibit its ability to repair itself^[2]. This response is regulated, in part, by inhibitory and stimulatory factors that are products of proto-oncogenes and tumor suppressor genes^[3].

TP53 gene, an important tumor suppressor gene, encoded *p53* protein. The *p53* tumor suppressor protein was initially isolated in 1979 as a 53 kDa protein that was associated with SV 40 large T antigen^[4]. It was a decade before *p53* was recognized as an important tumor suppressor because of its frequent mutation in human cancers. A large number of human cancers show the evidence of inactivation of the *p53* pathway, suggesting that malignant transformation requires reduction or elimination of *p53*'s function as "guardian of the genome". It is estimated that up to 50% of human cancers carry a mutation of the *p53* gene^[5,6].

Germ line polymorphism of genes involved in multiple steps of carcinogenesis may also account for genetic difference in stomach cancer susceptibility. The *p53* gene is the most intensively studied human gene because of its role as a central tumor suppressor, and has been widely studied in gastric cancer. However, although more than 75% of gastric cancer showed *p53* overexpression, less than 30% had mutation in this gene^[7]. The codon 72 polymorphism is located in exon 4 of the *p53* gene, a region involving very few mutations^[8]. At least two forms of wild-type *p53* protein exist among major human populations; these forms are ascribed to amino acid replacement at codon 72 of *Arg* (CGC) by *Pro* (CCC) in the domain of transactivation of the *p53* protein, though the functional difference between them is unknown. *Pro* variant allele of this *p53* polymorphism has been studied as a potential risk factor for cancer of the lung, breast,

and large bowel, with inconsistent results. Shepherd *et al*^[8] examined the relationship between codon 72 polymorphism and their susceptibilities to gastric cancer in a group of American gastric cancer patients.

In this study, we examined the genotypic frequency of codon 72 in early gastric cancer (EGC) and advanced gastric cancer (AGC) in 292 Korean patients to investigate the role of the *p53* polymorphism.

MATERIALS AND METHODS

Patients

Two hundred twenty two diagnosed gastric cancers were recruited from Ewha Womans University Mokdong Hospital from 2001 to 2005. Their mean age was 56 years (range, 26-88 years); 171 were males and 121 were females. Of the 292 patients, 189 (64.7%) showed advanced gastric cancer, 103 (35.3%) showed early gastric cancer. Two hundred sixteen controls were randomly selected from subjects attending routine medical check-ups (mean age 58 years; range 24-85 years; 128 males and 88 females) who were not affected with stomach cancer by endoscopy. Their details are presented in Table 1. Blood specimens, including serum, plasma, and white blood cells, from the study subjects were also obtained and frozen at -70°C for subsequent analysis. Informed written consent was obtained from all the enrolled patients.

DNA extraction

Genomic DNAs were isolated from peripheral whole blood, 200 μ L (which has been treated with EDTA) by a DNA purifying kit (QIAamp DNA kit Blood Mini Kit, Qiagen, Germany, Hilden) according to the manufacture's instructions.

p53 codon 72 polymorphism

Genotyping of *p53* at codon 72 in exon 4 [M22884. Human phosphoprotein (gi:189467)] was carried out by a polymerase chain reaction (PCR) amplification procedure using primers (*p53*-S: 5'-ATC TAC AGT CCC CCT TGC CG-3 and *p53*-AS: 5'-GCA ACT GAC CGT GCA AGT CA-3'). The amplification reaction was performed in a 6 μ L (0.1 μ g/ μ L) genomic DNA template, 0.1 μ L (10 nmol/mL) of each primer, 1.6 μ L (5 mmol/L per mL) dNTP, 0.1 μ L (0.5 U/ μ L) Taq polymerase (Promega, Madison, WI, USA), and 2 μ L of 10X reaction buffer (200 mmol/L per mL Tris-HCL (pH8.3), 500 mmol/L per mL KCL, and 30 mmol/L per mL MgCl₂). PCR was carried out by 30 cycles under the following conditions: 1 min at 95°C for denaturation, 1 min at 62°C for primer annealing, and 1 min at 72°C for primer extension, using the GeneAmp PCR System 9600 (Applied Biosystem, Foster City, CA). The PCR product was visualized on a 2% agarose gel by electrophoresis, followed by ethidium bromide staining. This generates a 296-base pair fragment. The restriction enzyme BstUI (10 unit, New England Biolabs, Beverly, MA) digests (for 3 h at 60°C) within the sequence corresponding to the *Arg* codon (CGC) at position 72 to generate two visible fragments of 169 bp and 127 bp and leaves the *Pro* allele uncut (Figure 1).

Table 1 Demographic characteristics of patients with stomach cancer (*n* = 292)

	<i>n</i>

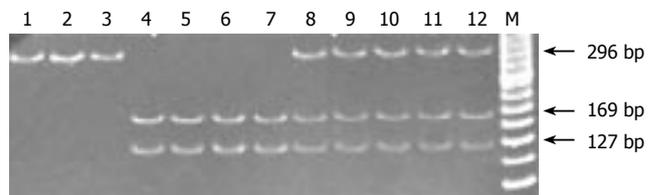

Figure 1 Restriction fragment length polymorphism of PCR-amplified fragment by BstUI. The Lane 1-3 showed only a single undigested band at 296 bp (homozygote of *Pro*), the fragment from lane 4-7 gave two bands at 169 and 127 bp (homozygote of *Arg*), while the fragment from lane 8-12 showed three bands at 296, 169 and 127 bp (heterozygote of *Arg/Pro*). M was a DNA marker.

Statistical analysis

Frequency tables were constructed using the SPSS (11.0 version) statistical package with statistical significance using the χ^2 test. The odd ratios and 95% Confidence interval (CI) were calculated as an approximation of relative risk and adjusted for confounding factors such as age and gender using a logistic regression model.

RESULTS

Distribution of the three genotypes of the *p53* gene

We determined the frequency of the three phenotypes of the *p53* gene in the patients with stomach cancer and controls (Table 2). Genotypes *Arg/Arg*, *Arg/Pro*, and *Pro/Pro* were found 41.2%, 47.7%, and 11.1% in individual controls and 34.5%, 43.1%, and 22.3% in the patients of stomach cancer, respectively. Distribution patterns of the germ line *p53* polymorphism of the patients with stomach cancer included EGC and AGC showed in Table 2. We observed a dramatically increased frequency of *Pro/Pro* allelotype in stomach cancer patient, especially in the patients of EGC.

A logistic regression analysis suggests that the homozygous 72 *Pro* genotype carries a 3.9-fold increased risk of developing gastric cancer (95% CI, 1.3-15.4, *P* =

Table 2 Frequency of the codon 72 genotype

	<i>n</i>	<i>Arg/Arg</i> (%)	<i>Arg/Pro</i> (%)	<i>Pro/Pro</i> (%)
Control	216	89/216 (41.2)	103/216 (47.7)	24/216 (11.1)
Stomach cancer	292	101/292 (34.5)	126/292 (43.1)	65/292 (22.3) ^{a,1}
AGC	189	75/189 (39.7) ^d	76/189 (39.9)	38/189 (20.4) ^b
EGC	103	26/103 (25.8)	50/103 (48.1)	27/103 (26.1) ^{c,2}

^a*P* = 0.032, control vs stomach cancer; ^b*P* = 0.029, control vs AGC; ^c*P* = 0.027, control vs EGC; ^d*P* = 0.038, AGC vs EGC; ¹OR = 3.9 (95% CI, 1.3-15.4, *P* = 0.039); ²OR = 5.25 (95% CI, 1.8-19.6, *P* = 0.021); OR: Odd ratio; CI: Confidence interval.

0.039) when compared to *Arg* homozygous and *Arg/Pro* heterozygous. The risk for 72 *Pro* homozygous patients to develop early gastric cancer is 5.35 (95% CI, 1.8-19.6, *P* = 0.021).

***p53* polymorphism and histology grading of stomach cancer**

We examined the frequency difference in each genotype of *p53* by histological type of all stomach cancers. Germ line *p53* polymorphism was associated with stomach cancer, especially the signet ring cell type of adenocarcinoma (*P* = 0.031, Table 2). There was no relationship between patient gender, tumor stage, the depth of invasion in the wall, histologic type of cancer (Laurence classification: intestinal and diffuse types) and the distribution of codon 72 genotypes.

DISCUSSION

The identification of genes involved in cancer development is critical for uncovering the molecular basis of cancer. The *p53* tumor suppressor protein is essential in the control of cell growth, apoptosis and the maintenance of genomic stability. Loss of *p53* function caused by genomic alterations or interaction with environmental and bacterial products has been suggested as a critical step in multistage human carcinogenesis^[9].

The *p53* gene consists of 11 exons; exons 2-11 code for the protein of 393 aminoacids. The majority of *p53* mutations identified have been found in exons 5-8. However, mutations outside exons 5-8 may occur and they were chiefly observed in exons 4 and 10^[10,11]. At least 10 different polymorphisms have been detected in the human genomic *p53*^[12]. The functional significance of these polymorphisms is currently unknown. The hypothesized relationship between the codon 72 *p53* polymorphism and cancer susceptibility does not have any mechanistic basis. The *Pro* variant allele of the *p53* polymorphism at codon 72 may not directly affect the *p53* function. It may be in linkage disequilibrium with an as-yet-undefined functional polymorphism. However, the single-codon difference of the *p53* gene has been demonstrated to result in structurally different proteins^[13]. The polymorphism is localized within a region of polypeptide that was lacking in a deletion mutant of mouse *p53* that had an enhanced ability to immortalize primary rat cells^[14,15].

In a literature review, there was little report about investigation of *p53* gene polymorphism between AGC

Table 3 Distribution of *p53* genotypes and histopathological classification among the patients with gastric cancer

Histopathological classification (<i>n</i>)	<i>p53</i> genotypes		
	<i>Arg/Arg</i>	<i>Arg/Pro</i>	<i>Pro/Pro</i>
Control (216)	89/216(41.2)	103/216(47.7)	24/216(11.1)
Differentiation			
Well to poorly (246)	88/292 (30.1)	151/292 (51.7)	53/292 (18.2)
Signet ring cell (46)	17/46 (37.0)	11/46 (23.0)	18/46 (39.1) ^{a,b}
Tumor histologic type			
Intestinal type (140)	48/140 (34.2)	60/140 (42.8)	31/140 (22.1)
Diffuse type (152)	53/152 (34.8)	66/152 (43.4)	34/152 (22.4)

^a*P* = 0.031, Well to poorly differentiation vs Signet ring cell; ^b*P* = 0.019, Control vs Signet ring cell.

and EGC comparing with control. We have observed that TP53 codon 72 genotype in stomach cancer and control subjects. Our data further suggest that a *p53* genetic polymorphism was associated with the susceptibility for stomach cancer, especially advanced stomach cancer.

There were several studies conducted to investigate the association between the codon 72 *p53* polymorphism and lung cancer or gastric cancer. The risk increased approximately twofold for smoking-related lung cancer among individuals carrying the *Pro/Pro* genotype compared with those with other genotypes of the codon 72 *p53* polymorphism^[16-18]. A recent study in the patients of gastric cancer showed the significant difference from healthy control, with 48.6% *Arg/Arg* and 3.6% *Pro/Pro* in gastric cancer patients compared with 41.5% and 10.9% in healthy controls^[19]. They showed an increased frequency of *Arg/Arg* genotype in cancer patients at age 75 or more than at a younger age. They suggested the prognosis in patients with *Pro* allele (proline homozygote or *Pro/Arg* heterozygotes) was worse than that those with *Arg/Arg* genotype. They also showed that preferential frequency of codon 72 *Arg p53* acts as a survival factor in gastric cancer patients who have homozygous *Arg* alleles which confer a late start of gastric cancer when compared with those with the *Pro* allele.

In this study we found that the distribution of genotypes had significant difference between the patients of stomach cancer and controls, with 34.5% *Arg/Arg* and 22.3% *Pro/Pro* in stomach cancer patients compared with 41.2% and 11.1% in controls (*P* = 0.032). We observed a significantly higher distribution of *Pro/Pro* genotype in the patient with stomach cancer, especially in the patients with EGC than control. Also in comparison between AGC and EGC, the frequency of *Arg/Arg* genotype was higher than the frequency of AGC, statistically (*P* = 0.038).

The reason for the tissue-specific difference of the germ line *p53* polymorphism was unknown, though an association with histopathologic grading was suggested for gastric cancer^[16]. In this study, we divided two groups whether signet ring cell type or not. Generally, we knew that the stomach cancer with signet ring type was highly malignant and had worse prognosis than other cell types. There was statistically significant difference that the patients with signet ring cell type had a higher ratio of *Pro/Pro* genotype than non-signet ring cell type (*P* = 0.031, Table 3). So the association with histopathologic grading

may suggest that germ line p53 polymorphism is involved in survival as a clinical prognostic factor as well as cancer susceptibility. Further studies are needed to examine this possibility.

There were several explanations about the role of different genotypes. First, transcriptional properties are different. It has been shown that the *Arg/Arg* and *Pro/Pro* variants differ in binding activity at transcription, to activate transcription, and to induce apoptosis or cell cycle arrest^[20]. The p53 *Arg/Arg* variant induces apoptosis with faster kinetics more efficiently than the p53 *Pro/Pro* variant and the p53 *Arg/Arg* variant is a better inducer of transcription^[19]. Namely, if there was a high proportion of *Arg/Arg* genotype in stomach cancer, it induced the efficient apoptosis or cell cycle arrest, and then it could be better prognosis. Second, wild-type p53 protein is rapidly degraded, and has a short half-life and low intracellular levels. Stabilization of the protein following an appropriate stimulus such as DNA damage is a physical regulation to increase function^[6]. Different structure of p53 proteins resulting from a substitution of *Pro* for *Arg* at codon 72 may have different functions in the responsiveness to different stimuli caused by diverse carcinogens such as *H pylori*, dietary, or nutritional deficiency. The reaction of *Pro* genotype and various carcinogens may have more carcinogenic properties. *H pylori* is the well-known cause of chronic gastritis, gastro-duodenal ulcer, and gastric cancer. Some reports studied the relationship between p53 polymorphism and *H pylori* and found the genotypic frequency of p53 was similar between cases and controls^[21,22]. We cannot confirm results of *H pylori* status of all patients with stomach cancer in this study, we cannot represent the relationship between *H pylori* and p53 polymorphism.

In conclusion, the *Pro/Pro* genotype of the p53 codon 72 polymorphism carries a higher risk for gastric cancer in general (3.9-fold) and is also associated with a higher risk for EGC (5.25-fold) than AGC. Although this finding is provocative, it should be considered preliminary because of the limited sample size. Clearly, a well-designed follow-up study with a larger number of samples is needed to confirm these findings.

Abstract

AIM: To determine the genotypes in Mexican hepatitis B virus (HBV) isolates and characterize their precore and core promoter mutations.

METHODS: Forty-nine HBV isolates of Mexico obtained from sera of 15 hepatitis patients, 6 hemodialysis patients, 20 men seeking HIV testing, and 8 AIDS patients were analyzed. HBV isolates were amplified by PCR, and genotyped by line probe assay (INNO-LiPA HBV Genotyping; INNOGENETICS N V, Ghent, Belgium). HBV genotype confirmation was performed by DNA sequencing part of the sAg region. Precore and core promoter mutation characterization was performed by line probe assay (INNO-LiPA HBV PreCore; INNOGENETICS N V, Ghent, Belgium).

RESULTS: Overall, HBV genotype H was found in 37 (75.5%) out of the 49 isolates studied. HBV genotypes G, A, and D were found in 5 (10.2%), 4 (8.2%), and 3 (6.1%) isolates, respectively. HBV genotype H was predominant in isolates from hemodialysis patients (100%), hepatitis patients (80%), and men seeking HIV testing (75%), and accounted for half of infections in AIDS patients (50%). Six (12.2%) out of the 49 HBV isolates showed both wild type and mutant populations at precore codon 28. These mixed wild type and precore mutant populations were observed in one HBV genotype A isolate and in all HBV genotype G isolates. A dual variant core promoter mutation was observed in 1 (2%) of the isolates, which was genotype H.

CONCLUSION: HBV genotype H is highly predominant in HBV isolates of Mexico followed by genotypes G, A and D. A low frequency of precore and core promoter

INTRODUCTION

Hepatitis B virus (HBV) is an important cause of morbidity and mortality worldwide. It is estimated that 2 billion people are infected with HBV and 350 million individuals suffer from chronic HBV infection in the world^[1,2]. Chronic HBV infection may lead to hepatic fibrosis, cirrhosis and hepatocellular carcinoma (HCC)^[3]. In addition, HBV infection is the 10th leading cause of death worldwide^[1]. HBV is a hepadnavirus that possesses a double stranded DNA genome^[4]. The genetic organization of HBV has been described elsewhere^[4]. Briefly, HBV genome consists of four partly overlapping open reading frames: *S* that encodes for envelope proteins (HBsAg), *C* for core protein (HBcAg) and e antigen (HBeAg), *P* for polymerase protein and *X* for transcriptional transactivator protein^[4]. Based on sequence divergence of the entire genome of > 8%, HBV genomes have been classified into 8 genotypes designated A to H^[5,6]. The distribution of HBV genotypes is geographically restricted. In the American continent, HBV genotypes A and C are common in the USA^[7,8], while genotype F is predominant in Central American countries^[9]. In Europe, HBV genotype D is prevalent in Mediterranean Europe^[10], while genotype A is frequent in Northwest Europe^[11]. In the African continent, HBV genotype E is common in the Sub-Saharan Africa^[12], and genotype A in South Africa^[13]. In the Asian continent, HBV genotypes B and C predominate in south east countries^[14-16], while genotype D is prevalent in central Asia^[17]. Reports indicate that HBV genotypes are related with the severity of liver disease. HBV genotype C has

been associated with the development of liver cirrhosis and hepatocellular carcinoma^[14,18-21]. In addition, HBV genotypes are related with the response to antiviral therapy. Asian studies have shown that compared to HBV genotype B, genotype C has a lower response to interferon alpha (IFN- α) therapy^[22,23]. A recent European randomized trial showed that patients infected with HBV genotypes A and B respond significantly better to pegylated IFN- α -2b alone or in combination with lamivudine than patients infected with HBV genotypes C and D^[24]. Mutations in the precore and core promoter regions of HBV have been also related with genotypes. Precore and core promoter mutations have been observed mainly in HBV genotypes D and B^[25-27], as well as A and C^[25,28,29], respectively.

Little is known about the molecular epidemiology of HBV in Mexico. A previous study on HBV genotypes published in 1998 showed that HBV genotype F is predominant in Mexico^[30]. However, more recently it was discovered that HBV genotype F is divergent^[31], to the extent that a new genotype is split off from genotype F, this new genotype has been designated as HBV genotype H^[9]. Thus some divergent strains formerly classified as HBV genotype F could now be classified as HBV genotype H. Therefore, in order to obtain an updated classification we sought to determine the HBV genotypes and characterize the precore and core promoter mutations in HBV isolates of Mexico.

MATERIALS AND METHODS

HBV isolates

Forty-nine HBV isolates of Mexico were analyzed. HBV isolates were obtained from serum samples of 15 hepatitis patients, 6 hemodialysis patients, 20 men seeking HIV antibody testing, and 8 AIDS patients. All samples were collected in Mexico City and Guadalajara City; both cities are located in central Mexico. Participants were of Mestizo ethnicity. All samples were HBsAg positive. HBeAg, anti-HBe, and HBV DNA levels were not determined. Men seeking HIV antibody testing came from a high risk population for sexually transmitted infection acquisition. Seropositivity for anti-HBc among them (30.4%) was associated to men who had sex with men exclusively and seropositivity for both HIV and herpes simplex virus type 2^[32].

HBV DNA detection and genotyping

HBV DNA was extracted from 200 μ L of serum by using the high pure PCR template preparation kit (Roche Applied Science, Penzberg, Germany) as recommended by the manufacturer. HBV DNA was amplified with HBV pol gene domain B and C primers (INNO-LiPA HBV DR amplification, INNOGENETICS N. V., Ghent, Belgium) by nested PCR as described in the product insert. Primer sequences were used as previously described^[33]. PCR conditions were as follows: 40 cycles at 94°C for 30 s, at 45°C for 30 s and at 72°C for 30 s. HBV genotyping was performed by INNO-LiPA HBV genotyping (INNOGENETICS N. V., Ghent, Belgium) following the manufacturer's instructions.

Sequence analysis was done directly on the second round PCR products using the big dye terminator V3.1 cycle sequencing kit of Applied Biosystems. Sequencing PCR was performed for 25 cycles (at 95°C for 10 s, at 50°C for 5 s, at 60°C for 4 min) and purified on a sephadex column. Three μ L dextran blue/deionised formamide loading buffer was added to the dried pellet and 1 μ L was then loaded on a 4.5% acrylamide slab gel. After electrophoresis of 14 h on the automated sequencer ABI377, data analysis was done using software sequencer 4.1.2.

HBV precore and core promoter mutation characterization

HBV DNA was additionally amplified with basal core promoter and precore primers (INNO-LiPA HBV PreCore amplification, INNOGENETICS N. V., Ghent, Belgium) by nested PCR as recommended by the manufacturer. Primer sequences were used as previously described^[25]. PCR conditions were as follows: 40 cycles at 94°C for 30 s, at 50°C for 30 s and at 72°C for 30 s. Characterization of precore mutations was performed by INNO-LiPA HBV precore (INNOGENETICS N. V., Ghent, Belgium) according to the manufacturer's instructions. This method could identify nucleotide polymorphism at nt 1762 and nt 1764 in the basal core promoter and at codon 28 in the precore region of HBV^[34].

RESULTS

HBV genotyping by INNO-LiPA

For all the 49 HBV isolates, INNO-LiPA HBV genotyping assay was able to provide a genotype result. HBV genotype H was found in 36 (73.5%) out of the 49 isolates studied, while HBV genotypes G, A, D and F were found in 5 (10.2%), 4 (8.2%), 3 (6.1%) and 1 (2.0%) isolates, respectively.

HBV genotyping by DNA sequencing

Thirty-two out of the 36 isolates of HBV genotype H, all 5 isolates of genotype G, and only 1 isolate of genotype F genotyped by INNO-LiPA were selected for DNA sequencing confirmation. All 32 isolates of genotype H and all 5 isolates of genotype G were confirmed by phylogenetic analysis of the HBsAg sequences. However, sequencing and subsequent phylogenetic analysis of the HBV genotype F showed a genotype H. This was caused by a single nucleotide mismatch with the probe on line 11 of the INNO-LiPA HBV genotyping, abolishing the reaction with this probe. This in turn led to a single reactivity with the genotype F probe on line 15. When we compared the HBV genotype H sequences obtained in this study with other published sequences by means of the phylogenetic program PHYLIP, we found that our sequences formed two separate branches within genotype H (Figure 1).

Thus, the final adjusted prevalences of HBV genotypes were 37 isolates (75.5%) of genotype H, 5 isolates (10.2%) of genotype G, 4 isolates (8.2%) of genotype A, and 3 isolates (6.1%) of genotype D. HBV genotype H was predominant in the hepatitis patients, men seeking HIV

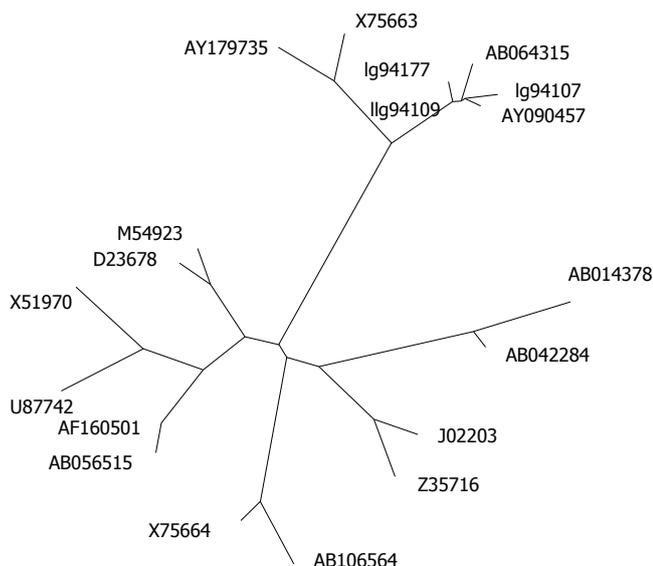

Figure 1 Phylogenetic tree constructed with HBV sequences representative of the eight major genotypes, established using neighbor joining based on Kimura 2 parameter method. The three HBV genotype H sequences obtained in this study are shown and have been assigned as IG94107 (Genbank accession number: DQ990454), IG94109 (Genbank accession number: DQ990455) and IG94177 (Genbank accession number: DQ990456).

Table 1 Distribution of HBV genotypes in the populations studied *n* (%)

Group of subjects	<i>n</i>	Genotypes, <i>n</i> (%)			
		A	D	G	H
Hepatitis patients	15	1 (6.7)	2 (13.3)	0	12 (80)
Men seeking HIV testing	20	3 (15)	1 (5)	1 (5)	15 (75)
AIDS Patients	8	0	0	4 (50)	4 (50)
Hemodialysis patients	6	0	0	0	6 (100)
Total	49	4 (8.2)	3 (6.1)	5 (10.2)	37 (75.5)

testing, and hemodialysis patients, and accounted for half of infections in AIDS patients (Table 1). Since the number of HBV isolates analyzed in some groups was very small, we were unable to provide statistical evidence for the distribution of HBV genotypes within the groups.

HBV precore mutations

In the precore region, 41 (83.7%) isolates showed wild type (G) sequence at nucleotide 1896, 6 (12.2%) had a mixture of wild type and G₁₈₉₆A mutation, and 2 had an indeterminate sequence (Table 2). Mixed wild type and precore mutant populations were observed in only one isolate of HBV genotype A but in all isolates of HBV genotype G. Statistical analysis showed that the frequency of mixed wild type and precore mutant populations was significantly higher (*P* = 0.04) in isolates of HBV genotype G than in isolates of HBV genotype A. Mixed wild type and precore mutant populations were observed in 10%

Table 2 Prevalence of precore and core promoter variants and its correlation with genotypes found in Mexican HBV isolates

Region and variant	<i>n</i> (%)	Genotypes			
		A (<i>n</i> = 4)	D (<i>n</i> = 3)	G (<i>n</i> = 5)	H (<i>n</i> = 37)
Precore (nt 1896)					
Wild type (G)	41 (83.7)	3	2		36
Wild type + variant (G + A)	6 (12.2)	1		5	
Indeterminate	2 (4.1)		1		1
Core promoter (nt 1762 and 1764)					
Wild type (AG)	44 (89.8)	4	2	5	33
Dual variant (TA)	1 (2)				1
Indeterminate	4 (8.2)		1		3

of isolates from men seeking HIV testing and in 50% of isolates from AIDS patients only. The frequency of these mixed wild type and precore mutant populations in AIDS patients was significantly higher than that in isolates from hepatitis patients (*P* = 0.007), and men seeking HIV testing (*P* = 0.03). This frequency of mixed wild type and precore mutant populations in AIDS patients was also higher but not statistically significant (*P* = 0.06) than that in isolates from hemodialysis patients.

In the core promoter region, 44 (89.8%) isolates had wild type sequence (A at nucleotide 1762 and G at nucleotide 1764), 1 (2%) showed the classical dual variant (A₁₇₆₂T, G₁₇₆₄A), and 4 (8.2%) had an indeterminate sequence. The only one dual variant was found in a sample of a hepatitis patient infected with HBV genotype H. For its part, all 4 samples with indeterminate sequences were found in hepatitis patients too. Three of them were found in isolates of HBV genotype H, and in one isolate of HBV genotype D.

DISCUSSION

In this work, we found a predominant frequency of HBV genotype H in Mexican isolates. The extremely high frequency of this HBV genotype H in Mexico has not been reported before. A previous study in Mexican isolates from blood donors and patients with liver disease showed infections with only 3 HBV genotypes: A, D and F in both populations^[30]. Nevertheless, in the present study we have found 4 HBV genotypes. It was known that HBV genotype F was predominant in Mexico^[30], but also it was observed that the predominant genotype F in Mexico is divergent^[31]. These results contrast with those found in the present study since HBV genotype H was predominant whilst HBV genotype F was not present anymore. Genotype H which was discovered recently is closely related with genotype F, while genotype H is most likely split off from genotype F^[9]. Therefore, a number of HBV isolates previously classified as genotype F are now classified as genotype H. Thus, it explains the remarkable change in HBV genotype distribution in Mexico with a predominant circulation of genotype H. The high

frequency of HBV genotype H in this study is the highest reported worldwide. Indeed, this genotype has been rarely found or not reported at all in most countries^[35-39]. HBV genotype H has been found only in HBV isolates of Nicaragua, Mexico, USA^[9,31,35], and Japan^[37,39]. In our study, HBV genotype H was predominant in the hepatitis patients, men seeking HIV testing, and hemodialysis patients. In addition, genotype H was responsible of 50% of infections in AIDS patients. Reports on genotypes found in hepatitis patients from other countries remark the differences in geographical distribution of HBV genotypes in the world. In the USA and other countries a high frequency of HBV genotype B and C has been found in hepatitis patients^[40,41]. HBV genotypes B and C have been linked to Asian ethnicity^[7,35], and the absence of these genotypes in our populations studied reflects the absence of HBV isolates of Asian origin. Frequencies of HBV genotypes found in men seeking HIV antibody testing are difficult to compare since there are not further reports for the comparison. Concerning hemodialysis patients, HBV genotype H was responsible for all infections in our study. This prevalence is clearly different from those found in hemodialysis patients of other countries. For instance, in a Turkish study all isolates of hemodialysis patients were genotype D^[42], in an Indonesian study all isolates were genotype B^[43], and in a Brazilian study genotypes A and D were the most frequently found^[44]. These HBV genotypes reported in hemodialysis patients certainly reflect the predominant HBV genotypes found in their respective countries. For its part, HBV genotype G is responsible for half of infections in AIDS patients. HBV genotype G has been discovered in USA and France isolates by Stuyver *et al.*^[45]. Interestingly, all HBV genotype G isolates were found as single isolates (no co-infections) in our study. This finding is unexpected, since HBV genotype G is frequently found as a co-infection with HBV genotype A^[46,47]. The HBV genotype frequencies in AIDS patients found in our study differ substantially from those found in a Spanish study where researchers found a predominant HBV genotype A followed by genotype D among the AIDS patients studied^[48]. The low frequency of precore mutants in Mexican isolates found in the present study confirms a previous observation^[30]. In addition, this frequency of precore mutations contrasts with a higher frequency observed in the USA and Hong Kong^[7,34,49]. The distribution of precore mutations in HBV genotypes found in the present study differs substantially from those found in other studies. While other researchers have found precore mutations in HBV genotypes B, C^[50,51], and D^[27], we have found the mutations only in HBV genotypes G and A, being mutations largely predominant in HBV genotype G (all HBV genotype G isolates in this study). The existence of precore mutations in HBV genotype G has been reported in patients chronically infected with HBV^[45]. Remarkably, all mutated HBV genotype G isolates in this study came from samples of AIDS patients and one of the men seeking HIV testing. No similar findings are reported in AIDS patients. Concerning mutations in the core promoter region, it is remarkable that the classical dual variant ($\Delta_{1762}T$, $G_{1764}A$), and indeterminate sequences were observed only in hepatitis patients. The prevalence

of core promoter mutations and its distribution in HBV genotypes found in this study also differ from those reported in other countries. A large study with Hong Kong and USA samples showed that the frequency of dual variant is 20% and 30.2%, respectively^[34], which is significantly higher than that found in our study. HBV core promoter mutations have been found in HBV genotypes A, B C and D^[25,29,34]. Nevertheless, these mutations were found mainly in HBV genotype H followed by HBV genotype D in the present study. Indeterminate sequences in precore and core promoter regions as well as the change in genotype F in LiPA to genotype H found in the Mexican isolates are most probably due to mismatching of the sequences with the probes used. A single mismatch is sufficient to abolish hybridization to a probe under the conditions of the assay as previously described^[34].

The INNO-LiPA HBV genotyping and precore assays have proved to be rapid, sensitive and reliable for the detection of HBV genotypes and precore promotor/precore mutations.

The genetic variability of HBV has implications on the sensitivity of immunologic and molecular based assays^[5]. In addition, HBV genotyping has shown its utility not only in epidemiology studies but also in predicting prognosis and therapeutic response^[6,52,53].

In conclusion, HBV circulates in at least 4 different genotypes in Mexico. HBV genotype H is highly predominant in HBV isolates of Mexico followed by genotypes G, A and D. The frequency of precore mutations in Mexican HBV isolates is low and associated mainly with HBV genotype G. Core promoter mutations seem to be rare in HBV isolates of Mexico.

Abstract

AIM: To determine the prevalence of celiac disease in a group of volunteer blood donors at a blood bank in the city of Curitiba, Brazil through detection of the serum marker immunoglobulin A (IgA) antitransglutaminase antibody.

METHODS: Blood samples collected from 2086 healthy subjects at the Paraná State Center for Hematology and Hemotherapy in Curitiba were submitted to ELISA testing for the IgA antitransglutaminase antibody. Positive samples received IgA antiendomysium antibody test through indirect immunofluorescence using human umbilical cord as substrate. Subsequently, patients who were positive on both tests underwent small bowel (distal duodenum) biopsy.

RESULTS: Six subjects, four males and two females, tested positive for the two serum markers. Five of the six were submitted to intestinal biopsy (one declined the procedure). Biopsy results revealed changes in the distal duodenum mucosa (three classified as Marsh IIIb lesions and two as Marsh II lesions). Most donors diagnosed having celiac disease presented multiple symptoms (gastrointestinal tract complaints). One donor reported having a family history of celiac disease (in a niece).

CONCLUSION: Among apparently healthy blood donors,

INTRODUCTION

Celiac disease (CD) is a chronic disease that affects genetically susceptible individuals and is characterized by permanent intolerance to gluten and other related proteins, causing nonspecific, characteristic lesions in the small bowel mucosa^[1]. These lesions prevent nutrient absorption in the affected area. Treatment involves a strict gluten-free diet (elimination of products containing wheat, barley, rye and probably oats). Clinical manifestations of CD are protean in nature and vary markedly with the age of the patient, the duration and extent of disease, and the presence of extraintestinal pathologic conditions. In addition to the classical gastrointestinal form, a variety of other clinical manifestations of the disease have been described, including atypical and asymptomatic forms^[2].

Serologic tests developed over the past decades provide noninvasive tools for screening individuals at risk for the disease in both general and selected populations. However, for diagnosis of CD, it is necessary to perform histological evaluation in order to confirm intestinal damage in individuals presenting positive exam results.

Initially, the disease was considered a low-prevalence disorder and, consequently, diagnosis was based on clinical findings alone. Most prevalence studies of the disease have been carried out in European countries and have evaluated the prevalence based on symptomatic cases. Therefore,

atypical and asymptomatic cases were frequently misdiagnosed. Currently, prevalence is higher due to the availability of reliable, easily administered serologic tests of high sensitivity and specificity.

In CD patients, a wide variety of clinical manifestations are seen, and the disease may be seen in conjunction with other diseases. Therefore, as well as being important tools for prevalence studies, serologic tests (performed prior to the mandatory intestinal biopsy used for diagnosis confirmation) have become important markers for the disease^[3].

Studies carried out in Europe, USA and Brazil in order to investigate the prevalence of CD have shown that the prevalence of the disease is considerably higher than previously presumed. Recent studies of serum markers in blood donors have shown a prevalence of 1 to 250 in Sweden^[4], 1 to 524 in Denmark^[5], 1 to 333 in Holland^[6], 1 to 157 in Israel^[7] and 1 to 250 in the USA^[8]. The first Brazilian epidemiologic study using serum markers was published in 2000 and showed the prevalence of CD to be 1 to 681 among blood donors in the national capital of Brasília^[9].

In order to get further insight into the prevalence of CD in Brazil and to evaluate the influence of genetic and environmental predisposition, we chose the city of Curitiba (in the state of Paraná). The city is located in the southern part of Brazil, and its population is of mostly European ancestry. Eating habits in Curitiba are similar to those seen in the countries of origin, and the diet features a significant wheat component. We decided to evaluate the epidemiology of CD in blood donors at a blood bank and to simultaneously analyze the ethnic profile of these donors. To that end, we used serum markers and conducted a genealogical study.

MATERIALS AND METHODS

Subjects

We analyzed 2086 serum samples collected from healthy donors at the Paraná State Center for Hematology and Hemotherapy in Curitiba from January to December 2001, regardless of gender. Donor ages ranged from 20 to 62 (mean, 33 years). The Ethics Committee of the University of São Paulo School of Medicine Hospital das Clínicas and the Ethics Committee of the Paraná State Center for Hematology and Hemotherapy approved the study. Donors gave written informed consent and answered a standardized questionnaire on demographics and health. No significant disease was diagnosed, and all serologic tests for human immunodeficiency virus (HIV), hepatitis B, hepatitis C, and alanine transaminase were normal. Serum samples were centrifuged and stored at -80°C after serologic tests.

Methods

Serologic tests were performed in three University of São Paulo School of Medicine Medical Investigation Laboratories (LIM), LIM 06, LIM 07 and LIM 56. Samples positive for IgA antitissue transglutaminase (anti-tTG) by enzyme-linked immunosorbent assay (ELISA) were submitted to an immunofluorescence test for IgA antiendomysium

antibody (EMA) using human umbilical cord as substrate. Each patient positive for both IgA anti-tTG and IgA EMA underwent small bowel (distal duodenum) endoscopic biopsy in which four samples were collected. This is the classical procedure accepted by the European Society of Pediatric Gastroenterology and Nutrition (ESPGAN)^[10] for confirmation of a diagnosis of CD.

Anti-tissue transglutaminase antibody test

Technique carried out in accordance with the method described by Dieterich *et al.*^[11]. Microplates (96 wells; Corning, New York, NY, USA) were coated with 1 µg of guinea pig liver tTG (T 5398; Sigma, St. Louis, MO, USA) per well (activity: 1.5-3 KU/g of protein) in 100 µL Tris-HCl (50 mmol/L); NaCl (150 mmol/L) and CaCl₂ (5 mmol/L), pH 7.5, and incubated at 37°C for 2 h. The wells were extensively rinsed in an Immunowash microplate washer (Bio-Rad, Hercules, CA, USA) in Tris-HCl (50 mmol/L), NaCl (150 mmol/L), EDTA (10 mmol/L) and Tween 20 (1 g/L), pH 7.4, and the microplates were incubated in washing buffer (100 µL/well) at 4°C overnight. The microplate solution was aspirated; serum samples were diluted (1/100) in washing buffer, poured into the respective wells (100 µL/well) and incubated for one hour at room temperature. After rinsing the plates (3 times), peroxidase-conjugated IgA-α antibody (A 0295, Sigma), diluted (1/1000) in washing buffer (100 µL/well), was added to the wells, which were then incubated at room temperature for one hour. Extensive rinsing eliminated unbound antibodies. The tetramethylbenzidine substrate (100 µL/well) promoted the color reaction. Microplates were placed in the dark for approximately 10 min, and subsequently blocked with 0.5 mol/L H₂SO₄ (50 µL/well). Absorbance values were read at 450 nm using an ELISA reader (VERSAmix tunable microplate reader; Molecular Devices, Sunnyvale, CA, USA). After subtraction of background values < 0.100, absorbance (A) readings were multiplied by the serum dilution in order to calculate the ELISA titers. With the inclusion of two control serum samples in every test, intra-assay variations ($n = 22$) and inter-assay variations ($n = 24$) were 8.68% and 8.38%, respectively. Statistical evaluation was carried out through receiver operator characteristic (ROC) curve analysis^[12] using SPSS® software.

Antiendomysium antibody test

Immunofluorescence tests for antiendomysium antibodies were carried out using 2 µm cryosections of human umbilical cord, which were incubated with patient serum prediluted (initial dilution = 1:5) in buffer (PBS and 1 g/L Tween 80, pH 7.2), in a humid chamber at 37°C for 30 min. Slides were rinsed twice in PBS, pH 7.2, for 5 min. Samples were then incubated with fluorescein-conjugated anti-human IgA (Sigma) and diluted in dilution buffer (1:30). Subsequently, samples were rinsed twice with PBS and the slides were again incubated in humid chamber at 37°C for 30 min. Later, samples were read under fluorescence microscopy. Samples were considered positive if there was a hexagonal pattern of fluorescence throughout the peritubular muscle layer of the human umbilical cord vessels, marking the extracellular connective tissue.

Table 1 Celiac disease diagnosed in apparently healthy blood donors

Age	Gender	Race	Ancestry	GI symptoms	Anti-tTG ¹	EMA ¹	Histology
26	F	W	Italian and Portuguese	Diarrhea, distension, abdominal pain and flatulence	1025	1/1280	Marsh IIIb

Histology

Samples were fixed with buffered formalin and stained with hematoxylin and eosin (H&E) for histological study. The following aspects were evaluated: (1) crypt/villus ratio; (2) crypt regeneration; (3) characteristics of the inflammatory infiltrate in the section itself; (4) type of atrophy. Two pathologists examined every slide for the standardization of the histological aspects, using the histological classification developed in 1992 by Marsh and modified in 1997 by Rostami *et al.*^[13-15]. This modified system establishes five lesion classes. In Marsh 0, there is normal architecture of the mucosa and less than 40 intraepithelial lymphocytes per 100 enterocytes in the villus epithelium. Marsh I is defined as normal architecture of the mucosa and more than 40 lymphocytes per 100 enterocytes in the villus epithelium. Marsh II involves crypt enlargement (hyperplasia), in which immature epithelial cells are produced in large numbers and there is an influx of lymphocytes and plasmocytes. Under this system Marsh III has been reclassified and divided into three separate classes. In Marsh IIIa, there is partial villus atrophy combined with slight lymphocyte infiltration in epithelial cells and crypt hyperplasia. Marsh IIIb is marked by near total atrophy of the villi (villi still recognizable), crypt hyperplasia in which immature epithelial cells are produced in greater proportions, and influx of inflammatory cells. The final designation, Marsh IIIc, indicates total villus atrophy, hyperplastic crypts and infiltrative lesions^[13-15].

RESULTS

Of the 2086 blood donors, 1437 (68.88%) were males and 649 (31.12%) were females. Mean age was 33. There were 1977 Whites (94.77%), 82 Blacks (3.93%), and 27 Asians (1.30%). There were 1179 who claimed European ancestry (56.52%). Ethnic data were obtained through a genealogical study of the preceding three generations (Figure 1).

We identified six donors (four males and two females) who were positive for both anti-tTG and EMA. Five of these were submitted to intestinal biopsy and one declined the procedure. The procedure revealed that, in the mucosa of the small bowel (distal duodenum), three of the subjects presented Marsh IIIb lesions and two presented Marsh II lesions. Most subjects diagnosed with CD reported various gastrointestinal symptoms. One subject reported a family history of CD in a first-degree relative (a niece) (Table 1).

The prevalence of biopsy-confirmed CD was approximately 1:417 among apparently healthy blood

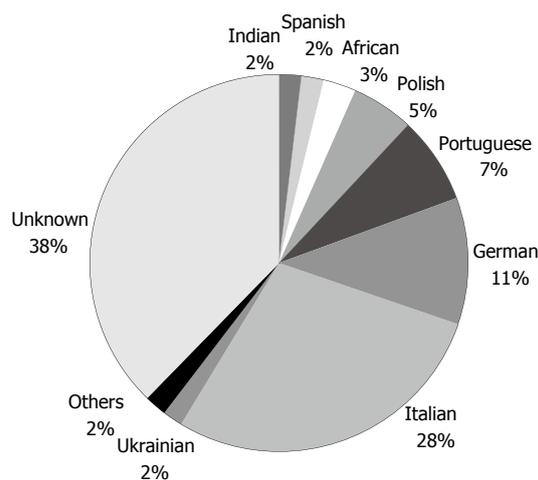

Figure 1 Blood donors by ancestry.

donors. When the cases were positive for antitransglutaminase antibody were confirmed through the use of another marker, antiendomysium antibody, the prevalence was 1:347.

The sensitivity and specificity of the anti-tTG test were 100% and 96%, respectively. The OD cutoff value, established through analysis of the ROC curve, was 0.238. The area of the ROC curve was 0.999 ± 0.002 .

DISCUSSION

In blood donors at a blood bank in Curitiba (Paraná), the prevalence of CD was 1:347 when samples positive for IgA anti-tTG antibodies were tested for a second marker (IgA antiendomysium antibodies). When subjects positive for both serum markers underwent distal duodenum biopsy, the prevalence was 1:417. This high prevalence is similar to that seen in European countries. This is unsurprising since most of the subjects in the study group were of European descent: 56.52% claimed European ancestry, and 37.78% were unaware of their ancestry (Figure 1). We can assume that most of the subjects of unknown ancestry were also of European descent since this ethnic group is predominant in Curitiba.

Factors that influence the high prevalence of CD are the genetic component (HLADQ₂ and DQ₈ haplotypes, which are strongly associated with CD and highly prevalent in the European population) and the consumption of grains containing gluten^[2]. These two factors are present

in the city of Curitiba, where, in recent decades, there has been an increase in the consumption of wheat flour. This increase is related to the lifting of sanctions on the importation of special wheat grains. In addition, the consumption of foods containing wheat has increased as a consequence of economic plans that have created conditions which facilitate consumption among the population^[17]. Currently, wheat consumption in the south of Brazil, where Curitiba is located, is 61 kg/person per year—the highest in the country^[17]. This corresponds to 43.57% of the consumption in Italy, which, according to the World Health Organization, is 140 kg/person per year.

Another relevant and notable aspect is that, of the six positive donors, five were of Italian descent, most from the region of Veneto (northern Italy). A study carried out in that region using serum marker screening showed a CD prevalence of 1:200^[18].

The CD prevalence observed in the present study was higher than the 1:681 prevalence found in a similar study involving blood donors at a blood bank in the city of Brasília^[9]. This low prevalence could be attributed to low numbers of individuals of European descent, although the actual ethnic composition of the Brasília population is not known. However, it is known that most of the population of the city migrated from the Central-West region of Brazil, where individuals of European ancestry are in the minority and the consumption of wheat is lower (23 kg/person per year)^[17].

In the literature, the prevalence of CD is higher in females when studies are based on cases with clinical evidence^[19]. However, recent studies of blood donors showed that, when the diagnosis is made through the use of serum markers, this relationship is not maintained^[7,8]. In our study, approximately one-third of the participants were female, and we found the prevalence of CD to be similar between males and females and proportionate to their respective representation in the study population (four males and two females tested positive).

A prevalence study of CD in a population composed of the descendants of European immigrants to New Zealand was conducted in the city of Wellington^[20]. The study was based on clinical findings in children and adults and showed that prevalences of the disease in children and adults were lower and the same as those seen in the respective European cities of origin. The authors attributed the lower prevalence in children to underdiagnosis. Although the population under study presented the same ancestry and possibly the same eating habits, the authors evaluated only “the tip of the celiac iceberg”. In the present study, which was conducted in a region of high wheat consumption and included a genealogical search and the use of serum markers, we evaluated “the rest of the iceberg”. Our results show that, when ethnic and environmental factors are constant, the prevalence of the disease remains stable, even if members of the population migrate to other areas. A recent study^[21], conducted in Argentina, using serum markers to evaluate a population of European descent in an area with 85 kg/person per year of wheat consumption, showed a CD prevalence of 1:167, reinforcing our hypothesis.

In the present study, we found a prevalence of CD of 1:417 among apparently healthy blood donors. Our results demonstrate that the high prevalence of CD in the city of Curitiba is comparable to that seen in European countries. This finding supports the hypothesis that the prevalence of the disease remains stable if predisposing genetic and environmental conditions are maintained.

Abstract

AIM: To evaluate clinical presentation, etiology, complications and response to treatment in elderly patients with acute cholangitis.

METHODS: Demographics, etiology of biliary obstruction, clinical features, complications and associated systemic diseases of 175 patients with acute cholangitis were recorded. Endoscopic biliary drainage was performed using nasobiliary drain or stent. The complications related to ERCP, success of biliary drainage, morbidity, mortality and length of hospital stay were evaluated.

RESULTS: Of 175 patients, 52 aged ≥ 60 years (group I, age < 60 years; group II, age ≥ 60 years) and 105 were men. Fever was present in 38 of 52 patients of group II compared to 120 of 123 in group I. High fever (fever $\geq 38.0^{\circ}\text{C}$) was more common in group I (118/120 vs 18/38). Hypotension (5/123 vs 13/52), altered sensorium (3/123 vs 19/52), peritonism (22/123 vs 14/52), renal failure (5/123 vs 14/52) and associated comorbid diseases (4/123 vs 21/52) were more common in group II. Biliopancreatic malignancy was a common cause of biliary obstruction in group II ($n = 34$) and benign diseases in group I ($n = 120$). Indications for biliary drainage were any one of the following either singly or in combination: a fever of $\geq 38.0^{\circ}\text{C}$ ($n = 136$), hypotension ($n = 18$), peritonism ($n = 36$), altered sensorium ($n = 22$), and failure to improve within 72 h of conservative management ($n = 22$). High grade fever was more common indication of biliary drainage in group I and hypotension, altered sensorium, peritonism and failure to improve within 72 h of conservative management were more common indications in group II. Endoscopic biliary drainage was achieved in 172 patients (nasobiliary drain: 56 group I, 24 group II, stent: 64 group I, 28 group II) without any significant age related difference in the success rate. Abdominal

pain, fever, jaundice, hypotension, altered sensorium, peritonism and renal failure improved after median time of 5 d in 120 patients in group I (2-15 d) compared to 10 d in 47 patients of group II (3-20 d). Normalization of leucocyte count was seen after a median time of 7 d (3-20 d) in 120 patients in group I compared to 15 d (5-26 d) in 47 patients in group II. There were no ERCP related complications in either group. Five patients (carcinoma gallbladder $n = 3$, CBD stones $n = 2$) died in group II and they had undergone biliary drainage after failure of response to conservative management for 72 h. There was a higher mortality in patients in group II despite successful biliary drainage (0/120 vs 5/52). Length of hospital stay was longer in group II patients (16.4 ± 5.6 , 7-30 d) than in group I patients (8.2 ± 2.4 , 7-20 d).

CONCLUSION: Elderly patients with acute cholangitis have a high incidence of severe cholangitis, concomitant medical illnesses, hypotension, altered sensorium, peritonism, renal failure and higher mortality even after successful biliary drainage.

INTRODUCTION

Acute cholangitis is a difficult diagnostic and therapeutic problem. Classically, Charcot's triad of jaundice, abdominal pain and fever have been the main basis of diagnosis however 30%-45% of the patients with acute cholangitis do not satisfy the criteria of Charcot's triad^[1].

Altered sensorium, hypotension and renal failure can often be seen in patients with suppurative cholangitis^[2]. In many cases, bile duct infection is latent and does not cause symptoms. Cholangitis varies in severity from a mild form which responds to parenteral antibiotics alone to severe or suppurative cholangitis which requires early drainage of biliary system to reduce the incidence of

systemic complications^[3]. Endoscopic biliary drainage is an established mode of treatment for acute cholangitis with high success rate, low morbidity and mortality^[1,3-20].

Old age is considered as a risk factor associated with significant mortality in acute cholangitis^[21,22]. It is also a factor which adversely affects the outcome and survival in patients with acute cholangitis, which may be due to associated other systemic diseases and comorbid conditions, underlying etiology of biliary obstruction, poor immune status and poor general health in old age^[21-23]. However, there is no study on clinical presentation, etiology, complications and survival after endoscopic biliary drainage in elderly patients with acute cholangitis. We prospectively compared the clinical presentation, etiology, associated systemic diseases, complications and response to treatment in elderly patients with acute cholangitis.

MATERIALS AND METHODS

Over past 5 years, 175 patients with acute cholangitis were recruited in this study. The diagnosis of acute cholangitis was based on presence of clinical evidence of infection (fever, leucocytosis and abdominal pain) in patients with biliary obstruction in the form of jaundice or hyperbilirubinemia^[1,3]. Patients with biliary obstruction and associated hypotension, impaired level of consciousness and renal failure were specifically looked for associated features of acute cholangitis like fever and leucocytosis. They were labelled to be having acute cholangitis if they had any of features like hypotension, impaired level of consciousness and renal failure along with fever and /or leucocytosis in absence of infection at other sites or other causes for hypotension, impaired level of consciousness and renal failure. Details of demographic data, etiology of biliary obstruction, clinical features, biochemical parameters, microbiological spectrum, complications and associated other systemic diseases were recorded.

Immediate endoscopic biliary drainage was performed in patients with high fever, hypotension, peritonism, altered sensorium and associated renal failure. In patients without these features, endoscopic biliary drainage was performed only if they did not respond to conservative treatment. All patients were treated with intravenous antibiotics and metronidazole. Concomitant medical illnesses were also recorded and treatment was started to control these medical illnesses. Endoscopic retrograde cholangiopancreatography (ERCP) was performed with a side viewing duodenoscope with a large accessory channel in a standard manner. Patients were subjected to either nasobiliary drain (NBD) placement or placement of biliary stent. After cannulation of the common bile duct, bile was aspirated to confirm the position of the cannula. Injection of contrast was avoided as far as possible to prevent any sudden increase in bile duct pressure which could lead to sudden cholangiovenous and cholangiolymphatic reflux. Endoscopic sphincterotomy was not performed. Either a 7-F nasobiliary drain or 7-F straight flap stent was placed in bile duct. After ERCP and biliary drainage, all the patients were kept under strict observation and treated in a critical care ward and the amount of bile drained from

Table 1 Demographic and clinical characteristics of patients with severe acute cholangitis

	Group I	Group II

^a*P* < 0.05.

NBD was monitored daily.

The patients were closely observed for evidence of ERCP-related complications. Clinical improvement was defined as normalization of fever, leucocytosis, hypotension, peritonism, altered sensorium and renal functions. After clinical improvement, a repeat ERCP or NBD cholangiogram was obtained in each patient. Clinical monitoring and biochemical tests were performed before ERCP and then on d 1, 3 and 7 after ERCP or earlier if indicated. After improvement of their cholangitis, patients underwent some form of definitive management. Primary outcome measures included complications related to ERCP and the treatment outcomes including success of biliary drainage, morbidity, mortality and length of hospital stay.

Statistical analysis

Quantitative data were expressed as the mean \pm SD or as the median. The Mann-Whitney *U* test was used for comparing continuous variables and a Chi-square test with Yate's correction was used to analyze clinical variables and the two tailed Fisher's exact test was used when numbers were small. A *P* value < 0.05 was considered to be statistically significant.

RESULTS

Of 175 patients, 52 patients were aged \geq 60 years (group I, age < 60 years; group II, age \geq 60 years) and 105 were men. Most patients presented with right upper quadrant abdominal pain, jaundice and fever with chills. Of 175 patients, right upper quadrant abdominal pain and fever were more common in group I compared to group II (Table 1). Fever was present in 38 of 52 patients of group II compared to 120 of 123 patients in group I. However, high fever (fever \geq 38.0°C) was more common in patients of group I (118/120 *vs* 18/38) (Table 1). Of 175 patients, hypotension (5/123 *vs* 13/52), altered sensorium (3/123 *vs* 19/52), peritonism (22/123 *vs* 14/52) and renal failure (5/123 *vs* 14/52) were more common in patients of group II compared to patients with group I.

Table 2 Etiology and site of biliary obstruction in common bile duct

Etiology of biliary obstruction	Site of biliary obstruction	Group I n = 123 (%)	Group II n = 52 (%)

Serum albumin, g/dL	3.6 ± 0.8	3.8 ± 0.8	NS

Some patients in group II presented with hypotension or altered sensorium despite no or mild abdominal pain and low grade fever.

Etiology and site of biliary obstruction in 175 patients are summarized in Table 2. The biliopancreatic malignancy was a common cause of biliary obstruction in patients of group II (n = 34) compared to benign diseases in group I (n = 120) (Table 2).

Of 175 patients, 25 patients had other associated comorbid systemic conditions (group I, n = 4 and group II, n = 21) like diabetes mellitus (n = 10), hypertension (n = 12), coronary artery disease (n = 6), cerebrovascular accidents (n = 4), chronic obstructive pulmonary disease (n = 4) and pulmonary tuberculosis (n = 3) in group II patients compared to pulmonary tuberculosis (n = 2), rheumatic heart disease (n = 1), diabetes mellitus (n = 1), hypertension (n = 1) and thyrotoxicosis (n = 1). Laboratory investigation revealed higher elevation of leucocytes in group I and higher elevations of bilirubin and alkaline phosphatase levels in group II patients (Table 3). Blood cultures were positive in 70 cases (40%, group I, n = 50; group II, n = 20) with organisms such as *Escherichia Coli* (n = 50; group I, n = 38; group II, n = 12), *Klebseilla* (n = 12; group I, n = 9; group II, n = 3), *Acinobacter* (n = 13; group I, n = 9; group II, n = 4), *Proteus* (n = 9; group I, n = 6; group II, n = 3) and *Pseudomonas* (n = 9; group I, n = 6; group II, n = 3). Twenty-three patients had mixed infections. The biliary obstruction was most commonly found to be in the lower part of common bile

Table 4 Indications of biliary drainage

Indication	Group I n = 123 (%)	Group II n = 52 (%)	P
Fever ≥ 38.0°C	118 (96)	18 (34.6)	< 0.01
Hypotension	5 (4)	13 (25)	< 0.01
Peritonism	22 (18)	14 (26.9)	< 0.01
Altered sensorium	3 (2.6)	19 (36.5)	< 0.01
Failure to improve with conservative management	2 (1.6)	20 (38.4)	< 0.01

duct in both group I (n = 107) and group II (n = 33) patients. Indications for biliary drainage were any one of the following either singly or in combination: a fever of ≥ 38.0°C (n = 136), hypotension, with systolic blood pressure < 100 mm Hg (n = 18), right upper quadrant abdominal pain with guarding (peritonism) (n = 36), impaired level of consciousness (n = 22), and failure to improve within 72 h of conservative management (n = 22). High grade fever was more common indication of biliary drainage in group I and hypotension, altered sensorium, peritonism and failure to improve within 72 h of conservative management were more common indications of biliary drainage in group II patients (Table 4). None of the patients had undergone prior endoscopic or percutaneous transhepatic biliary drainage. After hospital admission, ERCP and endoscopic biliary drainage were performed in patients with severe acute cholangitis after a median interval of 20 h (range 3-42 h) in 153 patients and after a median interval of 96 h (range 72-106 h) in 22 patients who failed to respond to conservative management.

Endoscopic biliary drainage was achieved in 172 patients without any significant age related difference in the success rate. A nasobiliary drain was placed in 80 patients (56 group I, 24 group II) and a stent was placed in 92 patients (64 group I, 28 group II). ERCP with biliary drainage therefore could be achieved in 120 patients in group I and 52 patients in group II. Abdominal pain, fever, jaundice, hypotension, altered sensorium, peritonism and renal failure improved after median time of 5 d in all the 120 patients in group I (range 2-15 d) and after median time of 10 d in 47 patients of group II (range 3-20 d). Similar normalization of leucocyte count was seen after a median time of 7 d (range 3-20 d) in 120 patients in group I and after a median time of 15 d (range 5-26 d) in 47 patients in group II. There were no immediate ERCP related complications in either group of patients. There were no episodes of displacement, kinking or occlusion of NBD or of occlusion or migration of stent.

Five patients (carcinoma gallbladder n = 3, CBD stones n = 2) died in group II after 3, 5, 6, 9 and 10 d of endoscopic biliary drainage. All the five patients were subjected to endoscopic biliary drainage (2 NBD, 3 stent) after they failed to respond to conservative management for 72 h. All the five patients died because of uncontrolled cholangitis and septicemia despite antibiotics and successful endoscopic biliary drainage.

There was a higher mortality in patients in group II despite successful biliary drainage (0/120 vs 5/52). There was no significant difference in mortality between group

II patients with (2/21) and without (3/31) concurrent diseases. Also there was no difference in mortality between group II patients with benign (2/18) and malignant causes (3/34) of biliary obstruction. Length of hospital stay was significantly longer in group II patients (16.4 ± 5.6 , range 7-30 d) than in group I patients (8.2 ± 2.4 , range 7-20 d). Altered sensorium, hypotension, peritonism, mortality and length of hospital stay were more in group II patients with CBD stones ($n = 18$) than in group I patients with CBD stones ($n = 104$) (Table 5).

DISCUSSION

Older age has been considered a risk factor for increased morbidity and mortality rates in the treatment of acute cholangitis^[21,22]. However there is little specific information available on clinical features and treatment of acute cholangitis in the elderly. In present study elderly patients with acute cholangitis were found to have relatively higher incidence of severe cholangitis, hypotension, altered sensorium, peritonism and renal failure. Symptoms in elderly patients did not correlate with the severity of acute cholangitis. Many elderly patients with severe cholangitis presented with deceptively mild symptoms. Presence of abdominal pain and high grade fever was less common in elderly patients compared to young patients. Almost 40% of elderly patients had low grade fever and nearly 1/4 did not have fever. Therefore early diagnosis of acute cholangitis based on symptoms alone was difficult as reported earlier^[21]. However on examination many elderly patients had features suggestive of severe cholangitis in form of jaundice, hypotension, altered sensorium, peritonism and associated renal failure. All the elderly patients showed abnormal results of laboratory tests. However rise in leucocyte count was less compared to leucocytosis in younger patients and bilirubin and alkaline

phosphatase levels were higher in elderly patients than in younger patients. This could be due to biliopancreatic malignancy, a common cause of biliary obstruction in elderly patients compared to benign diseases in younger patients. Elderly patients also had a higher incidence of coexisting medical problems like cardiovascular, pulmonary, neurological and other systemic diseases. Due to the high incidence of severe cholangitis, features like hypotension and altered sensorium and associated other concurrent systemic diseases, the management of acute cholangitis in the elderly becomes difficult^[21].

Urgent endoscopic biliary drainage has been recommended for severe acute cholangitis or cholangitis that does not respond to conservative treatment^[1,3-20]. Endoscopic biliary drainage including endoscopic sphincterotomy, nasobiliary drainage and stenting has been advocated as safe and effective measure for the treatment of acute cholangitis with a mortality ranging from 2% to 8%. In present series, urgent endoscopic biliary drainage yielded favorable outcome for all the young patients. However endoscopic biliary drainage for elderly patients was associated with significant mortality. Earlier studies have shown that the success rates of therapeutic ERCP are similar between elderly and young patients^[24,25]. However the morbidity and mortality associated with therapeutic ERCP are significantly greater in the elderly than in young patients^[23-25]. There were no serious complications of endoscopic biliary drainage procedures in both elderly and younger patients. In elderly patients higher morbidity and mortality even after biliary drainage are considered due to advanced acute cholangitis, exacerbation of concurrent medical illnesses, unsuccessful biliary drainage procedures, underlying biliopancreatic malignancy as a cause of biliary obstruction, complications characteristic of elderly such as delirium, pneumonia or atelectasis and need for prolonged ventilatory support after the endoscopic drainage procedures^[21-25]. Elderly patients are often unable to tolerate endoscopic procedures because they are critically ill or uncooperative. In this situation, the endoscopic procedures can be performed safely and successfully under general anesthesia and endotracheal intubation^[21,25]. However none of the elderly patients in present series required general anesthesia, endotracheal intubation and ventilatory support after endoscopic procedures for biliary drainage.

In present study, the clinical profile and response to endoscopic biliary drainage in elderly patients was similar in patients having biliary obstruction due to benign and malignant causes. Elderly patients with CBD stones had different clinical profile, poorer response to biliary drainage and higher mortality as compared to young patients with CBD stones. In present series, all the five elderly patients were subjected to endoscopic biliary drainage after they failed to respond to conservative management for 72 h. All the five patients died because of uncontrolled cholangitis and septicemia despite antibiotics and successful endoscopic biliary drainage. None of the patients who underwent immediate endoscopic biliary drainage because of high grade fever or associated features like hypotension, altered sensorium and peritonism had died. It is possible that patients with low grade fever and

without features like hypotension, altered sensorium and peritonism also had severe acute cholangitis which was not clinically evident. Therefore they did not fit into indications of immediate endoscopic biliary drainage without waiting for assessment of response to conservative management for 72 h and accounted for 25% (5/20) of mortality in subgroup of elderly patients not responding to conservative treatment for 72 h. Some of the elderly patients presented with hypotension or altered sensorium despite absent or mild abdominal pain and without or with low grade fever suggesting thereby that elderly patients may have severe acute cholangitis without fever or with low grade fever and should be subjected to immediate endoscopic biliary drainage without waiting for 72 h to assess the response to conservative treatment for 72 h. Higher mortality has earlier been reported in patients with acute cholangitis who fail to respond to antibiotics and therapeutic intervention is performed after 72 h of hospital admission^[23,26]. It has been found that many times it is not always clinically apparent which patients will respond to medical treatment alone and which will require urgent biliary drainage. The mortality rate is high for patients who undergo delayed biliary drainage after failure of medical therapy^[23,26]. In elderly patients, the levels of bilirubin and alkaline phosphatase were significantly higher than in young patients. It has been reported that higher levels of bilirubin and alkaline phosphatase are associated with higher mortality in patients with acute cholangitis^[22]. The differences in clinical profile, laboratory parameters and response to biliary drainage in elderly patients can not be attributed to differences in type of bacteria causing cholangitis because the bacteriological spectrum was similar in elderly and young patients in present study.

Elderly patients with acute cholangitis have a high incidence of severe cholangitis, concomitant medical illnesses, hypotension, altered sensorium, peritonism, renal failure and higher mortality even after successful biliary drainage.

INTRODUCTION

Surgical resection of colorectal liver metastases is nowadays a standard of care for resectable disease with 5-year survival rate approaching 60%^[1-3]. Because of several theoretical benefits, preoperative systemic chemotherapy has been frequently used to downsize the disease.

We report here the development of two complications, partial portal vein thrombosis and hepatic steatosis with lobular inflammation, during the course of preoperative chemotherapy with FOLFIRI plus bevacizumab for colorectal liver metastases, and discuss the surgical management and implications.

Abstract

In order to discuss the role of preoperative chemotherapy for colorectal liver metastases, which is used frequently before hepatic resection, even in patients with resectable disease at presentation, we herein report the development of two complications, partial portal vein thrombosis and hepatic steatosis with lobular inflammation, during the course of preoperative chemotherapy with FOLFIRI plus bevacizumab for colorectal liver metastases, which recognition led to timely discontinuation of chemotherapy as well as a change in the surgical strategy to resect the tumors and the damaged liver through advanced techniques. We conclude that duration of treatment and drug doses and combinations may impact the development of chemotherapy-induced liver injury. Surgeons and medical oncologists must work together to devise safe, rational, and oncologically appropriate treatments for patients with multiple colorectal liver metastases, and to improve the understanding of the pathogenesis of chemotherapy-induced liver injury.

CASE REPORT

A 61-year-old woman was referred for treatment of synchronous multiple bilobar colorectal liver metastases. Six months after a laparoscopic right hemicolectomy for a pT3N2 colon cancer, a multiphase spiral computed tomography (CT) performed without and with intravenous (IV) contrast revealed bilateral disease with a total of five lesions distributed in segments I, II, IVA, VI and VII amenable to hepatic resection (Figure 1). Because of the known high risk of disease recurrence after liver resection for multiple bilobar and synchronous metastases in patients with N2 classification of primary tumor, the patient was treated with six courses of preoperative chemotherapy with FOLFIRI (irinotecan, 5-fluorouracil, and high-dose leucovorin) plus bevacizumab.

Repeat CT performed without and with IV contrast 3 wk after the completion of chemotherapy with bevacizumab showed downsizing of the lesions in segments I, IVA, VI-VII, and stable disease in the segment II. Non-contrast images also showed the development of diffuse fatty infiltration of the liver with sparing of segments V and VIII while the images acquired after IV contrast administration revealed absent portal perfusion of the right anterior sector associated with right anterior portal branch occlusion. The lack of portal flow to segments V and VIII explained sparing from steatosis and increased arterial flow to these segments. Some compensatory hypertrophy of the left liver was evident (Figure 2). The patient had no evidence of hypercoagulation and no other known risk factors for thrombosis. Even though this patient experienced downsizing of bilobar liver metastases, the new finding

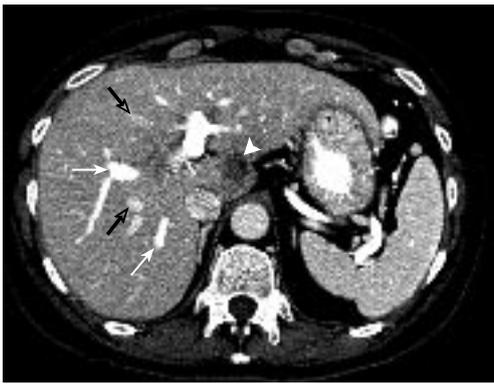

Figure 1 Contrast enhanced CT at the level of the portal bifurcation before treatment shows metastasis in segment I (arrowhead), opacified right anterior and posterior segmental portal veins (white arrows), and opacified middle and right hepatic veins (open arrows).

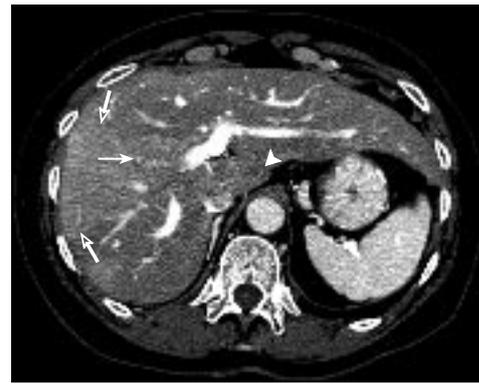

Figure 2 Contrast enhanced CT at the level of the portal bifurcation after treatment shows improved hepatic metastasis in segment I (arrowhead), non-visualization of the thrombosed anterior right segmental portal vein (arrow), opacified posterior segmental portal veins, middle and right hepatic veins, and wedge shaped increased enhancement (open arrows) of the anterior sector secondary to portal vein occlusion.

of portal vein thrombosis led to discontinuation of chemotherapy and reassessment of the treatment plan. Prior to occurrence of portal vein thrombosis, a partial right hepatectomy plus resection of the metastases in segments IVA, II and I, was planned. The finding of right portal vein thrombosis led to a change in operative plan to include resection of the segments involved both by tumor and by portal vein thrombosis in a 2-stage fashion. At the first stage, segmental resection of the lesions in segments I and II was performed, preserving the majority of the parenchyma of the lateral bisegment. Three-dimensional liver volumetry revealed the planned remnant liver (bisegment II/III) was of inadequate volume to permit resection of the right liver plus segment IV. Therefore, in order to increase volume and function of the liver remnant prior to the 2-stage resection, percutaneous right portal vein embolization extended to segment IV was performed. Repeat CT volumetry after 4 wk revealed adequate liver remnant hypertrophy, and the remaining diseased liver was resected by extended right hepatectomy (resection of Couinaud segments IV through VIII). The postoperative course after each stage was uneventful. The pathological review of the specimen revealed 50% necrosis in the tumors and moderate-severe steatosis with lobular inflammation in the resected liver.

DISCUSSION

We report the development of partial portal vein thrombosis in combination with hepatic steatosis and lobular inflammation (steatohepatitis) during the course of preoperative chemotherapy with FOLFIRI plus bevacizumab for colorectal liver metastases. This thrombotic complication, which occurred during chemotherapy, was possibly not because of the presence or treatment effect of a metastatic lesion since no tumor was associated with the thrombosed portal vessel. Absence of previous data on vascular events in association with 5-fluorouracil alone, a drug which has been in use for more than 50 years, raises the possibility of an event associated with bevacizumab and/or irinotecan treatment.

Bevacizumab is a humanized recombinant murine monoclonal antibody to vascular endothelial growth

factor A (VEGF-A) that competitively blocks binding of VEGF-A to its receptors, resulting in inhibition of angiogenesis. Bevacizumab has been reported to be associated with delayed wound healing, venous and arterial thromboembolism; however, to our knowledge bevacizumab has not been reported to cause portal venous thrombosis^[4-8]. The proposed mechanism of bevacizumab-related thrombosis is complex-both hemorrhagic and thrombotic events may be involved. Briefly, bevacizumab by antagonizing VEGF's functions might decrease the renewal capacity of endothelial cells in response to trauma, leading simultaneously to a tendency to bleeding and thrombosis^[9,10].

Preliminary evidence that irinotecan may be associated with arterial and venous thrombotic events has been reported as well, but portal vein thrombosis has not been reported previously and the pathophysiology of irinotecan-related thrombotic events remains unclear^[6,11].

The baseline incidence of thrombosis in cancer patients is significant, and the development of portal vein thrombosis in our patient cannot be definitively attributed to chemotherapy^[12]. However, the pattern of thrombosis, the occurrence during chemotherapy treatment, and the absence of any vascular complications after colectomy, portal vein embolization or 2 sequential hepatectomy procedures, suggest that combination of FOLFIRI and bevacizumab contributed to this complication.

Histopathologic review of the resected liver confirmed not only moderate-severe steatosis consistent with the CT findings, but also revealed lobular inflammation^[13]. Steatosis plus lobular inflammation can progress to steatohepatitis, which has been associated with preoperative chemotherapy with irinotecan, and may raise the risk of death after liver surgery^[14-17]. Adverse outcomes related to chemotherapy-induced injury likely relate to a decreased regenerative capacity of injured hepatocytes in response to major hepatectomy, possibly through alterations of nuclear factors such as nuclear factor-kappa B, which is crucial for the priming phase of liver regeneration^[18].

In the patient reported, who had resectable disease at presentation, development of both portal vein thrombosis

and hepatic steatosis suggests that chemotherapy treatment contributed to these events and raised the possibility that curative surgery would not be possible. Fortunately, the recognition of these complications led to timely discontinuation of chemotherapy as well as a change in the surgical strategy to resect the tumors and the damaged liver through advanced techniques (portal vein embolization, extended hepatectomy, 2-stage approach) in an effort to minimize morbidity.

Chemotherapy will be used with more frequency before hepatic resection. Duration of treatment and drug doses and combinations may impact the development of chemotherapy-induced liver injury. Surgeons and medical oncologists must work together to devise safe, rational, and oncologically appropriate treatments for patients with multiple colorectal liver metastases, and to improve the understanding of the pathogenesis of chemotherapy-induced liver injury.

Abstract

Gallbladder tuberculosis (GT) is an extremely rare disease, and very few cases have been reported in the literature. The first case of GT was described in 1870 by Gaucher. A correct preoperative diagnosis of GT is unusual, and it is frequently confused with various gallbladder diseases. We present a new case of a patient who underwent surgery with the preoperative diagnosis of gallbladder cancer after a false positive positron emission tomography scan in the diagnostic work-up.

INTRODUCTION

Abdominal tuberculosis is common in developing countries but gallbladder tuberculosis (GT) is an extremely rare disease^[1,2], and very few cases have been reported in the literature^[1]. The first case of GT was described in 1870 by Gaucher.

A correct preoperative diagnosis of GT is unusual, and it is frequently confused with various gallbladder diseases. We present a new case of a patient who underwent surgery with the preoperative diagnosis of gallbladder cancer after a false positive positron emission tomography (PET) scan in the diagnostic work-up.

CASE REPORT

A 64-year-old man was admitted to our department for abdominal pain and jaundice. Abdominal examination revealed a palpable mass in right hypochondrium. Laboratory tests were normal. A gallbladder mass was observed on ultrasound. A computed tomography (CT) scan showed a thickened gallbladder wall with possible infiltration of liver parenchyma and duodenum, and we proposed a diagnosis of advanced neoplasm of gallbladder (Figure 1). A PET scan showed a hypermetabolic area in the right liver lobe in the usual location of the gallbladder, infiltrating the liver parenchyma (Figure 2) and reaffirming our suspected diagnosis of advanced neoplasm of gallbladder.

We performed a subcostal laparotomy and observed a very large tumor that involved gallbladder and duodenum. A biopsy of the gallbladder wall was taken, and the histologic perioperative study reported gallbladder tuberculosis with no signs of malignancy. We then performed a cholecystectomy and observed the presence of cholecistoduodenal fistulae, so that we closed the duodenum. An exhaustive examination of the abdominal cavity revealed no other foci of tubercular infection. The definitive histologic study showed granulomatous reaction with the presence of multinucleated giant cells and caseum necrosis compatible with GT.

The postoperative course was uneventful. A Mantoux test was positive. Other techniques (chest X-ray, bronchoscopy) showed no tubercular infection in other organs. Antitubercular drugs were prescribed for six months.

DISCUSSION

The gallbladder is highly resistant to tubercular infection, and the presence of cholelithiasis and cystic duct obstruction is essential for the development of GT^[1,2]. About 70% of GT cases are accompanied by gallstones^[2]. Four types of GT have been described, according to whether only the gallbladder is involved or there is generalized tuberculosis and whether the gallbladder mucosa is histologically involved^[1]. GT often occurs together with other intra-abdominal tuberculosis, usually in women over 30 years of age^[2]. However, in the present case it was restricted to the gallbladder, because the duodenum was only locally involved. The route of infection may be peritoneal, hematogenous or lymphatic^[2]. Histologically, the lesion may be in the form of a localized

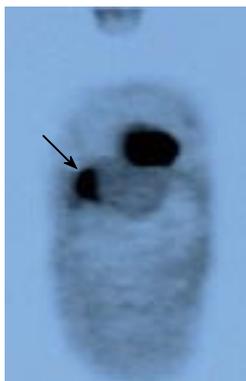

Figure 1 CT scan suggestive of image of gallbladder neoplasm.

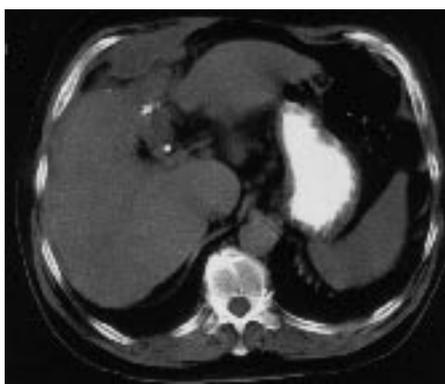

Figure 2 High uptake in gallbladder fossa (false positive for gallbladder cancer).

ulceration or there may be typical tuberculosis nodules in the wall of varied size and numbers.

A wide spectrum of symptoms have been described in patients with GT, including abdominal pain in right hypochondrium, weight loss, fever, anorexia, diarrhea, nausea, vomiting and a palpable abdominal mass^[2]. Anemia, elevated ESR and positive tuberculin test are usually found in laboratory examinations.

The correct diagnosis of GT is difficult, and it is usually made after a cholecystectomy^[1]. Ultrasound and CT may show an enlarged gallbladder, a thickened gallbladder wall, soft tissue masses, or nodular lesions, although neither ultrasound nor CT lesions are specific^[2]. The diagnosis of tuberculosis in other abdominal organs (liver, spleen, lymph nodes or peritoneum) is very helpful for diagnosing GT.

The differential diagnosis of GT includes acute and chronic cholecystitis, polypoid lesions and gallbladder carcinoma^[2]. The presence of a mass that fills the gallbladder associated with cholelithiasis is indistinguishable from carcinoma of the gallbladder^[1]. Moreover, both GT and carcinoma can give rise to regional lymph nodes. The presence of liver metastasis or liver infiltration suggests the presence of a gallbladder carcinoma. On the other hand, lung lesions or mesenteric thickening is frequent in patients with tubercular infection.

PET is a very accurate diagnostic method for cancer.

PET can image the metabolic differences between normal and malignant cells using tumor-seeking tracers^[3]. According to some authors, it is difficult to distinguish patients with lung cancer from those with pulmonary tuberculosis due to the high uptake rate of patients with active tuberculosis^[3,4]. This is because an increased glycolysis of macrophages, cells present in tubercular infection, results in a high FDG uptake value^[3]. 11C-choline tracer is more accurate than 18F-fluorodeoxyglucose for making the differential diagnosis between tubercular infection and cancer^[3].

There has been little experience with PET as a diagnostic tool in gallbladder cancer but the first published reports are fairly encouraging, showing a sensitivity of 75%^[5,6]. At our department, a prospective trial is in progress to establish the sensitivity of PET scan in patients with suspicion of gallbladder cancer based on CT scan. The present patient was included in this trial and the results obtained appeared to confirm the suspected diagnosis of gallbladder cancer. To our knowledge, this is the first case of a false positive PET scan in a gallbladder cancer due to GT. There is one previous report of pancreatic tuberculosis that was misdiagnosed as pancreatic cancer after a positive PET scan^[7].

Tuberculosis was common in Spain in the past but is now an uncommon finding in immunocompetent patients, and the GT diagnosis was therefore unexpected. In the countries with a high rate of tuberculosis infection, the possibility of a tuberculosis infection should be considered in patients suspected of a hepatobiliary cancer (liver, pancreas or gallbladder) with a positive PET if the patient has a positive Mantoux test or a history of tuberculosis.

INTRODUCTION

Isolated splenic vein thrombosis is a rare clinical syndrome that may lead to left-sided portal hypertension. Metastasis to the spleen from solid tumors is also considered rare. When identified it usually occurs in the setting of widely disseminated diseases. We report a case of isolated splenic vein thrombosis secondary to splenic metastasis of an adenocarcinoma of the colon. The splenic lesion was detected before the resection of the primary colon lesion during a complete metastatic work-up.

CASE REPORT

A 49-year-old woman presented complaining of abdominal pain in May 2003. There was no relevant medical history. Her performance status was not impaired. Physical examination revealed upper abdominal tenderness with mild guarding. Laboratory findings revealed anemia with hemoglobin of 84 g/L and hematocrit of 29.9%. Esophagogastroduodenoscopy revealed no remarkable finding. Colonoscopy revealed ascending colon cancer of 7 cm in diameter. The level of tumor markers was elevated with carcinoembryonic antigen of 36.7 µg/L and CA19-9 of 1870 kU/L. Computed tomography of the abdomen showed splenic metastasis (Figure 1A), but no metastasis in the liver. Contrast-enhanced computed tomography and angiography showed occlusion of the splenic vein, a shadow defect at the portal vein, and development of collaterals, which suggested tumor thrombosis extending from the splenic vein to the portal vein (Figures 1B, 2A, B).

We diagnosed her as having an ascending colon cancer with splenic metastasis and splenic vein tumor thrombosis (T3NXM1, Stage IV). She underwent right hemicolectomy, splenectomy, and distal pancreatectomy. The tumor of the spleen was adherent to the left hemidiaphragm, so a small segment of the diaphragm was removed en bloc. The portal vein was resected at its junction with the splenic vein and reanastomosed.

Histological findings showed a moderately differentiated adenocarcinoma of the ascending colon (Figure 3A) that invaded into serosa, with one of the five lymph nodes being positive for metastatic adenocarcinoma.

Abstract

A 49-year-old, previously healthy woman sought treatment for abdominal pain. Colonoscopy revealed ascending colon cancer. Computed tomography and angiography showed splenic metastasis and thrombosis extending from the splenic vein to the portal vein. She underwent right hemicolectomy, splenectomy, and distal pancreatectomy. Histological findings showed no malignant cell in the splenic vein which was filled with organizing thrombus. We postulate the mechanism of splenic vein thrombosis in our case to be secondary to the extrinsic compression of the splenic vein by the splenic metastasis or by the inflammatory process produced by the splenic metastasis. In conclusion, we suggest that splenic metastasis should be added to the list of differential diagnosis which causes splenic vein thrombosis. In the absence of other sites of neoplastic disease, splenectomy seems to be the preferred therapy because it can be performed with low morbidity and harbors the potential for long-term survival.

Hiraiwa K, Morozumi K, Miyazaki H, Sotome K, Furukawa A, Nakamaru M, Tanaka Y, Iri H. Isolated splenic vein thrombosis secondary to splenic metastasis: A case report. *World J Gastroenterol* 2006; 12(40): 6561-6563

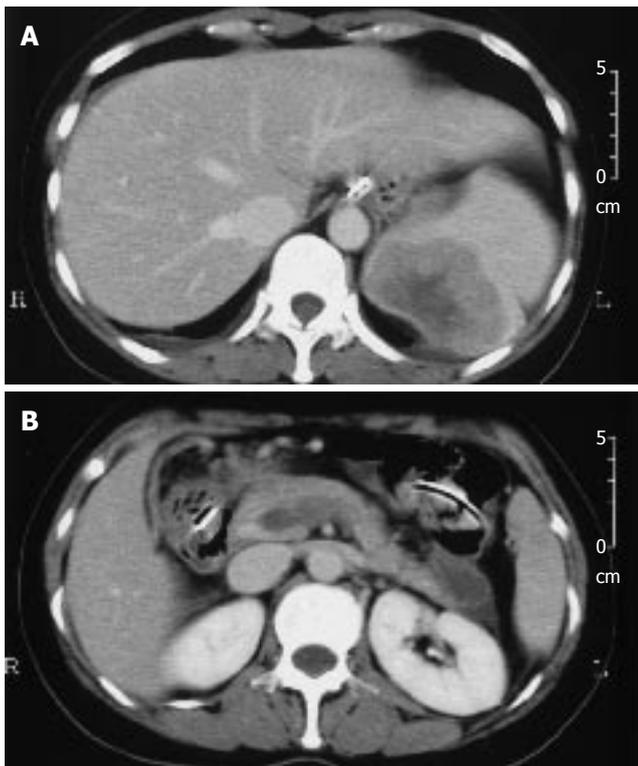

Figure 1 Contrast-enhanced computed tomography of the abdomen. **A:** Enlarged spleen with hypodense lesion in the superior spleen which was considered to be splenic metastasis; **B:** Hypoattenuating thrombus in the splenic vein and the portal vein.

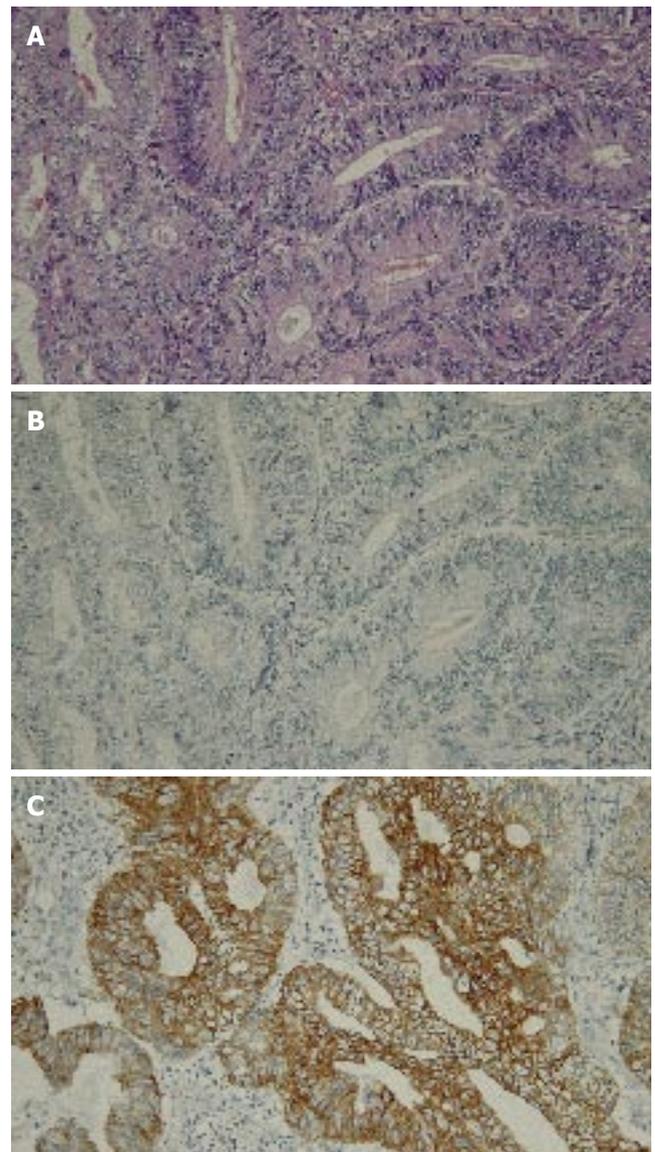

Figure 3 Histological findings of the tumor of the ascending colon. **A:** Moderately differentiated adenocarcinoma (HE, x 20); **B:** Immunostaining for cytokeratin 7 showing a negative reaction (x 20); **C:** Immunostaining for cytokeratin 20 showing a positive reaction (x 20).

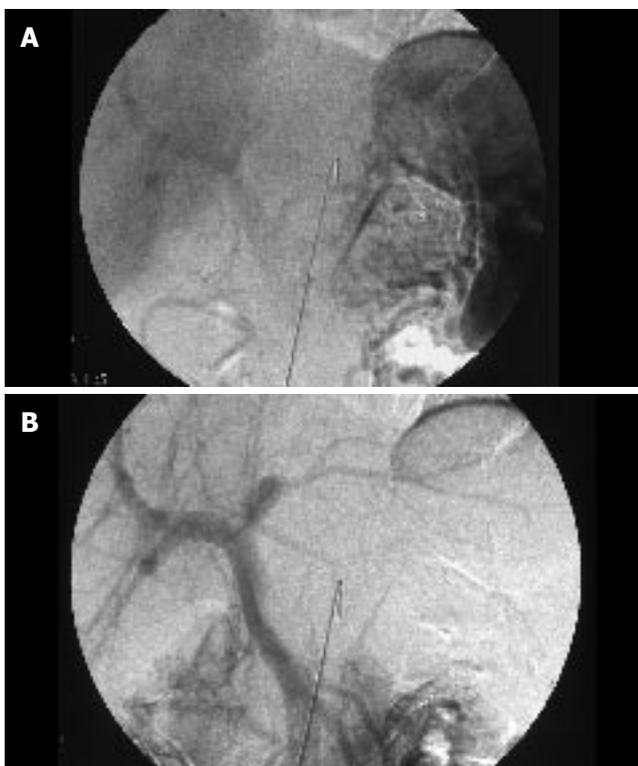

Figure 2 Digital subtraction angiography. **A:** The venous phase of the celiac artery angiogram reveals occlusion of the splenic vein and development of collaterals; **B:** The venous phase of the superior mesenteric artery angiogram reveals a defect shadow in the portal vein at its junction with the splenic vein.

The tumor of the spleen consisted of a moderately

differentiated adenocarcinoma similar in histology to the tumor of the ascending colon (Figure 4A). These sections were stained with immunohistochemical reactions of antibodies to cytokeratins 7 and 20 (Figures 3B, C, 4B, C). Negative staining for cytokeratin 7 and positive staining for cytokeratin 20 was consistent with splenic metastasis of an adenocarcinoma of the colon^[1].

On the contrary to the preoperative diagnosis, no malignant cell was recognized in the splenic vein which was filled with organizing thrombus (Figure 5).

The postoperative course was uneventful. Two years and three months later, the patient is alive and well except for a nodule in the Douglas fossa which seems to be metastasis.

DISCUSSION

Isolated splenic vein thrombosis is a rare clinical syndrome that causes left-sided portal hypertension. It may lead to

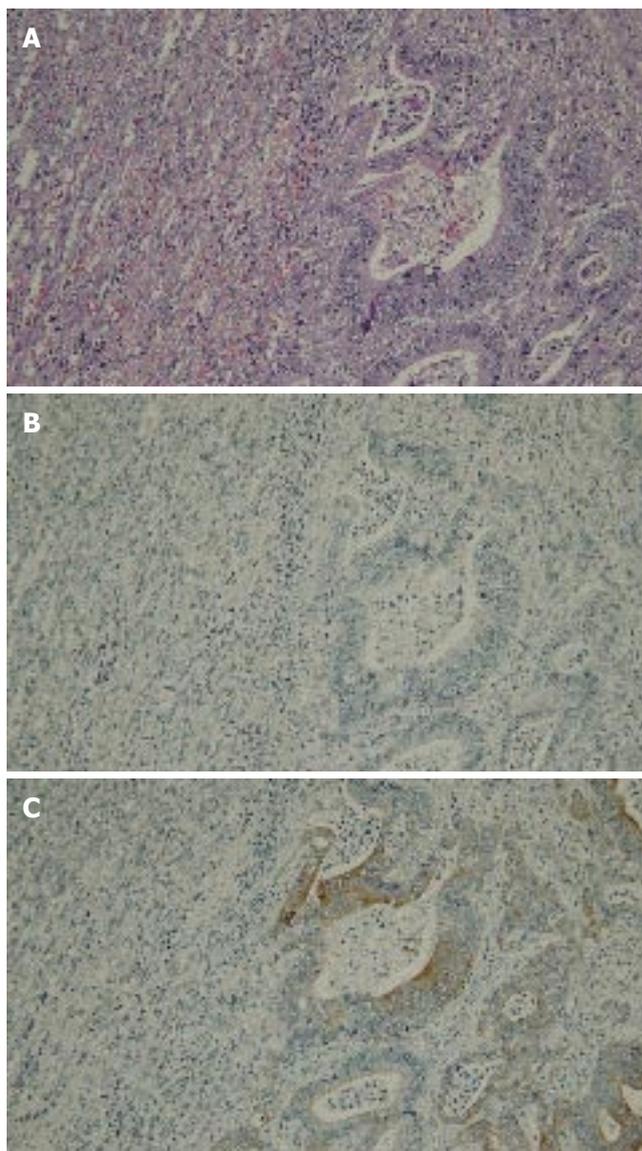

Figure 4 Histological findings of the tumor of the spleen. **A:** Moderately differentiated adenocarcinoma (HE x 20); **B:** Immunostaining for cytokeratin 7 showing a negative reaction (x 20); **C:** Immunostaining for cytokeratin 20 showing a positive reaction (x 20).

bleeding from gastric varices. The majority of splenic vein thrombosis are the result of pancreatic pathologies, including acute and chronic pancreatitis, pancreatic pseudocyst, pancreatic tumor and abscesses^[2]. Other reported causes are traumas, umbilical vein catheterizations, lymphomas and sarcomas, retroperitoneal fibrosis, gastric surgeries, splenic artery aneurysms, myeloproliferative diseases, hereditary thrombocythemia^[3], renal diseases including renal cell carcinomas^[4] and benign renal cysts^[5], and tuberculous lymphadenitis^[6]. Our case did not have these diseases, and so we postulate the mechanism of splenic vein thrombosis in our case to be secondary to the extrinsic compression of the splenic vein by the splenic metastasis or by the inflammatory process produced by the splenic metastasis. To our knowledge, there has been no report of isolated splenic vein thrombosis secondary to

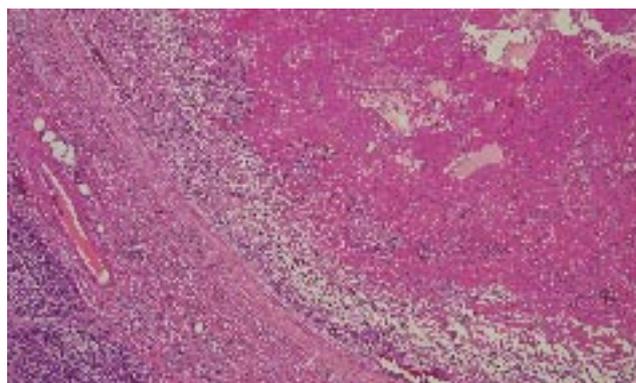

Figure 5 Histological findings of the splenic vein filled with not tumor thrombus, but organizing thrombus. The elastic tissue ring is intact (HE, x 4).

splenic metastasis.

Carcinoma of the colon frequently metastasizes to the liver but only occasionally involves the spleen. The spleen is considered an unfavourable site for the development of metastases but the reason for this is not fully understood. Metastatic carcinoma that involves the spleen is usually a manifestation of widely disseminated disease involving multiple organs. Berge conducted an autopsy study on 7246 patients with various types of malignant tumors^[7]. Splenic metastases were found in 21 out of the 1019 (2%) patients with colorectal carcinoma, but all were associated with involvement of other organs as well.

There are no long-term follow-up data of splenectomy for metastasis from colon cancer. Our patient underwent splenectomy, as it would deem to provide the only chance for long-term survival.

In conclusion, we suggest that metastatic tumor of the spleen should be added to the list of differential diagnosis which causes splenic vein thrombosis. Splenic metastasis from adenocarcinoma of the colon is a rare finding. In the absence of other sites of neoplastic disease, splenectomy seems to be the preferred therapy because it can be performed with low morbidity and harbors the potential for long-term survival.

Abstract

A rare case of pseudo-Budd-Chiari Syndrome in a patient with decompensated alcoholic liver disease is reported. Although clinical and radiological findings suggested Budd-Chiari Syndrome, the liver biopsy revealed micronodular cirrhosis and absence of histological signs of hepatic outflow obstruction.

INTRODUCTION

Budd-Chiari Syndrome (BCS) is a rare, heterogeneous and potentially lethal condition caused by obstruction of the hepatic venous outflow tract^[1], situated anywhere between the small hepatic venules until the right atrium^[2]. In Western countries, thrombosis from multiples causes is the predominant factor in the etiology of BCS^[3]. The correct diagnosis is very important for the therapeutic approach. Doppler ultrasound, computed tomography (CT) scan, and magnetic resonance imaging (MRI) provide evidence of hepatic vein (HV) thrombosis, with different specificity

and sensitivity^[4-7].

Pseudo-BCS is a condition which until now has not been well known. Only four reports were found in the literature and all of these concerned patients with a mechanical compression of the hepatic outflow due to an enlarged liver and liver cirrhosis.

The diagnosis of pseudo-BCS is difficult, because clinical and radiological findings are extremely similar to BCS, making invasive methods necessary.

We report a case of presumed BCS in a patient with alcoholic liver disease and emphasize the importance of the differential diagnosis for the correct management of these patients.

CASE REPORT

A 49-year-old female was admitted to our hospital with a 6-mo history of abdominal pain, progressive ascites, weight loss, anorexia and fatigue. There was no previous history of GI bleeding, surgery, hemotransfusions or spontaneous abortion. Also, she denied the use of oral contraceptives. Right up until admission day, she had consumed excessive amounts of alcohol for over 8 years. On physical examination we found mild jaundice, anemia, spider nevi, palmar erythema, hepatomegaly of 16 cm below the lower edge of the ribs, moderate ascites and edema. A systolic ejection murmur at the abdominal right upper quadrant was also found. Cardiac and pulmonary auscultation was normal. There was no jugular venous distention or pulsatile liver. Laboratory results are listed in Table 1.

Spontaneous bacterial peritonitis was diagnosed and treated. During endoscopy, three small esophageal varices were found. Doppler ultrasound revealed gross hepatomegaly 20 cm, with only a narrowed middle HV visible and a tributary branch. Absence of flow in the HV was reported. The CT-scan showed the massive hepatomegaly with irregular distribution of contrast, enlarged caudate lobe, and contrast hypercaptation at the left hepatic lobe.

The possibility of hepatocarcinoma plus BCS was considered. Serum viral markers were all negative and α -fetoprotein level was normal (4.61 U/mL).

MRI examination suggested the diagnosis of BCS due to patchy enhancement, absence of left and right HV and a narrowed middle HV with two narrowed tributary branches. An arterio-portal shunt was seen and hepatocarcinoma was excluded (Figure 1).

The diagnosis of BCS was made with a high degree of certainty by radiological exams. The search for hypercoagulable states was all negative.

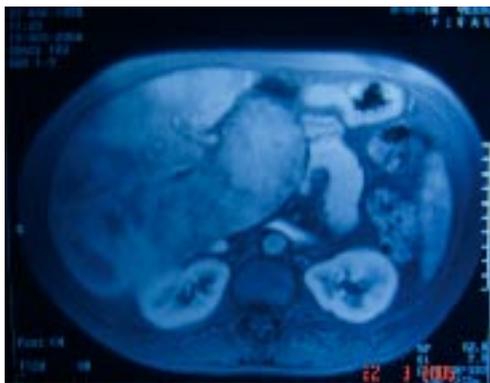

Figure 1 MRI in arterial phase showing a massive hepatomegaly with enlarged caudate lobe and patchy enhancement of contrast. A branch of portal vein is shown (arterio-portal shunt).

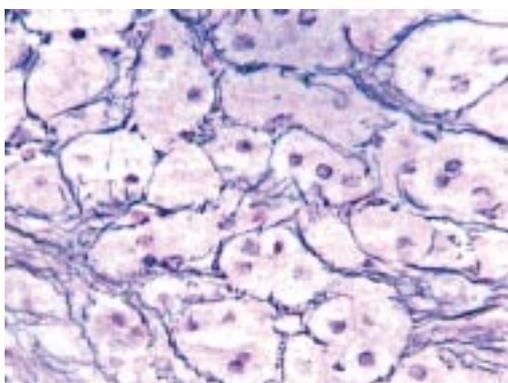

Figure 2 Liver biopsy reveals perisinusoidal and pericellular fibrosis (Gomori's reticulin stain, original magnification x 100).

Due to the patient's previous history and clinical condition, a liver biopsy was performed in order to clarify the extent of liver damage due to alcohol abuse as well as venous occlusion.

The liver biopsy showed micronodular cirrhosis, perisinusoidal and pericellular fibrosis (Figure 2). There was neither pericentral congestion nor other histological signs of hepatic outflow congestion and the use of anticoagulant therapy was not indicated. The venography was not performed due to the results of the liver biopsy.

The patient was discharged four weeks after admission with improvement of her clinical condition and laboratory results (Table 1).

DISCUSSION

BCS is a rare disease, varied in cause, presentation and progression, with different diagnostic and therapeutic approaches. The radiological methods are part of the diagnostic work-up for BCS^[1,8].

The first-line test is Doppler ultrasound of the liver^[1] that has a sensitivity of 87.5% in the diagnosis of BCS^[4]. The presence of a caudate vein equal or larger than 3 mm in diameter^[9] or abnormalities in the flow of the HV outflow tract are suggestive of BCS^[5,10].

MRI is the second-line test for BCS^[1]. It permits differentiation between all forms of BCS^[11]. Due to the high cost and low availability of this test, MRI is only

Table 1 Laboratory results

	Admission day	Discharge day	Normal values
Hemoglobin (mg/dL)	9.7	11.0	12.0-16.0
Mean corpuscular volume (fL)	108.1	103	80.0-96.0
Leukocytes (/mm ³)	21800	10100	4000-11000
Platelets (mil/mm ³)	306	250	140-360
Prothrombin time (s)	17.6	15.2	13
INR	1.52	1.2	1.0-1.4
Aspartate aminotransferase (U/L)	135	44	15-37
Alanin aminotransferase (U/L)	32.7	40	30-65
Gamma-GT (U/L)	907	312	5-85
Bilirubin (mg/dL)	2.73	1.4	0-1.0
Albumin (g/L)	24	36	34-50
Creatinine (mg/dL)	0.5	0.6	0.6-1.3
Alkaline fosfatase (U/L)	217	118	50-136

recommended when the diagnosis is not clear after Doppler ultrasound^[1,8,12].

A CT-scan may show an enlargement of the liver (caudate lobe), with patchy enhancement after contrast; but with indeterminate results due to false-positive in 50% of the cases^[5,7]. Combination of the three techniques in the appropriate clinical setting increases sensitivity to 80%-90%^[13].

In accordance with international guidelines, in BCS, liver biopsy and venography of hepatic veins are indicated when the diagnosis remains uncertain^[1,14]. The third-line investigation is liver biopsy, which provides information for important differential diagnoses^[14]. In current practice venography is rarely considered necessary for establishing a diagnosis and is carried out only when treatment is being planned^[1].

Clinical exams and radiological testing strongly indicated that our patient was suffering from BCS. Due to the radiological results during the clinical evolution, it was no necessary to perform the venography. However, when the possible causes of BCS in our patient were extensively sought, by other means, all of them turned out to be negative.

The hypothesis of hepatocarcinoma was made due to the findings in the CT-scan. But this, too, was excluded after the MRI showed an arterio-portal shunt. It is well known that arterio-portal shunts can be present in a cirrhotic liver and confuse the diagnosis with hepatocarcinoma^[15], as was the case in our patient.

Hypercoagulable states and thrombosis of other causes represent more than 75% of the etiology in patients with BCS^[8]. Other authors suggest that more than 85% of idiopathic causes of BCS are due to myeloproliferative disorders^[16,17].

One doubt in this case was the possibility that alcoholic intake could have been the cause of this BCS or in some way be associated with it. Two reports in the literature show this rare association^[13,18].

Shankel *et al* in 1987 described a patient with BCS and alcoholic liver disease. The patient presented both inferior vena cava (IVC) and nephrotic syndromes. In spite of the BCS diagnosis, absence of thrombus and only a mechanical compression of the IVC was found at

autopsy^[18].

The second report was made by Janssen *et al*, fifteen years later. It described three patients with alcoholic liver disease and BCS, without any thrombotic occlusion. These cases were denominated pseudo-BCS^[13].

Another two cases of pseudo-BCS were reported in association with liver cirrhosis of unknown causes, without HV occlusion findings^[19,20].

Dhawan *et al* in 1978, described a patient with clinical and radiological findings of BCS and concomitant liver cirrhosis. A complete constriction of the right HV and a narrowed left HV were shown to be present due to the hypertrophy of the left lobe of the liver and a regenerative nodule. No thrombotic occlusions were seen at the autopsy^[19]. This was the first paper to introduce the term pseudo-BCS.

Rector *et al* two years later, also reported a patient with liver cirrhosis, probably by non-alcoholic steatohepatitis and BCS. A distortion of the IVC caused by cirrhosis and increased abdominal pressure suggested BCS due to membranous obstruction, but no thrombus or membranous occlusion was found^[20].

All the cases reported had similar clinical, laboratory and radiological features and diagnostics.

Some of the described patients had a good evolution after alcohol withdrawal^[13,18], including our patient. The other patients had fatal outcomes because of severe hepatic damage due to excessive alcohol intake or advanced liver disease^[18,19]. One patient died after unnecessary anticoagulant therapy^[13], which worsened the coagulation profile. No patients had pericentral congestion nor histological signs of hepatic outflow obstruction characteristic of BCS. A mechanical compression of the hepatic outflow due to an enlarged liver was seen in all cases. Histological changes in the architecture of the small hepatic veins were also observed in our patient.

Structural lesions of the hepatic venules, such as veno-occlusive changes, perivenular fibrosis and lymphocytic phlebitis have been well documented in patients with alcoholic liver disease^[21].

Probably the structural lesions at the hepatic venules in association with mechanical compression due to anatomic abnormalities caused by an enlarged liver contributed to the misleading picture of BCS in these patients.

In conclusion the alcoholic steatohepatitis with liver cirrhosis can show a BC-like syndrome. Patients with this rare association denominated pseudo-BCS should be extensively investigated because management will depend on the correct diagnosis. The treatment of pseudo-BCS caused by alcoholic liver disease consists basically in discontinuing alcohol ingestion and generally is associated with a good prognosis.

Abstract

Focal nodular hyperplasia (FNH) is a relatively rare benign hepatic tumor, usually presenting as a solitary lesion; however, multiple localizations have also been described. The association of FNH with other hepatic lesions, such as adenomas and haemangiomas has been reported by various authors. We herein report a case of a hepatocellular carcinoma arising within a large focal nodular hyperplasia, in a young female patient.

INTRODUCTION

Focal nodular hyperplasia (FNH) is a relatively rare benign liver tumor, often asymptomatic and discovered incidentally^[1,2]. It occurs in both men and women, but shows a predilection for young women. FNH presents as a solitary lesion in 70% of the cases, while in 30% of patients two to five lesions are present^[3]. Multiple lesions occur rarely^[4-7].

Although an association with the use of oral contraceptives has been shown^[6,7], its pathogenesis is still unclear.

The potential for malignant transformation of FNH into hepatocellular carcinoma (HCC) has not been demonstrated^[8]. However, cases of anatomical adjacency of fibrolamellar carcinoma (FL-HCC) and FNH in the same patient have been described, and some authors have suggested a direct link between the two tumors^[9,10].

The simultaneous presence of HCC in its typical form and FNH is exceptional. To the best of our knowledge, only few cases regarding simultaneous occurrence of FNH and HCC of the liver have been reported in literature^[8,11]. In this case report we describe a case of co-existent FNH and HCC and discuss the clinical management and therapeutic implications.

CASE REPORT

A 23-year-old woman was referred to the Outpatient Department of our hospital with a present history of fatigue and a past medical history of atresia of oesophagus which was reconstructed during her neonatal age and underwent oesophageal dilatations in her adolescence. She has never used oral contraceptives and had no history of hepatitis or alcohol abuse. Physical examination did not reveal any abnormal findings. Laboratory findings including serum α -fetoprotein and carcinoembryogenic antigen levels were within normal ranges. Contrast-enhanced abdominal CT scan showed five lesions in the liver (both left and right lobes), with the largest of the lesions located in the left lobe, an angiomyolipoma in the right kidney and multiple small angiomyolipomas of the left kidney. All liver lesions enhanced greatly during the early arterial phase (Figure 1A and B).

Three months later, a new contrast-enhanced abdominal CT scan was repeated and revealed apart from the known masses an increase in the size of the tumor in the left lobe of the liver (diameter from 4 cm to 7 cm). On unenhanced scans all masses appeared well-defined and homogeneously hypodense. Following an i.v. bolus of contrast, the masses showed early arterial contrast enhancement, with the exception of a centrally located area in the largest lesion, which remained hypodense (Figure 2A and B). On portal venous phase scans all lesions became isodense. The central hypodense area of the largest lesion remained unchanged during the portal venous phase scans, while became hyperdense on delayed scans. This area was attributed to a central scar, a finding consistent with a typical FNH. The remaining three masses were also con-

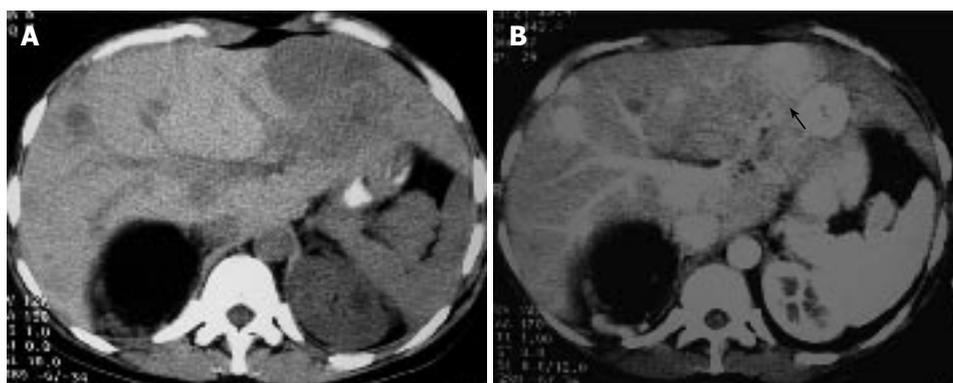

Figure 1 **A:** Unenhanced transverse CT scan demonstrates multiple hypoattenuating masses located on both liver lobes. Fatty tissue (known angiomyolipoma) replaces the most of the upper pole of the right kidney; **B:** Post-contrast CT scan depicts multiple round liver lesions, with a smooth margin, which demonstrate intense homogeneous enhancement. The lesion located in segment three, has a small central area of hypodensity, consistent with a central scar.

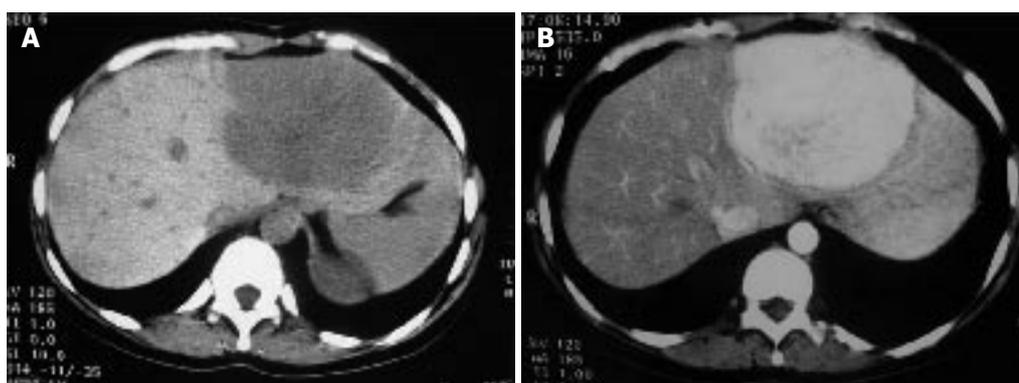

Figure 2 **A:** Pre-contrast CT scan 3 mo later, revealing the significant increase in the size of the lesion located in the left liver lobe; **B:** Post-contrast image at the same level showing the increased contrast uptake of the lesion.

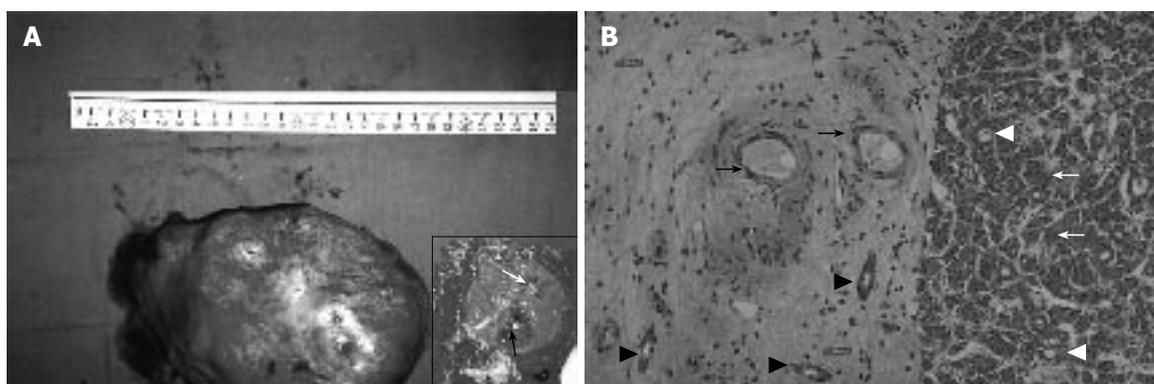

Figure 3 **A:** Photograph of the surgical specimen. The inset shows the cut surface: White arrow points at the scar of FNH and black arrow shows the hepatocellular carcinoma; **B:** Photomicrograph from the lesion. Left: Connective tissue from the core of FNH containing thin wall vessels (black arrows) and cholangioles (black arrowheads). Right: hepatocellular carcinoma. The tumor shows a trabecular growth pattern (white arrows) and focal pseudoglandular transformation (white arrowheads) (HE x 100).

sidered as FNHs. MR imaging was carried out at the same time and the findings were consistent with multiple FNHs.

Due to the great increase in the size of the mass located in the left lobe, during such a short period (3 mo), a CT guided core liver biopsy was performed in the largest lesion. Pathologic examination of the biopsy revealed that the specimen composed of fibrous tissue surrounded a nodule of hyperplastic hepatocytes, contained numerous thin-walled vessels, as well as numerous proliferated bile ductules. No evidence of malignancy was observed. Based on the radiological and histopathological data, the provisional diagnosis of FNH was made. In order to exclude any coexistent brain pathology, the patient underwent brain MR imaging, which was normal.

The surgical procedure involved the resection of the

II and III liver segments. During the operation a frozen section was performed, revealing FNH. The surgical specimen measured 17.3 cm × 15.0 cm × 10.2 cm (Figure 3A). It consisted of a portion of liver which contained two masses, the larger measuring 9 cm × 6 cm × 5 cm and the smaller 4.5 cm × 3.5 cm × 2.0 cm. Macroscopically, both masses had a yellow-white cut surface and a central scar. In addition, the smaller mass contained another smaller tumor measuring 2.1 cm × 1.8 cm × 1.0 cm, which was located in the periphery and showed a brown-green cut surface (Figure 3A-inset). Microscopic examination of the specimen revealed the presence of FNH (two discrete tumors), whereas the smaller tumor included within the smaller mass represented a well-differentiated hepatocellular carcinoma (Figure 3B). Diagnosis of HCC was based

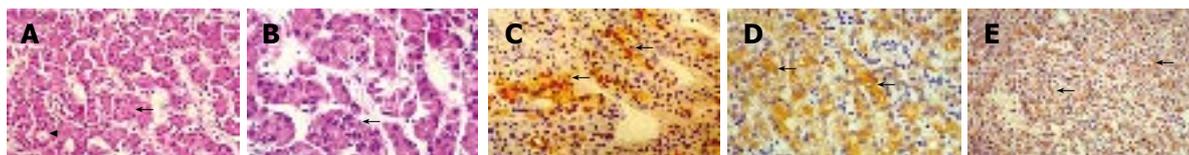

Figure 4 Microphotograph showing details of the tumor. **A, B:** The tumor displays a trabecular growth pattern (**A**-arrow, **B**-arrow) with focal pseudoglandular transformation (**A**-arrowhead) (HE, **A** × 250, **B** × 400); **C:** Tumor cells show positive immunohistochemical stain for hepatocyte antigen (arrows-streptavidin biotin peroxidase × 250); **D:** Tumor cells show positive immunohistochemical stain for cytokeratin 18 (arrows-streptavidin biotin peroxidase × 400); **E:** Immunohistochemical stain for polyclonal carcinoembryonic antigen displays a canalicular pattern (arrows-streptavidin biotin peroxidase × 100).

on morphological (HE stain) and immunohistochemical grounds (Figure 4): The neoplastic cells exhibited positive stain for hepatocyte paraffin antigen and cytokeratin 18 and negative stain for cytokeratin CK19, chromogranin, synaptophysin, common leukocyte antigen negative, CD34 antigen. In addition, polyclonal carcinoembryonic antigen displayed a canalicular pattern.

The postoperative period was uneventful. During the follow-up period, the patient underwent liver transplantation in another center abroad. Pathologic examination at that time revealed that the two small tumors in the right liver lobe represented liver angiomyolipomas (personal communication). At present time, eight years after the initial diagnosis, the patient is alive.

DISCUSSION

Benign liver tumors are uncommon in surgical practice (3%-5% of all liver tumors); haemangioma is the most common type (55%-60%), whereas adenomas (8%-19%) and FNH (21%-27%) are less frequent. FNH, also called mixed tumor represents a small percentage (1%-5%); its definition is derived from the coexistence of two or more tumor phenotypes^[1,12,13]. FNH is generally considered to be a hyperplastic response to an abnormal blood supply^[14].

The potential of benign liver tumors for malignant degeneration has been extensively discussed in the literature; in particular, a considerable risk of malignant transformation has been reported for hepatic adenoma^[15], which was supported by findings of HCC foci within the benign tumor mass. This is why surgical resection of hepatic adenomas is recommended by most authors (apart from considerations about possible rupture of larger adenomas and subsequent intra-abdominal bleeding).

Conversely, there is no agreement on the malignant potential of FNH. To the best of our knowledge only a few cases of co-existent FNH and HCC have been reported in the literature^[8,11] and the pathological correlation is not always clear. Saul *et al* reported one case in 1987 in which FNH and HCC were concomitant, although the HCC was a fibrolamellar variant (FL-HCC)^[9]; Chen *et al* recently reported one case of HCC partially surrounded by FNH^[8], while even more recently Cucchetti *et al* reported a case of simultaneous presence of FNH and HCC^[11].

Simultaneous appearance of FNH with adenoma^[16,17] and haemangioma^[18] has been reported. The simultaneous occurrence of adenoma, focal nodular hyperplasia and haemangioma has also been described and the authors have

concluded that adenoma, FNH and haemangiomas might have a common origin that should be attributed to vascular changes primarily caused by a congenital abnormality of the angioarchitecture and blood circulation of the liver^[19]. Various authors have described the co-existence of FNH with vascular cranial malformations^[20], cystic dysplasia of the kidneys^[21], Klippel-Trenaunay syndrome^[22]. In all cases described so far, the coexistence of the above findings were attributed to a so called syndrome or were described as coincidental^[23]. A useful diagnostic tool for the distinction between liver cell adenoma and FNH, when the routine histopathologic features are not very clear, is clonality analysis^[24].

The histopathological features of FL-HCC suggest a direct link between this tumor and FNH and some authors hypothesize a direct evolution from FNH to FL-HCC^[9,10]. Also, the simultaneous presence of adjacent adenoma does not exclude the development of HCC from malignant degeneration of the adenoma. Therefore co-existence of FNH and HCC in the same patient is an exceptional event, to the best of our knowledge reported only in two cases.

Recent insight into the molecular characteristics of the clonal growth of FNH failed to support further a possible derivation of HCC from FNH; two different studies, conducted by Gaffey^[12] and Paradis^[13], were undertaken to clarify the monoclonal or polyclonal nature of these tumors by a method that scans the molecular pattern of inactivation of chromosome X. The authors eventually came to opposite conclusions. In another study^[8], clonal analysis was applied to macroscopically different portions having different histological features within the same tumor, with concomitant FNH and HCC; the results showed that FNH was of monoclonal origin, but the FNH clone was similar to that of HCC and therefore the authors' conclusions did not support the hypothesis that HCC was the product of malignant transformation from FNH. The issue of an identical clonal origin of FNH and HCC therefore remains a matter of debate, although we feel it is rather imprudent at present to completely exclude any malignant potential of FNH.

The potential of FNH for malignant evolution would appear unlikely on the basis of the follow-up of patients with non-surgically excised FNH. Weimann *et al* observed an increase in the size of FNH lesions only in 9.5% of 53 cases, with no malignant transformation during a mean follow-up of three years^[25]. Likewise, in other studies no increase in lesion size was observed among 11 patients in a two-year follow-up, and in some cases the FNH even completely disappeared over time^[26]. This evidence

recently led Charny *et al*, to conclude that, if the diagnosis is unequivocal, surgical resection is not indicated for asymptomatic FNH^[27].

A clear and precise diagnosis of a benign liver tumor is difficult to obtain in every patient, particularly in the case of FNH. In the series collected by Terkivatan, difficulty in differentiating FNH from adenoma or HCC represented the indication for surgery in 32% of cases^[28]. FNH was rarely encountered by radiologists prior to the current practice of helical multiphase CT or MR imaging. It is also believed that as the imaging methods improve, FNH will be encountered more frequently. Many authors have reported the CT features of FNH. Imaging characteristics, typical of FNH, include a homogeneous well-defined hypo-, or iso-dense lesion on unenhanced scans, which shows bright enhancement during early arterial phase and becomes isodense on portal venous phase. Central scars are hypodense on early arterial and portal venous phases and become hyperdense on delayed scans^[29-32]. Magnetic resonance imaging is another modality also used for the confident diagnosis of FNH. The reported sensitivity and specificity values for contrast enhanced-MRI diagnosis of FNH was 70% and 98% respectively in an article by Cherqui *et al* in a series of 41 patients with clinical radiological and pathological correlations. The central scar was detected in 78% of the cases^[33]. An alternative to angiography could be hepatic cholestigraphy, which according to the study of Weimann, best reflected the vascular pattern and the typical biliary ductule proliferation of FNH (sensitivity \geq 82%, specificity \geq 97%)^[25].

Finally, the diagnostic value of liver biopsy in suspected FNH is rather limited; the lesion itself may not be reached or the specimen may not be sufficient for an accurate diagnosis, and false negative results are deleterious for the final outcome as hepatic adenomas or HCC may bleed or seed along the needle track.

In conclusion, at present there is no clear-cut evidence supporting the potential for malignant degeneration of FNH into HCC; the indication for surgery, particularly in small lesions (\leq 4 cm) and asymptomatic patients, is therefore rather controversial. In view of this uncertainty, a correct diagnosis which differentiates between FNH and HCC must be achieved for all cases by means of a multidisciplinary approach. Due to the rarity of the association between FNH and HCC it is difficult to draw solid conclusions for both the pathology of this entity and the appropriate management of these patients.

ACKNOWLEDGMENTS

Acknowledgments to Reviewers of *World Journal of Gastroenterology*

Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of *World Journal of Gastroenterology*. The editors and authors of the articles submitted to the journal are grateful to the following reviewers for evaluating the articles (including those were published and those were rejected in this issue) during the last editing period of time.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents[®]/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch[®]) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology

Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China

E-mail: wjg@wjgnet.com

<http://www.wjgnet.com>

Telephone: +86-10-85381901

Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5

line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

Key words

Please list 6-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P*<0.05, ^b*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, ^c*P*<0.05 and ^d*P*<0.01 are used. Third series of *P* values can be expressed as ^e*P*<0.05 and ^f*P*<0.01. Other notes in tables or under

illustrations should be expressed as 1F , 2F , 3F ; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (<http://www.wjgnet.com/cgi-bin/index.pl>), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.aushome.cn/cgi-bin/index.pl>)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂ not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please download CAF from <http://www.wjgnet.com/wjg/help/9.doc>.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to *WJG* all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The *WJG* requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1) direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3) supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The *WJG* does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to *WJG* if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Final check list for authors

The format is at: <http://www.wjgnet.com/wjg/help/13.doc>

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: <http://www.wjgnet.com/wjg/help/10.doc>

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee. EDITORIAL and LETTERS TO THE EDITOR are free of charge.
